Many factors influencing a salvage operation vary in relative importance – not all apply to every case. Information required and its significance depends on the type of casualty. Salvage engineers must understand the factors influencing the salvage operation. They must evaluate the relative priority and influence of each factor on the choice of salvage methods. Demands for additional information arise as the salvage plan develops and situations change. It is imperative that the salvor engineer be intimately familiar with the vessel's condition, particularly whether the locations of cargo and liquids aboard the casualty are a result of damage or normal stowage.

Many salvage operations are time-critical – particularly stranding and afloat casualties. There is not always time to wait until conditions are optimum, or until all information has been gathered. Salvage engineers must obtain the best information they can in the time available, estimate information they cannot obtain, perform the necessary analyses to assist in formulating

the salvage plan, and proceed with an analysis that is sufficiently flexible to change as more information is acquired.

42.3.2 Salvage Survey

In a salvage survey, information about a casualty is gathered by inspecting the ship and the surrounding area. The salvage engineer should be prepared to accompany the salvage crew on any and all surveys. The primary purpose of the survey is to gather information for the development of the salvage plan. Information gathering is a dynamic process that is never truly complete. It begins when the first salvor arriving at the salvage site takes stock of the situation. If communications can be established with the casualty's crew or other observers, or documentary information about the ship or area is available, information gathering should begin before salvors arrive on scene, and continue throughout the operation. Full or partial surveys should be repeated as often as necessary for salvors to stay abreast of changing conditions.

The keys to a good survey are the verification of observations and the organization and presentation of the information collected.

A survey will report only observations. It is the salvage engineer's task to interpret the conditions observed to determine their relevance to the condition of the ship. Like a survey, the interpretation of the results must be an ongoing process that continues throughout the operation and is constantly revised as the survey is refined.

Survey Breakdown

The salvage survey breaks down into several interdependent surveys (preliminary, detailed hull, topside, interior, diving, hydrographic, site, safety, and other surveys). How these surveys interrelate, and the extent and importance of each, depends on the type of casualty. Since stranding salvage is the most familiar and possibly the most frequent type of salvage, surveys are first presented as they pertain to strandings. Differences between stranding surveys and those for other types of casualties will be discussed afterward.

Preliminary Survey

The preliminary survey verifies information received from the casualty itself, ships in company, owners, or other observers. All reports should be checked because initial observations may no longer be relevant, or information important to salvage engineer may have been overlooked. A *desktop survey* should be conducted to assemble as much documented information as possible about the vessel, its contents, and the bathymetry of the salvage site. The documented information aids initial evaluation of the situation and provides starting points for detailed surveys. At least, the preliminary survey should:

- Verify the casualty's changes in drafts, trim, and list over several tide cycles.
- Verify bottom soundings reported by the crew – corrected to tidal datum.
- Determine if the vessel is merely aground, or stranded high and dry.
- Verify the casualty's position and attitude on nautical charts.
- Determine if shipboard equipment and systems are functioning.
- Determine if the ship is lively and moves with the tide.
- Verify tank soundings, flooding extent, structural damage.
- Determine if there is progressive flooding.

Aerial Observations

It may be extremely useful for key salvage personnel to fly over the salvage site to observe changes in color and other indications of shoal water. Because of its ability to move slowly or hover, a helicopter is the best platform for this type of aerial survey. Aerial observation provides a view of the overall site (including the shore). Potential beach gear locations, mooring sites, locations ashore for deadmen or highlines, lightering arrangements, retraction channels, etc., can be selected from the air. The suitability of these sites can then be confirmed by a detailed survey.

Initial Information

The preliminary survey should begin before salvage forces arrive and should incorporate reports from the ship's crew. Merchant ship information can be obtained from the owners or their agents. Information on many merchant vessels is also available through the USCG Headquarters, the National Cargo Bureau, and classification society registers. Aerial or satellite reconnaissance of the stranding site can also provide basic information about the casualty. The casualty or ships in company can provide a great deal of information about the casualty and site. Salvors can transmit portions of the standard survey form for completion. Post-stranding drafts should be taken as soon as possible after the incident. Early information forms a basis for preliminary planning and initial estimates of the effort, time, and assets required for the salvage. The salvage assets dispatched to the scene are determined by the information available at mobilization. Whether or not the salvage forces have means to stabilize the casualty immediately can make the ultimate difference between success and

failure. The casualty may deteriorate beyond the point of salvage, or fair weather windows may be lost while waiting for additional equipment or forces. It is better to arrive with too much equipment than too little, but salvage forces and assets are not unlimited. Information obtained before salvors arrive on scene can identify items requiring further investigation so surveys can be focused for the maximum return. Information to be requested from the salvage site includes:

- An accurate position of the stranding site giving latitude and longitude, along with applicable chart numbers, and means of fixing the position.
- Date and time of stranding.
- Drafts on sailing from the last port and estimated at time of stranding.
- Fuel, water, ammunition, and other weights expended or transferred since sailing.
- Post-stranding drafts forward, amidships, and aft, with the state of tide and the time taken.
- Soundings along the entire length of the ship, corrected to the datum of the chart of the area.
- Course and speed at time of stranding and ship's heading after stranding, with details of changes.
- Liveliness of the ship.
- Weather conditions, including wind direction and velocity, current weather, and forecast weather at the site.
- Sea and current conditions, including the direction and height of seas and swells; state of tide, weather, and sea conditions at time of tranding.
- Tide range and reference station.
- Extent and type of damage to the ship.
- Location of grounding points and estimated ground reaction.
- Type of seafloor at the site.
- Status of ship's machinery.
- Status of liquid loading (cargo, fuel, fresh water, ballast).
- Ship's cargo list or manifest, including amount and location of known HAZMAT.
- Assistance available on scene.

On Scene

The detailed on-scene survey refines the preliminary survey and collects the specific information listed in the salvage survey form. The detailed survey consists of five surveys:

- Topside
- Interior hull (including machinery)
- Diving and exterior hull
- Hydrographic
- Vessel attitude.

Topside Survey. The topside survey gathers information about the exterior of the ship above the weather decks. Particular items of concern are:

- Type, location, safe working load, and operating condition of all deck machinery and cargo gear
- Location and estimated safe working load of tug and beach gear attachment points, including working space for pulling devices
- Location and estimated weight of top hamper and superstructure if it appears that topside weight must be removed
- Operating condition of the ship's boats.

Interior Hull Survey. The interior hull survey gathers information about the interior of the ship and its contents. The interior survey includes:

- Examining in detail the condition and contents of every space below the main deck.
- Taking soundings or ullages of all spaces containing liquids.
- Determining the condition of installed drainage system piping, valves, pumps, and other associated equipment.
- Determining the location and operating condition of all cargo and ballast pumps and the arrangement of associated piping and manifolds.
- Determining the location and condition of all cargo and stores and obvious hazards, such as flammables and chemicals.
- Determining the location, weight, volume, and class of all ammunition magazines and the operating status of the magazine sprinkler systems and location of their controls.
- Determining the location of all structural damage, that is, holes, tears, cracks, weeping seams, panting bulkheads, etc.
- Determining the location, type, and estimated weight of loose or displaced cargo, equipment, or permanent/solid ballast that could be removed.
- Investigating items of special interest, such as open decks where the beach gear can be rigged, or identifying locations for necessary openings.
- Determining the availability and location of material that may be useful in salvage.
- Determining the location and size of any cross-connections for liquid tanks that could be closed or left open.

Machinery. Machinery status and condition are of great interest to the salvage engineer. The availability of electrical power, compressed air, deck machinery, pumps, and other equipment can greatly simplify the

task of salvaging the vessel. Operational propulsion machinery can assist the refloating effort and control the casualty once free of the beach. The value of the machinery plant may be a significant portion of the casualty's total value for either commercial or military considerations. Specialized cargos, such as refrigerated goods, may require certain equipment to prevent degradation or hazard formation. Proper operation of ventilation systems can prevent the accumulation of dangerous gases. In some cases, the machinery plant and other equipment may be the object of the salvage operations, with salvage of the hull conducted only to provide a convenient barge for transporting the machinery. Flooding can damage machinery severely, especially if the water level rises and falls, exposing saltwater-drenched machinery to air, or if adequate water damage protection measures are not taken when the space is dewatered.

Diving or ROV Exterior Hull Survey. The diving or ROV survey examines the underwater portions of the ship's hull and the exterior portion of the hull below the main deck. This survey may be conducted by a dive team, or in some cases using an ROV to view the sunken or stranded vessel. Underwater surveys may not be strictly required for all groundings; in some cases, the hull condition can be adequately determined from internal surveys. Diving surveys provide more accurate information concerning the hull and bottom conditions and should be conducted unless time constraints, lack of divers, or sea conditions prevent them. If a diving or ROV survey is not conducted or is severely limited, for whatever reasons, the interior survey must be unusually comprehensive to compensate for the lack of detailed hull and bottom condition information; conclusions about the bottom may have to be drawn from topside observations alone. The diving or ROV survey determines or checks for the following:

- Amount of the hull in contact with the seafloor and a description of the points of contact.
- Existence and location of pinnacles.
- Existence and location of impalements.
- Location and size of all cracks, tears, holes, and indentations in the underwater portion of the hull and in the portion between the waterline and the weather deck.
- Condition of all sea suctions, valves, and fittings, and whether or not they are clear.
- Condition and operability of all underwater appendages, including bilge keels, sensors, stabilizers, rudders, shafting and bearings, and propellers.
- Signs of leaks or escaping fuels, pollutants, or liquids.
- Type of seafloor soil and the presence, location, and extent of scouring or buildup.

Underwater Video. Whenever possible, video should be used for underwater surveys. Video – particularly low-light-level video – has greater sensitivity and can record more detail than the diver's eye. Videotapes can be reviewed repeatedly at the convenience of the viewers; tapes from earlier surveys can be compared with the most recent versions to measure changes. Technical personnel who are not divers can observe underwater conditions through video. Videotapes of areas of the hull in contact with the seafloor, underwater damage, and hull appendages and openings are particularly valuable. Black-and-white video generally provides better detail resolution and low-light performance, but color video may be preferable for general surveys because many seafloor features and damage to hull areas are highlighted by color contrasts, such as coral heads, rock formations, scraped paint, marine growth, etc.

Hydrographic Survey. The hydrographic survey determines the condition of the sea and seafloor in the area where operations will be taking place. Included in the hydrographic survey are:

- Comparison of the observed tides with the predicted tidal information.
- Determination of the strength, period, and times of local currents, and the durations of high and low water slack and their relationship to the times of high and low tide.
- Periodic observations of the sea and swell height, period and direction of seas, and their impact on the salvage operation.
- Soundings all around the ship, in areas where beach gear or moorings will be laid, or where salvage ships or other vessels will operate.
- A seafloor profile chart of the beach gear area to assist in design of the beach gear legs.

Vessel Attitude.

Draft Readings. Accurate stranded drafts are often difficult to obtain, but are essential because they form the basis for many salvage calculations. For instance, the ground reaction calculation is dependent on drafts; ground reaction influences much of the operation. Efforts to obtain accurate grounded drafts are well spent. In swells, draft readings taken from a boat are the most accurate. When the hull girder is significantly deflected, it may be necessary to obtain drafts at several locations along the ship's length to accurately determine buoyancy distribution for strength and ground reaction calculations. If drafts at stations between draft marks

are required (or the draft marks are obliterated), freeboard to the main deck or other convenient deck can be measured with a weighted line or chain. The freeboard is then subtracted from the height of the deck above the keel, as taken from a profile plan or tabulated data. As the sea surface is seldom calm, drafts should be determined by averaging at least three readings at each location.

Whenever drafts are taken, the time, date, and state of the tide are recorded and drafts are reduced to the tide datum; normally that datum is the same as that of charts of the local area. Reduction to the tide datum is required because the draft readings of a stranded ship vary with the tide. When ground reaction at the tide datum is known, the effect of tide on ground reaction can be determined.

Determining Casualty Movement. Early in the salvage operation, it should be determined if the ship is moving. Observation of widely separated navigation ranges – preferably one in line with the casualty and one on the beam – is the fastest way to detect casualty movement. Navigational ranges can be established on natural landmarks, or, if the depth of water permits, range poles can be set up and observed to see if the ship falls off the range. Alternatively, bearings to fixed, easily identifiable objects should be recorded at regular short intervals. When no movement is observed for some time, the interval between readings may be increased. A large pendulum-type clinometer should be set up on the casualty in an easily observed location to show changes in list (or roll, if the ship is lively).

Hull Deflection. Hull deflection can be related to hull stress and bending moment. Deflection can be determined by plotting drafts. It can also be determined by measuring heights relative to a horizontal datum with a surveyor's transit, theodolite, or siting level, or from a taut wire stretched between fore and aft points. The line or curve of deck or other measured surface plotted from the measurements is compared to ship's drawings to determine the amount and direction of hull deflection.

Hull Strain Readings. If the hull is lifting to the rising tide or swells, the hull deflection should be checked. Dial indicators installed between frames measure strain in adjacent longitudinal hull members. Increases in hull strain indicate an increase in hull stresses. Sudden increases in bending stresses may indicate that hull failure is possible, and that changes in loading must be made quickly to reduce stresses. Dial indicators can also show if the hull girder is suffering permanent strain. In many instances, the hull will flex measurably in response to water-level fluctuations or the passage of waves. Flexing will alternately increase and decrease longitudinal strain. In extreme cases, flexing will cause strain reversals, from elongation to compression and back again. If the strain is elastic, the range of dial indicator readings will remain fairly constant and an approximate midrange point can be determined after a few cycles. A steady shift in the midrange point in either the positive or negative direction that cannot be tied to observed water-level fluctuations indicates a change in the overall hull girder deflection. The change may be either increased or decreased elastic deflection resulting from changes in total bending moment, or permanent deformation, indicating that stresses have exceeded the yield limit in that part of the hull girder. If stresses have exceeded the yield limit, the hull is in danger of catastrophic failure. Hull members should be examined for signs of yielding; changes in hull girder loading should be carefully reviewed to determine the cause of the shift in deflection levels. In the same way, dial indicators can be set up between side-shell longitudinals to indicate vertical shear stresses and between deck girders to show horizontal shear.

Damage Reports. Damage reports prepared by the ship's crew can assist in prioritizing areas to be surveyed. Particular attention should be paid to secondary damage, such as abnormal bulkhead flexing, cracked seams, hatches and doors that no longer close, cracking or flaking paint, or other signs of stress or hull distortion. As these conditions may indicate more serious damage, their causes should be determined. The diving team should be briefed on the location and type of all damage found inside the hull, so that they can check for underwater damage in those areas. Frame numbers, spray- painted on the hull, help divers and boat crews to orient themselves along the length of the ship. Weighted lines, hung over the side and into the water at specified locations (frame numbers) help divers orient themselves underwater and locate damage relative to known points. Spreading damage, such as lengthening or widening cracks, increasing or decreasing dimensions of openings and clearances, increasing areas of deformation, or areas of paint cracking and flaking, is especially important because it indicates progressive weakening of the hull or increasing stress.

Tank Soundings. All tanks should be sounded frequently and the soundings compared to those taken before and since the stranding. On most tankers, the contents of cargo tanks are tabulated against ullages (the height of the empty space above the liquid, usually measured from the lip of the expansion trunk or ullage port), rather than soundings (liquid depth). Fuel

and other oil tanks should be checked for the presence of water with indicator paste, thief samples, or by opening the tanks. Some tankers are equipped with ultrasonic sounding devices that can locate the oil surface as well as the oil–water interface. Use of the casualty's tank capacity tables will be greatly simplified if survey crews measure liquid surfaces and interfaces from the same datum used in the tables, that is, soundings or ullages. It may be necessary to brief survey crews used to taking soundings on the correct method of measuring ullages.

Tides. Tides may vary, both in height and time, from those predicted in the tide tables. A tide gage should be set up, and regular readings taken and compared to predicted tides. Local mariners can often provide the best information about tides and currents at the stranding site.

Salvage Plan and Updates

Analysis of the data gathered by the surveys is not of full value until it is used to formulate a salvage plan. The salvage plan lists the work to be done, the salvage techniques to be employed, and matches them with the resources available, schedules it, sets forth the responsibilities of individuals and organizations, and provides a vehicle for the coordination of all salvage efforts to meet target dates and times. Development of the salvage plan begins when the initial information about the casualty is received and continues with updates throughout the operation. The salvage engineer's contribution to the salvage plan is to quantify the information to assist the salvage officer/master in communicating the salvage plan to officials and the salvage crew. The salvage engineer can expect to provide the salvage officer/master with updated calculations at any time during the operation. Often the updates will be required early in the AM local time for briefings. They can be very comprehensive updates and may require a long sleepless night. By way of example in the case of a grounding the engineer may have to provide calculations that include:

1. Ground reaction
2. Freeing force
3. Location of the neutral loading point, if applicable
4. Stability – aground and afloat
5. Strength of the hull girder, damaged areas, attachment points, and rigging
6. A summary of the rationale for the selection of specific retraction and refloating techniques.

42.4 Types of Operations

Salvage operations generally involve three basic casualty circumstances: free floating, grounded, or sunken. A free-floating vessel, whether intact or damaged, partially flooded, or even capsized will have some measure of longitudinal or transverse stability along with a waterplane as well as be lively to the sea. Tidal changes will not affect the casualty's buoyancy or stability. In contrast a grounded vessel, whether just touching ground and trimming or listing to its ground reaction (aground), or stranded and working to the current, surf, wind, and tide is being subject to forces that her designers had never intended and had never built into the design. High structural loads can hole the vessel, and the action of the sea can turn the grounding into a stranding, leaving the casualty high and dry with virtually no residual buoyancy no matter what the state of tide. In an exposed coastal or reef situation, the stranded vessel's predicament can progress from a simple grounding to a hopeless shipwreck in a matter of days. Sunken vessels have insufficient waterplane to float with the tide and are not going anywhere. Depending upon the sunken vessel's angle of repose and extent of ground reaction, the sunken vessel's plight will deteriorate with scouring and an accumulation of silt to add to the submerged weight of the vessel and her cargo. In a harbor or protected water setting, however, sunken vessel have remained for years before being refloated or wrecked in place. Sunken vessels may be grouped according to residual buoyancy characteristics as follows:

- Completely submerged (upright or on its side) or capsized (upside-down) with no residual buoyancy
- Submerged with a small portion of the exposed hull above the water surface
- Partially submerged with a substantial portion of the hull above the surface.

Sunken ships may start to refloat before all of the buoyancy lost in sinking has been recovered. At liftoff from the bottom residual water remaining on board can cause dangerous free surface and problems with stability, list, and local and overall hull girder strength. The salvage of a sunken ship requires not only recovering enough buoyancy to refloat the ship, but also distributing buoyancy to obtain suitable conditions of stability, trim, and strength.

The fundamental perils and physics of each type of casualty will dictate the techniques and equipment to undertake the salvage operation, as well as the tools and

methodology used by the salvage officer/master to control the situation. These tools and methodology selected will invariably involve salvage engineering to quantify the effects of various approaches.

42.4.1 Free Floating

A freely floating vessel, whether upright, or subject to extreme list and trim (or even capsized) will be in a state of stable equilibrium on the water surface. Naturally, as progressive flooding and loss of buoyancy continue for a holed vessel, the margin of stability will deteriorate and a stable situation may become unstable. In a state-of-stable equilibrium, the centers of buoyancy and gravity will be in longitudinal and transverse alignment even at excessive angles of trim and list and metacentric height (GM) will be positive. And despite these large angles of trim and list, or even in a capsize situation, there will be a waterline, with waterplane inertia and an instantaneous metacenter even if the vessel is upside-down and riding on a pocket of air. Free-surface effects of flooded spaces or partially filled tanks (slack) will have a huge impact on the state of trim and list, as well as the dynamic range of stability and the period of roll and pitch, and will contribute greatly as to how quickly the situation may become hopeless and the vessel founders and sinks. By definition, a submerged surface vessel is one without any waterplane and it is a rare case indeed if the fully submerged surface vessel does not touchdown on the bottom.

Battle or collisions damage, even the effects of loss of watertight integrity may lead to the ultimate loss of the vessel due to progressive interior flooding (settling), downflooding (after bulkhead deck submergence), or loss of stability due to a massive loss of waterplane between transverse watertight bulkheads invariably to be followed by capsize or diving when the flooding is largely symmetric between bulkheads. In addition to these effects, the hull girder strength may be compromised and bending and torsional loads may cause the ship to break up. Salvage operations on a free-floating vessel will generally involve continuing the damage control measures taken by the ship's crew at the earliest stages of casualty response, and if the vessel is unable to transit on her own power towing will be involved. Free-floating casualties as a result of fire, explosion, collision, or a massive shift of cargo weight are a particularly difficult form of casualty. For the purposes of this chapter on operations, it will be assumed that the damage control measures are being performed by the ship's crew at the time the salvage engineer's involvement begins. It is also assumed that the ship's condition will be one of excess trim and lists with massive internal flooding, such that the use of ship's standard intact stability data (Trim and Stability Booklet or Cross Curves) are of limited value.

Free Floating – Excessive Trim and List

Excessive list and trim will generally be characterized by loss of buoyancy hence freeboard coupled with unusually great trim or list angles (i. e., drafts and angles not found in the vessel's Cargo Loading Manual or Trim and Stability Booklet). The loss of the margin of stability will be a result of impaired dynamic stability and will usually be sensed by a very long period of roll (lolling) about an equilibrium angle of list, or even upright and apparently in stable equilibrium. The first concern in such situations is to determine the margin of stability and to analyze the consequences of various techniques to improve seaworthiness.

Many of the operational techniques used to improve seaworthiness involve discharge or transfer of liquid loads combined with efforts to minimize or neutralize the effects of large areas of liquid free surface. In cases where the ship's bilge and ballast or cargo transfer systems are operational, the liquid load may be modified to improve overall stability by raising the metacentric height, as in the case of ballasting. Unfortunately, adding ballast will rob the casualty of freeboard and introduce transient free surface effects during the transfer process. There are always trade-offs. For areas of the vessel that are flooded (as in the case of cargo holds), it may be necessary to patch hull or bulkhead penetrations and use salvage pumps to discharge the flooding water. Counterflooding from the sea is another technique often considered and one which will have a trade-off between the good effects of helping to correct off-center weight but will have a negative effect on transient free surface and a loss of freeboard. It is better to shift liquid cargo internally. In any event, techniques such as patching and de-watering will be essential to restoring seaworthiness where there are large areas of free surface.

Development of a lightering plan is essential to establish the sequence of liquid cargo and fuel as well as predict the effects of transient free surface on the vessel's margin of stability. Lightering can also include the discharge of weights from the deck, as in the case of discharging cargo containers from a disabled vessel.

On the structural side of the casualty analysis estimating the residual strength of the vessel's hull girder, and calculating the still water or wave bending moments on the hull from the changes in hull buoyancy and distribution of flooding water are necessary to prevent further structural damage and associated flooding. Structural calculations are often necessary when the use of compressed air is used to displace water as the loading on the boundary structure, such as the underside of the main deck, can be excessive.

Without benefit of a validated computer model of the hull, it may be necessary to extrapolate or estimate quantities, such as the displacement, transverse center of buoyancy (TCB) and longitudinal center of buoyancy (LCB) of the vessel from line drawings and bonjean curves. There is often a serious question to consider as to which method of analysis is best and quickest to use in doing hand calculations in the form of either the added weight or lost buoyancy method to quickly gauge the effect of various *what-if* scenarios. Free floating damaged casualties in peril of capsize or breakup will tax the naval architect/salvage engineer's best judgment and computational/estimating skill. In situations like this, intentionally grounding the vessel (beaching), if that option exists, may be prudent. Even then there will be questions to resolve such as of how to put the vessel aground (speed and heading) and at what state of tide so as to minimize capsize forces and distribute the ground reaction forces on the hull plating. Once aground, analyzing methods of stabilizing the situation and then refloating the intentionally grounded vessel must be carried out quickly. Stranding is generally considered an unintentional grounding of a vessel, as discussed in Sect. 42.4.2.

Appendix 42.A describes dewatering tools and methodology, and Appendix 42.B contains methods and provides common formulas, calculations, and references to refer to when developing salvage plans for a free-floating vessel.

Free Floating – Capsized

Experience has shown that ships freely floating upside down and exhibiting a freeboard roughly equivalent to, or only slightly greater than the height of the double bottom are generally quite stable. Similarly, full-bodied ships or barges floating at heel angles of 130–150° with the turn of their bilge a few feet out of the water are generally quite stable. These ships are often found to be riding on pockets of trapped air, or have great quantities of cargo that are buoyant in seawater. If the vertical center of buoyancy (COB) lies directly above the center of gravity (COG), the vessel will be in stable equilibrium. For capsized vessels, free floating or submerged it is always important to have B lie above G. Similarly, when the longitudinal centers of gravity and buoyancy align the vessel will stabilize in trim. It is quite possible for a vessel to be in stable transverse equilibrium yet unstable longitudinally and trim excessively before equilibrium is established. In this state, she may drift or possibly be towed with either her bow or stern dragging until fetching up and grounding as she nears shallow water. At this time, an additional set of forces will come into play as a result of the ground reaction. This phenomenon is discussed under the Grounding section.

Depending upon the vessel's subdivision, both transverse and longitudinal, the fluid interface at the free surface will affect the vessel's rise in its COG. Free surface reduces righting arm in floating capsized vessels in the same manner as it affects surface vessels floating right side up. The opposing shifts of liquid and air can be considered to cause a rise in the COG (added weight method) or a lowering of the COB (lost buoyancy method).

In most capsize circumstances, dive assets will be required for access and subsea entry into the vessel for survey work, to introduce compressed air into compartments from subsea, or to do the necessary rigging for a crane lift. This is a dangerous work, made even more difficult in the open ocean and the transfer from larger vessels to dive tenders. It is generally better to shift the capsized vessel into protected waters wherever possible. In harbor clearance operations, shifting the floating capsized vessel to shallow water can be the prelude to wrecking in place. Grounding the freely floating capsized vessel in a harbor, especially near a pier can often be the first step toward parbuckling the vessel into a righted and sunk position, from which the operation can become one of refloating a vessel that is stranded.

Salvors will often use compressed air to enhance the freeboard or trim of a floating capsized vessel and to recover buoyancy. Calculating the volume, pressure, and flow rate of air to be introduced and its likely effect on trim and stability is essential. Fortunately, in the case of a floating vessel, the issue of expanding air as the vessel rises in the water column is not important as it is when refloating a capsized ship from the bottom. The air pressure at equilibrium for a given increase in buoyancy will have an effect on the structural loading of shell or inner bottom plating as the air pressure required to dewater a space increases with hydrostatic head. In addition to using compressed air, it is possible to induce buoyancy and stability by using pontoons, foam, and other buoyant objects in the vessel's holds or even floating at the vessel's waterline outside of the hull.

On some salvage jobs involving a capsized vessel afloat, it will be possible to parbuckle the vessel to an upright position by flipping it or lifting it to a deck barge from its capsized state using heavy lift assets. This is a challenging job at sea because ship motions will affect loads on shear leg cranes and the rigging can be a nightmare for the lift or rotation. In addition, the balance of forces among the crane's load, the instantaneous center of residual buoyancy, and the casualty's flooded weight can become dramatically out of control as the rotation over-tops and the crane load goes slack. The suddenly upright vessel may skate directly toward the crane barge and collide. If possible, it is better to tow the vessel to sheltered water to complete the task and

simplify the rigging demands to control motion. With a thorough knowledge of heavy lift and rigging loads saddles, padeyes, and other rigging attachments must be designed, fabricated, and installed. In addition, it is not unheard of for the capsized vessel, especially if floating with her bilge high, to be pre-rotated by cutting holes through the shell plating into the low-side compartment, and pre-ballasting a space to shift the TCG to the low side. This operation is dependent on a large surplus of buoyancy and requires detailed calculations to move step by step through the process.

42.4.2 Grounded Ships

All grounding casualties have one essential feature in common: part, if not all, of the vessel's weight is supported by ground forces, commonly called the ground reaction. The distribution can range from a vessel simply touching down (aground) on a bar, reef, or ledge at her bow or bilge and lively with the tide and sea, to the stranded situation where there is little or no motion throughout the tide cycle. A stranded vessel that is high and dry will have virtually the entirety of its weight support by a uniformly distributed load or ground reaction (like a vessel in dry-dock), or in some cases it may be close to refloating if the buoyancy of the displaced volume of surrounding water can be made to exceed the ship's weight, for example, by lightering cargo or liquid loads to reduce the tons aground. In the aground case, trim and stability will join longitudinal strength considerations to dictate the course of action needed to refloat the casualty. When a vessel is stranded high and dry, its trim and stability characteristics are not uppermost in the salvor's thinking, which is generally how to stabilize the deteriorating situation and how to refloat. However, when the vessel is aground on what can be considered a pinnacle, or a single point, the ground reaction can have a significant effect on the vessel's trim, stability, and hull girder strength. In almost all cases of grounded ships in an exposed situation, there is the utmost urgency because the vessel is in a dangerous position and time will be of the essence with an exposure to wind, sea, tides, and currents combining to broach the vessel and drive it further ashore.

The type of grounding casualty and the extent of damage, as well as the conditions of exposure will have a huge impact on the salvage operation. In addition, the steps taken to initially stabilize the situation, for example, by pinning the vessel and taking steps to prevent broaching by deployment of anchors, where possible, will affect the best course of action and the options available. This in turn will dictate the techniques used to refloat and the computational tasks in quantifying refloat options. The fundamental goal in the partnership between the ship's crew in its Damage Control process and the salvors who arrive on scene is the safe refloating of the stranded ship, meaning the goals are to save lives, the ship, its cargo, and conduct pollution abatement. The reality is sometimes a steady sequence of ineffective steps to reduce the tons aground, or improve residual buoyancy leading to a deterioration of options and finally broaching. The sequence of unfortunate events from grounding to wrecking in place can easily follow well-established perils of the sea, grounding to broaching, to stranding, to being left high and dry, and finally to shipwreck. In the process of trying to beat the forces of nature, the salvage engineer may be called upon to exhaust his entire bag of engineering tricks.

The three phases of a grounding salvage operation are:

1. The stabilization phase – when steps are taken first by ship's crew and then salvors to prevent further damage to the vessel and keep the ship from being driven further around, or broaching.
2. The refloating phase – when the salvage plan is being executed, often in the form of a sequence of techniques applied to achieve piecemeal goals leading to extraction from the situation.
3. The post-refloating phase – when the ship returns to the situation of being a free-floating casualty.

Aground

The first successful steps taken to save the ship aground often begin with the master's actions within the first hours of grounding. These steps include the immediate notification of the ship's condition to the authorities, determination of the vessel's watertight integrity, and the survey of compartment flooding, perimeter soundings of the seafloor and draft readings, and an accurate determination of the vessel's liquid-loading conditions for consumables and fuel. Ship's personnel and remote salvors and salvage engineers can then begin to determine the tons aground. The master must begin the steps to pin the vessel to stabilize the situation if there is any indication that she will broach in the current and seaway, and resist the temptation to jettison weights or back down if the vessel's hull has been breached. If the assessment indicates that there is no flooding and the ground reaction calculation suggests that the vessel may be retracted at the next high tide through a revision to the vessel's cargo, fuel, and ballast loadout then the proper course of action will be to pin the vessel hard in the interim and develop the sequence of internal ship cargo, ballast, and fuel transfers to be completed during the tide cycle. The calculations involved in this analysis are derived from fundamentals of naval architecture augmented for grounding. If the

vessel is aground on a single pinnacle in water of sufficient surrounding depth, it will pivot about that point as the tide changes and may be treated as a statically determinate problem by equilibrating residual buoyancy and centers with the known ship weight and centers (from pre-stranding ship displacement and centers). The sequencing of shipboard cargo, fuel, or ballast transfer steps require the vessel to stay aground through the low water cycle until the extraction process is ready to start on the rising tide. At this time, the liquids used to pin the vessel will be discharged (ballast) thus lowering the ground reaction or shifted (fuel or ballast) to shift the LCG and trim the vessel to lower the ground reaction. A successful extraction like this will rely heavily on correctly estimating the freeing force, ground reaction, and the bottom's coefficient of friction. It also helps to have tugs assisting to augment ship's power. If the ship cannot be extracted at full power on the next tide the engines should be placed on standby and the vessel should be re-pinned to prevent being driven further ashore while awaiting the arrival of salvage tugs and salvors to take charge of the extraction operation. In the interim whatever assistance should be used to stabilize the ship in a position to safely ride the currents without broaching. Time is not on the side of a vessel aground.

Stranded and Beached

From the salvage engineer's perspective, the conditions of a stranding are seldom fully defined in the beginning and often are not completely defined during the salvage operation. Salvage of a stranded ship is time-critical because weather and sea conditions always worsen the situation. In addition, unlike the case of simple pinnacle groundings (with one with two pinnacle supports) a stranded situation will invariably involve a statically indeterminate set of engineering calculations (somewhat similar to dry-docking calculations with many of the blocks removed or of differing elastic properties). The appropriate soil mechanics characteristics of the seafloor, reef, or shelf must be quickly identified. There is no time to wait until conditions are optimum or until all information is known. Obtaining the best information possible, estimating unobtainable information, analyzing the sequence of activity, and developing quantitative information without delay are often the norm. There are many methods for refloating stranded ships; none is correct in every circumstance. There is no simple formula. Salvors are limited only by their knowledge and imagination. This section addresses conditions that affect stranded ships and what methodologies are typically used to refloat.

The initial salvage step for a stranded refloat operation is to stabilize the vessel by deploying a system of ground legs to control the vessel swing and keep her in the correct direction to facilitate extraction. The anchoring system will consist of the anchor itself (drag embedment, pile, deadweight, etc.), mooring line (chain, wire or synthetic rope), which together form the ground leg, and pulling system for tensioning (linear cable pullers, winches, purchases, etc.). Tugs are used to deploy the ground legs and can apply pulling forces directly on the casualty with their application of power measured in terms of bollard pull. These forces are typically applied in the plane of the casualty to achieve the following effects: retracting directly off the beach, swinging the casualty into a more favorable position, inducing wrenching motion to break suction or reduce ground friction, holding the casualty in position, as in a swift current, for example, or controlling the casualty's motion during the refloat evolution (checking lines).

Once stabilized or under control relative to her heading with the beach, reef, or shore the casualty will be lightered as much as possible to minimize the ground reaction and reduce the buoyancy needed for refloat. In addition, it will be necessary to safely remove all fuel and other pollutants that are potentially at risk if the vessel begins to break up, or is holed during the extraction phase of the refloat process. In compartments where cargo oil or fuel tanks have been holed and exposed to the sea, salvage pumps may be needed to strip the oils from the tank top and avoid the water bottom that would be sucked into the vessel's own cargo and fuel oil transfer system. Based upon hydrostatic balance between the head of oil and the casualty's draft at the holed tank's location, the quantity of oil in the tank at equilibrium can be estimated. Opening an inerted space is fraught with danger. Sometimes the lightering operation will be to shore instead of to a standby barge or vessel. Calculating estimated operation times for the transfers and evaluating how the ground reaction will change as a result is required to finalizing the lightering plan. As the tide changes, updates will be made to determine the buoyancy deficit for refloat. When possible, much of the deck cargo will be removed and predictions will have to be made to determine what the trim, list, and stability characteristic of the vessel will be at refloat. This will factor into the extraction process and depth of water requirements. If repeated efforts in cargo lightering are unsuccessful in refloat at high water, it may become necessary to start to dig the vessel out.

Difficult refloat operations may often require underwater excavation techniques to scour, jet, airlift or dredge seafloor material to reduce friction, modify the ground reaction, pass messengers, or create a channel to extract the vessel into deeper water. These techniques may use a tug's propeller wash to scour or a crew of divers with jet and airlift tools. Suction dredging is an

important tool to cut trenches alongside the stranded vessel, especially in high and dry situations, to set up pockets of deeper water where the vessel will settle, list or be pulled into a new position to increase buoyancy and thereby decrease ground reactions and eliminate friction. Each change in the angle of repose presents a new distribution of ground reactions and hull local and girder loadings. Continuous longitudinal strength calculations to analyze the hull girder sheer, bending, and torsional loads for each successive stage of the operation, so as not to break the vessel, must be undertaken. In addition, high spots in the contact points along the hull can create local loads sufficient to hole the vessel. Both unsupported and grillage panels of bottom plating must be analyzed to understand local loading. Sometime soil collapse may cause the casualty to roll suddenly and excessively to a new equilibrium position requiring an update of all of the structural loading and equilibrium calculations.

Appendix 42.C describes de-beaching tools and methodology and Appendix 42.B contains methods and provides common formulas, calculations, and references to refer to when developing salvage plans for a grounded vessel.

42.4.3 Sunken Ships

Stranded and Sunk – Refloat

A partially submerged stranded and sunken ship will typically be internally flooded in at least some very large spaces or tanks between transverse and longitudinal bulkheads. If the internal flooding rises and falls with the tide, the ship is said to be tidal, which is a sure sign that there is free communication with the sea in the area under survey, for example, in hold areas where the watertight integrity of the side shell is compromised as in the case of a collision followed by parallel sinkage without capsize in a harbor, port facility, or shipping channel. A similar phenomenon can happen when a vessel strands and tears open its shell plating into holds or tanks. If the space is not tidal and a differential level exists between the tidal waterline and internal flooding, residual buoyancy can be obtained by judicious pumping of accessible spaces (dewatering) that actually have a watertight envelope. The refloat evolution is undertaken by first establishing the tons aground for the sunken vessel and then developing a plan to remove enough weight or add enough additional buoyancy to float the vessel. Weight removal can be accomplished by dewatering spaces by pumping, use of compressed air in certain spaces to displace water (and being careful to be sure the air bubble cannot escape suddenly if the vessel rolls), lightering of cargo from holds or superstructure to lower both the weight and vertical distance from the keel to the center of gravity (KG). Any submerged space, like a forepeak tank, that is dewatered by displacing flooding water with air needs to be checked for residual strength as it in effect becomes a cofferdam habitat subject to hydrostatic head. The increased buoyancy developed as the air expands as the vessel rises in the water column must be calculated into the total buoyancy equation. Underwater cutting is often used to provide a path for the displaced water to exit and limit the expansion of air as the casualty rises in the water column. Hot taps can be employed as well to create a path for flooding water to discharge. Often the challenge of refloating a stranded and sunken vessel is one of the patching holes in the ship's water tight envelope (side shell, inner bottom, or internal longitudinal and transverse bulkheads). Divers are essential in completing this mission. At the conclusion of all of these preparatory steps, the key determination in planning the refloating operation is to predict at what stage of preparation and tide liftoff will take place.

For a vessel completely submerged, the challenge is even greater. Not only will all operations aboard the submerged vessel require diver interface, but also sunken ship stability in the water column is harder to control as there will be no waterplane. Dewatering can sometime be accomplished by fabricating surface piercing cofferdam bulkheads. Pontoons, side shell cofferdams, and sponsons can be attached to the hull to created buoyancy and provide some measure of stability at liftoff. The stability of an upright sunken ship at liftoff depends primarily upon whether the main deck is above water, partially submerged (i. e., there is limited waterplane), or completely submerged.

As the ship is raised, various methods are used to prevent it from capsizing while it passes through ranges where it is inherently unstable or develops instability from free surface. The most common method is to refloat one end of the vessel while keeping the other end firmly in contact with the bottom. The contact with the ground prevents the ship from taking on a dangerous list or capsizing. In deep water, keeping one end of the ship in contact with the ground and limiting the rise of the other end prevent extreme trim. Before the grounded end is raised, free surface in the floating end is reduced by dewatering. Spaces low in the ship, such as double bottom tanks, may be flooded and pressed up to both eliminate free surface and to lower the COG and increase the metacentric height. At the same time, topside weights are removed and other portable weights moved as low in the ship as possible to lower the COG. With free surface minimized from the floating part of the ship and the COG as low as practicable, the grounded end may be raised. These methods are not always adequate; careful stability calculations with a detailed

consideration of free surface should be made before attempting to raise the grounded end. Large free surfaces can be broken up by repairing damaged bulkheads and by building temporary bulkheads within flooded spaces. The work of building temporary bulkheads is considerably reduced if the bulkhead is built with high-pressure concrete pumped into simple forms. Both bulkhead reinforcements and temporary bulkheads should be built wider at the base than at the top to assist in lowering the COG. A force may be applied to the ship being raised to produce a moment that counters an upsetting moment. This is done by attaching barge or ship mounted cranes or tackles rigged to apply a vertical force near the side of the ship to steady her list. When the ship begins to list, a force is applied to counter the list and bring the ship back to the upright position. Pontoons, cofferdams, barges, or lift craft may be rigged to provide a force that counters a heeling moment and keeps the ship upright. The pontoons must be rigged tightly to the ship so that when the ship begins to heel, she will also attempt to submerge the pontoon on the low side. The additional buoyancy of the submerging pontoon, coupled with the loss of buoyancy from the pontoon on the high side, creates a moment that rotates the ship back to an upright position. Tightly rigged pontoons and lift craft not only provide an uprighting force from their buoyancy but also act as an increased waterplane of a system composed of the ship and pontoons. The waterplane of the pontoons increases the metacentric height and overall stability of the ship–pontoon system. This advantage is gained only when the ship and pontoons are so tightly rigged that they function as a unit. If the ship is free to render in a cradle formed by the rigging, the pontoons provide only buoyancy. Ships sunk in harbors have been kept upright by rigging purchases from their mastheads to anchoring points ashore. If this method is attempted, the ship should be held securely by mooring lines, as there will be a tendency for the ship to kick out from under the strain of the purchases on the masts.

One of the most secure methods of controlling the ship is to rig beach gear and haul the ship into shallower water as it is lightened or lifted. The beach gear is kept under constant heavy tension so that the ship moves into shallower water in constant contact with the bottom until it has reached a location where it may safely be dried out and refloated. Beach gear rigged ashore may be hauled with winches, linear pullers, or heavy vehicles. Tugs may be used to help move and direct the ship. Ashore, heavy tracked vehicles may also be used to haul lines for positioning the ship. Keeping a ship in contact with the bottom, either at one end or all along her length, also assists in controlling trim and preventing the loss of longitudinal stability caused by water rushing to the low end. Once the ship is refloated and stable, it can be handled as a free-floating casualty as discussed in Sect. 42.4.1.

Appendix 42.A describes dewatering tools, Appendix 42.D describes refloating tools and methodology and Appendix 42.B provides common formulas, calculations and references to refer to when developing salvage plans to refloat a stranded and sunken vessel.

Capsized and Sunk

Influences on capsized ships arise from two principal sources: condition in which the ship has capsized and sank and the environmental and physical working conditions. As often as not, ships will capsize as they sink in the water column, and they come to rest at a severe angle. Ships sunk in this condition present a more complex problem than those sunk upright. An entirely new dimension is added to the salvage operation because the vessel is usually righted before refloating. Ships are righted by developing a moment of force to overcome the moment of weight that holds the ship in her capsized position. With the exception of wreck removal there are four methods of handling a capsized and sunken ship:

- Refloating the ship as it lies and moving it to another location (Sect. 42.4.3)
- Wrecking in place or otherwise disposing of it in situ (Sect. 42.4.3)
- Rotating the ship until it is completely upside down and refloating the upside-down ship (Sect. 42.4.1)
- Rotating the ship until it is upright in place, then refloating it (Sect. 42.4.3).

Wreck Removal

Ships seldom capsize and sink in ways favorable to salvors, rarely allowing a convenient and comparatively straightforward righting operation. Statistically, it is as probable that a ship may capsize:

- Effectively blocking an entrance channel or canal
- In the middle of a wide river or navigable waterway where she is a traffic hazard
- In comparatively deep water, but where she is still a dangerous obstruction to traffic
- In the middle of a harbor or bay some distance from the nearest shoreline or harbor installation.

Relocate. The ship that capsizes and sinks effectively blocking a channel or canal creates a difficult situation because working methods often are reversed. Normally, salvors right a sunken ship before trying to refloat her. A capsized ship that blocks or seriously obstructs an important channel or canal is treated differently. As an obstruction to maritime operations, such a wreck must be moved quickly. Sometimes the most effective method of moving the ship is to refloat it on its side,

then haul or tow her away from the waterway. If the ship cannot be refloated completely, it may be practical to lighten or lift one end at a time, slewing or hauling the ship sideways to clear the channel. Under these circumstances, salvors have altered sunken ships' situations to their advantage by:

- Moving the ship, refloated on its side, to a more convenient righting location
- Swinging the refloated ship to face in the best direction for parbuckling
- Refloating the ship in such a way that it rotates, so that it is totally upside down and can be moved away immediately after refloating.

Without heavy lifting units that make wrecking in place an alternative, refloating first and righting later has many advantages. Where heavy lifting units are available, an analysis of both plans may show that refloating and moving away have both cost and time advantages over wrecking in place.

Wreck in Place. When a ship cannot be parbuckled into an upright position or a refloat and tow option is just not practical as in the case of a stranded vessel that simply cannot be refloated, then wrecking in place is the only remaining option. The wreck in place evolution will typically require heavy lift capabilities (shear leg cranes, derrick barges) along with jackup platforms configured to render chain or cutting wire to sever the hull much like a cheese slicer. Chopper beams are sometimes used, especially in shallower water where the wreck may have been beached some time before. The wreck in place evolution is driven by cutting, rigging, and lifting and the salvage engineer will be required to calculate weights and centers for portions of the ship that are to be severed from the hull girder, or superstructure, rigged for lifting successfully. There will be intensive diving operations often with tunneling operations to sling under the vessel. In situ welding, surface or subsea will be required along with detailed calculations and strength analysis for padeyes. The naval architecture and marine engineering disciplines will be of particular use in identifying internal structure that will need to be severed before taking up the load. This can include piping systems, box girders, and other massive structural subassemblies. Sections of the ship up to several thousand tons may be handled in a single pick using tandem cranes and then loaded on deck barges.

At times the wreck in place operation will resemble the shipbreaker techniques used to build down the superstructures and lighten the ship's weight, and then using linear pullers anchored to the shore to drag the hull ashore compartment by compartment and sequentially chop the hull. This is not a very sophisticated method but in the right circumstances it can be a very cost-effective technique to get the job done. One important note about wreck in place concerns the necessity to control pollution releases of petroleum, oil and lubricants (POL) and other contaminates aboard the vessel.

Appendix 42.E describes tools and methodology to refer to when developing a wreck in place salvage plan.

42.A Appendix: Dewatering

42.A.1 Dewatering Tools and Methods

1. Patching and sealing
   - Materials – steel, aluminum, wood, concrete, composites, glass-reinforced plastic (GRP)
2. Pumping:
   - Pump types
3. Compressed air:
   - Displacement method
4. Combined air and pump
5. Induced buoyancy.

Removing floodwater, or *dewatering*, recovers buoyancy lost by flooding, as opposed to increasing buoyancy by removing cargo, stores, or other weights that were in the ship before the casualty. Floodwater is removed by pumping, compressed air, or by *induced buoyancy* methods that displace water with buoyancy objects. Leakage into spaces to be pumped must be reduced to less than available pumping capacity by patching and/or securing open valves and fittings. Submerged compartments can be pumped through cofferdams that extend the boundaries of the space above the waterline. The tops and sides of spaces to be dewatered with compressed air must be made airtight. Spaces dewatered with induced buoyancy need not be made watertight, but other preparations may be necessary. Each dewatering method has advantages and disadvantages.

42.A.2 Compressed Air Dewatering

Buoyancy can be recovered by forcing water out of flooded spaces with compressed air. Compressed air dewatering is used when pumping is not practical or the construction of the casualty particularly suits it to use

of compressed air:

- Dewatering large tanks, holds, or machinery spaces that have bottom damage.
- Dewatering double-bottom or deep tanks.
- Dewatering cargo tanks in tankers and bulk liquid tanks in other ships.
- Dewatering holds filled with cargo that prevents placing of pump suctions or lowering of pumps to reduce suction lift.
- Dewatering sunken ships submerged too deeply for the practical use of cofferdams and pumps.
- Regaining sufficient buoyancy to refloat capsized vessels upside down or on their side.
- Recovering buoyancy in flooded submarine compartments and ballast tanks.

Because the tops and sides – as well as the bottoms – of liquid tanks are watertight and airtight, buoyancy can be recovered from flooded doublebottom or deep tanks without patching and little other preparation, so long as damage is confined to the bottom and lower side plating. Buoyancy quickly recovered from flooded tanks may be sufficient to refloat stranded ships, or prevent damaged ships from sinking.

Despite its advantages, compressed air dewatering has a number of disadvantages:

- The preliminary work to prepare most types of ships for blowing with compressed air is much greater than for pumping. Extensive patching and/or diving work may be required to obtain a sufficient degree of airtightness. An accepted rule of thumb is that compressed air will escape four to six times faster than water through a given opening. Considerable strengthening of decks and hatches may be required before dewatering with compressed air. Compressed air exerts its upward force on the tops of compartments, from the inside. A ship's structure is, in general, designed to withstand sea pressure from below and outside the hull.
- Compartments can be overpressurized if vents are not properly sized or become obstructed, or blowing operations are not carefully monitored.
- Ships raised on compressed air leave the bottom suddenly and can be difficult to control during ascent as the compressed air expands.
- Because of the inefficiencies of pumping compressible fluids, the dewatering capacity of a compressor is much less than that of a pump of equal weight.

The basic requirements for compressed air dewatering are a blowing connection to which an air hose is attached, a gage to monitor compartment pressure, and a route for the water to escape. The blowing connection can consist of an air fitting attached to a vent pipe or sounding tube, or permanently installed in the deck above the compartment to be dewatered. The diameter of the air fitting should equal or exceed the air hose diameter. An air fitting can also be mounted on a plate sized to fit a manhole, scuttle, or butterworth fitting. Figure 42.1 shows a typical salvage blowing fitting. As an alternative, air hoses can be led through hull openings below the waterline. A valve to control air pressure can be installed on the air fitting or in the supply hose if a relief or dump valve is installed upstream in the system. The pressure gage should be installed on the air fitting plate or other *direct access* to the space. If the gage is installed in the air supply line, air flow must be secured to get an accurate reading of the pressure inside the space (this means the gage must be *downstream* of the supply valve).

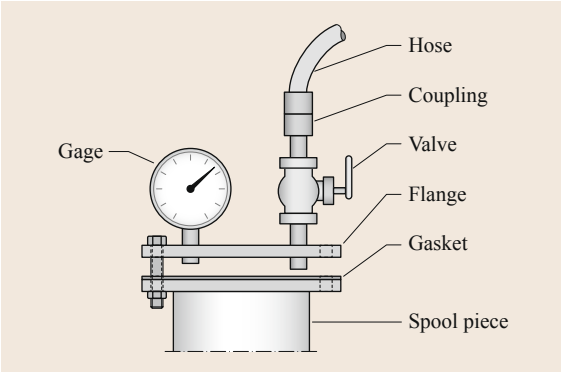

Fig. 42.1 Blowing fitting

42.A.3 Recoverable Buoyancy

The buoyancy that can be recovered from any compartment is directly proportional to the volume of the compartment that can be blown down without air leaking from the compartment. If a compartment has damage only at the bottom, nearly all the buoyancy can be recovered. If damage extends up the side of the compartment, only the volume above the highest extent of the damage represents recoverable buoyancy.

42.A.4 Vents and Standpipes

In a compartment with holed bottom plating, water is forced out through the openings in the bottom of the space as compressed air fills the compartment from the top down. A space flooded without free communication to the sea can be dewatered by use of a standpipe, or by cutting openings in the hull as shown in Fig. 42.2. The volume of water expelled, and thus the buoyancy regained, can be varied by adjusting the length of the standpipe or height of the hull openings.

Compressed air volume, and therefore added buoyancy, can also be limited by securing blowing before the water level reaches the vent holes or standpipe. This method is acceptable for strandings, afloat casualties, and ships sunk to shallow depths. By controlling the amount of buoyancy recovered in different spaces, trim, list, and draft can be controlled as desired.

For deeply submerged ships or objects, partly dewatering a space with compressed air is very hazardous and should not be attempted; as the casualty rises, the air expands, adding buoyancy in a rapid and uncontrolled manner. The resulting instability can cause the casualty to assume extreme trim or list; other components of the lifting system can be overloaded or fail. Buoyancy should be recovered in small increments in deeply sunken ships to avoid instability.

42.A.5 Expedient Blowing Fittings

It is occasionally necessary to restore buoyancy to flooded spaces rapidly to prevent sinking or capsize. Tanks and similar spaces that can be made airtight easily can be dewatered quickly with compressed air. Tanks are made airtight by removing the gooseneck standpipes from the tank vents and hammering damage control (DC) plugs into the vent pipes. A positive seal is ensured by coating the plugs with an epoxy compound; air pressure will force the epoxy into small gaps between the plug and pipe. Compressed air can be introduced into the space through the most appropriate expedient fittings available. After the situation has stabilized, the fittings can be systematically replaced by steel blowing plates with valves, gages, and hose couplings. In many cases, introducing compressed air through vent pipes is the fastest way to regain buoyancy in damaged double-bottom tanks. Ships damaged by grounding can be kept from sinking in this manner.

42.A.6 Removing Liquids Other than Floodwater

Compressed air can be used to remove fuel or other liquids from submerged tanks by leading a discharge hose from the standpipe to a receiving ship or barge. It is preferable to use pressurized inert gas rather than compressed air to move a flammable liquid. Blowing with compressed air increases partial pressure of oxygen in the space, possibly creating an explosive atmosphere, even if the tank was previously inerted. Inert gas systems often use the main engine flue gas that is inherently oxygen deficient. These gases are themselves flammable when mixed with sufficient oxygen. Inert gas-generating systems can create high enough pressures to be used for shallow depths; for higher pressures, it may be possible to discharge an inert gas generator into a volume tank, which in turn is led to the inlet of an air compressor. Carbon dioxide or nitrogen from high pressure flasks can be used, but large quantities are required.

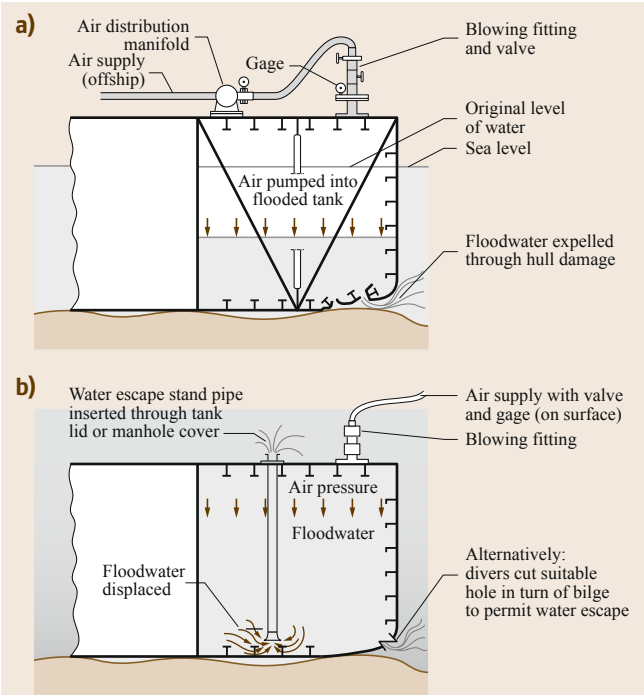

Fig. 42.2a,b Compressed air dewatering: **(a)** dewatering through hull damage; **(b)** dewatering a closed compartment

42.A.7 Combined Use of Air and Pumping

The most common use of combined pumping and blowing is to keep the pressure differential across bulkheads or shell plating within acceptable limits. Excessive pressure differentials can result from either of two conditions:

- When a compartment is dewatered by pumping, the inner sides of the bulkheads, shell, and decks are subjected to atmospheric pressure. The outer sides are subjected to an opposing hydrostatic pressure that varies with depth. If the water depth is great enough, hydrostatic pressure will be excessive.
- To completely dewater a compartment with compressed air, air pressure in the compartment must be greater than the hydrostatic pressure at the bottom of the space. When blowing deep compartments, such as tanks or holds, the high blowing pressure can cause an excessive outward pressure near the top of the compartment.

Combined pumping and blowing is advantageous in those situations where the work and time required to seal the compartment are less than that to shore or strengthen the casualty's structure against excessive pressures.

Combined pumping and blowing is a difficult technique because all the problems of both methods are present:

- Compartments must be sealed for blowing with special attention paid to boundary penetrations for pump suctions, discharges, power lines, hydraulic hoses, etc.
- Pressure on each compartment must be monitored carefully to ensure that the maximum blowing pressure is not exceeded.
- Air flow rate must be matched to water outflow rate (total pumping capacity) to avoid overpressurization.
- Holes must be double-patched.

Air flow must be controlled to ensure that internal pressure does not rise so high that the compartment cannot contain it or fall so low that hydrostatic pressure collapses the structure. Air flow rate is controlled by throttling air inlet lines or varying compressor speed. Correct matching of air and water flow will be verified by relatively constant compartment pressure. If it is not possible to vary air flow, compartment pressure can be maintained between upper and lower limits by intermittently admitting compressed air.

Under some conditions, it may be desirable to use air pressure to increase net positive suction head (NPSH) to improve pump performance. When pumping both flammable liquids and pressurizing the tank with an inert gas improve pump performance and reduces the danger of ignition. Many tanker cargo pumps are designed for optimum operation with a 5–10 psi inert gas pressure.

When some compartments are best dewatered by pumping and others by compressed air, each may be handled independently by the most suitable method. Care must be taken to ensure that pressure differential across bulkheads separating compartments to be blown from those to be pumped does not exceed the design pressure of the bulkhead.

42.A.8 Induced Buoyancy

Although pumping and compressed air dewatering induce buoyancy, the term *induced buoyancy* is specifically applied to methods where water is removed from a space and replaced with a buoyant medium other than air. Two general methods are used:

- Buoyant objects – Buoyant objects are introduced into a flooded space. By displacing water and reducing the space's permeability, a portion of the lost buoyancy is regained. Both purpose-built and improvised systems have been used.
- Cast-in-place foam – A buoyant foam is used to displace water and fill all or part of the space with a homogeneous, continuous mass.

The principal advantage of using induced buoyancy methods instead of compressed air or pumping is that it is not necessary to make the spaces to be dewatered completely air or watertight. However, these methods recover less buoyancy than compressed air, and cast-in-place foam and purpose designed buoyant object systems are generally more expensive to use than compressed air.

42.A.9 Expedient Buoyancy Recovery

Virtually, any buoyant object that is available in sufficient quantity can regain buoyancy by being injected, inserted, or placed in the spaces to be dewatered. Some examples include:

- Lifejackets, empty oil drums, small spheres, or other buoyant objects placed by divers or special-purpose equipment.
- Lift bags or collapsible pontoons placed inside flooded spaces, then inflated.
- Rigid pontoons placed in cargo holds so that they lodge under overhanging deck edges, as shown in Fig. 42.3.
- Wood chips, cork floats, etc., pumped into spaces as a slurry.

A buoyant cargo that has not lost its buoyancy through leakage, rupture, or waterlogging may carry a significant portion of the casualty's weight. The buoy-

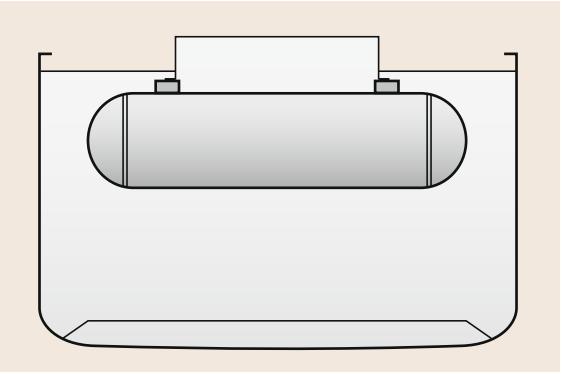

Fig. 42.3 Pontoons placed inside holds

ancy of the cargo reduces the lift required and should not be neglected in the salvage calculations.

42.A.10 Cast-in-Place Foam

In this technique, liquid chemicals are mixed on the surface or in a submerged mixing gun and pumped or blown into interior spaces of the casualty. There, the mixture undergoes a chemical transformation into polyurethane foam. The foam consists of a matrix of tiny gas-filled cells. The gas, usually a fluorocarbon, is blown into the liquid urethane as it is injected into the space and causes the expansion necessary to displace water; the cell walls, after hardening and curing, are strong enough to resist further expansion of the gas as water pressure changes as the vessel refloats. The foam hardens very quickly – within a minute or so of being injected – and forms a rigid, buoyant mass. The foam collects on the top of the compartment, displacing the water. Foam density, strength, and curing time depend on a number of factors, including water depth and temperature, and should be determined by on-site experimentation. Theoretically, cast-in-place foam could be used at very great depths, but foam density increases with water depth, so less buoyancy is recovered. It is unlikely that cast-in-place foam would be practical or economical for water depths greater than 200 ft.

Cast-in-place foam has the following advantages:

- The required equipment and chemicals are transportable by air and small craft.
- The expanding foam blocks and seals small holes, cracks, and splits.
- Buoyancy is recovered without creating free surface.
- The rigid foam possesses shear strength and adheres to internal structural members. The buoyant force is distributed through the casualty; less deck stiffening is required than when using compressed air or other water displacement methods. The hardened foam has some compressive strength and contributes to the overall hull girder compressive strength. The foam also inhibits buckling in shell and bulkhead plating. The contribution of foam to overall strength varies with foam quality and thoroughness of application, and is difficult to quantify. Foam installed in the hull may justify the use of a reduced factor of safety for compressive hull loading.
- The COG of the system, once cast in place, is fixed and predictable. The same is true for the COB so long as the entire foam block is submerged.
- The volume and shape of the foam mass are not subject to change as the vessel rises.
- Foam can be selectively distributed throughout large, undivided spaces, optimizing effects on trim and stability.

The use of cast-in-place foam has several disadvantages:

- The chemicals used to create the foam are toxic, flammable, and vapor-producing. Blending foam components gives off highly toxic vapors, and the foam may create irritating and toxic vapors while curing after the space is dewatered. When the foam is cut or crushed for removal, fluorocarbon gas (freon) is liberated from the foam cells that may displace oxygen in confined spaces, and is considered an environmental pollutant (damaging to upper atmosphere ozone layer).
- Urethane foam is very flammable.
- Foam is relatively expensive.
- Especially trained personnel and sensitive pumping and proportioning controls are required to reliably produce foam of consistent quality.
- The chemical reaction that creates the urethane will produce enough heat to self-ignite if laid down in air in thick layers that cannot dissipate the heat rapidly. The heat can ignite other flammables and induce undesirable chemical reactions.
- The hardened foam is very difficult to remove, especially from cluttered spaces such as machinery rooms.
- Foam components must be batched exactly to suit water and air temperatures, especially in very cold conditions.
- A foam mass in the top of a compartment, as high weight, may cause instability when the vessel is refloated.

The apparent simplicity of foam in salvage is deceiving. It is difficult to produce good quality foam consistently in the field. Foaming is a major operation involving serious safety and fire hazards. Foam should be used only when it is clearly the best alternative.

42.B Appendix: Common Formulas, Calculations, and References

42.B.1 Trim and Stability

Free Communication Effect

A partially flooded, noncenterline space open to the sea introduces the effects of both off center weight and free surface. In addition, floodwater is free to enter or leave the space as the ship inclines. The distribution and weight of floodwater vary with time as the ship inclines. This creates virtual rise in the COG, in addition to that caused by free surface

$$\text{Virtual rise of } G = \frac{A(y2)}{\nabla 1}\,, \tag{42.1}$$

where A is plan area of the flooded compartment, y is transverse distance from the center of the flooded compartment to the ship's centerline, and $\nabla 1$ is volume of displacement after flooding to the waterline.

Free communication exists only when the water level inside the damaged compartment remains the same as the sea level outside the hull. This occurs only when the hull opening is relatively large compared to the volume of the space, and the compartment is vented.

Added Weight Versus Lost Buoyancy

The added weight method assumes that flooding, with or without free communication, increases the weight of the ship by the weight of the floodwater and that none of the hull surface exposed to the buoyant force of the water is lost.

An alternative method, the lost buoyancy method, can be used where floodwater in free communication with the sea is assumed to remain part of the sea, and the flooded portion of the ship no longer contributes buoyancy. The vertical pressure forces about the flooded compartment are assumed to act on the sea rather than on the ship.

Flooding in free communication with the sea can be assessed by either method, but the two methods cannot be mixed during calculations. Table 42.1 itemizes the important points of the two methods. The method used is a matter of personal preference, although the added weight method is more commonly used.

Table 42.1 Added weight versus lost buoyancy

Item	Added weight	Lost buoyancy
Change in displacement	Yes	No
Change in volume of displacement	Yes	No
Change in draft, trim, and list	Yes	Yes
Shift of center of gravity	Yes	No
Shift of COB	Yes	Yes
Shift of metacenter	Yes	Yes
Free surface correction required	Yes	No
Free communication correction required	Yes	No

Ground Reaction Calculations

Residual Buoyancy Distribution Method. Analysis of as-grounded weight and buoyancy distribution can determine the ground reaction and help to determine its distribution and center of pressure. The area between the weight curve and the buoyancy curve for the stranded waterline is the total ground reaction. While the area between the weight and buoyancy curves is equal to the ground reaction, the shape of this area does not define the ground reaction distribution precisely. The load curve formed by the sum of weight, buoyancy, and ground reaction curves is not zero at every point, even though overall equilibrium exists. For equilibrium to exist, ground reaction must be distributed so that the combined COB and ground reaction is in vertical line with the COG. By distributing ground reaction increments over the grounded length so that the combined COB and ground reaction is in line with the COG, the ground reaction distribution may be described with reasonable accuracy. This method is well suited for use with computers and automated hull form databases.

The buoyancy curve is developed from section areas taken from Bonjean's curves or calculated from offsets. For most strandings, entering drafts can be determined by linear interpolation between forward and after drafts by either calculative or graphical means. If the ship is noticeably hogged or sagged, the buoyancy curve should be developed from drafts taken at several stations.

Change of Displacement Method. Ground reaction can be estimated by entering the curves of form or hydrostatic table with the drafts before and after grounding and reading the displacements for the two conditions

$$R = \Delta b - \Delta g\,, \tag{42.2}$$

where R is the ground reaction, Δb is the displacement immediately before stranding, Δg is the displacement after stranding.

Change of Draft Forward Method. The change of draft forward method considers the ground reaction as equivalent to a weight removal that causes both parallel rise and the change of trim. The center of ground reaction must be known or estimated with reasonable accuracy to determine the trimming lever. The distances

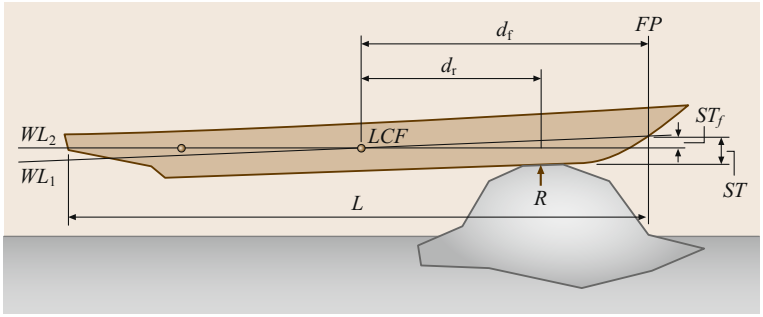

Fig. 42.4 Change of draft forward method

used in the following derivation are shown in Fig. 42.4.

$$R = \frac{\Delta T_f(\text{TPI})(\text{MT1})(L)}{(L)(\text{MT1}) + (d_r)(d_f)(\text{TPI})} , \tag{42.3}$$

where Δt is the total change of trim [in], ΔT_f is the change of draft forward $= T_{fb} - T_{fa}$, d_f is the distance from the center of flotation to the forward perpendicular, d_r is the distance from the center of flotation to the center of ground reaction, R is the ground reaction [tons], MT1 is the moment to trim one inch, TPI is the tons per inch immersion [TPI].

The basic relationship can also be solved for d_r

$$d_r = \frac{1}{\text{TPI}(d_f)} \left[\frac{\Delta T_f(\text{MT1})(\text{TPI})L}{R} - L(\text{MT1}) \right] . \tag{42.4}$$

Tons per Inch Immersion Method. A simple, but often satisfactory estimate of the ground reaction can be made by multiplying the change in the mean draft on stranding by the TPI

$$R = (T_{mbs} - T_{mas})\text{TPI} , \tag{42.5}$$

where T_{mbs} is the mean draft before stranding, T_{mas} is the mean draft after stranding.

The TPI method is often used because mean drafts and TPI can be estimated in the absence of detailed information.

This method considers only the bodily rise of the ship and is suitable for a first estimate of ground reaction when trim has not been changed greatly by the stranding. If the stranding causes a significant change of trim, the accuracy of the method can be improved by correcting the mean draft for trim by the displacement correction for trim.

Change of Trim Method. The change of trim method is most useful when the total trim exceeds 1% of the ship's length, the center of pressure of the ground reaction is known or can be estimated with reasonable accuracy, and the change of trim is the dominant effect of the stranding. Ground reaction is treated as a force that causes only a change of trim.

$$R = \frac{\text{MT1}(\Delta t)}{d_r} , \tag{42.6}$$

where Δt is the total change of trim [in].

Neutral Loading Point. When a weight is added to a floating ship at a point other than the LCF, there is a point on the opposite side of the LCF where the opposing changes in draft caused by trim and parallel sinkage are exactly equal and draft remains constant. By applying this principal to a stranded ship, a neutral loading point (NP), where weight can be added or removed without changing the ground reaction, can be defined. There is no tendency for the hull to move at the point of ground reaction, so the ground reaction remains unchanged. Using the referenced dimensions as shown in Fig. 42.5, location of the neutral loading point is

$$d_n = \frac{(\text{MT1})(L)}{(\text{TPI})(d_r)} , \tag{42.7}$$

where: d_n is the distance from LCF to NP, MT1 is the moment to change trim one inch, L is the length between perpendiculars, TPI is tons per inch immersion, d_r is the distance from the center of ground reaction to LCF (location of LCF should be based on stranded drafts).

The neutral loading point is a datum which helps predict the effect of weight changes at other locations. Weights added aft of the neutral loading point will decrease the ground reaction; weights added forward will increase the ground reaction. The opposite is true for weight removed. As weight is added or removed, the ship will trim; if trim is sufficient to alter MT1, TPI, or the position of LCF, the location of the neutral loading point must be recalculated.

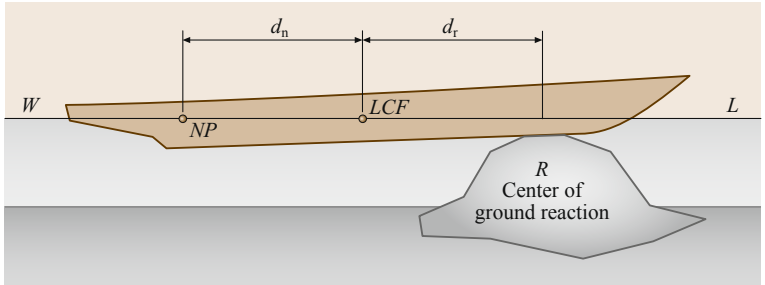

Fig. 42.5 Neutral loading point

The change in ground reaction (ΔR) resulting from a weight change at any point along the length of the ship can thus be predicted by the following relationship

$$\Delta R = w\left(\frac{d}{d_{nr}}\right) , \tag{42.8}$$

where w is the weight added or removed, d is the distance from the added or removed weight to the neutral loading point, d_{nr} is the distance from the neutral loading point to the center of ground reaction $= d_n + d_r$

Tide and Ground Reaction. The waterline of a stranded ship rises and falls with the tide. For a ship that cannot trim, the change in ground reaction caused by the tide is nearly equal to the change in height of the tide multiplied by TPI. For a ship that can trim with tide changes, the change in ground reaction can be estimated by relating the change of ground reaction to change in draft at LCF. For a change of trim, draft is constant at the center of ground reaction. The change of draft at LCF from trim is then given by

$$\Delta T_{\text{LCF, trim}} = \Delta t\left(\frac{d_r}{L}\right) , \tag{42.9}$$

where Δt is the change of trim [in], d_r is the distance from the center of ground reaction, or assumed pivot point, to the center of flotation, and L is the length between perpendiculars.

The total change in draft at LCF is the sum of the changes caused by trim and rise or fall of tide. The change in draft because of tide is simply the change in tide height. The two changes are opposed; a falling tide tends to decrease draft, but the rotation of the ship about the pivot point tends to increase draft at LCF. A rising tide has the opposite effect. Total change in draft at LCF is then

$$\Delta T_{\text{LCF}} = \Delta h - \left(\frac{d_r}{L}\right) , \tag{42.10}$$

where Δh is the tide change [in].

Change in ground reaction can be estimated by multiplying change in draft at LCF by TPI.

$$\begin{aligned}\Delta R &= \left[\Delta h - \Delta t\left(\frac{d_r}{L}\right)\right]\text{TPI} \\ &= \Delta h(\text{TPI}) - \Delta t\left(\frac{d_r}{L}\right)\text{TPI} .\end{aligned} \tag{42.11}$$

Expressing Δt as $\Delta R d_r/\text{MT1}$ implies an assumption that the ship is trimming about its center of flotation; it is not. This assumption introduces errors into ground reaction predictions for different heights of tide. As salvage operations progress, drafts should be taken regularly and ground reaction estimated for the height of tide at that time. Plots of ground reaction as a function of height of tide can be used to predict ground reaction. The relationship between ground reaction and state of tide will not remain constant. The working of the casualty on the bottom will deform both the hull and seafloor, shifting the pivot point and altering the response to tidal fluctuations. The degree to which the vessel response is altered depends on the degree of motion of the casualty, range of tide, effects of currents and waves, and strength of the supporting seafloor. Analysis of ground reaction versus tide plots will show trends that can be used to refine predictions of ground reaction.

Effect of Grounding on Center of Gravity. Ground reaction is equivalent to removing an equal weight from the keel, and causes a virtual rise in the COG similar to that caused by the block reaction on a ship in drydock

$$\text{GG}_1 = \frac{R(\text{KG})}{(W-R)} . \tag{42.12}$$

The effective height of the COG can be calculated directly

$$\text{KG}_1 = \frac{(\text{KG})(W)}{(W-R)} , \tag{42.13}$$

where GG1 is the virtual rise of the COG, KG1 is the effective height of the COG when the ship is aground, KG is the original height of the COG above the keel, W is the weight of the ship, and R is the ground reaction.

Grounding Off Centerline. A stranding with the center of ground reaction off the centerline experiences both a loss of displacement and an upsetting moment. If free to incline, the ship will assume a list. The upsetting moment can be calculated by multiplying the distance off center of the effective point of ground reaction by the magnitude of the ground reaction as shown in Fig. 42.6. Summing moments about the effective point of grounding

$$Rs = Bt = W\,\mathrm{GZ} = W\,\mathrm{GM_{eff}}\sin\theta \text{ (at equilibrium)}\,, \qquad (42.14)$$

where R is the ground reaction, s is the distance off centerline of effective point of ground reaction, B is the buoyant force (displacement aground, $W-R$), t is the lateral distance from effective point of ground reaction to COB, W is the gross weight of the ship (displacement before stranding $\pm$ weight changes after stranding), GZ is the righting arm, taken from the stability curve, $\mathrm{GM_{eff}}$ is the metacentric height, as stranded (corrected for free surface and virtual rise of G), and θ is the angle of list.

The ship will incline until the moments are balanced or until it slides off the bank or rock. Unless restrained from sliding off the pinnacle, there is little probability of capsize in still water. In order to capsize, the ship must lift off of the pinnacle; ground reaction and upsetting moment will fall to zero and the ship will settle back onto the pinnacle. Off center ground reaction may reduce righting energy to the point where external forces (wind, waves, towline pull) or internal weight shifts (free surface, cross-flooding, intentional weight movements, sliding objects) can capsize the ship. Fine-lined ships aground on rocky shores with large tidal ranges are most at risk.

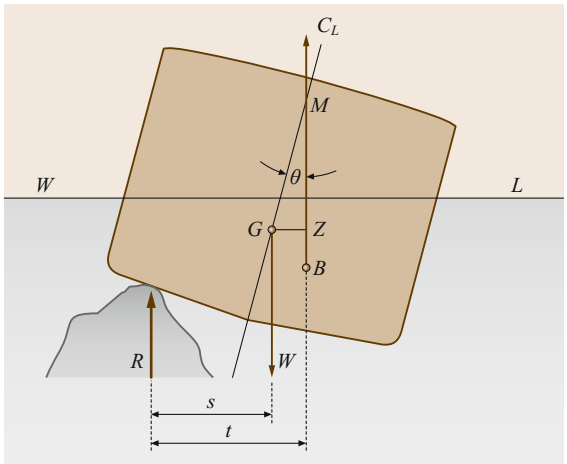

Fig. 42.6 Grounding off centerline

Friction and Freeing Force. Friction between the seafloor and the casualty's hull must be overcome to pull the ship free. On rock, coral, and cohesionless soils, the frictional force resisting the movement of a stranded ship is a function of the ground reaction component normal to the bottom and a coefficient of friction (μ). For the shallow bottom slopes encountered in most strandings, the normal component of ground reaction is essentially equal to the ground reaction (R) and

$$F_\mathrm{f} = \mu R\,, \qquad (42.15)$$

where F_f is the friction force.

Table 42.2 provides coefficients of friction for seafloor and shore soils based on the operational experience.

For cohesive soils, friction is a function of the contact area and soil shear strength

$$F_\mathrm{f} = sA\,, \qquad (42.16)$$

where s is the soil shear strength and A is the area of hull in contact with the seafloor.

42.B.2 Hull Strength in Salvage

Ships are designed and constructed to withstand the shear forces and bending moments expected in their normal service. In an intact floating ship, maximum bending moment occurs at or near the midships section. Maximum shear force occurs near the quarter-length points. Ships have heavier scantlings in high-load areas to keep stresses within acceptable levels. Two conditions common in salvage operations cause unusual hull stress distribution:

- The ship is loaded in ways the designer has not foreseen. Due to flooding, grounding, or other unusual conditions of loading, maximum bending moment occurs at a section other than midships, and maximum shear is at points other than the quarters.

Table 42.2 Coefficients of friction for strandings

Seafloor type	Coefficient of static friction [μ]	Remarks
Silt or mud	0.2–0.3	Suction effects not included
Sand	0.25–0.4	μ increases with grain size
Gravel or pebble	0.4–0.5	
Hardpan	0.5–0.8	Densely consolidated sand and clay, may include gravel
Coral	0.5–0.8	Lower values for dead or pulverized coral
Rock	0.8–1.5	See accompanying text

- Damage alters the geometry of the ship sections, so that maximum stress is in a section other than that of maximum bending moment or shear. Damage, even over a short distance, disrupts the continuity of longitudinal members and reduces the load-carrying ability of the structure for some distance on either side of the damaged section.

Casualty hull girder stresses should be monitored carefully throughout the salvage operation. The salvage engineer takes three actions with regard to hull girder strength:

- Analyzes the casualty's initial condition.
- Determines the casualty's ability to carry loads imposed by environmental conditions and planned salvage actions.
- Determines methods to reduce excessive hull stresses by altering load distribution or reinforcing critical sections.

Initial determination of strength deck and keel bending stresses, including the effects of damage and altered loading, sets a baseline for analysis. As a minimum, stress levels should be determined at damaged sections, where shear force or bending moment is maximum, and where the salvage engineer's judgment indicates there may be problems. The potential effects of major weight changes on load, shear, and bending moment should be examined before making the changes. Curves of maximum acceptable (limiting) shear forces and bending moments, based on actual section geometry, should be developed. Plotting bending shear force and bending moment curves and comparing them with allowable limits determines if planned actions will result in acceptable conditions.

Hull girder failure in bending usually starts with the compressive failure of the top or bottom of the girder. Compressive failure of longitudinally stiffened deck and single-bottom structures almost always takes the form of local inelastic buckling of longitudinals and attached plating. Hull girder failure may not be visible; the failure area may be obscured by other structures or the ship contents. Tensile failure is characterized by athwartship fractures in the outer flange of the structure. The fracture is accompanied by a loud report.

Damaged Strength

The hull's structural design keeps longitudinal bending stresses at acceptable levels under expected loads. Longitudinal bending stresses are highest in the sheer strake, strength deck, keel, bottom longitudinals, and bottom plating. In salvage operations, strength members should be inspected carefully for damage. Salvors should avoid intentional damage to members subject to high stress. Damage to members close to the neutral axis in the midships region, such as holing near the design or service waterline, has much less impact on longitudinal strength than damage to the strength deck and upper side strakes or bottom. Damage in the vicinity of the neutral axis near the quarter-length points can result in very high shear stresses.

A serious consequence of damage is the loss of structural continuity in critical strength members. The application of simple beam theory to ship girders is predicated on the assumption that the ship responds to shear forces and bending moments essentially as a single continuous beam. Loss of continuity in longitudinal members reduces the ability of the structure to spread shear loads across adjacent sections – both shear and bending stresses are increased. Loss of continuity in transverse members reduces the rigidity of the structure and allows longitudinal members to act independently, reducing longitudinal strength. Loss of transverse continuity in regions subject to shear or torsional loading increases shear stress and deformation. Increased shear stress and/or deformation in a section alters the bending stress distribution in that section. In addition, discontinuities in load-bearing members always act as stress raisers or concentration points. These effects, singly or in combination, can raise stresses in the hull girder to unacceptable levels.

When subjected to high enough stress, the hull will fail catastrophically. Usually, total hull failure begins with the compressive failure of the extreme fibers:

- Buckled plating, flange stiffeners, and tripped web stiffeners are evidence of compressive failure. Load shirking by the buckled members and hull deformation cause increased stress in other structural members that may then fail sequentially.
- Shear failure is characterized by wrinkles or cracks in side plating at a 45° angle to the line of stress.
- While not causing immediate failure, cyclic stressing of the hull to levels near the yield limit will reduce the endurance limit greatly, causing fatigue failure at tensile stresses below the ultimate stress. Casualties exposed to severe cyclic loading from wave or tidal action may fail in days or even in hours.

Structural members cut or torn away by battle damage, collision, or grounding cannot contribute to a section's ability to carry loads. Other types of damage reduce load-carrying capacity:

- Buckled members that have lost essentially all of their abilities to carry compressive loads, but keep a large portion of their original tensile strength.

- Large areas of heavily indented or dished plate that cannot carry compressive loads as high as undamaged plating. The tensile strength remains about the same.
- Cracks may appear around the edges of other damage or in otherwise undamaged structure. The great danger of cracks is that they will propagate under tensile loads perpendicular to the crack axis.
- Structural members exposed to high heat or fire suffer a loss of material from wastage due to accelerated corrosion, melting, or burning. Metal strength properties are altered unpredictably by the heating and cooling process, but strength and hardness are always taken as lowered. Fire-damaged members may have very little residual strength in either tension or compression.
- Holes, cuts, or tears act as stress raisers in tensioned members and induce buckling or tripping in members under compression.
- Accesses should not be cut where the loss of material will reduce the section modulus unacceptably or interrupt strength member continuity. If holes are cut in decks or shell plating, the effects of reduced plating area and stress concentration on hull girder strength must be determined, or the openings reinforced to compensate for the lost material.

Table 42.3 Standards for steel double barrel bitts

Bitt size (barrel diameter) [in]	Working load at 1/2 height, pounds	
	Welded[a]	Cast[b]
6	30 130	29 450
8	47 530	47 210
10	92 590	86 650
12	121 070	114 020
14	180 350	159 120
16	236 300	210 970
18	299 360	271 380
20	320 840	313 390
22	390 820	355 560
24	476 610	430 020

[a] based on safety factor of 2 and material yield of 36 ksi (AISI grade 1030)
[b] based on safety factor of 2 and material yield of 30 ksi (AISI grade 6030)

When stresses are within the elastic range, deleting damaged and missing structural members from the moment of inertia and shear area calculations gives a conservative estimate of a damaged hull's ability to carry shear and bending loads.

42.B.3 Lifting and Heavy Rigging

Identify suitable rigging points on a ships hull. Tables 42.3 and 42.4 provide reference load allowances for standard bitts and cleats, respectively.

Determination of Minimum Ground Leg Scope

The minimum ground leg scope is determined in the following manner:

1. Determine the *anchor depth* by summing:
   a) The height of the deck upon which the heaving gear is rigged above the waterline. (When spring buoys are used, the height of the deck above the water is not used.)
   b) The depth of water at the anchor.
   c) The embedded depth which equals:
      - 0 ft for firm sand or clay, coral, or rock
      - 5 ft for medium density sand or clay
      - 10 ft for soft mud.

   These depths are illustrated in Fig. 42.7.
2. Enter Table 42.5 with the anchor depth and read the basic ground leg scope. The basic ground leg scope includes the drag required to set the anchor properly.
3. To obtain the minimum ground leg scope, add the distance the ship must travel to refloat and the length of wire rope on deck to the basic ground leg scope. These distances are illustrated in Fig. 42.7. When the beach gear is laid to a salvage ship or barge, the distance the ship must travel is omitted from the calculation.
4. The total length of components that make up the ground leg should equal or exceed the minimum ground leg scope. Shorter scopes will cause anchor drag.
5. As chain and wire rope come in standard lengths, the next longer scope that can be made up with the components on hand is used.

Table 42.4 Steel welded horn-type cleat (after [42.4])

Cleat size (distance across horns) [in]	Rope Circumference [in]				Rope diameter [in]	Test load [lbs]
	Manila	Nylon	Dacron	Polypropelene	6 × 37 fiber core wire rope

24	107	78	63	54	47	43	39

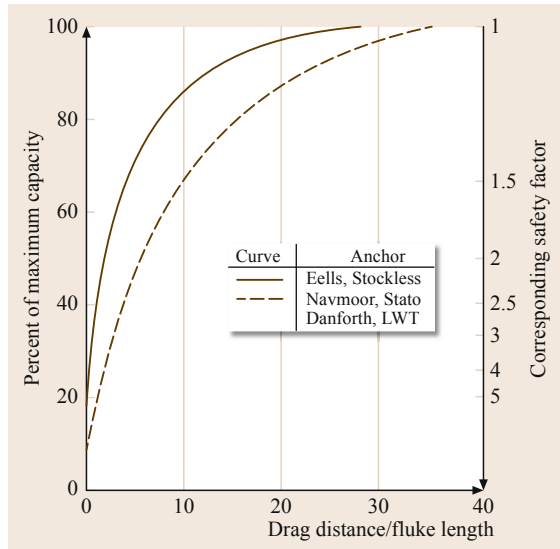

Fig. 42.8 Percent holding capacity versus drag distance in mud

In sand, maximum holding power is reached in less than 10 fluke lengths of drag. Figures 42.8 and 42.9 will help predict anchor drag distances in mud and select an anchor that will develop the required holding power in an acceptable drag distance.

Figure 42.10 shows a typical lift configuration. Each wire is rigged from one lift craft under the wreck to the other lift craft. There is a pair of wires at each transverse location. Each pair of wires has four lifting parts. The total of the vertical components equals the wreck's weight in water. The wire tension may be calculated by

$$T = \frac{W}{2N(1 + \sin \Phi)} , \qquad (42.17)$$

where N is the number of lift wire sets, W is the weight of wreck in water, T is the lift wire tension, and Φ is

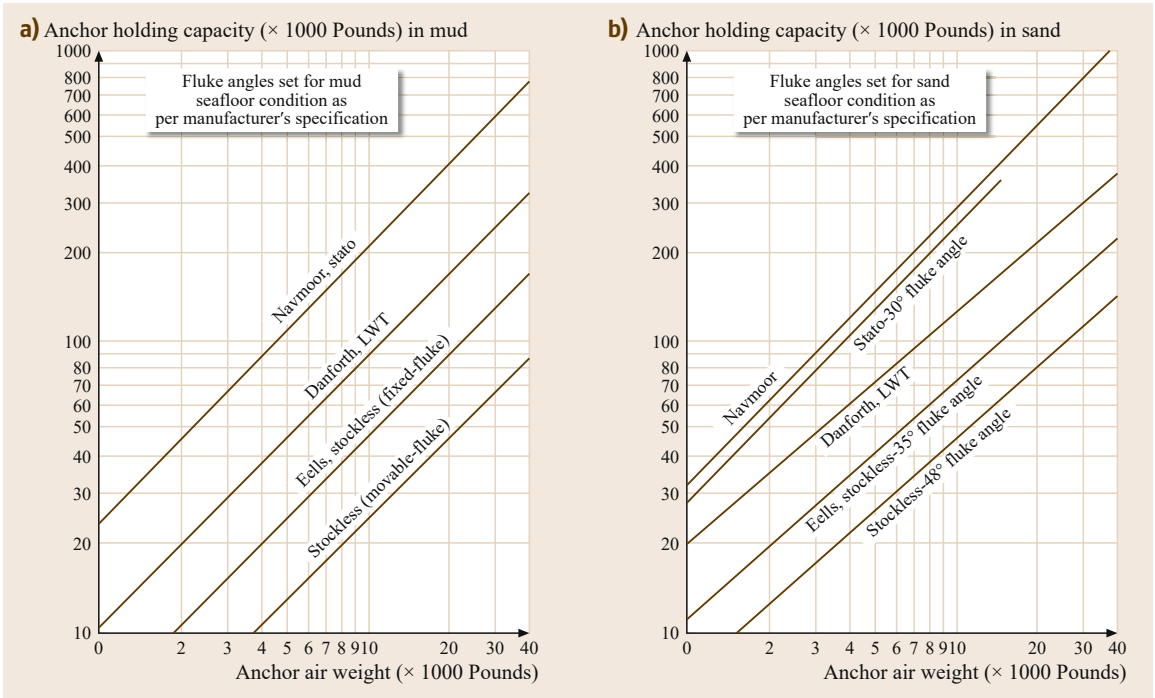

Fig. 42.9a,b Anchor holding capacity

the angle between bottom of lift craft and the outboard wire.

The possibility of lifting wire slicing, particularly at bilges, can be estimated with the empirical data presented in Table 42.6 and Fig. 42.11, a nomogram for the values of lift wire tension between 5 tons and 200 tons.

To estimate the possibility of bilge slicing occurring, with Table 42.6:

1. Calculate the lift wire tension T by taking direct readings from the hook, puller, or purchase readout gages.
2. Enter the K stress factor table with bilge radius and hull plating thickness to get K.
3. Draw a line connecting K and T; the estimated hull stress in way of each lifting wire is shown where the line crosses the principal stress line Z.

For a factor of safety of 1.5, the allowable stress for steel should be taken at 22 000 psi.

Wire Rope Selection

Breaking strength, fatigue resistance, crushing resistance, etc., and availability establish the base for conventional wire rope selection. An approximate selection formula is written as

$$\mathrm{DSL} = \frac{(\mathrm{NS})K_\mathrm{b}}{K_\mathrm{s}}\,, \qquad (42.18)$$

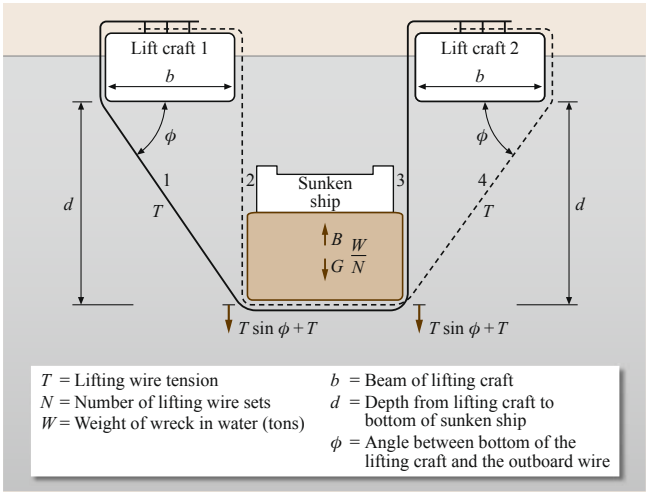

Fig. 42.10 Lifting wire tension sketch

where DSL is the demanded static load = known or dead load plus additional loads caused by sudden starts and stops, shocks, bearing friction, etc., NS is the nominal strength = published test strength, K_b is the bending factor from the curves in Fig. 42.12, and K_s is the safety factor, chosen as discussed below. In that sharp bends decrease both the strength and service life of wire rope, efforts should be taken to maintain a large ratio of sheave or drum diameter (D) to rope diameter (d).

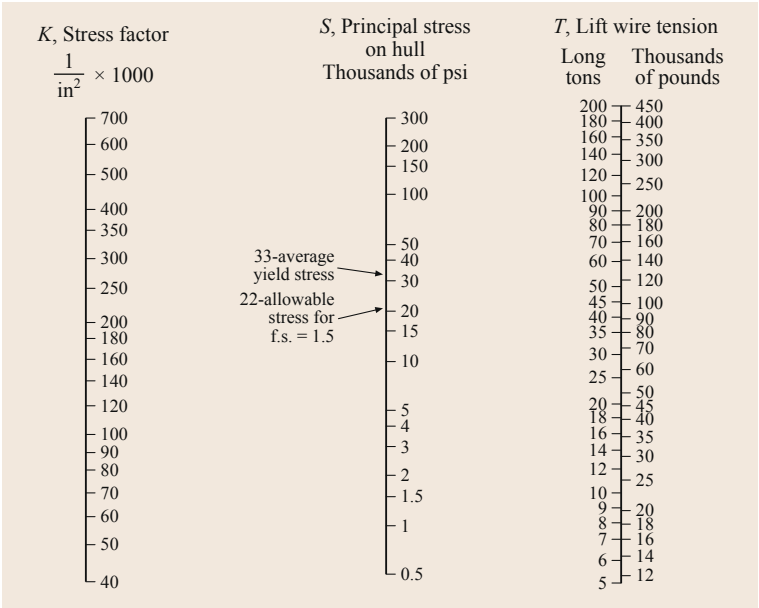

Fig. 42.11 Hull stress nomogram

Figure 42.12 provides bending factors used to calculate wire rope strength reductions as well as service life reductions.

A safety factor is selected after careful consideration of loads, accelerations, shocks, rope speeds, rope attachments, sheave arrangements and sizes, environment, etc. Standard salvage practice is to use safety factors of $3-1/2$ for standing rigging, 5 for running rigging, and 8–12 for situations with danger to life.

42.B.4 Compressed Air

Compressed Air Basics

Air compressors are rated in terms of their discharge pressure and flow rate, for example, a 500 psi/900 cfm compressor. Flow rate is given in terms of air at a standard condition. The following are the standard conditions:

- Pressure – one atmosphere (14.7 psi)
- Temperature – 68 °F
- Relative humidity – 36%
- Density – 0.075 lbm/ft^3.

In English units, flow rates are expressed in standard cubic feet per minute (SCFM). The actual volume occupied by the air delivered by a compressor depends on the pressure of the system or receiving vessel (volume tank, ships compartment, etc.). Volumes of air at standard conditions are expressed in standard units, for example, standard cubic feet (SCF). The quantity of standard air required to fill an actual volume, under nonstandard conditions, measured in actual units (actual cubic feet, ACF) can be found by a modification of

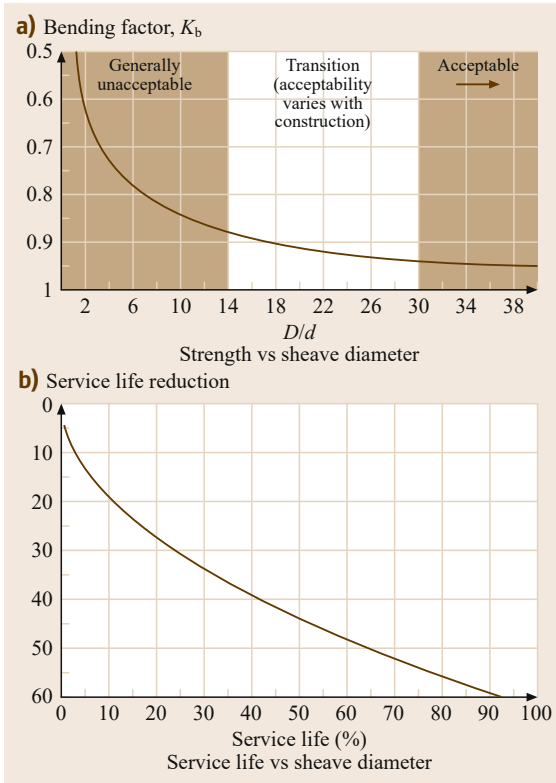

Fig. 42.12a,b Effect of sheave diameter on 6×9 and 6×37 class ropes

the gas law

$$V_s = \left(\frac{P}{P_{atm}}\right)\left(\frac{T_a}{T_w}\right)(V_a)\,, \tag{42.19}$$

where V_s is the standard air volume (length^3), P is the pressure in the space where air is required, absolute [force/length^2], P_{atm} is the atmospheric pressure, absolute [force/length^2], T_a is the water temperature at depth, absolute $= T_{Fahrenheit} + 460 = T_{Centigrade} + 273$, T_w is the water temperature at depth, absolute $= T_{Fahrenheit} + 460 = T_a$ the air temperature, absolute $= T_{Fahrenheit} + 460 = T_{Centigrade} + 273$.

Pressure can be expressed in feet of seawater (FSW):

- 1 FSW = 0.445 psi
- 33 FSW = 14.7 psi = 1 atmosphere.

When pressures are expressed as FSW, standard volume is given by

$$V_s = \frac{D+33}{33}(V_a)\left(\frac{T_a}{T_w}\right)\,. \tag{42.20}$$

Compressors

Compressors and compressed air systems are classified by their pressure rating:

- Low pressure (LP) – 150 psig or less
- Medium pressure (MP) – 150–1000 psig
- High pressure (HP) – 1000 psig or higher.

Compressors, like pumps, are classified by their design and operating features. There are two principal compressor types:

- Positive-displacement (reciprocating and rotary) compressors
- Dynamic (centrifugal and axial) compressors.

Positive-displacement compressors collect a fixed volume of air within a chamber and compress it by reducing the chamber volume. Dynamic compressors operate by transferring momentum to the air via a high-speed rotor. Blowers operate on the same principles as compressors, but at lower pressures. Thirty-five psig is the commonly used arbitrary dividing line between compressors and blowers.

Compressor displacement is the actual swept volume of the air chamber. Capacity is the quantity of air delivered by the compressor, in SCFM. Efficiency (η) is the ratio of capacity to displacement swept per minute

$$\eta = \frac{\text{SCFM}}{(\text{Displ})(\text{RPM})}\,, \tag{42.21}$$

where SCFM is the compressor capacity, standard cubic feet per minute, Displ is the compressor displacement [ft^3], and RPM is the compressor speed, rotations per minute.

If compressor displacement is given without capacity or efficiency, capacity can be estimated by assuming 80% efficiency.

Positive-displacement compressors can reach very high pressures. Unless a relief valve is installed, damage to the compressor, prime mover, or system is very likely. Dynamic compressors will reach a maximum pressure where the momentum imparted to intake air is insufficient to overcome the back pressure on the outlet; flow is zero at this pressure. All dynamic compressors have a minimum flow point, called the surge limit, below which the operation of the machine is unstable. Operation at or below the surge limit must be avoided.

Blowing and Differential Pressures

The pressure required to dewater a space is a function of water depth at the opening or bottom of the standpipe through which the water will be forced

$$P_b = 0.445D + P_L\,, \tag{42.22}$$

where P_b is the blowing pressure (psig), D is the water depth (feet), 0.445 the pressure increase per foot of seawater, and P_L the pressure required to overcome air line losses and standpipe friction, normally taken to be 2 psi.

In deep compartments, the differential pressure required to completely dewater a space may be greater than the bulkheads and top of the compartment can withstand. If so, it will be necessary to reinforce the ship's structure or limit the differential pressure by varying the length of the standpipe or the height of the vents

$$l = \left(\frac{P_d - P_L}{0.445}\right)\,, \tag{42.23}$$

where l is the length of the standpipe or distance of vent from top of compartment, P_d isthe maximum acceptable differential pressure (psig), and P_L is the pressure required to overcome air line losses and standpipe friction, normally taken to be 2 psi.

Air Flow Requirements

The standard volume of air (V_s) required to completely dewater a space is based on the pressure at the opening or bottom of the standpipe

$$V_s = \frac{D+33}{33}(V_a)\left(\frac{T_a}{T_w}\right)\,, \tag{42.24}$$

where D is depth to the vent or bottom of the standpipe (feet), V_a is the water volume, actual cubic feet = space

volume × permeability, T_w is the water temperature at depth, absolute, and T_a is the air temperature, absolute.

If the standpipe or hull openings are too small, water will flow out of the compartment at a slower rate than air flows in, creating a hydraulic block that can cause pressure to build up. To avoid damage to the space or air system, it will be necessary to secure blowing periodically until sufficient water has been forced out of the space to lower the pressure. If compartment pressure is not carefully monitored, the space can be easily over pressurized, causing damage or injury. To avoid over pressurization, the water flow rate out of the compartment must equal the actual air flow rate (Q_a) into the compartment. To find Q_a

$$Q_a = \frac{Q_s}{\text{ATA}}\,, \tag{42.25}$$

where: ATA is the absolute pressure in atmospheres $= \frac{D+33}{33}$ and Q_s is the air delivery rate.

By transposing the equation for flow through a hole or orifice, required outlet area can be found

$$Q = C_d A\sqrt{2gh_{eq}}\,, \quad A = \frac{Q}{C_d\sqrt{2gh_{eq}}}\,, \tag{42.26}$$

where: Q is the water flow rate, $\text{ft}^3/\text{sec} = Q_a$, C_d is the discharge coefficient, from Fig. 42.13, $A =$ area of outlet [ft^2], g is the acceleration due to gravity $\approx 32.2\,\text{ft/sec}^2$, and h_{eq} is the blowing pressure, expressed as an equivalent head of seawater, ft $= P_b/0.445$.

The air pressure in the compartment will equal the hydrostatic pressure at the depth of the water level in the compartment; as blowing progresses, the water level falls, air pressure increases, and flow rates (water and actual air) decrease. The standpipe or opening should be sized to accommodate the maximum flow rate – the flow corresponding to the depth at the top of the compartment.

The variation in flow rate and pressure through the dewatering may give the impression that higher driving pressure shortens dewatering time. While raising the driving pressure increases initial water flow rate, total dewatering time depends on the volume flow of the compressed air system; the compartment will not be dewatered until the air system has delivered sufficient actual cubic feet of air to fill the required volume. Flow rates of centrifugal compressors are related to delivery pressure and the higher flow rate accompanying the increased pressure will in fact shorten dewatering time.

42.B.5 Pumping

Pump Theory and Terminology

Pump terminology is based on the concept of head. Head is a measure of the energy possessed by the liquid because of its pressure (pressure head), velocity (velocity head), or elevation above a datum (static head). Head is most commonly expressed in units of distance (height) or pressure.

In the English system, pressure is usually measured in pounds per square inch (psi) and density in pounds per cubic foot. A conversion factor of $144\,\text{in}^2/\text{ft}^2$ must be used to obtain pressure head in feet

$$H = \frac{144P}{\gamma}\,, \tag{42.27}$$

where H is head, feet of liquid, P the pressure (psi), and γ the fluid density [lb/ft^3].

Densities of various liquids are tabulated in Table 42.13. Additional head terms are used to describe work done by the pump or energy available to the pump

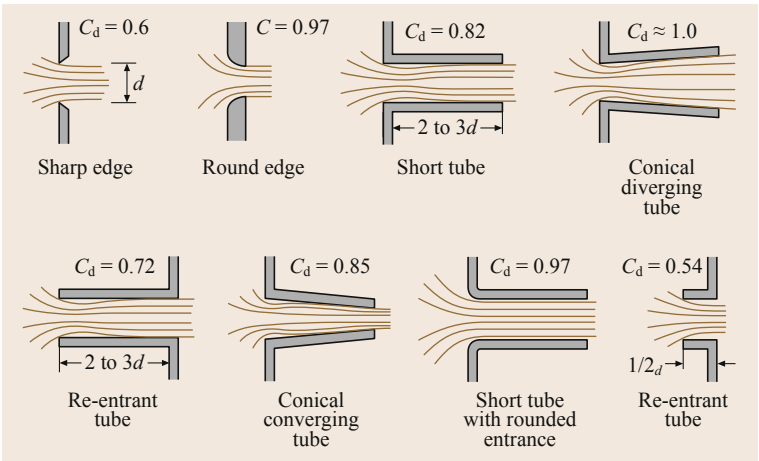

Fig. 42.13 Discharge coefficients

(because of the system configuration), and pump operating characteristics and requirements. These terms are described in the following paragraphs and illustrated in Fig. 42.14.

Atmospheric Head (H_a)

Atmospheric head is the atmospheric pressure expressed as feet of the pumped liquid. For seawater at normal atmospheric pressure

$$H_a = \frac{(144\,\text{in}^2/\text{ft}^2)(14.7\,\text{lb/in}^2)}{(64\,\text{lb/ft}^3)} = 33\,\text{ft}\,. \qquad (42.28)$$

Vapor Pressure Head (H_{vp})

Vapor pressure head is the fluid vapor pressure expressed as feet of the pumped liquid. For seawater at 68 °F, $P_{vp} = 0.34$ psi, and

$$H_{vp} = \frac{144(0.34)}{64} = 0.765\,\text{ft}\,. \qquad (42.29)$$

Vapor pressures for some common liquids at 68 °F are given in Table 42.7.

Static Suction Head (H_s)

Static suction head is the vertical distance between the liquid surface and the pump inlet. If the pump is above the liquid surface, suction head is negative. When working against negative suction head, or suction lift, a pump must create a vacuum so that the pressure differential between the liquid surface and the suction side of the pump is sufficient to lift the liquid, overcome vapor pressure in the pump casing and friction in the suction line, and accelerate the liquid. Maximum suction lift is equal to the atmospheric head (H_a) less vapor pressure head (H_{vp}), and friction head in the suction line (H_{fs})

$$\text{Max Suction Lift} = H_a - H_{vp} - H_{fs}\,. \qquad (42.30)$$

Actual suction lifts will be slightly less because of work required to accelerate the liquid and losses due to pump inefficiencies. The maximum practical suction lift for seawater at atmospheric pressure is about 25 ft for most centrifugal pumps; positive-displacement pumps can achieve slightly higher lifts. For efficient pump performance, suction lift should be minimized, below 15 ft if possible. Most centrifugal pumps must be primed to achieve any suction lift.

Table 42.7 Vapor pressures a 68 °F

Liquid	Vapor pressure [psi]
Water	0.34
Ethyl alcohol	0.85
Turpentine	0.0077
Diesel fuel (typical)	0.041
Heavy oils	0.042
Vegetable oil	0.030

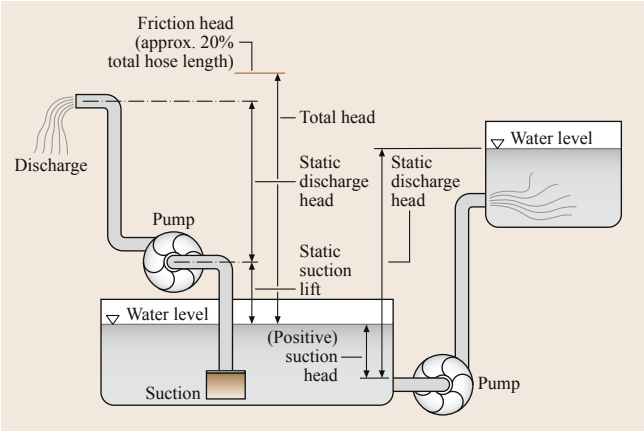

Fig. 42.14 Pumping heads

Static Discharge Head (H_d)

Static discharge head is the vertical distance from the pump to the point of free discharge, and represents the energy the pump must impart to the liquid to raise it to that height in an ideal system. If the discharge is submerged, the static discharge head is measured to the liquid surface.

Friction Head (H_f)

Friction loss in a real system is equivalent to lifting the liquid an additional height in a frictionless system. Head required to overcome friction in pipes, hoses, valves, fittings, etc., is sometimes given as pressure drop, or head loss, as a function of flow rate and length for specific types of hose, pipe, or fittings. Friction head can also be calculated as a function of velocity head, as in the Darcy–Weisbach formula

$$H_f = \frac{fLV^2}{2Dg}\,, \qquad (42.31)$$

where f is the Darcy–Weisbach friction factor, dimensionless, L is the length [ft], D is the diameter [ft], V is the flow velocity [ft/s], g = acceleration due to gravity [ft/s^2] ≈ 32.2 ft/s^2.

For laminar flow ($R_e \leq 2000$), $f = 64/R_e$, where R_e is the dimensionless Reynolds ($\Re$) number

$$R_e = \frac{DV}{\nu} = \frac{\rho DV}{\mu}\,. \qquad (42.32)$$

With kinematic viscosity (ν), fluid density (ρ), and absolute viscosity (μ), expressed in units consistent with the units of velocity and diameter. Friction head

is a function of fluid velocity, flow area, and surface roughness; for a given flow diameter, friction head increases with flow rate. Friction factors can be seen in Fig. 42.15. Friction loss in valves, fittings, and other obstructions is normally expressed as a function of velocity head

$$H_f = K\frac{V^2}{2g}\,, \tag{42.33}$$

where K is an obstruction loss factor taken from Table 42.8.

More extensive lists of friction factors or friction loss tables can be found in pipefitter or civil engineering handbooks. If unknown, friction head can be taken as not more than 20% of the total length of suction and discharge piping or hose for most salvage applications.

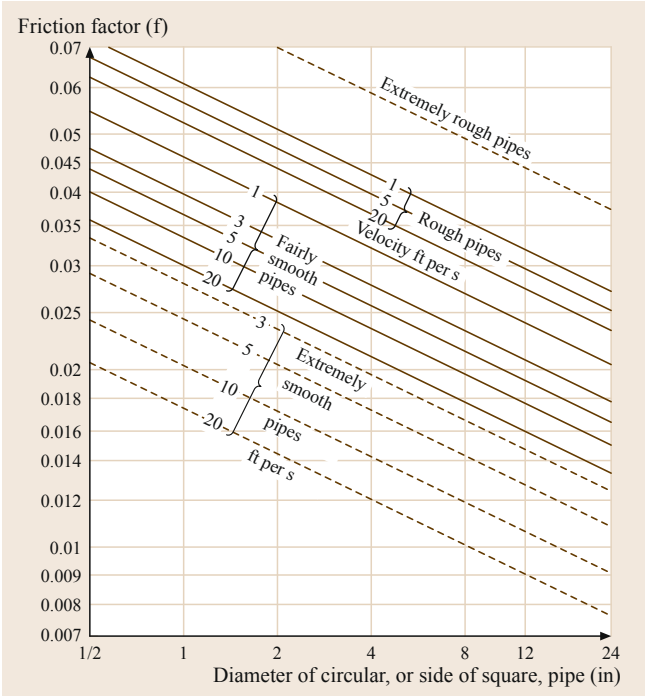

Fig. 42.15 Friction factors for pipe flow

Table 42.8 Obstruction factors (after [42.5])

Fitting	Obstruction factor [K]
Globe valve, wide open	10
Angle valve, wide open	5
Gate valve,	
wide open	0.19
half open	5.6
Strainer	2
Smooth bend	0.3
Short radius elbow	0.9
Long radius elbow	0.6

Total Dynamic Head Required (TDHR)

Total dynamic head required is a measure of the energy necessary to move the liquid through the system to the desired discharge. This measure is equal to discharge head, plus friction head, less suction head

$$\text{TDHR} = H_d + H_f - H_s\,. \tag{42.34}$$

As negative suction head (suction lift) increases, TDHR is also increase. Power used to overcome suction lift is not available to impart energy to the pumped liquid; discharge capacity and/or head are reduced.

If the pump is below the surface of the liquid to be pumped, there is a positive hydrostatic pressure on the inlet side of the pump; no work is required to raise the liquid to the pump. The positive suction head represents increased pump capacity as reflected by the reduced TDHR. Figure 42.16 shows the effect of positive suction head on a typical centrifugal pump.

Total Dynamic Head Available (TDHA)

TDHA is a measure of the total energy imparted to the fluid by the pump, and is equal to the sum of pressure and velocity head at the pump outlet

$$\text{TDHA} = H_{p2} + H_v\,. \tag{42.35}$$

Net Positive Suction Head (NPSH)

Net positive suction head is the absolute suction pressure, less vapor pressure at the pump inlet, under actual pumping conditions. It is the sum of atmospheric head and static suction head, less vapor pressure head and friction head in the suction lines

$$\text{NPSHA} = H_a + H_s + H_{vp} + H_{fs}\,. \tag{42.36}$$

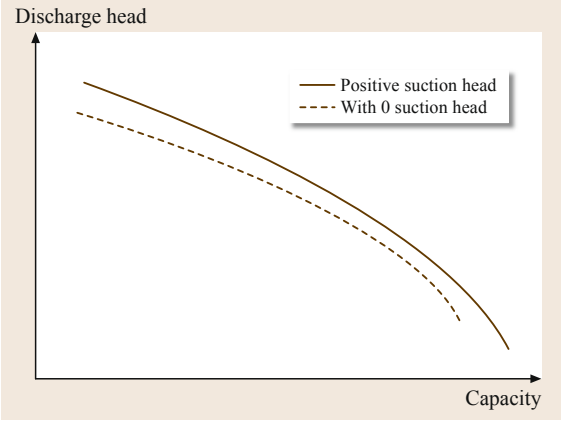

Fig. 42.16 Effects of positive suction

Net positive suction head required (*NPSHR*) is a measure of the minimum fluid energy necessary for satisfactory pump operation and is usually specified by the pump manufacturer. NPSHR is a means of quantifying the work required to accelerate the liquid and other losses. Some pump manufacturers prefer to define net inlet pressure required (NIPR); NPSH multiplied by fluid density gives net inlet pressure (NIP).

Pump Classification

Pumps are classified by their design and operating features:

- Movement that causes the pumping action
- Submersible or nonsubmersible
- Characteristics of the fluid pumped
- Flow characteristics
- Self-priming or non-self-priming
- Constant or variable speed
- Variable or constant capacity.

Major pump types are:

- Dynamic pumps, including centrifugal, axial flow, and mixed flow pumps
- Positive-displacement pumps, including diaphragm, rotary, and reciprocating pumps
- Jet pumps and air lifts.

Table 42.9 gives general characteristics of each type of pump.

Positive-Displacement Pumps

Positive-displacement pumps discharge a specific volume for each stroke or revolution; at a constant speed, capacity is essentially the same for any pressure within the capability of the driver and strength of the pump. At some discharge heads (pressure), the power required to maintain pump speed will exceed the capacity of the prime mover; as the pump slows and eventually stalls, capacity falls off rapidly. In practice, some component of the pump or piping system will fail before the prime mover is overloaded. To avoid failure, a relief valve may be installed in the discharge line.

Table 42.9 Pump characteristics

Characteristic	Displacement	Centrifugal and axial	Jet
Flow rate	Low	High	High
Pressure rise per stage	High	Low	Low
Constant variable over operating range	Flow rate	Pressure rise	–
Self-priming	Yes	No	Yes
Outlet stream	Pulsing	Steady	Steady
Works with high-viscosity fluids	Yes	No	Yes

Dynamic Pumps

Dynamic and jet pumps operate by imparting the kinetic energy of a rotating impeller (centrifugal, axial flow, and mixed flow pumps) or fluid stream (jet pumps) to the pumped liquid; the energy imparted to a liquid is converted to velocity and pressure. To some extent, velocity of the moving fluid can be converted to pressure and vice versa. Velocity head is related to capacity

$$Q = A\sqrt{2gH_v} \Rightarrow H_v = \frac{Q^2}{2gA^2} \,. \tag{42.37}$$

Jet Pumps

Jet pumps use the low pressure created by the passage of a working fluid through a restricting nozzle to draw the pumped fluid into a mixing chamber, where it is entrained with the working fluid and carried out of the eductor. Jet pumps using a liquid as a working fluid are called eductors; those using gas (such as steam or compressed air) are called ejectors. Eductors used in salvage are almost always water driven. Head and volume capacity depend on nozzle and mixing chamber geometry, pressure and flow rate of the working fluid (supply flow), suction lift, and discharge head. For most eductors designed for damage control or salvage dewatering, discharge flow (including the supply flow) is about $1-1/2$ to 2 times the supply flow, with a maximum working head of about 70 ft of water.

All eductors have the minimum supply pressure and flow requirements below which they will not operate. If the supply pressure and flow are inadequate, the supply water may dump through the eductor suction, flooding the space. Because they have no moving parts, eductors are extremely rugged and reliable. They are particularly suited for pumping slurries and contaminated water. The annular ring-type (*Peri-jet*) eductor uses several nozzles arranged around the lower periphery of the mixing chamber rather, than a single nozzle directly below the mixing chamber. This arrangement results in a straightline fluid path through the eductor that is clear of obstructions. A 4-in Peri-jet eductor can pass 2 in contaminants, although large quantities of solid contaminants may clog long discharge hoses.

Large eductors are often installed as bilge and ballast pumps. Some tankers use eductors as cargo pumps. The working fluid is cargo, delivered under pressure by other types of cargo pumps.

Air Lifts

An air lift operates by introducing compressed air into the lower end of a submerged or partially submerged

pipe. The air–liquid mixture inside the pipe is less dense than the liquid outside the pipe. The mixture rises and creates a low pressure at the bottom of the pipe that draws liquid and loose solids up the pipe. Air lifts can handle all kinds of slurries, including those consisting of relatively large particles, such as coal, gravel, ore, canned goods, or other odd-shaped objects. Air lifts are frequently used to clear mud and loose sediments from diver-working areas and to remove sediments from inside wrecks.

The efficiency of an air lift depends on air pressure and flow rate, ratio of immersed to emerged pipe length, water depth, position of the air inlet on the pipe, and the nature of the material being lifted. Air lifts will normally lift loose material only in the immediate vicinity of the lower end. Disturbing heavy or hard-packed material with water jets or other means will improve air lift efficiency. Clay, paper pulp, and similar materials tend to choke air lifts. Although air lifts are not particularly efficient as pumps, they are easy to build in the field and can move slurries, semisolid materials, and contaminants that would clog or damage other pumps.

Air lifts differ from other pumps in that the energy (air pressure) required to lift the liquid is governed by submergence, h, rather than by total head, H. For most efficient operation, air lifts should be submerged for at least two-thirds of their length, although they can operate with as little as 35% submerged. Air pressure at the air line outlet at the bottom of the lift only slightly greater than hydrostatic pressure is sufficient for operation. An empirical formula, based on experience with air lifts in mining applications, estimates required air flow

$$Q_{\text{air}} = \frac{H}{C \log(ATM)} , \tag{42.38}$$

where: Q_{air} is the air flow, standard cubic feet per minute per gallon of liquid per minute lifted, H is the total vertical lift [ft], C is the empirical factor, based on ratio of submergence to lift, from Table 42.10, ATM is submergence, expressed as equivalent atmospheres $= (h + 33)/33$ for seawater, $(h + 34)/34$ for fresh water, $(h + 34\gamma_{\text{g}})/34\gamma_{\text{g}}$ for other liquids, h is submergence (depth to foot of air lift) [ft], and γ_{g} is the liquid specific gravity.

Table 42.10 Air lift constants, C (after [42.6])

Submergence percent	C	
	Outside air line	Inside air line
75	366	330
65	348	306
55	318	262
45	272	214
35	216	162

Pipe size is determined from the initial estimates for air and liquid flow

$$d = 13.54 \sqrt{\frac{Q}{A}} , \tag{42.39}$$

where d is the air lift (discharge) pipe diameter [in], Q is the air–liquid mixture flow rate [ft^3/min], and V is the velocity of the mixture in the pipe [ft/min].

For pipes of uniform diameter and lifts of 40–200 ft, best discharge velocity of the air-liquid mixture ranges from 2000 ft per minute at 70% submergence to 700 ft per minute at 35% submergence. Maximum velocity at the bottom of the pipe ranges from 450 ft per minute at 70% submergence to 800 ft per minute at 35% submergence.

Air lifts cannot completely dewater a space because they cannot operate with more than about two-thirds of the pipe out of the water. When depth allows 25% submergence, a compound lift can be employed. Water and solids are lifted half way in one lift and allowed to run to the closed bottom of a large-diameter pipe at the same depth as the first lift. A second air lift can operate in the large pipe with 50% submergence. In deep mine shafts, water has been raised as much as 1385 ft by a series of air lifts in series using air at 60–80 psi. Air lifts are useful for removing sediments, bulk cargo, and other materials from the bottoms of spaces before dewatering with other pumps.

Salvage Pumps

Special-purpose pumps are used in salvage to meet particular requirements; salvage pumps are usually portable, general purpose dewatering pumps, adapted for marine use. A good salvage pump must have the following features:

- Rugged construction and protective framework or packaging to reduce the risk of accidental damage
- High pumping-capacity-to-pump-weight ratio
- Discharge head greater than 60 ft
- Ability to pump a variety of contaminated liquids
- Comparatively simple construction for rapid routine maintenance and repair.

Submersibility or a low NPSHR, and the ability to self-prime as well as to handle a wide range of fluid viscosities and specific gravities are also desirable. Experience has shown the following pumps to have the widest application to salvage:

- Electric- or hydraulic-motor-driven submersible pumps (centrifugal or axial flow)

- Self-contained, heavy-duty, diesel- or gasoline-engine-driven centrifugal pumps
- Pneumatic diaphragm and centrifugal pumps
- Eductors and air lifts.

Table 42.11 compares the advantages and disadvantages of commonly used salvage pumps.

Pumping Calculations

Salvage pumping calculations are usually undertaken to answer one of the three questions:

- What pumping capacity (and number of pumps) will be required to dewater a flooded space in a given time?
- How much time will be required to dewater a space with a specified pump capacity?
- At what rate will the water surface be lowered?

Suction and discharge heads do not remain constant, but change as pumping proceeds. For a fixed position pump, suction lift increases as the water level drops. If the pump is lowered to limit suction lift, discharge head will increase. Discharge head of a submersible pump remains constant, but the positive suction head decreases as the water level drops.

The means of accounting for friction and vapor pressure heads depends on the format of the pump performance data. Friction head for assumed lengths of discharge and suction piping is sometimes accounted for in performance curves or tables. The vapor pressure head is not factored into the performance curves of most pumps. Increasing fluid vapor pressure decreases a net positive suction head, so vapor pressure head can be taken into account for by adding it to the actual suction lift to determine an effective suction lift (negative suction head). The entering arguments to the performance curves or tables are thus

$$H_{s\,\mathrm{eff}} = H_{s\,\mathrm{actual}} + H_{\mathrm{vp}}\,,$$
$$\mathrm{TDHR} = H_{s\,\mathrm{eff}} + H_{\mathrm{d}} + H_{\mathrm{f}}\,, \qquad (42.40)$$

where $H_{s\,\mathrm{eff}}$ is the effective suction lift, $H_{s\,\mathrm{actual}}$ is the actual suction lift, measured from liquid surface, H_{vp} is the vapor pressure head, TDHR is the total dynamic head required, H_{d} is the static discharge head, and H_{f} is the friction head of hose or piping not accounted for in performance data.

Dewatering time for a given pumping capacity is the volume of water to be removed, divided by the pumping capacity. Since pumping capacity will vary as suction and discharge heads change through the pumping op-

Table 42.11 Pump characteristics

Pump type	Discharge head	Self-priming	Suction lift	Suitability to pump			Typical installations
				Entrained solids	Slurries	Viscous liquids	
Reciprocating	High	Yes	High	Fair	Good	Good	General marine use with steam propulsion plans. Slurry pumps. Oilfield mud pumps
Rotary	High	Yes	High	Poor	Poor	Good	Marine and industrial fuel, cargo, lube oil systems
Diaphragm	High	Yes	High	Fair	Good	Good	General-purpose. Metering
Centrifugal	Medium[a]	No[b]	Low	[c]	[c]	Poor	General use for nonviscous liquids, F/F systems. Water pumps for agricultural, construction, mine, industrial, salvage use
Mixed flow	Low[a]	No	Very low	[c]	[c]	[d]	General use for nonviscous liquids, F/F systems. Water pumps for agricultural, construction, mine, industrial, salvage use
Axial flow	Very low[a]	No	Very low	[c]	[c]	[d]	General use where high discharge head not required. Submersible pumps
Jet pumps	Low	Yes	Medium	Good	Good	Fair	Distilling plant air ejectors. Bilge dewatering/drainage. Portabtle dewatering. F/F foam proportioning systems

[a] Head can be increased by series multistaging or operating pumps in series, [b] Some centrifugal pumps are self-priming at low (< 12 ft) suction lift, [c] Pimps designed as trash or salvage pumps, [d] Impeller must be designed for specific viscosity range

eration, an incremental solution is required. The time required to pump out layers of convenient thickness (10 ft, for example) of the flooded space is calculated based on the pump capacities corresponding to the average suction and discharge heads for each layer. The total dewatering time is the sum of the dewatering times for all the layers.

To determine the rate of fall of the water surface, the volume of one unit (inch, foot, centimeter, etc.) is first calculated or estimated. The volume of the unit layer divided by the pumping capacity is the rate of fall of the water surface.

Pumps in Unusual Service

Pumps are designed to operate with a specific set or range of fluid properties. If fluid properties of the pumped liquid vary significantly from those for which the pump was designed, pump performance and service life will be affected. There are five fluid properties to be considered:

- Specific gravity
- Viscosity
- Vapor pressure
- Abrasiveness
- Corrosivity.

Viscosity

Fluid viscosity affects the pump performance in a complex manner. Figure 42.17 shows the effect of viscosity on pump capacity and discharge head. The chart is entered on the bottom horizontal scale with the pump's rated capacity (water). A vertical line is followed from the capacity until it intersects the corresponding head on the diagonal head scales. A horizontal line is then followed to the left until it intersects the viscosity of the liquid being pumped. A vertical line from this intersection intersects the correction factor curves; correction factors are read from the scale on the left. The example (dotted line) shows that a pump rated for 55 gpm at a 100-foot discharge head has a capacity of 45 gpm (0.82×55) against a 103 ft discharge head (1.03×100) when pumping a liquid with a viscosity of 400 SSU (Saybolt universal seconds).

Approximate viscosity limits of basic types of pumps are:

- Centrifugal: 3000 SSU
- Axial flow: 8000 SSU
- Reciprocating: 10 000 SSU
- Rotary: 2 000 000 SSU.

As a rule, pump speed must be reduced 25–35% for each tenfold increase in viscosity above 1000 SSU to avoid overloading the pump prime mover. This results in a 10% reduction in efficiency. The suction requirements of the pump also vary with viscosity and are referred to by viscous liquid pump manufacturers as net inlet pressure required (NIPR).

Viscosity varies with temperature and extreme pressure. The pressures encountered in dewatering and weight removal operations will have no significant effect on fluid viscosity. Table 42.12 gives viscosities for some common liquids.

42.B.6 Petroleum, Oils, and Lubricants

Definitions

There are descriptive terms for the characteristics of petroleum products that influence behavior during handling. Knowing these terms leads to a better understanding of the mechanics of POL operations allowing the user to anticipate and avoid some of the problems that occur during transfer operations.

Viscosity

A measure of the resistance to flow (internal friction) of the product at a particular temperature. Kinematic viscosity is expressed in centistokes (cSt). The viscosity of water at 68 °F is approximately 1.0 cSt. Highly viscous liquids are thicker and flow more slowly than less viscous liquids. A viscosity of about 875 cSt is the upper limit of pumpability for centrifugal pumps. An-

Table 42.12 Viscosities

Liquid	Viscosity	
	SSU	Centistokes

other type of viscosity, absolute viscosity, is measured in poise. The absolute viscosity of water at 32 °F is 1.8086 centipoise. The two viscosities are related by

$$\text{Kinematic viscosity} = \text{Absolute viscosity/density}\,.$$

Both kinematic and absolute viscosities are used in petroleum operations. Saybolt Universal Second (SSU) and Saybolt Furol Second (SSF) are units of kinematic viscosity given by readings on a Saybolt viscometer and are used primarily in marine petroleum operations. The Saybolt Universal viscometer is used for liquids having viscosities below 1000 cSt. The Saybolt Furol viscometer is used for more viscous fuel oils (*furol* is an acronym for fuel and road oils). The Furol viscosity readings are roughly 1/10 the Universal readings. For liquids whose viscosity exceeds 50 cSt at 37.8 °C (100 °F), one SSU is approximately 0.2158 cSt or 0.2158 mm^2/s. For very viscous liquids (viscosity exceeding 500 cSt) at 50 °C (122 °F), one SSF is approximately 2.120 cSt or 2.120 mm^2/s. The Saybolt seconds are considered obsolete, but they have been used traditionally in the petroleum industry and are common in technical articles. Figure 42.18 provides a means for converting between Saybolt Seconds and centistokes with sufficient accuracy for salvage work.

Specific Gravity

The specific gravity of seawater is 1.025 and must be taken into account in some oil–water calculations. Spe-

Table 42.13 Liquid densities

	Density [lb/ft]	Density [lb/gal]	Volume [ft³/ton]	Volume [gal/ton]	Specific gravity

Note: Liquids consisting of a mixture of compounds, such as petroleum products and vegetable derivatives, may vary in density from sample to sample. The densities given in this table are average or typical values. Liquid densities, especially those of petroleum products, can also vary significantly with temperature.

cific gravity is also expressed as American Petroleum Institute (API) gravities (degrees API). API gravities are based on the arbitrary assignment of a gravity of 10° to fresh water. Liquids with higher gravities are lighter than water; those with lower API gravities are heavier than water. Conversion between specific gravity and degrees API is described below. Table 42.14 gives specific and API gravities and weight-volume data for water and representative petroleum products.

Conversion from specific gravity to Degrees API is by

$$\text{Degrees API} = \left(\frac{141.5}{\text{specific gravity at } 60\,^{\circ}\text{F}}\right) - 131.5\,. \tag{42.41}$$

Table 42.14 Specific gravity, API gravity and weight of representative petroleum products

Product	Specific gravity	API gravity	lb/gal	bbl/ton
Fresh water	1.000	10.00	8.33	6.30

Table 42.15 Flammability classification of petroleum products

Class	Flash point	Reid vapor pressure
A (flammable)	80 °F or below	14 psi or above
B (flammable)	80 °F or below	Between 8.5 and 14 psi
C (flammable)	80 °F or below	Below 8.5 psi
D (combustible)	80–150 °F	NA
E (combustible)	Above 150 °F	NA

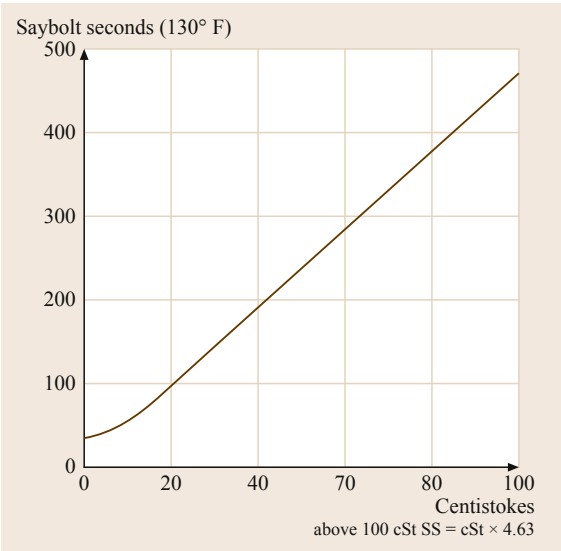

Fig. 42.18 Approximate conversion between saybolt seconds and centistokes

Flammability

A relative measure of how easily a product burns. The U.S. Coast Guard has divided POL products into two broad categories: flammable – products with flash points below 80 °F, and combustible – products with flash points above 80 °F. Products are subdivided into five grades: A, B, and C are flammable, whereas D and E are combustible. Grade A, B, and C products are defined by their Reid vapor pressure – the pressure generated by vapor when the product is placed in a sealed container and heated to 100 °F. Grade D and E products are defined by their flash points. Both Grade D and E products are relatively safe to handle. Table 42.15 gives the specifics of flammability classification.

Explosive Range

The range of hydrocarbon gas concentrations in air that is capable of being ignited and of burning. The range is bounded by upper and lower explosive limits. Concentrations of vapor lower than the lower explosive limit (LEL) are too low in hydrocarbon vapor (lean) to burn and concentrations above the upper explosive limit (UEL) are too high in hydrocarbon vapor (rich) to burn. The explosive range is usually between 1% and 6% of hydrocarbon vapor in air but varies with the petroleum product. Small quantities of volatile POL products can produce vapor concentrations within the explosive range. The explosive range is affected by the oxygen content of the atmosphere; explosive atmospheres cannot form if the oxygen content is 11% or less by volume. Figure 42.19 illustrates the explosive range as a function of oxygen content in a hydrocarbon vapor atmosphere.

Toxicity

All POL products are toxic to humans to some extent. Toxic effects range from contact dermatitis to almost immediate unconsciousness and death. Toxicity is quantified by allowable exposure described by

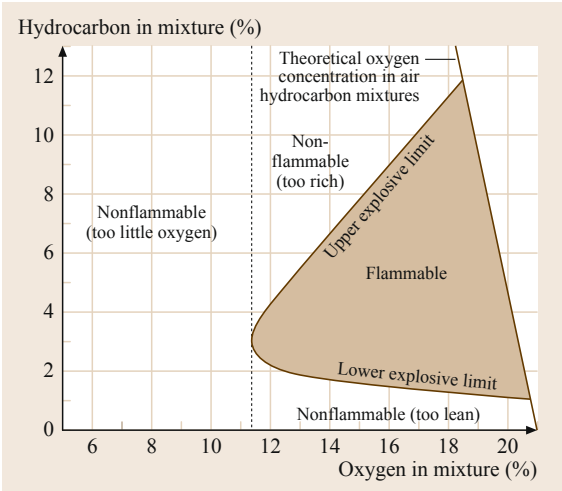

Fig. 42.19 Explosive range

concentration in parts per million and time. National Institute of Occupational Health Guide to Chemical Hazards and NAVOSH instructions contain information on toxicity of POL products. The characteristics of the products to be handled should be known before undertaking emergency transfer operations.

Oily-Water Hydrostatics

An understanding of how oil in ruptured tanks behaves is basic to correct handling of oil in casualties. The weight of the petroleum product, as indicated by specific gravity, determines the mechanism by which spills occur. POL with a specific gravity less than 1.0 is lighter than pure water and floats on the surface of water. If a tank containing oil is holed, either the oil spills from the tank or water enters the tank until the hydrostatic pressures of the water outside the hole and of the oil inside balance. When the balance is achieved there is no flow.

The effectiveness of water bottoms is limited for water-soluble liquids or liquids with a specific gravity very near one. Water bottoms cannot be created at all under liquids with specific gravities greater than 1. Many bulk chemicals fall into this category, as well as some crude oils and bunker fuels.

$$P_w = P_o \,,$$

where P_w is the hydrostatic pressure of the water outside the hull in pounds per square inch (psi) and P_o is the hydrostatic pressure of the oil inside the hull in psi.

The hydrostatic pressure of a fluid is proportional to the specific gravity of the fluid and its depth so that at hydrostatic equilibrium

$$(SG_w)(D_w) = (SG_o)(D_o) \,, \tag{42.42}$$

where SG is the specific gravity of the water in which the ship is floating (SG_w) or of the petroleum product in the tank (SG_o) and D is the depth of the water (D_w), or of the petroleum product (D_o).

For seawater

$$D_o = (1.025)\left(\frac{D_w}{SG_o}\right) \,. \tag{42.43}$$

Hot Taps

Hot taps cut through the oil container with an extendable rotary cutter enclosed in a watertight and oil tight cylinder and operated through an open gate valve. When the cut is completed, the cutter is withdrawn through the valve, the valve closed, and the cutter replaced with a hose, pipe, or other means of carrying the oil away.

High-Viscosity Oil

For vessels carrying very viscous oils, the addition of annular water injection to the pump suction and discharge may be necessary to pump the oil to the surface. For some oils, such as Bunker C oil (#6 or IFO380) in cold water, the tank may also need to be heated to get the oil to flow. Even if the oil will flow to the pump, it may require an annular water injection system, as well as heat, to bring pumping rates up to an acceptable flow rate without over pressurizing the offloading hose.

42.C Appendix: De-Beaching

42.C.1 Refloating Stranded Ships

Stranded ships are refloated by the following actions:

- Moving the ship to water deep enough to float it at the draft corresponding to its weight (displacement).
- Deepening the water around the casualty.
- Reducing the required draft at the grounded portion by removing weight lifting or altering trim.

In practice, a combination of methods is normally used. In most cases, the stranded ship is lightened until the required freeing force is less than

the available tractive forces, then pulled into deeper water.

42.C.2 Moving Stranded Ships

The force required to move a casualty over its strand is the sum of the forces required to:

- Overcome friction between the ship and seafloor.
- Move loose seafloor material that may be pushed ahead of the ship.
- Break or crush obstructions or impalements, such as rock outcroppings, coral heads, etc.
- Overcome suction on soft bottoms.

Friction is a function of ground reaction as modified by other factors, such as the coefficient of friction of the bottom, the area of the hull in contact with the bottom, and the casualty's list and trim. Freeing force is reduced by decreasing the effects of these factors, as well as by decreasing ground reaction.

42.C.3 Reducing Ground Reaction

Ground reaction is reduced chiefly by removing weight, although external lifting may be employed. In situations where the casualty is aground over only a short length at one end, trimming moments induced by weight shifts or additions can reduce ground reaction.

- *Weight Removal*: Removal of floodwater and other weights is one of the principal means of reducing ground reaction. The ship must be controlled by ground tackle, tugs, or her own propulsion to prevent being driven further ashore as she refloats. Weight should be removed so that the ship will lift off her strand with her keel approximately parallel to the beach slope, or so that the bow remains in contact after the stern lifts. The affects of weight removal on casualty strength and stability should be considered.
- *Lifting*: Lifting is a means of spreading the casualty's weight over additional vessels or buoyancy devices in order to reduce its draft enough to float free, or to reduce ground reaction. Pontoons of any description may be placed alongside the stranded ship and rigged to the hull or to slings under the hull to provide lift and reduce ground reaction. Where space and water depths permit, cranes and sheer legs may be brought alongside and rigged to lift the stranded ship to reduce the ground reaction. When sheer legs and cranes are used, the refloating should be slow and controlled to prevent sudden high loading of lifting gear or side loading of cranes as the ship comes afloat and the center of buoyancy moves forward.

42.C.4 Reducing Friction

Methods used to reduce friction depend on the type of seafloor. Cohesive and cohesionless soils develop friction forces in different ways; actions that effectively reduce friction on one type of soil may have little or no effect on another type. The following general guidelines apply:

- *Hard seafloors* (*rock, coral, hardpan, very stiff clay*): Friction is essentially a function of ground reaction and is independent of contact area. Hull contact is generally not continuous. Reducing the ground reaction is the only way to reduce friction – reducing contact area and attempts to induce vibration are generally ineffective. Friction-reducing water films cannot be maintained between the small areas of hull-to-seafloor contact because of the high unit pressure.
- *Cohesionless soils* (*sand, gravel, crushed coral, nonplastic silts*): Friction is essentially a function of ground reaction and is independent of contact area. Reducing the ground reaction reduces friction. Sands and gravels have good resistance to lateral flow under distributed vertical loads, so increasing pressure alone is not effective. Heavy vertical loads on wedge shapes, such as a narrow forefoot, may cause lateral flow in loose soils. Low-frequency vibrations can cause sand to assume fluid properties. High-volume water flow through a sand bed can create quicksand, with fluid behavior. It is possible to maintain short-duration water films between the soil and the hull with high-volume water flow.
- *Cohesive soils* (*clay, plastic silts*): Friction is a function of soil shear strength and contact area. Soil strength and adhesion depend on its ability to inhibit water flow. These soils have low resistance to lateral flow under vertical pressure. Decreasing contact area and increasing unit pressure are effective means of reducing friction. Vibration has little effect, but active disturbance and other measures to open water flow paths to the hull effectively decrease friction. Disturbing adjacent soil masses is also helpful; it reduces the distance water must flow through the essentially impermeable, undisturbed soil.

If some motion, however small, between the casualty and the bottom can be induced, the freeing force will be based on the smaller dynamic coefficient of friction. Initial motion may also allow a film of water to

develop between the hull and bottom, further reducing friction. Specific actions to reduce friction include the following:

- *Wrenching*: Wrenching uses the length of the casualty as a lever arm to multiply pulling force and rotate the casualty about the center of ground reaction. The induced motion reduces friction to dynamic levels and opens water flow paths in cohesive soils.
- *Sallying*: Ships with significant deadrise can sometimes be sallied by shifting weights back and forth athwartships. Contact area is decreased and unit pressure increased momentarily on each cycle as the ship rolls across its keel.
- *Vibration*: Inducing vibration in the hull causes very small movements between the casualty and the bottom, and may reduce the coefficient of friction. Vibration transmitted into the seafloor can fluidize cohesionless soils and may improve water flow through cohesive soils very slightly. Vibration can be induced by operating the casualty's machinery, moving heavy vehicles within the ship or on deck, veering anchor chain, etc. Casualty machinery should be operated only if all support systems (cooling water, lubrication, etc.) are operational.
- *Reducing Contact Area*: Measures taken to reduce ground reaction often reduce contact area by altering trim or removing ground from under the casualty. Weight shifted or added forward may reduce contact area and increase pressure under a narrow forefoot. Generating a strong trimming moment uses the ship's length as a lever arm to break suction; the increased pressure under the forefoot can reduce friction and cause lateral flow in soft soils. If the casualty is to plow through the bottom, it will take less force to plow a narrower furrow.
- *Disrupting Soil Continuity*: Water or air jets can be directed under the casualty to disturb the soil. On mud bottoms, hogging lines can be dropped over the bow and drawn along the hull. Disturbing cohesive soils reduces their shear strength and opens water flow paths. Similar disturbances may fluidize cohesionless soils and induce quicksand-like behavior.
- *Increasing Pressure or Ground Reaction Forward*: Experience has shown that trimming ships with a narrow forefoot or very fine lines forward stranded on sand or gravel bottoms hard by the bow often reduces resistance to sliding. The reasons for this reduction in sliding friction are not clear. The extreme pressure may cause a reduction in coefficient of friction, or be sufficient to cause lateral flow in the soil. The high bearing pressure may actually increase friction to the point that the underlying soil fails in shear before sliding is initiated between the hull and soil. If this occurs over a reduced area, the total force required may be less than that required to overcome friction between the hull and seafloor over a larger area. If the ships form is narrow enough, the ship may penetrate into the seafloor, gaining buoyancy as it settles.
- *Drainage Tubes*: Perforated pipes inserted into the soil in contact with the casualty's hull will allow water to flow between the hull and the soil.
- *Slipways*: If a casualty or portions of it can be lifted by jacks or other means, slipways can be built underneath, allowing the ship to be moved across a lower friction surface. Effective slipways are arranged so that the ground reaction is shared equally by the ways. The slipways and underlying soil or rock must be strong enough to support the ship without deforming, so the ship can slide smoothly. Jacks consisting of modified aircraft landing gear, complete with tires, arranged so that the tires could roll as the casualty was pulled across them, have been used successfully on flat-bottomed hulls.

42.C.5 Increasing Water Depth

Water depth under and around a casualty can be increased to:

- Obtain sufficient water depth to refloat the vessel.
- Reduce ground reaction by increasing buoyancy.
- Free one end of a vessel to allow it to be pivoted by other methods.

Water depth inside small coves or estuaries can be increased by closing the entrance with sheet-steel piles or cofferdams. In some navigable rivers and canals, water level can be controlled to some extent by lock gates and dams – it may be possible to raise water level by increasing flow past upstream dams. On very soft soils, it may be possible to increase the ship's weight, by flooding or other means, so that she settles more deeply into the seafloor. After she has settled, the excess weight can be removed to allow her to float free. More commonly, water depth around a casualty is increased by removing ground from under it. Ground removal is accomplished by scouring or dredging soft bottoms, or by blasting hard bottoms. These methods can also be used to cut channels to deep water through bars or behind vessels stranded high and dry.

42.C.6 Temporary Reduction

Dynamic friction is almost always less than the static friction between two objects. If freeing force can be re-

duced long enough for the pulling system to start the ship moving, it can usually be kept moving:

- Swells increase the buoyancy of the stranded ship and decrease the ground reaction as they pass. High seas or heavy swells running during a retraction decrease the pulling force required to refloat the ship. If the pulling force is enough to start the ship moving at the top of a swell when ground reaction is lowest, the coefficient of friction is lowered instantly to the dynamic level.
- Jacking reduces freeing force by changing the nature of the ground reaction, rather than reducing it. Hydraulic jacks of 60 tons capacity or greater are employed to temporarily lift the ship. By taking up part of the ship's weight on the jacks, the amount of weight bearing on the high friction interface between the ship's bottom and seabed is decreased. The jacks are rigged on long spuds that can pivot at their bases, allowing the casualty to be moved when the friction force is sufficiently reduced. Jacks are placed symmetrically about the estimated position of the center of ground reaction and are secured with a retrieving line led to the deck.

For jacking to be successful, the seafloor must be hard enough, or must be reinforced, to support the jacking forces. On rock seafloors, concrete rubble-filled beds or heavy timbers topped by steel plate are adequate foundations. On sediment seafloors, plate or timber mats are used to spread the load until the unit pressure is less than the bearing capacity of the soil. Crushed coral, stone, shell, or gravel can be laid in to increase soil bearing strength. Similarly, the hull of the ship must be protected from the jacking forces. If these forces are not spread out along the hull, they will cause local damage at the point of application and may even rupture the hull. Steel weldments or heavy steel angles welded to the hull and padded with timbers are suitable jacking pads. The load is transmitted to the ship structure by shear stress in the welds and side plating.

42.C.7 Applying Forces

Forces are applied to a stranded casualty to achieve the following effects:

- Move the casualty directly off the beach.
- Swing the casualty into a more favorable position.
- Induce wrenching motion to break suction or reduce friction.
- Hold the casualty in position.
- Control the casualty's motion during refloating/retraction.

Pulling systems are combinations of mechanical components that work together to apply a controlled, essentially horizontal force to a stranded ship. Pulling systems include, but are not limited to, the following:

- *Tugs*: Tugs can pull directly on the casualty, or power purchases for beach gear systems. Tugs are particularly useful for applying wrenching forces, and can be placed in action quickly to restrain a casualty.
- *Ground tackle*: Heaving systems located on the casualty, on salvage vessels, barges, or on shore can tension ground tackle to move or restrain the casualty.
- *Winch pulling systems*: Heavy winches mounted on barges, salvage vessels, or ashore can pull directly on the casualty.

Tugs and ground tackle are the pulling systems used most frequently in salvage. Tugs attached to the stranded ship with a towline develop pulling forces with their engines. Salvage ground tackle is a system of anchors, ground leg, and hauling gear rigged to pullers, purchases, or winches on a platform. The platform may be the stranded ship, an assisting ship, a barge, or the shore. In many salvage operations, the total pulling force is developed by a combination of systems. Pulling systems are tailored to the particular stranding to gain maximum effect and minimize interference. In rare circumstances, shallow draft tugs, jacks, heavy vehicles, or barges rigged with ground tackle can be used to push a casualty off the beach. Figure 42.20 shows typical pulling arrangements. Figure 42.21 shows two examples of innovative pulling systems tailored to particular situations.

42.C.8 Tug Bollard Pull

Bollard pull is the pulling force or tow wire tension generated by a tug. Bollard pull is essentially the propeller thrust at zero speed and is related to engine power and propeller characteristics. Propellers in shrouds (Kort nozzles) and controllable-pitch propellers produce greater thrust than fixed-pitch propellers for the same amount of horsepower. As refloating efforts generally require a tug to maintain steady bollard pull for much longer than 5 min, bollard pull should be based on the continuous duty or intermittent duty power rating.

Bollard pull is measured by a standardized trial conducted when the tug is new and after major modifications. If there is no bollard pull certificate, static bollard (BP) can be expressed as a function of brake

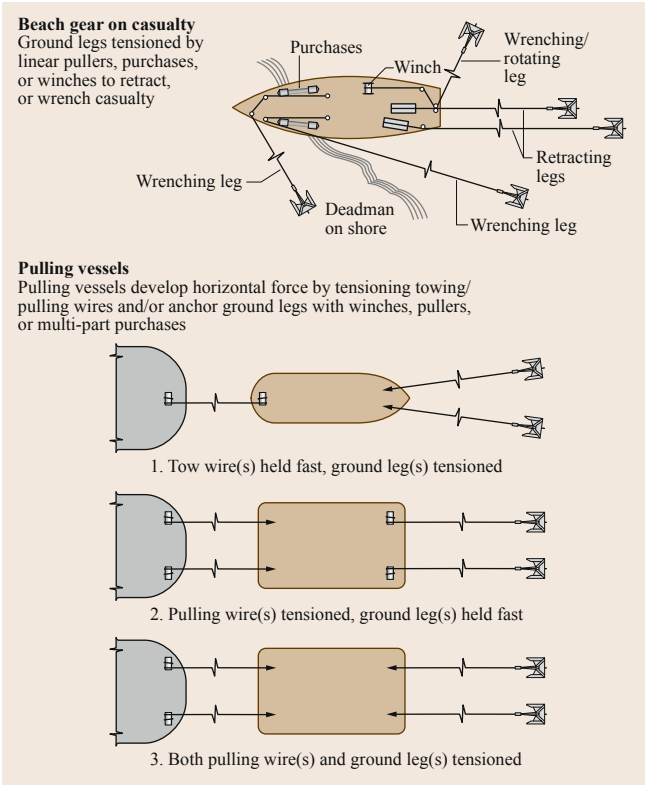

Fig. 42.20 Typical pulling arrangements

horsepower (BHP) and propeller design

$$\mathrm{BP} = 0.011 \times \mathrm{BHP} \text{ for open fixed-pitch propeller,}$$
$$\mathrm{BP} = 0.012 \times \mathrm{BHP} \text{ for open controllable-pitch propeller,}$$
$$\mathrm{BP} = 0.013 \times \mathrm{BHP} \text{ for shrouded fixed-pitch propeller,}$$
$$\mathrm{BP} = 0.016 \times \mathrm{BHP} \text{ for shrouded controllable-pitch propeller,}$$

where BP is the bollard pull in short tons and BHP is the brake horsepower of the tug's main engines.

BHP can be estimated from shaft horsepower SHP (power at the propeller)

$$\mathrm{BHP} = \mathrm{SHP} \times 1.05 \, .$$

42.C.9 High-Capacity Winches

Heavy winches can heave directly on the casualty from a firmly anchored barge or vessel, stationary platform, or location ashore. Large winches can be mounted on barges or ashore to power the beach gear systems. Mounting large winches on the casualty is not usually practical, but installed heavy winches can be used to tension the beach gear ground legs.

42.C.10 Ground Tackle

A disadvantage of linear pullers is that the ground leg cannot be released quickly. If quick release is desired, a 1 5/8-inch wire pendant with a carpenter stopper can be used to pull on the ground leg. The principal advantage of purchase systems is the light weight and portability of individual components, compared to other heaving systems. Purchase systems enable relatively low-powered line-handling equipment to exert high forces against the ground leg anchors. The standard set purchase requires a five- to eight-ton line pull, for example. By using luff-on-luff purchases, chain hoists, or grip hoists to increase mechanical advantage, manual labor can power the purchase, albeit at a very slow speed.

42.C.11 Heaving System Location

Heaving systems can be sited on the casualty, on salvage vessels or tugs, on barges, and occasionally ashore.

- *On the casualty*: The preferred placement for beach gear is on board the stranded ship. Beach gear is usually more effective when tensioned from the casualty where the salvor can observe heaving operations and their effect on the stranded ship directly, and has maximum control over the operation.

It is often advantageous to heave on the beach gear when a heavy swell or surf is running, because the lift of the passing waves momentarily reduces ground reaction. A salvage ship in harness with taut ground legs over the bow is effectively in a multipoint moor. In rough weather, the restrained ship motion can create excessive loads in the towline or ground legs.

On steeply shelving beaches, ground legs must be laid close to shore in shallow water to keep the pull roughly horizontal; placing the salvage ship between the casualty and the anchors may not permit enough scope for the ground legs to hold.

- *On a salvage vessel*: When heaving systems are located on the salvage vessel, a towline from the salvage vessel transmits the ground leg tension to the casualty. The salvage vessel pulls itself toward the ground leg anchors, pulling the casualty along with it. If deck fittings are of sufficient strength, the pulling vessel can be made up alongside the casualty.

Beach gear heaving systems are rigged routinely on salvage vessels when it is impossible or inconvenient to rig them on the casualty, or additional beach gear legs are required. Conditions that may preclude heaving from the casualty are:

1. Weather, surf, location, or other conditions prevent the transfer of necessary equipment to the casualty.
2. The casualty does not have sufficient deck space, operating winches, or attachment points for purchase systems.
3. An immediate heavy pull is warranted; heaving systems can be rigged on the salvage tug while enroute to the casualty, ready for use as soon as the ground legs are laid.

Heaving systems can be rigged on the salvage vessel in sheltered waters before moving to the salvage site.

- *On a barge*: Barges are used as heaving system platforms in the same manner as salvage vessels. Typical situations where heaving systems are rigged on barges include the following conditions:
  1. Operations require more legs of the beach gear than can be operated from the casualty and salvage ships.
  2. Neither the casualty nor the assisting vessels have adequate deck space or fittings to operate beach gear.
  3. It is undesirable to foul the deck of either the casualty or the assisting vessels.
  4. A beach gear leg leading across shallow water cannot be tensioned from the casualty.

If the towline and heaving system are connected directly to the barge, the ground leg tension is transmitted through the barge structure. Ordinary flat-topped barges are not built for this kind of loading and may be severely damaged if not properly reinforced. Padeyes should be installed. Alternatively, a length of plate strong enough to carry the pulling loads can be tack welded to the deck. The winch and padeyes for the holding stopper and block are then welded to the plate.

- *Ashore*: Heaving systems and ground legs located ashore can be used to wrench or turn a casualty. Winches or heavy vehicles located ashore can power purchases on the casualty's deck. Winches, standing blocks, and stoppers can be secured to concrete footings, deadmen, or natural rock outcroppings. Advantages of locating heaving systems ashore normally include accessibility and large working area. The most obvious disadvantage is that the heaving system cannot follow the casualty as it is retracted. Lines led to vehicles must be attached so that they can be quickly released to avoid pulling the vehicle into the water; winches must be able to spool their wire off as the ship retracts.

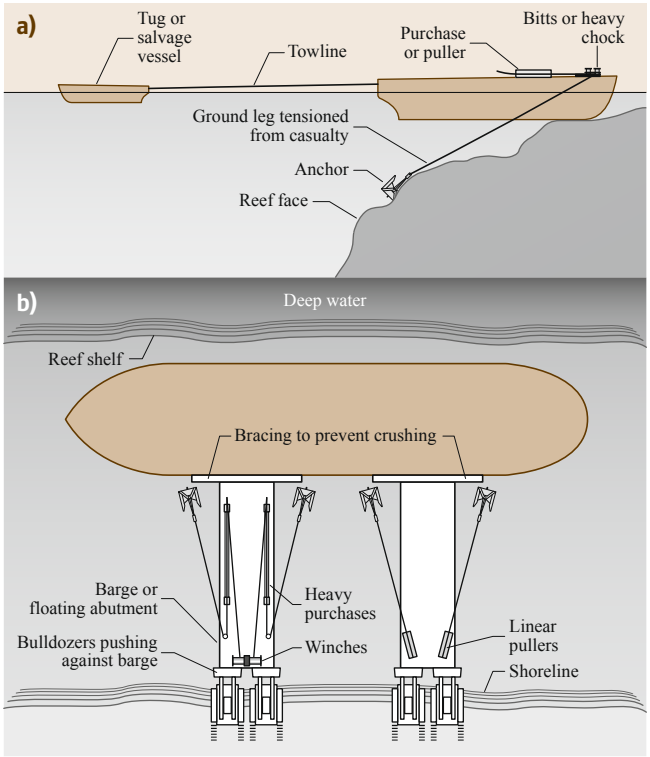

Fig. 42.21a,b Pulling arrangements for unusual situation circumstances: **(a)** water depth astern of casualty too deep for the beach gear anchores to be effective, **(b)** shallows in shore and steep shelf near shore favor pushing

42.C.12 Underwater Excavation

Underwater and semisubmerged excavation and earthmoving are conducted in support of several types of salvage operations:

- Removal of seafloor material from under stranded ships to reduce friction and/or ground reaction.
- Removal of accumulated sediments from sunken ships to reduce weight.
- Dredging channels for the retraction of stranded ships.
- Digging trenches into which stranded ships can slide or be pulled.
- Tunneling under sunken ships to pass messenger wires.
- Disturbing cohesive soils under and around sunken or stranded ships to reduce suction effects.

- Cutting new channels or widening/deepening existing channels in harbor clearance operations.
- Digging holes to topple wrecks into, or drawing seafloor material from under a wreck, during wreck burial operations.
- Removing sediments as they build up around a stranded casualty to prevent severe hull stresses and keep machinery sea suctions clear.
- Removing accumulated sediments to gain access to objects or portions of a casualty.

There are five general methods of excavating and/or moving seafloor material available to the salvor:

- Scouring
- Air lifting
- Jetting
- Dredging
- Blasting.

Table 42.16 compares the relative advantages of various excavation methods for different circumstances.

42.C.13 Scouring

Water currents can scour loose soils from around a ship or out of a channel. Scouring currents can be produced by the propeller wash of tugs or workboats, a stranded ship's propeller wash, by pumps, or by channeling natural currents. Breakwaters or groynes built perpendicular to the beach can set up currents that will prevent sediment buildup around the ship or will scour away the ground. Scouring is most effective on loose, fine-grained sediments, such as sand or silt. Scouring is usually less efficient than dredging. The method of scouring chosen depends upon the assets available, the conditions at the site, and the amount of ground to be moved:

- Tugs or workboats, trimmed by the stern to direct the propeller wash downward, can be moored alongside a stranded casualty with their sterns directed toward the area from which ground is to be removed. The tug lies alongside the ship at an angle of 40–50° to her heading, then builds up to full power and gradually works her way aft. Lines from the stranded ship and the tug's towline may be slacked or hove taut to change the direction of the wash. The wash from the tug's propeller scours against the stranded ship's bilge, carrying seafloor material down the side and clear of the casualty. Tugs can also work from amidships forward and scour both sides simultaneously. Twin-screw vessels with outward turning propellers produce more effective scouring streams than single-screw vessels. The swirling propeller streams are angled toward each other at the bottom of the propeller cir-

Table 42.16 Comparison of underwater excavation methods

Excavation factor	Excavation method				
	Scouring	Air lifting	Jetting	Dredging	Blasting
Type of seafloor	Loose sediments	Loose sediment, Cobbles	Loose sediments	All except rock and coral	Rock, coral, hardpan, stiff or hard clay
Water depth	Less than 30 ft below scouring vessels propeller(s)	25–75 ft	Unlimited	depends on dredge type; unlimited for depths encountered in salvage	Unlimited
Horizontal spoil transport	Short	Short	Short	Short to long, depending on dredge type	Short
Vertical spoil transport	Negligible	Up to 70 ft	Short	Depends on dredge type	Short
Current dependence	Not required but can be beneficial (or detrimental)	Not required, may be detrimental	Required for most efficient operator	Not required, may affect dredge maneuvering	Not required but beneficial so long as charges are not disturbed
Ancillary equipment[a]	Tug or powerful workboat	LP air compressor	HP pump	HP pump	Rock drill for most efficient blasting
Relative shipping space/weight	Large	Large (can be reduced if lift pipe shipped in sections)	Small to medium	Small to medium	Large (if drilling equipment shipped)

[a] In addition to work platform

cle, where they merge into a nearly straight stream directed aft at the level of the vessels keel. Twin-screw vessels of less than 500 shaft horsepower and single-screw vessels of less than 1000 horsepower are generally ineffective scouring platforms. Scouring by tugs can move moderate amounts of material from under specific areas of the ship. Tugs with controllable-pitch propellers should not be used for scouring because sand and other abrasive material stirred up may damage the pitch-control mechanism. Figure 42.22 shows scouring by a tug. Some salvage vessels have been fitted with propeller nozzles or propwash deflectors to better direct the propwash against the seafloor. If there is a possibility of the casualty working free from her strand while a scouring vessel is working alongside, the casualty should be restrained by ground tackle. This method of scouring can also be used to cut channels in sand, gravel, or mud. If an appropriate vessel can be trimmed by the stern enough that her propwash strikes the bottom, she can scour material aay from a series of areas while held in place by anchors.

- A stranded ship's propeller may be run *ahead* to wash ground away from the after section of the ship. The effect will be limited to the area immediately forward and for some distance aft of the propeller. When the ship's propeller is used for scouring, machinery cooling water intake should be shifted to high sea suctions to minimize the infusion of seafloor material into the ship's machinery, or pumps rigged to provide machinery cooling water. As an alternative, the sea suction(s) can be blocked with a plate fitted with a large-diameter pipe or noncollapsible hose fitting, with the pipe led to an area of clear water. The ship must be restrained by ground tackle to prevent her from driving herself further aground. Scouring should not be attempted when the ship has controllable-pitch propellers or other underwater installations that may be damaged by grit. This method of scouring can be used to open a channel in an obstructing bar behind the ship as she is drawn off her strand by tugs and/or beach gear. Stranded ships have worked themselves across miles of mud flats in this manner.
- Jetting pumps or other high-pressure pumps may be used to scour limited areas. Pumps may be operated from the stranded ship, but it is usually better to locate them on tugs or barges that are closer to the water and more mobile.
- Many small water jets are often more effective than one large jet. High-volume flow through perforated pipes or hoses rigged alongside the ship can scour seafloor material away and/or effectively prevent sediment buildup.

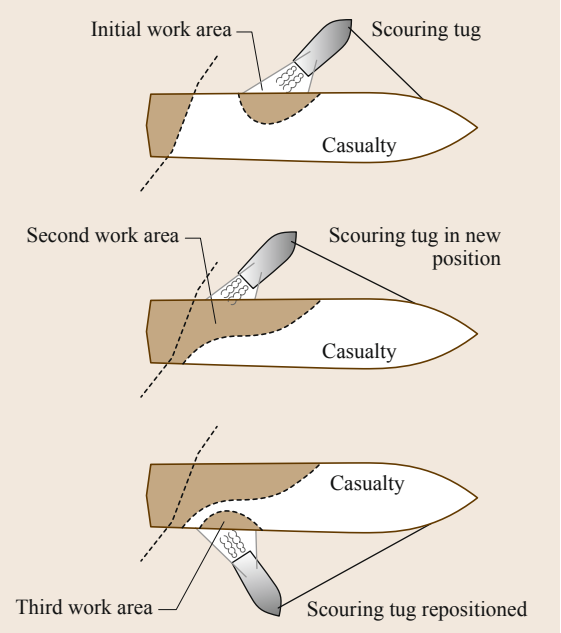

Fig. 42.22 Salvage tug scouring away soft material

42.C.14 Air Lifting

Air lifts can effectively remove loose materials at moderate depths (25–75 ft). The amount of material lifted depends on the size of the air lift, submerged depth of the pipe, air pressure and volume, and discharge head or lift.

42.C.15 Jetting

In its simplest form, jetting moves quantities of mud, silt, or sand by directing a high-velocity water stream at the material to be moved. This process is normally performed by a diver with a nozzle and a high-pressure water hose. It can be performed from the surface in shallow water with lances improvised from 10 and 12 ft firefighting applicators or lengths of pipe. A flow rate of about 100 gpm and a discharge pressure between 50 and 150 psi over bottom pressure is adequate for most jetting. Jetting is most efficient when there is a strong current to carry the disturbed material away from the work area.

42.C.16 Dredging

Dredges can remove large quantities of seafloor material from around and under a casualty and dig channels to deep water. Dredges are most effective in soft soils,

but some can dig coral, hardpan, stiff clay, and some kinds of soft rock (limestone, shale, etc.). The equipment used for dredging depends on the casualty location and attitude, seafloor type, and water depth.

A dredge's *production rate* is its rate of removing seafloor material, or *spoil*. Production rate depends on the dredge type, size, digging depth – depth to the bottom of the cut – and seafloor type.

If dredging appears to be a viable technique for a salvage operation, the nearest Army Corps of Engineers district office should be consulted for advice concerning the best type and size of dredge to use, and the probable production rate.

The two basic types of dredges are mechanical (bucket dredge) and hydraulic.

42.C.17 Mechanical Dredges

Mechanical dredges are classified as *grab*, *dipper*, and *ladder* dredges. Mechanical dredges move spoil by physically picking it up and depositing it elsewhere.

A *grab dredge* is a grab bucket operated from a derrick mounted on a barge. Either clamshell or orange peel buckets are used, depending on the consistency of the spoil. Digging action depends on the weight of the bucket, so grab dredges work best in soft soils. The production rate for a dredge with a one cubic yard bucket is 45–55 cubic yards of mud per hour in 15–20 ft of water. The production rate in clay is about half as much. Digging depth is limited only by the length of the lift wires, although the production rate decreases rapidly with increasing depth.

A *dipper dredge* is simply a power shovel operating from a barge. It is most effective in hard seafloors, such as gravel, broken rock, or shale. Bucket capacities vary from 1 to 5 cubic yards. A dredge with a 1 cubic yard bucket may move 50–250 cubic yards of mud per hour; about half as much clay per hour. Digging depth is limited by the length of the boom; 65 ft is about maximum. Dipper dredges are uncommon outside the United States.

A *ladder dredge* moves spoil with an endless chain of buckets running on an inclined ladder, like a department store escalator, that is lowered to the bottom. Bucket sizes vary from 5–55 cubic feet. The bucket cycle will average 20–30 buckets per minute in silts and muds, 18–24 in medium soils, and 9–12 in stiff clay, with an average of 85% bucket fill. Maximum digging depth is usually about 40 ft, but may be as deep as 75 ft.

42.C.18 Hydraulic Dredges

Hydraulic dredges move spoil with high-capacity centrifugal or jet pumps. *Plain suction dredges* draw seafloor material through a suction pipe into a pump in the hull. The pump discharges into hoppers within the hull or into barges alongside. Some suction dredges have water jets at the lower end of the suction pipe to break up the seafloor material.

42.C.19 Salvage Dredging

The principal dredging operations in salvage are:

- Digging retraction channels for stranded ships
- Trenching
- Ponding.

When dredges cut trenches close alongside casualties in soft or fluid soils, soil from under the ship will flow into the hole, and the ship will settle, increasing buoyancy and decreasing ground reaction. Because of the currents set up at the suction head, hydraulic dredges can draw material from under the ship. It may be possible to dig deep enough to refloat the ship. Ships can be pulled or heeled into trenches dug alongside when the soil is too firm to flow. In a similar manner, dredges can trench alongside wrecks to be buried, allowing them to settle as sediments are drawn from under them.

If a ship is high and dry, a basin can be dug by earth-moving equipment, leaving columns or ridges of seafloor material under the ship to support her as blocks do on a drydock. A channel from the sea is opened into the basin with a dredge. The inrushing water, assisted as necessary by high-pressure water jets, washes the supports from under the ship, allowing it to refloat.

Salvage dredging is a complicated operation requiring time, work, planning, and careful coordination with other work.

42.D Appendix: Refloating

42.D.1 Stability of Sunken Ships

The initial stability of a ship, sunken and resting upright on the seafloor, depends primarily upon whether the main deck is above water, partially submerged, or completely submerged.

42.D.2 Main Deck Above the Surface

If the ship is sunk with the main deck above the surface of the water, there is a waterplane and the metacentric radius (BM) and metacentric height (GM) can be calculated or estimated. In such cases, the COB (B) may lie above the center of gravity (G). As can be seen from Fig. 42.23, the hull will be stable in this condition. When buoyancy is restored, the COB moves down in the hull, crossing the position of the COG, eventually lying below it. As this happens, the metacentric radius increases because the moment of inertia of the waterplane (IT) remains the same and the displacement volume (V) decreases. Ideally, the ship will remain positively stable throughout the process. If, however, the ship was unstable in her afloat condition, she will be unstable as that condition is restored. The addition of high weight or the removal of low weight during the salvage operation can cause an unstable afloat condition. Far more common is a loss of positive stability caused by free surface in an otherwise stable ship being refloated. It is possible that the free-surface effect will be so great that the ship cannot be made positively stable under some conditions. When this occurs, precautions must be taken to prevent capsizing. Methods to prevent capsizing of sunken ships during refloating are discussed in Appendix 42.D.13.

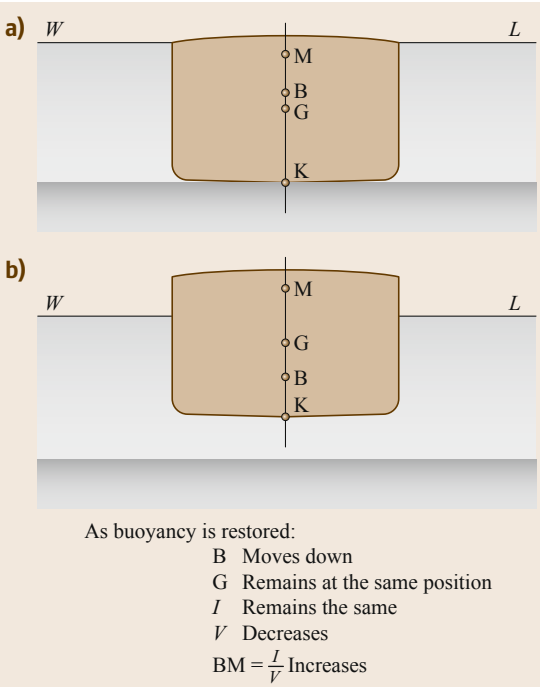

Fig. 42.23a,b Sunken ship stability, main deck above water **(a)** before refloating **(b)** after refloating

42.D.3 Main Deck Partially Above the Surface

If the ship is sunk so that the main deck is partially above the surface, the metacentric radius may be calculated based on the moment of inertia of the existing partial waterplane. Because of the relatively small value of the moment of inertia of the waterplane and the large underwater volume, the metacentric radius may be quite small. Depending on the location of the COG, the metacentric height may be positive, negative, or in rare cases, zero. As buoyancy is restored, the length of the waterplane increases causing the moment of inertia of the waterplane to increase and the underwater volume to simultaneously decrease. The overall result is that the metacentric radius increases and the ship becomes potentially more stable. As when the main deck is completely above water, the overall stability of the ship depends upon the position of the COG and the free surface in partially flooded spaces. Figure 42.24 illustrates the stability situation in a ship being raised in which the main deck was initially partially above water.

42.D.4 Main Deck Submerged

By far, the most complex and difficult stability situation occurs when a ship is to be raised from a position where the main deck is completely submerged. Under this condition, there is no metacentric radius because there is no waterplane. The positions of the metacenter and the COB are coincident, and the distance between the centers of gravity and buoyancy (BG) becomes the measure of stability. It should be emphasized that B and G must be in line vertically, both transversely and longitudinally, at equilibrium. If B is above G, as shown in Fig. 42.25, the ship is stable. If B and G are colocated, stability is neutral. If B is below G, the ship is unstable. When a stable ship is displaced from an upright position, a righting couple will be formed by the weight and buoyancy. In an unstable ship, the couple formed by weight and buoyancy acts to upset the ship.

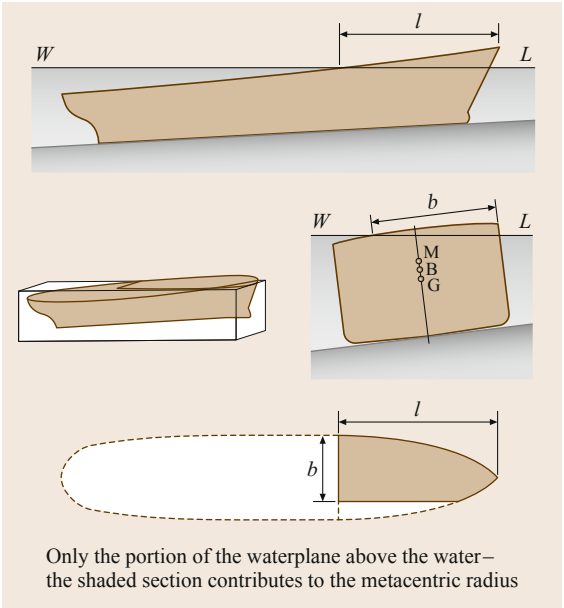

Fig. 42.24 Sunken ship stability, main deck partially above water

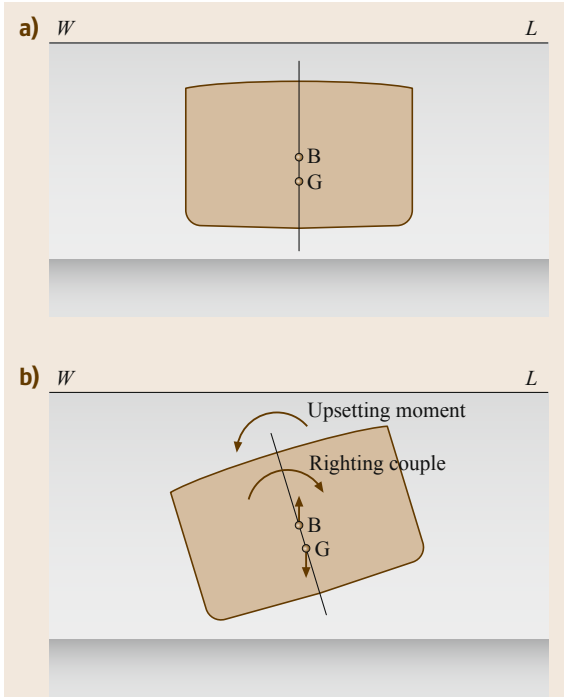

Fig. 42.25a,b Sunken ship stability, completely sunken ship: **(a)** Ship upright, clear of bottom no waterplane, **(b)** if G is above B, ship is unstable

Stability of a completely submerged ship is generally not a concern if the ship is resting and restrained from capsizing by the seafloor; however, it will be of concern if the ship has floated free, but is still completely submerged.

As the ship begins to surface and a waterplane is developed, a metacentric radius is formed and normal stability considerations apply. The metacentric radius is quite small at first; the metacentric height probably will be negative and the ship unstable, especially when there is an appreciable free surface. As additional waterplane is gained and the underwater volume decreased, the ship becomes more stable. The period between the time the ship being raised begins to develop a waterplane and when it becomes positively stable is critical. During this period, the ship must be stabilized to prevent capsizing. Figure 42.26 illustrates the stability of a ship being raised from a completely submerged condition.

42.D.5 Longitudinal Stability

Longitudinal stability is the measure of a ship's ability to return to its original position after being disturbed by a force that rotates it around a transverse axis. Longitudinal stability is important to refloating operations because changes in the longitudinal stability of a stranded or sunken ship will not be apparent since the ship does not respond in the same manner as a ship afloat. The changes must be calculated to ensure that salvors have an accurate assessment of the actual longitudinal stability situation. Because of the contribution of length to the longitudinal moment of inertia of the waterplane, ships with any significant length of waterplane are inherently longitudinally stable. In ships with little or no internal transverse subdivision, free surface may present a major problem while the ship is being raised.

The greatest danger to longitudinal stability from free surface lies not in the reduction of longitudinal metacentric height but in the trimming moment caused by the mass of water rushing to the low end of compartments as the ship trims from redistribution of weight. If transverse subdivision is nonexistent or inadequate, the trimming moment may cause the ship to trim sufficiently to allow downflooding with subsequent loss of buoyancy and plunging. In a submerged hull, trim is affected by the longitudinal separation of B and G. Longitudinal and transverse stability are essentially the same, in this situation, because there is no waterplane. A ship with no waterplane and no longitudinal metacentric radius has only the longitudinal righting moment provided by the relative positions of the centers of gravity and buoyancy. Care must be taken to raise the ship so that trim does not develop, or to keep it in contact with the bottom.

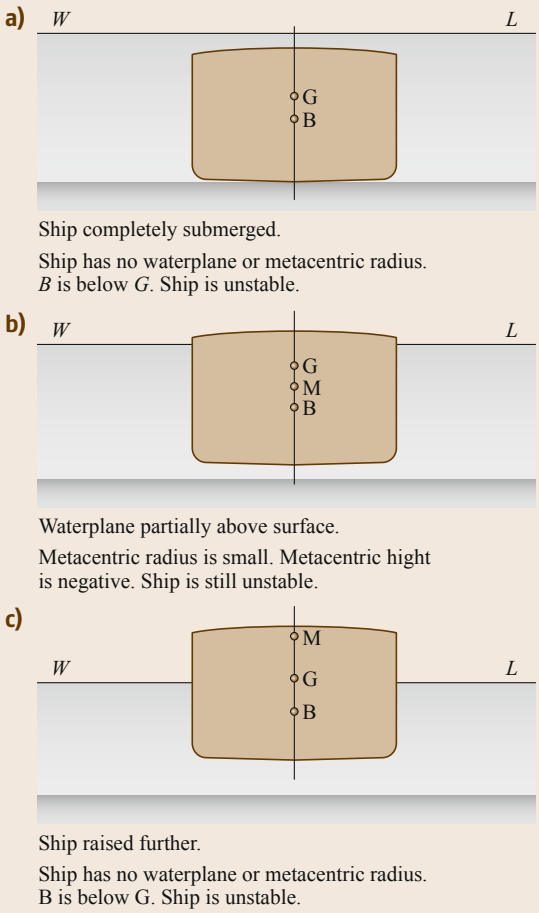

Fig. 42.26a–c Development of stability in raising a completely sunken ship

42.D.6 Longitudinal Position of Center of Gravity (LCG)

The LCG is as important to longitudinal stability as the height of the COG is to transverse stability. Its position is determined solely by the distribution of weight along the length of the ship. The longitudinal position of the COG is measured in feet from the midships section or the forward perpendicular. It is determined in a manner similar to determining the height of the COG above the keel in that the sum of the moments of the weights about either the forward perpendicular or the midships section is divided by the total weight to obtain the desired position. The following steps are necessary:

1. Classify all the weights in the ship.
2. Determine the longitudinal distance of each weight from the reference.
3. Multiply each weight by the longitudinal distance from the reference to determine the moment of the weight.
4. Total the weights and the moments of weight.
5. Divide the total of the moments of weight by the total weight to determine how far the longitudinal position of the COG lies from the reference.

42.D.7 Longitudinal Position of the Center of Buoyancy (LCB)

The LCB is measured in feet from either the forward perpendicular or the midships section. For a ship in equilibrium, the longitudinal position of the COB is in the same vertical line as the longitudinal position of the COG. At any given time, there is only one point that is the COB; the height and longitudinal position are two coordinates of that single point. Determination of the longitudinal position of the COB is lengthy and tedious, requiring calculation of the underwater volume of the ship and its distribution. The longitudinal position of the COB may be obtained from the curves of form. In salvage, the longitudinal position of the COB is important primarily in making strength calculations when buoyancy must be distributed to place the longitudinal positions of the centers of gravity and buoyancy in the same vertical line.

42.D.8 Longitudinal Center of Flotation (LCF)

The LCF is the point about which the ship trims. It is the geometric center of the waterline plane. The longitudinal position of the center of flotation is measured in feet from either the midships section or the forward perpendicular. In ships of normal form, it may lie either forward or aft of the midships section. In fine-lined ships, the LCF is usually slightly abaft the midships section. The longitudinal position of the center of flotation is required to calculate final drafts when trim changes. It can be calculated if the exact shape of the waterplane is known, or it may be obtained from the curves of form. If the position cannot be obtained, it can be assumed to be amidships.

42.D.9 Longitudinal Metacenter (ML)

The ML longitudinal metacenter is an imaginary point of importance in longitudinal stability.

Like the transverse metacenter, it is located where the force of buoyancy's lines of action running through the LCB intersects the vertical line through the COB of the untrimmed ship. While the COG and the COB are points whose heights above the keel and longitudinal position are two coordinates of the same point, the

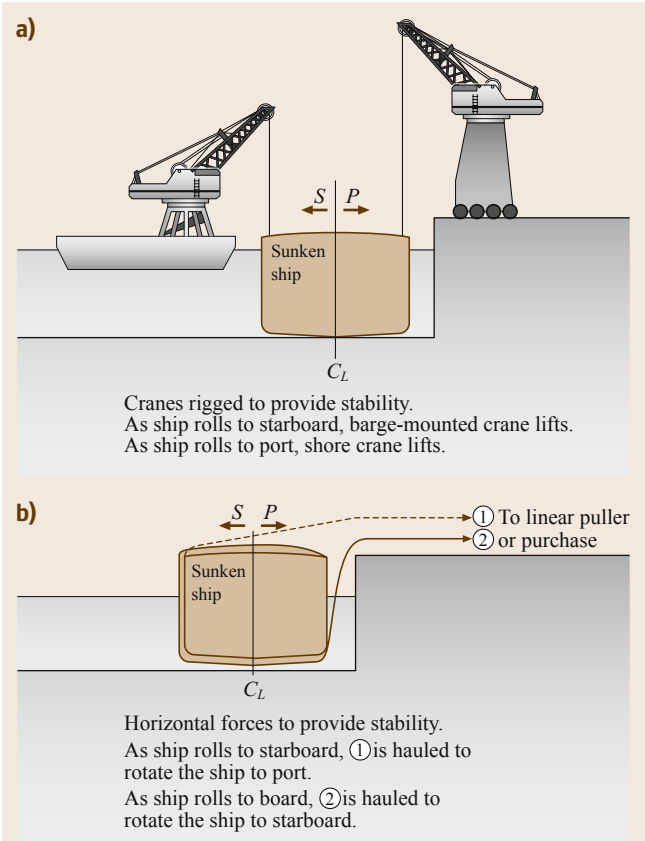

Fig. 42.27a,b Stabilizing sunken ships with cranes or tackles

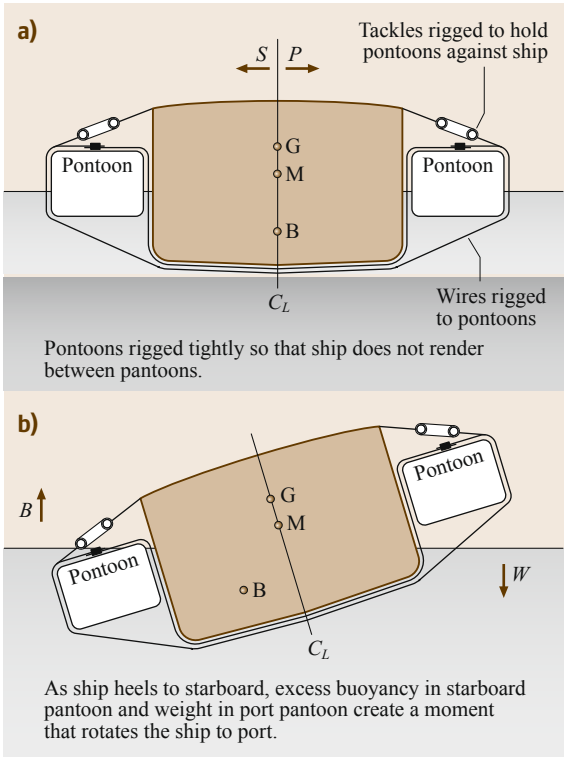

Fig. 42.28a,b Pontoons rigged to stabilize sunken ship during refloating

transverse metacenter and the longitudinal metacenter are separate points, each with its own set of coordinates.

42.D.10 Longitudinal Metacentric Radius (BML)

The BML is the distance between the COB and the ML. The BML is measured in feet. It is defined as the moment of inertia of the waterline waterplane about a transverse axis divided by the volume of displacement.

42.D.11 Height of the Longitudinal Metacenter (KML)

The KML is the distance between the metacenter and the keel, and is measured in feet. The height of the ML is the sum of the height of the COB and the BML.

42.D.12 Longitudinal Metacentric Height (GML)

The GML is the distance between the height of the COG and the longitudinal metacenter measured in feet. The GML is the difference between the longitudinal height of metacenter and the height of the COG.

42.D.13 Keeping the Ship Upright

As the ship is raised, various methods are used to prevent it from capsizing while it passes through ranges where it is inherently unstable or develops instability from free surface. The most common method is to refloat one end of the vessel while keeping the other end firmly in contact with the bottom. The contact with the ground prevents the ship from taking on a dangerous list or capsizing. In deep water, keeping one end of the ship in contact with the ground and limiting the rise of the other end prevent extreme trim.

Before the grounded end is raised, free surface in the floating end is reduced by dewatering. Spaces low in the ship, such as doublebottom tanks, may be flooded and pressed up to both eliminate free surface and to lower the COG and increase the metacentric height.

At the same time, topside weights are removed and other portable weights moved as low in the ship as possible to lower the COG. With free surface minimized from the floating part of the ship and the COG as low

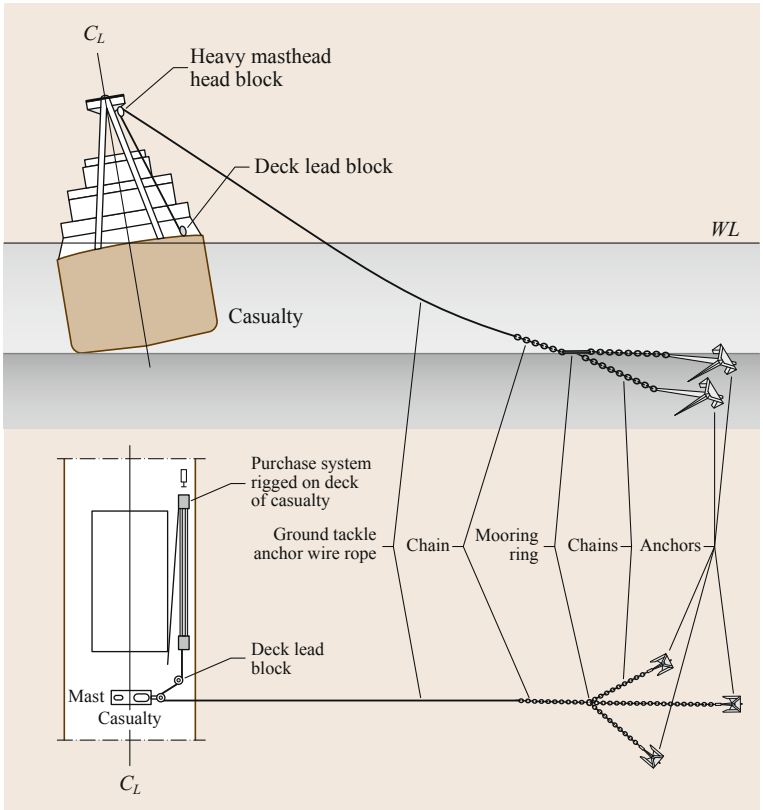

Fig. 42.29 Restraining a casulty with masthead tackle

as practicable, the grounded end may be raised. These methods are not always adequate; careful stability calculations with detailed consideration of free surface should be made before attempting to raise the grounded end.

Large free surfaces can be broken up by repairing damaged bulkheads and by building temporary bulkheads within flooded spaces. The work of building temporary bulkheads is considerably reduced if the bulkhead is built with high-pressure concrete pumped into simple forms. Both bulkhead reinforcements and temporary bulkheads should be built wider at the base than at the top to assist in lowering the COG.

A force may be applied to the ship being raised to produce a moment that counters an upsetting moment. This is done by attaching cranes or tackles rigged to apply a vertical force near the side of the ship. When the ship begins to list, a force is applied to counter the list and bring the ship back to the upright position. Figure 42.27 shows methods of accomplishing this technique.

As illustrated in Fig. 42.28, pontoons, barges, or lift craft may be rigged to provide a force that counters a heeling moment and keeps the ship upright. The pontoons must be rigged tightly to the ship so that when the ship begins to heel, she will also attempt to submerge the pontoon on the low side. The additional buoyancy of the submerging pontoon, coupled with the loss of buoyancy from the pontoon on the high side, creates a moment that rotates the ship back to an upright position. Tightly rigged pontoons and lift craft not only provide an uprighting force from their buoyancy but also act as an increased waterplane of a system composed of the ship and pontoons. The waterplane of the pontoons increases the metacentric height and overall stability of the ship–pontoon system. This advantage is gained only when the ship and pontoons are so tightly rigged that they function as a unit. If the ship is free to render in a cradle formed by the rigging, the pontoons provide only buoyancy.

Ships sunk in harbors have been kept upright by rigging purchases from their mastheads to anchoring points ashore. If this method is attempted, the ship should be held securely by mooring lines, as there will be a tendency for the ship to kick out from under the strain of the purchases on the masts. Figure 42.29 illustrates this technique.

One of the most secure methods of controlling the ship is to rig the beach gear and haul the ship into shallower water as it is lightened or lifted.

The beach gear is kept under constant heavy tension so that the ship moves into shallower water in constant contact with the bottom until it reaches a location where it may safely be dried out and refloated. Beach gear rigged ashore may be hauled with winches, linear pullers, or heavy vehicles. Tugs may be used to help move and direct the ship. Ashore, heavy tracked vehicles may also be used to haul lines for positioning the ship.

Keeping a ship in contact with the bottom, either at one end or all along her length, also assists in controlling trim and preventing the loss of longitudinal stability caused by water rushing to the low end.

42.D.14 Strength of Sunken Ships

The local, longitudinal bending, and shear strength of sunken ships are often impaired by the damage that led to their sinking. The strength of the sunken ship can have a major effect on the methods used to salvage it.

Weakened local areas can usually be reinforced adequately by simple double patches, or may sometimes be ignored where patches are placed to restore the watertight envelope. The decision whether or not to repair locally weak areas depends upon the loads that will be placed in those area during the salvage operation, the nature of the potential failure, and the consequences of a failure.

Local cracks can be dangerous, particularly if they are in high-stress areas. These cracks may grow as the operation proceeds and may eventually lead to serious failure.

Longitudinal and shear strength in sunken ships are evaluated in the same way they are for intact ships.

The most common type of hull failure is compressive failure of the deck or bottom structure. Compressive failure can be recognized by athwartships buckling – up-and-down wrinkles in the plate – in way of the failed section. Buckled structure has essentially no ability to carry compressive load but may carry almost its entire design tensile load. Ships that have failed in compression may be raised by distributing weight and buoyancy in the ship so that the failed plating is in tension throughout the salvage operation.

Shear failure may be dealt with most simply by adjusting weight and buoyancy to keep shear stresses in the failed area to a maximum of 25% of design shear stress. Attempts to double plate in the affected areas generally are unsuccessful because the deformation of the plating and internals usually prevents making the structure sufficiently straight and continuous for proper load carrying. Massive hull damage that leaves the ship in one piece but with a hinge likely or already developed requires a decision about the basic techniques to be used. The ship may be:

- Cut into pieces with each piece refloated separately
- Refloated by zero-stress/zero-shear techniques
- Wrecked in place.

When portions of the hull can be made watertight and stable, the wreck may be cut into sections and each section refloated individually. Each section may be handled by methods that are most appropriate for it. For instance, one may be refloated while another is wrecked in place. However, cutting the wreck into sections may be time-consuming and expensive.

Often the most efficient and sophisticated means of floating a badly damaged sunken ship is by using zero-shear/zero-stress methods. With these methods, the ship is loaded so that throughout the operation, shear force and bending moment are zero at the hinge or section where a hinge is likely to develop. Zero-stress/zero-shear techniques require detailed engineering analysis and planning, as well as careful attention to the hull loading throughout the operation.

Wrecking in place is always an option but is dependent upon the availability of equipment to cut the wreck effectively and to lift and handle the pieces. Wrecking in place may be the most laborintensive, time-consuming, and expensive option; on the other hand, it is usually a zero-risk-of-failure option.

42.D.15 On-the-Side Refloating

Methods of restoring enough buoyancy to refloat a ship on its side include:

- Sealing off enough major spaces to allow dewatering by compressed air, pumping out, inducing buoyancy, or a combination of these methods
- Deploying enough lifting power to lift the ship bodily on its side
- A combination of lifting and restoration of buoyancy.

The transverse and longitudinal stability of a ship to be refloated on its side must be examined thoroughly by the salvage engineer. Figure 42.30 shows the relative positions of both the transverse and longitudinal metacenters in on-the-side refloating. Ships that capsize and sink in the middle of wide rivers or navigable waterways are traffic hazards. One-way traffic on one side of the sunken ship probably can continue, but two-way traffic may be either restricted or impossible. In such cases, refloating the sunken ship on its side before dragging it to the most suitable channel edge

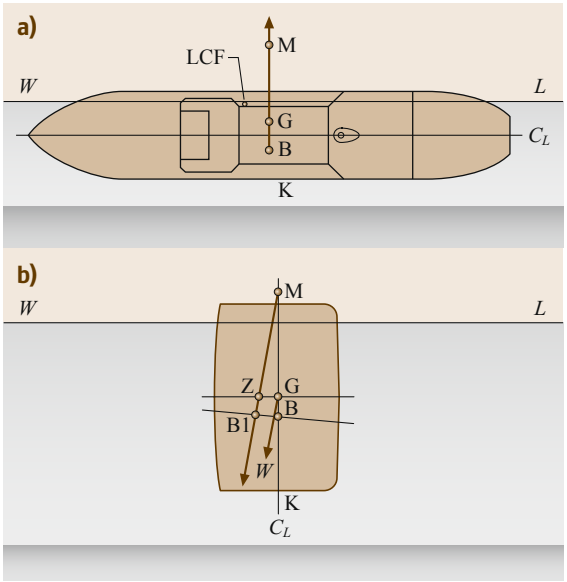

Fig. 42.30a,b Stability of a ship refloated on its side **(a)** longitudinal metacenter **(b)** transverse metacenter

for righting is convenient. An operation of this type involves:

- Setting up hauling equipment on the selected channel bank or shoreline
- Preparing the ship for refloating on its side or at an acute angle to reduce ground reaction
- Rigging attachments and lifting points for the floating cranes, lift barges, or other lifting devices that will stabilize the ship
- Removing structure, top hamper or masts, stacks, or equipment that increases the capsizing moment.

It is important to complete all preparations and system tests before rigging hauling equipment that blocks a working channel or fairway. When there is no operational necessity for salvors to obstruct channel traffic, it is better to allow normal traffic to continue for as long as possible. Safe navigational practice dictates that channel traffic is either restricted or stopped while a sunken ship is hauled to shore.

42.D.16 Upside-Down Refloating

Ships may capsize and sink in water that is deeper than the beam of the ship. The sunken ship becomes an underwater obstruction and hazard to maritime traffic. Water depth around and over the ship at high water determines the extent and seriousness of the hazard and the urgency of removal. Refloating the ship upside down is sometimes suitable in such cases.

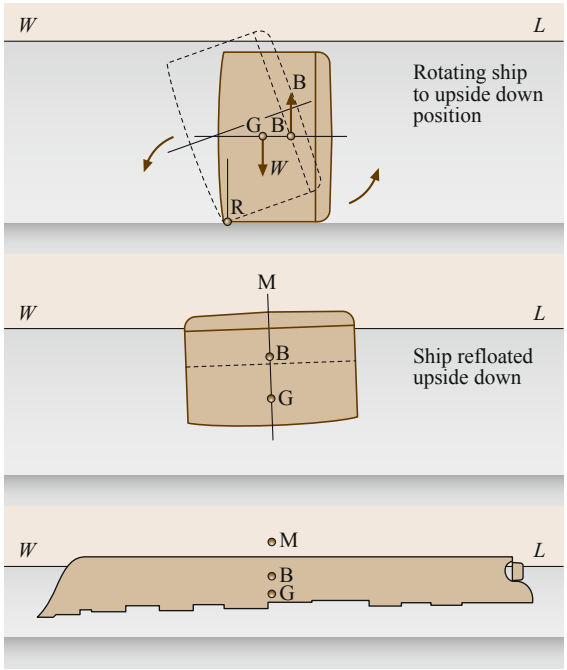

Fig. 42.31 Refloating ships upside down

Floating a ship upside down is particularly suitable when:

- The ship is capsized to more than 90°.
- The ship's bottom is relatively intact or can be made airtight.
- The top hamper, superstructure, and other items that will increase the navigational draft of the inverted ship can be removed easily.
- The channel to the ultimate destination is deep enough to allow the inverted ship to pass.
- The refloated ship is to be scuttled in deep water, scrapped in a drydock, or taken to a location that can accept the upsidedown ship.

Ships are refloated upside down by restoring their buoyancy with compressed air. Therefore, it is important that the ship's bottom plating is intact or can be made airtight with minimal work. Rotation to the completely inverted position usually is accomplished by a combination of inducing buoyancy and applying a comparatively small amount of external buoyancy or rotational force to help the vessel to capsize completely. Figure 42.31 shows a ship capsized and sunk and the sequence of restoration of buoyancy, rotation, and upside-down refloating.

Transverse and longitudinal stability are calculated the same way for an upside-down ship as for the same ship floating normally. Normally, the stability charac-

teristics of an upside-down ship differ from those of the same ship floating upright by having:

- Greater transverse stability
- Somewhat less longitudinal stability
- Greater initial stability
- Considerably greater resistance to external inclining forces.

Upside-down ships usually are very stable and handle easily when the waterline is about at the tank top level. Ships without double bottoms should have a freeboard of about three feet.

Air leaks from ships under tow or sitting for long periods while they are upside down. If the air is not replenished, the ship will sink when sufficient buoyancy is lost. Compressors are provided on board or connected to the casualty for replacing lost air. This is particularly important when towing upside-down ships in harbors or on long coastal passages.

42.D.17 Righting Capsized Ships

Righting a capsized ship is almost always an expensive and complex operation. It is usually done to remove a ship that is obstructing a berth, harbor area, or access channel, although increasingly wrecks are being salvaged for environmental or aesthetic reasons. There is no guarantee that a righted and refloated ship can be returned to service. More often than not, the combined costs of righting, refloating, repairing, and refurbishing make returning the ship to service financially impractical. Almost every righting operation involves the removal of considerable superstructure under less than optimum conditions. These removals increase repair costs considerably.

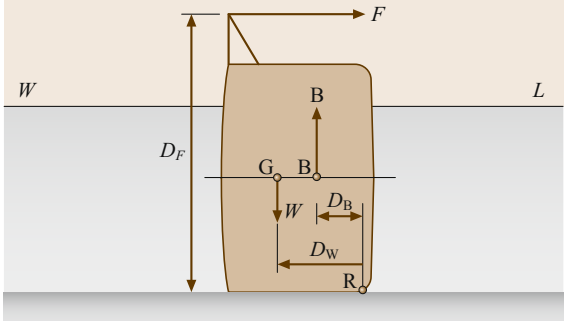
Before deciding what method, or combination of methods, is to be used to right a capsized ship, there are several important engineering and technical questions to be investigated and answered. These include:

- Calculations of righting moments to be developed to overcome the capsizing moment
- Investigations and, where appropriate, calculations to determine the physical point about which the ship will rotate, such as seafloor/soil load-bearing and shear calculations
- Investigation of local hull stresses in the ship during righting operations
- Determination of load-bearing abilities of hull areas critical to righting
- A detailed transverse and longitudinal stability analysis at selected stages of the parbuckling process (a parallel series of hull shear and bending moment analyses may be necessary)
- Weight reductions, additions of buoyancy, and other methods to reduce righting forces or lower the capsizing moment must be investigated and calculated.

42.D.18 Initial Calculations

Ships are righted by creating a moment with buoyancy, externally applied forces or both, that act around a pivot point to overcome the moment of weight, acting through the COG, that is holding the ship capsized. The location of the pivot point lies at or near the turn of the bilge. Normally, a point near the turn of the bilge is selected for initial calculations. The pivot point may be moved farther up the hull by altering or dredging away the sea bottom supporting the ship. Moving the pivot point up the hull shortens the weight's moment arm. The righting force should be applied as far as possible from the pivot point.

Initial calculations on capsized ships establish the moment of weight to be overcome to right the ship. An order of magnitude of capsizing moment is obtained by arbitrarily basing calculations on a point of rotation at the bilge in contact with the seafloor. A lever arm is measured by projecting vertical lines from the free-floating center of gravity, G, to the seafloor.



Ship assumed to rotate abaut the point R.

Righting moment (clockwise):

Any remaining buoyancy acting through the center of buoyancy.

Force F applied at 90 degrees to headframes to rotate ship.

Moment = $B \times D_B$
Moment = $F \times D_F$

Resisting moment (counterclockwise):

Weight W acting through the center of gravity.

Moment = $W \times D_W$

Fig. 42.32 Measurement points for calculation of rotation forces on righting ships

The distance between the pivot point, R, and the intersection of the vertical through G with the seafloor, W, as shown in Fig. 42.32, is the arm for the moment of weight that resists righting.

Figure 42.33 shows the change in measurement points as force is applied.

Note

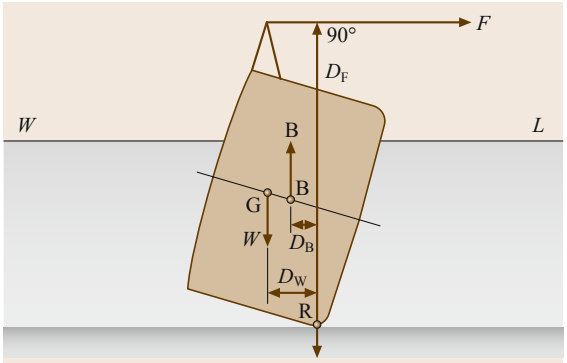
Salvors making righting calculations must be careful to keep their units straight. Ships' displacements and weights are given in long tons (2240 pounds), while lifting and pulling systems are rated in short tons (2000 pounds). Salvors in the field may find it easier to convert all units to pounds or kips (1000 pounds).

The initial moment is the greatest that is required during the righting. As the ship rotates her COG gets closer to the pivot point, reducing the moment arm and the moment. Once the COG final passes the pivot point, the weight provides a moment that assists in the righting.

42.D.19 Righting Methods

Figures 42.34–42.42 illustrate basic methods for righting capsized ships. Most of these methods involve righting the ship with the bilge firmly in contact with the seafloor, a static righting. There are circumstances when a static righting is not practical. If the ship is refloated in its capsized condition and then righted while in a floating condition, different criteria apply:

- Method 1 (Fig. 42.34): Selective sealing of major spaces in the ship allows controlled dewatering to restore buoyancy. Buoyancy, along with the addition of ballast to the high side, produces a couple to right the ship.
- Method 2 (Fig. 42.35): Inducing buoyancy into selected spaces with compressed air, and adding water ballast to provide a couple. A small external force to provide the initial rotating moment is usually necessary. This system is a variation of Method 1, but usually involves compressed air dewatering.
- Method 3 (Fig. 42.36): Applying external static forces to lever arms mounted on the hull. This method is most often combined with Methods 1 and 2.
- Method 4 (Fig. 42.37): Applying external counterweights to the high side of the hull with buoyant lifting systems attached to the low side.
- Method 5 (Fig. 42.38): Applying a direct, external, rotational force or pull to the low side of the hull with external pulling or heaving systems. This is not a particularly common method because of the difficulty of generating enough righting moment unless the ship is made buoyant first.
- Method 6 (Fig. 42.39): Extending lever arms, or headframes, from the hull and applying righting forces at the head of this system. This is one of the



Ship rotates abaut the point R.
Righting moment (clockwise):
Any remaining buoyancy acting through the center of buoyancy.
Moment = $B \times D_B$
Force F applied to headframes.
Moment = $F \times D_F$
Capsizing moment (counterclockwise):
Weight W acting through the center of gravity.
Moment = $W \times D_W$

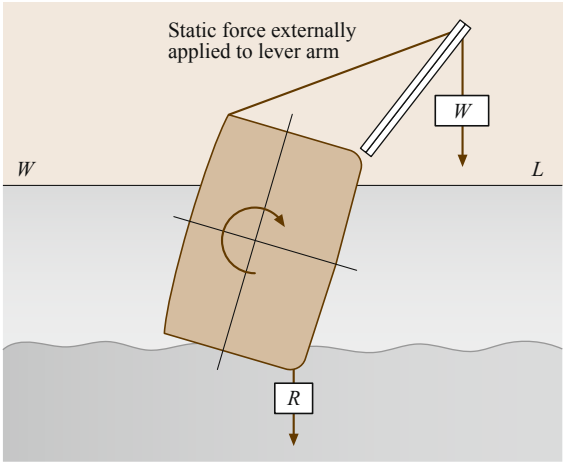

Fig. 42.36 Righting method 3

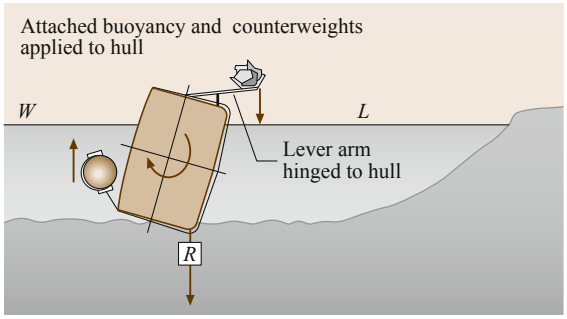

Fig. 42.37 Righting method 4

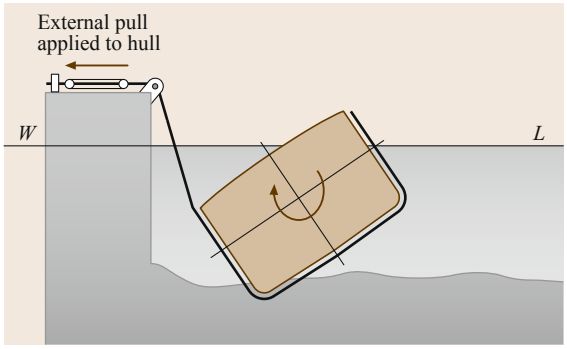

Fig. 42.38 Righting method 5

most common righting or parbuckling methods involving external haulage.

- Method 7 (Fig. 42.40): Applying a combination of direct, dynamic lifts to the low side of the hull, and an external pull to the high side of the hull. This largely mechanical system is used when sufficient hauling/lifting power is readily available and sealing off the hull for induced buoyancy is not practical.

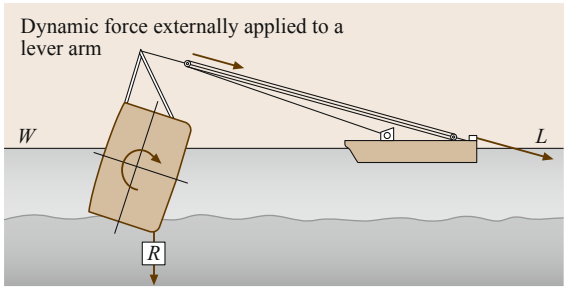

Fig. 42.39 Righting method 6

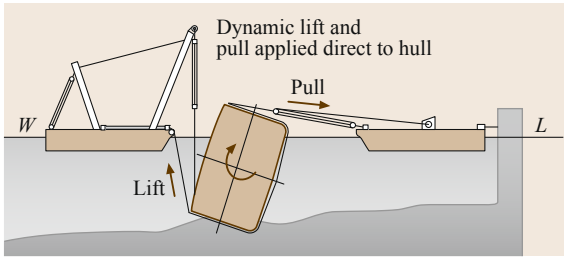

Fig. 42.40 Righting method 7

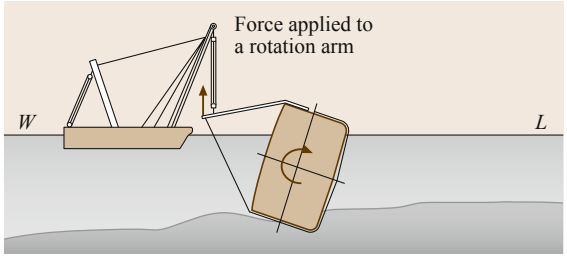

Fig. 42.41 Righting method 8

- Method 8 (Fig. 42.41): Constructing and fixing righting beams to the high side of the capsized ship, then applying a lifting force to these righting beams. This method is usually satisfactory in conjunction with large floating cranes or salvage sheer legs.
- Method 9 (Fig. 42.42): A combination of methods including:
  1. Restoring buoyancy by dewatering selected spaces
  2. Adding rotational ballast to the high side
  3. Applying a dynamic pull to the high side of the ship, along with a mechanical lift on the low side.

42.D.20 Variable Factors

The method or combination of methods selected will depend upon several variable factors that include, but are not limited to:

- Quantity of buoyancy that can be restored to the sunken ship
- Availability of heavy lifting and heavy hauling equipment in the casualty area
- Working considerations, including time and effort, required to restore buoyancy factors that may prevent the use of one or more obvious methods because the method will seriously disrupt port operations
- Environmental factors.

42.D.21 Offshore Operations

A ship that is capsized and sunk a considerable distance offshore presents several problems. The problems are rarely insurmountable, but can add greatly to the cost and time of the operations. Some of the most common offshore or exposed-location righting difficulties are:

- Hauling and lifting systems usually are operated from barges or floating cranes that are subject to weather limitations. Parbuckling, lifting, or combined parbuckling and lifting can be done only in good weather.
- When righting forces are generated by barge-mounted hauling systems and holding ground is poor, it may be necessary to build piled anchorage systems or use propellant-embedment anchors. Piled anchorages normally must be removed or cut off at the mud line when the job is finished.

Figure 42.43 shows an exposed offshore area where a parbuckling operation is undertaken with a pulling barge.

42.D.22 Righting Plans

With a proposed righting plan sketched out on paper, salvage officers and salvage engineers make a twofold analysis of the plan.

42.D.23 Calculations

Calculations are made to ascertain the following:

- Movement of the COG at successive intervals (usually 5° or 10°) of righting and applied pull required at each stage.
- Stage of inclination at which ship reaches a neutral point and capsizing moment becomes the righting moment.
- Changes, if any, at the assumed point of rotation and an accurate assessment of sinkage that may occur during rotation.

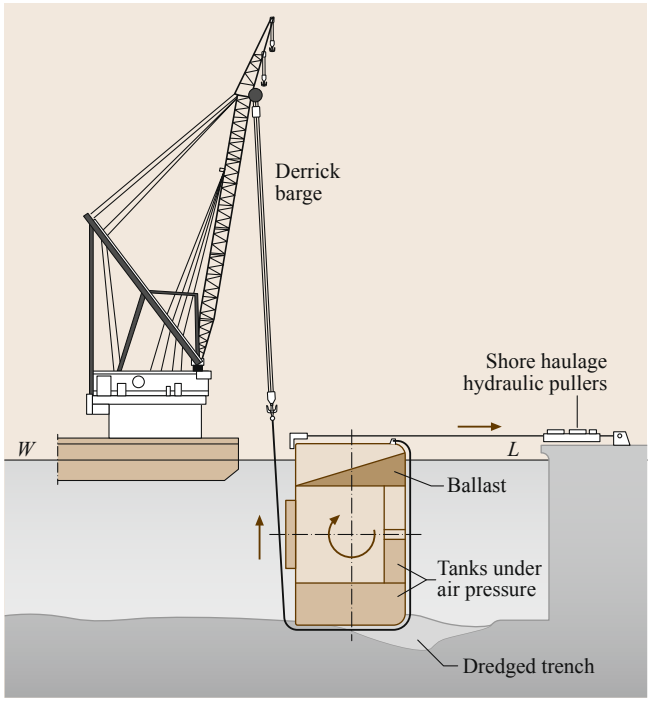

Fig. 42.42 Combination of methods used to upright a capsized ship

- Soil load-bearing characteristics and, if necessary, arrangements for detailed soil analysis.
- Existing quantities of siltation, residual stores, and cargo; in many instances, estimates will have to be made.
- Soil load-bearing characteristics of areas proposed for mounting the shore-based hauling systems (design calculations for hauling anchorages are a special task in themselves).
- Hull strength calculations to determine the amount of local stiffening or reinforcement required where head frames are mounted.
- Checks on pressure differentials created by dewatering major spaces, some of which may be partially submerged.
- That the necessary pulling power can be developed by the proposed methods, and that any proposed mechanical system is suitable for the task.
- Whether righting operations would be simplified by a trench dredged along the bilge.
- Whether an air bubble introduced temporarily into selected compartments or further dewatering of major compartments would help to right the ship.
- Whether a weight reduction program, including cutting down superstructure sections, masts, stacks, and other structural members, is necessary and useful in the overall righting and refloating plan.

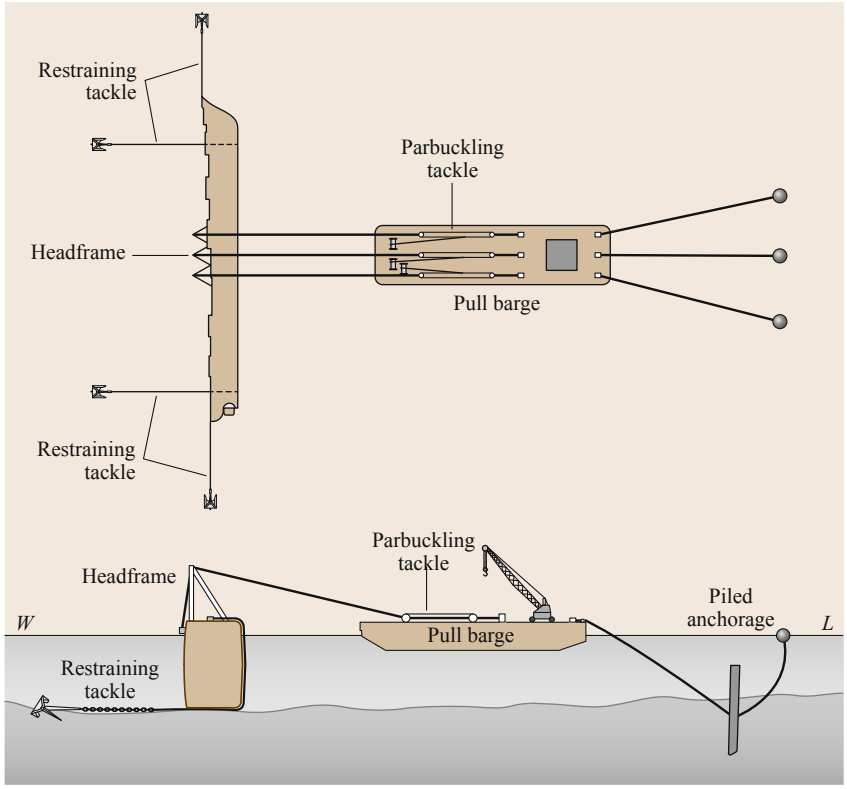

Fig. 42.43 Offshore parbuckling operation

42.D.24 Headframes

The use of headframes offers significant leverage in parbuckling operations. Numbers and individual strengths of headframes are determined by a combination of rigging and engineering factors, including:

- Pull applied to each headframe, a function of the hauling system capacity. Headframes increase in size, strength, and foundation complexity with increasing pull.
- Whether wires pull directly from headframe tops or are connected to fittings on the ship's hull and led over shoes or guides set into headframe tops.
- Whether doubling sheaves are used.
- Availability of suitable structural steel to construct headframes.

42.D.25 Types of Headframes

Headframe construction usually follows one of four principal designs.

Braced Girder Design

In the braced girder design (Fig. 42.44), the bracing leg or legs extend outward from the headframe tops toward the pull direction. The design is similar to a bipod or tripod mast and is connected rigidly to the ship's hull. Connections are made at the main or strength deck level. Braced girders re-

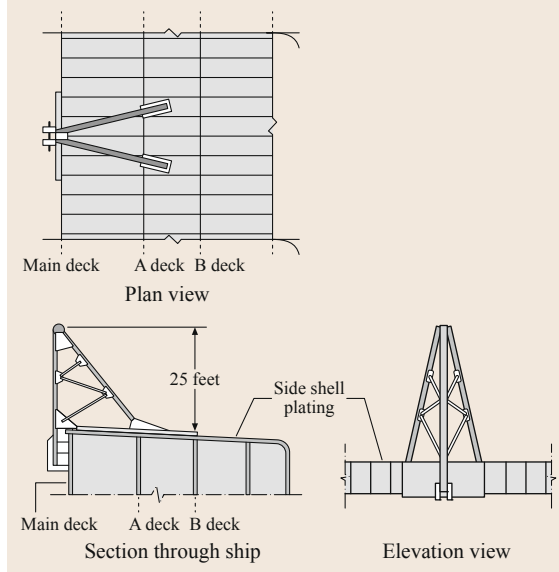

Fig. 42.44 Braced-girder headframe

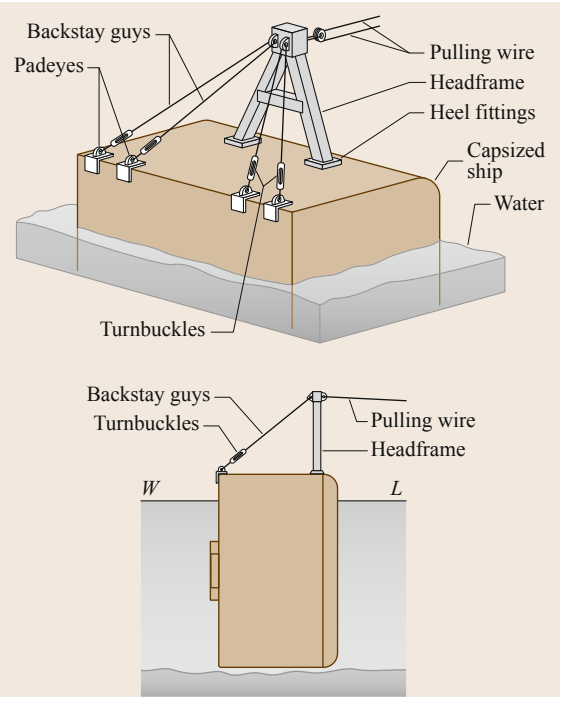

Fig. 42.45 Stayed girder headframe

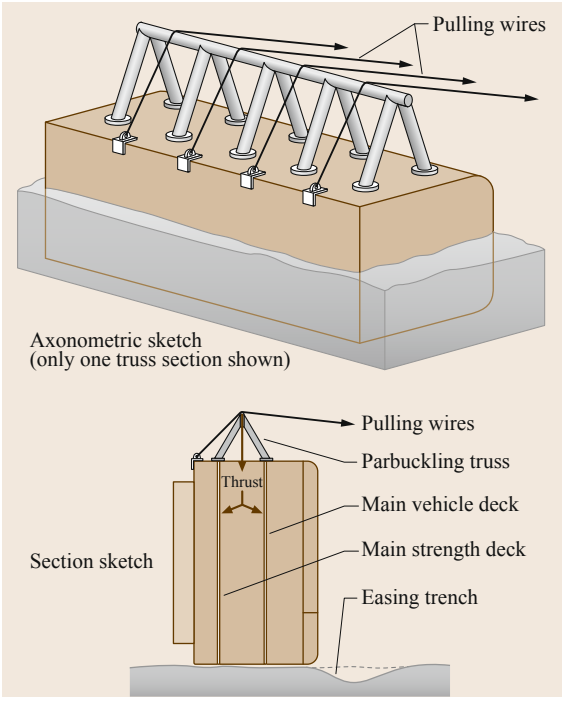

Fig. 42.47 Triangular braced semicontinuous girder headframe

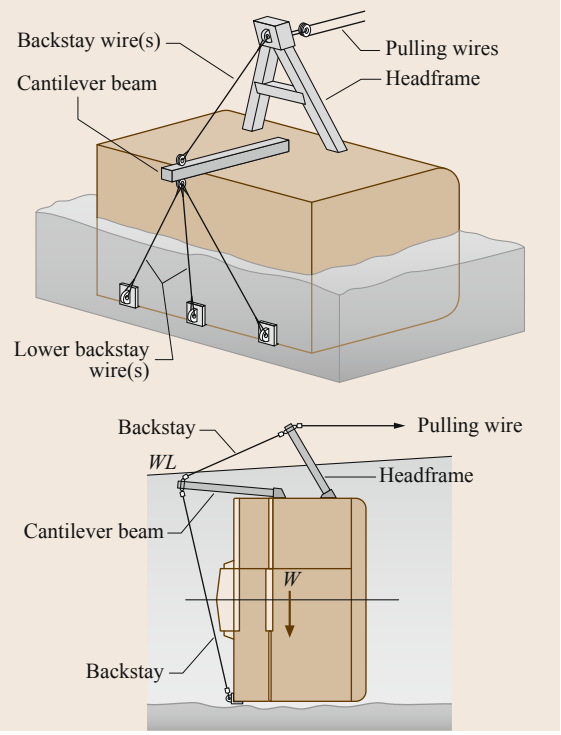

Fig. 42.46 Cantilevered strut headframe

quire more shoreside or shop fabrication than any other design.

Stayed Girder Design

In the stayed girder design (Fig. 42.45), headframes are stayed back to hull connections on the sunken ship. This design is advantageous when there is a shortage of structural steel. Stayed girder designs require numerous wire backstays and are more time-consuming and costly field rigging work than the braced girder design. It is difficult to achieve uniform stayback tension and to control quality because of the number of anchorages, padeyes, and field connections.

Cantilevered Strut Design

In the cantilevered strut design (Fig. 42.46), each headframe is a simple sheer leg braced to a horizontal strut or outrigger. The system is associated most commonly with wooden construction. In addition to difficulty in obtaining uniform strength with wooden spars or logs, this design requires a complex backstay rigging system. Backstay wire ropes are arranged from the headframe to the horizontal strut and from the horizontal strut to the ship. The principal advantage of this system is that when the hauling wire is led over the headframe and connected to the ship's hull, the righting

pull remains at right angles to the hull throughout the operation.

Triangular Braced Semicontinuous Girder Design

In the triangular braced semicontinuous girder design (Fig. 42.47), each headframe resembles triangular leg sections of offshore oil drilling rigs. The headframe structures usually are fabricated from heavy wall tubulars. A continuous length of pipe or girder has six- or eight-leg struts welded so that they are perpendicular to one another at the pipe or girder. The struts are welded to the hull with the girder elevated. It is usual with this system to lead pulling wires over the girder and connect them to special brackets, bollards, or padeyes welded to the hull.

Variations of all four systems have been successful, depending upon material availability, specific problems on the ship, and local conditions. As a rule, it is better practice to pass the hauling wires over the headframe and attach them directly to the hull than to connect them to the top of the headframe. In Fig. 42.47, triangular braced semicontinuous girder headframe, one of the advantages of this system is the ability to share leg thrust between two decks: the main vehicle deck and the main strength deck.

42.D.26 Connection of Pulling Wire

Main hauling wires are connected to either headframes or the hull by several methods. Figure 42.48 shows connection methods.

42.D.27 Connection to Headframes

Main hauling wires are shackled directly, or made up to bolted or pinned connections at the tops of individual head frames. Direct attachment of main hauling wires to headframes is one of the more common connection methods. The headframes incorporate a heavy joining lug, padeye or plate shackle arrangement to which hauling wires are shackled or bolted. This method has the advantage that all connection components can be built to uniform specifications when headframes are fabricated. Headframe connection material and component requirements are analyzed by the salvage engineer as part of the overall analysis of the headframe design.

42.D.28 Connection to the Hull

Main hauling wires are bolted or shackled to especially fabricated anchorage points welded to strong points on the hull. In such cases, hauling wires are led *over* the top of each head frame to the hull anchorage point.

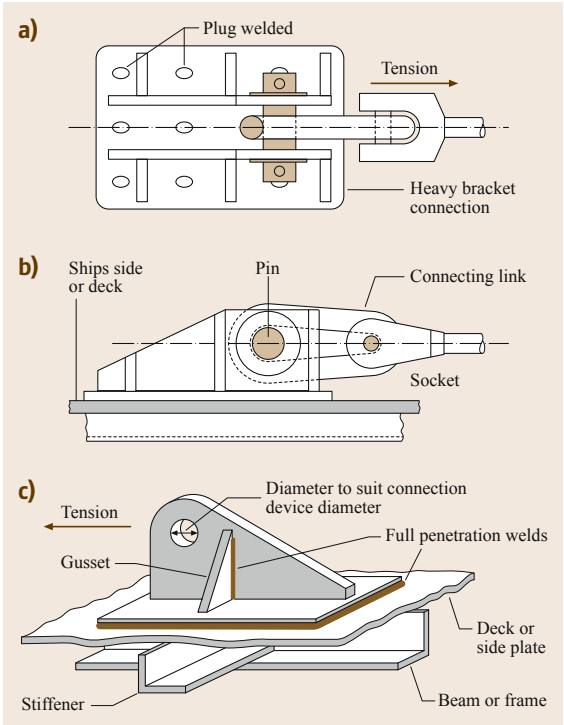

Fig. 42.48a–c Typical connection points for pulling and restraining wires: **(a)** Plan view, **(b)** elevation sketch, **(c)** heavy padeye connection

Special anchorage points welded directly to the capsized ship's hull or deck are usually made for wires of between 2 1/2 and 3 1/2-inch diameter. Typically, such anchorage points consist of two heavy steel plates welded to plate foundations attached to the capsized ship's deck. Each anchorage point is located beneath and aligned with a parbuckling headframe or deck edge bolster serving a hauling wire. This connection has the added advantage that foundation plate designs pick up several frame stations or strong points where analysis indicates load spreading is necessary.

42.D.29 Padeyes

Main hauling wires are attached to padeyes where enough local strength exists at wire connection points. Where analysis shows that not enough strength exists, it is usually not worth the time and effort to stiffen the structure for padeye connections. In such a situation, it is usually preferable to have purpose-built anchorage points fabricated ashore. The eye opening must be large enough to accept the pin of a shackle of strength equal to that of the padeye. There must be enough metal around the eye to prevent failure in bearing or tension. Padeyes should be installed so that loads are in

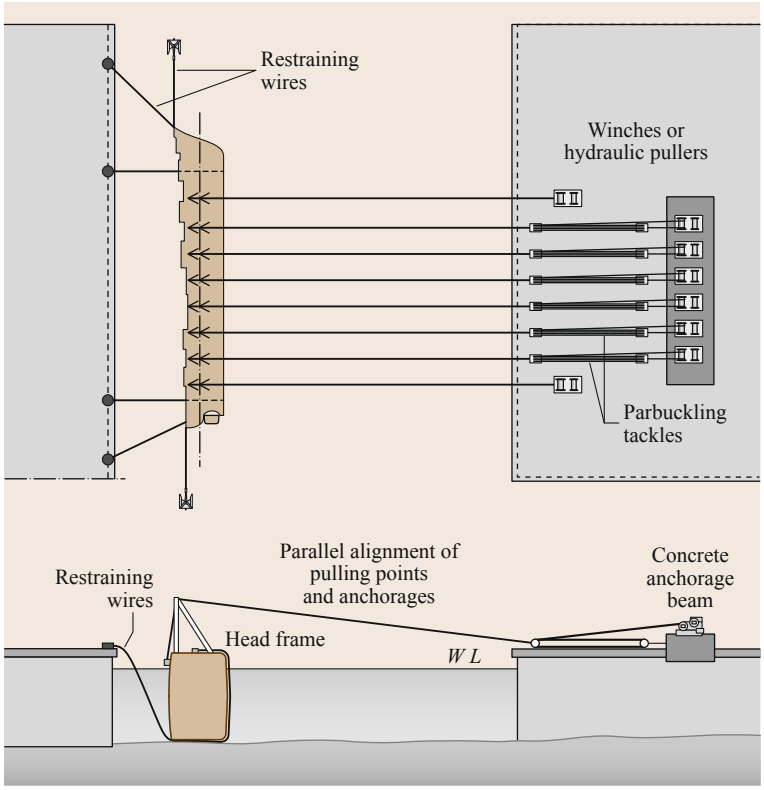

Fig. 42.49 Parallel alignment of pulling points and tackle

their own plane. Doubler plates and/or underdeck reinforcements spread the padeye loads through the ship's structure. Padeyes should be located to take advantage of existing stiffeners.

42.D.30 Special Bollards

Short, heavy-wall-thickness pipe bollards, welded to suitable long girders or structural steel sections, are a relatively efficient method of connecting multiple pulling wires to capsized ships. Each short bollard is fitted with a wide-top flange to prevent pulling wires from slipping off accidentally. Bollard-type connections are not suitable for all righting or hauling operations. This system is most often used with purpose-built pulling barges that deploy several wires to the capsized ship.

42.D.31 Chain Pigtails

Main hauling wires may be shackled to chain pigtails rove through specially cut holes or apertures in the capsized ship's hull. Chain pigtails rove through hull openings are most common when dragging partially submerged capsized ships out of channels. Decisions to use chair pigtail connectors are influenced by diving conditions and time required to prepare and weld special wire connection anchorages to the hull, especially if the attachment would otherwise require wet welding. Chain pigtails are not particularly effective unless the ship has an extremely heavy framing system to withstand the combined pulling and cutting effects of the chains. The method does not allow very detailed analysis of connection strength.

42.D.32 Location of Both Hauling and Lifting Points on Hull

Several factors that act individually and in combination influence the location of hauling and lifting points for mechanical righting. Hull construction and ship strength are considered along with the mechanical method to right the ship.

42.D.33 Headframe Attachment Position

To ensure that each purchase or pulling system develops almost identical righting moments, headframe top and hauling system anchorage point baselines must be in the same plane. To achieve this, it is customary to locate all headframe attachment positions on the capsized ship's parallel midbody.

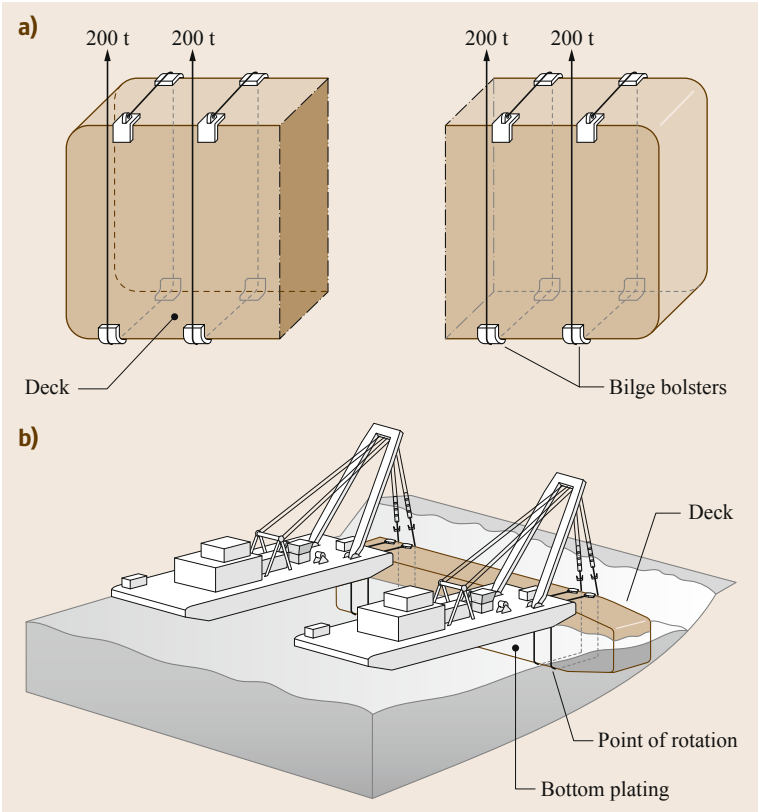

Fig. 42.50a,b Sheer legs uprighting capsized ship: **(a)** Sheer leg lifting wires, **(b)** detail of rigging arrangement

Large areas of parallel midbody seldom exist on modern warships, so salvors may have to construct headframes of different heights to be sure headframe tops are in alignment. Larger fleet auxiliaries and most large merchant ships have long parallel midbodies that simplify headframe mounting arrangements. Figure 42.49 shows this alignment.

Headframes must be set over strength decks to ensure that the strongest hull areas absorb the vertical thrust or pull. Salvors try to set headframes at junctions of sheer strake and weather deck plating, or junctions of main longitudinal strength deck and side shell plating. Where headframes cannot be set on hull junction points, salvors may have to install heavy stiffening.

42.D.34 Floating Cranes and Sheer Legs

Floating cranes and sheer legs in a righting role typically lift in the parallel midbody at the low or seafloor side of the capsized ship, opposite the bottom plating. Lifting slings or straps from cranes normally are passed underneath the capsized ship's hull, taken up along bottom plating, and then alongside the shell plate. This may involve tunneling, sawing, or sweeping messenger wires under the capsized ship. The wires connect to padeyes or special side bolster fittings welded to the high side sheer strake. As large forces or pulls are applied in localized areas, bolsters are fitted to side shell and deck plate junction areas in way of lifting pendants. Figures 42.50 and 42.51 show sheer legs uprighting a capsized ship and a schematic of pontoon attachment for righting.

Salvage personnel and crane barge operators must establish close liaison and mutually agree on connection methods to ensure that crane barge shackles and associated rigging jewelry match bolster fittings or padeyes made by salvors. Some superstructure elements, masts, and other fittings may be removed from the capsized ship to prevent them from damaging the barges during rotation operations.

High-capacity, single main hook offshore derrick barges employed in parbuckling operations may require several under hull pendants and connecting points because of their lifting power. Figure 42.50 shows typical righting arrangements with salvage sheer legs. The sheer legs have deployed both main lift hooks and deck tackles for maximum righting power.

42.D.35 Small-Capacity Buoyant Lift Devices

Salvage pontoons and other small-capacity buoyant lifting devices are connected to capsized ships by fittings and rigging methods that support the buoyant force. Rigging for buoyant lift systems does not involve the degree of engineering or component strength required for large cranes or sheer legs. Figure 42.51 shows a typical salvage pontoon attachment for righting with external buoyancy.

42.D.36 Hauling System Anchorages

Mechanical hauling methods for righting capsized ships require an anchorage system to pull against. The engineering and building or laying of anchorage systems are two of the most important and time-consuming parts of preparing for a mechanical righting operation. Failure or drag of any individual hauling anchor point creates a situation that results in either an embarrassment or a catastrophic stoppage of righting operations. This section describes some of the more important practical matters in selecting and establishing strong points for hauling anchorages.

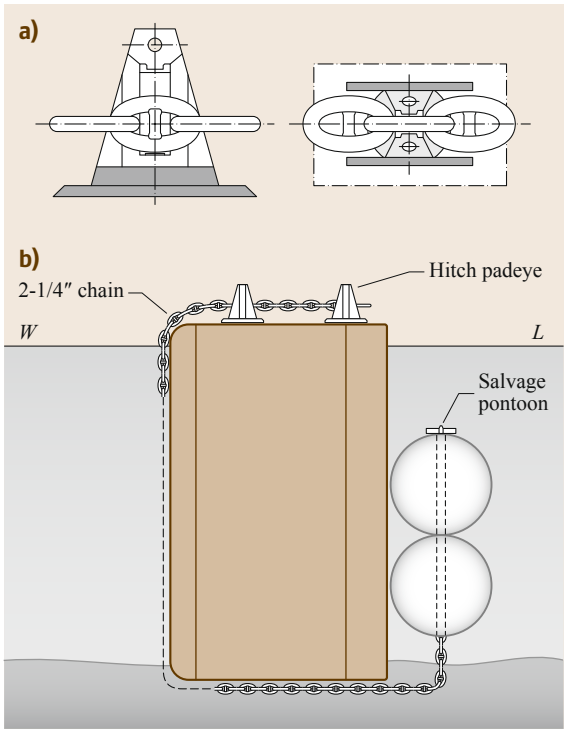

Fig. 42.51a,b Pontoon attachment for righting: **(a)** Hitch padeye, **(b)** typical arrangement of salvage pontoons

Anchorages are divided into two basic classes:

- Shore-based hauling foundations
- Marine-based pulling anchorage systems.

Anchorage or foundation systems for large righting systems require careful engineering and design analysis that consider:

- Total pulling force on the system
- Individual pull or reaction force on each anchorage
- Soil shear and strength characteristics, including the loadbearing capacity of the foundation area
- Methods of installing, removing and, where appropriate, demolishing and/or rehabilitating areas of foundation construction
- The relative merits and disadvantages of proposed anchorage systems and their cost in time and materials
- Effects in cost and time for the construction of specially engineered anchorage systems compared to intelligent improvisations with locally available components.

42.D.37 Shore-Based Anchorages

Anchorages for shore-mounted hauling systems cover a wide range of designs, depending on total pull exerted on each anchorage point and soil characteristics. Some systems designed to absorb 40–60 tons per point may use convenient materials of opportunity and involve simple excavations with backhoes. At the opposite end of the scale, major foundation works and site engineering are required with individual point pulls of 200–300 tons or more.

Basic designs for shore-hauling foundations include:

- Simple deadman systems that consist of an excavated pit with its front, or pressure face, lined with vertical balks or logs of heavy timbers. A chain for the standing purchase block is secured around a horizontal beam laid behind the face timbers. The chain is laid up outside before the pit is filled with soil, crushed rock, or reinforced, ready-mixed concrete.
- Simple piled anchorages, driven or drilled into soil or bedrock, to which tail chains or heavy padeyes are connected. Basic piled anchorages of this type are suitable as attachment points for standard hydraulic pullers or standard beach gear purchase blocks.
- Individually excavated pits in which steel structural beams are placed as foundations for winches. After structural steel members are welded together, the

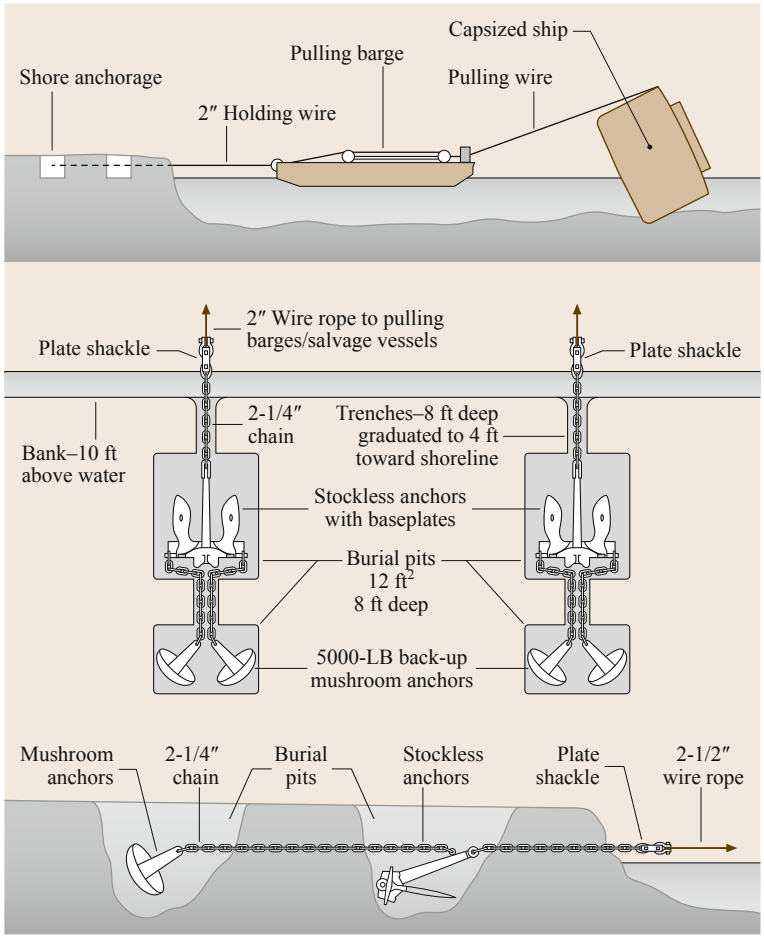

Fig. 42.52 Ancorage for small righting job

pits are filled with concrete to complete each anchorage unit. Variations on this method are quite common; winch foundation blocks.

- Large, composite foundation blocks for mounting several winch or hydraulic puller systems. Typically, such foundations are deeply excavated, prismatic trenches incorporating raker piles and large quantities of reinforced concrete. Excavation, preparation, steel fixing, and concrete pours make such foundations major tasks that may best be subcontracted to military or civilian engineering organizations.
- On occasion, bulldozers, crawler cranes, and other heavy tracked vehicles, including tanks, packed in roughly excavated pits have served as satisfactory shore anchorage points.

Innovative salvors have constructed their own shore-hauling system anchorages for smaller righting tasks. Simple and effective shore-hauling foundations have been constructed by taking beach gear anchors and chain cables ashore, excavating suitable pits, and burying them. Other salvors have successfully used large concrete mooring clumps, discarded structural steel or other materials of opportunity as shore-hauling foundations. Figure 42.52 shows such a system.

42.D.38 Weight Removal

In almost every case where ships capsize and sink, salvors must remove the structure or steel weight before righting the ship. Structure most frequently removed includes:

- Masts, stacks, and cranes
- Superstructure
- Weapons mounts and weather deck fittings
- Large sections of hull structure below the main deck.

No two sunken, capsized ships exhibit identical characteristics to salvors, even when ships are of the same type. In stranding situations, no two casualties are exactly the same. In capsized ships, a weight that must be removed on one ship becomes a useful weight to retain on a sister ship capsized under different circumstances.

42.D.39 Weight Removal

Weight or structural sections of capsized ships are removed for one of four reasons:

- Structures that will prevent righting of the ship, or will cause damage to salvage vessels, are removed to allow operations to proceed.
- Total capacity of available righting forces cannot overcome the calculated capsizing moment unless weights are removed.
- Weight, such as mud, silt, or debris, that enters a capsized ship after it has sunk, usually is removed to reduce righting force as a matter of good salvage practice.
- The weight concerned is of a hazardous or pollutant nature, such as ordnance or fuel oil.

Weight removal plans consider several factors, including:

- Getting maximum reduction of capsizing moment with minimum possible surface and diver work
- Not compromising or making refloating operations more difficult as a result of structural removals
- Availability of lifting equipment, either mechanical or buoyant, that governs the size and weight of sections that can be handled safely.

42.D.40 Weight Removal Methods

Methods of removing weight from capsized ships depend upon the location of weight or structure relative to average high and low water levels. As a general rule, any structural elements that are out of water throughout the tidal cycle are wholly or partially removed by conventional surface burning and cutting. Structural sections or individual weight elements that are wholly underwater are cut away by divers. Subject to equipment availability, some major surface and underwater sections may be removed by mechanical or explosive cutting.

42.E Appendix: Wrecking in Place

42.E.1 Wrecking-in-Place Methods and Techniques

Wrecking-in-place operations employ several specialized methods in addition to normal salvage techniques. These methods can be classified very broadly as:

- Manual cutting by divers and surface workers
- Mechanical demolition using heavy lift cranes
- Explosive sectioning, dispersal, or flattening
- Burial or settling by hydraulic dredging.

Each method has its own particular equipment requirements, operational techniques, and specific advantages and disadvantages. A method that is operationally suitable and acceptable for one wreck may be technically impractical or environmentally unacceptable under different circumstances. Salvors must determine what method, or combination of methods, is most suitable for their wreck and if appropriate equipment is available. Where the opportunity exists, salvors may combine wrecking in place with conventional salvage techniques.

42.E.2 Manual Cutting

Manual cutting by divers and surface crews is the most common method of performing small wrecking-inplace jobs and is used extensively on large wrecking operations. Topside crews cut with conventional oxy-acetylene or oxy-arc burning gear, or semiautomatic cutting machines. Divers make underwater cuts with underwater cutting equipment. Topside manual cutting is the most precise wrecking-in-place method, but it is also labor-intensive. Many environmental and wreck-related conditions influence underwater cutting speed and precision.

42.E.3 Mechanical Demolition

Mechanical demolition is usually performed by heavy lifting and hauling equipment mounted on floating cranes, salvage sheer legs, salvage vessels, or improvised salvage barges. Mechanical demolition methods include:

- Chain and wire cutting or sawing
- Direct ripping or stressing of weakened steel structures

- Tearing wrecks apart with heavyweight dredging grabs or specially designed wreck grabs
- Smashing wreck sections with wrecking chisels.

42.E.4 Explosive Sectioning

Explosives are an important wrecking-in-place tool that can be effective in both wreck removal and wreck dispersal operations. Explosive uses include:

- Cutting or breaking hull and superstructure sections
- Pounding or flattening wrecks into the seafloor
- Breaking wreck sections that cannot be handled by other methods
- Dispersing wreck sections or entire wrecks as part of channel clearing operations.

42.E.5 Burying or Settling Wrecks

Where seafloor conditions are suitable, and sufficient depth of water exists, it may be possible to dredge a trench, or a series of trenches, for the wreck to settle or skid into as the surrounding soil collapses. To reduce the amount of dredging work, divers cut away the wreck's superstructure, masts, and stacks before dredging begins. Before a wreck is buried, a soil analysis should be made to determine if the soil is suitable for this technique. Excavation for wreck settling or burial operations is done in three principal ways, either singly or in combination:

- Mechanical or profile dredging with clamshell or hydraulic cutter dredges
- Explosives
- High-pressure water jetting or sluice pumping.

Wreck burial normally is the least favored method of wreck disposal. While the problem of obstruction of a waterway or berth may be dealt with by burying a wreck, the wreck remains at the site where it may become an obstruction to future dredging or construction. Buried wrecks have been known to work their way back to the surface. Wreck burials should not be attempted without a thorough civil engineering investigation, consultation with long-term planning authorities, and approval from cognizant or governing environmental agencies.

42.E.6 Problems in Wrecking in Place

Wreck removal and wrecking-in-place operations are subject to all the difficulties of other salvage operations plus:

- A large quantity of unknowns about contents of and extent of damage to the ship
- Stringent safety and accident prevention policies and procedures
- Siltation and subsidence into the seafloor
- The physical working environment relative to port activities
- Removal and disposal of remaining cargo, stores, ordnance, and provisions
- Environmental regulations and restraints
- Acceptable and realistic work plans and schedules
- Equipment, manpower, logistics, and funding limits
- Postoperation cleanup and rehabilitation.

42.E.7 Environmental Regulation and Constraint

In all but purely military operations in wartime, wrecking-in-place operations are usually subject to the same environmental protection rules, regulations, and guidelines as other marine or harbor industrial activity. Salvors performing harbor or coastal wrecking operations often believe that environmental protection rules hinder their work. The rules are seldom waived because of the special circumstances of the work. While local regulations concerning matters such as explosives storage and handling and permissible charge rates may be negotiable, wrecking plans should not be based on any exceptions to environmental rules.

Wrecking in place invariably generates pollution in the form of:

- Unintentionally liberated cargo and debris
- Mud, silt, and solids in the water column
- Offensive garbage and trash liberated during the work
- Accidental spills of residual oil.

42.E.8 Manual Cutting

Manual cutting is surface or underwater cutting operations performed with man-portable cutting gear or tools including:

- Oxy-fuel gas cutting torches employed on the surface or underwater
- Electric or hydraulic cutting, grinding, or shearing
- Diver-operated cutting equipment such as oxy-arc, thermic lance, and Kerie cable.

Wrecking in place often requires extensive surface and underwater cutting. Numerous minor operations are

best performed by surface workers or divers cutting steel structural members, piping, and internal fittings with basic flame or oxy-arc techniques. Manual cutting is deployed for large-scale wrecking-in-place operations when:

- Mechanical wrecking systems are unavailable or unsuitable.
- Large portions of the superstructure or hull is above the surface.
- Debris or wreckage obstructing main working areas or cut lines must be removed for access.

Manual cutting supplements other wrecking-in-place techniques. Preliminary phases of mechanical and explosive cutting operations may require preparatory manual cutting to ensure efficiency.

42.E.9 Underwater Manual Cutting

Diver-operated manual cutting systems are used on almost every wrecking-in-place operation. Work assigned to underwater cutting teams ranges from cutting hull-section slinging holes to cutting entire hulls. The success and speed of underwater cutting depends upon several factors including:

- Experience and skill of the divers
- Limitations imposed on divers by diving conditions, current, wreck attitude, and depth
- Location of cut lines relative to hull structural features, machinery, piping, and internal fittings
- Access to the cut line.

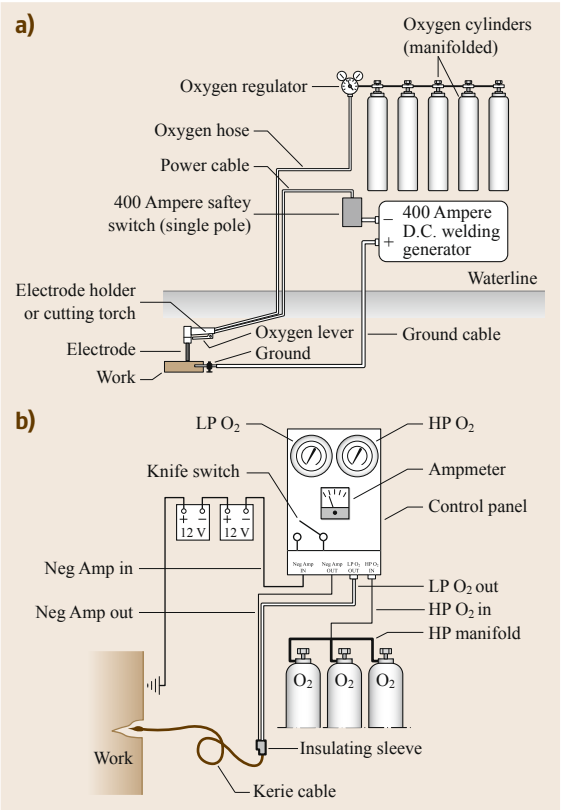

Fig. 42.53a,b Typical underwater cutting systems (**a**) typical oxy-arc arrangement (**b**) typical Kerrie Cable arrangement

42.E.10 Underwater Cutting Processes

Two underwater cutting processes are primarily employed:

- Oxy-arc cutting with exothermic electrodes, steel-tubular electrodes, and exothermic cable
- Shielded metal-arc cutting (cutting with ordinary welding leads and rods).

Oxy-arc is preferred because of its ease of use. There are two types of electrodes (rods) for oxy-arc cutting: exothermic and steel tubular. The exothermic is preferred because it burns independently after an arc is struck and oxygen is flowing.

In shielded metal arc cutting, the metal is cut by the intense heat without the oxygen. Shielded metal arc cutting is particularly suitable for cutting steel 1/4-inch or less thick, and nonferrous metals or corrosion-resistant metal of any thickness.

Figure 42.53 shows typical arrangements for underwater cutting with oxy-arc and Kerie cable systems.

42.E.11 Surface Manual Cutting

Surface cutting is often an important part of wrecking-in-place work. Cutting tasks vary from cutting holes for slings or access to demolition and removal of major hull sections above the waterline. Topside flame cutting teams range from one man with a portable cutting torch to several gangs of burners distributed all over the wreck. Most flame cutting is done with oxy-acetylene or oxy-propane gas mixtures. Cutting gases are compressed flammable and explosive substances that carry with them fire and explosion hazards. Wrecking operations with gas cutting systems require stringent safety programs to prevent accidents.

42.E.12 Lifting

Accidents during lifting operations occur easily when untrained personnel are allowed to rig, sling, or break

out even small lifts. Most wrecking-in-place operations employ bargemounted crawler or revolving cranes for general-purpose lifting. Crane operators are not always able to see lift areas and depend upon signals from the wreck. Many lifting accidents occur because:

- The lift area is not cleared of personnel before lifting.
- Incorrect or misleading signals are given to the crane operators.
- Adequacy of attachment lifting points.
- The sling is inadequate or incorrect for the weight, geometry, or behavior of the lift.
- Movements of the barge-mounted crane in the sea and swell is not taken into account.

Most lifting accidents can be avoided by assigning a small group of qualified salvage personnel as a rigging team. Because lifts take place from different areas, the rigging team moves from site to site. The team's duties include:

- Providing and rigging lifting gear to each section or component structure as it is ready to lift
- Checking that each piece is cut free and ready for lifting
- Planning and directing any final cuts necessary to break out difficult lifts
- Ensuring all hands and their equipment are clear of the working area before lifting begins
- Directing the crane operator by hand signals, whistle, or radio to make lifts
- Controlling lifts until the crane operator slews the lifts away from the wreck.

42.E.13 Mechanical Demolition

Mechanical demolition describes cutting with heavy lifting and hauling equipment. Such systems reduce the amount of diving and surface labor time required for wrecking in place operations. Mechanical cutting can be very effective, either in conjunction with explosive cutting or as a stand-alone technique, provided suitable heavy lifting and hauling equipment is available. Mechanical demolition methods include:

- Chain and wire cutting or sawing wrecks into sections suitable for lifting
- Tearing wrecks apart with specially designed wrecking grabs or heavy dredging grabs
- Direct impact cutting and smashing with wrecking chisels or wreck punches
- Stressing weakened steel structures to breaking point by direct ripping.

Mechanical cutting is usually performed by heavy lifting and hauling equipment mounted on floating cranes, salvage sheer legs, salvage vessels, or improvised salvage barges. Under certain circumstances, some mechanical cutting systems can be operated by shore-based lifting or hauling systems.

42.E.14 Chain Cutting

Chain-cutting sections wrecks to suit lift capacity and local circumstances. Chain cutting does not have precise guidelines to suit every wreck situation. Wrecks may be cut into sections either vertically or horizontally, depending upon wreck attitude and availability of suitable hauling or lifting equipment. Chain cutting is more efficient than wire cutting and is advantageous when:

- Suitable heavy-lift salvage sheer legs or cranes to operate cutting system are available.
- Tidal or river currents severely restrict diving operations.
- Cut lines with oxy-arc or explosives have not been completely successful.
- Damage to the wreck makes precision cutting difficult and dangerous, particularly where wreck sections are partially buoyant and hinged.
- Large quantities of cargo or debris create serious obstructions to clearing away and maintaining access to cut lines.

Figure 42.54 shows heavy salvage sheer legs with a cutting chain rigged into position underneath a wreck.

42.E.15 Advantages and Disadvantages of Chain Cutting

Chain cutting of wrecks has advantages and disadvantages. The advantages include:

- The system is basically independent of divers after the cutting chain has settled into its starting notches.
- Chain sawing usually cuts any given section faster than any diver-operated underwater methods.
- Chains are not hampered by mud, poor underwater visibility, or bottom time limitations.
- Buoyancy exerted by salvage cranes operating chain cutting systems usually has positive effects on cutting speed by increasing tearing and breaking action.

Disadvantages of chain cutting systems include:

- It is difficult and frequently dangerous for divers to examine progress of cutting due to jagged and

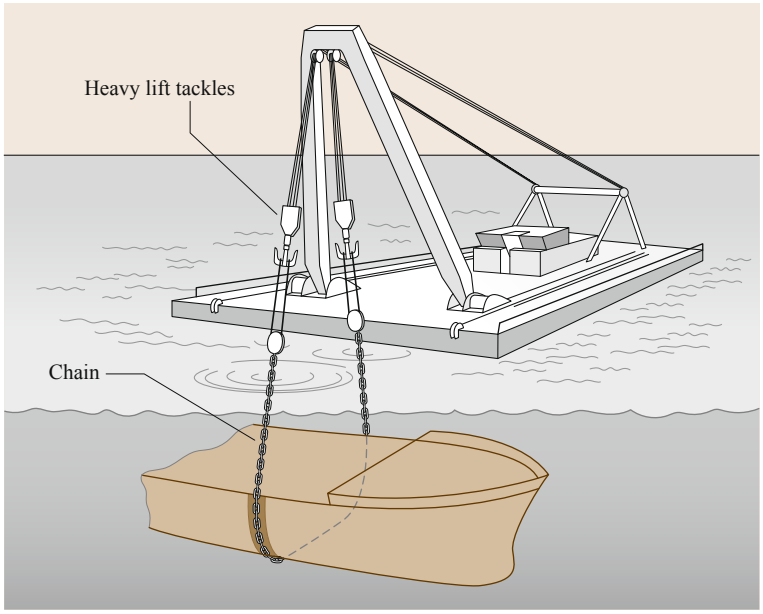

Fig. 42.54 Chain-cutting rig

torn metal edges along cut lines. Visual monitoring of progress can be difficult, if not impossible, even with underwater TV systems.

- Cutting delays may be encountered where chains deflect from planned cut lines and unintentionally cut into heavy beams and girders.
- Chains sometimes break inside the cut line. Extracting broken chain ends and re-rigging a new length of chain into cut lines can be time-consuming and difficult.
- Large salvage sheer legs perform the most efficient chain cutting work. These craft are not always available.

42.E.16 Cutting Chains

Chain cutting requires high-grade chain, such as Di-Lok or near equivalent flash-butt-welded, stud link chain. Cutting chains must be free of flaws, loose studs, and structural distortion. Scrap chain is rarely suitable for cutting. Heavy, good quality, used oil rig quality (ORQ) chain of 2 3/4 to 3 1/2-inch diameter has been successful in chain cutting. As a general rule, chain cutting should not be attempted with chain of less than 2 1/4 -inch diameter. The Di-Lok chain should be reserved for this type of work and lifting operations.

42.E.17 Preparation for Chain Cutting

The effectiveness and speed of chain cutting depend on the lifting capacity and outreach of the cranes available to salvors. Chain cuts are most efficiently performed by salvage sheer legs or heavy lift cranes rigged with two or more lift purchases of equal capacity. Lifting capacity of 150–200 tons per lift purchase appears to be the lowest acceptable level of lifting power for cutting large ship sections. Salvage sheer legs with several 300-ton lift capacity purchases are more suitable, but not always available. Preparatory steps for making chain cuts are:

1. Suitable messenger wires are passed, swept, or sawn under the wreck at each cut station.
2. Cutting chains are passed or dragged underneath the wreck and connected to crane lift purchase hooks with heavy wire slings.
3. Both lift purchases are lightly tensioned to bring the cutting chain into contact with wreck hull. Both contact points are marked and chain slacked off to allow divers to cut *starting notches* with oxy-arc equipment or shaped charges.
4. The size and depth of starting notches depends upon the aspect of the wreck and the diameter of the cutting chain. As a general rule of thumb, at least three or four links of chain should bury themselves in each starting notch.

In some cases, starting notches may have been pre-cut by an advance team so crane barge crews and divers rig cutting chains into pre-cut notches or a previously attempted cut line. Some pre-cutting of heavy structural section, such as propeller shafts and machinery foundations, may be necessary and advisable if hull cuts are to be made in such areas. Chain cutting through machinery spaces should be avoided whenever possible.

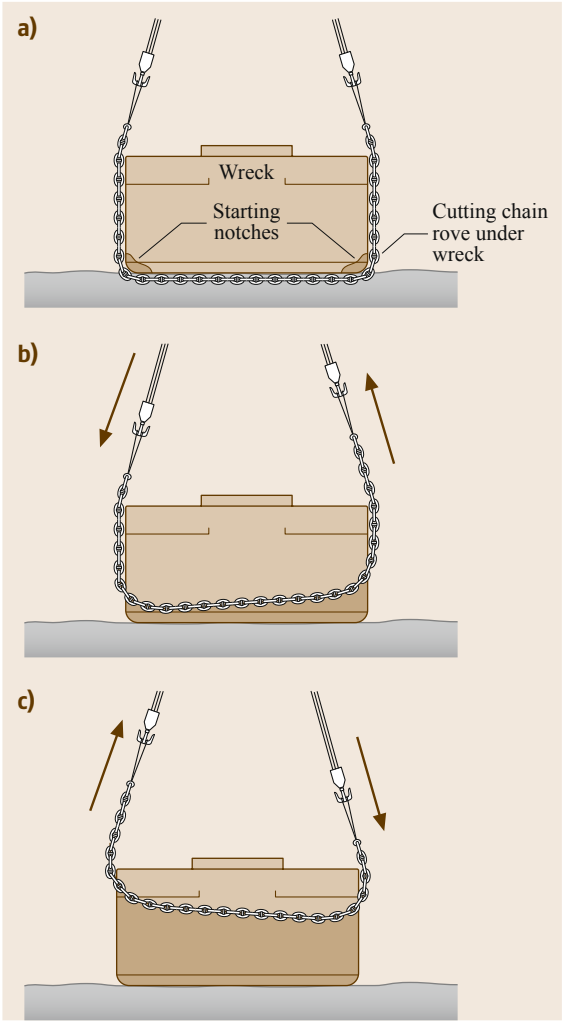

Fig. 42.55a–c Chain-cutting sequence: **(a)** Commencement of cutting sequence, **(b)** cutting sequence in progress, **(c)** cutting sequence almost complete

Figure 42.55 shows two starting notches cut into bilge radius plates of a wreck and the general progress of a chain cut.

42.E.18 Chain-Cutting Operations

Cutting chains are sawn alternately backward and forward through the wreck's hull and superstructure. Cutting is achieved by stressing, shearing, and tearing of steelwork by controlled lifting forces. Each link of the cutting chain acts like a blade on a chain saw. Steel plate and structural sections are crushed or distorted to their failure point as successive chain links wear and rip at the metal.

After a cutting chain is settled in its starting notch, operations usually proceed as follows:

1. A heaving or lifting strain of 150–200 tons is put on one end of chain, while the other purchase system slacks away slowly at about half that tension.
2. Several cycles, alternating each purchase between heaving and slacking, are usually necessary before the chain cuts or breaks into the wreck's hull.
3. Cutting rate is monitored by both hook weight readouts from strain gages and observing travel lengths of purchase tackles. Successively shorter purchase fleets indicate that a cut is proceeding efficiently.
4. When purchase fleet lengths become unworkably short, the long wire slings connecting each lift hook to the cutting chain ends must be replaced by shorter wire slings.
5. Cutting is completed when the cutting chain's bight is torn free of the wreck and recovered to the salvage crane.

42.E.19 Improvising Chain-Cutting Systems

Chain-cutting systems can be improvised from assets of opportunity, with varying degrees of success, depending upon knowledge, experience, and skill of salvors. Extremely powerful winches, such as the oilfield truss winches are suitable for chain cutting in either barge- or horemounted configurations.

Figure 42.56 shows an improvised chain sawing system rigged on a single-hook sheer legs crane. This system operates with a deck purchase leading over a bow fairlead, working in conjunction with the sheer leg purchase tackle. In this system, the main cutting and tearing load is applied by the Aframe purchase, with the deck purchase backhauling cutting chain after each tension cycle.

Successful chain cuts can be made by pairs of single-hook floating cranes or sheer legs. One derrick is located on each side of the wreck or section to be cut, and the chain saw steadily between both cranes. This method is technically relatively efficient, but requires two floating cranes or sheer legs that should be fairly well matched in size and capacity. Because the operation is performed from two separate vessels, coordination and control between crane operators is a critical factor in a safe and successful operation. Startup is characterized by some degree of trial and error as crane operators and salvors adapt themselves and their craft to the method. A strong mooring system for each crane and between the crane barges is essential to operate the system effectively. Figure 42.57 shows

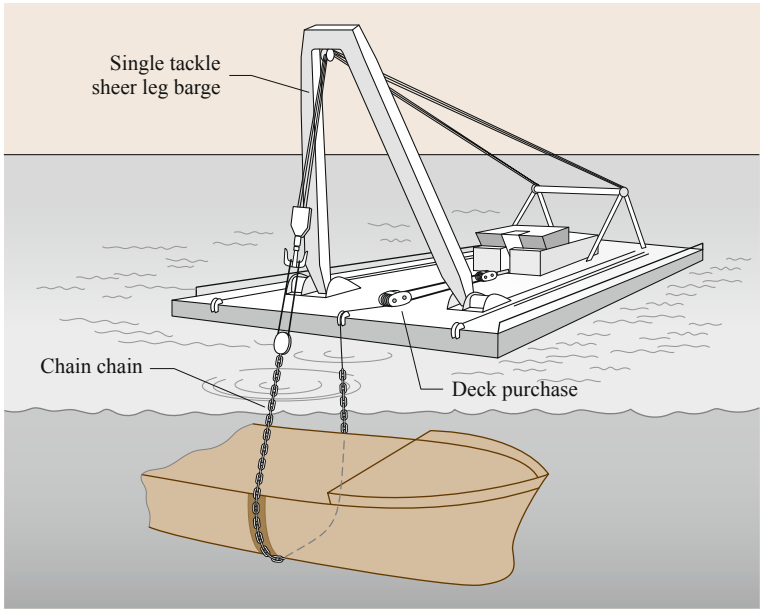

Fig. 42.56 Improvised chain cutting system with a-frame and deck tackle

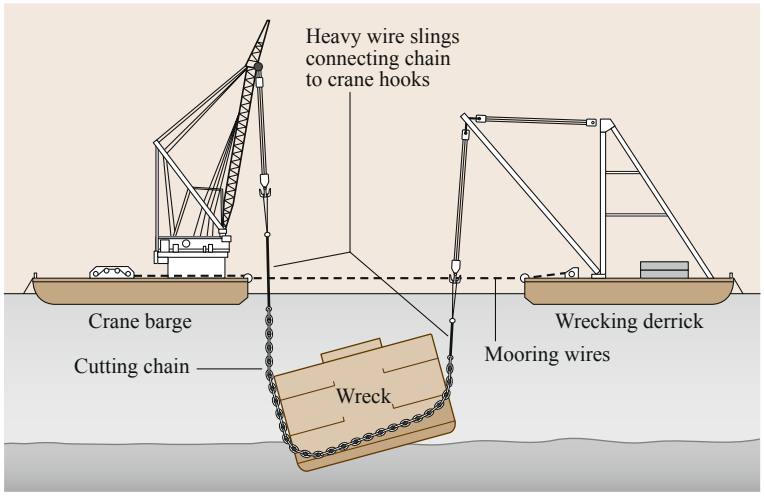

Fig. 42.57 Two crane barges operating a sawing chain

a chain sawing arrangement operated by two floating cranes.

Single kingpin mobile or tracked cranes such as barge-mounted crawler cranes are not designed or constructed to operate chain cutting systems. Improvised chain cutting systems with lattice boom rotating cranes may result in boom or pivot systems being unacceptably overloaded.

42.E.20 Wreck Grabs

Wrecks that lie partially or wholly buried in the seafloor, that have deteriorated with age, or that are seriously damaged, present a difficult wreck removal problem. Diving operations on such wrecks are usually hindered by strong currents, poor visibility, and a high degree of risk. Without mechanical systems, attempts to demolish or remove seriously damaged or partially destroyed sunken wrecks are usually time-consuming and very often extremely costly.

Dredging grabs are usually unable to crush steel effectively, and do not withstand the heavy stresses of wrecking. However, modified *cactus grabs* are extremely useful for gripping and tearing away weakened steel plates. These cactus grabs, also known as *orange peel grabs*, successfully tear away steel structure previously weakened or partially cut by explosives.

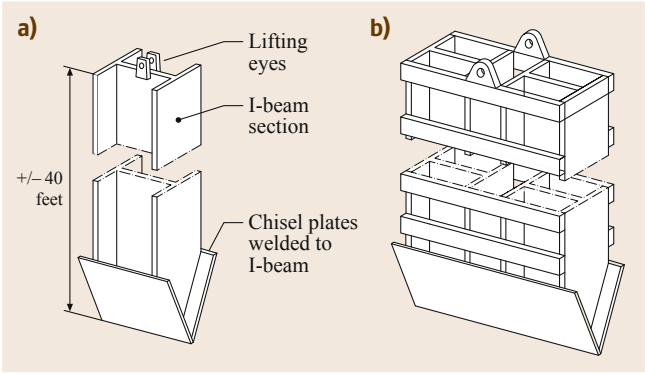

Fig. 42.58a,b Field fabrication wreck chisels: **(a)** Single I-beam chisel, **(b)** double I-beam chisel

Cactus grabs are strongly built, but do not have a wide total jaw opening. The grabs are suitable for demolition and wreckage purposes because they:

- Are strongly built, and relatively simple to operate
- Can be operated independently of divers, reducing risks to personnel
- Have the ability to grip even badly distorted steel structures.

The basic procedure for demolition and removal of sunken wrecks by wreck grabs is:

1. After completion of wreck survey, a decision is made on which end of the wreck will be demolished first. Grabbing operations usually commence at wreck's shallowest end and work steadily toward the more deeply buried section.
2. Heavy moorings are laid out around the wreck, and the sheer legs or salvage crane are aligned facing, or on the same heading as the wreck. Alignment of the crane is determined by the current and the basic demolition sequence.
3. The grab is lowered in the fully open position until it contacts the wreck. Closing tackles are hove up slowly to bite grab jaws into hull wreckage. As the grab jaws close, they penetrate steelwork and begin crushing and tearing.
4. When the grab will not close any more, its lifting tackles are hove up to lift the grab and the wreckage gripped in its jaws. Breaking out a closed grab is a contest of strength between the sheer legs and the wreck.
5. Wreck structure held by grab jaws is torn, crushed, and sheared away from the wreck as the sheer legs heaves up its grab. A combination of brute force and the buoyant upthrust of the sheer legs hull breaks overstressed and damaged steelwork.
6. The wreck grab is brought to surface where recovered wreckage is lowered onto a barge. Bites of 60–80 tons of wreckage can be taken under ideal conditions.

42.E.21 Wreck Punches and Chisels

A wreck punch or wreck chisel is a steel I-beam section cut to a chisel-shaped point at its lower end. Wreck punches smash steel hulls that have not been completely cut by explosive, oxy-arc, or surface cutting techniques. Under some circumstances, wreck punches cut hulls into sections.

Wreck punches are usually made up from heavy I-beams that are stiffened and sometimes boxed in with thick plates welded to beam flanges. Lead billets can be arranged inside beam flanges to add extra weight. Wreck punches are typically made up about 40 ft long, with a weight of between 10 and 15 tons. Wreck punches are operated by cranes. The punch is lifted above the wreck and then dropped repeatedly on the area to be cut. A heavily constructed punch, dropped from sufficient height, obtains enough energy to cut or break plate sections and frames on impact. Figure 42.58 shows typical wreck punches constructed from locally available materials.

Where chain cutting is not practical and wreck grabs are not available, wreck punches are comparatively effective mechanical cutting devices. Most large barge-mounted crawler cranes are capable of operating wreck punches. Heavy oilfield construction cranes can operate very large wreck punches. Improvised heavy wreck punches have been constructed from:

- Large dredge spuds, on which the pointed end was covered with welded steel plate to form a chisel end. Some of these converted spuds weigh 35–40 tons.
- Pairs of large section I-beams welded together and weighted with railroad track and scrap billets.

Not all cranes or derricks are suitable for operating wreck punches. Free-fall capability of the main crane hook is essential for wreck punching. Candidate cranes must be able to release and free-fall a heavy weight from a high boom elevation. Successful wreck punching depends upon a combination of punch weight and drop velocity. Cranes designed or specially adapted for marine clamshell dredging are almost always suitable for operating wreck punches. Auxiliary hooks on large offshore derricks have designed free-fall capability and sufficient lift combined with suit-

ably long booms to handle wreck punches quickly and safely.

42.E.22 Explosive Cutting

Explosives are an important salvage tool in wreck removal, harbor clearance, and wreck dispersal operations. Principal salvage and harbor clearance related explosive uses are:

- Cutting and breaking hull and superstructure sections
- Pounding down, flattening, or burying wrecks into the seafloor
- Dispersing wrecks or wreck sections as part of harbor or channel clearances
- Widening, deepening, and straightening channels
- Demolishing concrete masonry and steel harbor installations that obstruct port or salvage operations.

42.E.23 Burial, Flattening, and Reduction of Wrecks

In some situations, the combination of time, cost, and physical conditions make total wreck removal uneconomical or impractical. Under those conditions, the hazards of sunken wrecks may be sufficiently reduced without physically removing major portions of the wrecks. Three common techniques of wreck reduction are:

- Wreck burial
- Flattening wrecks
- Cutting down wrecks.

Wreck burial may be conducted as a wartime military operation with heavy explosive charges or as a peacetime task involving special dredging techniques. In the past, cutting down wrecks was a common method of increasing navigational depths over sunken wrecks. Military circumstances may still require salvors to cut down wrecks, but civilian port authorities do not encourage the practice. Each method described in this section results in hull structures remaining at or close to wreck sites, potentially creating future navigation, construction, or environmental hazards.

42.E.24 Burial of Wrecks

Burial of a wreck minimizes a navigational hazard, but does not remove a potential obstruction. Buried wrecks have changed their position because of scouring, and in the worst cases, have worked their way back toward the surface. Wreck burials should not be attempted without detailed consultation and approval of port operating, navigational, and environmental authorities. Detailed engineering investigations and dredging expertise are key elements in peacetime wreck burial tasks. Combination of careful profile dredging and explosive or gravity induced skidding undercut and settle wrecks into burial trenches.

Site conditions and lack or cost of wreck removal equipment may combine with suitable soil conditions to permit wreck burial. Seafloor soil characteristics are critical in the decision process. Detailed seafloor investigations and tests are necessary to:

- Establish the level below the seafloor and navigational datums where the bedrock or undredgable material strata is located.
- Confirm that the wreck can be lowered or buried to the clearance depth required by authorities. Clearance depths over the buried wreck are critical to the operation.
- Estimate rates of current-induced soil deposit or back filling that will occur during dredging operations.
- Establish soil characteristics for calculation of trench profiles and skidding angles.
- Decide a suitable method of dredging or combination of dredging and blasting necessary to excavate the burial trench.

Salvage engineering studies of wreck movement are conducted in conjunction with soil engineering and excavation investigations. These studies combine to produce a wreck burial and excavation plan based on either dredging or combined dredging and explosive trenching. Dredging methods include:

- Undercutting one side of the wreck so that it capsizes into a preexcavated trench or burial area.
- Alternately dredging and undercutting on each side of wreck so that it subsides in a rocking motion from port to starboard.
- Dredging a deep trench near the wreck, then profile dredging a sloping skidway from that trench to wreck.

Most work in a conventional wreck burial task is performed by dredging and civil engineering personnel. Salvage aspects of the work in terms of utilizing salvors' skills include:

- Detailed wreck surveys and assistance with moorings and seamanship aspects of soil investigations.

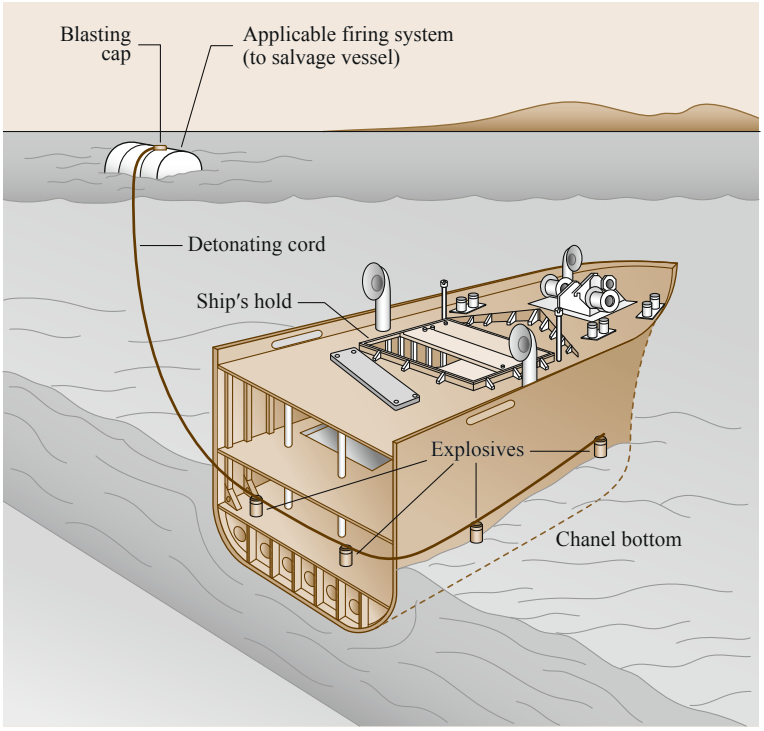

Fig. 42.59 Charge placement for wrecking settling

- Underwater cutting and removal of masts, stacks, superstructure, and other wreckage that may project above cut line.
- Monitoring project and providing technical advice and assistance with explosive charge placement, if required.

42.E.25 Flattening Wrecks

Flattening wrecks encompasses practices that are more specifically known and referred to as:

- Ship settling
- Ship flattening
- Wreck dispersal.

These three practices, grouped together because they have similar end results, employ different techniques, but all have common features including:

- The primary intention of destroying wrecks is to disperse navigational hazards or increase navigable depths.
- Time and circumstances do not permit wrecks to be removed conventionally.
- Wrecks are settled, flattened, or dispersed by explosive demolition.
- Most major wreck components and structures are left in situ as shattered debris.

Ship flattening or settling is usually only performed as an emergency means of channel or harbor clearance. Explosive wreck dispersal may be conducted before follow-up clearance with wreck grabs.

42.E.26 Ship Settling

Ship settling is making a sunken wreck entrench itself deeper into the seafloor. Ship settling may be the sole method of lowering a wreck to increase depth over it, or may be done in conjunction with ship flattening or wreck dispersal. Suitable soil conditions must exist for explosive ship settling to be successful. Soft sand or muddy seafloors permit settling, but hard clay soil may present some difficulties. Wreck settlement is done by:

- Placing heavy charges inside the hull and blowing holes along the bottom or side of the wreck where it is in contact with the seafloor. Damage to hull plating and reduction of bearing surface area causes the hull to sink. Seafloor material oozes into the hull through the holes blasted by the charges.
- Charges placed around the hull and simultaneously detonated to excavate a rough trench around the

wreck. In strong current areas scouring occurs and expedites settling.

These methods may be sequential; first the wreck's side or bottom plating is blasted out, followed by detonation of trenching charges around the wreck.

Figure 42.59 shows internal placement for settlement of an upright wreck.

42.E.27 Ship Flattening

Flattening procedures depend upon how the ship is sunk relative to the seafloor. A wreck lying on its side presents a different problem from one that is substantially upright on the bottom. Upright wrecks are flattened from top downward. Masts, stacks, and superstructure may be cut away with oxy-arc or explosive cutting methods and removed or blasted and allowed to scatter on the seafloor. Some methods of explosive hull flattening follow a combination of pounding down and linear cutting along deck edges to collapse the hull. Combined explosive heavy linear cutting and pounding often results in the wreck collapsing in on itself as a distorted scrapheap.

Another explosive wreck flattening method, more commonly associated with wreck dispersal, places a series of very heavy charges internally. Charges are located inside the wreck's hull with the most powerful charges sited amidships. When the forward, midships, and after end charges are simultaneously detonated, very heavy and opposing pressure surges occur. Internal over-pressure causes side plating and bulkheads to rupture and decks to collapse. Blast and overpressure effects from very heavy explosive charges detonated inside or against wrecks cannot be easily controlled and result in a shattered and distorted wreck.

Diving activities around such wrecks are hazardous and must be conducted with extreme caution. Wrecks that have been flattened or dispersed with heavy explosive charges usually make subsequent wreck removals difficult.

42.E.28 Cutting Down Wrecks

Sometimes navigational obstructions can be reduced by cutting a wreck down to a specified depth below a specified water level. Clearance levels over wrecks are established by port or area operating authorities with regard to present and future traffic. Wrecks can be cut down to specified levels by various wrecking techniques including:

- Oxy-arc cutting
- Explosive cutting
- A combination of oxy-arc and explosives
- Wreck grabbing.

Manual and explosive cutting methods are most common for this type of wreck reduction. Where cost and lack of suitable floating equipment influences wreck removal plans, partial reduction of wrecks is a short- to medium-term solution to a wreck removal problem.

43. Oil Spills and Response

Merv Fingas

Oil spills are random phenomenon and occur in many sizes and forms. The largest 50 spill events are listed, noting that the Gulf War spill in 1991 remains the world's largest oil spill. Organized and rapid response to oil spills is very important to minimize environmental damage. Contingency plans detail the planned response. Five types of oils and fuels are frequently spilled and include gasoline, diesel fuel, light and heavy crude oils, and bunker fuels. Two important properties of these oils include the viscosity and density. The viscosity of spilled products can vary over orders-of-magnitude. The behavior of oils when spilled dictates the environmental impact these will have. The most important oil behaviors are evaporation and water uptake. Evaporation is an exponential factor with time and thus most of the evaporation (about 80%) occurs in the first 2 days. Water uptake takes place in any of the five ways:

- Soluble water
- Entrained water
- Meso-stable emulsions
- Stable emulsions
- Those that do not form any of the other types or unstable.

An important facet of oil spill assessment is laboratory analysis. The most common analytical method is by gas chromatography with mass spectrometric detection (GC-MS) or with flame ionization detection (FID). These methods are not only used for quantification but also for identification and measurement of amounts evaporated or biodegraded. Remote-sensing techniques especially that of satellite radar, are used to map oil spills on the sea. Once spilled, oils on the sea are typically contained using booms and recovered using skimmers, the most important of which are weir and oleophilic surface skimmers. Dealing with recovered oil and disposing of it are important steps. Spill-treating agents are occasionally used, especially oil spill dispersants. There are many conditions and considerations for the use of these. In-situ burning of oil is now being used more frequently and under correct conditions, can rapidly remove spilled oil. Finally, spilled oil often contacts shorelines, therefore assessment and careful removal techniques for shorelines are essential.

Oil spills receive significant media attention when they are large or in areas of high significance and little attention otherwise. This also reflects the wide diversity of spill sizes and impacts. The movement of petroleum from the oil fields to the consumer involves as many as 10–15 transfers between many different modes of transportation including tankers, pipelines, railcars, and tank trucks. Oil is stored at transfer points and at terminals and refineries along the route. Accidents can happen during any of these transportation steps or storage times.

The rate of spillage has decreased in the past 10 years. This is especially true for tanker accidents at sea. Intensive training programs have been developed to reduce the potential for human error. Despite this, experts estimate that 30–50% of oil spills are either directly or indirectly caused by human error, with 20–40% of all spills caused by equipment failure or malfunction [43.1, 2].

43.1 Frequency of Oil Spills

Oil spills of any size, are a frequent occurrence, because of the heavy use of oil and petroleum products. The United States uses about 4×10^6 t of oil per day and worldwide, about 20×10^6 t are used per day. In the United States, more than half of the approximately 4×10^6 t of oil and petroleum products used per day is imported, primarily from Canada, Saudi Arabia and Africa [43.3]. About 40% of the daily demand in the United States is for automotive gasoline and about 15% is for diesel fuel used in transportation. About 40% of the energy used in the United States comes from petroleum, 25% from natural gas, and 20% from coal.

Spill statistics are collected by a number of agencies in the United States. The coast guard maintains a database of spills into navigable waters, while state agencies keep statistics on spills on land which are sometimes gathered into national statistics. The Bureau of Safety and Environmental Enforcement (BSEE) in the United States maintains records of spills from offshore exploration and production activities.

It can sometimes be misleading to compare oil spill statistics, however, because different methods are used to collect the data. The spill volume or amount is difficult to determine or estimate. For example, in the case of a vessel accident, the exact volume in a given compartment may be known before the accident, but the remaining oil may have been transferred to other ships immediately after the accident. Some spill acci-

dent data banks do not include the amounts burned, if and when that occurs, whereas others include all the oil lost by whatever means. Sometimes the exact character or physical properties of the oil lost are not known and this leads to different estimations of the amount lost.

Only a small percentage of oil used in the world is actually spilled. Oil spills in the United States are summarized in Fig. 43.1 in terms of the volume of oil spilled and the actual number of spills [43.4]. In terms of oil spills, many countries have similar trends.

A list of the largest oil spills in the last 50 years is provided in Table 43.1 [43.1, 4]. The spills are listed according to their volume beginning with the largest spill to date – the release of oil during the Arabian Gulf War in 1991. It is important to note that because of the differences in record keeping and spill reporting, the list of the largest spills may vary from source to source.

There is a misconception that oil spills from tankers are the primary source of oil pollution in the marine environment. While it is true that some of the large spills are from tankers, it must be recognized that these spills still make up less than about 5% of all oil pollution entering the sea. The sheer volume of oil spilled from tankers and the high profile given these incidents in the media have contributed to this misconception. Half of the oil spilled in the seas is due to the runoff of oil and fuel from land-based sources rather than from accidental spills.

43.2 Response to Oil Spills

Rapid and effective response to oil spills will minimize damage to the environment. While it is important to focus on ways to prevent oil spills, methods for controlling them and cleaning them up must be rapidly and effectively implemented. An integrated system of contingency plans and response options can significantly reduce the environmental impact and severity of spills.

The purpose of contingency plans is to coordinate all aspects of the response to an oil spill. This includes stopping the flow of oil, containing the oil, and cleaning it up. The area covered by contingency plans could range from a single bulk oil terminal to an entire section of coastline. Oil spills, like forest fires, are not predictable and can occur anytime and during any weather. Therefore, the key to effective response to an oil spill is to be prepared for the unexpected and to plan spill countermeasures that can be applied to a range of possible conditions.

Most contingency plans utilize a tiered response, which means that response steps and plans escalate as the incident becomes more serious. As the seriousness of an incident is often not known in the initial phases, one of the first priorities is to determine the magnitude of the spill and its potential impact.

A contingency plan usually includes background information on the area covered by the plan. This consists of data collected from studies and surveys and often takes the form of a sensitivity map for the area. Sensitivity maps are now computerized in geographic information systems (GIS). These systems allow a composite map or image to be drawn up in layers. This allows personnel to rapidly update and analyze data in the area. Detailed information is usually kept in tables as part of the GIS. Sensitivity maps can also be integrated with computerized oil spill models.

As most oil companies or firms that handle oil do not have staff dedicated to cleaning up oil spills, several companies in the same area often join forces to form cooperatives. By pooling resources and expertise, these oil spill cooperatives can develop effective response programs. The cooperative purchases and maintains containment, cleanup, and disposal equipment and provides the training for its use.

43.3 Typical Oils and Their Properties

43.3.1 Oil Composition

Crude oils are mixtures of hydrocarbon compounds ranging from smaller, volatile compounds to very large compounds. This mixture of compounds varies according to the geological formation of the area in which the oil is found and strongly influences the properties of the oil. Petroleum can be conceived as consisting of groups of compounds called saturates, aromatics, resins, and asphaltenes [43.1].

The saturate group of components in oils consists primarily of alkanes, which are compounds of hydrogen and carbon with the maximum number of hydrogen atoms around each carbon. Thus, the term *saturate* is used because the carbons are saturated with hydrogen. Larger saturate compounds are often referred to as

Table 43.2 Typical oil properties (after [43.5])

Property	Units	Gasoline	Diesel	Light crude	Heavy crude	Intemediate fuel oil	Bunker C
Viscosity	mPa s at 15 °C	0.5	2	5–50	50–50 000	1000–15 000	10 000–50 000
Density	g ml^{-1} at 15 °C	0.72	0.84	0.78–0.88	0.88–1.00	0.94–0.99	0.96–1.04
API gravity		65	35	30–50	10–30	10–20	5–15

waxes. The saturate group also includes cyclo-alkanes, which are compounds made up of the same carbon and hydrogen constituents, but with the carbon atoms bonded to each other in rings.

The aromatic compounds include at least one benzene ring of six carbons. Three double carbon-to-carbon bonds are shared around the ring and add stability. Because of this stability, compounds containing benzene rings are very persistent and can have toxic effects on the environment. The most common smaller and more volatile compounds found in oil are often referred to as (BTEX) or benzene, toluene, ethyl-benzene and xylenes. Polyaromatic hydrocarbons (PAHs) are compounds consisting of at least two benzene rings. PAHs make up between 0 and 30% of the composition of oil.

Polar compounds are those that have a significant molecular charge as a result of bonding with compounds such as sulfur, nitrogen or oxygen. The polarity or charge that the molecule carries results in behavior that is different from that of un-polarized compounds, under some circumstances. In the petroleum industry, the smallest polar compounds are called resins. The larger polar compounds are called asphaltenes and they often make up the largest percentage of the asphalt commonly used for road construction. Asphaltenes are very large molecules and if in abundance in an oil, they have a significant effect on oil behavior.

43.3.2 Properties of Oil

The principal properties of oil are viscosity, density, and specific gravity. These properties for the oils discussed below are listed in Table 43.2 [43.5].

Viscosity is the resistance to flow in a liquid. The lower the viscosity, the more readily the liquid flows. The greater the percentage of light components such as saturates and the lesser the amount of asphaltenes, the lower the viscosity. As with other physical properties, viscosity is affected by temperature, with a lower temperature yielding a higher viscosity. In terms of oil spill cleanup, viscosity can affect the oil's behavior. Viscous oils do not spread rapidly, and do not penetrate soil as readily and hamper the ability of pumps and skimmers to handle the oil.

Density is the mass of a given volume of oil and is typically expressed in grams per cubic centimeter (g cm^{-3}). It is the property used by the petroleum industry to define light or heavy crude oils. Density is also important as it indicates whether an oil will float or sink in water. As the density of seawater is 1.03 g cm^{-3}, even heavier oils will usually float on it. The density of oil increases with time, as the light fractions evaporate. Occasionally, when the density of an oil becomes greater than the density of freshwater or seawater, the oil will sink. Sinking is rare, however and happens only with a few oils, usually residual oils.

Another measure of density is specific gravity, which is an oil's relative density compared to that of water at 15 °C. It is the same value as density at the same temperature. Another gravity scale is that of the American Petroleum Institute (API). The API gravity is based on the density of pure water which has an arbitrarily assigned API gravity value of 10° (10 degrees). Oils with progressively lower specific gravities have higher API gravities. The following is the formula for calculating API gravity

$$\text{API gravity} = \frac{141.5}{(\text{density at } 15.5\,^{\circ}\text{C})} - 131.5\,.$$

Oils with high densities have low API gravities and vice versa [43.1].

43.4 Behavior of Oil in the Environment

The specific oil-weathering behavior processes that occur after an oil spill dictate how the oil should be cleaned up and its effect on the environment. The fate and effects of a particular spill are determined by the behavior processes which are in turn almost entirely determined by the type of oil and the environmental conditions at the time of the spill [43.6].

The processes included in weathering are evaporation, emulsification, natural dispersion, dissolution, photooxidation, sedimentation, interaction with mineral fines, biodegradation, and the formation of tar balls [43.7]. These processes are discussed in order of importance in terms of their effect on the percentage of total mass balance, the greatest loss from the slick

in terms of percentage, and what is known about the process.

43.4.1 Evaporation

Evaporation is usually the most important weathering process for many oils. It has the greatest effect on the amount of oil remaining on water or land after a spill. Over a period of several days, a light fuel such as gasoline evaporates completely at temperatures above freezing, whereas only a small percentage of a heavier Bunker C oil evaporates. The evaporation rates of the oils discussed in this chapter are shown in Fig. 43.2 and [43.1]. The rate at which an oil evaporates depends primarily on the oil's composition. The more volatile components an oil or fuel contains, the greater the extent and rate of its evaporation.

The rate of evaporation is very rapid immediately after a spill and then slows considerably. About 80% of evaporation occurs in the first 2 days after a spill, which can be seen in Fig. 43.2. The evaporation of most oils follows a logarithmic curve with time. Some oils such as diesel fuel, however, evaporate as the square root of time, at least for the first few days. The properties of an oil can change significantly with the extent of evaporation. If about 40% of an oil evaporates, its viscosity could increase by as much as a thousand-fold. Its density could rise by as much as 10%.

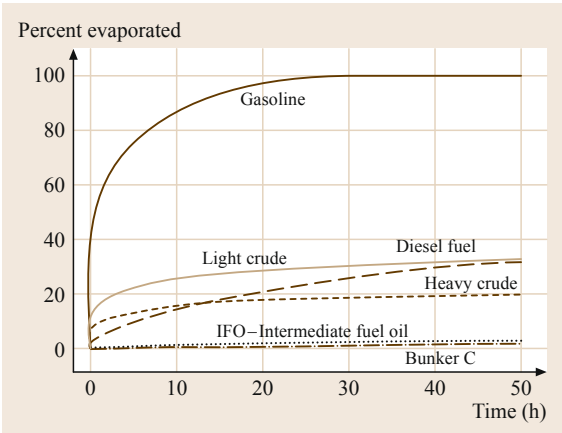

Fig. 43.2 Evaporation of typical oils at 15 °C (after [43.2])

43.4.2 Water Uptake

Water can enter oil through several processes. Emulsification is the process by which one liquid is dispersed into another one in the form of small droplets. To be called an emulsion, the product must have a certain amount of stability. Otherwise, the process is called water. Water droplets can remain in an oil layer in a stable form and the resulting material is completely different from the starting oil. Table 43.3 lists the five ways oil uptakes water and the resulting properties after water is in the oil [43.8].

The understanding of emulsion formation is in the early phases, but it starts with sea energy forcing the entry of small water droplets, about 10–25 μm in size, into the oil. If the oil is only slightly viscous, these small droplets will not leave the oil quickly. On the other hand, if the oil is too viscous, droplets will not enter the oil to any significant extent. Once in the oil, any asphaltenes and resins in the oil will interact with the water droplets to stabilize them. Depending on the quantity and type of asphaltenes and resins, an emulsion may be formed. The conditions required for emulsions of any stability to form may only be reached after a period of evaporation. Evaporation lowers the amount of low-molecular-weight compounds and increases the viscosity to the critical value.

Water can be present in oil in five ways:

1. First, some oils contain about 1% water as soluble water. This water does not significantly change the physical or chemical properties of the oil.

Table 43.3 Five methods by which oil uptakes water (after [43.8])

Type	Mechanism	Starting oil characteristics	Requirements	After water uptake			
				Color	Typical lifetime	Typical viscosity increase[a]	Typical water uptake
Soluble oil	Solubility	Most		Same	Years	1	< 1%
Unstable or does not uptake water	None	Many oils		Same		1	
Meso-stable	Viscous entrainment and A/R interaction	Moderate viscosity and some A/R	Sea energy	Reddish until broken	3–6 days	50	50–70%
Stable	*Viscous entrainment and A/R interaction*	*Moderate viscosity and some A/R*	*Sea energy*	*Reddish*	*Months*	800–1000	60–80%
Entrained	Viscous entrainment		Sea energy	As oil	2–10 days	2–5	30–40%

A/R: asphaltenes and resins, [a] viscosity increase from starting oil

2. The second way is when water droplets are not held in the oil long enough to form an emulsion. These are called oils that do not form any type of water-in-oil mixtures or unstable emulsions. These result when water droplets are incorporated into oil by the sea's wave action and there are not enough asphaltenes and resins in the oil and/or if there is an insufficient viscosity to prevent droplets from quickly leaving the oil mass. Unstable emulsions break down into water and oil within minutes or a few hours at most, once the sea energy diminishes. The properties and appearance of the unstable emulsion are the same as those of the starting oil.
3. Meso-stable emulsions represent the third way in which water can be present in oil. These are formed when small droplets of water are stabilized to a certain extent by a combination of the viscosity of the oil and the interfacial action of asphaltenes and resins. The viscosity of meso-stable emulsions is 20–80 times higher than that of the starting oil. These emulsions generally break down into oil and water or sometimes into water, oil, and emulsion remnants within a few days. Meso-stable emulsions are viscous liquids that are reddish-brown in color, until broken.
4. The fourth way in which water exists in oil is in the form of stable emulsions. These form in a way similar to meso-stable emulsions except that the oil contains sufficient asphaltenes and resins to stabilize water droplets. The viscosity of stable emulsions is 800–1000 times higher than that of the starting oil and the emulsion will remain stable for weeks and even months after formation. Stable emulsions are reddish-brown in color and appear to be nearly solid.
5. The fifth way in which oil can contain water is by viscosity entrainment. If the viscosity of the oil is such that water droplets can penetrate, the oil can contain about 30–40% water as long as it is in an energetic sea. Once the sea calms or the oil is removed, the water slowly drains. Typically most of the water would be gone before about 2 days. Such water uptake is called entrained water. This is not an emulsion type such as the meso-stable or stable emulsions which are stabilized by the chemical action of resins and asphaltenes.

These increases in volume and viscosity make cleanup operations more difficult. Stable emulsified oil is difficult or impossible to disperse, to recover with skimmers or to burn. Emulsions can be broken down with special chemicals in order to recover the oil with skimmers or to burn it. It is thought that emulsions break down into oil and water by further weathering, oxidation, by dilution with un-emulsified oils and freeze-thaw action. Meso-stable emulsions are relatively easy to break down, whereas stable emulsions may take months or years to break down naturally.

43.4.3 Natural Dispersion

Natural dispersion occurs when fine droplets of oil are produced by wave action or turbulence. Small oil droplets (less than about 30 μm) are somewhat stable in water for short periods of time. Large droplets (lager than about 100 μm) tend to rise and will not stay in the water column for more than a few seconds. Depending on oil conditions and the amount of sea energy available, natural dispersion can be insignificant or it can temporarily remove the bulk of the oil. Natural dispersion is dependent on both the oil properties and the amount of sea energy. Heavy oils such as Bunker C or a heavy crude will not disperse naturally to any significant extent, whereas light crudes and diesel fuel can disperse significantly. In addition, significant wave action is needed to disperse oil. In 30 years of monitoring spills on the oceans, those spills where oil has dispersed naturally have all occurred in very energetic seas sometimes with winds as high as 80 kn (40 m s^{-1}). The long-term fate of dispersed oil is that most of the dispersed oil may also rise and form another surface slick or it may become associated with sediment and be precipitated to the bottom.

43.4.4 Dissolution

Through the process of dissolution, some of the most soluble components of the oil are lost to the water under the slick. These include some of the lower molecular weight aromatics and some of the polar compounds. As only a small amount, usually much less than a fraction of a percent of the oil, actually enters the water column, dissolution does not measurably change the mass balance of the oil in the environment. The significance of dissolution is that the soluble aromatic compounds are particularly toxic to fish and other aquatic life. If a spill of oil containing a large amount of soluble aromatic components occurs in shallow water and creates a high localized concentration of compounds, then significant numbers of aquatic organisms can be killed. Gasoline, diesel fuel, and light crude oils are the most likely to cause aquatic toxicity. On open water, the concentrations of hydrocarbons in the water column are unlikely to kill aquatic organisms.

43.4.5 Photooxidation

Photooxidation can change the composition of an oil. The photooxidized products may be somewhat soluble

and dissolve into the water. It is not well understood how photooxidation specifically affects oils, although certain oils are susceptible to the process, while others are not. For most oils, photooxidation is not an important process in terms of changing their fate or mass balance after a spill.

43.4.6 Sedimentation and Oil–Mineral Particle Interaction

Sedimentation is the process by which oil is deposited on the bottom of the sea or other water body. While the process itself is not fully understood, certain facts about it are. Most sedimentation noted in the past has occurred when oil droplets reached a higher density than water after interacting with mineral matter in the water column. This interaction sometimes occurs on the shoreline or very close to the shore. Once oil is on the bottom, it is usually covered by other sediment and degrades very slowly. In a few well-studied spills, a significant amount (about 10%) of the oil was sedimented on the sea floor [43.9]. Such amounts can be very harmful to a biota which may come in contact with the oil on the sea bottom.

Oil slicks and oils on shorelines sometimes interact with mineral fines suspended in the water column and the oil is thereby transferred to the water column [43.9]. Particles of mineral with oil attached may be heavier than water and sink to the bottom as sediment or the oil may detach and refloat. Oil–fines interaction does not generally play a significant role in the fate of most oil spills in their early stages, but can have an impact on the rejuvenation of an oiled shoreline over the long term.

43.4.7 Biodegradation

A large number of microorganisms are capable of degrading petroleum hydrocarbons. Many species of bacteria, fungi, and yeasts metabolize petroleum hydrocarbons as a food energy source [43.10, 11]. Bacteria and other degrading organisms are very abundant in areas where there have been petroleum seeps, although these microorganisms are found everywhere in the environment. As each species can utilize only a few related compounds at most, broad-spectrum degradation does not occur. Hydrocarbons metabolized by microorganisms are generally converted to an oxidized compound, which may be further degraded, may be soluble, or may accumulate in the remaining oil. The aquatic toxicity of the biodegradation products is sometimes greater than that of the parent compounds.

The rate of biodegradation depends primarily on the nature of the hydrocarbons and then on the temperature. Generally, rates of degradation tend to increase as the temperature rises. Some groupings of bacteria, however, function better at lower temperatures and others function better at higher temperatures. Indigenous bacteria and other microorganisms are often the best adapted and most effective at degrading oil as they are acclimatized to the temperatures and other conditions of the area. Adding super-bugs to the oil does not necessarily improve the degradation rate.

The rate of biodegradation is greatest on saturates, particularly for those oils containing approximately 12–20 carbons. Aromatics and asphaltenes, which have a high molecular weight, biodegrade very slowly, if at all. This explains the durability of roof shingles containing tar and roads made of asphalt, as both tar and asphalt consist primarily of aromatics and asphaltenes. On the other hand, diesel fuel is a highly biodegradable oil as it is largely composed of biodegradable saturates. Light crude oils are also biodegradable to some extent. While gasoline contains biodegradable components, it also contains some compounds that are toxic to some microorganisms. Gasoline will evaporate before it can degrade. Heavy crude oils contain little material that is readily biodegradable and Bunker C contains almost none.

The rate of biodegradation is also highly dependent on the availability of oxygen. On land, oils such as diesel can degrade rapidly at the surface, but very slowly if at all only a few centimeters below the surface, depending on oxygen availability. In water, oxygen levels can be so low that degradation is limited. It is estimated that it would take all the dissolved oxygen in approximately 400 000 l of sea water to completely degrade 1 l of oil [43.1]. The rate of degradation also depends on the availability of nutrients such as nitrogen and phosphorus, which are most likely to be available on shorelines or on land. Oil degrades significantly at the oil–water interface at sea and on land, mostly at the interface between soil, oil, and air.

Biodegradation can be a very slow process for some oils. It may take weeks for 50% of a diesel fuel to biodegrade under optimal conditions and years for 10% of a crude oil to biodegrade under less optimal conditions. For this reason, biodegradation is not considered an important weathering process in the short term.

43.4.8 Tar Ball Formation

Tar balls are agglomerations of heavy oil less than about 10 cm in diameter. Larger accumulations of the same material ranging from about 10 cm to 1 m in diameter are called tar mats. Tar mats are pancake-shaped. Their formation is still not completely understood, but it is known that they are formed from the residuals of heavy crudes and Bunker fuels. After these oils weather at sea

and slicks are broken up, the residuals remain in tar balls or tar mats. The formation of droplets into tar balls and tar mats has also been observed, with adhesion being the binding force.

The formation of tar balls is the ultimate fate of many spilled oils at sea. These tar balls are then often deposited on shorelines. The oil may come from spills, but it is also residual oil from natural oil seeps or from deliberate operational releases such as from ships. Tar balls are regularly recovered by machine or by hand from recreational beaches by various agencies or resort owners.

43.4.9 Spreading and Movement

Oil spilled on water spreads relatively rapidly [43.12]. After an oil spill on water, the oil tends to spread into a slick over the water surface. This is especially true for the lighter petroleum products such as gasoline, diesel fuel, and light crude oils, which rapidly form very thin slicks. Heavier crudes and Bunker C spread to slicks as thick as several millimeters. Heavy oils may also form tar balls and tar mats and thus may not go through progressive stages of thinning.

Oil spreads horizontally over the water surface even in the complete absence of wind and water currents. This spreading is caused by the force of gravity and the interfacial tension between oil and water. The viscosity of the oil opposes these forces. As time passes, the effect of gravity on the oil diminishes, but the force of the interfacial tension continues to spread the oil. The transition between these forces takes place in the first few hours after the spill occurs.

Oil slicks will elongate in the direction of the wind and currents and as spreading progresses, take on many shapes depending on the driving forces. Oil sheens often precede heavier or thicker oil concentrations. If the winds are high (more than $20\,\mathrm{km\,h^{-1}}$), the sheen may separate from thicker slicks and move further downwind.

In addition to their natural tendency to spread, oil slicks on water are moved along the water surface, primarily by surface currents and winds. The slick generally moves at a rate that is 100% of the surface current and approximately 3% of the wind speed.

43.4.10 Submergence/Sinking

When oil is denser than the surface water, it may sink. Some rare types of heavy crudes and Bunker fuels can reach these densities and sink. When this occurs, the oil may sink to a denser layer of water rather than to the bottom. It is important to note that sinking of any form, whether to the bottom or to the top of a layer of dense sea water, is rare. When oil does sink, it complicates cleanup operations as the oil can be recovered only with specialized underwater suction devices or special dredges.

Over-washing is another phenomenon that occurs quite frequently. At moderate sea states, a dense slick can be over-washed with water. When this occurs, the oil can disappear from view if the spill is being observed from an oblique angle, as would occur if someone is observing from a ship. Over-washing causes confusion about the fate of an oil spill as it can give the impression that the oil has sunk and then resurfaced.

43.5 Analysis, Detection, and Remote Sensing of Oil Spills

43.5.1 Laboratory Analysis

Laboratory analysis can provide information to help identify an oil if its source is unknown and a sample of the starting oil is available. With a sample of the source oil, the degree of weathering and the amount of evaporation or biodegradation can be determined for the spilled oil. Through laboratory analysis, the more toxic compounds in the oil can be measured and the relative toxicity of the oil at various stages of the spill can be determined. This is important information to have as the spill progresses.

Taking a sample of oil and then transporting it to a laboratory for subsequent analysis is common practice [43.13]. The simplest and the most common form of analysis is to measure the quantity of oil in a sample. Such analysis results in a value known as total petroleum hydrocarbons (TPH). The TPH measurement can be obtained in many ways, including extracting the oil from the soil or by further chemical analysis.

A typical form of analysis is to use a gas chromatograph (GC). The system is calibrated by passing known amounts of standard materials through the unit. The amount of many individual compounds in the oil is thereby measured. The compounds that pass through the detector can also be totaled and a TPH value determined. While it is highly accurate, this TPH value does not include resins, asphaltenes, and some other components of the oil with higher molecular weight which do not pass through the column.

A typical chromatogram of a light crude oil with some of the more prominent components of the oil

identified is shown in Fig. 43.3. The two most common types of detector used on a gas chromatogram are flame ionization detectors (FID) and mass spectrometers (MS). The latter method is usually called GC-MS and can be used to quantify and identify many components in oil. The mass spectrometer provides information about the structure of the substance so compounds can be more positively identified. This information can then be used to predict how long the oil has been in the environment and what percentage of it has evaporated or biodegraded. The same technique can be used to fingerprint an oil and positively identify its source. Certain compounds are consistently distributed in oil, regardless of weathering, and these are used to identify the specific oil.

43.5.2 Detection and Surveillance

Oil spills are often located and surveyed from helicopters or aircraft using only human vision [43.14]. There are some conditions, however, such as fog and darkness, in which oil on the surface cannot be seen. Very thin oil sheens are also difficult to detect as is oil viewed from an oblique angle (less than 45°) especially in hazy or other conditions that limit vision. Oil can also be difficult to see in high seas and among debris or weeds and it can blend into dark backgrounds, such as water, soil, or shorelines.

In addition, many naturally occurring substances or phenomena can be mistaken for oil. These include weeds and sunken kelp beds, whale sperm, biogenic or natural oils such as from plants, glacial flour (finely ground mineral material), sea spume (organic material), wave shadows, sun glint and wind sheens on water and oceanic and riverine fronts where two different bodies of water meet, such as a river entering the sea.

A very thin oil sheen as it appears on water is shown in Fig. 43.4. This figure shows the thickness and appearance of oil that could be present under such circumstances. It is important to note that color and slick appearance are only roughly related to thickness and that this relationship only applies to very thin slicks.

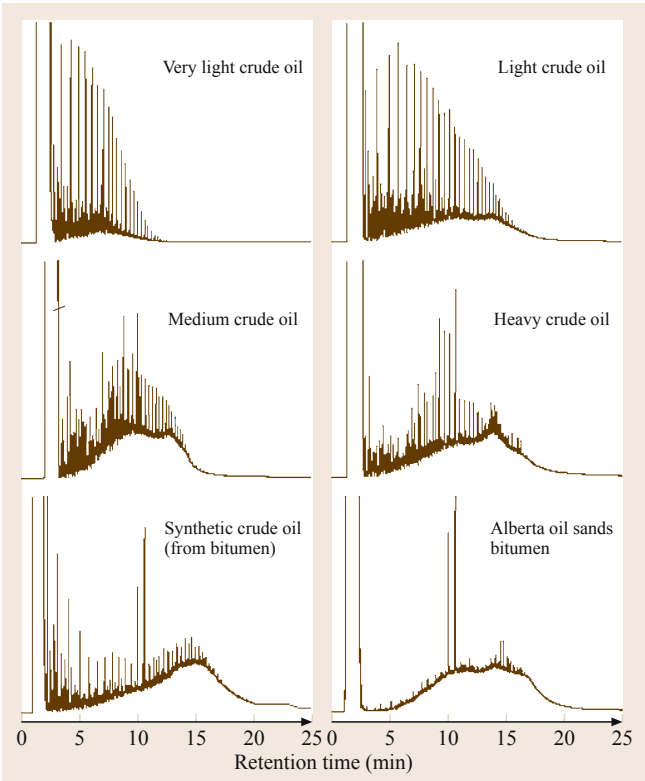

Fig. 43.3 Chromatograms of several types of oil. The detector used was a flame ionization detector (FID) (courtesy of Environment Canada)

43.5.3 Remote Sensing

Remote sensing of oil involves the use of sensors to detect or map oil spills. Oil often cannot be detected in certain conditions using visual means. Remote sensing provides methods to map out the locations of spills under many conditions. Remote sensing is usually carried out with instruments onboard aircraft or from satellite. Table 43.4 shows a summary of sensors, their characteristics, and their suitability to various missions [43.14].

Many devices employing the visible spectrum, including the conventional camera and video camera, are available at a low cost. As these devices are subject

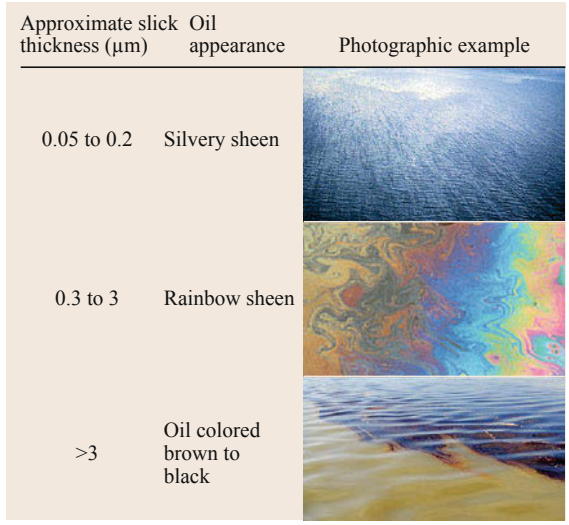

Fig. 43.4 The appearance of thin films of oil on water (courtesy of Merv Fingas)

Table 43.4 Sensor characteristics and suitability (after [43.14])

Sensor	Mission suitability					Typical coverage width [km]	Acquisition cost range k$	State of development

to the same interferences as visual surveillance, they are used primarily to document the spill or to provide a frame of reference for other sensors.

Thick oil on water absorbs infrared radiation from the sun and thus appears in infrared imagery as hot on a cold ocean surface. Unfortunately, many other false targets such as weeds, biogenic oils, debris, and oceanic and riverine fronts can interfere with oil detection. Infrared sensors are relatively inexpensive and widely used for supporting cleanup operations and directing cleanup crews to the nonsheen portions of an oil spill.

Oils that contain aromatic compounds, as most oils do, will absorb ultraviolet light and give off visible light in response. Since very few other compounds respond in this way, this can be used as a positive method of detecting oil at sea or on land. Laser fluorosensors use a laser in the ultraviolet spectrum to trigger this fluorescing phenomenon and a sensitive light detection system to provide an oil-specific detection tool. There is information in the visible light return that can be used to determine whether the oil is a light or heavy oil or a lubricating oil. In a sense, using laser fluorosensors is like performing chemistry from the air. Laser fluorosensors are the most powerful remote sensing tools available because they are subject to few interferences. Laser fluorosensors work equally well on water and on land and are the only reliable means of detecting oil in certain ice and snow situations.

Few types of sensors can be used to measure the thickness of an oil slick. The passive microwave sensor can be calibrated to measure the relative thickness of an oil slick. Absolute thickness cannot be measured for the multiple reasons. Other factors such as atmospheric conditions also change the radiation levels; the signal changes in cyclical fashion with spill thickness and the signal must be averaged over a relatively wide area and the slick can change throughout this area. The cyclical nature of the microwave radiation variance with

thickness has been overcome by some suppliers by using multi-frequency units – for example, five different frequencies.

Oil on the sea calms smaller waves (waves on the order of a few centimeters in length), therefore radar can detect oil on the sea as a calm area. The technique is highly prone to false targets, however, and is limited to a narrow range of wind speeds (approximately 2–6 m s^{-1}). Below this wind speed, there are not enough small waves to yield a difference between the oiled area and the sea. At higher winds, the waves can propagate through the oil and the radar may not be able to see into the troughs between the waves. Radar is not useful near coastlines or between head lands because the wind shadows look like oil. There are also many natural calms on the oceans that can resemble oil. Despite its large size and expense, radar equipment is particularly well suited for searches of large areas and for work at night or in foggy or other bad weather conditions.

Several radar satellites are available which operate in the same manner as airborne radar and share their many limitations [43.14]. Despite these limitations, radar imagery from satellite is particularly useful for mapping large oil spills. Much modern spill response depends on radar satellite data. Figure 43.5 shows a major spill as imaged in a satellite-borne radar sensor.

While many satellites provide images in the visible spectrum, oil cannot be seen in these images unless the spill is very large or rare sea conditions are prevalent that provide a contrast to the oil. Oil has no spectral characteristics that allow it to be enhanced from the background.

43.6 Containment on Water

Containment of an oil spill is the process of confining the oil, either to prevent it from spreading to a particular area, to divert it to another area where it can be recovered or treated, or to concentrate the oil so it can be recovered or burned. Containment booms or simply booms are the most frequently used piece of equipment for containing an oil spill on water. Booms are generally the first equipment mobilized at a spill and are often used throughout the operation.

43.6.1 Containment Booms

A boom is a floating mechanical barrier designed to stop or divert the movement of oil on water. Booms resemble a vertical curtain with portions extending above and below the water line. Most commercial booms consist of four basic components:

- A means of flotation
- A freeboard member to prevent oil from splashing over the top of the boom
- A skirt to prevent oil from being swept underneath the boom
- Connectors and one or more tension members to support the entire boom.

Booms are constructed in sections, usually 15 or 30 m long, with connectors installed on each end so that sections of the boom can be attached to each other, towed, or anchored. A section of a typical boom is shown in Fig. 43.6 [43.1].

Boom fabrics consist of various fiber types such as nylon, polyester, aramid (kevlar), or blends of the same. These are then saturated or coated with polymeric coatings of various types ranging from polyvinyl chloride (PVC), polyurethane, nitrile, or blends of those materials to provide an impervious layer over the woven base fabric.

Most booms are also fitted with one or more tension members which run along the bottom of the boom and reinforce it against the horizontal load imposed by waves and currents. Tension members are usually made of steel cables or chains but sometimes consist of nylon or polyester webbing or ropes. The boom fabric itself is not strong enough to withstand the powerful forces to which booms are subjected, except in protected waters. For example, the force on a 100 m long section of boom could be as much as 10 000 kg, de-

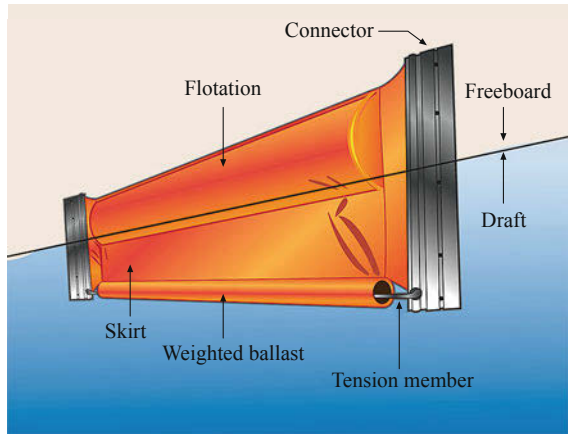

Fig. 43.6 Boom components (after [43.1])

pending on sea conditions and the construction of the boom.

The three basic types of booms are fence and curtain booms, which are common, and shoreline seal booms, which are relatively rare. Booms are also classified according to where they are used – offshore, inshore, harbor, and river booms, based on their size and ruggedness of construction. The fence boom is constructed with a freeboard member above the float. Although relatively inexpensive, these booms are not recommended for use in high winds or strong water currents. Curtain booms are constructed with a skirt below the floats and no freeboard member above the float.

The characteristics of booms that are important in determining their operating ability are the buoyancy-to-weight ratio or reserve buoyancy, the heave response, and the roll response [43.15–17]. The buoyancy-to-weight ratio or reserve buoyancy is determined by the amount of flotation and the weight of the boom. This means that the float must provide enough buoyancy to balance the weight of the boom with the force exerted by currents and waves, thereby maintaining the boom's stability. The greater a boom's reserve buoyancy, the greater its ability to rise and fall with the waves. The heave response is the boom's ability to conform to steep waves. It is indicated by the reserve buoyancy and the flexibility of the boom. A boom with good heave response will move with the waves on the surface of the water and not be alternately submerged and thrust out of the water by the wave action. The roll response refers to the boom's ability to remain upright in the water and not roll over.

Booms are used primarily to contain oil, although they are also used to deflect oil. When used for containment, booms are often arranged in a U, V, or J configuration. The U configuration is the most common and is achieved by towing the boom behind two vessels, anchoring the boom, or by combining these two techniques. The U shape is created by the current pushing against the center of the boom. The critical requirement is that the current in the apex of the U does not exceed $0.5\,\mathrm{m\,s^{-1}}$ or 1 kn, which is referred to as the critical velocity. This is the speed of the current flowing perpendicular to the boom, above which oil will be lost from the boom. Booms are also used in a *sweep* configuration to either deflect oil or contain it for pickup by skimmers. The sweep is held away from the vessel by a fixed arm and the boom allowed to form a U shape. A skimmer is usually placed in the U or is sometimes fixed in the vessel's hull and the oil is deflected to this position.

If used in areas where the currents are likely to exceed $0.5\,\mathrm{m\,s^{-1}}$ or 1 kn, such as in rivers and estuaries, booms are often used in the deflection mode. The boom is then deployed at various angles to the current so that the critical velocity is not exceeded. The oil can then be deflected to areas where it can be collected.

43.6.2 Boom Failures

A boom's performance and its ability to contain oil are affected by water currents, waves, and winds. Either alone or in combination, these forces often lead to boom failure and loss of oil. Eight common ways in which booms fail are discussed here. Some of these are illustrated in Fig. 43.7 [43.1].

Entrainment Failure

This type of failure is caused by the speed of the water current and is more likely to happen with a lighter oil. When oil is being contained by a boom in moving water, if the current is fast enough, the boom acts like a dam and the surface water being held back is diverted downward and accelerates. The resulting turbulence causes droplets to break away from the oil that has built up in front of the boom, referred to as the oil headwave, pass under the boom and resurface behind it. The water speed at which the headwave becomes unstable and the oil droplets begin to break away is referred to as the critical velocity. It is the speed of the current flowing perpendicular to the boom, above which oil losses occur. For most booms riding perpendicular to the current, this critical velocity is approximately $0.5\,\mathrm{m\,s^{-1}}$ (about 1 kn).

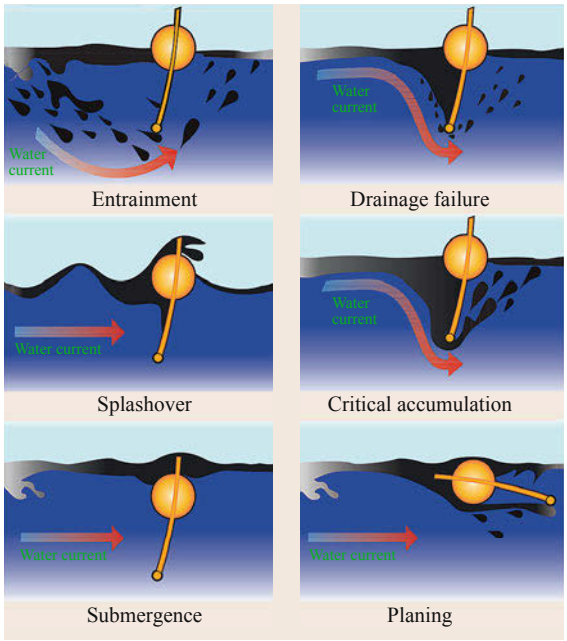

Fig. 43.7 Boom failure modes (after [43.1])

Drainage Failure

Similar to entrainment, this type of failure is related to the speed of the water current, except that it affects the oil directly at the boom. After critical velocity is reached, large amounts of the oil contained directly at the boom can be swept under the boom by the current.

Critical Accumulation

This type of failure usually occurs when heavier oils, which are not likely to become entrained in water, are being contained. Heavier oils tend to accumulate close to the leading edge of the boom and are swept underneath the boom when a certain critical accumulation point occurs. This accumulation is often reached at current velocities approaching the critical velocities, but can also be reached at lower current velocities.

Splashover

This failure occurs in rough or high seas when the waves are higher than the boom's freeboard and oil splashes over the boom's float or freeboard member. It can also occur as a result of extensive oil accumulation in the boom compared to the freeboard.

Submergence Failure

This type of failure occurs when water goes over the boom. Often the boom is not buoyant enough to follow the wave motion and some of the boom sinks below the water line and oil passes over it. Submergence failure is usually the result of poor heave response. Failure due to submergence is not that common as other forms of failure, such as entrainment, usually occurs first.

Planing

Planing occurs when the boom moves from its designed vertical position to almost a horizontal position on the water. Oil passes over or under a planing boom. Planing occurs if the tension members are poorly designed and do not hold the boom in a vertical position or if the boom is towed in currents exceeding the critical velocity.

Structural Failure

This occurs when any of the boom's components fail and the boom lets oil escape. Sometimes structural failure is so serious that the boom is carried away by the current. Floating debris, such as logs and ice, can contribute to structural failure.

Shallow Water Blockage

This type of failure occurs when rapid currents form under a boom when it is used in shallow waters. With the boom acting like a dam, the flow of water under it increases and oil is lost in several of the ways already described. Shallow water is probably the only situation in which a smaller boom might work better than a larger one. It should be noted, however, that booms are not often used in shallow water.

43.6.3 Sorbent Booms and Barriers

Sorbent booms are specialized containment and recovery devices made of porous sorbent material such as woven or fabric polypropylene, which absorbs the oil while it is being contained. Sorbent booms are used when the oil slick is relatively thin, that is, for the final polishing of an oil spill, to remove small traces of oil or sheen, or as a backup to other booms. Sorbent booms are often placed off a shoreline that is relatively unoiled or freshly cleaned to remove traces of oil that may re-contaminate the shoreline. They are not absorbent enough to be used as a primary countermeasure technique for any significant amount of oil.

Sorbent booms require considerable additional support to prevent breakage under the force of strong water currents [43.18]. They also require some form of flotation so they do not sink once saturated with oil and water.

43.7 Oil Recovery on Water

43.7.1 Skimmers

Skimmers are mechanical devices designed to remove oil from the water surface. Skimmers are classified according to the area where they are used, for example, inshore, offshore, in shallow water, or in rivers and by the viscosity of the oil they are intended to recover, that is heavy or light oil [43.19]. Skimmers are available in a variety of forms, including independent units built into a vessel or containment device and units that operate in either a stationary or mobile (advancing) mode. Some skimmers have storage space for the recovered oil and some of these also have equipment such as separators to treat the recovered oil.

The effectiveness of a skimmer is rated according to the amount of oil that it recovers, as well as the amount of water picked up with the oil. Removing water from the recovered oil can be as difficult as the initial recovery. Effectiveness depends on a variety of factors including the type of oil spilled, the properties of the oil such as viscosity, the thickness of the slick, sea conditions, wind speed, ambient tempera-

ture, and the presence of ice or debris. Most skimmers function best when the oil slick is relatively thick. The oil is usually collected in booms before skimmers are effective.

Weather conditions at a spill site have a major effect on the efficiency of skimmers. All skimmers work best in calm waters. Depending on the type of skimmer, most will not work effectively in waves greater than 1 m or in currents exceeding 1 kn. Most skimmers do not operate effectively in waters with ice or debris such as branches, seaweed, and floating waste. Very viscous oils, tar balls, or oiled debris can clog the intake or entrance of skimmers and make it impossible to pump oil from the skimmer's recovery system. Skimmers are also classified according to their basic operating principles [43.1]:

- Oleophilic surface skimmers
- Weir skimmers
- Suction skimmers or vacuum devices
- Elevating skimmers.

Oleophilic Surface Skimmers

Oleophilic surface skimmers, sometimes called sorbent surface skimmers, use a surface to which oil can adhere to remove the oil from the water surface. This oleophilic surface can be in the form of a disk, drum, belt, brush, or rope, which is moved through the oil on the top of the water. A wiper blade or pressure roller removes the oil and deposits it into an onboard container or the oil is directly pumped to storage facilities on a barge or on shore. The oleophilic surface itself can be steel, aluminum, fabric, or plastics

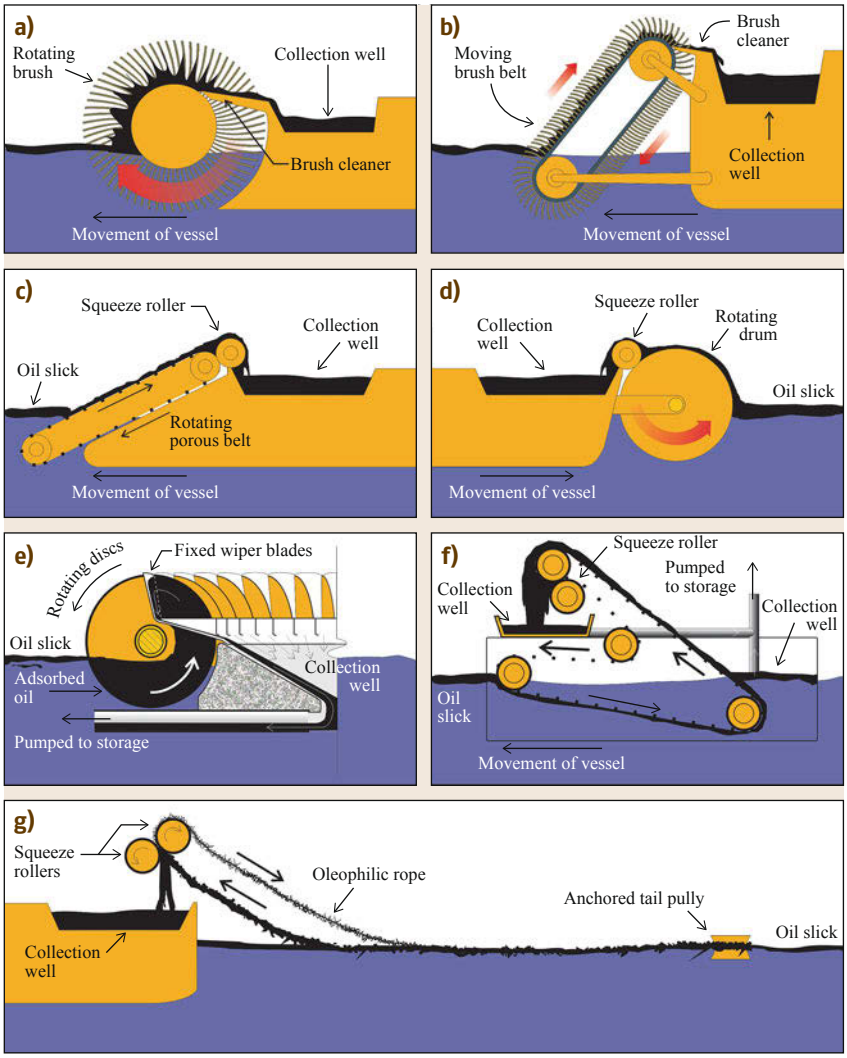

Fig. 43.8a–g Schematics of oleophilic skimmers: **(a)** brush drum skimmer, **(b)** brush belt skimmer, **(c)** adsorbent belt skimmer, **(d)** drum skimmer, **(e)** disk skimmer, **(f)** inverted belt skimmer, **(g)** rope skimmer

such as polypropylene and polyvinyl chloride. Figure 43.8 shows schematics of several types of oleophilic skimmers.

Oleophilic skimmers pick up very little water compared to the amount of oil recovered, which means they have a high oil-to-water recovery ratio. They can operate efficiently on relatively thin oil slicks and are not as susceptible to ice and debris as some other types of skimmers.

The disk skimmer is a common type of oleophilic surface device. The disks are usually made of either polyvinyl chloride or steel. Disc skimmers work best with light crude oil and are well suited to working in small waves and among weeds or debris. New grooved disks have proved to be useful for recovering heavier oils.

The drum skimmer is another type of oleophilic surface skimmer. The drums are made of either a proprietary polymer or steel. The drum skimmer works relatively well with fuels and light crude, but is less effective with heavy oils. Drum skimmers are often smaller in size like the disk skimmer. One such skimmer is shown in Fig. 43.9.

Belt skimmers are constructed of a variety of oleophilic materials ranging from fabric to conveyor belting. Most belt skimmers function by lifting oil up from the water surface to a recovery well. Belt skimmers of all types work best with heavier crudes and some are specially constructed to recover tar balls and very heavy oils. Belt skimmers are large and usually built into specialized cleanup vessels.

Brush skimmers use plastic brushes attached to drums, chains, or belts to recover the oil from the water surface. The oil is usually removed from the brushes by wedge-shaped scrapers. Brush skimmers are particularly useful for recovering heavier oils, but are less effective for fuels and light crudes.

Rope skimmers remove oil from the water surface with an oleophilic rope of a polymer material, usually polypropylene. Some skimmers have one or two long ropes which are held in the slick by a floating, anchored pulley. Others use a series of small ropes that hang down to the water surface from a suspended skimmer body.

Weir Skimmers

Weir skimmers are a major group of skimmers that use gravity to drain the oil from the surface of the water into a submerged holding tank. In their simplest form, these devices consist of a weir or dam, a holding tank, and a connection to an external or internal pump to remove the oil. Many different models and sizes of weir skimmers are available.

Most weir skimmers are mounted at the center of 3 or 4 floats which keep the weir edge at the water–oil interface. Weir skimmers do not work well in ice and debris or in rough waters and they are not effective for very heavy oils or tar balls. Weir skimmers are economical, however, and they can have large oil recovery capacities.

Suction or Vacuum Skimmers

Suction or vacuum skimmers use a vacuum to remove oil from the water surface. Often the skimmer is only a small floating head connected to an external source of vacuum, such as a vacuum truck. Suction skimmers are similar to weir skimmers in that they sit on the water surface, generally use an external vacuum pump system such as a vacuum truck and are adjusted to float at the oil–water interface.

Elevating Skimmers

Elevating skimmers use conveyors to lift oil from the water surface into a recovery area. A paddle belt or wheel or a conveyor belt with ridges is adjusted to the top of the water layer and oil is moved up the recovery device on a plate or another moving belt. The operation is similar to removing liquid from a floor with a squeegee. The oil is usually removed from the conveyer by gravity.

Other Devices

Many other devices are used to recover oil. Several skimmers combine some of the principles of operation already discussed. For example, one skimmer uses an inverted belt both as an oleophilic skimmer and a submersion skimmer.

43.7.2 Skimmer Performance

A skimmer's performance is affected by a number of factors including the thickness of the oil being recov-

ered, the extent of weathering and emulsification of the oil, the presence of debris and weather conditions at the time of recovery operations [43.20].

A skimmer's overall performance is usually determined by a combination of its recovery rate and the percentage of oil recovered. The recovery rate is the volume of oil recovered under specific conditions. It is measured as volume per unit of time, $m^3\,h^{-1}$ and is usually given as a range. If a skimmer takes in a lot of water, it is detrimental to the overall efficiency of an oil spill recovery operation. The summary results of performance testing on various types of skimmers are given in Table 43.5.

In addition to these characteristics, other important measures of a skimmer's performance include the amount of emulsification caused by the skimmer, its ability to deal with debris, ease of deployment, ruggedness, applicability to specific situations, and reliability.

43.7.3 Sorbents

Sorbents are materials that recover oil through either absorption or adsorption. They play an important role in oil spill cleanup and are used in the following ways:

- To clean up the final traces of oil spills on water or land
- As a backup to other containment means, such as sorbent booms
- As a primary recovery means for very small spills
- As a passive means of cleanup.

An example of such passive cleanup is when sorbent booms are anchored off lightly oiled shorelines to absorb any remaining oil released from the shore and prevent further contamination or re-oiling of the shoreline.

Sorbents can be natural or synthetic materials. Natural sorbents are divided into organic materials, such as peat moss or wood products and inorganic materials, such as vermiculite or clay. Sorbents are available in a loose form, which includes granules, powder, chunks, and cubes, often contained in bags, nets, or socks. Sorbents are also available formed into pads, rolls, blankets and pillows. Formed sorbents are also made into sorbent booms and sweeps.

The use of synthetic sorbents in oil spill recovery has increased in the last few years. These sorbents are often used to wipe other oil spill recovery equipment, such as skimmers and booms, after a spill cleanup operation. Sheets or rolls of sorbent are often used for this purpose. The capacity of a sorbent depends on the amount of surface area to which the oil can adhere as well as the type of surface. A fine porous sorbent with

Table 43.5 Performance of typical skimmers

Skimmer type	Recovery rate [$m^3\,h^{-1}$] for given oil type[a]				Percent oil[b]
	Diesel	Light crude	Heavy crude	Bunker C	
Oleophilic skimmers					
Small disk	0.4–1	0.2–2			80–95
Large disk		10–20	10–50		80–95

Paddle conveyer		1–10	1–20	1–5	10–40
Suction skimmers					
Small	0.3–1	0.3–2			3–10
Large trawl unit		2–40			20–90
Large vacuum unit		3–20	3–10		10–80

[a]Recovery rate depends on the thickness of the oil, type of oil, sea conditions, etc.
[b]This is the percentage of oil in the recovered product

many small capillaries has a large amount of surface area and is best for recovering light crude oils or fuels. Sorbents with a coarse surface are best for cleaning up a heavy crude oil or Bunker.

The performance of sorbents is measured in terms of total oil recovery and water pickup, similar to skimmers [43.21]. Oil recovery is the weight of a particular oil recovered compared to the original weight of the sorbent. For example, highly efficient synthetic sorbent may recover up to 30 times its own weight in oil and an inorganic sorbent may recover only twice its weight in oil. The amount of water picked up is also important. Ideally a sorbent would not recover any water.

43.8 Separation, Pumping, Decontamination, and Disposal

43.8.1 Temporary Storage

After oil is recovered, sufficient storage space must be available for the recovered product. The recovered oil often contains large amounts of water and debris which increase the amount of storage space required.

Several types of specially built tanks are available to store recovered oil [43.1]. Flexible portable tanks, often constructed of plastic sheeting and a frame, are the most common type of storage used for spills recovered on land and from rivers and lakes. These are available in a range of sizes from approximately 1 to 100 m^3 and require little storage space before assembly. Most of these types of tanks do not have a roof, however, so rain or snow can enter the tank and vapors can escape. Rigid tanks, which are usually constructed of metal, are also available and are often used at sea. Pillow tanks, constructed of polymers and heavy fabrics, are usually used to store oil recovered on land. Oil recovered on land is often stored in stationary tanks built for other purposes, and in dump trucks and modular containers, lined with plastic. Recovered oil can also be temporarily stored in pits or berms lined with polymer sheets, although this open type of storage is not suitable for volatile oils.

Oil recovered at sea is often temporarily stored in barges. Many cleanup organizations have barges that are used solely for storing recovered oil and lease barges for use at larger spills.

43.8.2 Pumps

Pumps play an important role in oil spill recovery. They are an integral part of most skimmers and are also used to transfer oil from skimmers to storage tanks. Pumps used for recovered oil differ from water pumps in that they must be capable of pumping very viscous oils and dealing with water, air, and debris [43.1]. The three basic types of pumps used for pumping oil recovered from spills are centrifugal pumps, vacuum systems, and positive displacement pumps.

Centrifugal pumps have a spinning vane which moves the liquid out of a chamber by centrifugal force. These pumps, which are regularly used for pumping water and wastewater, are not designed for use with oil and are generally not capable of dealing with material more viscous than light crudes. They are economical and universally available.

Vacuum systems consist of vacuum pumps and tanks mounted on a skid or truck. The vacuum pump creates a vacuum in the tank and the oil moves directly through a hose or pipe to the tank from the skimmer or the source of the oil. Vacuum systems can handle debris, viscous oils, and the intake of air or water.

Positive displacement pumps are often built directly into skimmers to recover more viscous oils. These pumps have a variety of operating principles, all of which have a common scheme. Oil enters a chamber in the pump where it is pushed by a moving blade, shoe, or piston to the exit of the pump. The oil and other material with it must move through the chamber because there is no alternative passage, thus the name *positive displacement*.

The screw or auger pump is a common type of positive displacement pump. The oil drops into part of the screw and is carried to an output. Wiper blades remove oil from the auger flights to prevent it from remaining on the auger shaft. The screw pump can deal with very viscous oils and is often built into skimmers.

The diaphragm pump uses a flexible plate or diaphragm to move oil from a chamber. This type of pump usually requires a valve, which limits its use to material that can pass through the valve making it unsuitable for oil containing debris.

A vane pump, which uses a movable metal or polymer plate to move oil in a chamber, functions in a manner similar to a centrifugal pump, but with positive displacement.

A piston-like plunger in the sliding shoe pump moves oil along between the input and output ports. This pump does not require valves, although certain models do include them. The piston pump is similar to the sliding shoe pump except that oil is simply pushed out of the cylinder from the input valve to the output valve. Both sliding shoe and piston pumps can handle viscous oils, but generally cannot handle debris.

The progressive cavity pump uses a rotating member inside a molded cylinder that together form a cavity that moves from input to output as the center is rotated.

The performance of pumps is usually measured in terms of the volume displaced per unit of time at a given viscosity, suction head, and pressure head. The suction head is the maximum height that a pump can draw the target liquid and the pressure head is the maximum height that a pump can push the liquid. Other important factors to consider are the pump's ability to deal with emulsions and debris and the degree of emulsion formation that takes place in the pump itself.

43.8.3 Separators

As all skimmers recover some water with the oil, a means to separate oil and water is usually required [43.22]. The oil must be separated from the recovery mixture for disposal, recycling, or direct reuse by a refinery. Sometimes settling tanks or gravity separators are incorporated into skimmers, but separators are more often installed on recovery ships or barges. Portable storage tanks are often used as separators, with outlets installed on the bottom of the tanks so that water that has settled to the bottom of the tank can be drained off, leaving the oil in the tank. Vacuum trucks are also used in this way to separate oil and water. Screens or other devices for removing debris are also incorporated into separators.

A gravity separator is the most common type of separator. In its simplest form, this consists of a large holding tank in which the oil and water mixture is held long enough for the oil to separate by gravity alone. When inflow volumes are large, it can be difficult to find large enough separators to provide the long residence times required.

Separators are often made with baffles or other interior devices that increase the residence time and thus the degree of separation. The parallel plate separator is a form of gravity separator. Many parallel plates are placed perpendicular to the flow, creating areas of low water turbulence where drops of oil can re-coalesce from the water and rise to the surface.

Centrifugal separators have spinning members that drive the heavier water from the lighter oil, which collects at the center of the vessel. These separators are very efficient but have less capacity than gravity separators and cannot handle large debris. Centrifugal separators are now becoming more common. Centrifugal separators are best suited to constant amounts of oil and water.

As emulsions are not broken down in separators, emulsion-breaking chemicals are often added to the recovered mixture before it enters the separator. Heating the emulsions to 80 or 90 °C usually results in separation and the water can then be removed, although this process uses a lot of energy.

Separator performance is measured by the water removal efficiency and the throughput volume. Important factors affecting performance include the ability to handle small debris (larger debris is usually removed) and a wide variety of oil and water ratios, with oil content and flow rate sometimes changing suddenly.

43.8.4 Decontamination

Equipment and vessels used during spills often become contaminated with oil. Before transporting this equipment further, it is decontaminated. This typically involves removal to a lined area, a high-pressure wash and treatment of the recovered water. Special areas are prepared for the decontamination of vessels, booms or skimmers. Large vessels, must of necessity, be decontaminated on the sea and this involves circling the vessel with booms and recovering the oil released from the vessel. Often lightly contaminated vessels are cleaned by hand using sorbent cloths. The primary tool for oil removal is high-pressure water. The water released from decontamination is treated as recovered oil would be.

Workers must also decontaminate their boots and clothing if covered with oil. Stations are often set up very close to embarkation points to avoid carrying contamination further.

43.8.5 Disposal

Disposing of the recovered oil and oiled debris is one of the most difficult aspects of an oil spill cleanup operation [43.23]. Any form of disposal is subject to local, provincial, or state and federal legislation. Unfortunately, most recovered oil consists of a wide range of contents and cannot be classified as simply liquid or solid waste. The recovered oil may contain water which is difficult to separate from the oil and many types of debris, including vegetation, sand, gravel, logs, branches, garbage, and pieces of containment booms. This debris may be too difficult to remove and thus the entire bulk material may have to be disposed of.

Spilled liquid oil is sometimes directly reused either by reprocessing in a refinery or as a heating fuel. Some power plants and even small heating plants can use a broad spectrum of hydrocarbon fuels. Often the equipment at refineries cannot handle oils with debris, excessive amounts of water, or other contaminants and the cost of pretreating the oils can far exceed the value that might be obtained from using them.

Heavier oils are sometimes sufficiently free of debris to be used as road cover when mixed with regular asphalt. Recovered material from cleaning up beaches can sometimes be used in this way. If the material is of the right consistency, usually sand, the entire mixture might be mixed with road asphalt.

Incineration is a frequent means of disposal for recovered oil as large quantities of oil and debris can be disposed of in a relatively short time. Disadvantages are the high cost, which may include the cost of transporting the material to the facility. In addition, approval must be obtained from government regulatory authorities. Several incinerators have been developed for disposing of either liquid or solid materials, but these all require special permits or authority to operate. In remote locations, it may be necessary to burn oiled debris directly on the recovery sites without an incinerator because it is too bulky to transport to the nearest incinerator.

Contaminated beach material is difficult to incinerate because of the sand and gravel content. There are also machines to wash oily sand or gravel. The oil recovered from this process must be separated from the wash water and then disposed of separately. Burning debris on site is usually only applied to lightly oiled driftwood and special permission must be obtained from the appropriate authorities.

Oiled debris, beach material, and sorbents are sometimes disposed of at landfill sites. Legislation requires that this material not contain free oil that could migrate from the site and contaminate groundwater. Most governments have standard leachability test procedures which determine whether the material will release oil in a given period of time.

43.9 Spill-Treating Agents

43.9.1 Dispersants

A dispersant is a term used for chemical spill-treating agents that promote the formation of small droplets of oil which disperse into the top layer of the water column [43.24]. Dispersants contain surfactants that have molecules with both a water-soluble and oil-soluble component. Surfactants or surfactant mixtures used in dispersants have approximately the same solubility in oil and water, which temporarily stabilizes oil droplets in water so that the oil will disperse into the water column.

Two major issues associated with the use of dispersants – their effectiveness and the toxicity of the resulting oil dispersion in the water column – have generated controversy in the last 40 years. Some products used in the late 1960s and early 1970s were highly toxic and severely damaged the marine environment [43.25]. The effectiveness of a dispersant is determined by measuring the amount of oil that it puts into the water column and comparing it to the amount of oil that remains on the water surface. When a dispersant is working, a coffee-colored plume of dispersed oil appears in the water column and can be seen from ships and aircraft. This plume can take up to half an hour to form. If there is no such plume, it indicates little or no effectiveness. If only a white plume forms, this is the dispersant alone, also indicating little or no effectiveness.

Effectiveness is influenced by many factors, including the composition and degree of weathering of the oil, the amount and type of dispersant applied, sea energy, salinity of the water, and water temperature. The composition of the oil is the most important of these factors, followed closely by sea energy and the amount of dispersant applied. Below a certain oil thickness, the applied dispersant will interact with the water and not the oil.

Upon forming a dispersion in the water, the plume spreads. Some of the surfactant in the dispersant forming the dispersion, slowly leaches into the water. This slowly destabilizes the dispersion. After about 1–3 h some of the heavy components of the oil may resurface. During this time, there is a competition between re-dispersal of the droplets by wave action and the slow, continual rise of droplets. A significant portion of the slick may resurface within about a day. As the transport of the subsurface and the surface slick often differs, the resurfacing slick may be too thin to be seen and may be in a different location than the un-dispersed slick.

43.9.2 Surface-Washing Agents

Surface-washing agents or beach cleaners are different from dispersants although historically both products were sometimes referred to as dispersants. Surface-washing agents are effective in some situations, but they have not been widely accepted, partially because of the confusion with dispersants [43.26]. While toxicity has been a problem with some dispersants in the past in surface applications, testing has shown that the better surface-washing agents have less aquatic toxicity than dispersants and their use could prevent damage to shoreline species.

While both products contain surfactants, those in dispersants are equally soluble in both water and oil,

whereas in surface-washing agents, the surfactants are more soluble in water than in oil. Surface-washing agents operate by a different mechanism than dispersants. This mechanism is known as detergency and is similar to the use of detergents for washing clothes. Rather than causing the oil to disperse, surface-washing agents are intended to be applied to shorelines to release the oil from the surface. During low tide, the oil is sprayed with the surface-washing agent that is then left to soak for as long as possible. The oil is then washed off with a low-pressure water stream in an area that has been isolated using booms. Skimmers are typically used to remove the released oil.

43.9.3 Solidifiers

Solidifiers are intended to change liquid oil to a solid compound that can be collected from the water surface with nets or mechanical means. Solidifiers consist of cross-linking chemicals that couple two molecules or more, or polymerization catalysts that cause molecules to link to each other. Solidifiers usually consist of powders that rapidly react with and fuse the oil. Depending on the agent, about 10–40% by weight of the agent is required to solidify the oil, under ideal mixing conditions.

Solidifiers have not been used in the past for a number of reasons. Most importantly, if oil is solidified at sea, it makes recovery more difficult as skimming equipment, pumps, tanks, and separators are built to deal with liquids. Secondly, such a large amount of agent is required to solidify oil that it would be impossible to treat even a moderate spill.

43.9.4 Biodegradation Agents

Biodegradation agents are primarily used to accelerate the biodegradation of oil in the environment. They are used primarily on shorelines or land. They are not effective when used at sea because of the high degree of dilution and the rapid movement of oil. Biodegradation agents include bioenhancement agents which contain fertilizers or other materials to enhance the activity of hydrocarbon-degrading organisms, bioaugmentation agents which contain microbes to degrade oil and combinations of these two.

43.10 In-Situ Burning

In-situ burning is an oil spill cleanup technique that involves controlled burning of the oil at the spill site. The technique has been used at actual spill sites for some time, especially in ice-covered waters where the oil is contained by the ice. During the 2010 oil spill in the Gulf of Mexico, it was extensively used and contributed greatly to the removal of oil from the surface [43.27].

43.10.1 Advantages

Burning has some advantages over other spill cleanup techniques, the most significant of which is its ability to be a final solution and its capacity to rapidly remove large amounts of oil [43.28]. Burning can prevent oil from spreading to other areas and contaminating shorelines and biota. Burning oil is a final, one-step solution. When oil is recovered mechanically, it must be transported, stored, and disposed of, which requires equipment, personnel, time, and money. Often not enough of these resources are available when large spills occur. Burning generates a small amount of burn residue which can be recovered or further reduced through repeated burns.

In ideal circumstances, in-situ burning requires less equipment and much less labor than other cleanup techniques. It can be applied in remote areas where other methods cannot be used because of distance and lack of infrastructure. In some circumstances, such as when oil is mixed with or on ice, it may be the only available option for dealing with an oil spill.

Finally, while the efficiency of a burn varies with a number of physical factors, removal efficiencies are generally greater than those for other response methods such as skimming and the use of chemical dispersants. During several test and actual burns, efficiency rates as high as 95% were achieved.

43.10.2 Disadvantages

The most obvious disadvantage of burning oil is the large black smoke plume. The concerns revolve around toxic emissions from the smoke plume. These emissions are discussed in this section. The second disadvantage is that the oil will not ignite and burn quantitatively unless it is thick enough. Most oils spread rapidly on water and the slick quickly becomes too thin for burning to be feasible. Fire-resistant booms must typically be used to concentrate the oil into thicker slicks so that the oil can be burned.

43.10.3 Ignition and What Will Burn

Early studies of in-situ burning focused on ignition as being the key to successful burning of oil on wa-

ter [43.28]. It has since been found that ignition can be difficult, but only under certain circumstances. Studies have shown that almost any type of oil will burn on water or land if the slick can be ignited. Ignition may be difficult, however, at winds greater than 20 m s^{-1} (40 kn).

An important fact of in-situ burning is that oils can be more easily ignited if they are at least 1–3 mm thick and will continue to burn down to slicks about 0.5–1 mm thick. Sufficient heat is required to vaporize material so the fire will continue to burn. In very thin slicks, most of the heat is lost to the water and vaporization/combustion is not sustained. In general, heavy oils and weathered oils take longer to ignite than lighter oils. Often a primer, such as diesel fuel, may be needed to start the combustion of heavy oils. This is also the case for oil that contains water, although oil that is completely emulsified with water may not ignite at all. While the ignitability of emulsions with varying water concentrations is not well understood, oil containing some emulsion can be ignited and burned.

43.10.4 Burn Efficiency and Rates

Burn efficiency is measured as the percentage of starting oil removed compared to the amount of residue left. The amount of soot produced is usually ignored as it is a small amount and difficult to measure. Burn efficiency is largely a function of oil thickness. Oil thicker than about 2–3 mm can be easily ignited and will burn down to about 0.5–1 mm. If a 2 mm thick slick is ignited and burns down to 1 mm, the maximum burn efficiency is 50%. If a 20 mm thick pool of oil is ignited, however, and burns down to 1 mm, the burn efficiency is about 95%. Higher efficiency is usually achieved when towing a fire-resistant boom as the oil is continually driven to the rear, burned, and leaving only a small amount of residue unburned at the end.

Most of the residue from a burn is unburned oil with some lighter or more volatile products removed. The residue is adhesive and therefore can be recovered manually. Residue from burning heavier oils and from very efficient burns may sometimes sink in water, although this rarely happens as the residue, when cooled, is only slightly denser than sea water. Most oil pools burn at a rate of about 2–4 mm per minute which means that the depth of oil is reduced by 2–4 mm a minute. This burn rate varies with the type of oil, the degree of weathering, and the water content of the oil.

An optimal burn rate for diesel fuel and light crudes is about 5000 l m^{-2} of oil per day (100 gal ft^{-2} per day).

43.10.5 Use of Containment

For most crude oils, however, a sufficient thickness is only maintained for a few hours, at most, after the spill occurs [43.28]. Most oil on the open sea rapidly spreads to an equilibrium thickness, which is about 0.01–0.1 mm for light crude oils and about 0.05–0.5 mm for heavy crudes and residual oils. Containment is required to concentrate the oil so it is thick enough to ignite and burn efficiently.

Fire-resistant booms are also used by spill responders to isolate the oil from the source of the spill. When considering burning as a spill cleanup technique, the integrity of the source of the spill and the possibility of further spillage is always a priority. If there is any possibility that the fire could flash back to the source of the spill, such as an oil tanker, the oil is not ignited.

Special fire-resistant booms are available to contain oil when using burning as a spill cleanup technique. As they must be able to withstand heat for long periods of time, these booms are tested for fire resistance and for containment capability and designs are modified in response to test results. Fire-resistant booms require special handling because of their size and weight.

Fire-resistant booms are made of a variety of materials including ceramic, stainless steel, and water-cooled fibre glass. Fire booms must withstand the high temperatures, high heat-flux, as well as the mechanical forces during an oil spill burn. In addition, it is expected that a particular fire-resistant boom should withstand a multi-hour burn and be able to be re-used several times.

During the Deepwater Horizon spill in the Gulf of Mexico, more than 400 burns were carried out using fire-resistant booms. In this spill, some time had passed between the rise of the oil to the surface and its movement to the zone designated for in-situ burning. Fire resistant booms were both used to collect sufficient oil for a burn and also to isolate the burns from adjacent areas.

One approximately 200 m length of fire-resistant boom can contain about 50 000 l (11 000 gal) of oil, which, if it were a light crude, takes about 45 min to burn. In total, it would take about 3 h to collect this amount of oil, tow it away from the slick and burn it. One burn team, consisting of two tow vessels and one fire-resistant boom, could burn about three lots of oil per working shift. If there were two shifts each day, about 300 000 l of oil could be burned by each team in one day.

Lastly, it should be noted that thick oils, typically greater than about 5–10 mm, can be burned without containment on water. Such thick oils are typically

high-weathered crude oils or heavy fuel oils. Opportunities to perform uncontained burning are not frequent.

43.10.6 Emissions from Burning Oil

The possibility of releasing toxic emissions into the atmosphere or the water has created the biggest barrier to the widespread use and acceptance of burning oil as a spill countermeasure. Some atmospheric emissions of concern are particulate matter precipitating from the smoke plume, combustion gases, and unburned hydrocarbons [43.28]. While soot particles consist primarily of carbon particles, they also contain a number of absorbed chemicals. The residue left at the burn site is also a matter of concern. Possible water emissions include sinking or floating burn residue and soluble organic compounds.

Extensive studies have been conducted recently to measure and analyze all these components of emissions from oil spill burns [43.28]. Most burns produce an abundance of particulate matter. Particulate matter at ground level is a health concern close to the fire and under the plume, although concentrations decline rapidly downwind from the fire. The greatest concern is the smaller or respirable particles which are 2.5 μm or less in size. Concentrations at ground level (1 m) can still be above normal health concern levels (35 $\mu g\,m^{-3}$) as far downwind as 500 m from a small crude oil fire, such as from the amount of oil that could be contained in a 500 m long boom.

Polyaromatic hydrocarbons, or PAHs, are a primary concern in the emissions from burning oil, both in the soot particles and as a gaseous emission. All crude oils contain PAHs, varying from as much as 9% down to about 0.001%. Most of these PAHs are burned to fundamental gases except those left in the residue and the soot. The amount of residue left from a crude oil fire varies but generally ranges from 1 to 10%. It has been found that, compared to the original oil, the soot from several experimental burns contained a similar concentration of some PAHs of higher molecular weight and lower concentrations of PAHs of lower molecular weight. This could be a concern as the higher molecular weight PAHs are generally more toxic. This is offset, however, by the fact that in all cases the overall amount of PAHs in the soot and residue is much less than in the original oil.

The amount of soot produced by in-situ oil fires is not known exactly, although estimates vary from 0.5 to 3% of the original oil volume.

43.11 Shoreline Cleanup and Restoration

43.11.1 Fate and Behavior on Shorelines

The fate and behavior of oil on shorelines are influenced by many factors [43.29]. These factors include the type and amount of oil, the degree of weathering of the oil, both before it reaches the shoreline and while on the shoreline, the temperature, the state of the tide when the oil washes onshore, the type of beach substrate, its material composition, the type and sensitivity of biota on the beach, and the steepness of the shore.

The extent that an oil penetrates and spreads, its adhesiveness and how much the oil mixes with the type of material on the shoreline are all important factors in terms of cleanup. Cleanup is more difficult if the oil penetrates deeply into the shoreline. Penetration varies with the type of oil and the type of material on the shoreline. For example, oil does not penetrate much into fine beach material such as sand or clay, but will penetrate extensively on a shore consisting of coarse boulders. A very light oil such as diesel on a cobble beach can penetrate to about a meter under some conditions and is difficult to remove. On the other hand, a weathered crude deposited on a fine sand beach can remain on the surface indefinitely and is removed fairly easily using mechanical equipment.

The extent of oil coverage often depends on the stage of the tide when the oil is deposited on the shoreline. At high tide, oil can be deposited above the normal tide line and often spreads over a broad intertidal area. The least amount of oiling occurs when the oil is deposited on the shoreline during the falling tide, although this is less likely to occur as the water is moving away from the shoreline. The nature of the intertidal zone, for example, its composition and slope, will often dictate the fate of the oil. If large amounts of oil are not retained in the intertidal zone, then the oil will have less impact on the area.

The fate of oil on shorelines also depends on the wave regime. Oil can be removed and carried away by energetic waves within days whereas it can remain for decades in sheltered areas. Beaches are dynamic environments that change in profile during seasonal storms. This can result in oil being buried on the beach in layers, often as deep as 1 m, or buried oil can be brought to the surface.

Oil stranded on shorelines, especially above the high tide line, weathers with time and becomes more

adhesive, viscous, and difficult to remove [43.30, 31]. As oil stranded above the high tide line is above the limit of normal wave action, physical removal can occur only during storm events.

Another mechanism that can significantly affect the fate of oil on shorelines is the mixing of the oil with beach material. Oil often mixes with sand and gravel on beaches and then weathers to form a hard, resilient material called asphalt pavement which is difficult to remove. This material may be only 1–30% oil by weight, which greatly increases the amount of material to be removed. Sometimes this stranded oil causes no environmental concerns because the oil is entirely bound and none is lost to the water or refloated, but there may be a concern with this oil being visible on the shoreline, depending on the location of the shoreline.

43.11.2 Types of Shorelines and Their Sensitivity to Oil

The type of shoreline is crucial in determining the fate and effects of an oil spill as well as the cleanup methods to be used [43.29]. In fact, the shoreline's basic structure and the size of material present are the most important factors in terms of oil spill cleanup. The types summarized here are:

- Bedrock
- Man-made solid structures
- Boulder beaches
- Pebble-cobble
- Mixed sand-gravel beaches
- Sand beaches
- Sand tidal flats
- Mud tidal flats
- Marshes.

Bedrock shorelines consist of rock that is largely impermeable to oil, although oil can penetrate through crevices or fractures in the rock. Oil is more likely to be deposited in the upper tidal zone. If the shore is exposed to wave action, a significant amount of oil is likely to be removed after each tidal cycle.

Shorelines consisting of man-made solid structures include retaining walls, harbor walls, breakwaters, ramps, and docks and are generally made of rocks, concrete, steel, and wood. This type of shoreline is usually considered impermeable to oil, although there are some types that are permeable and these may be considered similar to their natural counterparts.

Boulder beaches consist primarily of materials that are more than 256 mm in diameter. These beaches are not altered by any conditions other than ice, human activity, or extreme wave conditions. Boulder beaches often give way to mud or sand tidal flats in the lower intertidal zone. Because of the large spaces between individual boulders, oil can be carried down to the sediments and remain there for years.

Pebble-cobble beaches consist of materials ranging in size from 2 to 256 mm. Pebbles range in size from 4 to 64 mm and cobbles from 64–256 mm. Some fine materials may be present in the interstitial areas between pebbles and there may also be large boulders in the area. Oil readily penetrates pebble-cobble beaches through the open spaces between the rocks.

A mixed sediment beach consists of a variety of materials from 0.1 to 64 mm in size and possible cobbles up to 256 mm. These are sometimes called sand-gravel beaches and sometimes gravel beaches, because the larger gravel appears to predominate. Only lighter oils can penetrate sand-gravel beaches. For this reason, these beaches are not considered to be particularly sensitive to oil spills. Oil from spills can form asphalt pavement at the upper-tidal reaches. Oil residence times vary, but are generally shorter than other types of beaches.

Sand beaches are what most people envision as a beach. Sand is defined as a particle 0.1–2 mm in diameter, consisting of several different sizes and types of minerals. Coarse sand is usually defined as 0.5–2 mm in size and fine sand is less than 0.5 mm in size. On many coasts, sand beaches are often located between other types of beaches. Only lighter oils penetrate sand beaches and the residence time is likely to be short, except when oil is buried or carried to the upper tidal areas. Oil can easily become buried in sand and over time this can result in layers of sand and oil. In recreational areas, sand beaches are given a high cleanup priority if oiling of any type occurs.

Sand flats consist of material similar to sand beaches but are at shallow angles and never drain completely. They contain a lot of silt or very fine material. The surface layer of sand flats, which consists of a few centimeters, is dynamic and unstable. This surface layer is usually water-saturated and thus impermeable to oils. Sand tidal flats are difficult to access and cleanup is therefore limited.

Mud flats are similar to sand tidal flats in that they are at shallow angles and have a thin, mobile surface layer consisting of water-saturated mud that is impermeable to oil, although oil can penetrate through holes made by burrowing animals. Oil is likely to concentrate on the upper tidal zones. Mud flats are not accessible to vehicles or response personnel and thus cannot be readily cleaned.

Marshes are important ecological habitats that often serve as nurseries for marine and bird life in the area. Marshes range from fringing marshes, which are narrow areas beside a main water body, to wide salt marsh

Table 43.6 Cleanup techniques and shoreline types (after [43.29])

meadows. Salt marsh meadows often flood only during high tides in spring or during storm surges. Marshes are rich in vegetation that traps oil. Light oils can penetrate into marsh sediments through animal burrows or cracks. Heavier oils tend to remain on the surface and smother plants or animals. Oiled marshes, fresh or salt, may take years or even decades to recover. Marshes are difficult to access and entering them by foot or by vehicle can cause more damage than the oil itself.

43.11.3 Cleanup Methods

Many methods are available for removing oil from shorelines. Most of them are costly and take a long time to carry out. The selection of the appropriate cleanup technique is based on the type of substrate, the depth of oil in the sediments, the amount and type of oil and its present form/condition, the ability of the shoreline to support traffic, the environmental, human, and cultural sensitivity of the shoreline and the prevailing ocean and weather conditions. Some cleanup techniques suitable for use on the various types of shoreline are listed in Table 43.6 [43.29].

The primary objective of cleanup operations is to minimize the effects of the stranded oil and accelerate the natural recovery of affected areas. The length of time required to complete the cleanup is another important criterion when selecting a cleanup technique. The longer oil is on a beach, the harder it is to clean up. A method that removes most of the mobile oil rapidly is much better, in many circumstances, than a more thorough one that takes weeks to carry out. Time often dictates the cleanup method used.

43.11.4 Recommended Cleanup Methods

Some recommended shoreline cleanup methods are natural recovery, manual removal, flooding or washing, use of vacuums, mechanical removal, tilling and aeration, sediment reworking or surf washing and the use of sorbents or chemical cleaning agents [43.29]. Sometimes the best response to an oil spill on a shoreline may be to leave the oil and monitor the natural recovery of the affected area. This would be the case if more damage would be caused by cleanup than by leaving the environment to recover on its own.

Manual removal is the most common method of shoreline cleanup. Teams of workers pick up oil, oiled sediments, or oily debris with gloved hands, rakes, forks, trowels, shovels, or sorbent materials. It may also include scraping or wiping with sorbent materials or sifting sand to remove tar balls.

Flooding or washing shorelines are also common cleanup methods. Low-pressure washing with cool or lukewarm water causes little ecological damage and removes oil quickly. Warmer water removes more oil, but causes more damage. High pressures and temperatures cause severe ecological damage but might be safely used on man-made surfaces.

Low-pressure cool or warm water washing uses water at pressures less than about 200 kPa (50 psi) and temperatures less than about 30 °C. Flooding is a process in which a large flow or deluge of water is released on the upper portion of the beach.

Low-pressure washing and flooding are often combined to ensure that oil is carried down the beach to the water, where it can be recovered with skimmers.

In Part E, a range of contemporary ocean energy technologies are covered in six chapters, encompassing a resource assessment and an overview of wave energy, current energy, hydrokinetic energy, thermal energy, and last but not least, offshore wind.

Specifically, in Chap. 44, ocean energy resource assessment is given. Marine hydrokinetic energy includes energy due to waves, tides, and ocean currents. The characteristics of these forms of energy and the assessment of their potential for extraction are discussed briefly. Detailed consideration is given to the assessment of ocean current energy, including a case study of the resource assessment of the Florida Current. Estimates of global and local open ocean current resources are obtained based on data from an ocean model. The power densities of major western boundary currents are estimated, and the potential for development of ocean currents globally is assessed. The principal factors that govern economic viability of harnessing an ocean current at a location include the in-situ energy density, the distance of the location from the shore, and the local depth of the seafloor. A metrics based on these considerations is developed. Once potential sites have been identified, considerations would need to be given to regulatory and permitting requirements, including assessment of the potential impact on the environment and its ecosystems, and the impact on the energy resource itself; development of optimal design of devices for high performance; and mitigation of deployment and maintenance costs.

In Chap. 45 the most important ocean wave energy conversion concepts are presented. Basic concepts in primary ocean wave energy capture and its conversion to electricity using power takeoff systems are described. Several patented inventions in harnessing wave energy have been reported over the past 4 decades and many continue to be filed. They are typically based on these basic concepts in wave energy capture and appropriate power takeoff systems for conversion to electricity. An introduction to these methods is provided, and recent developments are discussed. Finally, an account of some of the well-known practical field applications of ocean wave energy technologies is presented in an appendix, with emphasis on commercial technologies.

In Chap. 46, ocean current energy conversion is investigated. Ocean currents in tidal flows and at the western boundaries of the ocean basins, as well as currents in rivers, can have as much potential for power production as the wind. With the increased interest in sources of renewable energy, realizing this potential has undergone a renaissance in recent years. This overview provides an introduction to ocean current energy conversion by emphasizing the contrasts between winds and currents and discussing some of the unique challenges associated with this untapped renewable energy source.

In Chap. 47, a detailed account of hydrokinetic energy conversion is given. Marine hydrokinetic (MHK) energy is clean, renewable, and available worldwide. It comes in two forms: vertical in waves and horizontal in currents, tides, and rivers. Apart from a few major ocean currents, most ocean currents have flow speeds of less than 3 kn, and most rivers have speeds of less than 2 kn, making harvesting of their MHK energy by steady-lift technologies (turbines) challenging. Horizontal MHK energy can also be harnessed using alternating-lift technologies. Fish utilize alternating lift to propel efficiently in water either as individuals or in schools. Engineered structures – bluff bodies such as circular cylinders and prisms, or slender bodies like hydrofoils – may generate alternating lift in quasi-steady uniform flows. When these structures have scale-relevant flexibility, severe flow-structure interaction (FSI) phenomena may be induced. In typical engineering applications, FSI phenomena are destructive and, thus, avoided by design or suppressed using excessive damping or appendages. If, instead, FSI are enhanced, they may result in vigorous flow-induced motion (FIM) of the body, leading to conversion of MHK energy to potential and kinetic energy in a mechanical oscillator. Hydrofoils can harvest MHK energy through flutter – a well-studied and understood form of instability. On the other hand, bluff bodies such as circular or rectangular cross-section cylinders may exhibit several forms of FIM, individually or in *schools*; these have been studied extensively but are still not well understood for either suppression or enhancement. Those FIMs are vortex-induced vibration (VIV), galloping, buffeting, and gap-flow in multi-body interactions. When enhanced, they convert MHK energy to mechanical energy with a high power density (power-to-weight ratio), even from low-speed horizontal flows. This chapter presents an overview of the concepts of alternating-lift technologies, the underlying physical principles, the available experimental and computational methods for studying the relevant FIM, the research challenges that have been overcome and those lying ahead, field-deployment progress, technology development, and benchmarking.

In Chap. 48, ocean thermal energy conversion is visited. Ocean thermal energy conversion (OTEC) utilizes the thermal gradient available in the ocean to operate a heat engine to produce work output. Even though the concept is simple and has been used for almost one century, during the last three decades it has gained momentum due to a worldwide search for

a clean, continuous energy source to replace the fossil fuels. There are technological hurdles to overcome to tap the immense potential of OTEC. However, the technology is still mature enough to establish commercial power plants. This chapter presents the technological and economical aspects of OTEC, with an overview of the current status. It also suggests some further research and technological guidance based on the Indian OTEC experiences for this promising technology for future.

Finally, in Chap. 49, an insight of offshore wind energy conversion is presented. In 1991, the Vindeby Offshore Wind Farm, the first offshore wind farm in the world, started feeding electricity to the grid off the coast of Lolland, Denmark. Since then, offshore wind energy has developed from this early experiment to a multibillion dollar market and an important pillar of the worldwide renewable energy production. Unit sizes grew from 450 kW at Vindeby to the 7.5 MW-class offshore wind turbines that are currently (by October 2014) in the prototyping phase. This chapter gives an overview of the state-of-the-art in offshore wind turbine technology and introduces the principles of modeling and simulating an offshore wind turbine (OWT). The OWT components rotor, nacelle, support structure control system, and power electronics are introduced, and current technological challenges are presented. The OWT system dynamics, as well as the environment (wind and ocean waves), are described from the perspective of OWT modelers and designers. Finally, an outlook on future technology is provided. The descriptions in this chapter are focused on a single OWT – more precisely, a horizontal-axis wind turbine – as a dynamic system. Offshore wind farms and wind farm effects are not described in detail in this chapter but an introduction and further references are given.

44. Marine Hydrokinetic Energy Resource Assessment

Manhar R. Dhanak, Alana E.S. Duerr, James H. VanZwieten

Marine hydrokinetic energy includes that due to waves, tides, and ocean currents. The characteristics of these forms of energy and the assessment of their potential for extraction are discussed briefly herein. Detailed consideration is given to the assessment of ocean current energy, including a case study of the resource assessment of the Florida Current. Estimates of global and local open ocean current resources are obtained based on data from an ocean model. The power densities of major western boundary currents are estimated and the potential for development of ocean currents globally is assessed. Principal factors that govern economic viability of harnessing an ocean current at a location include the in-situ power density, the distance of the location from the shore, and the local depth of the seafloor. A metrics based on these considerations is discussed. Once potential sites are identified, considerations would need to be given to regulatory and permitting requirements, including assessment of potential impact on the environment and its ecosystems, marine spatial planning and the impact on the energy resource itself; development of optimal design of devices for high performance; and mitigation of deployment and maintenance costs.

The energy in the oceans may be classed as hydrokinetic when it is in the form of waves, and tidal and ocean currents, and as potential energy when it in the forms of thermal and salinity gradients, and tidal water levels. The prevalence of these forms of energy is geographic specific. Major ocean currents are typically western boundary currents on the eastern coasts of the continents. Tidal energy typically represents significant ocean energy resources in the estuaries and channels at a number of locations worldwide, such as the northeast of United States or the western coast of Europe. Significantly high wave energy sources are typically found in mid to high latitudes (40–60°) along coastlines facing large open oceanic regions with significant wind fetch, such as the northwest coast of the US. Thermal gradients are significant at certain locations in low to mid latitudes (0–35°). The feasibility of cost-effectively harnessing any of these forms of energy from a specific region depend on a number of factors, including the distance of the region from the shore, the local water depth, and the potential impact of harnessing the energy on the environment and on the local stakeholders. Developing just a small fraction of the available wave energy resources could allow for millions of homes to be powered.

In this chapter, we provide a brief assessment of the various forms of marine hydrokinetic energy and provide details of the methodology for estimating the potential for energy extraction in the particular case of the hydrokinetic energy of an open ocean current, together with an overview of the world's major ocean currents as significant ocean energy resources. The ocean current energy potential at identified global locations is estimated using a computational ocean model. The model's accuracy in predicting the actual current conditions and hence the resource potential is discussed. In Sect. 44.1, the potential for wave energy is discussed; in Sect. 44.2, the potential for tidal and ocean currents is discussed; in Sect. 44.3, practical considerations in extracting ocean and tidal current energy are discussed; and in Sect. 44.4, a case study for assessing extractable ocean current energy resource is discussed.

44.1 Wave Energy Resource

Waves are significant sources of hydrokinetic energy. Typically, waves generated by winds are of interest here. Waves form in a complex evolving process involving fluctuations in air pressure over a range of frequencies induced by unsteady turbulent winds, shear layer instabilities, and interaction between waves [44.1–3]. The height, period, wavelength, and direction of propagation of waves are governed by the wind velocity, wind duration, fetch – the distance over water that the wind blows along a particular direction – and water depth and bottom topography. Large waves correspond to high winds operating over long duration over considerable fetch. The absence of significant wind strength, duration, or fetch curtails the growth of waves. Waves in a given area typically have a spectrum of heights, periods, and wavelengths, from very small, short capillary waves of periods $T < 0.1\,\mathrm{s}$ to chops of wave heights of $O(0.1-10\,\mathrm{m})$ and periods $1\,\mathrm{s} < T < 10\,\mathrm{s}$ to swells of wave heights of the same order but periods in the range $10\,\mathrm{s} < T < 30\,\mathrm{s}$. While chops are associated with local winds, have relatively short wavelength and are of short duration, swells are typically generated by distant storms, are narrow banded, have longer wavelengths and travel long distances; as waves disperse from the region of the storm, shorter waves get dissipated, while longer $O(100\,\mathrm{m})$, faster traveling, waves persist over great $O(1000-10\,000\,\mathrm{km})$ distances. The wave height of a group of waves is characterized by the significant wave height, H_s. For specific wind velocity, duration, and fetch, a threshold, referred to as *fully developed seas*, is reached, whereby additional action of the wind results in breaking of wave tops and formation of *whitecaps*. Wave-induced oscillatory motion in the water column is highest at the surface and diminishes rapidly with depth.

Wave energy propagates with the group velocity. The wave energy flux per unit along crest width (wave power density), which is the mean rate of transport of the wave energy through a vertical plane of unit span along a wave crest, for unidirectional waves is given in units of W/m by

$$P_\mathrm{h} = \rho g \int_0^\infty C_\mathrm{g} S(f)\,\mathrm{d}f\,, \tag{44.1}$$

where $S(f)$ is the wave spectrum and $C_\mathrm{g}(f,d)$ is the group velocity of the harmonic wave component of frequency f Hz in waters of depth d. In the case of directional spread, we consider $S(f) = \int_{-\pi}^{\pi} S(f,\theta)\,\mathrm{d}\theta$. According to linear wave theory,

$$C_\mathrm{g} = \frac{g \tanh kd}{4\pi f}\left(1 + \frac{2kd}{\sinh 2kd}\right)\,,$$
$$(2\pi f)^2 = gk \tanh kd\,. \tag{44.2}$$

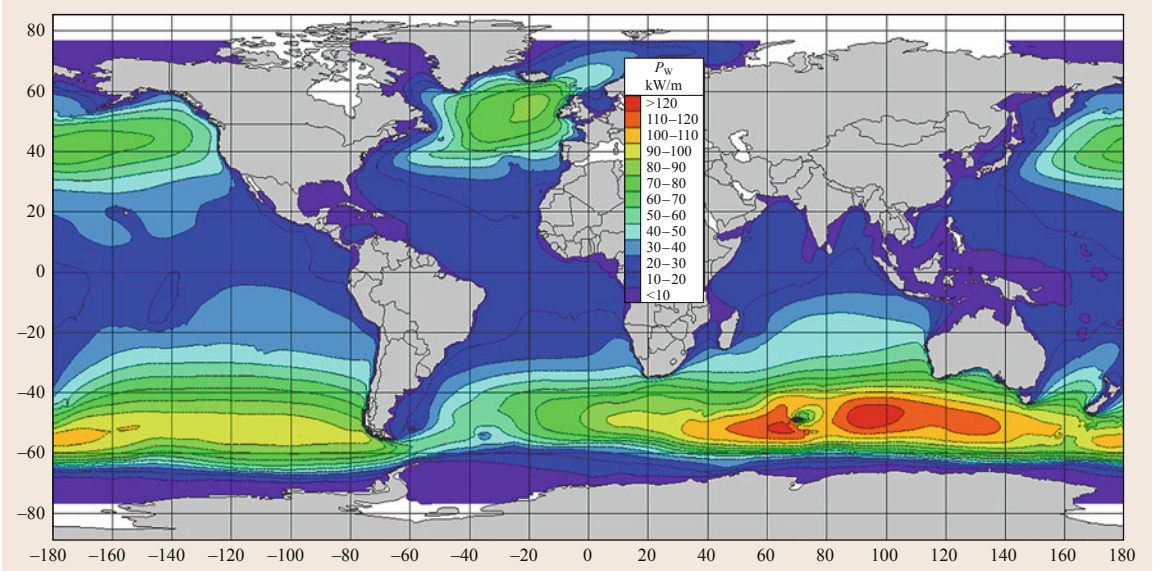

Fig. 44.1 Global distribution of annual mean wave power. Wave power density in kW/m is shown, based on NOAA WAVEWATCH-III (NWW3) wind–wave model (after [44.4])

In deep water, $C_g = \frac{g}{4\pi f}$, so that

$$P_h = \frac{\rho g^2}{4\pi} \int_0^\infty \frac{S(f)}{f}\,df = \frac{\rho g^2}{4\pi} m_{-1} = \frac{\rho g^2 H_0^2 T_e}{64\pi}\,, \tag{44.3}$$

where

$$H_0 = 4\sqrt{m_0} = 4\sqrt{\int_0^\infty S(f)\,df}$$

is the significant wave height and $T_e = \frac{m_{-1}}{m_0}$ is the wave energy period.

In shallow water, $C_g = \sqrt{gd}$ and $S(f) \to S_s(f)$, the shallow water spectrum, so that

$$P_h = \rho g \sqrt{gd} \int_0^\infty S_s(f)\,df = \frac{\rho g \sqrt{gd} H^2}{16}\,, \tag{44.4}$$

where H is the shallow-water wave height. As the waves approach the shore they undergo shoaling and refraction. Equating (44.3) and (44.4) gives the shoaling coefficient $\kappa_s = H/H_0 = (gT_e^2/(16\pi^2 d))^{\frac{1}{4}}$. In practice, some of the wave energy may be lost on approach to the shoreline through wave breaking.

As an example, consider a swell of wave energy period $T_e = 10\,s$ and wave height $H_0 = 0.5\,m$. For such a wave, (44.3) implies that the available energy is

$$P_h = \frac{\rho g^2 (2.5)}{64\pi} \simeq 1.2\,kW/m\,.$$

Figure 44.1 shows the global distribution of the annual mean available wave energy resource. As can be seen, major sources of wave energy along the continental coastlines lie on the western boundaries of the land masses in mid to high (40–60°) latitudes north and south of the Equator. In particular, northwest USA, western Europe, southern Chile, and south and west Australia have high wave power densities along their coastlines. *Gunn* and *Stock-Williams* [44.5] use NOAA Wavewatch III model [44.6] data to estimate that worldwide the total mean wave energy resource is over 2 TW or 17 532 TWh/year, with the mean resource being higher in winter than in summer in either hemisphere; they estimate that accounting for the effect of directional spread implies around 15% reduction in this estimate. Other estimates vary between 1.3 TW or 11 396 TWh/year [44.7] and 3 TW or 26 297 TWh/year [44.8]. *Gunn* and *Stock-Williams* [44.5] found that Australia (280 GW), USA (223 GW) and Chile (194 GW) have the highest potential for wave energy conversion.

The fraction of this available wave energy resource that can be extracted is based on a number of factors, including available conversion technologies, their efficiencies and packing capacities, economic viability, and environmental impact considerations. Using an example of an array of Pelamis devices, *Gunn* and *Stock-Williams* [44.5] suggest that based on current technologies, 4.6% of the 2 TW of available global wave energy may be extractable. An Electric Power Research Institute (EPRI) report [44.9] finds that technically recoverable resources for electric generation from waves around the US coastline is approximately 1170 TWh/year (134 GW), which is almost one third of the 4000 TWh of annual electricity usage in the USA.

44.2 Tidal and Ocean Current Energy Resource

Tidal currents are globally ubiquitous and together with major ocean currents represent important marine hydrokinetic sources of renewable energy. Importantly, tidal currents are highly predictable, while major ocean currents, such as the Gulf Stream and the Kuroshio Current, in a number of places around the world flow fairly persistently as part of ocean circulation systems. Therefore, tidal and ocean current energy conversion, along with solar, wind, waves, and other renewables, is an imperative consideration for a future energy portfolio for sustainability. Industry and governments worldwide are moving to invest in developing these forms of ocean energy; for example, the European Marine Energy Center (EMEC) has developed a major at-sea test facility for tidal current energy conversion devices in Orkney. A number of studies have been conducted worldwide, and various energy conversion devices have been designed and built, borrowing much of the technology from the wind industry. Since seawater is 800 times denser than air, ocean and tidal currents are energy dense, such that at low speeds they have kinetic energy per unit area comparable to that of winds of speed nearly an order of magnitude higher. For example, currents of speed 1 m/s have the same power capacity per unit area as winds of speed 9.3 m/s. Because of this physical property, ocean currents contain an enormous amount of energy that can be captured and converted to a usable form. Despite this potential, challenges remain

in research and development of efficient energy extraction devices, assessment of environmental impact, development of best practices and operating procedures, and establishment of policies and regulations.

44.2.1 Tidal Currents

Tides are very long waves, made up of harmonic constituents whose periods range from $O(1-10\times10^4\,\mathrm{hr})$, that flow to and fro between the oceans and coastlines in response to the gravitational forces exerted by the moon and the sun on the earth in combination with inertial forces, leading to the rise and fall of the sea level at the coastlines. At any coastal location, high and low tides correspond to the crest and trough of the tidal wave, respectively, reaching the location, the difference in sea levels between the two states being the tidal range at the location. The tidal range provides a good measure of the tidal energy resources at a location.

The tidal motion of the water is primarily a balance between the gravitational forces of the moon and the sun and the forces of inertia. In view of its relative proximity to the earth, the moon plays a greater role than the sun in generating the tides. The gravitational force of the moon on earth overcomes the inertial forces on the side closest to it and pulls the associated ocean into a bulge, while on the side furthest from the moon, inertial forces dominate and pull the water column away in the opposite direction, leading to a similar bulge furthest away from the moon. As the earth rotates and the moon moves around the earth and the alignment between the earth and the moon shift accordingly, the bulges maintain position with respect to the alignment causing cyclic variation in water levels over a lunar day, which is 24 hr 50 min long. If the earth were perfectly spherical and fully covered with water, this would result in semi-diurnal tides, involving two approximately equal high and two approximately equal low tides a day, everywhere. However, since the earth is not perfectly spherical and tidal flows of the oceans are interrupted by landmasses, tidal patterns are complicated. Many places, such as the east coast of the US, have semi-diurnal tides with the harmonic component M_2, of period of 12 hr, 25 min, being the major constituent of the tidal wave; other major constituents are the principal solar semi-diurnal S_2 component (12 hr period) and larger lunar elliptic semi-diurnal component (12 hr, 40 min period). Other places, such as in the Gulf of Mexico, have diurnal, or one high and one low tide a day, primarily governed by diurnal lunar components K_1 (23 hr, 56 min period), and O_1 (23 hr, 49 min period), and solar diurnal component S_1 (24 hr period). Yet other places, such as the western coast of the US, experience mixed semi-diurnal tides, involving two unequal high and two unequal low tides a day. Regionally, tidal flows are influenced by the shape of coastlines and opening to bays as well as by interactions with local riverine flows in estuaries, by weather patterns and winds as well as other currents. The tidal cycles and their amplitudes vary with time and position along a coast. During full moon and at new moon, the earth, the moon and the sun are aligned and the solar tide adds to the lunar tide, resulting in occurrence of maximum tidal ranges or *spring tides*. At first and third quarter moon, when the moon and the sun are at right angles, the lunar and solar tides act to dampen the tidal amplitudes, resulting in minimal tidal range or *neap tides*. Figure 44.2 shows the principal tidal component M_2, which is determined from satellite altimetry [44.10]. The associated tidal ranges are typically maximum at certain places near coastlines, particularly along the coast of northwest Europe, the northeast and northwest coasts of North America, the east coast of Africa, the northwest coast of Australia, southern and eastern parts of Asia, and northern and southern parts of South America. *Charlier* and *Justus* [44.11] (see also [44.12]) estimate that the theoretical mean global tidal power resource is around 3 TW, of which around 1 TW is available in shallow waters.

44.2.2 Ocean Currents

The mean flow in the ocean basins, separated by landmasses, comprises of large-scale subtropical gyres or circulation of surface currents that are set up by persistent action of prevailing winds, typically by the trade winds near the Equator and by the Westerlies at higher latitudes (see, for example, [44.14]). The subtropical gyres (Fig. 44.3), two in the Atlantic, two in the Pacific, and one in the Indian Ocean, rotate clockwise in the northern hemisphere and anticlockwise in the southern hemisphere and transport warmer waters from lower latitudes to higher latitudes and cooler waters from higher latitudes to lower latitudes. In the Atlantic, the North Equatorial Current, the Caribbean Current, the Gulf Stream (including the Loop Current in the Gulf of Mexico and the Florida Current), the North Atlantic Current, and the Canary Current mark the north Atlantic gyre, while the South Equatorial Current, the Brazil Current, the Antarctic Circumpolar Current, and the Benguela Current mark the south Atlantic gyre. In the Pacific, the North Equatorial Current, the Kuroshio Current, the North Pacific Current, and the California Current mark the north Pacific gyre, while the South Equatorial Current, the East Australian Current, the Antarctic Circumpolar Current, and the Peru Current mark the south Pacific gyre. In the Indian Ocean, the South Equatorial Current, the Agulhas Current, the

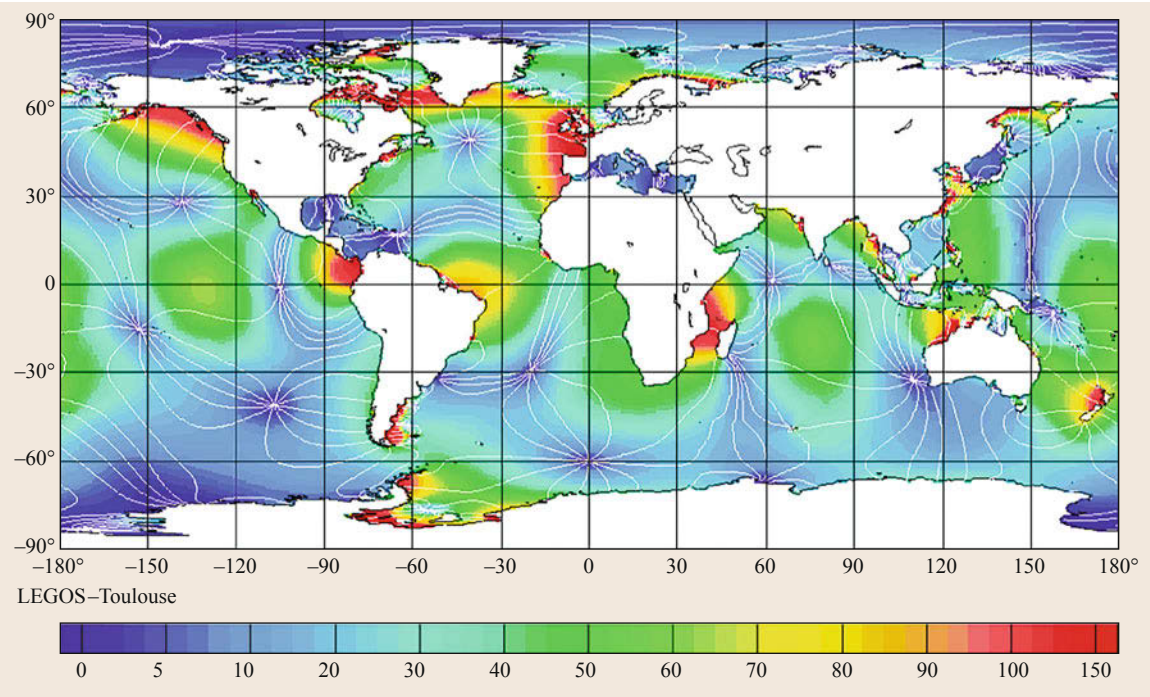

Fig. 44.2 M_2 tide (after [44.10])

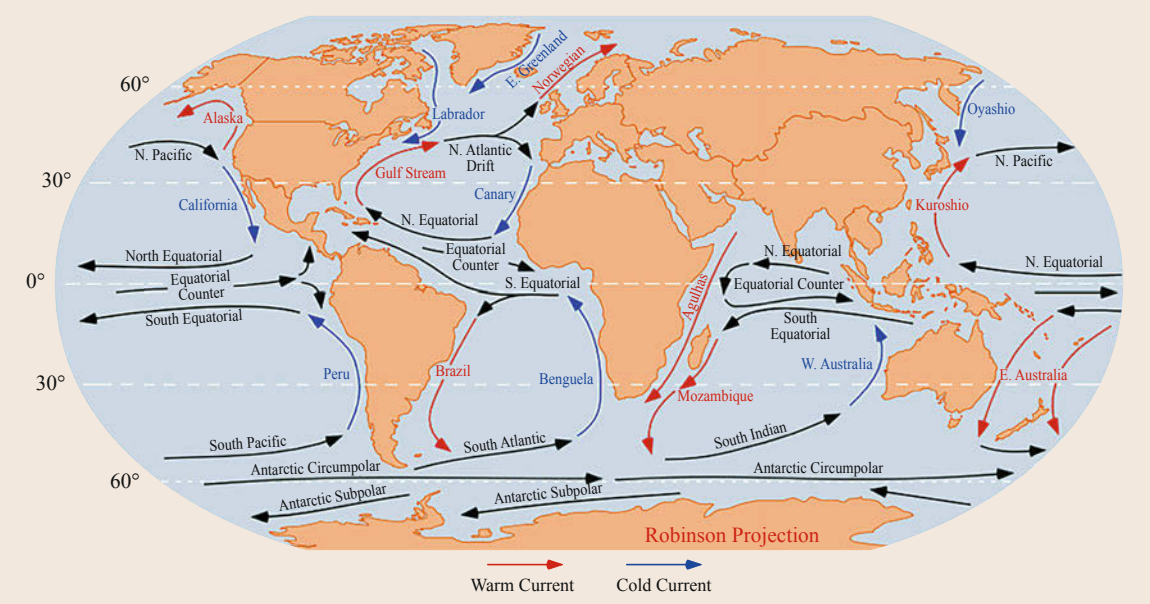

Fig. 44.3 Subtropical gyres and mean ocean currents (after [44.13])

Antarctic Circumpolar Current, and the West Australian Current mark the Indian Ocean gyre in the southern hemisphere. The landmass of the Indian subcontinent prevents full development of a gyre in the northern Indian Ocean; instead reversible currents associated with monsoon winds mark the region. In between the north and south subtropical gyres in the Atlantic and the Pacific lie Equatorial Counter Currents. Finally, smaller subpolar gyres occur, one in the North Atlantic and the other in the North Pacific.

The western arms of the subtropical gyres, referred to as *western boundary currents*, are narrow, fast, with mean speeds in the range 1–2.5 m/s, and extend deep, up to 400 m, while the eastern arms, or *eastern boundary currents*, are wide, slow, typically with mean speeds < 0.2 m/s, and shallow. The Gulf Stream and the Kuroshio Current are the most intense western boundary currents. The intensification of the western boundary currents is linked to the increasing strength of the Coriolis force as one moves away from the Equator [44.15]. The stronger Coriolis force deflects currents driven eastwards by the Westerlies south to form eastern boundary currents, which are broad so that the center of the gyre lie to the west of the basin. At lower latitudes, weak Coriolis force and the trade winds act to deflect the eastern boundary currents and transport its surface waters westwards. At the western boundary of the basin, the waters are driven towards the poles in a narrower region west of the center of the gyres, with the ocean surface sloping down westwards, thereby leading to significant contribution from the mean geostrophic flow. The time-averaged (over several days) velocity is given by the approximate equations [44.15], see also [44.16]

$$\begin{aligned}
\frac{1}{\rho}\frac{\partial p}{\partial x} &= \mathrm{g}\frac{\partial \zeta}{\partial x} = fv + \frac{\partial}{\partial z}\left(A_z \frac{\partial u}{\partial z}\right) \\
&\quad + A_H\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) , \\
\frac{1}{\rho}\frac{\partial p}{\partial y} &= \mathrm{g}\frac{\partial \zeta}{\partial y} = -fu + \frac{\partial}{\partial z}\left(A_z \frac{\partial v}{\partial z}\right) \\
&\quad + A_H\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}\right) , \\
\frac{1}{\rho}\frac{\partial p}{\partial z} &= -\mathrm{g} ,
\end{aligned} \tag{44.5}$$

where positive x and y are along east and north directions, z points vertically upwards, and u and v are the respective horizontal components of the current velocity; p is the pressure, A_z and A_H are coefficients of eddy friction, and ζ is the mean free surface elevation.

44.2.3 Power and Power Density of Tidal and Ocean Currents

Within a column of moving fluid, the power density P_u and the available power P or hydrokinetic energy flux across a cross-sectional area A within the current may be estimated using the following equations

$$P_u(y,z,t) = \frac{1}{2}\rho U^2 (\boldsymbol{U}\cdot\boldsymbol{n}) , \tag{44.6}$$

$$P = \iint_A P_u \, \mathrm{d}A , \tag{44.7}$$

where ρ is the density of the fluid, $\boldsymbol{U}$ is the velocity of the fluid, $\boldsymbol{n}$ is the unit vector normal to the area A through which the fluid flows. If the cross-stream components of velocity can be neglected, $P_u(y,z,t) \simeq \frac{1}{2}\rho(\boldsymbol{U}\cdot\boldsymbol{n})^3$.

The power that can be extracted by a single hydrokinetic turbine may be expressed as

$$P_E = \eta P , \tag{44.8}$$

where $\eta(<1)$ is efficiency of the extraction process. In open oceans, the maximum value of η is typically estimated using the ideal, frictionless, steady incompressible flow model due to *Betz* [44.17] (see also [44.18]), where the turbine rotor is represented by an actuator disk of area A_D (Fig. 44.4). We consider the axial speed upstream, at the rotor, and downstream of the rotor to be U_1, U_D, and $U_2 = \alpha U_1 (\alpha < 1)$, respectively, each being uniform across the appropriate section within the stream tube.

Conservation of mass requires that

$$\iint_{CS} \rho\,(\boldsymbol{U}\cdot\boldsymbol{n})\, \mathrm{d}A = 0 , \tag{44.9}$$

for the fluid enclosed by the control surface CS, shown by the dashed line in Fig. 44.4; here the normal vector $\boldsymbol{n}$ points out of the volume enclosed by CS. Since $(\boldsymbol{U}\cdot\boldsymbol{n}) = 0$ along the curved sections of CS, we have

$$U_1 A_1 = U_2 A_2 = U_D A_D , \tag{44.10}$$

where A_1 and A_2 are the areas of the upstream and downstream sections of CS.

Applying the energy equation to the control volume between sections 1 and 2, we have

$$-\dot{W} = \iint_{CS} \left(\frac{1}{2}\rho U^2 + p + \rho g z\right)(\boldsymbol{U}\cdot\boldsymbol{n})\, \mathrm{d}A , \tag{44.11}$$

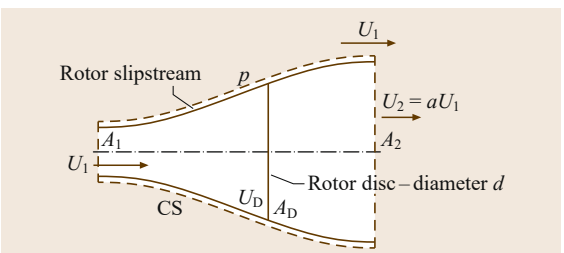

Fig. 44.4 Schematics of actuator disc model

where $\dot{W} = P_E$, is the extracted power or the work done by the fluid on the system enclosed by CS and p is the pressure. For the case of uniform flow considered here and the control surface as in Fig. 44.4, $p + \rho g z = C$, a constant over CS (using Bernoulli's equation outside of the stream tube), and (44.11) becomes

$$\begin{aligned}\dot{W} = P_E &= \left(\frac{1}{2}\rho U_1^2 + C\right) U_1 A_1 \\ &\quad - \left(\frac{1}{2}\rho U_2^2 + C\right) U_2 A_2 \,, \\ &= \frac{1}{2}\rho \left(U_1^2 - U_2^2\right) U_D A_D \,, \end{aligned} \tag{44.12}$$

using (44.10). Finally, conservation of momentum of the system enclosed by CS implies

$$\boldsymbol{F}_D = \iint_{CS} \frac{1}{2}\rho \boldsymbol{U}(\boldsymbol{U}\cdot\boldsymbol{n})\,\mathrm{d}A - \iint_{CS} (p + \rho g z)\boldsymbol{n}\,\mathrm{d}A \,, \tag{44.13}$$

where $\boldsymbol{F}_D = (-F_D, 0, 0)$ is the reaction force on the rotor to maintain it in position. Applying (44.13) to the CS in Fig. 44.4, we note that the pressure term integrates to zero so that, as in (44.10),

$$F_D = \rho(U_1 - U_2)U_D A_D \,. \tag{44.14}$$

Then extracted power P_E is also given by

$$P_E = F_D U_D = \rho(U_1 - U_2)U_D^2 A_D \,. \tag{44.15}$$

Equating (44.12) and (44.15), we obtain that the flow speed at the disk is given by

$$U_D = \frac{U_1(1+\alpha)}{2} \,, \tag{44.16}$$

where $\alpha = U_2/U_1$. Hence from (44.15), the extracted power is given by

$$P_E = \frac{1}{4}\rho U_1^3 A_D (1-\alpha)(1+\alpha)^2 \,. \tag{44.17}$$

If we regard the available reference power as $P = \frac{1}{2}\rho U_1^3 A_D$, corresponding to the energy flux through a circle of diameter A_D upstream of the disk, then the ideal efficiency of the extraction is given by

$$\eta = \frac{P_E}{\frac{1}{2}\rho U_1^3 A_D} = \frac{1}{2}(1-\alpha)(1+\alpha)^2 \,, \tag{44.18}$$

which has a maximum value of $\eta_{max} = 16/27 \approx 0.59$, when $\alpha = 1/3$ and hence $U_D = \frac{2}{3}U_1$. This maximum value is referred to as the Betz limit. Thus, maximum power that can be extracted is given by

$$P_{Emax} = \frac{1}{2}\rho U_1^3 A_D \eta_{max} \,. \tag{44.19}$$

Maximum efficiencies are lower than 0.59 when allowance is made for the finite number of blades and rotational speeds; the Betz limit is achieved only for higher values of the tip speed ratio $U_D/\Omega R_D$, where Ω is the rate of rotation and R_D is the radius of the rotor [44.19]. For nonuniform flows, the integral equations (44.9)–(44.13) must be used. Most designs for hydrokinetic turbines allow the turbine to yaw so that the turbine may be normal to the direction of the current; however, if the turbine is unable to yaw, then the full integral equations should account for the associated directional flow. Additionally, if the flow is unsteady, unsteady versions of the momentum and energy equations are needed.

Typically, tidal energy would be harnessed from tidal streams in channels and openings in coastlines or in estuaries. Therefore in making tidal energy resource assessment, consideration is given to the characteristics of the flow in such channels. *Garrett* and *Cummins* [44.20] consider an extension of (44.19) to flow in a finite tidal channel. They show that Betz limit applies when the rotor size is small compared with the channel's width. If the rotor size is comparable to the channel width, then they show that

$$P_{Emax} = \frac{\frac{1}{2}\rho U_1^3 A_D \eta_{max}}{\left(1 - \frac{A_D}{A_c}\right)^2} \,, \tag{44.20}$$

where A_c is the cross-sectional area of the channel – the efficiency of the turbine is increased due to the confining effects of the channel and associated increase in the pressure drop across the turbine. In practice, for larger blockage ratios A_D/A_c this increased efficiency needs to be balanced against the effect of increased blockage or drag on the flow that will lead to reduction in hydrokinetic energy flux [44.21]. Indeed, *Garrett* and *Cummins* [44.22] (see [44.23]), on the basis of an analysis of tidal flow in a constricted channel of variable cross-section connecting two large bodies of water, showed that if the pressure gradient in the channel is primarily balanced by frictional forces, the extractable mean power (averaged over a tidal cycle) is given by

$$P_E = 0.556\rho g a Q_m \left[1 - \left(\frac{Q_m}{Q_{0m}}\right)^2\right] \,, \tag{44.21}$$

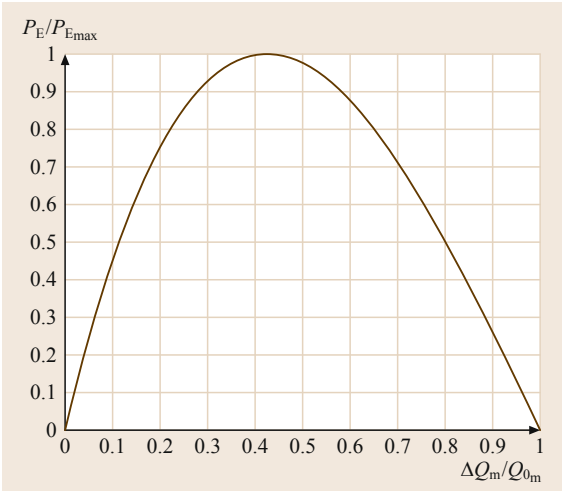

Fig. 44.5 Extracted power vs. reduction in flow rate, $\Delta Q_m = Q_{0m} - Q_m$, in the channel

where ρ is the density of water, Q_m and Q_{0m} are, respectively, the peak volume flow rates through the channel in the presence of/in the absence of power extraction, and a is the amplitude of a sinusoidal tidal head $a\cos(2\pi t/T)$ of period T between the two ends of the channel; the tidal volume flow rate is considered to be $Q = Q_m|\cos(2\pi t/T)|^{\frac{1}{2}}$. The result (44.21) is shown plotted in Fig. 44.5.

Extracting power from the tidal flow results in reduction $\Delta Q_m = Q_{0m} - Q_m$ in volume flow rate. Extractable power increases as ΔQ_m increases until

$$\Delta Q_m = \left(1 - \frac{1}{\sqrt{3}}\right) Q_{0m} = 0.42 Q_{0m}$$

(i. e., until there is 42% reduction in the flow rate), which marks the condition under which maximum mean power can be extracted from the channel,

$$P_{Emax} = 0.21\rho g a Q_{0m} \,. \tag{44.22}$$

Beyond this value of ΔQ_m, the extractable power drops to zero as $\Delta Q_m \to Q_{0m}$ or $Q_m \to 0$. If, on the basis of environmental impact considerations, a maximum of 5% reduction in channel flow rate (i. e., $\frac{\Delta Q_m}{Q_{0m}} = 0.05$) is permitted, then extraction of only 23% of the maximum extractable tidal power in the channel may be permitted. That is, $P_{EPermitted} = 0.23 P_{Emax}$.

On the basis of these considerations, and using (44.22) in a numerical simulation, *Haas* [44.24] assessed the theoretically available tidal energy resource in streams around the US coast, estimating the resource potential for tidal generation in USA to be 250 TWh/year. He showed that Alaska contains the largest number of locations with high kinetic power density, followed by Maine, Washington, Oregon, California, New Hampshire, Massachusetts, New York, New Jersey, North and South Carolina, Georgia, and Florida. The average tidal stream power density at a number of these locations exceeds 8 kW/m^2.

In practice, significant power extraction from tidal channels will require arrays involving thousands of turbines [44.25]. Theoretically, the power of an array of turbines can be estimated using (44.9)–(44.13); depending on the spacing of the turbines within the array, and the impact of the presence of the array and associated blockage of the overall flow of the current, the efficiency of each individual turbine will be affected [44.20, 21]. Additionally, if turbines are spaced not only cross-stream, but also upstream and downstream of each other, the wake effects of the upstream turbines will impact the inflow to the downstream turbine. This could potentially have a significant impact on the array's overall performance.

44.3 Assessment of Global Ocean Current Resources

In this section, we discuss the methodology for assessing ocean current energy resources and make an assessment of the energy potential of major ocean currents worldwide, with particular emphasis on the Florida Current [44.26–29], based on flow simulated using the Hybrid Coordinate Ocean Model (HYCOM) [44.30]. HYCOM is a data assimilative hybrid isopycnal-sigma-pressure coordinate ocean model aimed at depicting the state of the oceans at fine resolution in real time.

The 3-year time-averaged surface speeds of the global ocean currents computed using HYCOM are shown in Fig. 44.6, from which the strength of each of the major currents identified in Fig. 44.3 may be discerned. Correspondingly, regions with potential high ocean current energy resource potential can be identified from Fig. 44.6. Practical considerations, however, require that these regions be in accessible waters, generally close to shore, for cost-effective development and placement of the necessary infrastructure. On this basis, Fig. 44.6 suggests that the following regions, lying in the vicinity of the major western boundary currents, likely have good potential for development of ocean current energy: the east coast of the USA, the northeast coast of Brazil, the east and southeast coasts of Africa,

the east coasts of Japan and Taiwan, and the southeast coast of Australia.

The geostrophic components of western boundary currents may also be discerned from satellite altimetry data [44.31, 32].

As discussed in Sect. 44.2.2, major ocean currents are wind-driven surface currents that extend in a layer beneath the sea surface. The plot of time-averaged surface currents in Fig. 44.6 provides good indication of the global locations of high potential for development of ocean current energy. The actual levels of this potential also depend on the vertical extent and structure of the velocity field, which vary between the major currents and with associated geographic locations. In deep waters, the flow structure is primarily governed by baroclinic geostrophic flows associated with balance between pressure gradient forces and Coriolis force, whereas in shallower waters, frictional forces may become important, giving rise to steeper velocity gradients. The surface currents, therefore, penetrate relatively deeper in deep waters than in shallow waters; the ocean current energy resource is correspondingly higher at a site in deeper waters. The greater water depth, on the other hand, may pose challenges for installation of the infrastructure for energy extraction.

The ocean current energy flux per unit area or the power density at each node of the HYCOM computational grid may be estimated using

$$P_{\mathrm{u},i} = \overline{\frac{\rho_i}{2} U_i^3}\,, \tag{44.23}$$

where ρ_i is the seawater density and U_i the water speed at the i-th node (44.6). $P_{\mathrm{u},i}$ is averaged over the 3-year period considered. Here we compute and examine the characteristics of the power density at constant depths. In Figs. 44.7–44.11, the time-averaged power density $P_{\mathrm{u},i}$, for $P_{\mathrm{u},i} > 500\,\mathrm{W/m^2}$, is plotted globally at specified depths; $P_{\mathrm{u},i} < 500\,\mathrm{W/m^2}$ is likely to be too low to support commercial scale ocean energy extrac-

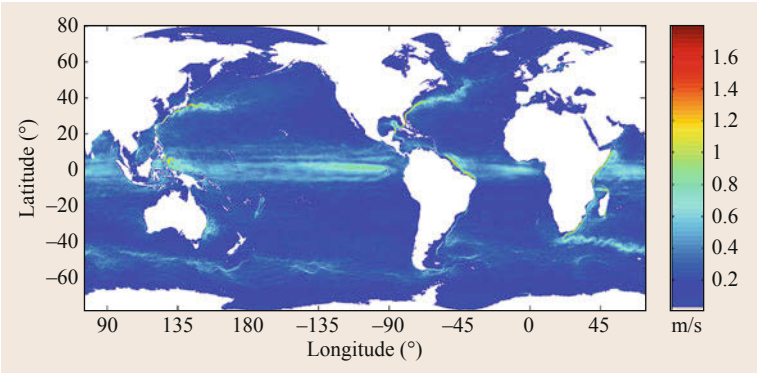

Fig. 44.6 3-year surface current average, HYCOM global model, 2009–2011

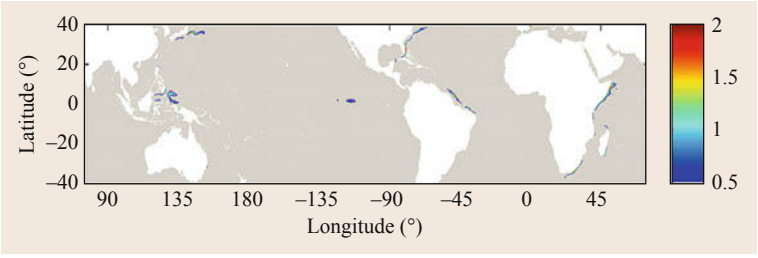

Fig. 44.7 3-year average ocean current power density at the sea surface in $\mathrm{kW/m^2}$

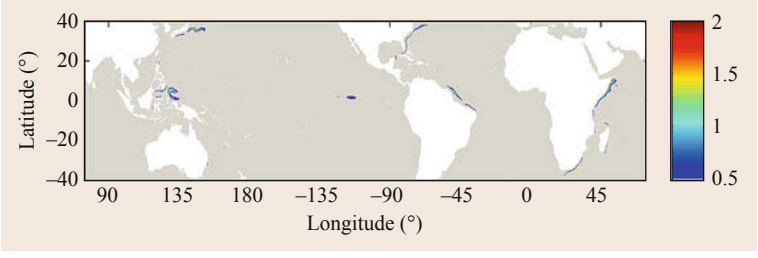

Fig. 44.8 3-year average ocean current power density at 30 m in $\mathrm{kW/m^2}$

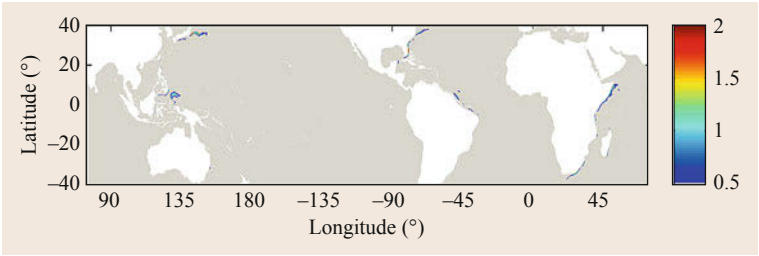

Fig. 44.9 3-year average ocean current power density at 50 m in kW/m^2

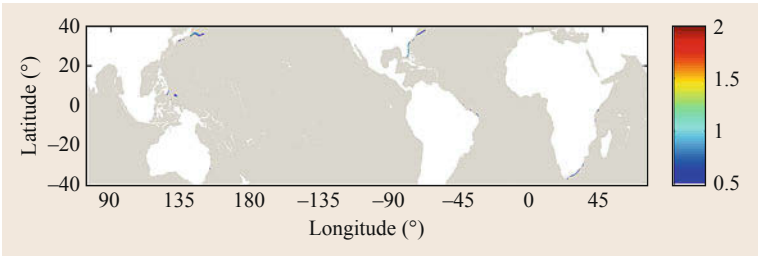

Fig. 44.11 3-year average ocean current power density at 100 m in kW/m^2

tion [44.24]. At the surface, where the current is the strongest, the power density is most dense. Since the surface currents decay with depth, the power densities decrease correspondingly, as is evident from Figs. 44.7–44.11.

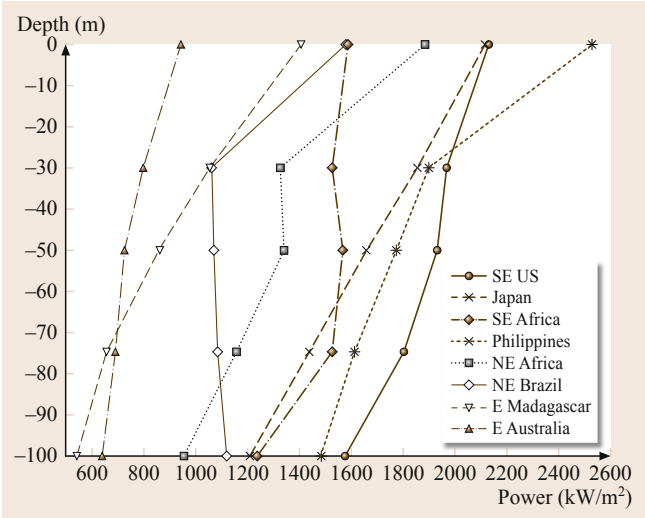

Fig. 44.12 Time average maximum power density in each region as a function of depth

Based on these plots, locations worldwide that have best ocean current energy potential are the east coast of the USA, the northeast and southeast coasts of Africa, the southeast coast of the Philippines, the eastern coast of Japan and Taiwan, the northeast coast of Brazil, the southeast coast of Africa, and the east coast of Madagascar; the corresponding currents are, respectively, the Gulf Stream (USA), the Agulhas Current (Africa), a combination of the North Equatorial, South Equatorial, and Equatorial Counter Current (the Philippines), the Kuroshio Current (Japan and Taiwan), the Southern Equatorial Current (Brazil), and the Mozambique Current (Madagascar).

The estimated maximum value of the time-averaged mean power density at various depths for each of the major ocean currents is provided in Fig. 44.12. The depth-specific maximum for each current is over the respective area where $P_{u,i} > 500\,\mathrm{W/m^2}$. The maxima are not necessarily at the same geographic points at each depth. At many of these locations, the ocean current energy potential extends to a depth of 100 m. This facilitates placement of turbine infrastructure at depths

Table 44.1 Ocean current energy extraction potential at 50 m depth

Region	Max power density [kW/m^2]	Sea floor depth [m]	Distance from shore [km]
US East Coast	1.93	500–600	57
Southeast Africa	1.66	700–800	28
The Philippines	1.57	3000–3500	32
Japan	1.78	3500–4000	116
Northeast Africa	1.34	400–500	12
Brazil	1.08	300–400	57
Madagascar	0.86	300–400	29
Australia	0.73	1400–1500	38

where impact on shipping is minimized but where the resource is still viable. It also facilitates placement of turbines with relatively large rotors.

The value of the power density is an important driving factor in choosing a viable location for turbine placement. The distance from the shore and the depth of the seafloor at the location are other factors, since they significantly determine the overall cost of designing, building, installing, and maintaining the turbine infrastructure. The length of power transmission cables and the associated costs increase the further the location is from shore. Additionally, operations and maintenance (OM) costs as well as installation costs of the turbine array at a distance from the shore increase accordingly. The depth of the ocean floor at the installation location significantly governs the type of installation required. The deeper the ocean floor, the more complicated the installation system and higher the OM costs, so that the overall costs are higher. For an installation depth of 50 m that avoids potential interference with shipping and interaction between the turbines and the free surface, the location of maximum power density, together with the associated distance from shore and the sea floor depth are compared in Table 44.1.

In Table 44.1, the highest maximum power density is 1.93 kW/m^2 and is off the US East Coast; however, it is 57 km offshore and the sea floor depth is 500–600 m. The choice of the installation location will, therefore, be a compromise between these three factors, as well as other considerations such as the state of the local electric grid infrastructure that will impact the overall economics of the installation. It is important to note that in several of these regions HYCOM predicted slightly lower power densities in much shallower water, a much more accessible resource for development; therefore a more rigorous regional site assessment, which is beyond the scope of this global analysis, is necessary. It is also important to note that HYCOM has been shown to significantly under predict the power density in some regions. For example, a measurement-based study estimates average power density of 2.2 kW/m^2 at 20 m-depth level at a location off South Africa, where the sea floor depth is approximately 100 m [44.33]. A second measurement-based study estimates average power density of 3.0 kW/m^2 at a 50 m-depth level off Florida [44.34]. These studies highlight the importance of conducting corroborative measurement based analyses.

Another factor of interest is the areal extent at an identified region over which viable hydrokinetic energy potential exists. In Table 44.2, average statistics for the area over which a given power density threshold is met are presented for the global currents 50 m-depth level. Additionally, the average power density over the region in which energy extraction may be viable – namely where the average power density is greater than 500 W/m^2 – is estimated.

An economics metric can be created to compare the energy development potential at these sites. A average power density and maximum power density would be positive factors in the economics metric of current energy development, while depth and distance from shore

Table 44.2 Area available for ocean current energy development at various locations at an operating depth-level of 50 m (1000 km^2)

Region	Area with power density greater than threshold (in ×1000 km^2)					
	> 500 W/m^2	> 750 W/m^2	> 1000 W/m^2	> 1500 W/m^2	> 2000 W/m^2	Average power density in area with $P_{u,i}$ > 500 W/m^2 [W/m^2]

Australia	33

would be negative factors. As the positive factors increase, so does the economic outlook of the array, and as the negative factors increase, the economic outlook of energy development at the site decreases. An example metric may be

$$F = \frac{(A\alpha)(P_{\text{umax}}\beta)(P_{\text{umean}}\gamma)}{(D\zeta)(d\xi)} , \qquad (44.24)$$

where A is the area over which the average power density is greater than 500 W/m^2 in units of 1000 km^2, α is the weighting factor for A in km^{-2}, $P_{\text{umax}} = \overset{\max}{i}\{P_{\text{u},i}\}$ is the maximum power density in W/m^2, β is the weighting factor for P_{umax} in m^2/W, $P_{\text{umean}} = \frac{1}{N}\sum_{i=1}^{N} P_{\text{u},i}$ is the mean power density within area A in W/m^2, γ is the weighting factor for P_{umean} in m^2/W, D is the distance from shore in km, ζ is the weighting factor for D in km^{-1}, d is the depth of the sea floor in m, and ξ is the weighting factor for d in m^{-1}. Using this example metric, and assuming that the weighting factors all have a numerical value of 1, the results for the global currents at 50 m are given in Table 44.3.

With all the weighting factors set to 1, the metric suggests that Northeast Africa is the best global location for hydrokinetic energy development, the metric being heavily biased by the distance of the potential from the shore (12 km). This metric can be modified not only by selecting other weighting factors, which were set to 1 in the case considered above, but also by changing the factors considered in the metric. Additional factors can be added or removed from this metric depending on the initial economic evaluation of the turbine array.

44.3.1 Gulf Stream Case Study

As an example, the Gulf Stream off the east coast of the United States is considered further for its hydrokinetic resources using the HYCOM Gulf of Mexico basin model data [44.26, 27]. The time-averaged power densities for various depths are plotted in Figs. 44.13–44.17. The figures highlight the power density decay with

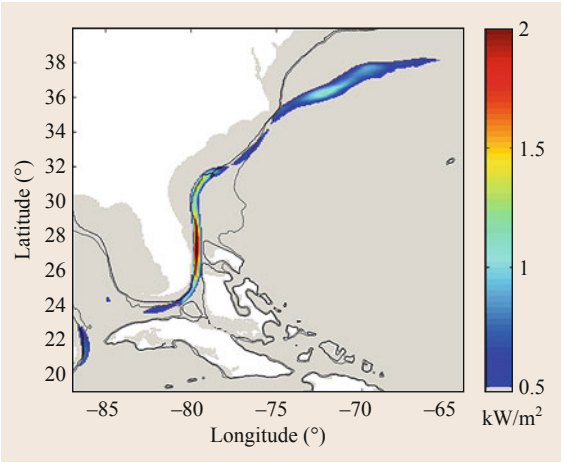

Fig. 44.13 3-year average power density of the Florida Current at the surface

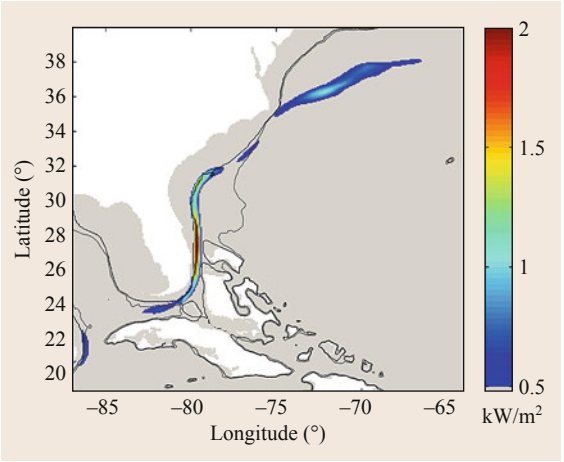

Fig. 44.14 3-year average power density of the Florida Current at 30 m

depth. This is especially apparent in comparing the plot for the power density at the surface (Fig. 44.13) with that at 100 m (Fig. 44.17). As seen in the figures, the highest power density in the Gulf Stream is off the east coast of Florida, corresponding to the Florida Current – the portion of the Gulf Stream that flows off the east coast of Florida. The proximity to large population centers, including Miami, Fort Lauderdale, and West Palm Beach, make the Florida Current an attractive energy resource for the state of Florida. Figure 44.18 highlights the relationship between latitude and power density in this region, suggesting that the latitude with the highest power density is approximately 27°N.

The factors that govern resource assessment are shown in Table 44.4. It may be noted that the location of the maximum power density at the surface is

Table 44.4 Gulf Stream hydrokinetic resource assessment factors (based on HYCOM data [44.26, 27])

Depth [m]	Location		Power density [kW/m^2]	Average power density in area with $P_{u,i} > 500$ W/m^2 [W/m^2]	Sea floor depth [m]	Distance from shore [km]
	Latitude, °N	Longitude, °E				
0	27.09	−79.76	2.13	797	400–500	35
30	27.45	−79.68	1.97	782	500–600	57
50	27.45	−79.68	1.93	776	500–600	57
75	27.45	−79.68	1.81	762	500–600	57
100	27.45	−79.68	1.58	739	500–600	57

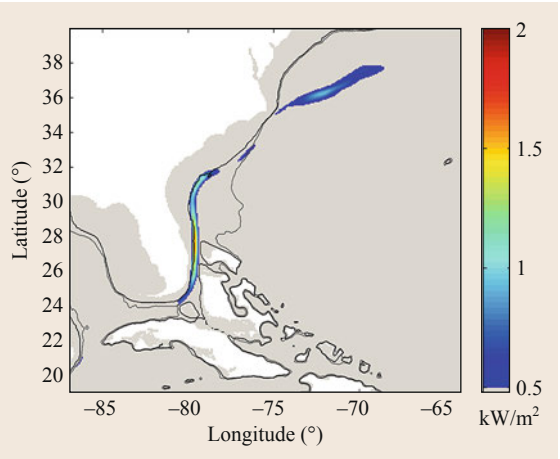

Fig. 44.17 3-year average power density of the Florida Current at 100 m

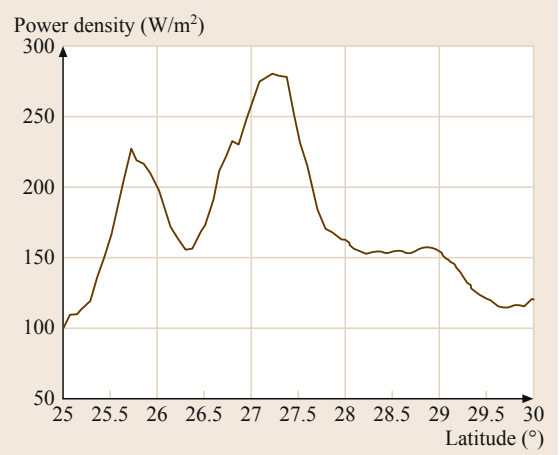

Fig. 44.18 Variation in Florida Current power density with latitude

different from the location of the corresponding values at depths between 20 and 100 m. This suggests that use of power density based on surface current data in site selection may be misleading, since turbine arrays would be installed at some depth below the water surface. The maximum power densities at 30, 50, 75, and 100 m depth are at a location 40 km away. The maximum power densities at these depths are at the same geographic location within the Florida Current; however, this may not happen in every global current. Care

is needed in making the resource assessment and deciding on optimal locations. The type and size of devices used and the water depth at which they operate optimally will dictate the depth at which a detailed resource assessment would be required.

Based on this overall assessment, the best location in the Florida Current for hydrokinetic energy extraction seems to be at 27.45°N, 79.76°W. However, use of the metric (44.21) may suggest an alternative location as being more desirable. A method for finding an ideal location in the Florida Current is suggested by *Duerr* [44.26], based on consideration of the variability of the hydrokinetic resource with latitude rather than water depth. The Florida Current is divided into constant latitude cross-sections to evaluate the hydrokinetic power over the entire cross-section, as in (44.7). In addition to the hydrokinetic power, the hydrokinetic power density, the depth at the core of the current, and the distance of the core from the shore are evaluated at each cross-section from 25 to 30°N.

The economics metric in this case is slightly modified from (44.24)

$$F = \frac{(A\alpha)(P\beta)(P_{\text{umean}}\gamma)}{(D\zeta)(d\xi)} , \tag{44.25}$$

where the P_{umax} term in (44.24) has been replaced with P, the average power at the cross-section in GW, and the unit of β is adjusted accordingly to GW^{-1}. The values of the metric F based on the HYCOM data, with the weighting factors set to 1 as before and with D now given by the location of the core of the current, are shown in Table 44.5.

This economics metric suggests that 26.95°N is the best latitude for hydrokinetic energy extraction. This

Table 44.5 Florida hydrokinetic resource assessment factors based on constant latitude cross-section analysis (using HYCOM data)

Latitude [°N]	Power [GW]	Mean power density [W/m^2]	Depth [m]	Distance [km]	Area with power density > 500 W/m^2 [km^2]	Metric F

29.76	11.9	115.1	700	132	7.28	0.11
29.90	11.7	115.4	700	132	7.12	0.10
30.04	11.7	123.6	600	140	7.02	0.12

is only one method of calculating a suitable metric, and other factors can be introduced into the equation. Overall, based on the constant-latitude economics metric (44.25) and the constant-depth economics metric (44.21), Florida Current's viable resource seems to be located between 26.45 and 27.45°N. These results, based on the ocean model, would need to be complemented by comprehensive in-situ surveys and in-depth studies to determine any discrepancies between the ocean models and in-situ data.

Overall, present-day ocean models based on data assimilation, such as HYCOM, provide excellent predictions of oceanic flows. However, care is needed when using ocean models. For instance, coarseness of the model grid may result in under or over prediction of, say, the speed of a current or the associated volume flow rate and correspondingly under or over-prediction of its hydrokinetic energy resource. Comparing the data from an ocean model with in-situ measurements is, therefore, essential in validating the predictions of the model. Once such deficiencies in the ocean model have been identified and characterized, the resource prediction can be better qualified. Local models with refined grids may be considered for improvement of the model.

While HYCOM is one of the most widely used ocean models, the velocity predictions of the global model are not perfect for ocean energy resource assessment. In both the Florida Current [44.28] and off the coast of Brazil [44.35], it has been shown that the HYCOM global model under-predicts the current velocities. While the overall trend in the difference between the in-situ data and the HYCOM is the same in both studies, the *Jeans* et al. [44.35] study suggests that HYCOM's prediction off Brazil is highly uncorrelated with the in-situ data, while the *Duerr* et al. [44.28] study suggests that HYCOM predicts the overall trend in the velocity data well – that is, the shape of the velocity profile predicted by HYCOM is very similar to the in-situ observations – but under-predicts the value of maximum velocity.

The applicability of an ocean model of sufficiently fine resolution to different global locations and oceanic conditions needs to be studied in order that hydrokinetic energy predictions based on the model can be suitably qualified. In *Duerr* et al. [44.28], it is suggested that a gain term – calculated using in-situ and model data – may be applied to the HYCOM data in order to improve the agreement between the model and physical conditions. This process is straightforward if in-situ field observations of currents are available. However, in the absence of such data, the details of the ocean model should be considered in order to understand possible implications in using the model for hydrokinetic resource assessment.

44.4 Other Considerations

A number of other considerations are involved in assessment of marine hydrokinetic energy resources. These include:

- *Design of devices and technologies*. To optimize performance while minimizing environmental impact at a specific site, special consideration is needed in designing devices and arrays of devices in light of prevailing local conditions. These factors could also be introduced in the metrics (44.21), (44.25). Particular considerations include:
  - Material selection, corrosion and bio-fouling control, and advanced coatings for devices and their components
  - Assessment of hydrodynamic loads and cavitation
  - Effect of shear and turbulence on hydrodynamic performance
  - Device machinery, generators and power takeoff systems
  - Optimization in design of single and arrays of devices through modeling and simulation
  - Flow and wake interactions in arrays of devices.
- *Deployment and operations*. Robust device deployment systems and low OM costs are required for viable ocean energy development. Special considerations are needed for:
  - The choice of mooring systems and offshore platforms
  - Access requirements for the devices for planned and unplanned maintenance
  - Implementation of smart machine condition monitoring for system reliability
  - Modeling and simulation studies to assess maintenance costs.
- *Environmental impact*. Regulatory agencies require that before permission to begin marine hydrokinetic ocean energy development can be granted, an assessment of the environmental impact the activity may cause needs to be made. It is expected that the activity will not have zero impact, but will require consideration of ways of mitigating the impact. Typical issues that arise are:
  - Impact on aquatic life and mortality around devices
  - Operational and construction noise

- Electromagnetic field emissions from device infrastructure and transmission cables
- Impact on shipping, protected sites and naval operations
- Impact on road traffic and other shore activities in the vicinity ocean energy development
- Impact on energy resource. In the case of ocean currents, determination of the potential effects of energy extraction on the ocean circulation systems.

- *Socio-economics of marine hydrokinetic energy*. Economic and social issues associated with the energy development, marine spatial planning and the social acceptability of the energy extraction technologies and their implementation, including their sustainability, are significant considerations in determining viability of the resource. These include:
  - Cost of electricity compared with other sources
  - Concerns with impact of the energy technologies on stakeholder activities and their livelihood
  - Political and social will.

Based on these considerations, an iterative process may result in making the final selection of a suitable location that has the desired attributes.

45. Ocean Wave Energy Conversion Concepts

Nikolaos I. Xiros, Manhar R. Dhanak

The purpose of this chapter is to present the basic concepts of ocean wave energy conversion as an extension to the supporting subjects presented earlier in this handbook so that they can be useful to scientists, engineers and inventors. Although new research regarding all wave energy conversion aspects has been unveiling continuously over the past few decades and is expected to remain so in the foreseeable future, they are based on only a few fundamental wave energy conversion techniques. These methods are described and their uses and performance are illustrated. Finally, an account of several recent developments and advances in ocean wave energy research is presented as an appendix with an emphasis to commercialization of different technologies in conjunction with their financial viability, techno-economic, and environmental impact.

Energy of progressive ocean surface waves transported by the waves across the ocean to the shores is a significant source of renewable energy worldwide. For a regular progressive wave of small height H, circular frequency ω, and wavelength λ propagating along the direction x, given by the surface elevation

$$\eta(x,t) = \frac{H}{2}\cos(\omega t - kx)\,, \tag{45.1}$$

where $k = 2\pi/\lambda$ is the wave number, the rate of transport of energy per unit length of the wave frontage J is given by

$$J = \frac{\mathrm{d}\hat{E}}{\mathrm{d}t} = \frac{1}{8}\rho g H^2 c_\mathrm{g}\,. \tag{45.2a}$$

Here, $\hat{E}$ is the mean energy density and c_g is the group speed of the waves; in deep water, using

$$c_\mathrm{g} = \mathrm{g}/2\omega\,,$$

we have

$$J = \frac{\rho g^2 H^2}{16\omega}\,. \tag{45.2b}$$

Equations (45.2) represent the available power per unit length of the wave frontage that can potentially be harnessed. A wave energy converter (WEC) is the name given to a device that captures and converts wave energy for electricity generation or other useful work.

45.1 Basic Concepts in Primary Energy Capture

A number of WEC devices have been designed and developed, although there is no clear best device and to date only a few devices have been deployed in the field. Several factors influence concept designs, including whether the device is located offshore, near-shore, or onshore or whether the device is to be floating, submerged, or bottom standing, and whether the energy conversion machinery is mechanical, hydraulic, or pneumatic. The choice of a particular WEC method of primary energy capture depends on these and other factors, including environmental impact, economic, and marine spatial planning considerations. *Grimwade* et al. [45.1], *Falcão* [45.2], and *Drew* et al. [45.3] provide a detailed review of WEC technologies. The basic concepts of primary energy capture of the typical WEC devices are typically classified as:

- *Point absorber* is typically a floating buoy of size small compared with the length of prevailing waves and captures wave energy through wave-induced heaving or pitching motion.
- *Oscillating water column* involves a tube-like structure with air in the tube above a column of water that oscillates and acts as a piston in compressing and decompressing the air and ducting it through a pneumatic turbine.
- *Submerged pressure differential device* is based on exploiting the dynamic pressure differential induced underwater through the motion of waves over the device.
- *Oscillating wave surge converter* extracts energy from the surge motion of the waves. They are generally seabed mounted devices located in near shore sites.
- *Attenuator and terminator* are generally long floating structures aligned in parallel with the wave direction, which then absorbs the motion caused by the waves. Its motion can be damped to produce energy.

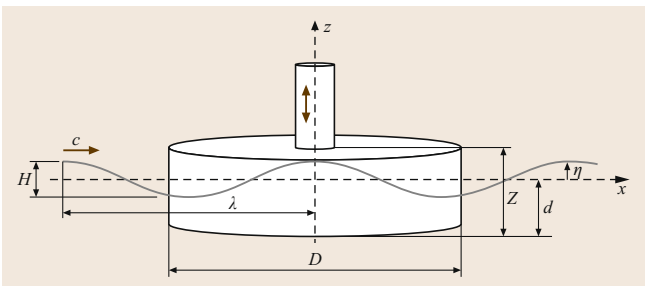

Fig. 45.1 Floating body undergoing purely heaving motion in waves

- *Overtopping devices*are composed of a wave surge/focusing system, and contains a ramp over which waves travel into a raised storage reservoir.

These concepts are discussed in detail below.

45.1.1 Point Absorbers

Point absorbers are small floating or submerged buoys that absorb wave energy through their heaving or pitching motion in response to the action of the waves. The size of the buoy is typically small compared with the wavelength λ of the dominant wave, or wave with the most energy, at the site. The heaving/pitching motion of the buoy in turn excites an electromechanical energy generator via a power takeoff (PTO) system.

A floating system such as the one shown in Fig. 45.1 undergoes heaving motion according to the following equation

$$(m + a_{33})\,\ddot{z} + b_{33}\dot{z} + Kz = F_Z + F_d + F_R\,, \qquad (45.3)$$

where z is the vertical displacement of the floating system, m is the mass of the system, a_{33} is the added mass, b_{33} is the coefficient of radiation damping associated with waves generated by the heaving response, K is the hydrostatic restoring force coefficient, given by $K = \rho g A_{wp}$ for a freely floating body with ρ the mass density of seawater and A_{wp} the water plane area of the float, F_Z is the wave exciting force, F_d is the viscous (nonlinear) damping force, and F_R is the force due to an associated PTO and other resisting forces and is represented here as mechanical damping, given by $F_R = -R_m\dot{z}$. In practice, the buoy in Fig. 45.1 would be connected to a large damping plate (Fig. 45.2) so that F_R includes additional contributions with spring-like restoring force, proportional to z and added-mass-type inertia force proportional to $\ddot{z}$. See [45.4] and (45.42) for the inclusion of these additional contributions to F_R.

The natural heaving frequency of the floating body is

$$f_z = \frac{1}{T_z} = \frac{\omega_z}{2\pi} = \frac{1}{2\pi}\sqrt{\frac{K}{m + a_{33}}}\,, \qquad (45.4)$$

where T_z is the natural heaving period, and ω_z is the natural circular heaving frequency; see Sect. 45.2.4 for the modification to ω_z to include restoring force and inertia forces associated with the PTO system. The design of a point absorber WEC is based on approximately matching this natural frequency with the frequency of the dominant waves at the site, and inducing resonant

or near resonant heaving motion of the floating body. A WEC is designed to ensure that f_z lies in the range of frequencies of waves at the site; this is achieved through the selection of its mass and restoring force.

For purely heaving motion in regular waves of frequency ω, given by (45.3), the corresponding induced wave force F_Z (choosing $x = 0$ to coincide with body center) may be expressed as

$$F_Z = F_0 \cos(\omega t + \gamma) \,, \tag{45.5}$$

where γ is a phase angle associated with the wave force ($\gamma = 0$ for a body that is symmetric in the x-z and y-z planes). Then from (45.3), on choosing $F_R = -R_m \dot{z}$ and ignoring the viscous forces F_d, the body displacement z is given by

$$\begin{aligned} z &= \frac{\left(\frac{F_0}{K}\right)\cos(\omega t + \gamma - \sigma_z)}{\sqrt{\left(1 - \frac{\omega^2}{\omega_z^2}\right)^2 + \left[2\frac{(\Delta_m + \Delta_D)\omega}{\omega_z}\right]^2}} \\ &= Z_0 \cos\left(\omega t + \gamma - \sigma_z\right) \,, \end{aligned} \tag{45.6}$$

where Z_0 is the amplitude of the motion, $\sigma_z = \tan^{-1}\left(2(\Delta_m + \Delta_D)\omega\omega_z/(\omega_z^2 - \omega^2)\right)$ is the phase lag between the wave motion and the heave response, and $\Delta_m = R_m\omega_z/2K$ and $\Delta_D = b_{33}\omega_z/2K$ are the dimensionless mechanical and radiation damping coefficients, respectively. If, for simplicity, the frequency dependence of $\Delta_Z = (\Delta_m + \Delta_D)$ and a_{33} can be neglected and these quantities considered as constants, then the amplification factor $Z_0/(F_0/\rho K)$ and the phase angle σ_z may be depicted as in Fig. 45.3 as functions of ω/ω_z. At resonance, $\sigma_z = \pi/2$, $\omega/\omega_z = 1$ and $Z_0 = F_0/(2(\Delta_m + \Delta_D)K) = F_0/((R_m + b_{33})\omega_z)$.

At resonance, the heave amplitude achieves a maximum value, the magnitude of which is governed by the damping factor. Minimizing the damping factor and the restoring force, as part of designing a WEC, contributes to maximizing the resonance response. The heave velocity and acceleration of the body are, respectively, given by

$$\begin{aligned} \frac{\mathrm{d}z}{\mathrm{d}t} &= -\omega Z_0 \sin(\omega t + \gamma - \sigma_z) \quad \text{and} \\ \frac{\mathrm{d}^2 z}{\mathrm{d}t^2} &= -\omega^2 Z_0 \cos(\omega t + \gamma - \sigma_z) \,. \end{aligned} \tag{45.7}$$

The exciting mechanical power is given by $F_Z\frac{\mathrm{d}z}{\mathrm{d}t}$, where F_Z is given by (45.5). Thus, choosing $\gamma = 0$ for a symmetrical body, the average exciting power over one wave period, $\hat{P}_{Ez}$, is given by

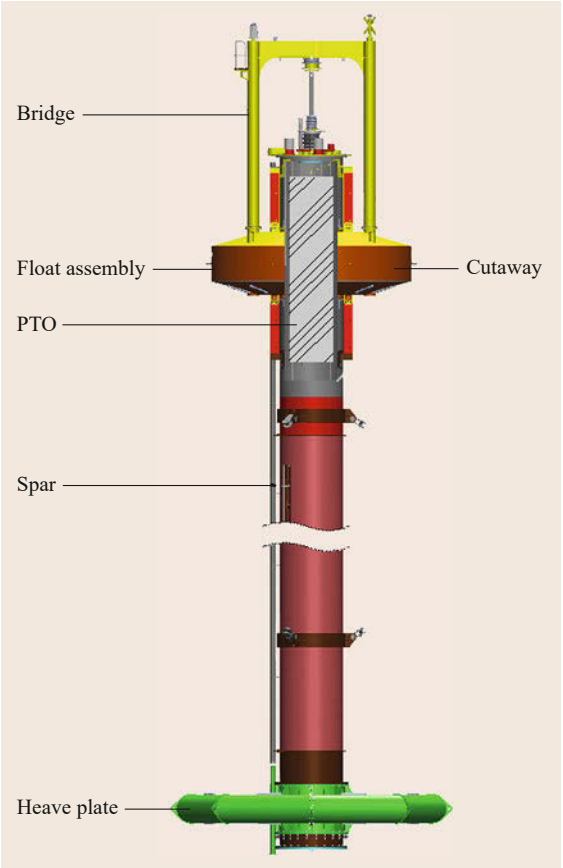

Fig. 45.2 Practical floating WEC buoy, PowerBuoy (from Ocean Power Technologies)

$$\begin{aligned} \hat{P}_{Ez} = \frac{1}{T_z}\int_0^{T_z} F_0\omega Z_0[-\cos\sigma_z \sin\omega t\cos\omega t \\ + \sin\sigma_z \cos^2(\omega t)]\mathrm{d}t = \frac{F_0\omega Z_0 \sin\sigma_z}{2} \,. \end{aligned} \tag{45.8}$$

The radiated power and the absorbed or mechanical power are, respectively, given by $b_{33}\dot{z}^2$ and $R_m\dot{z}^2$, so that the corresponding average radiated and absorbed power over one wave period, $\hat{P}_{Rz}$ and $\hat{P}_{az}$ are given by

$$\hat{P}_{Rz} = \frac{b_{33}(\omega Z_0)^2}{2} \,; \quad \hat{P}_{az} = \frac{R_m(\omega Z_0)^2}{2} \,. \tag{45.9}$$

$\hat{P}_{az}$ is the absorbed power that is utilized. It is optimized if $R_m = R_{m_{opt}}$ is selected so that $(\partial\hat{P}_{az}/\partial R_m)_{R_{m_{opt}}} = 0$

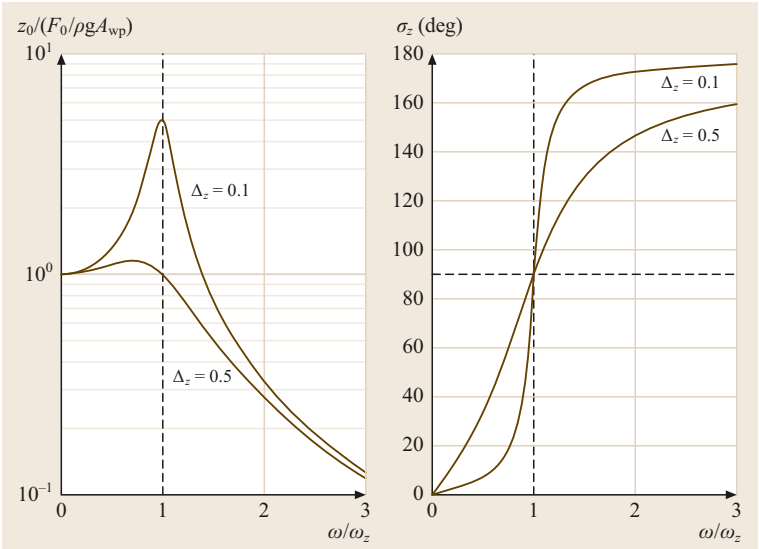

Fig. 45.3 Amplification factor and phase angle variation in heaving motion of a floating body; $\Delta_Z = \Delta_m + \Delta_D = (R_m + b_{33})\omega_z/2K$

[45.5]. Thus, for $R_m^2 \equiv R_{m_{opt}}^2 = K^2/\omega^2\left(1-\omega^2/\omega_z^2\right)^2 + b_{33}^2$, we obtain

$$\hat{P}_{az_{opt}}(\omega) = \frac{\frac{\omega F_0^2}{4}}{\omega b_{33} + \sqrt{K^2\left(1-\frac{\omega^2}{\omega_z^2}\right)^2 + \omega^2 b_{33}^2}} \,. \tag{45.10}$$

$\hat{P}_{az_{opt}}$ attains its maximum value when $\omega = \omega_z$, for which $R_m = b_{33}$ and

$$\hat{P}_{az_{opt}}(\omega_z) = \frac{F_0^2}{8b_{33}} \quad \text{and} \quad \hat{P}_{Ez_{opt}} = \frac{F_0^2}{4b_{33}} \,. \tag{45.11}$$

Equations (45.11) imply a maximum 50% efficiency $\eta_{eff_{max}} = \hat{P}_{az_{opt}}/\hat{P}_{Ez_{opt}}$ in the case of an axisymmetric body. For nonsymmetric bodies, involving destructive interference between the incident wave and waves generated by the heaving float downstream of the body, higher efficiencies may be expected [45.6, 7].

It may be noted from (45.5) and (45.7) that at the optimal resonance condition, with $\sigma_z = \pi/2$, $\omega = \omega_z$, and $R_m = b_{33}$, the heaving velocity of the buoy, $dz/dt = \omega_z Z_0 \cos(\omega_z t + \gamma) = F_Z/2b_{33}$, is in phase with the incident wave forcing.

Neglecting the frequency dependence of a_{33} and b_{33} (typically, this is so at high frequencies) the ratio $[\hat{P}_{az_{opt}}(\omega)/F_0^2(\omega)]/[\hat{P}_{az_{opt}}(\omega_z)/F_0^2(\omega_z)]$ is plotted in Fig. 45.4 for two different values of Δ_D.

Inspection of (45.10) and Fig. 45.3 suggests that while a smaller value of Δ_D means a larger value of $\hat{P}_{az_{opt}}(\omega_z)$, it implies a narrower range of frequencies over which wave energy can be harnessed. *Falnes* [45.5] shows that the maximum absorbed power $\hat{P}_{az}$ that can be utilized may alternately be given by

$$\hat{P}_{az_{opt}}(\omega) = \left(\hat{P}_{Ez} - \hat{P}_{Rz}\right)|_{R_m = R_D} = \frac{1}{2}\left[F_0 \omega Z_0 \sin\sigma_z - b_{33}(\omega Z_0)^2\right],$$

which is maximum when $\omega Z_0 = F_0 \sin\sigma_z/2b_{33}$, giving

$$\hat{P}_{az_{max}} = \frac{F_0^2 \sin^2\sigma_z}{8b_{33}} \,, \tag{45.12}$$

which at the condition of resonance, when $\sigma_z = \pi/2$, is the same as $\hat{P}_{az_{opt}}(\omega_z)$ in (45.11).

An absorption or capture width, $d_a = \hat{P}_{az}/J$, where J given by (45.1), is defined as the width of the wave front across which passes an average amount of power equal to that absorbed by the point absorber; note that J is the power density per unit length of the wave frontage. Thus, the maximum absorption width for a point absorber is $d_{a_{max}} = F_0^2/(8Jb_{33})$. For a heaving cylinder

$$b_{33} = \frac{2\pi F_0^2}{\lambda \rho g H^2 c_g} \tag{45.13}$$

using reciprocity [45.8]. Then we have from (45.12) with $\sigma_z = \pi/2$,

$$\hat{P}_{az_{max}} = \frac{F_0^2}{8b_{33}} = \frac{\lambda \rho g H^2 c_g}{16\pi} = \frac{\lambda}{2\pi} J \quad \text{and}$$
$$d_{a_{max}} = \frac{\lambda}{2\pi} \,. \tag{45.14a}$$

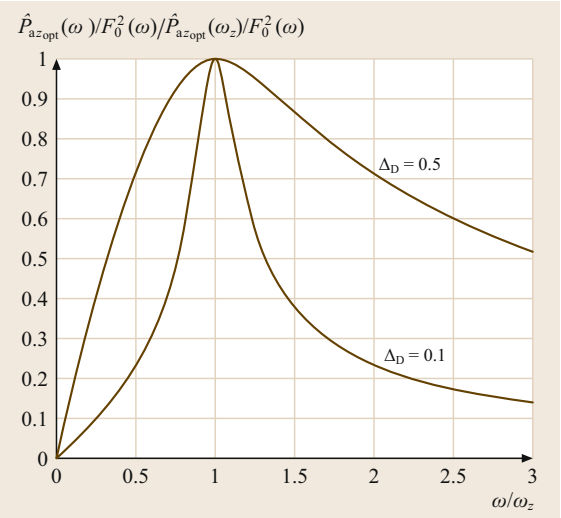

Fig. 45.4 Characteristics of optimal power absorption for two values of Δ_D

In deep water, using $c_g = g/2\omega$, and $\lambda = 2\pi g/\omega^2$, this becomes

$$\hat{P}_{az_{max}} = \frac{\rho g^3 H^2}{16\omega^3} \,. \tag{45.14b}$$

Thus a point absorber absorbs much more energy than it is incident on its cross-section [45.9–11]. Since the wave energy is typically available in a narrow spectral frequency band, a properly tuned point absorber can be an effective WEC. *Budal* [45.12] has shown that for two parallel rows of linear arrays in normally incident waves, the spacing can be as large as λ for perfect absorption, owing to the interference of adjacent buoys.

Similar considerations apply for pitching and combined heaving and pitching motions of a floating body [45.13, 14]. *Falnes* [45.7] provides consideration for the effect of inclusion of a PTO system (see [45.4] and Sect. 45.2.4), as well as consideration of arrays of point absorbers.

Well-known examples of point absorber systems include the Power Buoy, Seabased, Wavebob, AquabuOY, CETO III, and Wave Star.

45.1.2 Oscillating Water Column

An oscillating water column (OWC) is a hollow structure that is partially submerged, being open to the sea below the water surface. It encloses a column of air above the column of water (Fig. 45.4). Waves induce the water level in the structure to rise and fall, leading to compression and expansion of the air column. The trapped air flows to and from the open air through a turbine that can rotate due to airflow in either direction. The mechanical conversion of energy via the rotation of the turbine is used to generate electricity. *Heath* [45.15], and *Falcão* and *Henriques* [45.16] provide reviews of OWC WECs.

The instantaneous air pressure in the air chamber in Fig. 45.4 is commonly modeled as being uniform, taking into account the compressibility of the air in the chamber [45.5, 17–19]. Let the uniform air pressure in the chamber be given by, $p(t) = p_a(t) + p_{atm}$, where $p_a(t)$ represents the variation in pressure in the chamber in response to the oscillation of the water column from the equilibrium pressure p_{atm}, which is considered the same as the external ambient pressure and is assumed constant. For isentropic flows,

$$\frac{p}{p_{atm}} = \left(\frac{\rho}{\rho_{atm}}\right)^{\gamma} , \tag{45.15a}$$

where $\rho(t) = \rho_a(t) + \rho_{atm}$ and ρ_{atm} are the respective instantaneous air densities in the chamber corresponding to pressures $p(t)$, and equilibrium pressure p_{atm}, and $\gamma = 1.4$ under adiabatic conditions. $p_a(t)$ is the excess pressure in the chamber over the ambient. On the basis of linear theory with $|p_a| \ll p_{atm}$, (45.15a) can be shown using a Taylor expansion, to imply

$$\frac{d\rho_a}{dt} = \frac{1}{c_0^2}\frac{dp_a}{dt} \,; \quad c_0 = \sqrt{\frac{dp}{d\rho}} \approx \sqrt{\frac{\gamma p_{atm}}{\rho_{atm}}} \,. \tag{45.15b}$$

Here, c_0 is the speed of sound that is constant to leading order in the linearized analysis. The instantaneous rate of change of mass in the chamber in response to the OWC is then given by

$$\begin{aligned} \dot{m} &= \frac{d(\rho_a \Omega)}{dt} = \rho_a \frac{d\Omega}{dt} + \Omega \frac{d\rho_a}{dt} \\ &\approx \rho_{atm} \frac{d\Omega}{dt} + \Omega_0 \frac{1}{c_0^2}\frac{dp_a}{dt} \,, \end{aligned} \tag{45.16}$$

where $\Omega(t)$ is the instantaneous volume of the air chamber, and Ω_0 is the volume of the air chamber under equilibrium conditions. Then by the conservation of mass, we have

$$\dot{m} = -\rho_{atm} Q_{out} \,, \tag{45.17}$$

where Q_{out} is the airflow rate across the turbine. Considering that Q_{out} is primarily a function of the pressure difference across the turbine. Thus, linearizing about the equilibrium conditions,

$$Q_{out}(p_a) \approx Q_{out}(0) + p_a \left.\frac{\partial Q_{out}}{\partial p_a}\right|_{p_a=0} \,, \tag{45.18}$$

where $Q_{out}(0) \approx 0$ is the mean flow through the turbine for flow driven purely by the oscillatory motion; $(\partial Q/\partial p_a)|_{p_a=0}$ depends on the characteristics of the generator. *Sarmento* and *Falcão* [45.18] suggest that for a Wells turbine, $\dot{m} \approx (KD_2/n)p_a$, where D_2 is the turbine diameter (Fig. 45.4), n is the rotational speed of the turbine, p_a is the pressure drop across the turbine, and K is a dimensionless design constant that depends on the turbine characteristics; thus, from (45.18), $(\partial Q_{out}/\partial p_a)|_{p_a=0} = -KD_2/(\rho_{atm} n)$. Then from (45.16), we have

$$\frac{d\Omega}{dt} \approx \frac{KD_2}{\rho_{atm} n} p_a - \frac{\Omega_0}{\rho_{atm} c_0^2} \frac{dp_a}{dt} . \tag{45.19}$$

If the structure is fixed, $d\Omega/dt$ is given by the rate of volume of water that is pumped into the chamber by the wave motion,

$$\frac{d\Omega}{dt} = \iint_{S_1} w_1 dS \approx \iint_{S_1} \frac{d\eta_1}{dt} dS , \tag{45.20}$$

where $w_1(r, \theta, t)$ is the vertical velocity at the internal free surface, given by the small displacement $z = \eta_1$ of the surface as shown in Fig. 45.4, and the integral is over the area S_1 of the internal water surface; the last term on the right is based on the linearized kinematic boundary condition at the free surface. *Falnes* [45.5], and *Martins-Rivas* and *Mei* [45.17] provide a detailed analysis of the hydrodynamics associated with the OWC to enable determining Q and p_a [45.16], posing a linearized potential flow problem and decomposing it into diffraction and radiation problems. The full details of the analysis are fairly complex and can be found in these papers.

The power output rate, averaged over an oscillatory period, at which the chamber pressure does work in pushing the air through the turbine is

$$\begin{aligned} P_{out} &= \overline{\dot{m} \frac{p_a}{\rho_{atm}}} = \frac{KD_2}{n\rho_{atm}} \overline{p_a^2} \\ &\approx \left(\overline{\frac{d\Omega}{dt} p_a} + \frac{1}{2c_0^2 \rho_{atm}} \overline{\frac{dp_a^2}{dt}} \right) = \overline{\frac{d\Omega}{dt} p_a} , \end{aligned} \tag{45.21}$$

since $\overline{dp_a^2/dt}$ averages to zero for oscillatory variation of the pressure.

If the hollow structure is considered to be in the form of a fixed vertical circular pipe shown in Fig. 45.5, then the water column in the pipe has a natural frequency of oscillation [45.13]

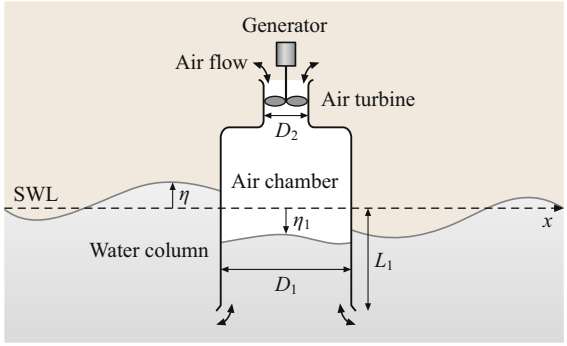

Fig. 45.5 Schematics of an OWC WEC

$$\begin{aligned} f_c = \frac{1}{T_c} = \frac{\omega_c}{2\pi} &\approx \frac{1}{2\pi} \sqrt{\frac{\rho g S_1}{\rho S_1 (L_1 + L_1')}} \\ &= \frac{1}{2\pi} \sqrt{\frac{g}{L_1 + L_1'}} , \end{aligned} \tag{45.22}$$

where L_1 is the undisturbed length of the water column and L_1' represents a contribution due to the added mass associated with the motion of the water column. When the frequency of a sinusoidal wave matches ω_c, resonance occurs and $|d\Omega/dt|$ is maximum. If the structure also undergoes heaving motion, a peak value in the air velocities can also be expected at the heaving resonant frequency ω_z of the structure given by (45.3) [45.20]. The air flow is optimized if the structure is designed so that $\omega_c = \omega_z$.

45.1.3 Submerged Pressure Differential Devices

For a surface wave of small amplitude in water of depth h, described by (45.1), the pressure in the water column is given by

$$p = \rho g \frac{\cosh[k(z+h)]}{\cosh(kh)} \eta(x,t) - \rho g z , \tag{45.23}$$

so that it varies in tune with the free-surface elevation. That is, the dynamic pressure is high at a location under a crest and low under a tough. Submerged pressure differential devices, which are typically located on the seabed near shore, exploit this variation for wave energy conversion to electricity. A well-known device in this category is the Archimedes wave swing (AWS), which heaves in response to the passage of a wave over it. A schematic of the device is shown in Fig. 45.6. AWS is an air-filled cylindrical chamber that consists of two parts, a lid, known as the

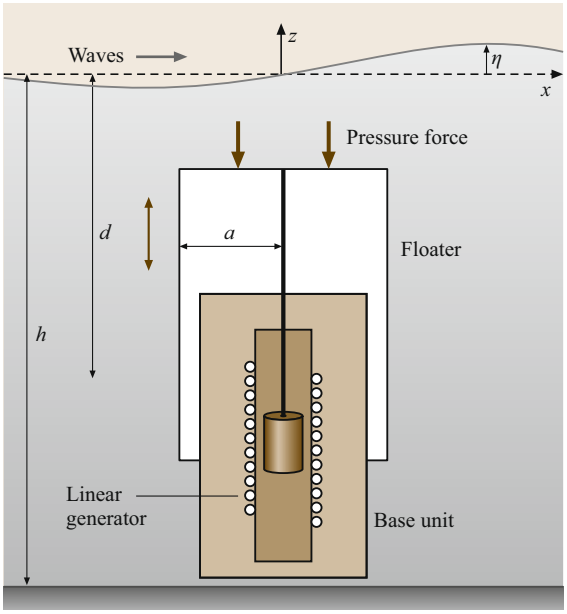

Fig. 45.6 Schematics of submerged pressure differential device, AWS (after [45.2])

floater, which heaves in response to wave motion, and a fixed bottom unit that houses a linear electric generator [45.21]. The floater, as it heaves, is closest to the base unit when under a crest and furthest from it when under a trough. By adjusting natural heaving frequency to match the average wave frequency, optimal energy harvesting conditions can be attained. The motion of the floater is governed by an equation similar to (45.3), with the spring constant K being given by $K = -(\mathrm{d}F_\mathrm{s}/\mathrm{d}z)|_{z_0}$, where F_s is the resisting force with contributions from the air pressure inside the chamber, the hydrostatic pressure, and the force associated with the generator [45.21] and the wave-induced force F_z contains contribution to the pressure force from the exciting and the scattered waves. Other forces are similar to the those defined in (45.3). The exciting force can be estimated by the Froude–Krylov force on the top of the cylindrical floater is given by

$$F_\mathrm{KR} = \int_0^a \int_0^{2\pi} pr\mathrm{d}r\mathrm{d}\theta \approx \frac{\pi\rho g H a}{k} \frac{\cosh(-kd + kh)}{\cosh(kh)} J_1(ka)\cos(\omega t)\,, \tag{45.24}$$

where a is the radius of the floater and $J_1(x)$ is Bessel's function of the first kind of order 1 and the force is in phase with the wave with the device located at $x = 0$.

Alternatively, *McCormick* [45.13] describes a system where the floater in Fig. 45.5 essentially is replaced by a piston of radius a and the linear motor is replaced by a hydraulic pump with a smaller piston of radius a_2. The wave-induced pressure sets the large piston into heaving motion and it in turn drives the smaller piston of the pump. The pressure force on the large piston surface transfers through to the smaller piston, resulting in dynamic hydraulic pressure whose amplitude is larger by the factor $(a/a_2)^2$. The hydraulic pump may be part of a PTO system for the WEC.

Examples of submerged pressure differential devices include the PYSIS, CETO I, and AWSI.

45.1.4 Oscillating Wave Surge Convertors

An oscillating wave surge converter (OWSC) typically comprises of a body that surges back and forth in response to horizontal particle velocity in the water column associated with a surface wave, either (a) as a hinged flap (Fig. 45.7a) or (b) as a piston (Fig. 45.7b). *Gomes* et al. [45.22] provide a review of OWSCs. A commercial form of a hinged body is the Aquamarine Power Oyster [45.23], while a patented device by

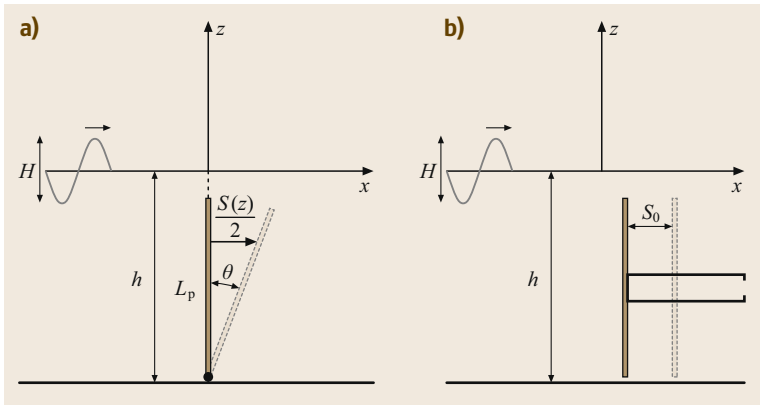

Fig. 45.7 (a) Hinged-flap-type OSWC. (b) Piston-type OSWC

E. A. Wall (1911) [45.13] provides an example of the horizontal piston-based system.

The stroke $S(z)$ of the flap or piston is given by

$$S(z) = \begin{cases} S_0\left(1+\frac{z}{h}\right) & \text{Flapcase}\,, \\ S_0 & \text{Pistoncase}\,. \end{cases} \tag{45.25}$$

For a regular progressive wave of small height H, circular frequency ω, and wavelength λ propagating along the direction x, given by the surface elevation (45.1), the horizontal particle velocity is given by

$$u = \frac{\omega H}{2}\frac{\cosh k(z+h)}{\sinh kh}\cos(\omega t - kx)\,. \tag{45.26}$$

Following *Milgram* [45.24], *Dean* and *Dalrymple* [45.25] suggest that in constrained motion, the reverse of wavemaker theory could be used to determine S_0. Thus, on the basis of linear theory and using the boundary condition on the flap/piston, $u(0,z,t) = S(z)/2\omega\cos(\omega t)$, they show, with reference to Fig. 45.7, that the stroke needed to absorb the wave energy incident on the flap/piston is given by

$$S_0 = \begin{cases} \frac{H}{4}\frac{kh}{\sinh(kh)}\frac{\sinh 2kh + 2kh}{kh\sinh kh - \cosh kh + 1} \\ \quad \text{Flapcase}\,, \\ \frac{H}{2}\frac{\sinh 2kh + 2kh}{(\cosh 2kh - 1)} \\ \quad \text{Pistoncase}\,. \end{cases} \tag{45.27}$$

In practice, incident waves will be diffracted at the finite-width WEC and secondary waves will be radiated from the oscillating body. Further, some of the energy will be lost to damping associated with the PTO system.

In the case of the hinged flap, if we model the torque associated with the mechanical PTO system as being proportional to the angular speed of the flap, $M_\mathrm{m} = -Q_\mathrm{m}\dot{\theta}$, then the equation for the angular displacement θ may be written as

$$\left(I_\mathrm{y} + I_{55}\right)\ddot{\theta} + (b_{55} + Q_\mathrm{m})\dot{\theta} + C\theta = M_\theta + M_\mathrm{d}\,, \tag{45.28}$$

where I_y is the moment of inertia of the flap about the hinge, I_{55} is the added moment of inertia about the hinge, b_{55} is the coefficient of moment of radiation damping, M_θ is the moment of the incident-wave-induced force, M_d is the torque due to viscous forces, C is the hydrostatic restoring moment. If the thickness t_p of the flap is small compared with its length L_f and width B of the flap, and the mass of the plate is uniformly distributed with mass density of the plate given by ρ_f, then

$$I_\mathrm{y} \approx \frac{1}{3}\rho_\mathrm{f} t_\mathrm{f} B L_\mathrm{f}^3\,,$$

$$C = \rho g t_\mathrm{f} B L_\mathrm{f} r_\mathrm{b} - \rho_\mathrm{f} t_\mathrm{f} B L_\mathrm{f} r_\mathrm{g} = \frac{1}{2}\rho g t_\mathrm{f} B L_\mathrm{f}^2\left(1 - \frac{\rho_\mathrm{f}}{\rho}\right)\,,$$

where r_b and r_g are the distance from the hinge of the center of buoyancy and center of mass of the flap, respectively, and for uniform mass distribution, $r_\mathrm{b} = r_\mathrm{g} = L_\mathrm{f}/2$. Then for a regular wave described by (45.1), θ is given by

$$\theta = \frac{\frac{|M_\theta|}{C}\cos(\omega t + \gamma - \sigma_\mathrm{z})}{\sqrt{\left(1 - \frac{\omega^2}{\omega_\theta^2}\right)^2 + \left(\frac{b_{55}+Q_\mathrm{m}}{C}\right)^2\omega^2}}\,, \tag{45.29}$$

where $\omega_\theta = \sqrt{C/(I_\mathrm{y} + I_{55})}$ is the natural frequency of oscillation of the system, γ is a phase angle associated with the moment of the wave force,

$$\sigma_\mathrm{z} = \tan^{-1}\left(2\frac{(\Delta_\theta + \Delta_\mathrm{m})\,\omega\omega_\theta}{\omega_\theta^2 - \omega^2}\right)\,,$$

$$\Delta_\theta = \frac{b_{55}\omega_\theta}{2C}\,,$$

$$\Delta_{\theta m} = \frac{Q_\mathrm{m}\omega_\theta}{2C}\,.$$

The average power generated by the flap is given by

$$P_\mathrm{PTO} = \frac{1}{2}Q_\mathrm{m}\omega^2\,|\theta|^2\,. \tag{45.30}$$

P_PTO has a maximum or optimal value $P_{\mathrm{PTO}_\mathrm{opt}}$ when

$$\omega^2 \mathrm{Q}_\mathrm{m}^2 = (\omega_\theta^2 - \omega^2)^2\left(I_\mathrm{y} + I_{55}\right)^2 + \omega^2 b_{55}^2\,, \tag{45.31}$$

given by

$$P_{\mathrm{PTO}_\mathrm{opt}} = \frac{\frac{1}{4}\omega\,|M_\theta|^2}{\omega b_{55} + \sqrt{(\omega_\theta^2 - \omega^2)^2\left(I_\mathrm{y} + I_{55}\right)^2 + \omega^2 b_{55}^2}} \tag{45.32}$$

or

$$P_{\mathrm{PTO_{opt}}} = \frac{1}{4C}\omega_\theta \left|M_\theta\right|^2 \times \frac{\frac{\omega}{\omega_\theta}}{2\Delta_\theta \frac{\omega}{\omega_\theta} + \sqrt{\left(1-\frac{\omega^2}{\omega_\theta^2}\right)^2 + 4\Delta_\theta^2 \frac{\omega^2}{\omega_\theta^2}}} . \tag{45.33}$$

Gomes et al. [45.22] provide numerical computations of the problem for regular and irregular waves.

Examples of OSWC include the Oyster, Wave Roller, and C-Wave.

45.1.5 Attenuator and Terminator

An extension of the point absorber is a line absorber, involving a number of modular array of oscillating units connected using mechanical joints and oriented so as to optimize the oscillations of the units. In one arrangement, the line absorber is aligned perpendicular to the direction of wave propagation and is referred to as a *terminator*. In another arrangement, it is aligned parallel to the prevailing direction of the wave propagation and is referred to as an *attenuator*. The size of a line absorber may be comparable to the wavelength of typical waves. An example of a terminator WEC is the Salter Duck, involving several pear-shaped ducks pitching with respect to a common *spine*, consisting of one or more horizontal cylindrical sections hinged together that accommodates a bending motion [45.6]. Each duck rocks and turns over in response to the varying dynamic pressure on its paunch as well as the varying hydrostatic pressure, both in phase, converting the oscillating motion to rotational motion of gyroscopes located within the duck (Fig. 45.8). The duck displaces the same volume of water as occupied by orbiting particles beneath the wave crest upstream of the duck. The natural frequency of motion of the duck is given by

$$\omega_\theta = \sqrt{\frac{C}{I_\mathrm{y} + I_{55}}} , \tag{45.34}$$

where C is the hydrostatic restoring moment, I_y is the moment of inertia, and I_{55} is the added moment of inertia about the axis of the spine (Fig. 45.9). The aim is to match this frequency to the frequency of the prevailing waves for resonant response. Wave-induced pitch moments react against a common cylindrical spine of the line absorber. Mathematical analysis and laboratory tests suggest a potential for up to 90% efficiency in capturing the incident wave energy [45.27, 28]; reduced efficiencies are expected in realistic ocean environment.

Examples of attenuator WECs include the Hagen–Cockerell raft [45.29], the Pelamis [45.30], the McCabe Wave Pump, Sea Power Platform, and Wello. The Pelamis involves a similar spine arrangement as the terminator, but oriented parallel to the wave direction. The attenuator follows the motion of the passing waves. Each element of the device is set into motion by the incident waves from crest to trough. The floating elements of the attenuator are usually located either side of suitable PTO module. As the waves pass, they generate relative motion between each element. The relative motion is typically converted to mechanical power in the PTO module, through either a hydraulic circuit or a suitable mechanical gear train. Motion of the hinged joints of the Pelamis is restrained by hydraulic rams that pump fluid into high-pressure accumulators, which absorb the wave power. The absorption of power is maximized when waves are small and the response is minimized in storms through control of the pumping action.

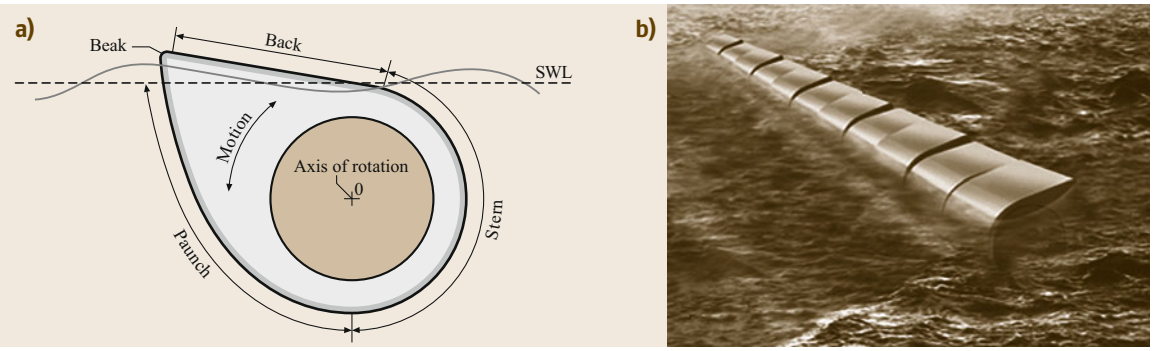

Fig. 45.8a,b Salter's Duck **(a)** individual unit (after [45.13]), **(b)** as a terminator line absorber (after [45.26])

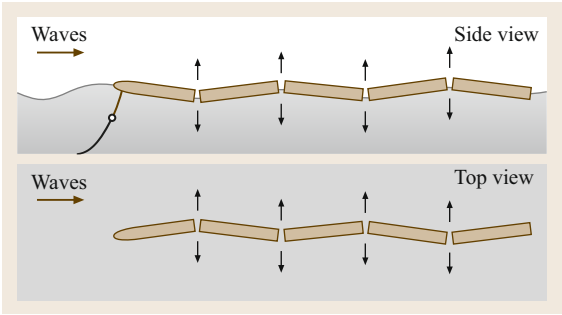

Fig. 45.9 Pelamis motion in waves (after [45.31])

45.1.6 Overtopping Devices

Overtopping devices [45.32] capture seawater driven by incident waves into a reservoir above sea level and through turbines before releasing the water back to sea (Fig. 45.10). Examples of such devices include the Wave Dragon, TAPCHAN, Seawave Slot-Cone Generator, and Floating Wave Power Vessel. Wave Dragon uses a pair of large curved reflectors to channel the flow associated with the waves to flow up a ramp and over the top into a raised reservoir, from which the water passes through a number of low-head turbines and is returned to the sea.

45.1.7 Other Advanced Concepts

An application of piezoelectric crystals to convert wave-induced pressure fluctuations to electrical energy was proposed by *Burfoot* and *Taylor* [45.33] and *Taylor* [45.34], utilizing the property that compressional piezoelectric material produces a voltage difference in response to a pressure force. The concept consisted of a system of piezoelectric films stacked together. Further, *Salomon* and *Harding* [45.35] proposed a *protonic conduction* method for WEC, involving pumping of hydrogen gas by wave-induced motion from one chamber to another across a porous-conducting electrodes, the gas deposits electrons on the electrodes, thereby generating an electrical current in an external circuit. Further details on these and related topics are provided by *McCormick* [45.13]; see also [45.36]. *Alam* [45.37] has proposed the development of a synthetic-seabed carpet for wave energy absorption on the basis of observations that muddy seafloors effectively overpassing ocean waves within a few wavelengths of the waves. The carpet drives hydraulic generators for conversion of wave energy to electricity. Professor *Ronald Yeung* and his team at Berkeley [45.38] report the development of a highly efficient tethered *Berkeley Wedge* point absorber that exploits its nonsymmetric shape to absorb wave energy, achieving around 90% efficiency in regular waves.

Several commercial WEC systems are described in Appendix 45.A.

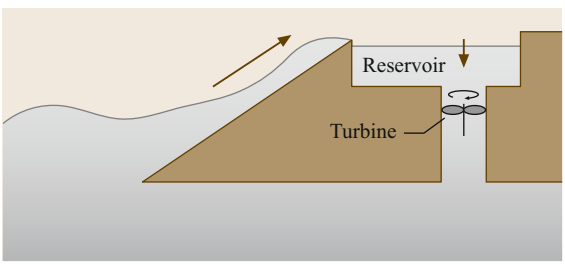

Fig. 45.10 Schematics of an overtoppping device

45.1.8 Control

As considered above, matching the natural frequency of oscillation of a WEC to the incident wave frequency is important for optimal energy capture. Otherwise the wave energy capture capacity typically decays rapidly. Therefore, the ability to control the WEC natural frequency and phase lag with respect to the incident wave is needed to optimize the power captured under various sea states as the wave frequency changes over time. The process of changing the natural frequency of a WEC is known as tuning, and involves adjusting one or more of the following: device shape, size, mass, stiffness, or damping. There are three types of tuning [45.39]: *fixed tuning*, *slow tuning*, and *fast tuning*.

Fixed tuning is a passive control that involves optimization during the design process of those properties of the WEC that may be impractical to change following construction. The optimization aims to provide a good overall match of the WEC response to the prevailing wave spectrum in the region.

Slow tuning is exercised over a period of minutes to hours and may involve altering WEC properties to match existing wave conditions or sea states. For example, slow tuning of a point absorber buoy may be achieved through changing its buoyancy through ballasting, thereby altering its mass and stiffness. Slow tuning is effective in the long term and typically involves, through real-time measurements, identification of the peak wave power characteristics.

Fast tuning is an ideal control system that can change the WEC response characteristics from wave to wave. It involves predicting the height and frequency of incident waves in order that WEC properties can be altered sufficiently rapidly to optimize the response when the waves reach the device. Fast tuning presents significant challenges both in terms of predicting wave characteristics in real time and minimizing the time needed to implement required changes on the device.

In practice, a combination of fixed, slow, and fast tuning need to be implemented in the WEC control system, in view of the challenges, to optimize WEC performance.

As discussed in Sect. 45.1.1, optimum energy absorption corresponds to resonant conditions with the amplitude of oscillation being such that the absorbed power is equal to the power radiated by the device to the sea as it oscillates. Since an idealized optimal control system itself may involve radiating energy to the sea as it is being implemented, the system is likely to be coupled, making it difficult to match the absorbed power to the radiated power. A suboptimal control strategy initially proposed by *Budal* and *Falnes* [45.40] that has been studied significantly is *latching control*; a variant called *declutching* and combinations of latching and declutching have also been studied [45.41, 42]. With reference to a heaving point absorber buoy, latching control involves controlling the phase between wave forcing and the buoy response velocity. It is based on the recognition, as pointed out in Sect. 45.1.1, that when the natural frequency of the buoy matches that of the wave and leads to resonance, the velocity of the buoy is in phase with the wave forcing. The objective is to achieve approximate optimum phase when the natural frequency of the WEC does not match the wave forcing frequency. This is met by locking the WEC in a fixed position at the instant when the device's oscillating velocity becomes zero and effectively the buoy displacement is maximum and releasing it after a time interval; this is facilitated through use of brakes. The length of the time interval is a single parameter in a discrete problem whose value is determined as part of the control strategy of the system. In particular, latching aims to slow down the natural oscillatory response of the buoy when its natural frequency is higher than the wave forcing frequency so that the heaving velocity of the buoy and the wave force reach their maxima at the same time [45.42]. Latching is a discrete control strategy. Latching considerably increases absorbed power [45.1].

Clément and *Babarit* [45.42] show how the analysis of monochromatic regular waves can be extended to real irregular seas, assuming linearity and considering the wave surface as a sum of harmonic components. However, the approach required the prediction of the incident irregular waves. The better the wave characteristics can be predicted, the closer the converted power approaches the optimum power determined for regular seas in Sect. 45.1.1.

45.2 Power Takeoff Systems

The methods of energy capture for WEC devices are generally classed as either *mechanical*, *turbine*, *hydraulic*, *pneumatic* or *linear generator*. The typical PTO components for WEC devices have been listed in [45.1] and are provided in Fig. 45.11. The mechanically driven method typically involves high-speed rotary electrical generators [45.3]. Point absorbers and line absorbers are not directly compatible with such rotary electrical machines and a hydraulic transmission system is typically used to interface the devices with electrical generators [45.43]. These different types of PTOs are described in the following.

Each WEC system involves a particular method of wave–device interaction (such as heave, pitch, or surge) and may need mechanical, pneumatic, hydraulic, or linear generator PTO. Some PTO systems are better suited for a particular primary wave energy capture system than others. There are a number of variations. A tentative guide is provided by *Grimwade* et al. [45.1] as shown in Table 45.1

45.2.1 Mechanical Transmission PTOs

A mechanical transmission system, involving gears, for a point absorber WEC, such as considered in Sect. 45.1.1, may be illustrated [45.13] using Fig. 45.12 which shows a heaving cylindrical point absorber attached to a vertical shaft outfitted with gearing on its right. These gears couple with a sprocket that is attached to an electrical generator axle. In regular monochromatic waves, the vertical velocity of the heaving buoy and the geared axle under resonance condition is given by (45.7), with $\sigma_z = \pi/2$ and setting $\gamma = 0$ for simplicity, as

$$\frac{\mathrm{d}z}{\mathrm{d}t} = \omega Z_0 \cos(\omega t) \,, \tag{45.35}$$

Table 45.1 Preferred PTO systems for various forms of primary energy capture (after [45.1]

WEC primary energy capture system	PTO: Transmission of mechanical energy
OWC	Pneumatic turbine
Attenuator	Hydraulic circuit
Point absorber	Hydro/hydraulic circuit, direct drive
Overtopping device	Low-head hydro turbine
OWSC	Hydro/hydraulic circuit
Submerged pressure differential	Hydraulic circuit/direct drive

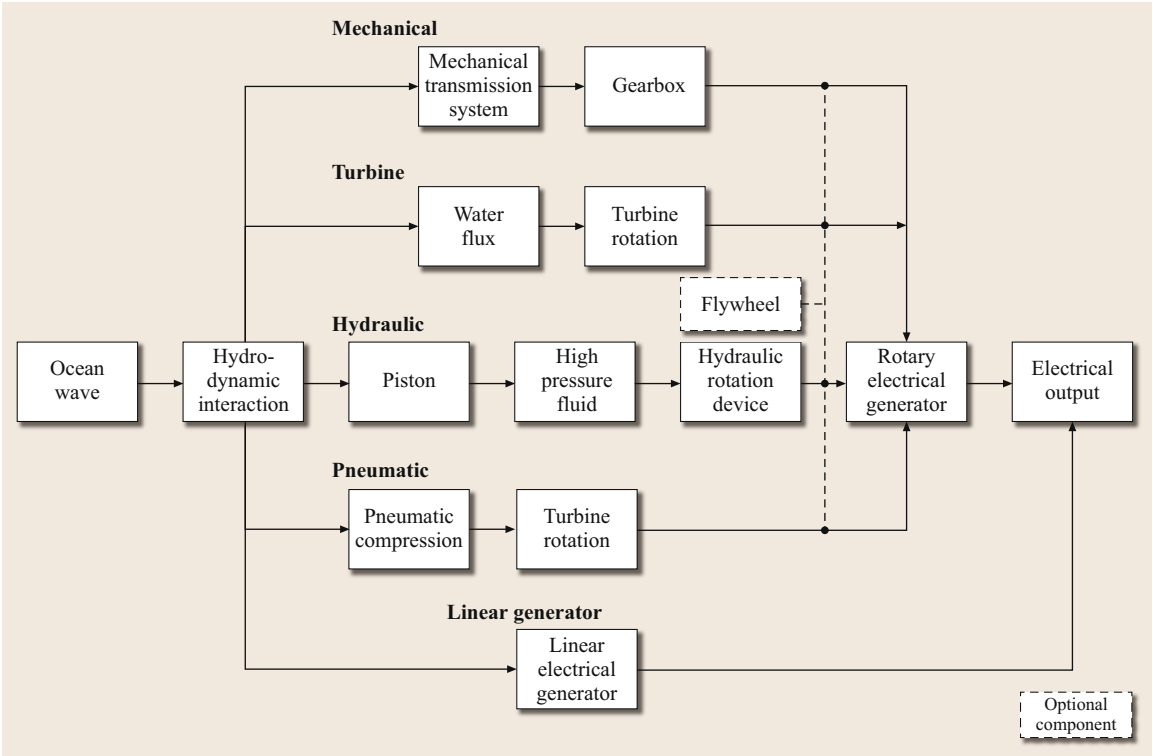

Fig. 45.11 PTO systems for WEC devices (after [45.1])

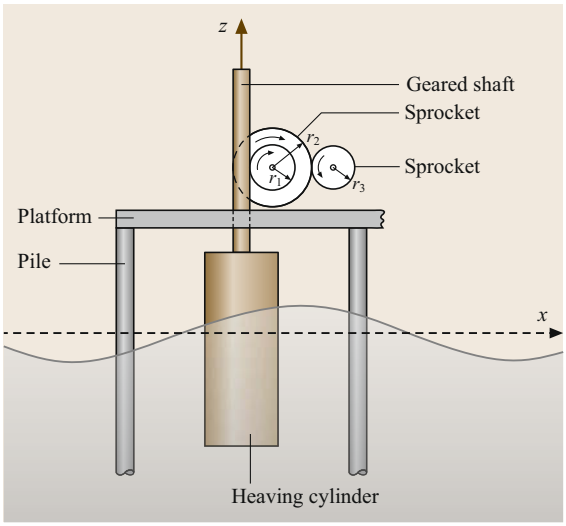

Fig. 45.12 Gearing-sprocket generator powertrain to harvest heaving wave motion (after [45.13])

where Z_0 is the heaving amplitude and ω is the angular frequency of the waves.

Then, assuming no slip between the gear and sprocket, the angular velocity ω_1 of the sprocket of radius r_1 is given by

$$\omega_1 = \frac{\omega Z_0}{r_1}\cos(\omega t)\,, \tag{45.36}$$

which varies with time. Let a sprocket of radius r_2 be rigidly interlocked with the one of radius r_1, so that they turn with the same angular speed. Then the angular speed ω_3 of the sprocket with radius r_3 is given

$$\omega_3 = \frac{r_2}{r_3}\omega_1 = \left(\frac{r_2}{r_1 r_3}\right)\omega Z_0 \cos(\omega t)\,, \tag{45.37}$$

where ω_3 exceeds ω_1 by a factor $(r_2/r_1 r_3)$. The sprocket with radius r_3 is connected to the axle of the electrical generator, which will provide the instantaneous power output given by

$$P = EI = E_0 I_0 \,|\sin(\omega_3 t)|\,|\sin(\omega_3 t + \phi)|\,, \tag{45.38a}$$

where $E = E_0\,|\sin(\omega_3 t)|$ is the instantaneous rectified voltage, $I = I_0\,|\sin(\omega_3 t + \phi)|$ is the instantaneous electrical current, and ϕ is the phase lag between voltage

and current. Using (45.37),

$$P = E_0 I_0 \left|\sin\left[\left(\frac{r_2}{r_1 r_3}\right)\omega Z_0 t\cos(\omega t)\right]\right| \times \left|\sin\left[\left(\frac{r_2}{r_1 r_3}\right)\omega Z_0 t\cos(\omega t)+\phi\right]\right| . \quad (45.38b)$$

The instantaneous power output therefore varies in amplitude and frequency. It is therefore quiet complex and needs to be processed and conditioned for transmission to a grid. The average frequency of the supply is given by

$$\hat{f} = \frac{\hat{\omega}}{2\pi} = \frac{1}{2\pi}\frac{1}{T}\int_0^T \left(\frac{r_2}{r_1 r_3}\right)\omega Z_0 \left|\cos\left(2\frac{\pi t}{T}\right)\right| \mathrm{d}t = \frac{1}{\pi^2}\left(\frac{r_2}{r_1 r_3}\right)\omega Z_0 . \quad (45.39)$$

45.2.2 Pneumatic and Hydro Turbines

The flow of fluid (seawater or air) induced by wave motion in typical WEC systems drives a turbine, which is directly coupled to a generator. The types of WEC devices using turbines include OWC and overtopping devices. Use of air in pneumatic turbines as the working fluid facilitates increasing the low speeds associated with wave motion to high rates of airflow. Disadvantages of pneumatic turbines are its low efficiency (though this can be improved through pitch control), poor starting, radiated noise, and high axial thrust in comparison with conventional turbines [45.41, 44]. Typical pneumatic turbines that are used are self-rectifying turbines, that is, they deliver a uni-directional torque for bi-directional airflow. They include the Wells turbine, and the Impulse turbine [45.1]. A comprehensive review of various turbine technologies is provided by *Takao* and *Setoguchi* [45.45].

Pneumatic Turbines

The basic Wells turbine has a rotor consisting of radial airfoils (Fig. 45.13). The airflow through the rotor generates a tangential force, which extracts the power, and an axial force related to drag on the airfoils. The rotor blades are symmetrical about the chord line of the blade cross-section. The air flows in the axial direction, normal to the rotor blades. However, the flow induced by the rotation of the rotor leads to an incident angle of attack at the blades. The angle of attack is small enough for the blades to perform without stall. The flow over

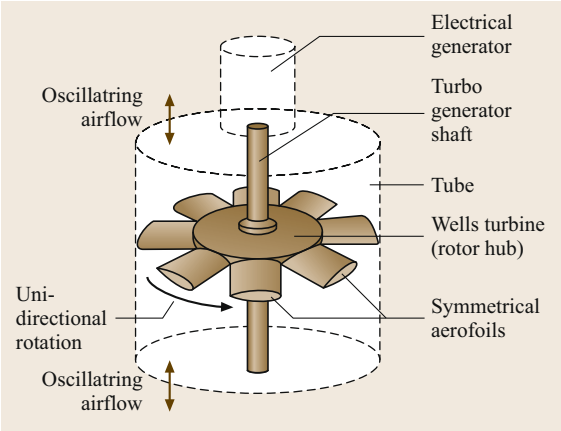

Fig. 45.13 Schematics of a Wells turbine (after [45.1])

the airfoils creates a lift force normal to the apparent flow direction and a drag force in the apparent direction of the flow. The tangential component of the lift force exceeds that of the drag force, resulting in a torque that drives the rotor. In view of the symmetry of the turbine, the sign of the torque is maintained even when the flow through the turbine reverses, so that an oscillating airflow is converted into a rectified, unidirectional, torque, whose value depends on the tip speed ratio, $\lambda_{TSR} = \pi n D/V$, where n is the rotor angular speed in s^{-1}, D is the rotor diameter, and V is the axial speed of the airflow. The turbines are not self-starting, and require an external source to initiate the rotation. For details of the Wells turbine, see [45.46]. The disadvantages of the Wells turbine are: limited operational flow range, poor starting conditions, induced noise, and high axial thrust. Examples of application of Wells turbine for OWC are the Pico and Limpet. A variant of the Wells turbine is the Dennis-Auld turbine [45.47]. In contrast to the Wells turbines, the blades are symmetrical in cross-section about the position of the maximum blade thickness rather than about the chord line. The turbine is still self-rectifying, but facilitates a variable pitch angle to enable optimal angle of attack. Other variants of the Wells turbine are discussed by *Takao* and *Setoguchi* [45.45].

In an impulse air turbine [45.22, 48], the airflow is deviated tangentially by guide vanes (Fig. 45.14) so that a tangential force on the rotor blades is directly produced by transferring the kinetic energy of the airflow to the rotor. The Impulse turbine can generally operate over a wider range of flow speeds than a Wells turbine. It has better starting characteristics and is less noisy [45.1]. The guide vanes can either be fixed or pitched. The pitching mechanism of the latter can either be controlled by the airflow or by another active mechanism. A disadvantage of the impulse turbine with

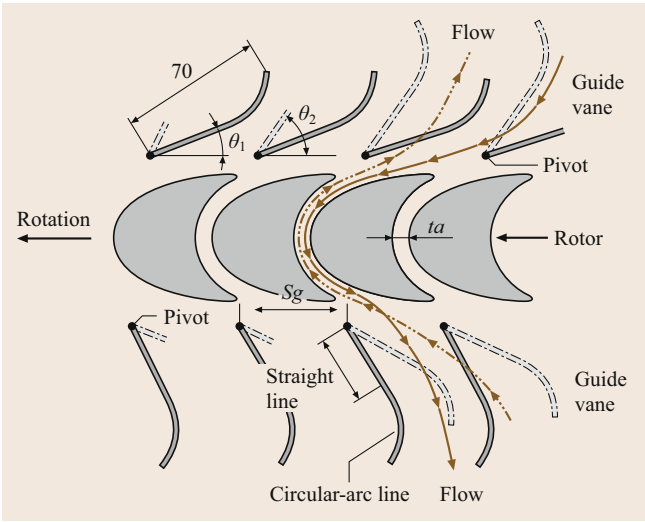

Fig. 45.14 Impulse turbine with self-pitch-controlled guide vanes (after [45.45])

movable guide vanes is that it has more moving parts that have to withstand a large number of oscillations per day. An example of the use of an impulse turbine for an OWC WEC is a plant at Vizhinjam, Kerala, India.

Hydro Turbines

For applications in overtopping WEC devices, various well-developed hydro turbines have been used that are classed as either hydro reaction turbines or hydro impulse turbines. Francis and Kaplan designs are examples of hydro reaction turbines while Pelton wheel is a hydro impulse turbine [45.1]. A hydro reaction turbine involves a rotating element that is fully immersed in water and is enclosed within a pressure vessel. A hydro impulse turbine runner, on the other hand, operates in air, and is driven by high-speed water jets that are developed by allowing low-velocity water to pass through a nozzle; the rotating blades of the turbine deflect the jets to maximize the force on the blades. The Kaplan turbine is suitable for overtopping WEC devices (Fig. 45.10), where the wave-induced flow is captured and directed over a ramp to a storage reservoir that is at a higher location above sea level, creating a head of water pressure that is released in a controlled manner via the Kaplan turbine, generating power in the process. In a Pelton wheel, nozzles direct streams of water against its spoon-shaped buckets mounted around the edge of the wheel. As the water flows into the bucket, its direction follows its contours, thereby exerting pressure on the bucket and the wheel. The water then decelerates and flows out on the other side of the bucket at low velocity. In the process, the water's momentum is transferred to the turbine.

45.2.3 Hydraulic Power Takeoff Systems

Hydraulics enable converting mechanical energy of linear motion into hydraulic energy and hydraulic energy into mechanical rotation, and thereby conversion to electrical power. As a result, hydraulic PTO systems are used in a number of WEC devices, most notably in Pelamis WEC. A possible medium for such a system may be seawater or other fluid such as fresh water or oil in a sealed system. Figure 45.15 illustrates a typical Hydraulics PTO system, adapted from the one used for Pelamis for a heaving buoy point absorber. The heaving motion of the buoy induced by surface waves drives a low-speed piston or pump back and forth, pumping hydraulic oil through the pipeline circuitry around the power generation system. Electronically controlled valves in the control manifold control the flow of fluid between the hydraulic pistons and the hydraulic circuit. The valves are controlled to facilitate passage of oil between different combinations of chambers to provide optimum benefit. For example, valves in the control

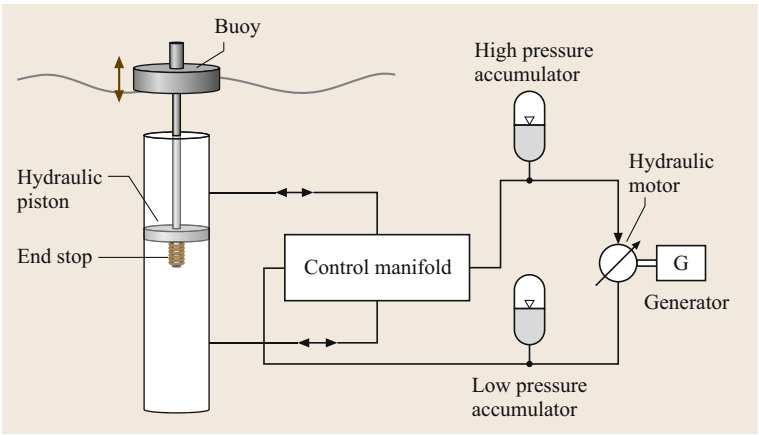

Fig. 45.15 Schematics of a typical hydraulic PTO system

manifold rectify the flow of oil from the low-speed piston so that it is unidirectional, even though the linear motion in the piston is oscillatory [45.3]. The oil flows through smoothing accumulators where it may be stored under pressure. It is then supplied at a controlled rate to hydraulic motors that drive electrical generators to produce electricity. Accumulators in the circuit not only facilitate energy storage and maintain constant flow to the hydraulic motor, but also decouple the hydraulic piston and the motors, thereby damping out the pulsatile nature of the energy captured by the hydraulic pumps and having a smoothing effect on power transmission; this facilitates the variation of the pump torque, in support of capturing optimal energy from the fluctuating pressure delivery, while the generator is driven at a steady rate. The low-pressure accumulator provides a small boost pressure to reduce the risk of cavitation on the low-pressure side [45.3]. In the case of the Pelamis, each individual unit of the attenuator has its own sealed PTO system, including power generation, which utilizes biodegradable transformer oil as the hydraulic fluid. The waves excite the motion of each joint of the attenuator, which in turn excites a hydraulic pump. The PTO hydraulic circuit is similar to that shown in Fig. 45.15. Pressurized chambers in the circuit exchange oil directly with storage accumulators [45.49].

Multiple WEC devices can be connected to a single sealed hydraulic circuit and generator. Likewise, a single hydraulic circuit can supply hydraulic power to multiple hydraulic motors and electrical generators, which can be engaged or disengaged from service as required [45.1]. Importantly, for floating devices, hydraulic circuits provide the flexibility in placement of motors and generators, including onshore.

Hydraulic PTO systems present some challenges [45.1, 3]:

1. Containment of oil in the hydraulic circuit is important. Special measures would therefore be needed to minimize leakages. Use of biodegradable hydraulic fluid would minimize risks to the marine environment on the basis that in the event of a leakage the fluid will biodegrade.
2. Duty-cycle maintenance of the hydraulic system involving several moving parts, pipes carrying hydraulic fluid, and seals that wear under friction, components that could fail due to fatigue under significant cyclic loads (order of thousands of cycles per day depending on the wave climate), coupled with the maintenance requirements posed by the harsh marine environment present a significant challenge [45.50]. Special design considerations, in terms of placement, material selection, use of corrosion resistant coatings, choice of electronic control systems, and other factors impacting maintenance requirements, would be needed. Locating the hydraulic PTO system above water on a barge or buoy or onshore may mitigate some of the maintenance requirements. An example of this is the Oyster WEC by Aquamarine in which the PTO system is located onshore [45.23].
3. Compressibility, bearing and seal friction of the hydraulic cylinders, and flow losses through valves and pipes are sources of inefficiencies. The impact could be minimized through careful design [45.49], including the development of optimal control strategies.
4. Extreme conditions. Special measures are needed to minimize potential risk of damaging systems under extreme loads, including use of end stops [45.3] on the hydraulic pumps or pistons that absorb the wave energy so that the hydraulic rams do not damage the pumps.

Hydraulic motors facilitate variable displacement operation in response to available power, and provide high-speed output in driving the electrical generator [45.1]. They are not required to be at the same location as the primary energy devices and can be placed at the best location for weight considerations. Types of hydraulic motors that may be considered are an axial or radial piston motors, vane motors for high-speed application, and gear motors. For further details, refer to the MARINET report [45.1] and reference provided therein.

45.2.4 Linear Generator

Use of an electrical machine as a PTO system for a WEC provides the possibility of directly converting mechanical energy into electrical energy. Linear mechanical motion associated with primary wave energy absorbing devices, as opposed to rotary motion induced by typical wind turbines, implies the need for a *linear generator* direct drive electrical machines for WECs. Such a machine involves power generation through one or more permanent magnets set to move through a coil by the primary energy capture device. The basic concept is schematically illustrated in Fig. 45.16. A series of magnets with alternating polarity are mounted on a *translator* that is directly coupled to a heaving buoy and that moves through a support structure, a *stator*, containing windings of the coil. The support structure may be fixed to the seabed or attached to a large drag or inertia plate. As the translator oscillates in response to the wave-induced motion of the primary wave energy capture device (the heaving point absorber in the

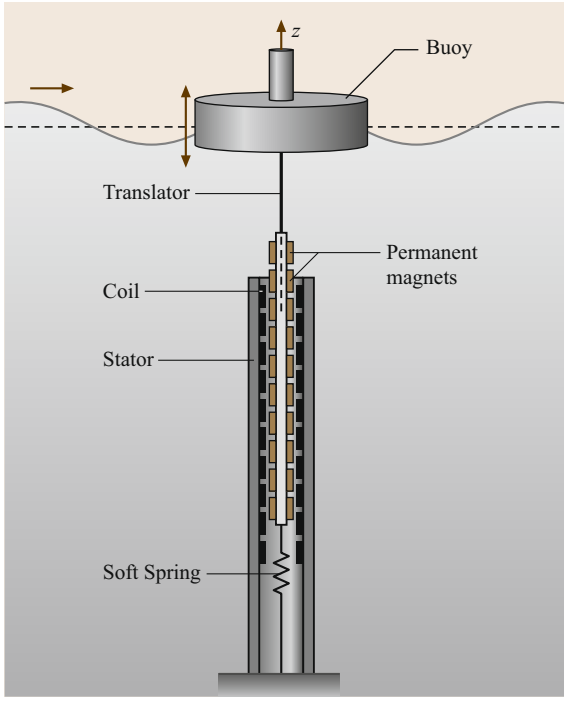

Fig. 45.16 Schematics of a typical Linear generator PTO system

figure), an electric current is induced in the stator windings.

If the translator moves at vertical velocity V_T and the stator is fixed to the seabed, the electrical power produced may be estimated by

$$P_e = \mathbb{Z} V_T^2 \,, \tag{45.40}$$

where $\mathbb{Z}$ depends on the number of turns in the windings, the strength of the magnetic field, the length of the wire and the resistance of the wire loop [45.51, 52]. For a buoy purely heaving in regular waves, since the translator moves in unison with the buoy, V_T may be estimated by (45.7)

$$\frac{dz}{dt} = -\omega Z_0 \sin(\omega t + \gamma - \sigma_z) \,, \tag{45.41}$$

where Z_0 is given by (45.3)–(45.6) with

$$F_R = -(m_{LG} + m_{33})\ddot{z} - R_m \dot{z} - K_{LG} z \,, \tag{45.42}$$

with $R_m \dot{z}$ being the mechanical damping force partly associated with the electromagnetic force resisting the motion of the translator, m_{LG} and K_{LG} are, respectively, the mass and the stiffness of the translator in the heaving system and m_{33} is the additional added mass due to its presence. The natural frequency of oscillation

$$\omega_z = \sqrt{\frac{\rho g A_{wp} + K_{LG}}{m + m_{LG} + a_{33} + m_{33}}}$$

of the system is accordingly modified so that [45.51].

The time-average electrical power is then estimated as

$$\hat{P}_e = \frac{1}{T}\int_0^T P_e dt = \frac{1}{2} Z \omega^2 Z_0^2 \,. \tag{45.43}$$

Use of a direct drive linear generator implies a brushless machine, fewer moving parts, potentially lower maintenance requirements, and higher efficiency. The linear generator appears particularly suitable for point absorber and submerged pressure differential devices, and its application to several WEC devices has been considered and demonstrated, including the AWS submerged pressure differential device [45.53], and the Seabased AB [45.54] device. There are, however, a number of challenges. This includes need for long-life lubrication. If the system is operated fully flooded to avoid requirements for tight seals and provides improved cooling, prevention of corrosion on the magnets needs to be addressed [45.43]. Output voltage varies both in frequency and amplitude. Mechanical strains are very high with low power factor. For a peak speed of $V_{Tmax} = 2\,\text{m/s}$, the air (or water) gaps that the generators need to overcome shear stress can be very large. Furthermore, possibilities of power storage and smoothing in the energy chain need to be addressed [45.1].

45.2.5 Other Considerations

Other considerations and requirements common with other sources of marine energy such as ocean thermal energy conversion (OTEC) include power transmission, including underwater power cables, cable power conditioning, and energy storage. These requirements are significant drivers of costs. Power transmission over long distances is one option, and involves consideration of configuration, choice of cables and transmission losses utilizing power to develop products offshore, such as hydrogen, ammonia, synthetic fuels and aluminum, are other. Storage and transport of electricity in large lithium batteries have been proposed. Further design considerations include simulation and experimental testing of systems. Details of these and related considerations can be found in [45.1, 13, 16, 55–57].

45.A Appendix: Practical Applications of Wave Energy Conversion Technologies

An important advantage in wave energy conversion (WEC) is that the supporting technologies can be located onshore, nearshore, or offshore. Several patented WEC methods and techniques have been developed over the last four decades. Practical and commercial applications of the concepts discussed in Sect. 45.1 and 45.2, resulting from these patents are described here and are grouped together accordingly as:

1. Point absorber systems
2. OWC systems
3. Attenuators
4. *Oscillating wave surge convertors*
5. Overtopping systems.

45.A.1 Point Absorber Systems

The principle of behind the point absorber system is discussed in Sect. 45.1.1. Here are some of some well-known point absorber systems that have been developed. Here are some well-known commercial point-absorber devices [45.1] (Table 45.2).

Power Buoy

The Power Buoy is composed of three main parts: a float, a spar, and a heave plate as shown in Fig. 45.17. The wave-induced motion of the float causes the spar to oscillate up and down. The heave plate ensures that the spar maintains a relatively stationary position. This relative oscillation of the float with respect to the spar acts as prime mover for a mechanical subsystem within the spar itself. This mechanical subsystem acts as a crank mechanism in a reciprocating engine since it transforms the rectilinear motion of the float into a rotational one. The spinning mechanical subsystem transmits motion to electric power generators that can power on-site payloads or for nearby maritime uses by a submerged cable.

OPT's PowerBuoy can accommodate two substantially different output ranges: up to 350 W and up to 15 kW. OPT's APB350 may play the role of an uninterruptable power supply (UPS) which can even recharge itself from the waves. The APB350 supplies uninterrupted power to either onboard payloads or to instrumentation on the seabed. It also maintains a real

time data transfer stream and telecommunication with remote coastal locations.

PB40 is a system for applications with higher power demand.

Seabased WEC

Seabased wave energy generators (Fig. 45.18) are point absorbers that utilize linear generator PTO that deployed on the seabed. These generators have been developed Seabased AB of Sweden. The linear generator is connected to a wave energy capturing surface buoy via a line. The series of WECs are connected to a central substation, from where electricity can be transmitted to a grid in the form of an AC current. The linear generators are encapsulated and anchored to the seabed.

CETO

Named after a Greek sea goddess, CETO offers the potential to harvest the energy content of ocean waves.

The CETO system (Fig. 45.19) is not similar to other wave energy harvesting concepts since it functions submerged where it is safely protected from the elements, for example, storms, and minimally visible from the coast. The buoys, positioned underwater, act as prime movers for pumping and generator outfits that are also located offshore, as part of the system package; power is transmitted to the coast by subsea cables to; finally, power is transmitted to the coast by subsea cables.

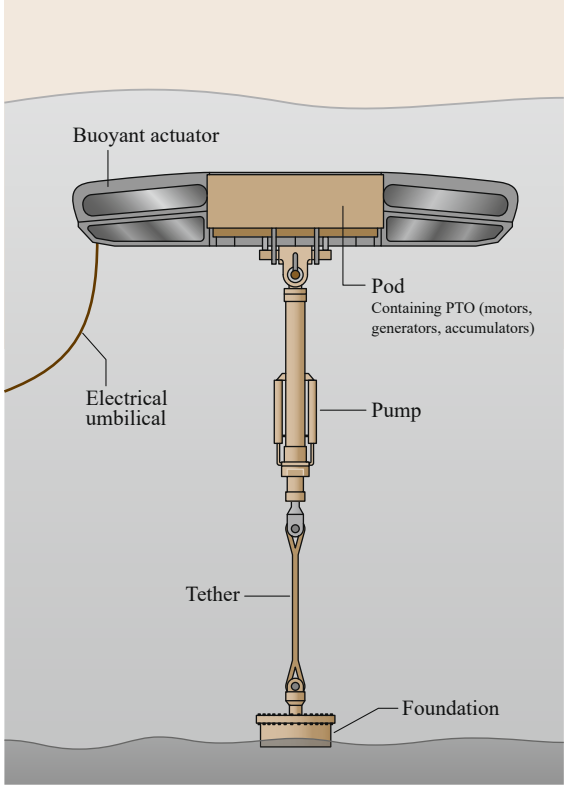

Fig. 45.19 The CETO 6 system developed by Carnegie Wave Energy Ltd.

The first effort toward CETO was made in 1999. Development of a CETO system demonstrator begun in 2003 with the first prototype. The CETO I model validated that it can deliver clean energy and freshwater from ocean waves.

Between 2006 and 2008, CETO 2 prototypes were developed and tested in the waters of Fremantle in Western Australia at Carnegie's purpose built Wave Energy Research Facility. These were approximately 1 kW prototypes and provided new commercial design concepts. Since then more prototypes have been built and further advances have been made.

Wavestar

This system was conceived by sailing enthusiasts Niels and Keld Hansen in 2000. The objective was to develop a stable power regular driven by ocean swells and crests 5–10 s apart. This is possible by a line of half-submerged buoys that emerge and sink in turn as each wave passes through, giving rise to the characteristic Wavestar design as shown in Fig. 45.20. Such design enables energy to be generated in a continuous manner in spite of the periodicity demonstrated by incident waves.

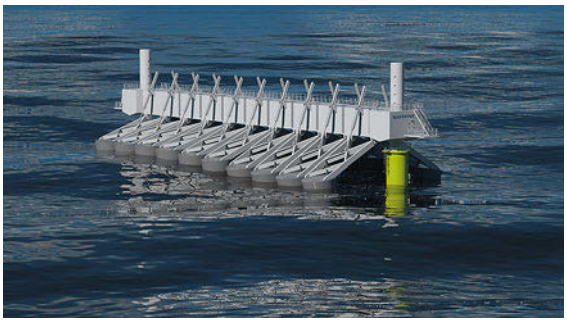

Fig. 45.20 The center bridge of Wavestar with the two buoy rows

The machine's unique storm protection system, one of the multitudes of patented elements in the design, and ensures its survivability. Furthermore it is in its own right a seminal point in the design of wave energy harvesting systems.

The Wavestar system can be built alongside with wind turbines, of for example, advanced design [45.58]. Such a concept can enhance efficiency and reduce initial costs.

In 2004, a tank trial campaign was carried out on a scale of 1 : 40 model. The objective was optimization of the fundamental conceptual architecture of the device and to record the electrical power output under common North Sea wave climate conditions.

In 2005, the first 1 : 10 prototype was procured, installed and connected to a power utility grid in waters at Nissum Bredning. At this location, waves are approx. 1 : 10 of North Sea waves. Research continues and 1 : 2 scale model was built and deployed for trials in Hanstholm during the second half of 2009.

LabBuoy

LabBuoy is a floating system for wave energy harvesting that has power transmission and conversion subsystems attached on a breakwater or a pier. In this manner, higher power output is enabled because of wave reflection developed at the breakwater face as well as being more reliable and safe to operate.

An entire EU-funded project has been carried out to investigate the LabBuoy concept. The main objectives of the project were evaluation of feasibility, socioeconomic and environmental footprint of the proposed system for a range of sea states commonly encountered in Europe. Furthermore, the LabBuoy project concerned model testing of an on-shore operational wave energy harvesting system. The system is floating, while power transmission and conversion subsystems are located above sea surface on a solid foundation (breakwater or pier), Fig. 45.21.

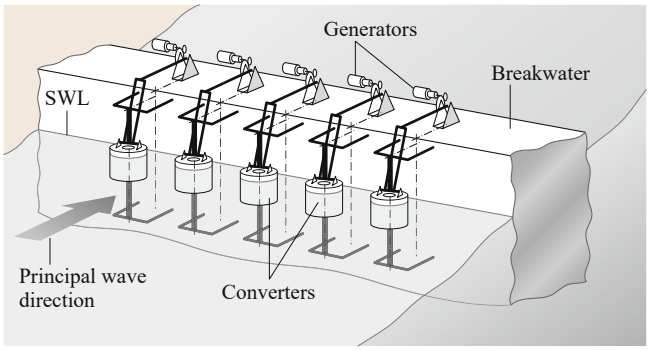

Fig. 45.21 The LabBuoy concept developed at the National Technical University Athens

A 1 : 15 scale model consisting of five converters in series was manufactured and deployed in the wave tank of the National Technical University of Athens, and a number of experiments under various wave conditions of interest were conducted. The central aim of the scale experiments was the validation of the numerical simulation models of the device.

A DC motor is attached to the rear end of the arm of each model, which provides a controllable resistance torque to the arm motion via a toothed belt. Each motor is controlled by a controller with encoder feedback. The motors can be controlled to excite the floats to specific motions, such as, for example, forced sinusoidal oscillations. Each model converter is equipped with the force sensor for the measurement of the vertical buoy force; angular position sensor for the measurement of the instantaneous position of the model arm, and; optical encoder for the measurement of the instantaneous rotational speed of the model arm.

In addition, simultaneously to the model properties, the instantaneous wave height was sensed by wave sensors in six significant locations.

The data acquisition and data management system is capable of real-time measurements, that is, it works independently of the operating system of the host computer, thus being not affected by limitations regarding data transfer rate. The system consists of a controller, a D/A converter, an analog signal conditioner, a strain gauge signal conditioner, an A/D converter, and a counter card.

A *virtual instrument* (vi) has been developed in the LabView s/w environment to control several functions of the data acquisition and data management system, in particular:

- Sensor calibration
- Adjustment of the hardware profile (scan rate, channel identification, amplification and filtering, etc.)

- Adjustment of the profile of the PTO (power-take-off) control system (operational mode, PID parameters etc.)
- Calibration and zero adjustment of the sensors; data conversion to physical units
- On-line data display
- Data storage
- vi's HMI (human machine interface)

The vi can be made available on the Internet to remote partners, allowing monitoring and operation. Data transfer to a remote location is also possible with an additional FTP module, also developed in the course of the project.

With the equipment described above a number of experiments were conducted, in particular:

- Diffraction measurements with fixed buoys under various wave conditions of interest. This series of experiments includes measurements of the vertical forces acting on the buoys at regular waves of various heights H and periods T, as well as irregular waves of various significant wave heights H_s and energy periods T_e. The experiments were conducted at two different wave incident angles (0° and 30°).
- Free oscillation measurements; this series of experiments includes measurement of the buoy motion and forces during the free oscillation of the buoy after its release from a submerged position, and parallel measurements of the waves radiated by the buoys. This experimental series provides information about the system inertia and the radiation coefficients of the buoys.
- Forced oscillation measurements: In this experimental series, the buoys are forced to harmonic oscillations about their state of equilibrium. The motion is driven by the DC motors. The experimental series includes measurement of motion, forces, and radiated waves at various oscillation frequencies and amplitudes.

Additional studies conducted in the project concerned the technical and economic feasibility of the device, the perspectives of the large-scale implementation of the technology in Europe and its expected economic and environmental impact. Some general conclusions are summarized in the following.

With some modifications in the original design, the LabBuoy technology is forecasted to provide an efficient, economic, safe, and environment-friendly source of energy. The main areas of environmental concern of the LabBuoy technology are typical for on/near-shore operating wave power devices: optical and acoustic intrusion, shore alteration, and impact on fauna.

Optical and acoustic intrusion is expected to be easy manageable. As with most wave power conversion technologies, the latter two impacts have to be studied carefully in subsequent projects. *LabBuoy breakwaters* are likely to find easy acceptance in built-up, coastal industrial areas, such as harbors, ports, shipyards, refineries etc. The noise level created in the energy conversion phase might also become a low priority consideration in this case.

Finally, Fig. 45.22 shows the European coastline exposed to exploitable wave power climate (dotted lines). The total length of this coastline is estimated to be at least ≈ 30 000 km. Assuming an initially available coastline in the EU (incl. Iceland and Norway) of 180 km in total for device deployment, this would correspond to a market of ≈ 23 500 devices with floater diameters of 2–4 m. This market corresponds to a job-market of ≈ 19 200 man-years of skilled technical personnel, not including operation, maintenance, and repair. The labor effort for project development would be approx. 700–1000 man-years of engineers and administrators.

45.A.2 Submerged Pressure Differential Devices

As described in Sect. 45.1.3, these devices are driven by pressure differential set-up by passage of waves

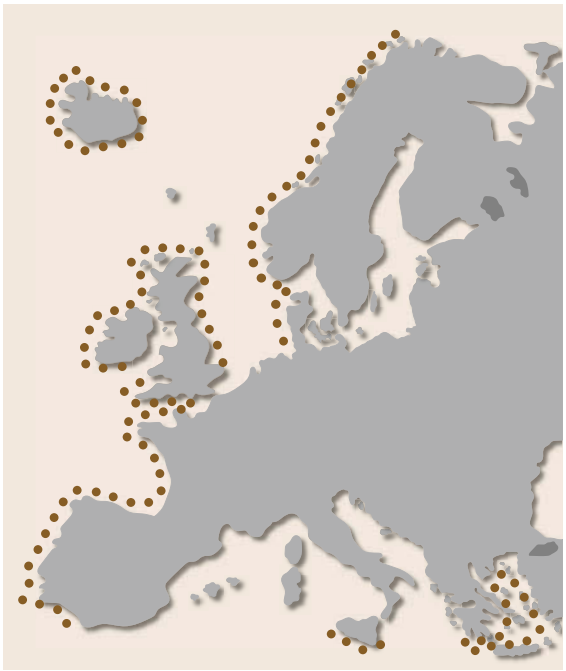

Fig. 45.22 Potential European market, candidate areas for device deployment are indicated by *dotted lines*

over the device. Here are some well-known commercial submerged pressure differential devices [45.1] (Table 45.3).

AWS

The patented AWS is an underwater wave energy harvesting buoy. It can provide reliable and affordable power for coastal settlements and offshore installations. The waves wing responds to fluctuation in seawater column pressure driven by passing waves. This motion is converted to electric power by a direct-drive generator. The concept works in seawater depths in excess of 25 m and is available for ratings between 25 and 250 kW by matching and choosing the proper scale.

The AWS is practically an underwater piston that entraps air, which in turn expands or contracts as seawater column pressure fluctuates due to waves. The relative motion of the two components of the system is converted to electric power by a rectilinear generator. Therefore, the system exhibits a tunable resonance that can be matched to dominant wave spectra in a region even in real time.

The concept was also put to the test offshore Portugal in 2004. Since that campaign, the waves wing has been further improved to match customer requirements closer.

45.A.3 Oscillating Water Column Systems

As described in Sect. 45.1.2, the principle of operation of this approach is an almost fully enclosed chamber, open at the bottom so that seawater waves can enter and exit and with openings toward its top where air turbines are placed. Specifically, incident ocean waves force the seawater column in the system's chamber to vertically oscillate causing air to flow out and in, respectively, and the turbine to turn. The following are known commercial OWC devices [45.1] (Table 45.4).

Limpet

In 1998, Queen's University Belfast in cooperation with Wavegen Ireland Ltd., Charles Brand Ltd., Kirk McClure Morton, and I.S.T. Portugal undertook the development and testing of an onshore power plant based on the OWC concept for the electricity generation. The system was named LIMPET an acronym for land installed marine power energy transmitter. It was set up on the island of Islay offshore the Scottish west coast. It started operations in November 2000. Since then the plant is running and operated by remote control. It supplies power to the UK. The successful unattended operation of this power plant has publicly shown what the potential of ocean wave energy can be toward a national energy portfolio.

The system employs three seawater columns that oscillate in concrete-built chambers with inner dimensions of 6×6 m and slope of 40° with respect to the calm sea surface plane, in effect, a total of 169 m^2 of water surface as shown in Fig. 45.23. The upper subpart of all three chambers, where atmospheric air is entrapped, is interconnected to each other so that electromechanical energy conversion can be performed by a single turbine-generator set instead of three.

The air turbine type employed in the system is that of Wells so that it can turn continuously in the same sense independent of the air-flow direction. LIMPET power plant consists of two such Wells turbines mounted in cascade; both turbines are made of stainless steel and have diameter of 2.6 m. The blades of each Wells turbine are directly mounted on an induction generator with specially modified design. Since each generator has a capacity of 250 kW, the total nominal power output of the LIMPET power plant is 500 kW.

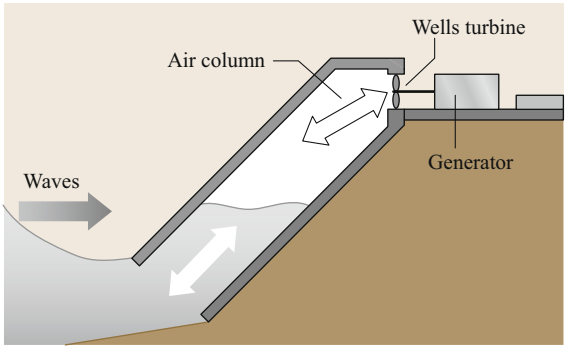

Fig. 45.23 Principle of operation of the LIMPET power plant

The use of induction generators allows for variable speed operation while at the same time minimizing maintenance requirements and maximizing reliability. The speed range of the system is between 700 and 1500 rpm and in order to connect with the power grid that requires constant speed and frequency, rectification, and then inversion is required; these processes are part of a power electronic drive of the VFD (variable frequency drive) type that is used in standard induction motors for motion control applications as well.

The operation of the LIMPET plant is continuously monitored in real time by a SCADA (supervisory control and data acquisition system) Also, the acoustic noise generated by the plant mainly due to the restricted air flows through the turbines is mitigated by intermitting a specially designed acoustic reverberation chamber between the power-plant core and the ambient.

By using the SCADA system and pressure transducers at various positions on the seabed oceanic wave data have been collected. Also, the wave loads on the walls of the facility's chambers have been recorded in conjunction with the seawater column level oscillations by employing both pressure transducers and sounding surface sensors.

Despite the fact that all electrical power generation technologies have some footprint on surrounding and environment at large, it is widely recognized that onshore wave energy harvesting is one of the friendliest to the environment. Essentially, they cause no problem to flora or fauna; just a minor visual distraction.

Pico Plant

Wave energy research in Portugal started as early as in 1978 in many national foundations and in cooperation with the country's government agency for industry and technology. In 1991, through program Joule, the European Commission began looking for a site to have some qualified wave energy harvesting along the European coastline. One of the sites selected was Porto Cachorro on Pico Island of the Azores archipelago of Portugal. In 1993 and 1995, the contracts with the European Commission were undersigned and the order for the studies, design and construction of the project to be carried out. The site was selected thanks to its demonstrated potential of 13.4 kW/m as well as it is easily accessible from land.

The technology employed is again that of OWC capable of delivering up to 400 kW. The chamber has dimensions of 12 m × 12 m and is founded on rocky seabed with a water depth of 8 m. In addition, one of the major objectives in developing the power plant was to be used as test site for PTO gear like turbines, generators, control equipment, and valves.

The facility of a concrete structure built on top of rocky seabed, spanning a small gully making the area a focal point of sea waves. The OWC has a 12 m × 12 m cross-sectional area. A horizontal-axis Wells turbine is driving a generator. There is space available for another turbine-generator set to be installed if desired. A relief valve is employed in order to mitigate positive or negative pressure excursions in the air chamber. In this manner, aerodynamic losses due to rotor blade stalling are greatly reduced in the system's turbine.

Simulation results for the powertrain from wave to wire were employed to specify the turbine as well as the relief valve. Design nominal value of 120 Pa s/m^3 was selected for the turbine damping coefficient. The turbine was expected to deliver 560 kW of shaft maximum instantaneous power with a maximum efficiency of 80%. An effective cross-sectional area of 0.8 m^2 was specified for the relief valve.

The air turbine, electric generator, and power electronics package of the plant are located in a 10 m × 12 m room on the rear of plant's main entrapped air chamber. The rest of the electrical, control, and monitoring outfit is installed in two rooms underneath the turbine housing.

A substantial civil engineering contract was put in place to get rid of rocks and boulders from the sea bottom on the side of the facility facing the sea. However damage to the front wall of the structure was identified during the summer of 1997. The damage was attributed to a poor underwater concrete pouring process that was used in 1996.

Some repair works were performed over the summer of 1998. The structural aspect encompassed the construction of the spaces housing outfit and gear as well as the topside of the chamber; works were finished in August of 1998.

The aerodynamic aspects of the Wells turbine development were performed during 1996. The turbine, associated ducts, and two of the air control valves were commissioned by Applied Research and Technology

Ltd. (ART, Inverness, Scotland) during 1997. Two different valves were used to handle airflow through the turbine's structure. A fast-acting valve positioned in proximity to the turbine controlled by a PLC (programmable logic controller) is regulates start and stop of the machine. A second valve, positioned toward the far end of the air duct where the plant's chamber is meeting with the turbine, can shut off the duct and machinery subsystems in the case of severe storms or during repairs.

Employing a variable speed electric generator spanning a range between 750 and 1500 rpm is considered a critical design element of this system. The configuration of such an unconventional electrical subsystem, encompassing advanced power electronics and controls, required substantial development effort and design work. The supplier of the conventional and unconventional electrical gear was EFACEC Engenharia SA (Portugal).

The concept of the Pico OWC plant is shown in Fig. 45.24. The integrated power plant, was completed during the summer of 1998. Accidental flood by seawater took place on September 5, 1998 when commissioning of some standard electrical gear was being installed in the lower housing space of the facility. Affected outfit like the 630 kVA transformer and a main AC panel was later shipped back to manufacturing facilities for repair or was replaced. This accident did not allow the facility to become functional before October 1998. Finally, first trials were not performed till 2005 and revealed major limitations in the original design. Improvements led to increased availability and power output of the plant from 2006 to 2008. Further improvements in 2009 led to significant reduction of the vibration level experienced by the turbine. After adding a secondary security circuit allowing for safer operation of the fully automated plant in 2010, the total output recorded over the period September–December 2010 was 45 MWh in 1450 h of operation.

In 2011, preparations to build a second platform for testing turbines were made. In the framework of EU-funded project MARINET pointed at the Pico power plant as an important wave energy-harvesting infrastructure. However, additional investment of at least 1.5–2 million Euros will be required.

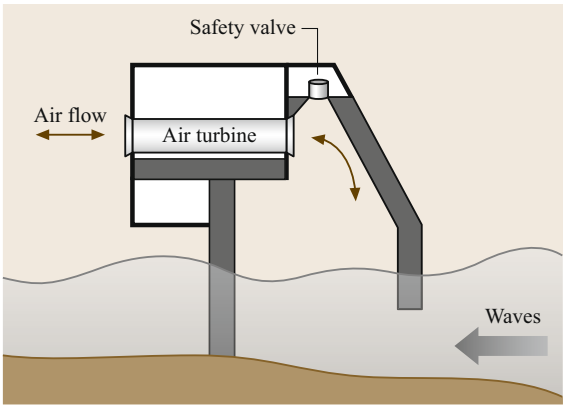

Fig. 45.24 Schematic representation of the Pico power plant (after [45.2])

The WECA System (Wave Energy Conversion Actuator)

Daedalus Informatics Ltd. in Greece has developed a technology employing the OWC concept that can be attached on existing infrastructures located on the coast, in shallow or even deep waters. The system employs a wedge-like form to focus the incident wave field to the interior chamber; there the enhanced wave action causes air pressure fluctuations that are harnessed by an accumulator. The full scale system will be 6 m high and 7 m wide and is expected to produce 20 kW at full capacity.

Oceanlinx Bluewave – greenWave

Oceanlinx is a company based in Australia since 1997. After many experimental campaigns, they have boiled down their designs to two major proposals employing the OWC concept. Even though the two proposed plants are of similar design (Fig 45.25), greenWave, is more suitable for shallow-water applications; in contrast, blueWave is for deeper water applications.

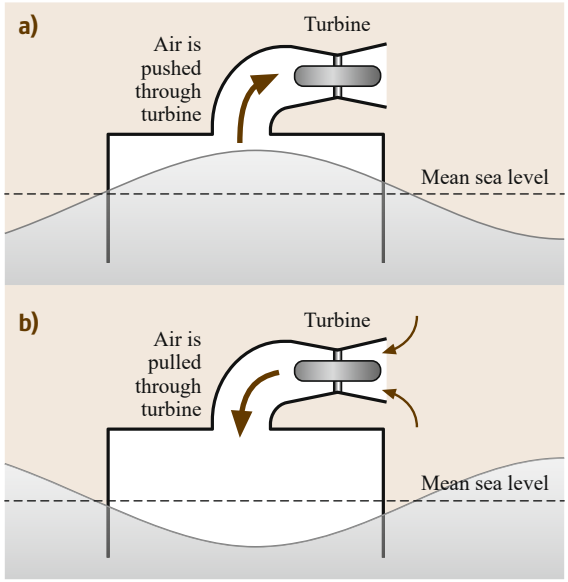

Fig. 45.25a,b Schematic concept of operation for **(a)** greenWave and **(b)** blueWave, working with the airWAVE turbine patended by Oceanlinx

A greenWave system can be installed in waters of depth not exceeding 10 m and founded on the seabed; in most cases use of concrete or steel is qualified. The foundation configuration is chosen to match the morphology of the seabed at the installation site. Since the system is originally waterproof and buoyant by design it can float. After being towed to the installation site, waterproofing is removed and the system ends up partially submerged. The distance from shore depends on the slope of the seabed. A typical greenWave system includes one OWC unit. Power output depends greatly on the wave potential of the installation site; a greenWave module with 20 m of width can output up to about 1 MW of power to be used either for electricity generation or seawater desalination or both.

Some of the major differences of a blueWave module when compared to a greenWave one, are that the former has to be built exclusively by using stainless steel and that the system includes six OWCs. It can be used for water depths between 40 and 80 m with appropriate mooring and anchoring. The power output can reach about 2.5 MW.

Both concepts of Oceanlinx employ the patented design air turbine airwave. This concept comes as an amendment to the pre-existing Denniss-Auld turbine design. Because of this, airWAVE is situated at a level significantly higher than the water line and has a smaller number of moving parts. It has significantly enhanced efficiency index when assessed vis-à-vis with other relevant turbine designs; in this manner, the overall wave-to-wire efficiency of Oceanlinx powertrains are also superior.

The majority of air turbine designs can work only with unidirectional flow. When looking at the concept of the OWC, unidirectional-flow designs simply fail to fully harness the resource. Early turbine design efforts to surpass this conceptual mismatch regularly come with grave efficiency reduction and other technical difficulties. The airWAVE design in contrast has met the objectives with higher success because it utilizes air pressure no matter how high or low the sea state is.

The major design modifications found in an airWAVE turbine include firstly two-ways action, 100%. Then pressure drop takes place across one single stage leading to significantly improved efficiency. Finally, an appropriate latching control and timing scheme in conjunction with the fact that the machine runs at almost constant RPM enables for optimum power generation.

As far as environmental footprint is concerned, the system does not include any contaminants or treatment in order to mitigate maritime life from growing. Also, note that since no moving components are needed underwater, it will be quite easy and safe for maritime life to move in and about the system. Moreover, the system behaves like a natural underwater cave and is expected that its impact on its immediate ecosystem will be rather small and indeed under conditions beneficial by playing the role of a manmade reef that allows living organisms to thrive. Given that the systems are developed to be installed at a distance quite far offshore, an insignificant visual impact is expected. The system's industry noise level emissions are not expected to raise any risk for sensitive mammals and birds of the maritime.

SPERBOY

SPERBOY is a system that has been conceived and patented by Embley Energy. It is a floating powertrain enabled for wave energy conversion using the OWC mechanism. Air entrapped in chamber(s) is driven by one or more OWCs, in turn driven by incoming waves, and then led through turbine-generator sets. Its design requires deployment in substantial arrays 8 to 12 miles offshore so that SPERBOY can output significant amounts of energy at rather competitive cost. Embley Energy Limited was established in 1998 and has, since 2002, implemented an ocean wave energy research project that may lead to commercialization of the system.

SPERBOY is practically an OWC system with a flotation buoy on top and an underwater fully confined column. On board the buoy and OWC, a superstructure holds the machinery, for example, generators and air turbines, as well as the rest of the powertrain outfit. The working principle is practically the same with that of stationary OWC's deployed on the coastline and permanent structures. However, the following critical differences were introduced: (a) the system can be deployed in deep water to maximize power output, and (b) the overall power plant is floating, maintaining optimal conditions for hydrodynamic interaction with the dominant yet rather volatile wave field, and generating power at low cost.

The procedure and requirements to deploy a SPERBOY are rather simple. The major subsystem can be manufactured close by the installation site. Then it can be carried and set up by appropriate watercraft. The actual installation site needs to be known to decide what infrastructure will be required. Research so far has investigated the development of a farm with 10 systems. However, this number or size is not optimal for commercial power generation. Spacing between adjacent units is about 350 m, depending on bathymetry. A full scale farm may include 1000 systems spanning up to $10-15\,km^2$.

Minimal to even zero routine maintenance is the objective of the modular design concept adopted for

SPERBOY. Such characteristics provide SPERBOY with a competitive advantage within the OWC type of power plants since the system is simple, easy to build, low in maintenance requirement, designed to operate over a long period and enable for competitively low costs of power generation. It is noted here that along the Atlantic seaboard of Europe each system is estimated to deliver a rated capacity of about 1 MW. The expected range of power generation cost from SPERBOY is £ 50–140 per MWh with estimates currently at hand. The simplicity of the SPERBOY wave energy harvesting concept, along with a highly competitive cost of generation, puts it at the cutting edge of wave energy harvesting technologies.

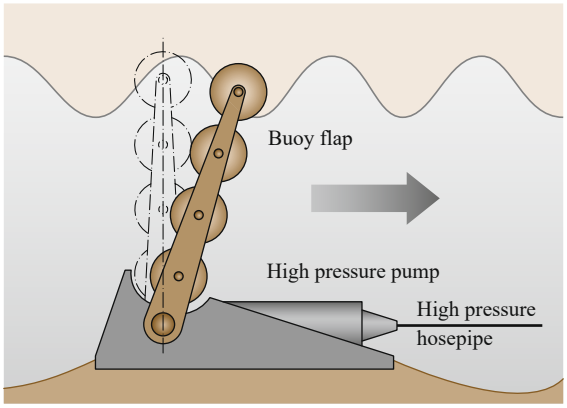

Fig. 45.26 Working principle of the Oyster wave energy system

45.A.4 Oscillating Wave Surge Convertors

This category includes systems that may float or are placed on the seabed and as sea waves, or even water currents, pass through the induced horizontal motion (surge) drives pumping of some hydraulic fluid acing as the medium for transfer of power. The concept is described in Sect. 45.1.4. The following are some the well-known commercial OWSC devices [45.1] (Table 45.5).

Oyster

Aquamarine Power's Oyster system can harvest energy from waves close to the coast. The captured wave energy is then converted into clean electric power. Practically, Oyster is a pump driven by waves that can thrust water at high pressure to run an onshore water turbine. The pumping concept is shown in Fig. 45.26.

Some of Oyster's main advantages include the following:

Simplicity due to being a mechanical offshore device with a minimum number of submerged moving parts. No automatic controller, gearbox, or shut-down mode is required and no complicated electronic modules offshore.

The system also demonstrates remarkable survivability due to the ability of the hinged flap to duck under waves exceeding a certain height in conjunction with the system's nearshore location and robustly designed supporting structure. An experimental Oyster system has been tested offshore in Orkney Islands in Scotland.

WaveRoller

WaveRoller is a system that can harvest wave energy and generate electric power or other forms of usable energy. The system can work in close-to-coast locations (approximately 0.3–2 km from the shore) and at depths between 8 and 20 m. Depending on locality prevailing conditions it is partly or entirely underwater and moored to the bottom. A standalone WaveRoller module (one panel) can generate between 500 and 1000 kW.

The concept of WaveRoller was inspired by a Finnish professional diver Rauno Koivusaari while exploring a shipwreck. He observed that a rather massive flat part of the ship's body was reciprocating back and forth, excited by the powerful water motion beneath the sea surface surge of water induced by incoming waves.

A WaveRoller responds practically in an identical manner as the part of the shipwreck that originally caught Rauno's attention. The reciprocating motion of the water triggered by waves puts a composite panel, into motion. As the module oscillates due to sea wave action, hydraulic piston pumps attached to the panel thrust hydraulic fluids inside a closed circuit. All the components of the system are sealed watertight in appropriate housing. Finally, the high-pressure fluid flow are driving a hydraulic motor that in turn acts as prime mover to an electric power generator.

bioWAVE

The bioWAVE is a system by BioPower Systems, Australia, that allows power generation from sea waves.

Table 45.5 Important wave energy conversion technologies employing oscillating water surge

Technology/plant name	Company	Country	Primary energy capture	PTO system
Oyster	AquaMarine Power Ltd.	United Kingdom	OWSC	Hydraulic circuit/hydro turbine
Wave Roller	AW-Energy Oy	Finland	OWSC	Hydraulic circuit
C-Wave	C-Wave Ltd.	United Kingdom	OWSC	Hydraulic circuit

The bioWAVE can work in swell waves, harvesting power both at sea surface and underwater. It is a pitching structure mounted on the seabed. The bioWAVE prototype under construction is expected to run in waters about 30 m deep. An envisioned 1 MW commercial unit will be able to run at water depths of 40–45 m.

The bioWAVE is attached to the seabed, with a pivot close to the bottom. The arrangement of buoyant floats, or *blades*, interacts with the oscillating surface (potential energy) and the sub-surface reciprocating water movement (kinetic energy). In effect, the pivoting module oscillates horizontally in synchronicity with incident waves. This motion is converted to electric power through an onboard self-contained hydraulic system, called O-Drive.

45.A.5 Attenuators

The principle of operation of this category is discussed in Sect. 45.1.5. These converters are built around a modular floating structure, the segments of which are connected using mechanical joints. Wave-induced motions compress hydraulic fluid in a closed circulation system in order to transfer the power to hydraulic motors that may be used to drive loads like electric generators. The following are some of the well-known attenuator WEC devices [45.1] (Table 45.6).

Pelamis

Pelamis Wave Power's Agucadoura Wave Farm isa commercial wave energy harvesting power plant situated 5 km off the Agucadoura coast in Portugal. The farm has been producing 2.25 MW by employing three Pelamis modules (Fig 45.27) since September 2008.

Wave energy harvesting of the technology that led to Pelamis was initiated by *Salter's Duck* (discussed in Sect. 45.1.5) invented by Professor Stephen Salter of the University of Edinburgh [45.6, 27, 28, 59, 60]). Pelamis is of cylindrical shape and consists of core tube segments held together by hinged joints. The system is 140 m long, 3.5 m in diameter. It can generate up to 750 kW rated power at a capacity factor 0.25–0.4.

During the design and development of Pelamis, special care has been taken to maximize survivability. The system's small cross-sectional area and streamlined hull form as well as compliant moorings in conjunction with the self-limiting hydrostatic loading, mitigate power absorption when wave height becomes too big to safely operate.

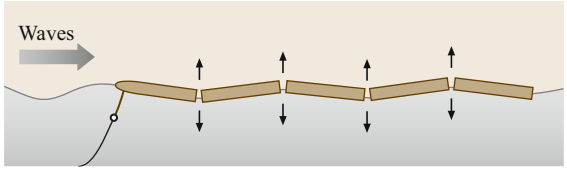

Fig. 45.27 Schematic representation of the Pelamis system, an attenuator WEC device

The system modules for the site in Portugal were manufactured in Stonehaven by Ross Deeptech. After commissioning of the electro-hydraulic power take-off systems was complete, the modules were transferred to Lewis. At this location, they were connected with the main tube segments made by Camcal. The components were transported in March 2006 to the Port of Peniche. There they were assembled, commissioned and installed at a location 5 km offshore north Portugal, near Póvoa de Varzim.

DEXA

The DEXAWAVE (or DEXA for short) (by DEXAWAVE, Denmark) wave energy harvesting concept is simple to build construction. It includes two rigid pontoons, hinged together using a patented hinge. Each one of those pontoons can pivot with respect to the other. A hydraulic PTO system on top of the device, can deliver up to 250 kW.

Just like Pelamis, the origins of DEXA can be traced to an earlier contraption, namely Cockerel's Raft that was developed in the early 1980s [45.61]. However, the DEXAWAVE development team came up with an improved design. In specific, the idea in Cockerel's Raft is that a floating body perturbed away from equilibrium will attempt to recover by a force equal to 44% of its total weight if one of its ends is fully emerged out of the water. By splitting the weight to two equal floating buoys connected with an almost weightless beam, the restoring force can be increased to 50% the total weight value while the amount of building material is also reduced significantly.

Table 45.6 Important wave energy conversion technologies employing attenuators

Technology/plant name	Company	Country	Primary energy capture	PTO system
McCabe wave Pump	Hydam Technology Ltd.	Ireland	Attenuator	Hydraulic circuit
Pelamis	Pelamis Wave Power Ltd.	United Kingdom	Attenuator	Hydraulic circuit
Sea Power Platform	Sea Power Ltd.	Ireland	Attenuator	Hydraulic circuit
Wello	Wello Finland	Portugal	Attenuator	Hydraulic circuit

Table 45.7 Important wave energy conversion technologies employing overtopping devices

Technology/plant name	Company	Country	Primary energy capture	PTO system
Wave Dragon	Wave Dragon Ltd.	Denmark	Overtopping	Hydro turbine
TAPCHAN	Norwave A.S.	Norway	Overtopping	Hydro turbine
Seawave Slot-Cone Generator	WAVEnergy AS	Norway	Overtopping	Hydro turbine
Floating Wave Power Vessel	Sea Power	Sweden	Overtopping	Hydro turbine

Owing to the simple mechanical construction of the DEXA converter, as a structure of floating pontoons, the converter can be installed relatively simple, and fast. Only a tug boat, and float with a simple chain crane is required. No divers, ROVs, crane platforms, etc. are required.

A scale model of the DEXAWAVE WEC is currently being tested in Danish waters and at Malta.

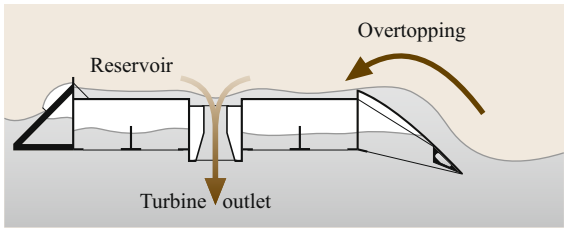

Fig. 45.28 Operation principle of Wave Dragon power plant (graphic by Erik Friis-Madsen)

45.A.6 Overtopping Devices

The principle of operation of this category is discussed in Sect. 45.1.6. Overtopping systems come with a seawater pool or tank that, when waves break, fills up. The seawater entrapped in the pool is then fed back to the ocean through a passage where a low-head water turbine produces electricity. Additional contraptions are often employed in overtopping systems, like e.g., collectors, in order to focus or otherwise enhance the energy harvested from the wave field. The following are some of the well-known commercial overtopping devices [45.1] (Table 45.7).

Wave Dragon

Wave Dragon is a floating wave energy harvesting overtopping system with a slack mooring. The concept allows deployment in either standalone modules or farms of Wave Dragon modules; the latter can be built up to match the power output of conventional power stations working, for example, with coal or hydrocarbon fuels.

A facility of this type, part of a utility grid, exists in Nissum Bredning, Denmark. Long-term trials are being conducted to assess performance including availability and power generation under the full range of operating conditions.

The Wave Dragon enables an incident wave to focus in the direction of a ramp. Located past the ramp, a tank of substantial size collects the seawater overtopping developing thus a head value. Seawater in the tank is then discharged from the tank through channels where water turbines are mounted in order to take advantage of the head between the level in the tank and the sea surface.

The size of a certain Wave Dragon is the outcome of an optimization procedure to match it with the wave climate at the installation site. The design variables include main body width, reflector length, overall weight, system number and turbine dimensions etc. The Wave Dragon at Nissum Bredning is built to match a rather modest wave climate at about 0.4 kW/m. This system is developed for trial purposes only and not meant for full-scale deployment. To maximize seawater overtopping capacity a joint system consisting of wave reflectors and a ramp with double curving has been developed and patented as shown in Fig. 45.28.

46. Ocean Current Energy Conversion

Howard P. Hanson, James H. VanZwieten, Gabriel M. Alsenas

Ocean currents in tidal flows and at the western boundaries of the ocean basins, as well as currents in rivers, can have as much potential for power production as the wind. With increased interest in sources of renewable energy, realizing this potential has undergone a renaissance in recent years. This chapter provides an introduction to ocean current energy conversion by emphasizing the contrasts between winds and currents and discussing some of the unique challenges associated with this untapped renewable energy source.

References 1160

In addition to surface waves, oceanic motions that can be used as sources for renewable energy include ocean current systems on a variety of time and space scales. These sources of *marine hydrokinetic energy*, and the most common rotating technologies used to harness this energy, are the topic of this chapter.

Ocean currents have three principal forcing mechanisms [46.1].

Seawater density differences associated with the global distributions of temperature and salinity drive a thermohaline circulation, which is sometimes called the *oceanic conveyer belt*; the Atlantic basin component of this circulation is the Atlantic meridional overturning circulation (AMOC) [46.2]. The currents of the thermohaline circulation are, by themselves, too slow to be of interest for renewable energy purposes.

Winds in the atmosphere exert stress on the ocean surface, and the latitudinal differences associated with the transition from easterly trade winds in the tropics to the mid-latitude westerlies translate into a torque on the surface of the oceans. This torque, combined with earth's rotation and nearly spherical shape, results in large-scale, *wind-driven gyres* in the various ocean basins, in which the effects of friction, negligible in the interior, cause western boundary currents on the bounding continents' east coasts – the Gulf Stream in the Atlantic and the Kuroshio in the Pacific are familiar examples. These currents, with speeds of $2\,\mathrm{m\,s^{-1}}$ and more in some locations, do have potential for marine renewable energy (MRE) extraction.

Finally, the gravitational attraction of earth's moon as the earth rotates under it causes the oceanic tides, and these changes of sea level can cause strong tidal currents, particularly at the inlets to large bays, of $5\,\mathrm{m\,s^{-1}}$ and even more. These are also of interest to energy developers. Quantifying the potential of these strong currents provides a useful starting point for a discussion of energy-extraction technology.

In the context of currents that can be used to produce power, it is also relevant to note that many rivers offer the potential for renewable energy production. Although the focus of this chapter is on MRE, most of the background here also applies to in-stream, riverine cases.

Much of what follows in this first section is familiar territory in the atmosphere, given the maturity of the wind-power industry [46.3]. Because MRE is a relatively young field, however, it is presented here as an introductory tutorial into some of the fundamental issues of extracting power from currents using rotating equipment. Ocean–atmosphere contrasts will be emphasized.

46.1 Fundamentals

Like the atmosphere, the ocean behaves as a Newtonian fluid, provided that the effects of earth's shape and rotation are taken into consideration. These complications, however, are not needed for the analysis here, and so they will be ignored in the following.

Fluid behavior is described by the equations of motion, for the ocean a closed set of nonlinear partial differential equations that includes Newton's second law as written for fluids (the Navier–Stokes equations), conservation principles for mass and its constituents as appropriate, and, if needed, heat energy via the first law of thermodynamics [46.1, 103ff.]. In the present case, we need only the three Navier–Stokes equations (one for each orthogonal direction, x, y, z, with z taken here to be opposite to the attraction of gravity, meaning, generally, up) and the conservation of mass as expressed by the continuity equation. In full, three-dimensional (3-D) form, these are, respectively,

$$\rho\frac{DU}{Dt} \equiv \rho\left(\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x} + V\frac{\partial U}{\partial y} + W\frac{\partial U}{\partial z}\right) = -\frac{\partial p}{\partial x} + \frac{\partial}{\partial x}\left(\mu\frac{\partial U}{\partial x}\right), \tag{46.1a}$$

$$\rho\frac{DV}{Dt} \equiv \rho\left(\frac{\partial V}{\partial t} + U\frac{\partial V}{\partial x} + V\frac{\partial V}{\partial y} + W\frac{\partial V}{\partial z}\right) = -\frac{\partial p}{\partial y} + \frac{\partial}{\partial y}\left(\mu\frac{\partial V}{\partial y}\right), \tag{46.1b}$$

$$\rho\frac{DW}{Dt} \equiv \rho\left(\frac{\partial W}{\partial t} + U\frac{\partial W}{\partial x} + V\frac{\partial W}{\partial y} + W\frac{\partial W}{\partial z}\right) = -\frac{\partial p}{\partial z} + \frac{\partial}{\partial z}\left(\mu\frac{\partial W}{\partial z}\right) - \rho g, \tag{46.1c}$$

$$\frac{D\rho}{Dt} \equiv \frac{\partial \rho}{\partial t} + U\frac{\partial \rho}{\partial x} + V\frac{\partial \rho}{\partial y} + W\frac{\partial \rho}{\partial z} = -\rho\left(\frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} + \frac{\partial W}{\partial z}\right) = 0. \tag{46.2}$$

Here, the velocities in the (x, y, z) directions are (U, V, W), respectively, t is time, ρ is the fluid's density, p is pressure, g is the gravitational constant ($9.81\,\mathrm{m\,s^{-2}}$), and μ is the fluid's viscosity, which will be ignored here.

In (46.1) the terms are, left to right, the change of the velocity component following the flow ($D[\,]/Dt$ represents the material, or total, derivative); which is defined as the sum of the *local* change of the velocity component with respect to time and three terms representing the advection of velocity up its gradient by the flow field; which equal the sum of forces acting on the fluid, in this case the pressure gradient force and the effects of friction expressed through viscosity. The equation for vertical motion (46.1c) also includes the gravitational force on the right-hand side. The terms in the continuity equation (46.2) are the time rate of change of density following the flow; which is defined by the four terms of the total derivative representing the local time rate of change and advection of density (all of these apply to compressible fluids), which equal the convergence (i. e., the opposite of the divergence) of the flow field multiplied by the density.

We will assume frictionless, incompressible flow, which is appropriate for the oceanic cases under consideration here – the friction terms in (46.1) will be dropped, and the derivatives of ρ in (46.2) vanish.

It is useful to define a kinetic energy per unit volume, $E \equiv \frac{\rho}{2}(U^2 + V^2 + W^2)$. Its conservation equation can be derived from (46.1) by multiplying (46.1a), (46.1b), (46.1c) by U, V, W, respectively, adding the three equations, and rearranging terms. This results (for frictionless flow with no body forces beyond gravity) in

$$\frac{DE}{Dt} \equiv \frac{\partial E}{\partial t} + U\frac{\partial E}{\partial x} + V\frac{\partial E}{\partial y} + W\frac{\partial E}{\partial z} = -\left(U\frac{\partial p}{\partial x} + V\frac{\partial p}{\partial y} + W\frac{\partial p}{\partial z}\right) - \rho g W. \tag{46.3a}$$

Changes of kinetic energy following the flow, then, are associated with the work of the pressure gradient force, or a change of potential energy in earth's gravity field. Multiplying the incompressible form of (46.2) by E/ρ and adding it to (46.3a) gives the *flux form* of the kinetic energy equation

$$\frac{\partial E}{\partial t} = -\left\{\frac{\partial (UE)}{\partial x} + \frac{\partial (VE)}{\partial y} + \frac{\partial (WE)}{\partial z}\right\} - \left\{U\frac{\partial p}{\partial x} + V\frac{\partial p}{\partial y} + W\frac{\partial p}{\partial z}\right\} - \rho g W. \tag{46.3b}$$

This shows that the local change of kinetic energy is the sum of the energy flux convergence and the work of the pressure field and of gravity.

This kinetic energy flux warrants further discussion. If the x direction is aligned with the flow (x positive downstream), then V and W can be ignored, and the magnitude of kinetic energy flux becomes

$$UE = \frac{\rho}{2}U^3 \equiv \Psi, \tag{46.4}$$

a very important quantity that represents the *power density* of the flow, that is, the power ($\mathrm{W\,m^{-2}}$) of the flow per unit area orthogonal to the flow direction. Note

the distinction between power $P \equiv \frac{DE}{Dt}$ and power density Ψ. Power is the (total) time derivative of energy, just as acceleration is the time derivative of velocity, while power density requires a different interpretation. In terms of (46.3b), the local change of energy with time is equal to the (opposite of) downstream gradient of power density, plus other work terms. In physical terms, the power density in an area A orthogonal to the flow is that power available to increase flow's kinetic energy by an amount (per unit time) $P = A\Psi$. However, other considerations prevent all of this power from being used, as will be seen in the next section.

It is useful to compare, using a simple order-of-magnitude analysis, power densities in the atmosphere and the ocean, because both the media flow (in winds and currents, respectively), and both are available for energy generation using turbines and other methods. Near the earth's surface, an order of magnitude for the density of air is $\rho_a \approx 1\,\mathrm{kg\,m^{-3}}$, while the density of seawater is much larger, $\rho_w \approx 1000\,\mathrm{kg\,m^{-2}}$. In contrast, characteristic values for winds and currents are the opposite, with winds occurring at factors of 10 or so higher than currents, in locations of interest to energy developers. The cubic dependence of Ψ on flow speed in (46.4) means, then, that the power densities in the two media are commonly of the same order of magnitude. More specifically, using actual values for the densities, it can be said that a $2\,\mathrm{m\,s^{-1}}$ (or 4 kt) ocean current has the power density of a gale-force (38 kt) wind. Because observations of flows in tidal channels and in western boundary currents routinely approach $2\,\mathrm{m\,s^{-1}}$, interest in the oceans as a source of renewable energy is high. And because these flows in the ocean can be harnessed with much the same equipment as the atmospheric winds (suitably modified for use underwater), much of the basis for ocean current energy conversion comes from the many decades of experience in the wind-power industry. An example is the fundamental limitation on energy extraction from a flow.

46.2 The Betz Limit

From a physical perspective, it is impossible to extract all the kinetic energy from a flow, because that would bring the flow to a halt, in which case it would not be able to continue to turn the device (the turbine) that is doing the extraction. Instead, there must be some optimal point at which the power extraction is maximized with respect to the flow's slowing down.

This was first considered by the German engineer *Albert Betz* in 1926 in a monograph (in German) called *Wind energy and its extraction through windmills* [46.4]; the topic has been discussed at length in numerous other publications since (a useful translation is [46.5]). Betz showed that the optimal extraction amount – now called the *Betz limit*, as it is impossible to extract more power than this – is about 60% of the inflow power. For completeness, we will re-derive this here. It is worth noting that the many claims of power generation above the Betz limit are all driven by marketing considerations rather than science and engineering, as they inevitably involve funnel-like shrouds and cowlings that allow the effective area of a given turbine to be increased and the flow to be accelerated accordingly.

Figure 46.1 provides a schematic of the flow under consideration, a steady, incompressible, 1-D (one-dimensional) flow (in its undisturbed state) in which an idealized *turbine* is introduced. The flow through the device is bounded by the two solid streamlines (in the plane of projection in the figure) that bound an upstream area A_u and the other areas downstream. Far upstream, the flow occurs at ambient pressure p_0 and velocity U_u. Far downstream, where the flow has returned to ambient pressure p_o, the streamlines bound an area A_d, through which the flow velocity is U_d. At the position of the turbine, which sweeps an area A_t, the flow velocity is U_t; the pressure field undergoes a pressure drop of δp from its (just) upstream value of p_t across the rotor – δp is therefore the force per unit area (downstream) across the face of the idealized turbine.

Continuing the notation that x represents the downstream direction (and therefore the areas in Fig. 46.1

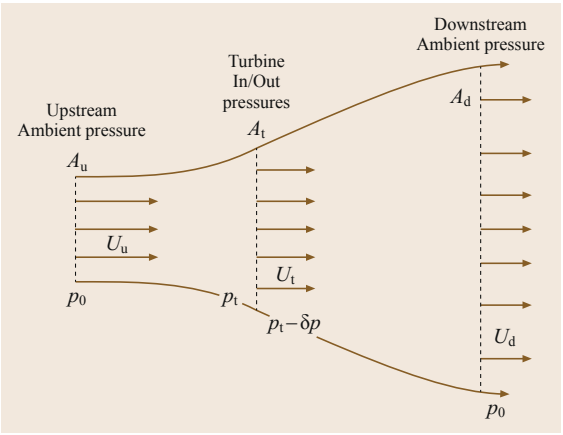

Fig. 46.1 Schematic of flow through an idealized turbine (not to scale in the streamwise direction)

are in the $Y-Z$ plane), (46.1a) becomes, for time-independent flow,

$$\rho\frac{DU}{Dt}=\rho\left(U\frac{\partial U}{\partial x}\right)=\frac{\rho}{2}\frac{\partial U^2}{\partial x}=\frac{\partial E}{\partial x}=-\frac{\partial p}{\partial x}\,. \tag{46.5}$$

The last equality implies that, along an undisturbed streamline, $E+p=$ const., thus recovering the Bernoulli principle, in which context E is often interpreted as the *dynamic pressure*. (Energy per unit volume [$\mathrm{J\,m^{-3}}=\mathrm{N\,m\,m^{-3}}$] has the same units as pressure [$\mathrm{N\,m^{-2}}$], so there is no inconsistency here). Applying this to the flow upstream of the turbine and, separately, to the flow downstream of the turbine, and then subtracting the resulting expressions results in

$$E_\mathrm{u}-E_\mathrm{d}=\delta p\,. \tag{46.6}$$

Note that this recovery of the Bernoulli principle comes directly from the Navier–Stokes equations, the momentum budget along streamlines – unlike many derivations, no energetic arguments were involved here.

It is also useful to consider the momentum budget of the entire flow structure in Fig. 46.1. A physical interpretation of the momentum budget is that, in any domain, the difference between the flux of momentum into and out of the domain is equal to the sum of the forces within the domain that are opposing the flow (because these forces are sinks of momentum). This implies that

$$U_\mathrm{u}\rho A_\mathrm{u}U_\mathrm{u}-U_\mathrm{d}\rho A_\mathrm{d}U_\mathrm{d}=A_\mathrm{t}\delta p\,. \tag{46.7a}$$

Continuity (i. e., no loss or gain of mass) in the system requires that $AU=$ const., and making use of this in (46.7a) allows it to be rewritten as

$$\rho U_\mathrm{t}(U_\mathrm{u}-U_\mathrm{d})=\delta p\,. \tag{46.7b}$$

By substituting the definition of E into (46.6) and eliminating δp between (46.6) and (46.7b), it is possible to show that $U_\mathrm{t}=(U_\mathrm{u}+U_\mathrm{d})/2$; that is, the velocity at the face of the turbine rotor is the average of the upstream and downstream velocities. In the following, it is convenient to define the ratio of these as $\eta\equiv U_\mathrm{d}/U_\mathrm{u}$.

Now, (46.3a) and (46.5) suggest that

$$P=U\frac{\partial E}{\partial x}=UF\,. \tag{46.8}$$

At the turbine, then, the power is

$$\begin{aligned}P_\mathrm{t}&=U_\mathrm{t}(A_\mathrm{t}\delta p)=\rho A_\mathrm{t}U_\mathrm{t}^2(U_\mathrm{u}-U_\mathrm{d})\\&=\frac{\rho}{4}A_\mathrm{t}U_\mathrm{u}^3(1+\eta)^2(1-\eta)\,,\end{aligned} \tag{46.9}$$

which makes use of (46.7b). Maximizing (46.9) with respect to η gives two roots, one negative, and therefore unphysical, and the other at $\eta=\frac{1}{3}$.

It is useful to compare this maximum power with that of the undisturbed flow through this area by defining a power coefficient (this one with the subscript B to denote Betz) as

$$C_\mathrm{B}\equiv\frac{P_\mathrm{t}}{A_\mathrm{t}\Psi_\mathrm{u}}=\frac{1}{2}(1+\eta)^2(1-\eta)=\frac{16}{27}\cong 0.593\,. \tag{46.10a}$$

Thus, the maximum power an idealized turbine can produce is just less than 60% of that available in the undisturbed flow. In a more general sense, it is useful to define a turbine power coefficient C_P as the ratio of the actual power produced by a device to that of the undisturbed flow. Due to internal friction and blade inefficiencies, $C_\mathrm{P}<C_\mathrm{B}$ in all cases without shrouds, with experimental device tests calculating values for C_P that approach 0.5 [46.6]. With this definition, the generalized expression for the power generated by a given device is

$$P=C_\mathrm{P}A\Psi, \tag{46.10b}$$

where C_P and A are properties of the device and Ψ is the power density of the undisturbed flow.

Note that substitution of the results for U_t and η into (46.7a) shows that $\delta p=\frac{4}{9}\rho U_\mathrm{u}^2$; that is, the pressure drop across the *turbine* in Fig. 46.1, which is the force on that turbine, is proportional to the flow velocity squared (the factor of 4/9 applies only at the Betz limit). Re-applying the order-of-magnitude argument above concerning power density to this result provides further insight. A similar comparison of atmosphere and ocean shows that, for identical power densities, the forces on objects in the ocean are about an order of magnitude larger than in the atmosphere. This has obvious implications for design of oceanic energy-recovery equipment, turbine rotors in particular.

46.3 Conversion Systems

As mentioned at the outset, this chapter focuses on rotating energy conversion systems, devices falling under the general description of ocean-current turbines (OCTs). Although MRE is a young field, progress is being made in many of its constituent areas; in particular, design requirements for OCTs are beginning to become standardized [46.7]. The purpose of this chapter is not to discuss such standards in detail; rather the discussion here is meant as background for further advancements in MRE development.

An important concept related to all OCTs, as well as wind turbines, is the *cut-in speed* of a particular device. This is simply the minimum flow speed, generally defined in terms of the undisturbed flow, or U_u in the terminology here, that will turn the system's rotor and generate power. Efficient rotor blades and minimal internal friction of the device will decrease cut-in speed, thus allowing an OCT to function at lower current speeds and to have a higher capacity factor, or fraction of the system's designed output, for the location in question.

At the same time, in real-world ocean currents there is a point of diminishing returns, as shown in Fig. 46.2. In this figure, the *production factor* is the amount of energy that hypothetical systems of various cut-in speeds installed at three hub depths would produce relative to the potential amount if cut-in speed were not a factor (Production factor differs from capacity factor in that capacity factor uses the system's designed power output as the denominator and does not take into account current variations above the cut-in speed, while production factor does). Note that, at this location, there is little to be gained by potentially expensive design and manufacturing improvements to lower cut-in speed below $1\,\mathrm{m\,s^{-1}}$. This underscores the importance of careful site characterization studies prior to choosing what equipment to install.

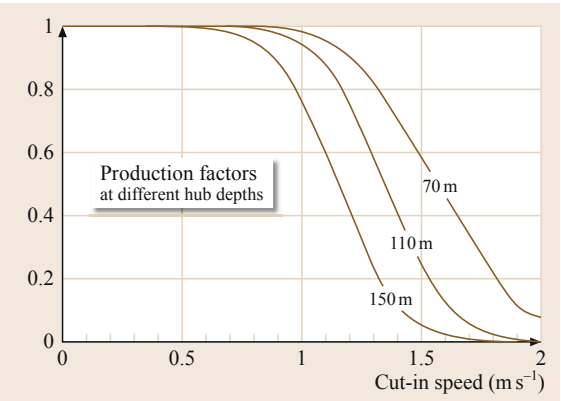

Fig. 46.2 Fraction of potential energy production as a function of system cut-in speed; this is an example from the Florida current off Fort Lauderdale. Based on acoustic Doppler current profiler ADCP data from the Florida current at 26° N, March 2009–March 2010

Such a site characterization would naturally include an estimate of the amount of power available at that location and some secondary estimate of what can be extracted. Cut-in speed is also useful in this context. For example, oceanographic measurements of the Florida current obtained using Pegasus floats in the 1980s across the straits of Florida at 27° N [46.8] were processed by *Hanson* et al. [46.9] to show that there is some 20 GW ($= 10^9$ W) of total power in the flow, but that the power available at and above a particular cut-in speed decreases markedly with cut-in speed (Fig. 46.3).

With this background, it is possible to discuss devices that can make use of this power.

46.3.1 Axial-Flow Systems

Figure 46.4 shows the main components of an axial-flow OCT designed and fabricated at the Southeast National Marine Renewable Energy Center (SNMREC) for the purpose of conducting at-sea research of OCT features and components. The designation of *axial-flow* for this and other such systems is fitting because such a concept aligns with the flow along that the rotor's axis of rotation. Note that the system is designed such the

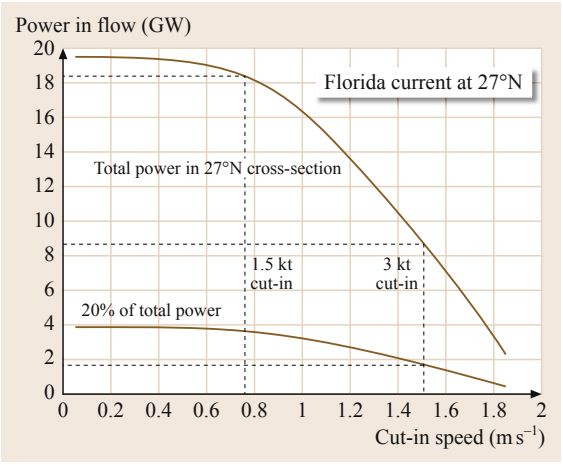

Fig. 46.3 Power in a Florida current cross-section at 27° N depicted as a cumulative function of cut-in speed. The extractable power is assumed to involve devices of 40% net efficiency ($C_P = 0.4$) that occupy half of the cross-sectional area at and above a particular speed (after [46.8])

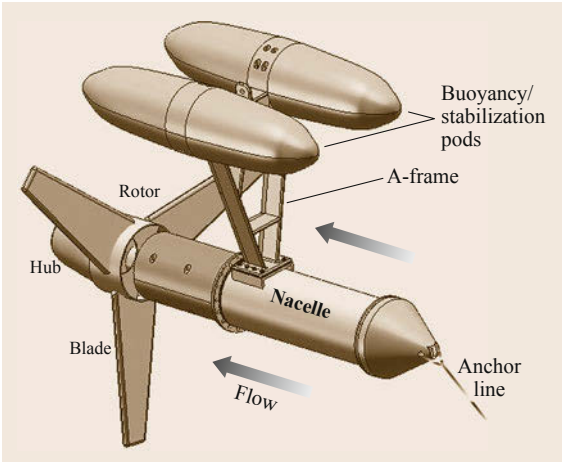

Fig. 46.4 Positively buoyant version of 20 kW SNMREC test turbine, showing main components

rotor is aft, unlike many wind systems. Internal components, including a gear-box and generator, along with other electrical components, are housed inside the nacelle (Fig. 46.5).

This system is designed to float at 50−100 m while moored to an anchor. A later variant is negatively buoyant, as shown in Fig. 46.5, to be deployed from a ship. In both versions, the two pods act as stabilization, with a moment arm created by the A-frame to provide resistance against the torque of the rotor to prevent the turbine from rolling. As an alternative to such stabilization, some systems are being designed with two counter-rotating rotors connected by a framework resembling a wing, such as that shown in Fig. 46.6. In this concept, a wing can generate lift for the system, providing a means for depth control.

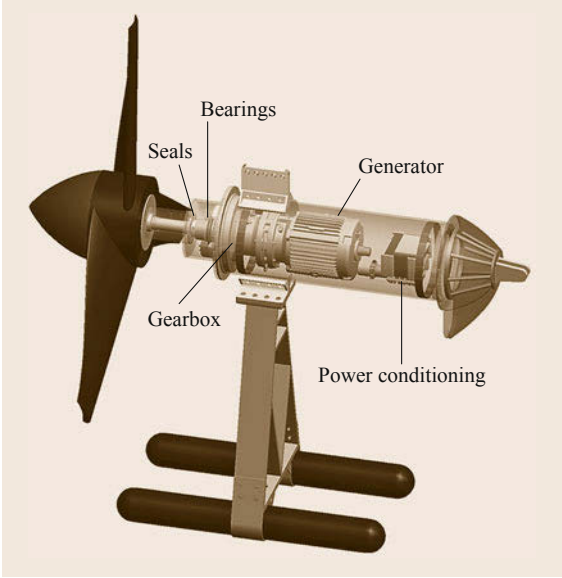

Fig. 46.5 Negatively buoyant version of Fig. 46.4 turbine system, with internal components depicted. This version is to be lowered from a work boat for testing purposes

An important concept in axial-flow rotor design is the *tip-speed ratio*, or TSR. This is the ratio of the speed of the tips of the rotor blades to the undisturbed flow speed U_u. Given a rotor of diameter D rotating at a frequency f (often expressed as revolutions-per-minute, or RPM, but formally having units of s^{-1}), the TSR is

$$\lambda = \frac{2\pi f(D/2)}{U_u} \,. \tag{46.11}$$

Typically, for a 3-blade rotor such as those depicted in Figs. 46.4–46.6 the optimum TSR is in the range $6 \lesssim \lambda \lesssim 7$. A physical interpretation of this provides insight into the importance of this parameter.

Rotor blades are most hydrodynamically efficient when undisturbed flow acts on them. It must be the case, therefore, that λ cannot be too large, because, for a given streamline, the turbulence generated by a given blade would not have time to clear the disk of the rotor before the arrival of the next blade. On the other hand, the smaller the value of λ, the less power will be generated (if $\lambda = 0$, the rotor is not turning and no power is generated).

Consider a highly efficient turbine for which the overall coefficient of power approaches the Betz limit, $C_P \approx C_B$. From the analysis in the previous section, it is easily shown that $U_t = \frac{2}{3}U_u$. The time it takes for an n-bladed rotor to turn the distance between two of the blade tips is $\Delta t_r = (nf)^{-1}$. During this time, the undisturbed water just upstream of the turbine in Fig. 46.1 will travel a distance Δx, which is

$$\Delta x = U_t \Delta t_r = \frac{2}{3}\frac{U_u}{nf} = \frac{2}{3}\frac{\pi D}{n\lambda} \,.$$

This means, for a 3-blade rotor turning at $\lambda = 6.5$, that $\Delta x \cong 0.1D$. If the size of the rotor hub is neglected in comparison to the blade length, then the blades are approximately $D/2$ in length, so that Δx represents approximately 20% of a blade length in this case. Because the cross-section of rotor blades is foil-shaped, blade length is much greater than blade width, which is called the *chord* of the blade. Consequently, Δx is much larger than the width of the blade tip. This means that, near the blade tips, at least, the turbulence from a blade passage can clear the rotor plane before the arrival of the next blade if the tip's chord is smaller than at the root, and relatively undisturbed water is available to lift each blade and turn the rotor. Note that maintaining a similar

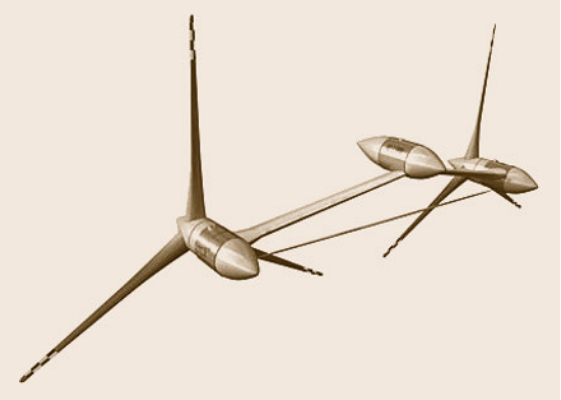

Fig. 46.6 The Aquantis C-plane dual rotor design; (courtesy of Aquantis, Inc.)

value for Δx requires that the TSR decrease in proportion to the number of rotor blades.

The order-of-magnitude analysis used previously is of interest here as well. Recall that, for wind speeds that are 10 times current speeds, the power densities of air and water are about the same, but the forces on structures in the water are a factor of 10 greater. On the other hand, blade-tip speeds, for identical TSRs, are a factor of 10 *less* in the water because, from (46.11) with U_u a factor of 10 less than the wind speed, rotors of the same diameter turn 10 times more slowly in the ocean. In addition, slow blade-tip speeds reduce the potential for cavitation, as resulting cavitation numbers lie in the range of 5–15.

The design of rotor blades, particularly for wind power, is a well-developed field with a rich literature that includes entire textbooks, and a full treatment of it here is beyond the scope of this chapter. In a fundamental sense, a rotor blade functions in much the same fashion as an airplane wing, as depicted in Fig. 46.7. The cross-section shown, a foil that is symmetric about its centerline, is positioned at a moderate angle of attack with respect to the flow. In response, the flow distorts asymmetrically, and the upper streamlines converge while the lower ones diverge. Why the flow converges above and diverges below the wing is a surprisingly complex phenomenon, well beyond the scope here. Suffice it to say that it is *not* due to the common explanation of equal transit times for air above and below but rather to more complex fluid mechanics. In any case, the convergence and divergence are well-documented from observations.

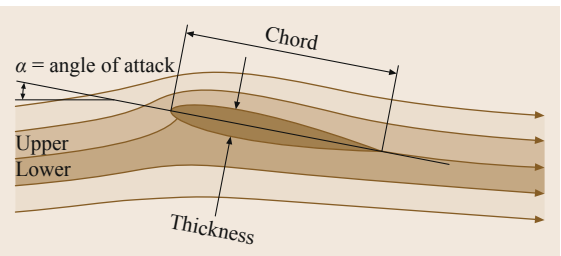

Fig. 46.7 Cross-section of an airplane wing – or a rotor blade – and its local flow field

By the continuity equation (46.2), this convergence and divergence imply that the flow accelerates above the wing and decelerates below, and, by the Bernoulli principle, implied by (46.5), the pressure above the wing decreases and that below increases – thus generating lift, a force at right angles to the flow (up, in Fig. 46.7, and opposite to gravity, for an airplane wing).

If, however, Fig. 46.7 is interpreted as a downward view of a rotor blade foil when the blade is at the twelve-o'clock position, the lift is seen to generate an anti-clockwise force (reckoned looking downstream) that would make the rotor turn in that direction. While flat plates will produce these same angle-of-attack effects, careful foil design provides improved lift as well as better structural integrity.

For an airplane wing, the flow is created by the forward motion (to the left, in Fig. 46.8) of the airplane plus any motion of the air itself. In general, for airplanes the former is much greater than the latter. However, in the case of a rotor blade, the background flow causes the blade to move, and, given TSRs of 6–7 or so, at a significant velocity. The combined relative motion of the fluid with respect to the moving blade is therefore what the blade sees as the flow. Further, because the speed of any section of a blade depends on its radial distance

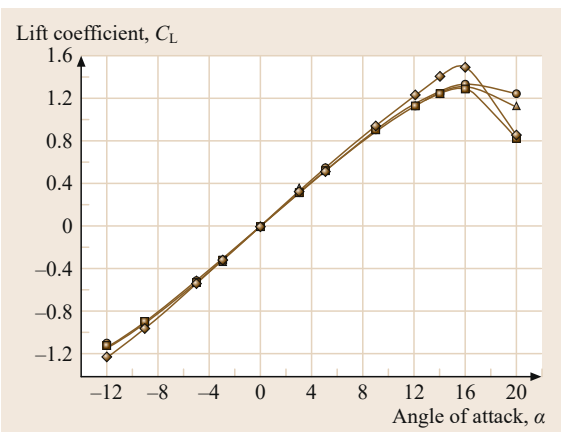

Fig. 46.8 Coefficient of lift as function of angle of attack for airfoil shown in Fig. 46.6. The airfoil begins to stall at about 16°, the point at which the experimental curve reaches the sharpest peak. The other curves represent results from computer simulations (after [46.10])

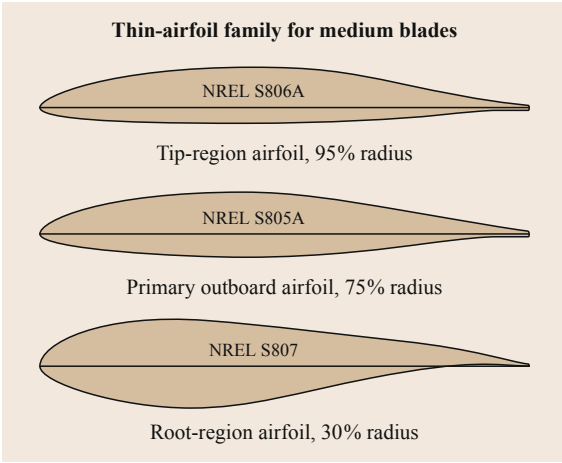

Fig. 46.9 Airfoils as a function of position along a wind-turbine blade from top to bottom, near the tip to near the blade root, shown with a standard chord. The blade thickness is increased near the root for strength; blades constructed on this pattern would decrease the chord toward the blade tip, and twist could be added as well. This family is for blades 5–10 m in length (after [46.11])

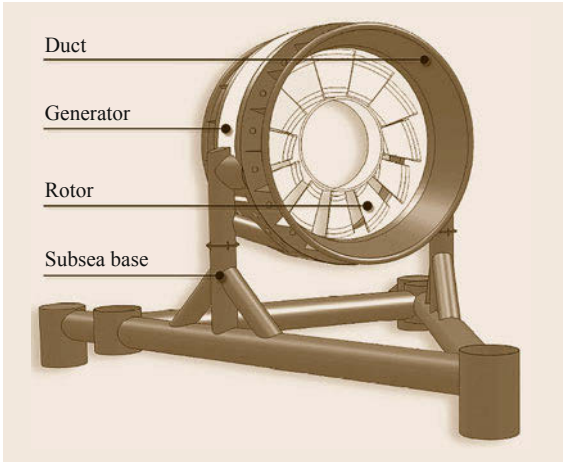

Fig. 46.10 OpenHydro, Ltd. Open Centre tidal turbine. The bearings are in the duct, and the center of the rotor is open. For tidal applications, the blades are designed to accommodate bi-directional flows (courtesy of OpenHydro & Nova Scotia Power, Inc.)

from the hub, this relative motion varies along the blade length.

To analyze blade performance, it is useful to define a lift coefficient C_L as the lift force per unit blade length divided by the dynamic pressure E (where the velocity relative to the blade is used) times the chord of the blade. Now, as shown in Fig. 46.8, lift increases with the angle of attack (up to the point that the foil stalls) as well as the square of the relative flow speed and the chord. Consequently, rotor blades are often twisted, so that the angle of attack is a function of distance from the hub, and tapered as well, in order to distribute the lifting force along the blade length in a way to accommodate the structural characteristics of the blade.

The wind power industry is sufficiently mature that standard blade shape sets exist. MRE, on the other hand, is relatively new, and OCTs, at this writing, either select standard blades or develop new, proprietary shapes. The US Department of Energy's (DOE) National Renewable Energy Laboratory (NREL) has taken a lead role in the wind industry to develop families of wind-turbine blades that are based on modified versions of US National Advisory Committee for Aeronautics (which transitioned to become the National Aeronautics and Space Administration (NASA) in 1958) standard airfoils. An example of how foil shape changes along the length of the blade is shown in Fig. 46.9, which is taken from [46.11].

In addition to systems with open rotors such as those in Figs. 46.4–46.6, other axial-flow systems with ducted rotors have been designed and fielded. The rotors of these systems tend to resemble those of high-pressure turbines rather than aircraft propellers. For example, the OpenHydro Group, Ltd. deployed its Open Centre system (Fig. 46.10) in several locations in Europe and North America for testing. As noted previously, the ducting can also be designed to increase the effective area of the rotor's sweep, thus increasing power production.

These examples of axial-flow systems are but three of a wide range of designs. The US Department of Energy maintains a database of technology describing systems that have been reported in the literature and online [46.12].

46.3.2 Cross-Flow Systems

Also included in the DOE database are examples of other rotating current energy conversion devices that can be considered cross-flow systems. In these systems, the axis of rotation of the turbine is at right angles to the flow; generally the axis is oriented either horizontally or vertically. The simplest such rotors, such as the Savonius rotor (Fig. 46.11a), are turned by the drag force of the moving fluid. These systems are not particularly efficient because the net drag available to turn the rotor is the difference between the drag on the two curved surfaces – the concave surface will *capture* the moving fluid and induce more drag than the convex surface, so that the rotor works much like a cup anemometer.

Efficiency can be improved by replacing the curved surfaces of the Savonius rotor with lifting surfaces in

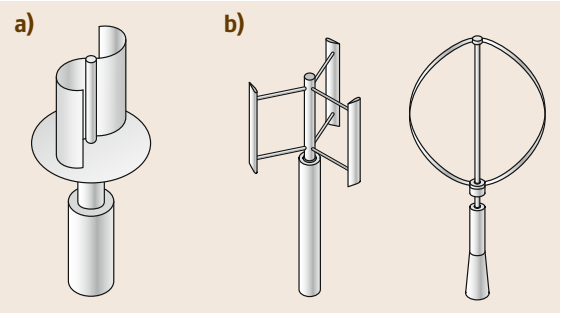

Fig. 46.11a,b Simple vertical-axis cross-flow rotors. **(a)** Savonius rotor; **(b)** Darrieus rotors

the form of blades, which then becomes a Darrieus rotor (Fig. 46.11b), with either straight or curved blades. Efficiency can be improved further by using helical blades, and these are the basis for some of the more promising designs today. For example, Ocean Renewable Power Corporation uses a helical-bladed, horizontal cross-flow design for its TideGen system (Fig. 46.12).

Although these cross-flow systems appear to be radically different from axial-flow systems, the fundamental principles discussed previously still apply. In particular, the power capability of a specific design depends on its size (the area A swept by the rotor), its efficiency (embodied in the power coefficient C_P) and the power density of the flow Ψ, and (46.10b) applies.

In wind power systems, the traditional axial-flow design dominates installed capacity, in part because they are more efficient ([46.13] and Fig. 46.13). There are, however, other important considerations for MRE, including structural requirements, site restrictions, and flow variations.

Recall, for example, the order-of-magnitude analysis comparing atmospheric and oceanic energy recovery. For nearly identical power densities, the ocean currents are about a factor of 10 less than the wind speeds, but in this circumstance, the forces on oceanic equipment are a factor of 10 higher than in the atmosphere – indeed, the previous results imply that the force/power ratio is proportional to U_u^{-1}. This suggests that vertical-rotor Darrieus turbines, such as those in Fig. 46.12, have far more challenging design requirements for oceanic applications, as all of the force on the device is transmitted through the single bearing at the base of the unit. Even if a cage is constructed around the rotor to allow bearings at the top and bottom, there remains the issue of affixing the system to the seabed. A mast-mounted system would present the same challenges as the single-bearing systems of Fig. 46.11.

Moreover, the horizontal configuration can be more advantageous from the perspectives of site and flow. Tidal channels can be shallow, and a horizontal axis-system would occupy less of the water column than a vertical system, thereby minimizing potential impacts on surface traffic. And vertical shear in the ocean tends to be much larger than horizontal shear, so systems such as that in Fig. 46.11 would tend to operate in a more homogeneous flow environment.

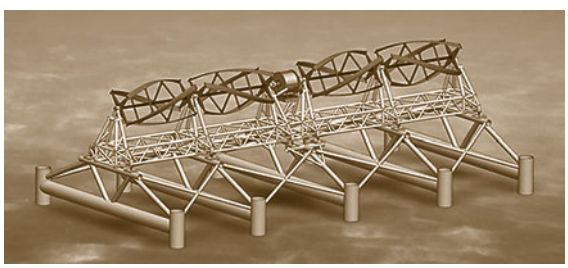

Fig. 46.12 Ocean Renewable Power Corporation's TideGen system for tidal channels. These are horizontal Darrieus rotors with helical blades (courtesy of ORPC)

46.3.3 Tidal/Open-Ocean/In-Stream Differences

Although, as shown in Fig. 46.13, axial-flow systems tend to be more efficient than cross-flow systems, the latter offer advantages in certain situations, tidal flows in particular. This is because tidal flows reverse direction twice a day, and bi-directional axial-flow rotors are unable to take advantage of the lifting characteristics of well-designed blades that makes them potentially so efficient. The alternatives, such as additional moving parts to reverse the orientation of the rotor to the flow or feather its blades through a large range, have their own practical and reliability challenges.

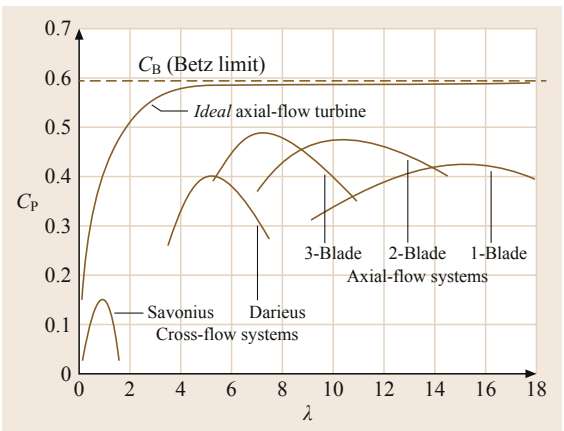

Fig. 46.13 Power coefficient as a function of TSR for several types of systems (after [46.13])

Table 46.1 Tidal/open-ocean/riverine trade-offs

Resource/issue	Current	Water depth
Tidal current	Bidirectional	Shallow: Pilings/ platforms
Open-ocean current	Unidirectional	Deep: Moorings
Riverine	Unidirectional	Shallow: Pilings/ platforms

Cross-flow systems, however, work equally well with flow in either direction, if properly designed. Thus it may be that, for certain sites, the relatively inefficient horizontal Darrieus-rotor systems would be more cost-effective. When depth restrictions of shallow tidal channels are also taken into account, this advantage multiplies.

These two factors, current and water depth, summarize the main differences between tidal, open-ocean, and in-stream river currents, as shown in Table 46.1, which notes, in the third column, the likely methods of deployment for MRE devices in each circumstance. Each type of resource has both an advantage and a disadvantage: tidal current locations offer relatively simple deployment methods but require that the bidirectional currents be managed. Open-ocean currents are sometimes unidirectional, but deployment is complex – indeed the systems must be designed around the requirement that they can be moored in a stable fashion, as discussed in the next section. River in-stream currents are both unidirectional and relatively shallow, but other considerations – the navigation hazard they present and interaction with debris, in particular – pose additional challenges.

There are, of course, other systematic differences between the two resources, such as turbulence levels and ecosystems. Turbulence levels in some tidal channels, in particular, can be daunting for designers. Careful site characterization is required to determine localized factors such as this.

46.4 Supporting Infrastructure

As suggested above, there are two main methods for deploying MRE equipment for current applications: masts (or pilings) and bases rigidly fixed to the sea bed, and moorings, where an anchor and its rode secure the equipment, which floats in the water column. Other possibilities exist for special circumstances, such as mounting equipment on bridge abutments or cables to shore securing a floating barge; the latter in use for many riverine applications.

46.4.1 Moorings

Deep water locations – and there is no strict definition of *deep* in this context – generally preclude the use of masts or bases for deployment of OCTs. For one thing, deep water makes masts impractical; for another, open-ocean currents tend to be strongest near the surface.

In deep water, OCTs will require moorings whose cables and anchors can provide sufficient holding strength and whose overall design can provide stability against variations in the current. Much of the engineering of these mooring components is discussed in the chapter on cables (Chap. 38) in this volume. However, because the currents are known to be subject to variations in both speed and direction, as functions of both time and height above the bottom (Fig. 46.14), and because most of the existing knowledge-base was developed for structures that float on the surface, it is useful to examine the stability of a simple mooring/OCT system in the presence of vertical shear. Moored OCTs will float in the water column well below the surface, for reasons noted above, and the dynamics of such systems are different from surface systems.

Consider the force diagram shown in Fig. 46.15. The current, flowing from left to right, induces a horizontal drag force $\boldsymbol{D}$ on the OCT, which is also subject

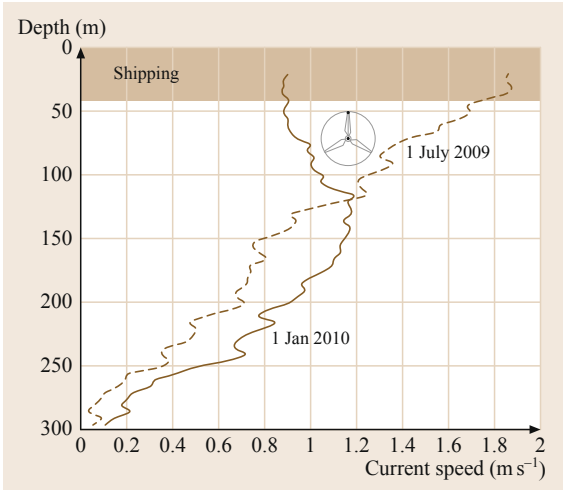

Fig. 46.14 Current speed as a function of depth in the Florida current 16 km offshore Dania beach. The stippled area at the top denotes a shipping-lane depth zone, and the symbol represents (to scale) a 40 m diameter system deployed at 70 m. Note that the sign of the vertical shear in this layer is different for the two profiles

to a net upward buoyancy force $\boldsymbol{B}$. The vector sum of these two forces is balanced, in steady state, by the tension force $\boldsymbol{M}$ on the mooring rode (the anchor line).

Figure 46.15 also shows the associated mooring geometry, in which the catenary of the mooring rode is ignored, a simplification that does not affect the analysis here. In steady state, it is clear that the scope S of the rode is R/H and that this also equals M/B (expressed as magnitudes).

A linear perturbation analysis of this system takes the various quantities to be the sum of a steady base state $[\,]_o$ and a small, time-dependent perturbation $[\,]'$. We (i) use the common notation $\frac{d[\,]}{dt} = \dot{[\,]}$, with two overdots for the second derivative, (ii) assume that the OCT has mass m, and (iii) neglect friction.

The reference frame of the OCT's mooring is properly formulated in polar coordinates, with the origin at the anchor. The two coordinates are the angle of the rode, θ, and the radial distance along the mooring rode. Projecting the drag force $\boldsymbol{D}$ onto these coordinates yields the two components D_θ and D_R shown in Fig. 46.15. As $\boldsymbol{D}$ varies with current speed, variations in D_R change the magnitude of $\boldsymbol{M}$ accordingly, while variations in D_θ induce a rotation about the anchor, changing θ. If ω is the rotation rate about the anchor, the appropriate expression of Newton's second law here is

$$mR\dot{\omega} = mR\ddot{\theta} = D_\theta = |\boldsymbol{D}|\sin(\theta)\,. \tag{46.12}$$

In order to analyze the effects of vertical shear, we set the perturbation drag $D'_\theta|\boldsymbol{D}'|$. $\sin(\theta_o) = \gamma H' \sin(\theta_o) = \gamma(H_o/R)H'$ and note that changes in $H' = R\sin(\theta')$. Finally, as shown in the upper left inset in Fig. 46.15 as a reminder, for small angles $\sin(\theta) \approx \theta$. Putting this all together gives

$$\ddot{\theta}' + \frac{\gamma}{mS_o}\theta' = 0\,, \tag{46.13}$$

where $S_o = R/H_o$ is the base-state scope of the rode.

Solutions to (46.13) take the form $\theta'\theta_1[\exp(i\omega t)]$, with θ_1 an arbitrary constant. The characteristic equation for this yields

$$\omega = \begin{cases} \varphi & \text{if } \gamma > 0 \\ i\varphi & \text{if } \gamma < 0 \end{cases}, \quad \text{where } \varphi \equiv \sqrt{\frac{|\gamma|}{mS_o}} > 0\,. \tag{46.14}$$

For cases in which the current speed, and therefore D'_θ, increase with height above the bottom (current is faster near the surface), then, small perturbations will lead to a free oscillation whose frequency depends on the base-state geometry, the mass of the OCT, and the strength of this positive shear. Of course, in the real ocean, this free oscillation would be damped by the frictional forces that are ignored here.

Cases of negative shear, $\gamma < 0$, in which the current speed decreases with height above the bottom (or, equivalently, increases with increasing depth from the surface), are of more interest. Here, the solution no longer oscillates

$$\theta' = \theta_1[\exp(-\varphi t) + \exp(\varphi t)] \text{ if } \gamma < 0\,. \tag{46.15}$$

The first term is of no concern, but the second term shows clearly that in cases of negative vertical shear, small depth perturbations will grow exponentially. Thus, in the absence of additional controls, negative shear is inherently unstable for moored OCTs.

It is worth re-emphasizing that this result depends on the assumption that the net buoyancy $\boldsymbol{B}$ is constant. It may therefore be possible to control this instability with variable (net) buoyancy, which could involve variable lift from the OCT control surfaces.

The physical basis for the instability can be stated in simple terms, because (for the assumptions here) flow perturbations affect the drag while the net buoyancy remains constant. Relative to a balanced base state, a slow-flow perturbation will create an imbalance of (positive) buoyancy, causing the OCT to rise; a fast-flow perturbation will create an imbalance of extra drag and therefore a buoyancy deficit relative to the base-state balance, causing the OCT to dive. If the OCT rises or dives into faster or slower water, respectively, then the imbalances will tend to be corrected. On the other hand, if the slow-flow, rising imbalance puts the OCT into even slower water, the imbalance will be amplified, as it will for the fast-flow imbalance that dives the

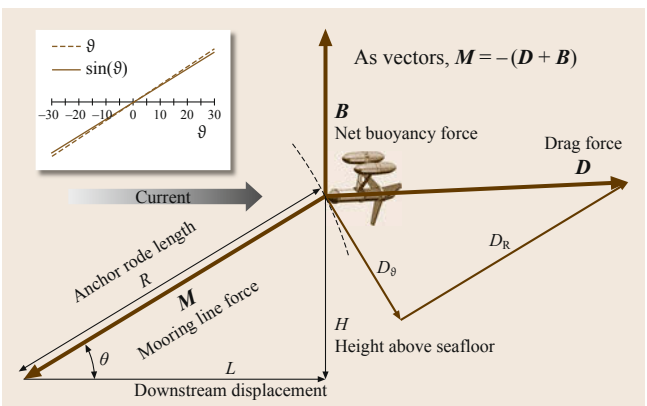

Fig. 46.15 Force diagram of a simple mooring. Current flows from left to right

OCT into faster water. In other words, the configuration of the rode is such that it pulls the OCT toward water of the same sense as the initial perturbation in the unstable case.

Note that the strength of the instability – the magnitude of the time constant φ – depends inversely on the base-state scope of the mooring: longer scope moorings, with longer time constants, are less sensitive to perturbations and therefore more amenable to control processes. Of course, these moorings are also more expensive due to the cost of the mooring rode.

In the context of this discussion of instability associated with vertical shear in the current, it is appropriate to include a qualitative look at two secondary effects on bottom-moored OCTs when one of the assumptions here is relaxed. These effects cannot be quantified without a dynamic model of a specific OCT and its mooring, but there are certain qualitative aspects of design that factor in to the stability issue.

Note that, in Fig. 46.15, the basic force balance of the system under consideration includes a *net* buoyancy force $\boldsymbol{B}$ (which, although a vector, can be assumed to have only a vertical component). This net buoyancy force is the sum of the buoyancy and whatever lift the design of the OCT generates; the previous results depend on the assumption that $\boldsymbol{B}$ is constant. In reality, the lift is likely to be dependent on both current speed and the OCT's angle of attack. Both of these dependencies factor in to the discussion of vertical shear.

Consider first the effects of vertical shear on angle of attack (Fig. 46.16). Below the lifting-surface stall limit, increases in angle of attack will tend to increase lift. To the extent that there is a cross-rotor torque introduced by vertical shear, the angle of attack becomes part of the overall effect of shear. For both leading-rotor systems and trailing-rotor systems, positive shear would tend to induce nose-up pitch, increasing the angle of attack; the opposite would happen with negative shear. Positive vertical shear, then, increases lift and negative vertical shear decreases lift. The latter would tend to exacerbate the instability associated with negative vertical shear discussed above.

The effects on lift of current speed are also relevant. In general, increased speed will increase lift (again, assuming that the system's angle of attack is below the stall limit). In the case of positive vertical shear, the overall effect here will be the same as that for the changes of angle of attack. In the case of negative vertical shear, however, they will be the opposite, tending to counterbalance the exacerbation of the fundamental instability. Quantifying the net effect of these two components of lift is not possible without a detailed model of the system under consideration. This result, however, argues for active lifting surfaces so that these effects can be controlled.

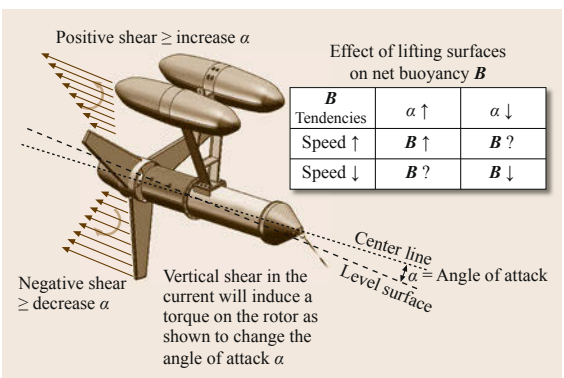

Fig. 46.16 Effects of vertical shear on lift

46.4.2 Masts, Bases, and Platforms

Shallow tidal channels, despite their potential for higher turbulence levels, eliminate the challenges associated with buoyant systems such as those discussed above. These channels allow mounting equipment directly on the sea bed in a rigid fashion, such as is implied in Figs. 46.10 and 46.12, or higher in the water column using masts, an example of which is shown in Fig. 46.17.

Thus, most tidal and river in-stream hydrokinetic devices are either rigidly attached to the channel floor or attached to a floating platform, such as a barge. Examples of barge-mounted turbines are the relatively small-scale vertical-axis devices deployed in Ruby and Eagle Alaska, which were mounted to the center of

Fig. 46.17 SeaGen tidal generation system, with two counter-rotating rotors that can be raised and lowered on the center mast (shown *raised* here) (courtesy of Marine current turbines/Siemens)

moored catamaran barges [46.14]. This mounting configuration keeps the electronics above the water line, which minimizes both equipment and maintenance costs. Drawbacks to this mounting approach include the installations being easily visible and that power cables often need to be run from the floating platform to the river bed before running to shore, leaving them exposed to possible entanglement.

Bottom-mounted devices can either be partially or completely submerged. The tidal device shown in Fig. 46.17 is attached to a mono-pile, with the control room above the water. The two horizontal axis rotors on the system can be lowered into the water during normal operation or retracted from the water for maintenance. While this approach does have a surface presence, it is much smaller than if the system were mounted from a floating platform. Alternatively, many bottom-mounted tidal devices are completely submerged. While systems such as these are attractive for many reasons, maintenance and monitoring can be challenging.

Individual device designs are typically driven by site-specific requirements, including water depth and flow characteristics. As discussed above, the flow type, tidal verses nontidal, is one important consideration. Nontidal flows are nearly unidirectional and therefore devices are optimized to take advantage of the known flow direction. In rivers, the magnitudes of these flows are driven by thawing snow or rainfall and therefore are more seasonally and event driven. Because specific events contribute to the magnitude of these flows, the power is less predictable than tidal flows. However, most large river systems that are good candidates for instream hydropower will be able to produce power year round. Conversely, devices deployed in tidal flows are typically designed to produce power from flows coming in two discrete directions. Vertical-axis systems are not typically impacted by flow direction and their performance does not degrade in these flows. Axial-flow turbines are more impacted by a changing flow direction, and therefore these devices often have rotors that have similar efficiencies regardless of the flow direction or rotate so that the rotor is always oriented in the optimal direction. Since tidal cycles are the primary drivers of these flows, the power potential for these installations are more predictable. However, systems operating in tidal flows do have a period of time between tidal cycles when no power is produced.

Design and performance of masts, bases, and platforms is a topic far beyond the scope of this chapter; some of the considerations are discussed in other parts of this volume. One factor that must be considered carefully, however, is the torque imparted to the attachment on the sea bed of masts and bases due to the forces on the OCT rotor. As noted previously, the latter are an order of magnitude larger than for wind systems, and designs must take this into account.

46.4.3 Other Components

An OCT system is, fundamentally, a machine for converting the kinetic energy of an ocean or river current into electrical energy. The rotor, turned by the current as discussed above, ultimately drives an electrical generator of some type, and the resulting voltage is either transmitted or stored. Only the most obvious of system components associated with this process are depicted in Fig. 46.5. Although most of these components, as well as those not depicted, are not unique to the world of MRE, there are challenges involved with using them in OCT systems.

As discussed previously, one advantage of OCTs is their relatively slow rotation rate, with blade-tip speeds approximately 10 times slower that wind-power systems operating at the same power densities. However, electrical generators operate most efficiently at high rotation rates. This means that the gearbox design and integrity are crucial to effective OCT operation.

Once the torque of the rotor has been transmitted through the gearbox, it drives a generator of some design. Both alternating- and direct-current generators have been proposed and designed into OCT systems, and each has its advantages and disadvantages. Alternating current (AC) generators are more efficient and, especially for high-power applications, relatively simple, but direct current (DC) transmits more efficiently through under-sea cables. Conversion between the two is always less than 100% efficient, so, as with mounting methods and overall system design, choices must be made on the basis of specific site requirements.

Similarly, cable transmission, to the on-land grid, or local use of the generated power to create a more portable fuel, is also a trade-off that depends on the nature of the resource and its location relative to load centers. The Florida current, which flows northward along the east coast of Florida approximately 25 km off shore, is relatively close to the major load center of the SE Florida metropolitan area, so direct transmission to the grid could be appropriate there. Conversely, there are significant tidal resources in many of the bays and inlets along the coast of Alaska, but there is no nearby load center to utilize generated power. Consequently, it may be more economically viable for that power to be used to create hydrogen (by electrolyzing sea water) or another portable fuel, which can be transported to where it is needed.

It is also relevant here to note that individual OCTs are unlikely to be able to capture a significant frac-

tion of the power available at a particular location, so that arrays of OCTs are likely to be deployed in commercial installations. This raises the issue of specific deployment strategies – how to design the array and the positions in it of the constituent OCTs to most efficiently capture the power of the resource. Although there is much to be learned from the experience of *wind farms* in this regard, there is also much research needed. Again, the solutions will emerge as site-specific deployment strategies are developed.

46.5 Beyond Engineering

MRE recovery requires a seamless integration of many of the ocean engineering topics discussed in this volume, especially including hydrodynamics, structures, corrosion and biofouling, acoustics and instrumentation, and underwater control systems. It also requires a clear appreciation of many topics that are normally considered to be outside engineering disciplines. Those most relevant to MRE from ocean currents are:

- Environmental impacts – from sea bed to the surface, both up- and downstream from the project
- User conflicts – including recreational, military, and commercial entities
- Public perception – because there are still so many unknowns, educating and informing the public is a necessary aspect of a project gaining access to public lands for energy generation.

All these are wrapped into the legal and regulatory processes and procedures associated with the particular location for the project. The planning process often requires a formal study of environmental impacts prior to permitting, and the various issues associated with the topics of concern need to be addressed.

In particular, the importance of public perception cannot be overestimated, as it influences the processes in place to address the technical issues associated with environmental impacts and it strongly affects issues related to user conflicts. What is critical is that initial impressions that become part of the public consciousness about a particular project tend to be extremely difficult to change. Leasing and permitting processes generally include such events as public hearings.

46.6 Summary

Equipment that can convert the kinetic energy of oceanic currents into other forms of power have much in common with wind systems, but there are critical differences between applications. In particular, while power densities in the oceans tend to be of the same order of magnitude as in the atmosphere, the forces on oceanic equipment tend to be an order of magnitude larger. On the other hand, for the rotating devices discussed here, rotation rates tend to be an order of magnitude slower. Nonetheless, animal strikes, especially when endangered or threatened species are present, are among environmental concerns.

Because oceanic systems are yet in their infancy, a general discussion has been presented here.

47. Harvesting Energy by Flow Included Motions

Michael M. Bernitsas

Marine hydrokinetic (MHK) energy is clean, renewable, and available worldwide. It comes in two forms: vertical in waves and horizontal in currents, tides, and rivers. Apart from a few major ocean currents, most of the ocean currents have flow speeds less than 3 kn and most rivers have speeds less than 2 kn, making harvesting of their MHK energy by steady-lift technologies (turbines) challenging. Horizontal MHK energy can also be harnessed using alternating-lift technologies (ALTs). Fish utilize alternating lift to propel efficiently in water either as individuals or in schools. Engineered structures – bluff bodies, such as circular cylinders and prisms, or slender bodies like hydrofoils – may generate alternating lift in quasi-steady uniform flows. When these structures have scale-relevant flexibility, severe flow–structure interaction (FSI) phenomena may be induced. In typical engineering applications, FSI phenomena are destructive and, thus, avoided by design or suppressed using excessive damping or appendages. If FSI are instead enhanced, they may result in vigorous flow-induced motion (FIM) of the body, leading to the conversion of MHK energy to potential and kinetic energy in a mechanical oscillator. Hydrofoils can harvest MHK energy through flutter – a well-studied and understood form of instability. On the other hand, bluff bodies, such as circular or rectangular cross-section cylinders, may exhibit several forms of FIM, individually or in *schools* that have been studied extensively but still are not well understood for either suppression or enhancement. Those FIMs are vortex-induced vibration (VIV), galloping, buffeting, and gap flow in multibody interactions. When enhanced, they convert MHK energy to mechanical energy with high-power density (power-to-weight ratio) even from low-speed horizontal flows. This chapter presents an overview of the concepts of ALTs, the underlying physical principles, the available experimental and computational methods for studying the relevant FIM, the research challenges that have been overcome and those lying ahead, field-deployment progress, technology development, and bench marking.

Marine hydrokinetic (MHK) energy – available in oceans and rivers – has been considered a major potential source of clean renewable energy since the Middle Ages, when tidal mills were used to grind grain in Northern Europe [47.1]. The first patent for a wave-energy converter was filed in 1799. In spite of such an early start, efforts to utilize this valuable resource have been limited all through the 1980s [47.2–9].

Through the early 1990s, the US Department of Energy (DOE) supported efforts in diverse aspects of marine energy. After a 15-year gap in funding, DOE started supporting major efforts in development of novel MHK energy technologies in 2008 [47.1, 5, 10]. The path to development of commercial devices has been very difficult due to the harshness of the marine environment, the cost of field deployment, and failures of pioneering devices leading to recent bankruptcies and project cancellations [47.11].

Several studies have estimated the available MHK energy in waves [47.3, 7, 12–16], and ocean currents [47.2, 6, 14, 16–19], rivers [47.20–23], or in all three of them [47.1, 4, 21, 24–27]. Those estimates vary widely because assumptions regarding the accessibility of energy source and technology performance, speculation, and efficiency vary widely [47.2–4, 17, 18]. Regardless of the uncertainty in estimation, comparison to past and projected worldwide production and consumption of energy in general and electricity in particular [47.4, 22, 28, 29] show that MHK energy cannot be overlooked as long as it can be generated at a competitive levelized cost of energy or LCOE [47.10, 30].

MHK energy comes in two forms, vertical in waves and horizontal in currents, tides, and rivers. In this chapter, studies in harnessing of the horizontal MHK energy from horizontal quasi-steady uniform flows are described. The majority of ocean currents are slower than 3 kn and most rivers are slower than 2 kn making harvesting of their MHK energy by turbines or watermills challenging.

Turbines and watermills [47.21, 31–33] are based on lifting surfaces in a steady flow resulting in steady lift. The term *steady-lift converter* or *steady-lift technology* (SLT) is introduced, hereafter referring to turbines and watermills. Steady lift is generated by lifting surfaces in air, such as bird wings, airplane wings, sails of sailboats, and blades of wind turbines. Horizontal MHK energy can also be harnessed using *alternating-lift converter* or *alternating-lift technology* (ALT). Fish utilize alternating lift to propel efficiently in water either as individuals or in schools [47.34–42]. SLT is more palatable to humans because we live in air. The picture in the marine environment though is totally different as fish use almost exclusively alternating lift to efficiently move through water.

Engineered structures with bluff cross-sections, such as circular cylinders and prisms, or slender structures, such as airfoils and hydrofoils, may generate alternating or oscillatory lift in uniform flows. When such structures are flexible or are rigid but mounted on flexible support, and have one or more natural frequencies of vibration in the range of frequencies of the oscillatory lift, significant flow–structure interaction (FSI) phenomena may be induced [47.43, 44]. In typical engineering applications, FSI phenomena are destructive and, thus, avoided by design or suppressed using excessive damping or appendages. If they are instead enhanced, FSI may result in vigorous flow-induced motion (FIM) of the body, leading to the conversion of MHK energy to potential and kinetic energy in a mechanical oscillator. Hydrofoils can harvest MHK energy through flutter – a well-studied and understood form of instability [47.43, 45].

On the other hand, bluff bodies such as circular or rectangular cross-section cylinders, may exhibit several forms of FIM, individually or in schools, that have been studied extensively but are still not well understood for suppression or enhancement. The five most commonly occurring FIMs are as follows:

1. Vortex-induced vibration (VIV): VIV is a nonlinear oscillation, broad-range, synchronization phenomenon between the oscillatory lift created by the alternating von Kármán vortex street in the wake of a bluff body and the body's elastic [47.46–59]. VIV is a phenomenon self-limiting in amplitude; see Sect. 47.2. Some researchers interpret it as a broad-range, lock-in phenomenon [47.43, 55] and others as a nonlinear resonance over the same broad range of flow velocities [47.60] due to variable added mass, which can be measured experimentally [47.53, 54, 61–63]. It should be noted though that the dependence of added mass on relative velocity and acceleration components is way more complex than the simple term typically used in Morison's equation [47.64].
2. Galloping: This is an instability phenomenon caused by geometric asymmetry due to the body cross-sectional geometry or the flow due to upstream turbulence [47.43, 65–67]. It results in unlimited amplitude response until the elastic structure is damaged as the flow velocity increases.
3. Coexistence of VIV and galloping: Depending on the flow speed, the body geometry, and the oscillator parameters, these two FIMs may coexist in a transition region between them, may overlap, or may be separated [47.67–73]. In the first two cases, a nonlinear oscillator can be built, which has high-amplitude response starting at low speeds using VIV and with no upper limit in flow velocity using galloping; see Sect. 47.2.
4. Buffeting: This is an instability phenomenon even more powerful than galloping due to upstream vorticity impinging on the oscillator [47.43]. Buffeting though, is random in nature and cannot be utilized to design and build a reliable energy converter.

5. Gap flow in multibody interaction: When multiple cylindrical bodies are in tandem or in close staggered formation, the interaction between them may be even more powerful than the FIMs of single cylinders [47.50, 57, 74–83]. By properly designing and positioning multiple bodies, vigorous oscillation of all elastic bodies in the array/school is induced resulting in even higher efficiency conversion of MHK energy to mechanical energy in the oscillator [47.68, 69, 84].

Elongated bodies with slender cross-section, such as hydrofoils and airfoils, in steady flow are typically subjected to steady lift perpendicular to the flow direction. Depending on the relative location of the supports and the center of pressure, the motion of such structures may become unstable resulting in flutter instability [47.43, 85]. This motion converts fluid-kinetic energy to mechanical energy and subsequently to electricity, a process that has been patented in various forms [47.86, 87].

Elongated bodies with bluff cross-section, such as circular or rectangular cylinders, in steady flow typically are subjected to alternating lift perpendicular to the flow direction. They may exhibit all five forms of FIM listed above. These FIMs convert fluid-kinetic energy to mechanical energy in an oscillator and subsequently to electricity, a process that has also been patented [47.88–90].

The VIVACE converter is a unique alternating-lift converter developed in the Marine Renewable Energy Laboratory MRELab [47.91] at the University of Michigan. Its name is the acronym for *vortex-induced vibrations for aquatic clean energy* as it started as a device to enhance VIV to convert MHK energy to mechanical in the oscillator. Since then, it has grown – as defined in the patents [47.88–90] – to include several other forms of FIM, discussed in Sect. 47.2.1, *Basic Concept*. VIVACE was introduced by *Bernitsas* et al. [47.48, 49] and developed extensively since then with model tests [47.67–69, 69, 70, 73, 77, 84, 92–110], field tests [47.111], computational fluid dynamics (CFD) [47.76, 112–118], and mathematical models [47.119–121]. VIVACE uses one [47.73, 106, 107] or multiple cylindrical oscillators [47.68–70, 77, 84, 101–103] with passive turbulence control (PTC) [47.96] or smooth cylinders to harness MHK energy and convert it to electricity, with a high-power density ratio for a renewable energy device [47.95, 100]. It utilizes several forms of FIM to generate alternating lift in a very broad range of horizontal flow velocities. It may also use more complex forms of cross-sections [47.116, 118]. The basic concepts in the VIVACE patents are presented along with the underlying physical principles implemented in its operation and development in Sect. 47.2.

Development of this novel concept involves several design parameters including one or more elongated bodies with bluff cross-sections, FIMs, multibody interactions, turbulence stimulation, wake structures, variable damping, stiffness and mass ratio, variable flow-speed placing the oscillating bodies in a variety of flow regimes, interaction of shear layers, effect of upstream vorticity wakes and shear layers on the FIM of downstream bodies, variable tandem spacing and staggering of multiple oscillators, energy conversion, and optimization of power conversion. All these make product development of VIVACE a challenge that requires pioneering research in many areas of fluid dynamics, FSI, and controls. A broad arsenal of tools is being used in the research and development of alternating-lift converters and understanding the complex relevant physics. Such tools include the low-turbulence free-surface water (LTFSW) channel of the MRELab [47.91] at the University of Michigan, two towing tanks, virtual oscillators to achieve the desired linear or nonlinear damping and stiffness models, flow visualization, and vortex tracking using lasers and aluminum oxide particles, field tests in the St. Clair River in Port Huron, Michigan, and canals in the Netherlands, dedicated CFD tools developed and validated by the MRELab, mathematical models for data post-processing and analysis, and a method developed in the MRELab to reduce data collected by different devices and experimental models and techniques to equivalent FIM data for comparison.

As an energy-generating device, designing VIVACE is a challenge more daunting than designing a propeller. The first propeller was designed by Archimedes, circa 200 BC. The first screw propeller was proposed by James Watt in the late 18th century. Optimal propeller designs were generated in the 1970s. Oscillators, even if designed to be identical, are not equivalent – as blades are in propellers – due to their relative position in a school of cylinders. Flow–structure interaction is the heart of the problem, not a higher order correction. Among the challenges encountered in the research and development of the VIVACE converter are high-damping, FIM for energy harnessing, overcoming flow transition, enhancing FIM through PTC, placing various forms of FIM back-to-back to create a broad-range, high-response oscillator, and using synergistic FIM of multiple bodies for optimal MHK energy conversion.

All FIM phenomena, which flexible cylindrical structures or rigid cylinders mounted on elastic support exhibit, are highly scalable. Cylinders, as tiny as fishnet filaments or as large as Spar offshore platforms, are subjected to vortex-induced vibrations (VIVs) for the entire range of Reynolds number with the ex-

ception of three flow-change regimes: Re$<\approx 40$; flow transition inside the vortices $\approx 150 <$ Re $<\approx 400$; transition in the boundary layer from laminar to turbulent $\approx 300\,000 <$ Re $<\approx 500\,000$. Consequently, ALTs can be developed over a very broad range of applications and configured to meet topography and flow particulars as well as power-output requirements. Most important, they can harness hydrokinetic energy even from low-velocity flows where SLTs are financially nonviable [47.103].

In Sect. 47.1, marine hydrokinetic (MHK) energy in horizontal flow is considered as a source of renewable energy. The challenges in harnessing horizontal MHK energy, converting it to mechanical energy, and meeting the requirements for a successful commercial converter are discussed. MHK energy technologies are categorized as based on steady lift or alternating lift. In Sect. 47.2, ALTs are presented using the VIVACE converter as a case study because it operates in several forms of FIMs to generate alternating lift in a very broad range of horizontal flow velocity. The basic concepts in the VIVACE patents are presented along with the underlying physical principles implemented in its operation and development. Sect. 47.3 presents the arsenal of tools being used in the research and development of alternating-lift converters and how results are used to understand the complex relevant physics. Such tools include the low-turbulence free-surface water LTFSW channel of the Marine Renewable Energy Laboratory (MRELab) of the University of Michigan, two towing tanks, virtual oscillators to achieve the desired linear or nonlinear damping and stiffness models, flow visualization and vortex tracking using lasers and aluminum oxide particles, field tests in the St. Clair River in Port Huron, Michigan, dedicated CFD tools developed and validated by the MRELab, mathematical models for data post-processing and analysis, and a method developed in the MRELab to reduce data collected by different devices and experimental models and techniques to equivalent FIM data for comparison. The challenges overcome and those lying ahead and the research approach used in addressing them are presented. Among those are high-damping FIM for energy harnessing, overcoming flow transition, enhancing FIM through PTC, placing various forms of FIM back-to-back to create a broad-range, high-response oscillator, and using synergistic FIM of multiple bodies for optimal MHK energy conversion. Targets and benchmarking are discussed as well. A summary of the state of the art, conclusions, and future development are presented at the end of this chapter.

47.1 Hydrokinetic Energy in Horizontal Flow

Hydrokinetic energy is defined as kinetic energy in moving water. The term *marine renewable energy* refers to energy generated by waves, tidal currents, open-ocean currents, river currents, ocean thermal gradients, and salinity gradients. Technologies utilizing these renewable resources are referred to as MHK energy technologies. Horizontal hydrokinetic energy usually refers to hydrokinetic energy in tidal, open-ocean, and river currents, even though there is some horizontal energy in the other sources of marine renewable energy. Typically, the term vertical hydrokinetic energy refers to hydrokinetic energy in waves, even though there is some vertical energy in the other sources of marine renewable energy.

Solar energy can be considered as the original source of all these forms of MHK energy. The sun sends 174 PW of power to earth. After reflection of energy by the atmosphere, the clouds, and the surface of the earth, 89 PW of power is absorbed by land, atmosphere, and water. That power is then radiated through the atmosphere or directly from the surface of the earth back to space. In the process, the marine environment (primarily oceans) absorbs 9 PW (285 ZJ/yr), winds capture 0.19 PW (6 ZJ/yr), and biomass captures 0.057 PW (6 ZJ/yr) [47.78]. These estimates are based on the assumptions of present technology, no loss due to mechanical efficiency, and no accessibility restrictions.

Given the vast source of renewable energy and the anticipated environmental benefit, there is pressure in the general direction of renewable energy. Thirty-seven states in the USA have introduced renewable portfolio standards (RPS) under which utility companies are mandated to generate a percentage of their total power from renewable sources in order to reduce carbon emissions. The set targets will increase in the near future as new power-generating technologies are developed [47.123]. The renewable energy use is expected to increase from 9% in 2012 to 12% in 2040 in response to RPS and Federal Tax Credits (Fig. 47.1a). Renewable energy generation is expected to grow by 1.9% per year after 2012 (Fig. 47.1b). Solar, photovoltaics, and wind dominate renewable capacity growth.

In the statistics shown in Fig. 47.1, MHK, in-steam hydroelectric, and hybrid solar–thermal combined cycle are not included. The relevant conclusion of this quick review is that the MHK-energy industry has not reached

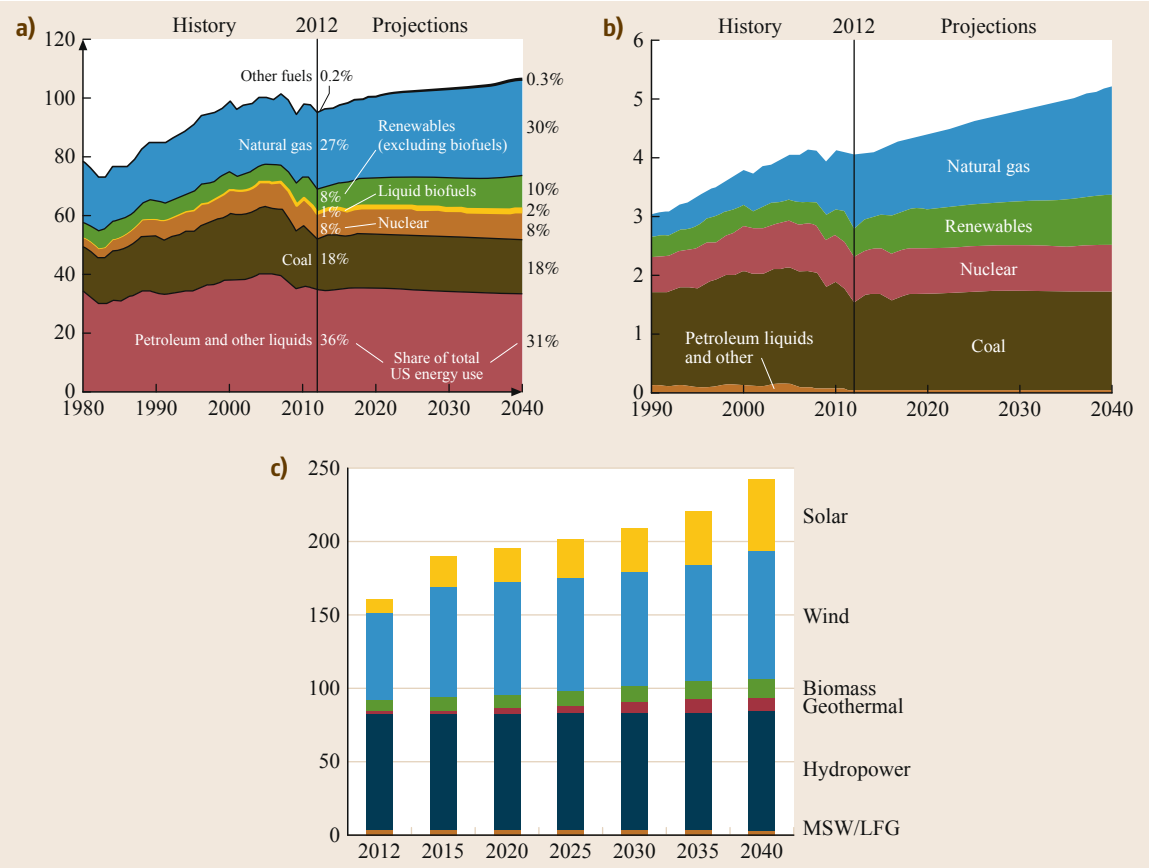

Fig. 47.1a–c Specifications of the MRELab VIVACE converter model. Energy and electricity consumption in the USA [47.122]. **(a)** US energy demand; primary energy use by fuel in 1×10^{12} BTU. **(b)** US electricity demand; generation by fuel in 1×10^{9} kWh. **(c)** US electricity generating capacity by source in GW

the maturity level where it can contribute to a national or international renewable energy portfolio.

47.1.1 Marine Hydrokinetic Energy

MHK energy, is also referred to as ocean power, marine renewable energy, and marine power. The MHK-energy industry is presently in its infancy. Many concepts have been proposed but with little technology convergence. Actually, the number of MHK-energy concepts is probably higher than the number of wind-energy concepts at the early stages of the wind-energy industry. The capacity of MHK devices installed around the world is quite small, only tens of megawatts, excluding tidal barrage plants, and these installations are generally engineering prototype test devices or small several-unit demonstration wave and tidal projects.

On the other hand, the amount of energy absorbed by the marine environment annually is vast. Ocean thermal energy is the majority with about 2 000 000 TWh, salt-gradient energy is 23 000 TWh, tidal and current energy is 22 000 TWh, and wave energy is about 18 000 TWh [47.124]. To put these numbers in perspective, the annual world electricity consumption is about 19 000 TWh and the world total energy consumption is of the order of 132 000 TWh. Thus, even though it is difficult to provide an accurate estimate of the accessible ocean power, and even more difficult to estimate the harnessable power, it is obvious that marine renewable energy is a vast resource and should not remain unexplored or underutilized. Technologies must be developed that are capable of efficiently harnessing MHK energy from areas that are easier to access in a financially viable and environmentally compatible way even if the energy source has lower power density.

The US National Renewable Energy Laboratory (NREL) has published useful reports on renewable energy. Most relevant is Chap. 9 on ocean power in reference [47.1]. It provides information on the size of the MHK energy resources for the USA. Some fig-

ures on estimate of the resources and the practicable extractable potential are summarized in the following.

Natural Wave Energy

1. The theoretical global natural wave-energy resource, including both kinetic and potential (due to the elevation of the wave) energy, is estimated between 18 000 [47.125] and 29 500 TWh/yr [47.1].
2. The total natural US wave-energy resource potential is estimated between 2100 and 2640 TWh/yr.
3. The practical extractable potential was estimated by *Bedard* et al. [47.126] at 260 TWh/yr, giving an average power output of 30 000 MW for all of the USA, including Hawaii and Alaska. They assumed a conversion of 15% wave energy to mechanical energy, a power train efficiency of 90%, and a plant availability of 90%. For a plant capacity factor of 33%, the installed capacity would be approximately 90 000 MW. The wave-generated electrical energy from this would be approximately 6.5% of the US yearly electrical energy generation in 2010 [47.1].

Natural Tidal Energy

1. The theoretical global natural tidal and current energy resources combined are estimated at 22 000 TWh/yr [47.124].
2. The total natural US tidal energy resource potential is estimated at 115 TWh/yr by *Bedard* et al. [47.17] and 111 TWh/yr by *Haas* et al. [47.19]. Both sources agree that the vast majority of the resource is in Alaska.
3. The practical extractable potential was estimated by *Bedard* et al. [47.126] only for three locations: Puget Sound in Washington, Golden Gate in California, and the Western Passage in Maine. The tidal energy available at those sources is 6 TWh/yr. The study assumed a conversion of 15% tidal kinetic energy to mechanical energy, typical power train efficiency of 90%, and a plant availability of 90% resulting in 0.73 TWh/yr of extractable power. This is equivalent to an average power of approximately 83 MW, and an installed capacity of approximately 220 MW, assuming a capacity factor of 38% [47.1].

Natural Ocean Current Energy

An ocean current is a continuous, directed movement of ocean water generated by the forces acting upon the mean flow, such as breaking waves, wind, Coriolis force, temperature and salinity differences, and tidal forces [47.1]. NREL concluded that in the United States, high-kinetic energy potential ocean current resources are found primarily in the Florida Current because of its high-core velocity of about 2 m s^{-1}. The other ocean currents have much lower flow rates and are not considered viable for energy generation. The relatively constant energy density near the surface of the Florida Current is about 1 kW m^{-2} of the flow area:

1. For the Florida Current, the natural energy of the resource was estimated at 175 TWh/yr [47.1, 126].
2. There is no established practicable extraction limit for ocean current energy. If the same engineering assumptions used for tidal energy would be applied to the Florida Current field, the extractable energy potential would be approximately 21 TWh/yr, or about 2.4 GW, of average power.

Based on the above discussion, the following conclusions are reasonable:

- The MHK energy is an abundant resource that is worth exploring by the development of new technology.
- Current technology is not capable of accessing efficiently the vast majority of the MHK energy resource at a competitive cost.
- Estimation of the available worldwide MHK-energy resource is hard.
- Estimation of the practically extractable MHK energy is approximate and depends strongly on speculation regarding the performance of technology presently under development.

47.1.2 Potential, Requirements, and Challenges

In spite of the fact that the MHK-energy industry is at its infancy, and the challenges ahead are many, MHK energy has the potential of becoming a major player in the quest for renewable and environmentally compatible energy. The potential of MHK energy, the requirements for a successful technology, and the challenges ahead are summarized below.

Potential

Besides the end product of electricity at a competitive cost, the following need to be considered in assessing the potential of MHK energy:

1. Water is the largest natural storage medium for energy and has high density; power-to-volume ratio.
2. Moving water is available worldwide and about 50% of the US population lives within 50 mile off a coast. This reduces the need for expensive storage and transportation of electricity.
3. If environmentally compatible devices that can harness MHK energy in resources of low flow speed could be developed, the environmental benefits would be substantial as shown in Table 47.1. Es-

Table 47.1 Advanced technology offers the opportunity to avoid substantial pollution

	161 MW	1700 MW	3700 MW
Offset resources			
Coal [ktons]	341	3600	7850
Natural gas [BCF]	2.3	24	52
Avoided pollution			
SO_x [tons]	7700	81 300	177 000
NO_x [tons]	4580	48 300	105 000
Particulate [tons]	3050	32 200	70 000
Greenhouse gases [equivalent ktons CO_2]	3150	33 300	72 500

Notes:
1. Offsets resources based on US average electricity generating mix
2. Avoided pollution from [47.127]

timates of the avoided pollution from installing advanced technology converters can be seen in Table 47.1. Three cases were selected to illustrate the potential savings: 161 MW (replacing the 461 MW of installed low power/low head capacity using 35% efficiency), 1700 MW (22.6% of low power/low head resources developed); and 3700 MW (includes low power/high head).

4. Horizontal MHK energy is predictable and, thus, dispatchable to an electric grid.
5. Horizontal MHK energy can be unobtrusive to people since the technology remains submerged at all times even when the resource is close to shore.

Requirements

For marine renewable energy – and particularly hydrokinetic – to contribute toward a solution of the world energy challenge, technology must be developed to generate electricity in a sustainable way. That has two attributes: First, harness energy from a clean and renewable energy source; MHK energy satisfies this requirement, second, use an environmentally compatible technology.

These two attributes can be expanded to the following list of requirements:

1. Be cost-competitive to alternative as well as conventional energy sources
2. Be unobtrusive to people; for example, remain out of sight at all times
3. Be unobtrusive to marine life; for example, by emulating fish propulsion or natural phenomena
4. Have tolerable levels of noise and electromagnetic interference
5. Have a source with high-energy density
6. Be predictable and, thus, dispatchable to an electric grid
7. Be simple to build, maintain, deploy, and retrieve
8. Be reliable and simple to maintain low cost
9. Be scalable and, thus, effective at a variety of environmental conditions
10. Be modular, reconfigurable, and adjustable to site topography
11. Be robust to environmental changes so that it functions efficiently even when the flow velocity changes
12. Be robust to floating debris and marine fouling
13. Be robust to environmental loading so that it can have a life of at least 20 years.

These requirements lead to a set of challenges as explained next.

Challenges

The challenges that the MHK-energy industry faces can be divided into research breakthroughs, technology challenges, regulatory barriers, and market issues.

Research Breakthroughs.

1. In the analysis of the horizontal MHK energy resource, the basic assumption by the MHK-energy community is that the required minimum velocity for a viable technology is $2\,m\,s^{-1}$ (≈ 4 kn). The Electrical Power Research Institute (EPRI) has concluded that for turbine technologies to be financially viable, an average flow speed of 5–7 kn (≈ 2.5–$3.5\,m\,s^{-1}$) is required [47.17]. There are only seven sites in the USA qualifying under this requirement. Furthermore, studies [47.1, 19, 126] practically limit ocean current resources to just one: the Florida Current. Since the vast majority of currents are slower than 3 kn ($\approx 1.5\,m\,s^{-1}$) and typical rivers are slower than 2 kn ($\approx 1\,m\,s^{-1}$) a breakthrough in technology is mandatory for the horizontal MHK energy to be developed. It raises the challenge of designing and building new technologies that can operate efficiently at lower speeds. The Gorlov [47.32] turbine and the ALTs discussed in Sect. 47.1.4 provide promising solutions.
2. Low-power density (power per footprint volume or power-to-weight ratio) is the Achilles heel of all renewable technologies – not just ocean-power technologies– compared to fossil fuels. It results in high cost in building, deploying, and retrieving MHK energy technologies. *Babarit* et al. [47.128] compared several wave-energy converters in operation and calculated the power density of the seven best to range from 0.065 to 0.2064 kW/Mg. Marine structures are typically large and heavy due to issues of balance between buoyancy and weight/ballast and this leads to another breakthrough requirement.

3. The challenge of low power-to-weight ratio leads to two separate challenges from the research point of view. The first one, is to increase the power-output hydrodynamically. Typical MHK-energy converters include point absorbers (buoys), line absorbers (one-dimensional (1-D) attenuators, for example, Pelamis), surface absorbers (two-dimensional (2-D), for example, oscillating water column), and area absorbers (two-dimensional, for example, turbines, propellers, watermills). Until three dimensions (3-D) are used for energy harnessing, the numerator of the power density will be proportional to two dimensions at best, while the denominator (volume or weight) will be proportional to three-dimensions. Thus, massive increase in scale will lead to lower power density for a given field of operation. A research breakthrough is mandatory in that direction. ALTs discussed in Sect. 47.1.4 provide a hydrodynamic solution to this challenge.
4. The second challenge that the low power-to-weight ratio leads to is the high weight or volume of MHK-energy converters. Classical wave-energy converters of all five concepts (point absorber, overtopping device, oscillating water column, attenuator, inverted pendulum) can be packed closer, but that would not lead to a real three-dimensional (3-D) MHK energy converter. There will be hydrodynamic interference effects that at best will result in a farm with less output than all the components harnessing power independently. That is, bringing devices closer together will be beneficial only if the support structure of the farm serves more than one device without proportional increase in mass or volume.

Technology Challenges. Several important technology development challenges have been stated by NREL [47.1]:

1. High capital cost
2. Unproven technologies that are not cost-competitive with conventional energy-generation technologies
3. Unproven functionality, performance, and reliability in the water at full scale
4. Resource quantity and variability are not well quantified
5. Undefined utility requirements.

Regulatory Barriers. NREL [47.1] has further identified the following regulatory barriers:

1. A stable, supporting policy that encourages development
2. Regulatory support to facilitate deployment and monitoring
3. Policies to minimize conflict and to align the benefits and priorities represented in environmental policy, tax policy, energy-supply policy, and energy security
4. Alignment of the regulatory process to minimize environmental impacts while facilitating responsible deployment of MHK technologies
5. Development of appropriate safety requirements and emergency procedures
6. Extensive permitting studies and lead times due to uncertain environmental impacts.

Market Issues. NREL [47.1] has further identified the following market issues:

1. New and unfamiliar technologies
2. Technologies that are not cost competitive
3. Lack of infrastructure, specialized equipment, and trained labor pool for installation, operations and maintenance.

Based on the above discussion, the following conclusions can be drawn:

- The MHK-energy industry is on a solid path to commercialization driven by the promise of the abundant MHK energy and supported by EERE (Office of Energy Efficiency and Renewable Energy) of the US-DOE since 2008.
- The MHK-energy industry has to overcome several challenges in technology development, market, and regulatory challenges before it can reach maturity.
- MHK energy needs research breakthroughs to improve its power-to-weight ratio before it can become competitive with other renewable energy technologies.
- A conceptual breakthrough is required for MHK energy technology to be able to tap into the vast majority of horizontal MHK energy, which is slower than the present technology threshold of 2 m s^{-1}.

47.1.3 Steady-Lift Technologies

The term *steady-lift converter* or *steady-lift technology* was introduced in this chapter to refer to turbines and watermills (Figs. 47.2–47.4). Steady lift is generated by lifting surfaces, such as airfoils and hydrofoils in a steady flow. Tidal turbines, ocean current turbines, watermills, propellers are SLTs. Tidal turbines are typically mounted on bottom fixed towers in shallower estuaries (Fig. 47.2a). Ocean current turbines may be mounted on a hydrofoil or a floating platform

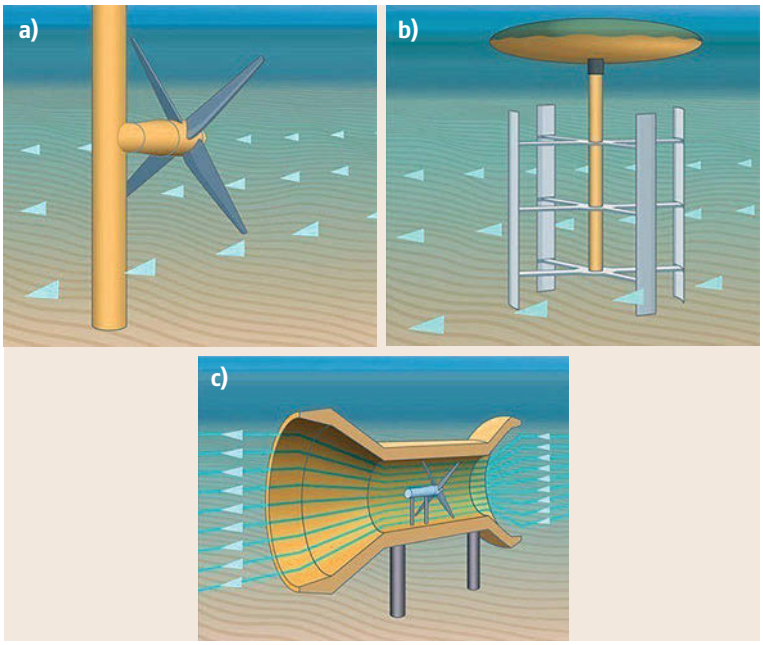

Fig. 47.2a–c Steady-lift technologies: turbines (after [47.85, 129]). **(a)** Horizontal axis turbine. **(b)** Vertical-axis turbine. **(c)** Ducted turbine

Fig. 47.3a–c Steady-lift technologies: turbines (continued). **(a)** Verdant propeller (photo by Verdant Power after [47.130]). **(b)** Sea Flow tidal stream generator (photo by Fundy, Wikicommons). **(c)** Open Hub Turbine (photo by Mike Roper)

(Fig. 47.2c) or moored in deep waters like the Florida current (Fig. 47.2c). Ocean current turbines are unrestricted in size and thus conceptually are similar to wind turbines.

Steady-lift turbines may also be classified as horizontal-axis turbines (Figs. 47.2a,c, 47.3, 47.4a) or vertical-axis turbines (Fig. 47.2b), open-hub turbines (Fig. 47.3c), and low-speed turbines (Fig. 47.4b). Ducts may be used to accelerate the flow past the turbine, thus increasing the rotor angular velocity and potentially the generator efficiency (Fig. 47.2b). Gorlov turbines may also be used horizontally (Fig. 47.4a) or vertically [47.32]. As their lifting surface is further away from the center of rotation, it results in a higher torque

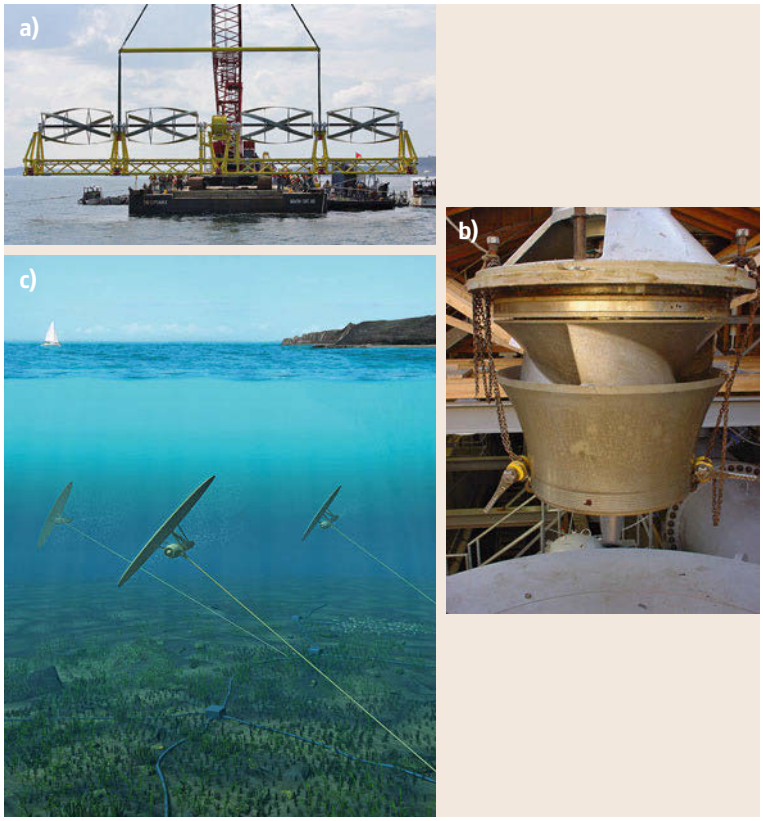

Fig. 47.4a–c Steady-lift technologies: turbines (continued). **(a)** ORPC Turbine (courtesy of Ocean Renewable Power Company after [47.131]). **(b)** Alden Turbine (courtesy of Alden Research Laboratory after [47.132]). **(c)** Underwater kite design (courtesy of Minesto)

turbine. Other turbines are designed to reduce their impact on fish, such as the Alden turbine by EPRI (Fig. 47.4b) and the open-hub turbine (Fig. 47.3c).

In the United States, several companies are developing MHK steady-lift turbines. The most notable ones are the following:

1. Verdant Power tested a 35 kW rated prototype, 5 m in diameter, 3-bladed tidal turbine in New York City's East River between 2002 and 2006. From 2006 to 2008, Verdant installed and tested six turbines in a tidal array at the same site (Fig. 47.3a) [47.122].
2. Hydro Green Energy [47.133], is developing a ducted current turbine that generates electricity from flowing water, such as river currents, tidal currents, and ocean currents.
3. In 2010, Alaska Power and Telephone installed a 25 kW, in-stream river turbine near Eagle, Alaska [47.134]. The low speed, vertical-axis turbine was mounted on a floating platform and was manufactured by New Energy Corporation in 2012.
4. Ocean Renewable Power Company is testing its new commercial TidGenTM Power System in Cobscook Bay near Eastport Maine, ORPC.

Many more technologies are undergoing testing around the world [47.135]. Numerous other technologies are at earlier stages of engineering development [47.5].

Regarding SLTs, the following conclusions/observations can be made:

- SLTs dominate the efforts to harness horizontal hydrokinetic energy.
- Turbines need a breakthrough to challenge the minimum flow-speed threshold of $2\,\mathrm{m\,s^{-1}}$.
- MHK companies, including turbine companies, face a variety of challenges and frequently go out of business, as harnessing ocean power is tougher and more expensive than expected [47.11].

47.1.4 Alternating-Lift Technologies

The term *alternating-lift converter* or *alternating-lift technology* was introduced above to refer to technologies that employ alternating lift occurring naturally in FSI phenomena. Fish utilize alternating lift to propel efficiently in water either as individuals or in schools at any speed with respect to the water flow. Lifting surfaces, such as fish fins, are used primarily for steering

rather than propulsion. Fins may contribute to propulsion as part of their entire body motion, which is alternating.

Bodies with either slender cross-sections like hydrofoils or bluff cross-sections like cylindrical pipelines are typically subjected to FSI phenomena. The scale of the fluid excitation is about the same as the size of the cross-section of the structure resulting in mutual interaction between the flow and the body motion.

Elongated structures that are flexible or are rigid on flexible support may have a natural frequency in the range of frequencies of the oscillatory lift, in which case severe FSI phenomena may be induced [47.43, 44]. FSI phenomena are destructive and, thus, avoided by design or suppressed using excessive damping or appendages. When enhanced, FSI may result in vigorous FIM of the body, thus, converting MHK energy to mechanical in an oscillator.

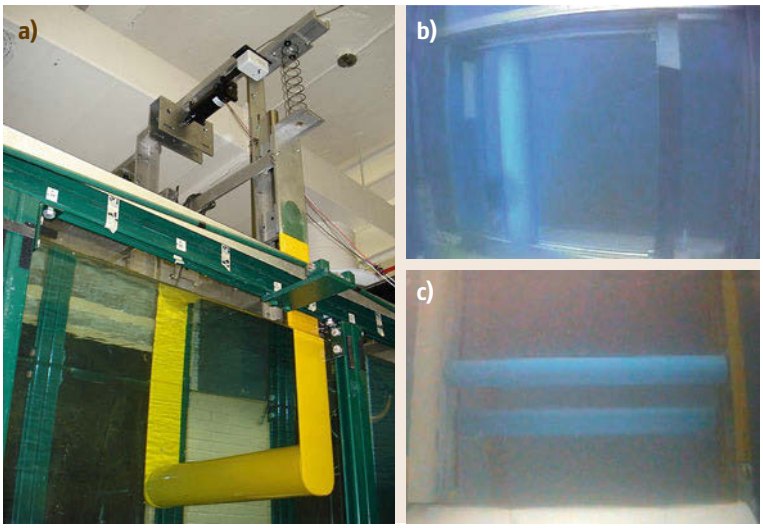

Fig. 47.5a–c Alternating-lift technologies: VIV, galloping, gap flow (see also Figs. 47.9–47.12). **(a)** MRELab model of early VIVACE based on VIV (courtesy of MRELab). **(b)** Model of VIVACE at OHMSETT (oil and hazardous materials simulated environmental test tank) towing tank based on VIV, galloping, and coexistence of VIV and galloping (courtesy of Vortex Hydro Energy). **(c)** VIVACE tests in the St. Clair river based on synergistic multibody FIMs: VIV, galloping, coexistence of VIV and galloping, and enhancement by gap flow (courtesy of Vortex Hydro Energy)

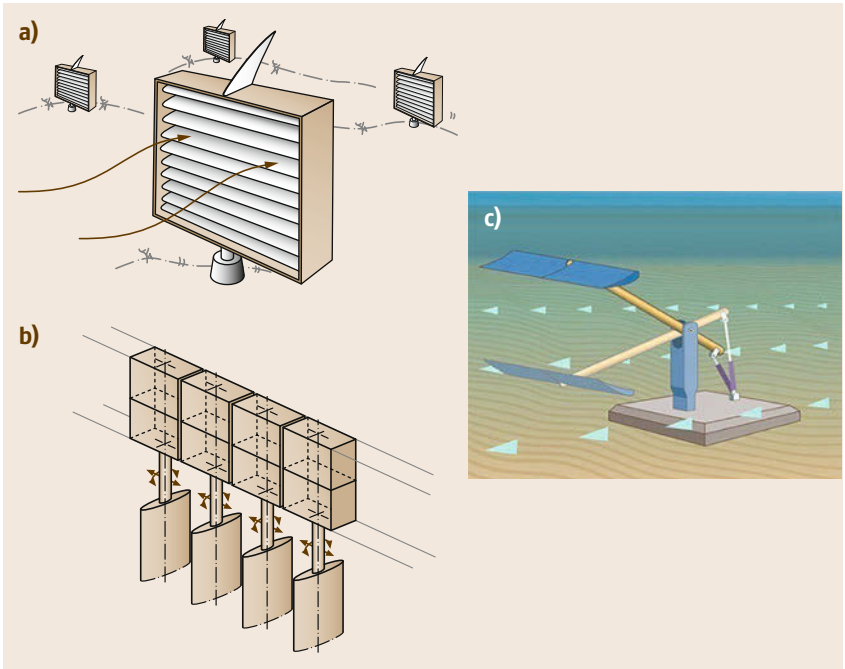

Fig. 47.6a–c Alternating-lift technologies: Flutter instability. **(a)** Flutter instability for energy harness (after [47.86]). **(b)** Flutter instability for energy harness (after [47.87]). **(c)** Hydrofoil flutter instability (after [47.85])

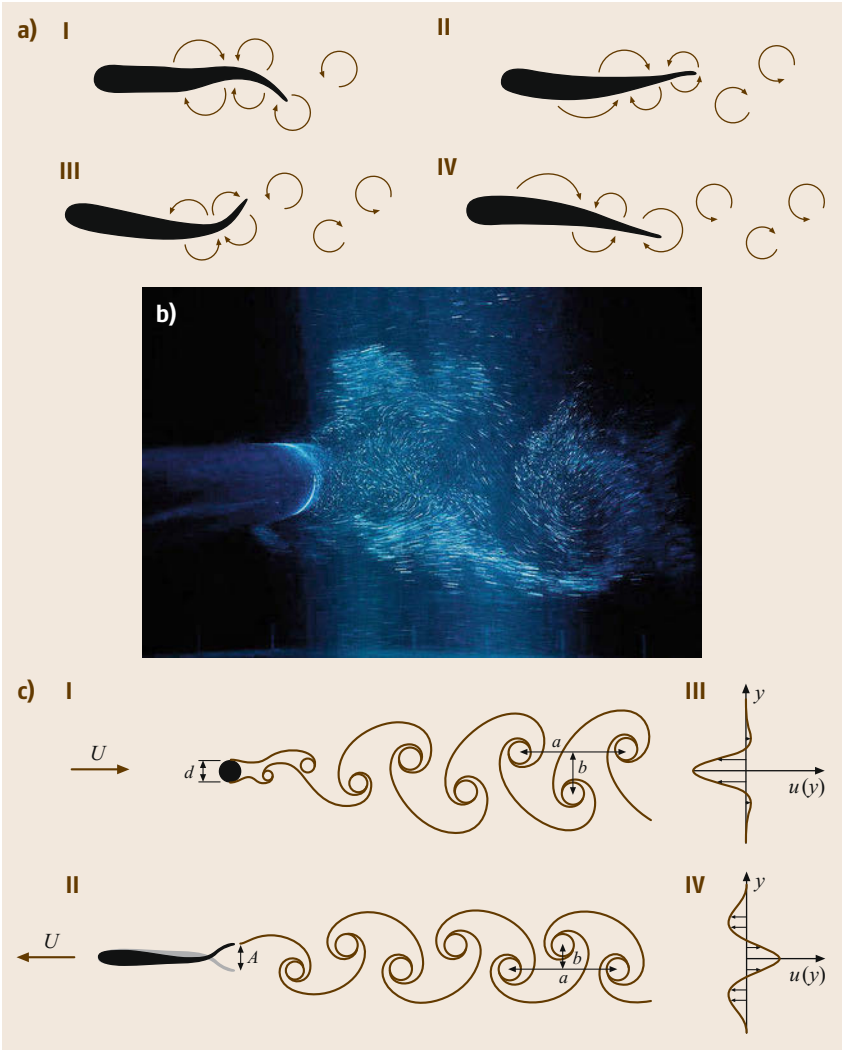

Fig. 47.7a–c Significance of alternating-lift. **(a)** Fish propulsion (after [47.136]). **(b)** Near wake of single VIVACE cylinder in VIV (courtesy of MRELab by photo by Don Boroughs). **(c)** Wake of cylinder in steady flow versus fish in forward motion (after [47.137])

Hydrofoils can harvest MHK energy through flutter – a well-studied and understood form of instability [47.43, 86, 87]. Two patents are shown in Fig. 47.5a,b and the same concept is shown for water in Fig. 47.5c.

On the other hand, bluff bodies, such as circular or rectangular cross-section cylinders, may exhibit several forms of FIM defined above. Alternating-lift MHK energy devices have been designed, individually (Fig. 47.6a,b) or in schools (Fig. 47.6c) and have been patented [47.86, 87]. VIVACE, which is a unique MHK energy device based on bluff cross-section cylinders utilizes all forms of FIM introduced above.

Significance of Alternating Lift

The details of flow mechanics of single and multiple cylinders in FIM will be discussed in Sect. 47.2. At this point, it is important to introduce the various forms of alternating lift involved in FIM of flexible cylinders with bluff cross-section. Their nature and the role each form plays in the marine environment as well as in FIMs of individual and schools of fish or elastic bodies are discussed. Figures 47.7–47.12 are used to illustrate each scenario of FIM:

1. Individual fish and vortex shedding: Fish actively curve their body, as shown in Fig. 47.7a, to collect a large vortex on the convex side. Then, actively push the vortex away forcing it to shed as they curve their bodies in the opposite direction to repeat the cycle shedding an opposite rotation vortex. Figure 47.7c II shows the alternating vortex street formed in the wake. The lift force exerted on the fish is proportional to the circulation, which is primarily

concentrated in the shed vortices. The lift force is alternating following the alternating pattern of the shed vortices. This is a thrust-wake pushing the fish forward.

2. Single cylinder in VIV and vortex-shedding frequency: In a steady flow, a street of alternating vortices forms in the wake of stationary cylinder. Figure 47.7b shows a laser-visualization picture of the near wake and Fig. 47.7c I shows schematically the alternating vortex street called von Kármán street. This is a drag wake providing zero-mean alternating lift and drag with a nonzero mean component and a zero-mean oscillatory component. Vortices shed passively downstream of the cylinder primarily following *Gerrard's* mechanism where shear layers and irrotational flow come together at a confluence point [47.138]. In the process, about 60% cancellation of vorticity occurs [47.46] resulting in 60% reduction in circulation and lift, based on the Kutta–Joukowski theorem. The wake has a dominant frequency over all Reynolds numbers with the exception of three transition regions. The vortex-shedding frequency for a stationary cylinder is called Strouhal frequency. Adding flexibility to the cylindrical body, so that it can respond to induced alternating forces, may result in nonlinear resonance with a very broad range of synchronization called VIV. This FIM phenomenon is used, as specified in Sect. 47.2, to convert MHK energy to mechanical in an oscillator.
3. Single fish in wake: As Fig. 47.7c shows, a streamlined body, such as a fish, generates a thrust wake and cylinders a drag wake. Figure 47.8a shows that fish in a school move in a diamond formation to take advantage of a street of vortices that can be used for thrust. Experiments have been conducted placing a fish in the wake of a bluff body (Fig. 47.8b) [47.36]. The fish positioned itself in such a way that the drag wake for the body becomes a thrust street for the fish. As a result, the black fish maintained its position in the flow stream with minimal effort [47.37].
4. Single cylinder in VIV and wake frequency: As velocity increases when the cylinder is in VIV, so does the number of shed vortices per cycle (Fig. 47.9) [47.76]. Thus, the vortex-shedding frequency becomes a higher multiple of the frequency of oscillation. Nevertheless, vortices shed in groups maintaining the predominant wake frequency to remain the same as the oscillation frequency. Thus, the nonlinear resonance persists and the oscillator can still be used as a powerful mechanism for converting MHK energy to mechanical.
5. Single cylinder in simultaneous VIV and galloping: Galloping is fundamentally different from VIV. The former is an instability in lift resulting from asymmetry due to geometry or impinging flow and results in much more vigorous lift. For a cylinder on elastic support or a flexible cylinder (e.g., pipeline, cable) nonlinear oscillations of amplitude even higher than VIV may occur. Typically, galloping occurs at higher velocity than VIV but depending on mass, damping ratio, absolute velocity, and cross-sectional geometry these two forms of FIM

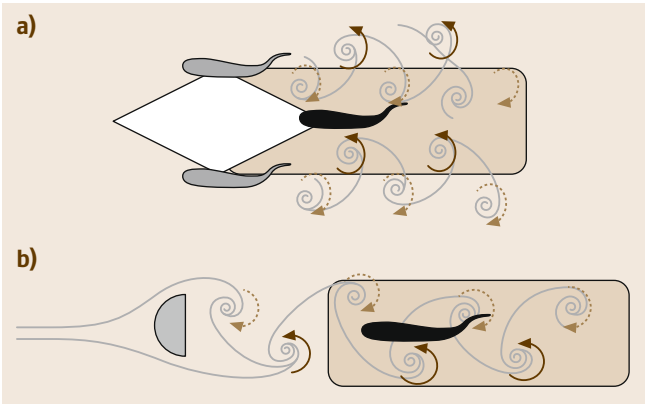

Fig. 47.8a,b Significance of alternating-lift. **(a)** Black fish utilizes reverse von Kármán street (thrust wake) generated by two grey fish. **(b)** Similar wake created by a reverse D-section cylinder. Fish exploit the energy of discrete vortices as well as the average reduced velocity in the Kármán street (after [47.36])

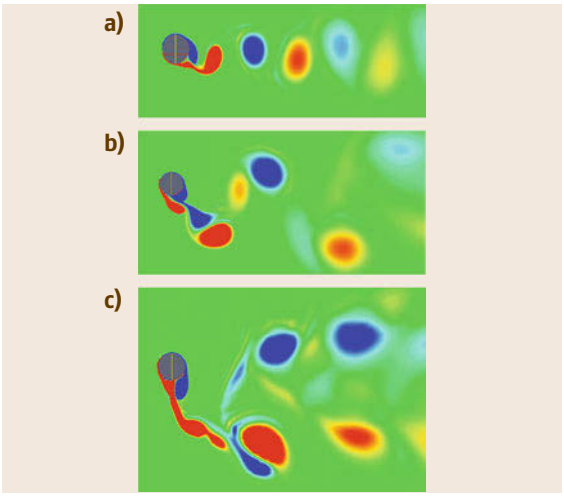

Fig. 47.9a–c Significance of alternating-lift: Single PTC cylinder in VIV (TrSL3 flow regime; $D = 3.5''$) (after [47.112, 139, 140]). **(a)** Initial-branch, 2S (S = single) vortex pattern, Re $= 35\,000$. The amplitude $A \approx 1 * D$. **(b)** Upper branch, 2P (P = pair) vortex pattern, Re $= 65\,000$. Amplitude $A \approx 1.5 * D$. **(c)** Later upper branch, PSSPSS vortex pattern, Re $= 95\,000$. Amplitude $A \approx 2 * D$

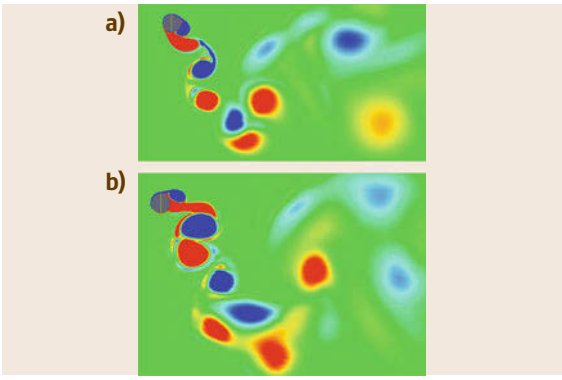

Fig. 47.10a,b Significance of alternating-lift: Single PTC cylinder in steady flow in VIV to galloping transition, and galloping (TrSL3 flow regime; $D = 3.5''$; [47.113]). **(a)** SPSSPS transition upper branch to galloping, Re = 110 000. Both the VIV and the galloping mechanisms coexist and are in phase. Amplitude $A \approx 3 * D$. **(b)** 2P + 8S galloping, Re = 130 000. The galloping mechanisms drives; vortex shedding is out of phase. Amplitude $A > 3 * D$

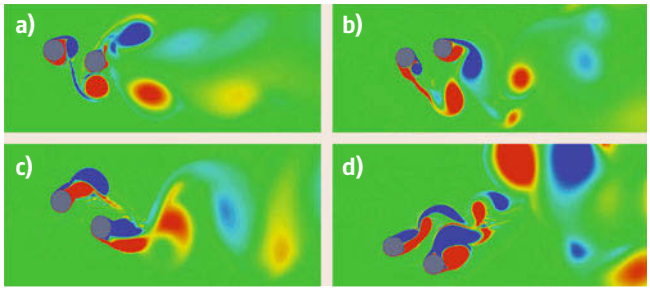

Fig. 47.11a–d Significance of alternating-lift: Two PTC cylinders in tandem in steady flow in a channel. (TrSL3 flow regime; $D = 3.5''$, 2-D center-to-center; (after [47.113]). **(a)** VIV, $R = 30\,000$. Timing of upstream vortices hitting the second cylinder is such that they grab same rotation vortices from the second cylinder leaving the second cylinder without circulation and lift. VIV of second cylinder is suppressed. **(b)** VIV, Re = 59 229. Second cylinder follows first and gap flow keeps wakes separated. Thus, each cylinder has its own wake providing alternating lift resulting in VIV. **(c)** Re = 60 000. The two cylinders are out of phase in VIV. With $m* = 1.68$ second cylinder has adequate momentum to cross the wake of the first. Partial vorticity coalescence occurs but the second cylinder maintains its wake, lift, and $A \approx 1.5 * D$. **(d)** Re = 90 000. The two cylinders are nearly in phase in VIV to galloping transition. Partial vorticity coalescence occurs increasing lift in the second cylinder as the VIV mechanism is in phase with the galloping instability. Amplitude $A > 2.5 * D$

may overlap over a transition region. Figure 47.10a shows that the vortex-shedding process is still in synchronization (Sect. 47.2.3) with the oscillations, while the galloping mechanism due to synchronization of the shear layers with the oscillations has taken effect. The asymmetry here is caused by the PTC attached to the cylinder [47.96].

6. Single cylinder in galloping: As velocity increases, the galloping mechanism becomes more powerful inducing higher amplitudes of oscillation (Fig. 47.10b). The number of vortices shed per cycle increases, but vortices fall out of synchronization with the oscillations. Shedding vortices push the cylinder away. As can be seen in Fig. 47.10b, some vortices push in the wrong direction. That is, vortex shedding continues but does not assist in increasing lift. The galloping mechanism by now is more powerful to drive the oscillations and the MHK energy conversion to higher levels [47.95, 141].
7. Multiple fish in a school: Figure 47.8a shows how fish position themselves in a school to better use the energy in the vortices. This formation fills the entire cross-section effectively making the school a three-dimensional device to convert MHK energy to mechanical energy. This is a real three-dimensional mechanism in the sense that an individual fish moves more effectively in a school than in isolation. This is not the same as packing close together converters of any kind. On the contrary, interference effects between devices may result in reduced efficiency.
8. Multiple cylinders in interference: When multiple bodies, stationary or elastic susceptible to FIM, are in close formation, interference effects may dominate their flow dynamics if they were isolated. That is, vortex shedding, wakes, and instabilities may be altered partially or completely. In that case, the basic forms of FIM discussed up to this point may not take place or may be enhanced, unless the cylinders are separated by as many as 9–10 diameters in the flow direction or 3–4 diameters perpendicular to the flow [47.57]. Figure 47.11a shows two cylinders in the early stage of the initial branch corresponding approximately to Fig. 47.9b. The configuration and dynamic particulars of the two oscillators are such that the second cylinder starts in VIV just like the first cylinder but in a few cycles its vortices coalesce with those from the upstream wake and its motion is suppressed. Figure 47.11b–d shows different kinds of interference. The timing the vortices from the upstream wake hit the second cylinder is such that the second cylinder maintains its vortex street and reaches amplitudes allowing flow between the two cylinders that further enhances FIM [47.114, 115].
9. Gap flow between cylinders: For two stationary interfering cylinders, gap flow entirely disrupts the vortex shedding and distorts the near wake of the

upstream cylinder. The region of the occurrence of the gap flow is $1 < L/D < 3.5$ and $0.2 < T/D < 0.4$, where L and T are the center-to-center in-flow and transverse spacing between the two cylinders, respectively [47.84, 113]. When two cylinders are in FIM the gap flow may enhance the FIM and result in more MHK energy converted to mechanical energy in the oscillator (Fig. 47.12).

10. Wake displacement between cylinders: For two stationary interfering cylinders, wake displacement does not disrupt the vortex shedding but only displaces the upstream wake. Wake displacement occurs for $L/D > 3.5$ and $T/D > 0$. When the two cylinders are in FIM, the wake displacement allows for flow between the two cylinders and may enhance the FIM and result in more MHK energy converted to mechanical energy in the oscillator. This scenario is shown in Fig. 47.12a between the 1st and 2nd cylinders.
11. Galloping with gap flow: At higher Reynolds number and reduced velocity – in the fully developed galloping region – flow between cylinders may enhance galloping as well, thus converting more hydrokinetic energy to mechanical energy in the oscillators. Figure 47.13 shows two cylinders in the fully developed galloping region with the 2nd cylinder consistently following the 1st. The amplitude of oscillation though changes periodically, so that sometimes the amplitude of the first cylinder (Fig. 47.13a) or the amplitude of the second cylinder (Fig. 47.13b) would be larger.

Regarding ALTs, the following conclusions/observations can be made:

1. There are two cross-sectional geometries of two-dimensional (cylindrical) bodies that when they are elastic – or rigid on elastic support – may result in alternating lift and alternating FIM:
   a) Slender cross-sections hydrofoils/airfoils that may flutter
   b) Bluff cross-sections that may be subjected to a variety of FIM due to alternating vortices, galloping instability, multibody interference, or combinations of those.
2. Flutter instability and galloping occur passively in engineered structures and are not used by marine life for propulsion.
3. Vortex streets and multibody interactions are used by fish to propel efficiently in water. Both mechanisms are highly scalable occurring practically over the entire range of Reynolds numbers.
4. By employing vortex streets, triggering galloping instability, and even superposition of the two mechanisms, nonlinear oscillators can be built using the naturally occurring alternating lift in all steady flows from very slow to very fast.
5. Interference between two-dimensional bodies with bluff cross-section in close proximity can induce much more vigorous FIM response of the same bodies when in isolation. This enables increased hy-

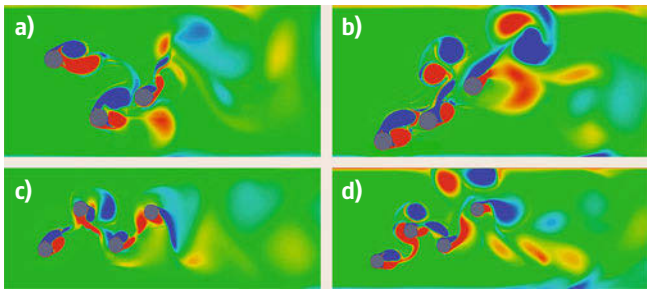

Fig. 47.12a–d Significance of alternating-lift: Three and four PTC cylinders in tandem in steady flow in a channel. drokinetic energy conversion to mechanical energy in an oscillator, while at the same time reducing the space occupied by the MHK energy conversion device.

6. The VIVACE converter is built based on conclusions 3–5 so that it has the following properties:
   a) It is based on alternating lift naturally occurring in the marine environment.
   b) The underlying physical mechanisms are highly scalable enabling the conversion of MHK energy to mechanical even at very slow flows.
   c) Multiple-body interference enables higher conversion of MHK energy to mechanical in an oscillator.
   d) Proximity of bodies reduces occupied space by VIVACE resulting in higher power density of conversion
   e) By properly configuring multiple cylindrical oscillators in close formation, a three-dimensional converter can be designed to achieve an impact on the Achilles heel of all renewable energy devices, which is the power-to-volume ratio.

47.2 Alternating-Lift Technologies: The VIVACE Converter as a Case Study

Among ALTs, the VIVACE converter is probably the closest to commercialization because it has undergone extensive laboratory testing (Figs. 47.5a,b, 47.7b) and several field deployments (Fig. 47.5c) since its introduction in 2006 [47.48, 49]. Further, several of its components and underlying principles are generic for ALTs. Accordingly, in this section, the VIVACE converter is used as a case study. It is described in Sect. 47.2.1. Its scales and applications are presented in Sect. 47.2.2, and the underlying principles are explained in Sect. 47.2.3.

47.2.1 Concept, Scales, and Principles

Physically, the VIVACE converter is a simple machine. Simplicity is a requirement (Sect. 47.1.2, *Requirements*) for reliable operation in the marine environment. The converter has few parts and they can be built to withstand the environmental loads and have low-maintenance requirements. Operating a device with moving components in the marine environment is a challenge. VIVACE prototypes and models have been built and operated in a recirculating channel, a fresh-water towing tank, a seawater-towing tank, a river, and canals. Even though each model is different, the basic concept remains unchanged and components are scaled to fit the facility and objectives of each test.

Basic Concept

Since its inception in 2005, the underlying concept for the VIVACE converter has been to enhance FIM so that more hydrokinetic energy can be converted to mechanical energy in an oscillator and subsequently to electrical energy [47.96, 100] Elastic slender bodies may exhibit FIM in response to quasi-steady flows from currents, tides, or rivers or to oscillatory flows due to waves. Given the intermittent nature of waves, quasi-steady flows present a better source of energy for eventual generation of base power and were thus selected as the source of MHK energy that VIVACE would target. Another early design decision made was to enhance, among FIMs, only VIVs, galloping, and the simultaneous presence of VIV and galloping. In multiple cylinder converters, gap flow between two cylinders in proximity and wake interference is also utilized not only to enhance FIM but, more importantly, to achieve synergistic operation resulting in energy conversion higher than that of the same number of cylinders in isolation [47.68, 69, 77, 84].

Some of these FIMs are based on synchronization and have large but bounded response and others are based on instability and may have unbounded response. Energy is harnessed by using damping, while at the same time limiting the oscillator response. A controller is required to bound the response of cylinders and harness energy through a power-take-off (PTO) system when the cylinder FIMs are enhanced.

Consequently, the following early design decisions were made:

- Buffeting, albeit being one of the most powerful forms of FIM, due to its random nature, should not be utilized in designing a commercial MHK energy converter.
- FIM due to wave excitation is a known phenomenon and can be enhanced for MHK energy conversion. The intermittent nature of waves as well as their randomness, however, makes waves a nonprimary target as a source of MHK energy for ALTs.
- VIVs, coexistence of VIV and galloping, and fully developed galloping are enhanced in single-cylinder ALTs to harness MHK.
- In multiple-cylinder ALTs, gap flow and wake-interaction phenomena are used to further enhance FIMs.

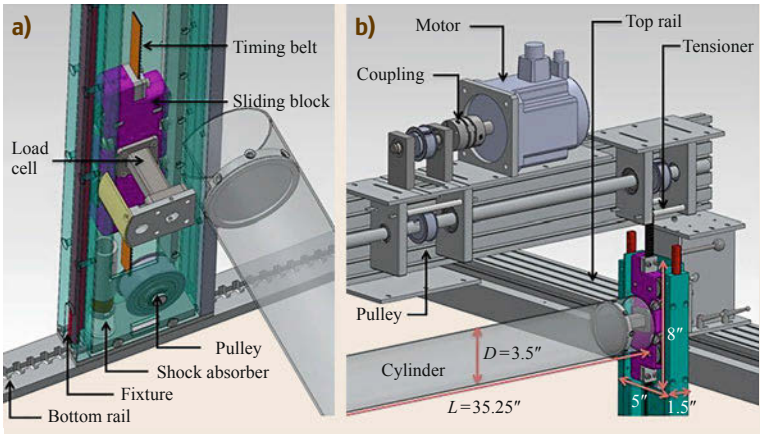

Fig. 47.14a,b Details of the VIVACE converter (after [47.142])

Description of the VIVACE Converter

The simplest form of the VIVACE converter consists of a single smooth cylinder (Fig. 47.5a) or a single cylinder with localized surface roughness (Fig. 47.5b) suspended by springs with a controller and a PTO system.

System. To describe the converter, the latest model in the MRELab is used as a generic representative of VIVACE converters. It should be pointed out that this is a model for the VIVACE converter itself not for ideal FIM tests. A separate system is used for VIV and galloping testing as explained in Sect. 47.3.8.

In early versions of the oscillator in the MRELab, the system operated on physical springs and dampers. Since 2010, *Lee* et al. [47.98, 99] introduced and implemented a virtual damping-spring device called V_{ck} system. V_{ck} replaced the physical springs and dampers in the oscillator using control feedback (Sect. 47.2.3, *Electro-Mechanical Principles*).

Between 2005 and 2012, the oscillators in galloping would reach the safety stops of the recirculating channel in the MRELab. In order to study the FIM of cylinders with fewer restrictions in amplitude, both the channel and the VIVACE converter were rebuilt. This third generation of test models was designed and built as shown in Figs. 47.14 and 47.15. In the new design, the linear motion mechanism was brought under water, which resulted in most of the structural elements being under water. The whole linear motion system, which consists of a sliding block, timing belt, and pulleys, is fitted inside of a 1.5 inch-wide slender tube. The sliding block connects the cylinder to the V_{ck} system through the timing belts and pulleys as shown in Fig. 47.14.

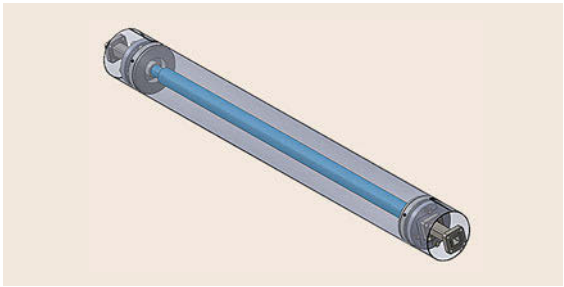

Fig. 47.15 Interchangeable cylinder with adjustable mass

The mass ratio can be changed by placing a rod of variable mass inside the cylinder, as shown in Fig. 47.15. Shock absorbers are used at both ends of the cylinder travel to protect the cylinder from hitting the plexi-glass bottom of the water channel. The center-to-center distance (d/D) between the cylinders in the flow direction can be adjusted by the rail system between 0.429″ (0.0109 m) and 5″ (0.127 m) in increments 0.5″ (0.0127 m). The features of the new VIVACE converter are summarized in Table 47.2.

The most important physical components of this alternating-lift converter are the following.

Cylinders. In tests, the cylinder diameter D has been varied between 2.0 and 6.0″ (5.08–15.24 cm) in the MRELab recirculating channel (Sect. 47.3.1), and between 6.0 and 10.0″ (15.08–25.4 cm) in towing tanks (Sect. 47.3.1) and field tests (Sect. 47.3.4). In future field-tests cylinders with $D = 36''$ (91.4 cm) have been designed by Vortex Hydro Energy (VHE) [47.111]. Up to four cylinders in tandem and staggered arrangements have been used in testing in the MRELab channel. Cylinders can be easily interchanged (Fig. 47.14) and their mass ratio $m*$ varies with insertion of mass rods inside the cylinder (Fig. 47.15). The basic properties of the cylinders used in this converter model are shown in Table 47.2.

Springs. Physical springs are required in the converter for two reasons. First, they provide a restoring force mandatory for the existence of an oscillator with a nat-

Table 47.2 Specifications of the MRELab VIVACE converter model

m_{osc} (kg) $0.634 \le m^* \le 2.00$	Equivalent mass of oscillating components including 1/3 of physical spring mass, equivalent mass of rotating pulleys, belts, and motor
m_d (kg)	Displaced fluid mass
$m^* = m_{osc}/m_d$	Mass ratio
$L = 0.89535\,\text{m} = 35.25''$	Cylinder length
$D = 0.0889\,\text{m} = 3.5''$	Cylinder diameter
$L/D = 10.7$	Aspect ratio
y_{max} (m)	Maximum allowable displacement of the upper and lower safety stops
$y_{max}/D_{3.5''} = 5.5$	Maximum allowable displacement in cylinder diameters
d	Center-to-center spacing of cylinders in flow direction
$1.429 \le d/D_{3.5''} \le 6.0$	Range of in-flow spacing of in cylinder diameters

ural frequency. Second, springs reverse the motion of the cylinder since the area spanned by the oscillating cylinder has to be finite as allowed by the size of the converter and/or the geometric restrictions imposed by the lab facility or the means of transportation in field deployments.

These two reasons would obviously collapse to just one in a regular oscillator but not in the VIVACE converter. Specifically, VIVACE is a nonlinear mechanical oscillator operating over a very wide range of velocities and, thus, spanning several FIMs as explained in Sect. 47.2.3 (Principle 9). In VIV, a spring of constant k is needed to establish a natural frequency and achieve synchronization between the frequency of oscillation and vortex shedding (Sect. 47.2.3, Principle 3). Some researchers interpret VIV as a broad range, lock-in phenomenon [47.43, 55] and others as a nonlinear resonance over the same broad range of flow velocities [47.60] with variable natural frequency in water due to variable added mass. The latter can be measured experimentally [47.53, 53, 54, 62, 63]. Both approaches are based on a simple expression of the added mass force being proportional to the relative acceleration of the fluid with respect to the body. An in-depth analysis reveals that the added mass depends on relative acceleration components as well as convective terms with relative velocities [47.123].

Galloping, however, is not a resonance phenomenon (Sect. 47.2.3, *Hydrodynamic Principles*, Principle 4). It is an instability phenomenon not driven by the oscillatory vortex structures which still exist in the wake. Springs are needed only to reverse the cylinder motion, not to establish a natural frequency and possible resonance. If the converter were not limited by size, the cylinder – once excited in galloping – would continue moving in one direction harnessing MHK energy from the stream and converting it to kinetic energy rather than alternating between kinetic and potential energy in the springs. Actually, the highest power conversion efficiency that has been achieved by the VIVACE converter was when no springs were used during most of the cylinder travel. The latter is defined by the frame holding the oscillator and is equal to twice the amplitude of oscillation. Very short springs were installed only at the two ends of the cylinder travel to reverse the motion of the cylinder in a high efficiency process. Springs have to be designed carefully to be very short to maintain the high efficiency in reversing the motion and preventing the cylinder from slamming against the converter frame, thus, wasting valuable energy.

When the converter spans over multiple FIMs, springs must be designed to accommodate the VIV oscillator and reversal of the direction of motion for galloping. These springs are highly nonlinear and their functionality is specified in synergy with the controller's function during regenerative breaking (Sect. 47.2.3, *Hydrodynamic Principle*, Principle 12).

An additional note on the springs is that in spite of the slow nature of oscillations – about a cycle a second – there are 32 million seconds in a year making the fatigue life of the springs a challenge. The design and analysis of the strongly nonlinear springs – with the dual role of serving the converter both in VIV and galloping – is difficult and is part of the optimal controller algorithm.

Finally, it should be noted that the springs are designed differently depending on the size of the converter and whether it is a model in the recirculating channel or a field prototype. In the former case, the springs are completely replaced by the virtual damping–spring system V_{ck} (Sect. 47.2.3, *Hydrodynamic Principle*, Principle 12). In field-prototypes, nonlinear springs are present and coexist with the controller for optimal regenerative breaking, motion reversal, and minimum maintenance.

Passive turbulence control (PTC) is designed and appended on the cylinder surface in the form of selective roughness. As explained in (Sect. 47.2.3, *Hydrodynamic Principle* Principle 7), PTC is applied in the form of two sandpaper strips parallel to the cylinder axis, symmetrically with respect to the flow. PTC acts as turbulence stimulation. PTC achieves the following:

1. Alters the flow around the cylinder including the boundary layer, separation point, shear layers, for-

mation length, vortex roll-up, fluid–structure interaction, stability, etc.
2. Initiates galloping at low speeds so that VIV and galloping can be reached back to back, thus, creating an open-ended high-response oscillator as explained in Sect. 47.2.3 (Principle 9).
3. Prevents suppression of FIM in the flow-transition region from the laminar to turbulent boundary layer. In this critical flow regime VIV is suppressed. With PTC properly applied, FIM persisted without any gaps in Reynolds number.

The MRELab managed to establish the *PTC-to-FIM Map* shown in Sect. 47.2.3 (Principle 7) establishing the effect that PTC can have on FIM including enhancement and suppression.

The effectiveness of the PTC depends on four parameters including the start and end points, the roughness of the grit, and the total thickness of the sandpaper in relation to the thickness of the boundary layer at the location of the PTC. Table 47.3 shows sample dimensions of PTC used routinely in the LTFSW channel of the MRELab. The boundary-layer thickness is discussed in Sect. 47.2.3, *Hydrodynamic Principle*, Principle 7.

Synergistic FIM of Multiple Cylinders. This is a critical system parameter: How many cylinders should be included in a converter; what should be the relative properties of the oscillators in terms of stiffness k, oscillating mass m_{osc}, and damping c; and in what configuration should they be placed in the school. As explained in Sect. 47.2.3 (Principle 8), gap flow and wake interference can be utilized not only to enhance FIM but, most important, to achieve synergistic operation resulting in energy conversion higher than that of the same number of cylinders in isolation [47.84]. The experimental setup in the MRELab allows for:

1. Variable center-to-center spacing between cylinders in the flow direction: $1.429 \leq d/D_{3.5''} \leq 6.0$
2. Variable center-to-center offset between cylinders transversely to the flow direction: $0.5 \leq t/D_{3.5''} \leq 1.0$
3. Reynolds number up to 130 000 for $D = 0.0889\,\mathrm{m}$ $(3.5'')$
4. Allowed amplitude of 5.5 diameters needed in galloping
5. Variable stiffness of springs $300\,\mathrm{N\,m^{-1}} < k < 5000\,\mathrm{N\,m^{-1}}$
6. Variable mass ratio
7. Variable location and properties of PTC.

All of the above parameters are important in achieving the most vigorous FIM to maximize the MHK energy converted to energy in the mechanical oscillator.

Conversion of Linear to Rotational Motion. An early design decision was made to go with off-the-shelf components in building VIVACE lab models and subsequent field prototypes. Linear generators were considered but rejected due to high cost and low efficiency even though they would be more convenient in converting the linear oscillatory motion to electricity directly. Instead, the decision was made to use high efficiency, commercially available, rotary generators at relatively low revolutions per minute (RPM), and deal with the conversion of the linear oscillatory motion to rotational oscillatory motion. The solution to this conversion is based on a pulley–belt system that has proven to be reliable both in the lab and in the field. It is described in Sect. 47.2.3, *Electro-Mechanical Principles* as part of the V_{ck} system.

Controller and Power Take Off (PTO) System. These two components are present both in models in the MRELab LTFSW channel and prototypes in towing tanks and in field tests. Their functionality and design, though, differ between models and prototypes. In field tests, the controller is used to optimize the converted power, while in the laboratory the controller is embedded in the V_{ck} system (Sect. 47.2.3, *Hydrodynamic Principles*, Principle 12) and aims to facilitate and expedite changing of testing parameters. The most important word of caution is not to include the hydrodynamics in the closed control loop, as that would introduce a phase lag, which would bias the FIM response and the converted power.

Table 47.3 Properties of roughness strips

Property	Commercial grade				
	P60	P80	P120	P150	P180
Average grit height (k/D)	3.03×10^{-3}	2.19×10^{-3}	1.42×10^{-3}	1.09×10^{-3}	0.92×10^{-3}
Thickness of the backing paper (p/D)	6.50×10^{-3}	6.24×10^{-3}	4.98×10^{-3}	5.54×10^{-3}	5.38×10^{-3}
Total height $T/D = (p+k)/D$	9.53×10^{-3}	8.43×10^{-3}	6.40×10^{-3}	6.63×10^{-3}	5.30×10^{-3}

Notes: Cylinder diameter $D = 3.5''$ (0.0889 m); T/D should be compared to the boundary layer thickness

V_{ck} System. For systematic testing in the laboratory, two issues are important:

1. Changing the physical springs and dampers requires extensive preparation for calibration and alignment.
2. The viscous damping of the system is rarely linear as modeled in classical mathematical models in vibration textbooks.

To compensate for these two major challenges, *Lee* et al. [47.98, 99] introduced and implemented the virtual damping-spring device called V_{ck} system [47.98, 142]. V_{ck} is a feedback loop that uses the servomotor encoder to keep track of the position and velocity of the cylinder, it provides the necessary torque to simulate the spring stiffness and provide the linear viscous damping required. After extensive model identification and calibration, V_{ck} is used to subtract the system damping and then impose mathematically correct linear viscous damping and spring stiffness at the press of a button. This first V_{ck} system supported the FIM experiments conducted in the MRELab between 2009 and 2011 [47.98]. A second generation of the V_{ck} system was built recently by *Sun* et al. [47.142] to support the VIVACE converter experiments being conducted presently in the MRELab in collaboration with VHE. The basic principles and mathematical models behind V_{ck} are provided in Sect. 47.2.3, *Hydrodynamic Principles*, Principle 12.

In summary, the following conclusions should be observed for the successful design of a commercial converter:

- Springs are a critical design component and should be designed carefully to meet multiple objectives:
  1. Support VIV
  2. Support only reversal of motion in galloping
  3. Work in collaboration with the controller
  4. Achieve a satisfactory fatigue life
  5. Obviously be nonlinear.
- Passive turbulence control is an essential element of the cylinders. Without PTC, only the lead cylinder would function efficiently in a school. PTC enables FIM of following cylinders required to achieve high power-density converters. In addition, only with PTC, cylinders can maintain FIM in the critical flow regime.
- Multiple cylinders properly placed in a school can achieve synergistically higher power output than the same number of isolated cylinders in FIM.

Operation

Models or prototypes of the converter are deployed in a stream with the axis of each cylinder perpendicular to the flow. Cylinders may be positioned horizontally or vertically depending on several factors that are discussed below. The process is simple in the laboratory but may take several hours in the field depending on the weather conditions. The major aspects of operation are described below.

How the VIVACE Converter Works. Following launching, the converter may be self-started in FIM or may require a push from the controller depending on various parameters, such as the uniformity of the flow, the FIM phenomenon anticipated at the flow speed, and the imposed damping. Depending on the flow speed, cylinder diameter, and system damping, the converter may be in the range of VIV, transition from VIV to galloping, or fully developed galloping. The linear oscillatory motion of the cylinder due to FIM and springs is converted to a rotational oscillatory motion of the axis of a rotary generator through belts and pulleys. The controller imposes damping through the generator in addition to the system damping in order to harness the MHK energy converted to mechanical energy in the oscillator. In laboratory tests and field tests so far, the energy generated is burnt in a heat bank. In the case of a commercial device, the power signal at the output of the generator needs to be conditioned before being dispatched to a power grid.

Operational Concerns. Operation in the marine environment may be hazardous and unforgiving to errors. Accordingly, the following words of caution are offered:

1. FIMs are powerful and destructive phenomena and in most cases self-initiated. Hard galloping is an exception requiring a threshold displacement. Thus, caution should be exercised when safety hooks are released to allow cylinders to move.
2. Flow uniformity is a strongly recommended flow characteristic. There are several situations where the flow may deviate significantly from a uniform flow and result in suboptimal conditions of operation of the converter. For example, if the cylinder is placed vertically and close to the riverbed, it will be partially immersed inside the boundary layer, which has a width of about 1 m in a 2–2.5 kn current. A turbulent boundary layer has a full profile following the $z^{\frac{1}{7}}$ rule but still creates a very strong shear flow along the cylinder length, thus, reducing the alternating lift that drives the cylinder. A second example would be that of a flow out of an orifice at the interface between flow cross-sections that differ dramatically, such as a small opening out of a big dam or wall holding back fluid. That flow would be highly nonuniform and may result in as little as

one-third of the converter cylinder to be subjected to alternating lift that would induce some form of FIM.
3. If converter cylinders are placed horizontally instead of vertically, proper positioning of the converter using a crane from a barge may take several attempts. It is very important though to position the horizontal cylinders perpendicularly to the flow.

Vertical Versus Horizontal Cylinders. Positioning of cylinders horizontally or vertically is an important issue affected by the following parameters:

1. A small misalignment of the converter with respect to the flow direction will not affect the expected FIM response of a vertical cylinder. The small error will result in asymmetric positioning of the PTC strips. A larger error can be corrected by a rotation of the cylinder with respect to its own axis. In the case of a horizontal cylinder, a misalignment of the converter will result in a less than a 90° angle between the current and the cylinder axis exposing an elliptical rather than a circular cross-section to the flow. That may result in severe implications on the cylinder FIM depending on the size of the error.
2. Buoyancy is a very large force particularly in larger field applications. In the case of a horizontal cylinder, the buoyancy must be accurately set equal to the cylinder weight to achieve a neutrally buoyant cylinder. Even a small deviation would result in significant loss of energy to compensate for the difference between weight and buoyancy.
3. Nonuniformity of the flow is expected due to the boundary layer at the bottom of a river. A horizontal cylinder will not be affected since the flow velocity may change with distance from the riverbed, but it will remain uniform along the length of the cylinder.
4. Distance from the bed will take the cylinder away from the boundary layer but will increase the overturning moment and thus the required structural strength.
5. Vertical cylinders are more likely to encounter limitation due to water depth and navigation restrictions.

Considering all five factors, a general decision on the vertical versus horizontal orientation of the cylinders in the VIVACE converter is hard to make. The design decision has to be made on a case-by-case basis.

Environmental Compatibility. ALTs, such as the VIVACE converter, are subjected to alternating lift present in various forms of FIM and cylinder interference as specified in C21 and C22. Several studies have been conducted in the past establishing that fish thrive in the wake of a cylinder in a flow. Fish relax in the oscillatory wake and, with minimal effort, stay behind the cylinder and are in general more active and spawn more. Most notable is the study by Harvard, MIT, and Oak Ridge National Laboratory [47.34–37]. More environmental studies need to be conducted for permitting in the United States, including noise levels and electromagnetic interference.

Is VIVACE exotic or natural in water? We live in air and observe around us mostly lifting surfaces – bird wings, airplane wings, sails of sailboats, windmills, etc. Lifting surfaces in air, under constant airflow, generate unidirectional lift. In water, the picture is totally different. The muscle power of a fish is smaller than its drag in forward motion. So fish move by generating alternating vortices by periodically curving their bodies (Fig. 47.7a,c) and pushing them away when those vortices have accumulated adequate level of circulation. This generates alternating lift. In motion of bodies in dense fluids like water, all alternating lift comes from bluff bodies with tail; from tiny sperm to huge whales. Vorticity, circulation, and lift generated by circular cylinders may appear exotic to humans but it is an integral part of fish kinematics in schools or as individuals. As a result, the kinematics of ALTs is compatible with the kinematics of schools of fish. In addition, fish have scales with thickness of the order of the boundary layer, which is under investigation in marine biology. Surface roughness varies with species and their speed. In cylinders, surface roughness as implemented by PTC has proven to be very effective in inducing a specific FIM.

The following design considerations should be noted:

- VIVACE can operate with horizontal cylinders when they are neutrally buoyant and can be positioned accurately perpendicular to the free stream. Vertical cylinders are recommended when the water depth is adequate and the flow velocity profile with respect to the water depth is reasonably constant above the boundary layer at the riverbed.
- As far as hydrodynamics is concerned, ALTs convert MHK energy in an environmentally compatible way whether they operate in a school or as individuals.

47.2.2 Scales, Models, Prototypes

The VIVACE converter is a highly scalable MHK energy device because the underlying FIM phenomena of VIV, galloping, gap flow, and wake interference are highly scalable. The various scales are presented in Sect. 47.2.2, *Scales* in relation to hydrodynamics and applications. The various models and prototypes

tested so far are presented in Sect. 47.2.2, *Models* and Sect. 47.2.2, *Prototypes*, respectively.

Scales

Definition of Scalability. The term *scale* has two possible interpretations. The first pertains to the wedge stabilization game [47.143] measuring the impact of pollution on the environment. The second interpretation relates to the technology or product size and the market it addresses (Table 47.4). VIVACE covers a broad range of applications from Scale-1 of just a few Watts to MW in utility Scale-4. It is expected to revolutionize some markets and have a major impact on others. In the wedge stabilization game, Scale-4 will have an impact.

Stabilization Wedge. If only 10% of the 22 000 TWh/yr horizontal MHK energy could be harnessed it would be equivalent to 0.62 of a wedge as defined by *Pacala* and *Socolow* [47.143]. The figure of 22 000 TWh/yr was calculated by *Bedard* et al. [47.18] based on present technology. VIVACE can have a major impact by harnessing also the slower flows that constitute the vast majority of water currents. For VIVACE to provide a full wedge – that is reduce CO_2 emissions by 1 Gt/yr – 16% of the 22 000 TWh/yr horizontal MHK energy or 3550 TWh/yr should be harnessed. This is well below the Betz limit. It would be an even smaller percentage when slower currents are included that can be harnessed by ALTs and not by SLTs being considered at the present time.

Returning to the more conventional definition of scale, as the size of the MHK energy device and the power it generates, the following four scales are identified. Figure 47.16 shows the hydrodynamic scales mapped on the Reynolds number and flow regimes.

Scale-1. It is the smallest scale and has very limited but unique and valuable applications. The four important aspects of this scale are:

1. Hydrodynamics: Ultraslow currents at $\approx 0.25\,\mathrm{m\,s^{-1}} \cong 0.5\,\mathrm{kn}$ abound in deep waters. This low-power scale can be used to power sensors AUVs (autonomous underwater vehicles) since battery life is too short for operations. In the MRELab, VIVACE works down to $0.4\,\mathrm{m\,s^{-1}}$ [47.67, 95] and recently to $0.31\,\mathrm{m\,s^{-1}}$, still remaining a compact device.
2. Power: About 10 W for a small converter adequate to power sensors and recharge batteries.
3. Products: The following are considered:
   a) The AUV garage shown in Table 47.4 designed by vortex hydro energy VHE with Northrop–Grumman.
   b) A self-powering AUV becoming the VIVACE cylinder itself, thus extending both the range and days of operation indefinitely. It is also shown in Table 47.4 approaching the garage.
   c) Direct powering of a spider-web of hardwired sensors.
4. Applications: Monitor coasts for defense, law-enforcement. Monitor offshore platforms, track fish populations, track spills, and other sources of pollution. Provide early alert to weather conditions.

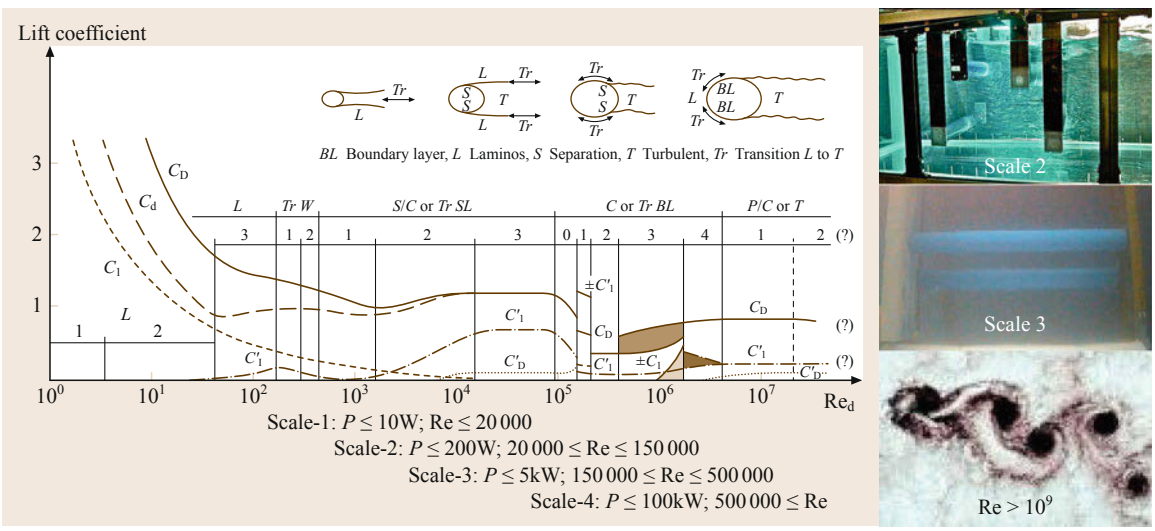

Fig. 47.16 Hydrodynamic and power scales for the VIVACE converter (after [47.56]). Scale-2: Channel MRELab test. Scale-3: Field test in St. Clair River. Large scale: NASA picture of clouds floating around an island mountain peak

Table 47.4 Hydrodynamic and power scales for the VIVACE converter (photos by Vortex Hydro Energy)

Scale	Scale-1 $1000 \leq Re \leq 20\,000$ Early laminar flow	Scale-2 $20\,000 \leq Re \leq 300\,000$ Late laminar flow	Scale-3 $300\,000 \leq Re \leq 500\,000$ Critical to turbulent	Scale-4 $500\,000 \leq Re$ Post supercritical
Unit				Weight	≈ 500 lbs	≈ 1000 lbs	≈ 20 000 lbs	≈ 100 000 lbs
Power[a]	≈< 10 W	200 W	3500 W	> 50 kW
$/kWh	TBD	$ 2.00	$ 0.80	$ 0.08–0.12
Application	UUV, sensors, tracking, pollution, weather, fish, defence	Portable, naval, expeditions, camps	Remote communities, lighthouses, naval operations	Utility scales, coastal communities, islands

[a] Power output is tested or calculated at 3 kt

Scale-2. This is the scale that has been tested extensively as it fits in the LTFSW channel of the MRELab. The four important aspects of this scale are:

1. Hydrodynamics: Scale-2 has been demonstrated and is being developed/tested in the MRELab since 2005 (Figs. 47.5a,b and Table 47.4). It operates in the TrSL3 flow regime, where the shear layers are fully turbulent, and lift is high reaching unprecedented amplitudes even under high damping as explained in Sect. 47.2.3.
2. Power: Proven in the MRELab to have power density about 14 600 times that of wind farms and 15–100 that of other MHK energy devices [47.100]
3. Products: VHE has designed two units at this scale (Table 47.4):
   a) A lightweight compact unit that can be transported by a single soldier in the field to power electronics.
   b) A more rugged unit to mount in an offshore lab in Brazil and a canal in the Netherlands.
4. Applications: Military expeditions in remote areas where a gallon of fuel costs $ 400, small camps near rivers or areas with no resources, such as Alaska and the Caribbean.

Scale-3. This is the scale that has been tested with field tests and in the towing tank of the University of Michigan. The four important aspects of this scale are:

1. Hydrodynamics: Scale-3 was demonstrated in the St. Clair river in August 2010 (Fig. 47.5c). Scale-3 operates in the TrSL3 subcritical (laminar), critical (transition from laminar to turbulent), and early post-critical (turbulent) flow regimes. In the transition, VIV is fully suppressed. The breakthrough achieved in the MRELab was that by applying PTC properly. FIM was sustained through the critical flow regime into the post-critical without losing amplitude.
2. Power: Of the order of 5 kW for a VIVACE unit of $\approx 10\,m^3$ in 3 kn current.
3. Product: A modular product that can build farms is VHE's target in this scale.
4. Applications: Powering of river and coastal camps and small communities.

Scale-4. This is the scale that has not been tested with field tests but is currently under funding by DOE for development and deployment in the summer of 2016. The four important aspects of this scale are:

1. Hydrodynamics: Scale-4 does not represent any challenge given that there is no change in hydrodynamics/FIM between Scales 3 and 4 that could affect operation. It operates in the fully turbulent flow.
2. Power: About 33 kW for a $80\,m^3$ VIVACE module at 3.2 kn.
3. Product: A modular product that can be repeated to build farms to achieve the next scale of 500 kW. There is no upper limit to this scale, as flow properties related to VIV and galloping are not known to change within the super-post-critical flow.
4. Applications: Powering of river/coastal communities at utility scale. Offshore farms can generate power of the order of MW. Ultimately, large-scale VIVACE converters can be installed along ocean currents for multi-MW power generation

(e.g., the Florida Current). According to the Energy Power Research Institute, the annual hydrokinetic tidal power output potential for North America is 115 000 GWh [47.18].

The following design considerations should be noted:

- Alternating-lift technologies, such as VIVACE, are highly scalable because the underlying principles are highly scalable. In this particular case study, all FIMs, as well as gap flow and wake interference are highly scalable.
- Four scales have been identified in this case study, primarily based on the consistency of hydrodynamics in each scale when using PTC. Scale-1, for low Reynolds numbers including the TrSL2 (Transition Shear Layer 2 – *Zdravkovich* [47.56], Fig. 47.16) flow regime. Scale-2, for moderate Reynolds numbers covering the first half of the TrSL3 flow regime. Scale-3, covering the second half of the TrSL3 flow regime and the critical flow. Scale-4, covering the post-critical flow regime.
- Commercial products with unique applications can be developed in each one of the four scales.

Models

Models are typically defined as scaled-down geometrically similar (geosims) devices built for the sole purpose of testing them in experimental facilities to extrapolate measurements to enable analysis and design of prototypes. Often, several geosims of different size are built and tested prior to building a prototype. A five-step protocol for the development and evaluation of tidal-current energy devices was published by *Bahaj* et al. [47.144]. They also showed the correspondence between the five steps in the proposed protocol to the nine levels of the NASA TRL (technology readiness level) process [47.145].

If the underlying hydrodynamic principles, however, hold over a very broad range of Reynolds numbers (Sect. 47.2.3, *Mechanical Principles*) as in the present case study, models could be considered and serve as smaller scale prototypes. Those scales were defined in Sect. 47.2.1, *Basic Concepts*. Hereafter, to minimize confusion, devices of Scale-1 and Scale-2 tested in the LTFSW channel or towing tanks are referred to as models while devices tested in field tests in Scale-2 and Scale-3 are referred to as prototypes. Several prototypes have been tested at full size in towing tanks before used in field tests.

Figure 47.17a shows a four, horizontal, PTC-cylinder model of a VIVACE converter tested in the old (prior to 2012) LTFSW channel of the MRELab. All FIMs used by VIVACE were observed and measured: VIV, galloping, coexistence of VIV and galloping, and enhancing gap flow [47.84]. Response in galloping reached three diameters hitting the safety stops, which led to rebuilding of the channel to accommodate larger amplitudes up to 5.5 times the cylinder diameter of $D = 3.5''$ (0.0889 m), as explained in Sect. 47.3.1.

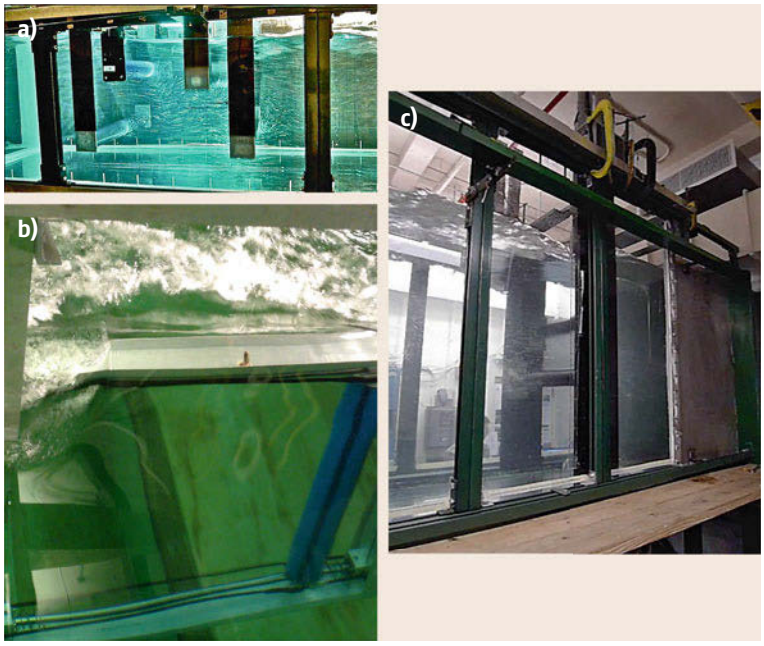

Fig. 47.17a–c Laboratory models of VIVACE: Scale-2 (photos courtesy of MRELab) **(a)** $D = 3.5''$ (0.0889 m), $L = 36''$ (0.914 m). MRELab tests observed synergistic multibody FIM: VIV, galloping, coexistence of VIV and galloping, and enhancing gap flow, **(b)** $D = 8''$ (0.203 m), $L = 60''$ (1.524 m). Towing-tank tests at the University of Michigan observed VIV, galloping, and coexistence of VIV and galloping, **(c)** $D = 3.5''$ (0.0889 m), $L = 35.25''$ (0.895 m). MRELab tests of 2 PTC cylinders in galloping with enhancing gap flow

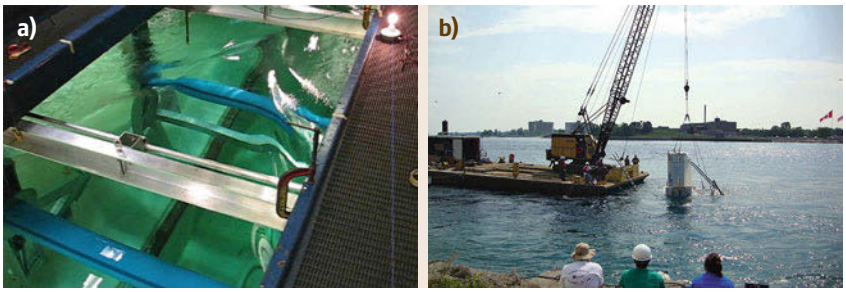

Fig. 47.18a,b Prototypes of VIVACE in field tests: Sacle-3 (photos courtesy of Vortex Hydro Energy). **(a)** VHE with MRELab tests of two PTC cylinders in galloping with enhancing gap flow. $D = 10''$ (0.254 m), $L = 105''$ (2.70 m), **(b)** St. Clair river tests based on synergistic multibody flow induced motions: VIV, galloping, coexistence of VIV and galloping, and enhancing gap flow

Figure 47.17b shows a single, vertical, PTC-cylinder model of a VIVACE converter tested in the towing tank of the Marine Hydrodynamics Laboratory at the University of Michigan. VIV, galloping, and coexistence of VIV and galloping used by VIVACE were observed and measured. Response in galloping reached four diameters for $D = 8''$ when hitting the safety stops.

Figure 47.17c shows a two, horizontal, PTC-cylinder model of a VIVACE converter tested in the new (since 2013) LTFSW channel of the MRELab at the University of Michigan. All FIMs used by VIVACE were observed and measured: VIV, galloping, coexistence of VIV and galloping, and enhancing gap flow [47.84, 142]. Safety stops were not hit as the new channel allows for amplitudes of 5.5 cylinder diameters for $D = 8''$ (0.203 m). In the new V_{ck} system (Sect. 47.2.3, *Electro-Mechanical Principles*, Principle 12), programmable stoppers are set by the controller at both ends of the cylinder travel, in addition to the physical bumpers, in order to protect the channel.

Prototypes

In contrast to models, which are tested only in experimental facilities, prototypes are field deployed. Since the VIVACE converter is highly scalable, devices that have been tested in the field are referred to as prototypes of various scales even if they have been tested in experimental facilities prior to their field deployment. VHE in collaboration with the MRELab has deployed two different prototypes in the St. Clair river and two in canals in the Netherlands in collaboration with TAUW.

River Prototypes. Two different river prototypes were deployed and tested at the same location in the St. Clair river, at Dunn's paper, near the Blue Water Bridge. The flow was steady with velocity in the range of 2.1–2.5 kn and water depth varying from 20 to 60 ft.

The first prototype was deployed in August 2010 after extensive testing in the towing tank at the University of Michigan as shown in Fig. 47.18. The synergistic kinematics of two PTC cylinders worked very well. Each horizontal cylinder was neutrally buoyant with $D = 10''$ (0.254 m) and $L = 105''$ (2.70 m), and weighed 150 pounds in air without ballast. FIM was self-initiated.

The second river prototype is shown in Fig. 47.19 during testing at the towing tank of OHMSETT

Fig. 47.19a,b Prototypes of VIVACE in field tests: Sacle-2; $D = 8''$, $L = 60''$ (photos courtesy of Vortex Hydro Energy). **(a)** VHE tests of VIVACE prototype at OHMSETT towing tank based on VIV, galloping, and coexistence of VIV and galloping, Pictures courtesy of VHE. **(b)** Deployment in St. Clair River in September 2012. $D = 8''$ (0.203 m), $L = 60''$ (1.524 m)

Fig. 47.20a,b VIVACE Prototype in field tests in the Netherlands: $D = 10''$ (0254 m), $L = 60''$ (1.524 m). **(a)** Model of VIVACE at MHLab towing tank. Shorter models require bigger diameter to overcome system friction (photo courtesy of MRELab). **(b)** Shorter models require uniform flow and bigger diameter to ensure adequate lift (after [47.146])

[47.147], in Leonardo, New Jersey, deployment in the St. Clair River, and in operation in the field viewed through an underwater camera. It was field tested in September to November 2012. It was smaller than the previous prototype, with $D = 10''$ (0.254 m) and $L = 105''$ (2.70 m). One cylinder was used and positioned vertically. Upon installation FIM was not self-initiated. It was quickly realized that the cylinder was placed too close to the riverbed with about 45% of its length inside the boundary layer of the river flow. The cylinder was raised by about 1 m and FIM was self-initiated immediately.

Canal Prototypes. Two deployments of the same, small, Scale-2 prototype took place in collaboration with TAUW, in canals in the Netherlands, in January 2013. The device was tested in the University of Michigan towing tank (Fig. 47.20a) and functioned well. It was not self-initiated but went into FIM when it was given an initial displacement. This is typical of hard-galloping [47.43]. This device was the smallest possible as it was constrained by the size of the opening in the gate shown in Figs. 47.20b and 47.21. Thus, overcoming the system friction required a bigger diameter cylinder reducing the allowable maximum amplitude of oscillation. The increased diameter provided the required force. The damping of the system associated with harnessing the energy was increased to achieve higher MHK energy conversion. That also reduced the amplitude response to avoid collision of the cylinder in FIM with the frame, which would have wasted valuable energy. When the water passed through the orifice in Fig. 47.20b, the flow was uniform only in about one-third of the length around the center of the cylinder. That is, two-thirds of the cylinder length was providing drag and one-third was providing lift. The lift was not sufficient to overcome the drag from the two-thirds of the cylinder length, plus the system damping. FIM was not sustained even with initial displacement. Side cuts were opened around the gate. This resulted in more uniform flow and initiation of FIM. The electrical output was small as expected under the adverse circumstances.

Scale-4 Farm. Vortex hydro energy (VHE) is developing a large-scale device called *Oscylator-4*. It is designed to produce 4 kW in a flow of 3.2 kn. It has four large PTC cylinders in close proximity that allows for high power-to-weight/volume density, which is the Achilles heel of all renewable energy devices. Several *Oscylator-4s* will form a small farm for commercial applications.

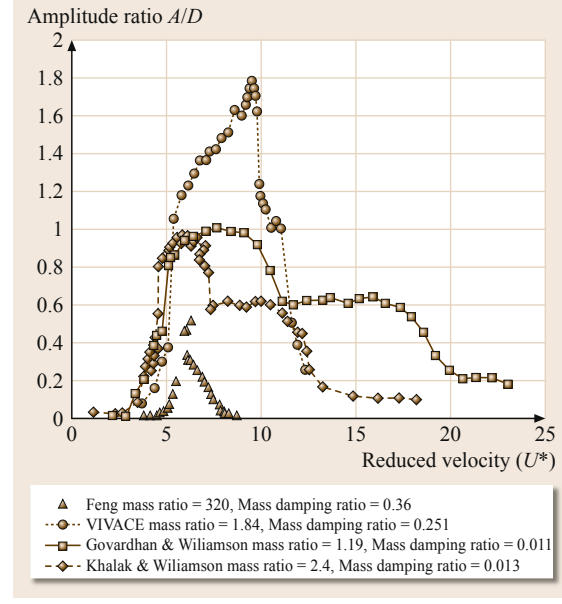

Fig. 47.21 In spite of high damping for energy harnessing, VIVACE amplitude in the TrSL3 flow regime is significantly higher than VIV response in the TrSL2 flow regime. In addition, the upper branch overtakes the lower branch and with amplitude increasing with velocity (after [47.107])

On the basis of the extensive laboratory experiments and four field deployments of models and prototypes of various scales, the following conclusions are important to record for the specific case study considered in Sect. 47.2.2:

1. Development of a MHK energy device – or any ocean structure for that matter – requires several stages of development described in detail in the Southampton Protocol [47.144]. It takes into consideration the special requirements of scaling, testing, building, and launching of ocean structures while observing the nine levels of Technology Readiness Levels developed by NASA [47.145].
2. ALTs may have an advantage – as in the case study of the VIVACE converter – that the hydrodynamic phenomena on which they are based are highly scalable. Accordingly, a small-scale prototype may serve as a larger scale model.
3. Small-scale models face additional challenges related to end flow conditions, which typically reduce the two dimensionality of the flow. Nonuniform flows result in the reduction of the length of the cylinder, which provides lift. Instead, they are subject to opposing forces in the lift direction in addition to the system damping. This double jeopardy may result in failure of an ALT to function at satisfactory efficiency.

47.2.3 The Underlying Principles

Following the analysis of the basic concepts behind ALTs, the discussion of scales, and the case study and its operational conditions considered in Sect. 47.2, it is appropriate to understand the underlying principles of ALTs. Twelve physical principles are implemented in the discovery and development of the case study of the VIVACE converter. Most of these would apply to a certain extent to all forms of ALT.

For easier presentation and understanding, they are divided into three categories: hydrodynamics, mechanical, and electromechanical.

Hydrodynamic Principles

Principle 1 – Fluid–Structure Interaction (FSI). When a flexible body or structural system is exposed to a fluid flow and the hydrodynamics, and the structural dynamics scales are comparable, the presence of each (fluid, structure) affects the other. In the case study of the VIVACE converter, FSI results in dynamic bifurcations and instabilities, such as various forms of FIM.

Principle 2 – Flow-Induced Motions (FIM). A buoy floating on waves is not in FIM as the buoy is too small to affect the frequency of the wave field. The diffracted waves have the same frequency as the incident wave field. On the contrary, a flexible cylinder or a rigid cylinder on elastic support has a diameter close in size to that of the von Kármán vortices generated in the cylinder wake. The frequency of the vortex street, which induces oscillatory lift (and drag) on the body, is affected drastically by the interaction with the body motion. A rigid cylinder on springs is excited nonlinearly in FIM in transverse current. The presence of the body affects the flow and vice versa. VIVs, galloping, buffeting, fluttering, and gap flows in schools of bodies are FIM phenomena.

Principle 3 – Vortex-Induced Vibrations (VIV). A cylinder with its axis perpendicular to a steady flow generates the von Kármán vortex street where the vortex size is about equal to the cylinder diameter (Figs. 47.7b, 47.16). When the cylinder is flexible it may oscillate driven by the alternating vortex street at a frequency of oscillation f_{osc}. The wake frequency f_{wake} is the same as f_{osc}. The vortex shedding frequency f_{vs}, though, is a multiple of the wake frequency f_{wake} depending on the vortex structure being 2S (two single vortices) or 2P (two pairs of vortices), etc. The vortex shedding frequency f_{vs} when the cylinder is in FIM, should not be confused with the vortex-shedding frequency f_s when the cylinder is stationary. f_s is also called the Stouhal frequency defined as

$$\mathrm{St} = \frac{f_s D}{U} \,. \tag{47.1}$$

This synchronization between f_{osc} and f_{wake} persists over a very broad range of stream velocities resulting in large amplitude oscillations. The frequency of oscillation f_{osc} changes with flow speed as the vortex structures change. Some researchers interpret this synchronization phenomenon between excitation and response as a lock-in phenomenon and others as a nonlinear resonance over the same broad range of flow velocities [47.60] with variable natural frequency in water ($f_{n,water}$) due to variable added mass. The latter can be measured experimentally. The mathematical modeling of VIV as lock-in is presented in Sect. 47.3.6. The mathematical model of VIV as a variable natural frequency – and thus added mass – phenomenon is presented in Sect. 47.3.7. $f_{n,water}$ is defined as

$$f_{n,water} = \frac{1}{2\pi}\sqrt{\frac{k}{m_{osc}+m_a}} \,. \tag{47.2}$$

This broad-band synchronization phenomenon between excitation and cylinder vibration is called VIV.

Leonardo da Vinci first observed VIV of a taut wire exposed to wind-flow transverse to the wire axis, in 1504. He called the emitted sound *Aeolian Tone*. Typically, VIV occurs in the range

$$\approx 5 < U^* = \frac{U}{f_{\mathrm{n,water}} D} <\approx 10\,, \tag{47.3}$$

where U = stream velocity, D = cylinder diameter, U^* = reduced velocity,

$$f_{\mathrm{n,water}} = \frac{1}{2\pi}\sqrt{\frac{k}{m_{\mathrm{osc}} + m_{\mathrm{a}}}}\,, \tag{47.4}$$

and the ideal flow added mass coefficient $C_{\mathrm{A}} = 1$ is used resulting in $m_{\mathrm{a}} = m_{\mathrm{d}}$ where m_{d} is the displaced fluid mass

$$m_{\mathrm{d}} = \rho\pi\frac{D^2}{4}L\,. \tag{47.5}$$

This is purely for data presentation reasons and does not support or negate any of the two interpretations of VIV explained in the previous paragraph.

As a synchronization phenomenon, VIV is destructive like linear resonance. Two differences are important:

1. VIV is self-limiting and in that sense not as destructive as liner resonance
2. VIV is broad-banded while linear resonance is very narrow-banded.

In that respect, VIV is much more difficult to prevent in designing structures in dynamic response. On the other hand, the broad range of synchronization makes VIV a much more suitable principle to base an MHK energy converter than the principle of a linear oscillator.

Another very important characteristic of VIV is its strong dependence on Reynolds number [47.107, 148] as shown in Fig. 47.21 and explained further (Figs. 47.42– 47.45) in Sect. 47.3.1, *First Low-Turbulence Free-Surface Water (LTFSW) Channel*. Dependence on Reynolds number brings the VIV response to new heights in the TrSL3 flow regime – around two diameters amplitude – and reveals a very different response operator as a function of reduced velocity+U^* than the VIV response operator in the TrSL2 flow regime. That is, the TrSL3 flow regime is much more efficient for VIVACE to convert MHK energy. This is confirmed by the high-lift coefficient C_{L} as shown in Fig. 47.16.

Principle 4 – Galloping. It is a FIM more vigorous than VIV. It is an instability phenomenon caused by geometric/hydrodynamic asymmetry and once initiated has no end with increasing velocity until structural failure [47.43]. A smooth circular cylinder in a uniform stream could not be destabilized to gallop.

A simple mathematical model of an oscillator leading to galloping is shown in Fig. 47.22

$$(m_{\mathrm{osc}} + m_{\mathrm{a}})(\ddot{y} + 2\zeta_{\mathrm{water}}\omega_{\mathrm{n,water}}\dot{y} + \omega^2_{\mathrm{n,water}}y) = F_{\mathrm{Y}}(t)\,, \tag{47.6}$$

where the damping ratio is defined as

$$\zeta_{\mathrm{water}} = \frac{c}{2\sqrt{k(m_{\mathrm{osc}} + m_{\mathrm{a}})}}\,, \tag{47.7}$$

the natural frequency in water is

$$\omega_{\mathrm{n,water}} = \sqrt{\frac{k}{m_{\mathrm{osc}} + m_{\mathrm{a}}}}\,, \tag{47.8}$$

and

$$\begin{aligned} F_{\mathrm{Y}}(t) &= -F_{\mathrm{L}}\cos\alpha - F_{\mathrm{D}}\sin\alpha \\ &= -\frac{1}{2}\rho DLU^2 C_L\cos\alpha - F\frac{1}{2}\rho DLU^2 C_{\mathrm{D}}\sin\alpha\,, \end{aligned} \tag{47.9}$$

and, thus, C_{Y} is given by

$$C_{\mathrm{Y}} = -C_{\mathrm{L}}\cos\alpha - C_{\mathrm{D}}\sin\alpha\,. \tag{47.10}$$

For a small angle of attack, C_{Y} can be expanded in Taylor series to yield

$$C_{\mathrm{Y}} = -\left[\left(\frac{\partial C_{\mathrm{L}}}{\partial\alpha}\right)_{\alpha=0} + C_{\mathrm{D}}(\alpha = 0)\right]\frac{\dot{y}}{U}\,, \tag{47.11}$$

resulting in the following equation of motion

$$\ddot{y} + 2\zeta_{\mathrm{total}}\omega_{\mathrm{n,water}}\dot{y} + \omega^2_{\mathrm{n,water}}y = 0\,, \tag{47.12}$$

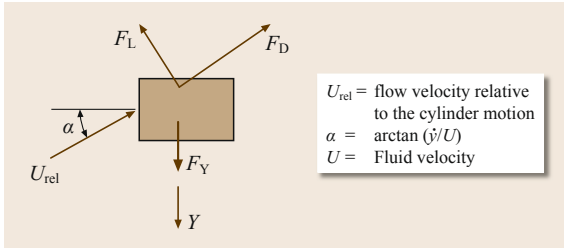

Fig. 47.22 Kinematics of a square prism leading to galloping instability (after [47.43])

where

$$\zeta_{\text{total}} = \zeta_{\text{system}} - \frac{1}{4}\frac{\rho D U}{(m_{\text{osc}} + m_{\text{a}})\omega_{\text{n,water}}}\left(\frac{\partial C_L}{\partial \alpha}\right)_{\alpha=0} . \tag{47.13}$$

Galloping initiates when

$$\zeta_{\text{total}} < 0 . \tag{47.14}$$

There are several forms of galloping, which are well described in the literature:

1. Soft or regular galloping which is self-initiated and thus does not require a push on the VIVACE cylinders by the controller. This is a typical Hopf bifurcation [47.45].
2. Hard or regular galloping which is not self-initiated and thus does require a push on the VIVACE cylinders by the controller. This is a subcritical Hopf bifurcation [47.45].
3. Interference galloping, which is further divided as: proximity (P), wake interference (W), and combination of both proximity plus wake interference ($P + W$) depending on the relative position of the two bodies [47.81].

Differences Between VIV and Galloping. VIV and galloping are fundamentally different phenomena. It is important to understand these differences as ALTs would be designed differently to take advantage of the underlying FIM (VIV verses galloping) for MHK-energy harnessing. Most important differences are the following:

1. The hydrodynamic driving mechanisms are different. VIV is driven by synchronization of the wake frequency with the frequency of oscillation, that is

$$f_{\text{wake}} = f_{\text{osc}} . \tag{47.15}$$

   In galloping, even though vortex streets are generated in the cylinder's wake, these vortices are not the driving FIM mechanism in galloping. This is obvious in Fig. 47.10b where galloping is fully developed at Re = 130 000. Some vortices are out of phase with the cylinder motion. Vortices push the cylinder away from the side they shed.
2. The galloping instability is due to the negative lift created by the geometric asymmetry. Thus, the cylinder is being pushed in the direction it moves. If it was not for the limited width of the converter's frame and the restoring springs, the cylinder's motion would not be reversed.
3. VIV is self-limiting in amplitude. When the relative flow velocity exceeds a certain limit, either due to increased stream velocity or due to increased amplitude of oscillation (in forced oscillations), vortices mature and shed prior to the end of the cylinder travel. At that point, the wake frequency from vortex shedding f_{wake} falls out of synchronization with the frequency of oscillation f_{osc} and results in the lift opposing the transverse motion and terminating VIV.
4. In galloping, f_{osc} drops below $f_{\text{n,water}}$. In VIV, f_{osc} increases above $f_{\text{n,water}}$.
5. The VIV synchronization range hardly changes in terms of reduced velocity U^*. As stated in the double inequality (47.3), the range of synchronization for VIV is dictated by the range $\approx 5 < U^* = U/(f_{\text{n,water}}D) <\approx 10$. Accordingly, VIV can be moved into the range of stream velocity for energy harnessing by changing the cylinder diameter D, or its $f_{\text{n,water}}$ by changing its mass m_{osc} or its spring constant K. For example, if we assume that the end of the VIV synchronization range occurs approximately at $U^* = 10.0$, we have

$$U^* = \frac{U}{f_{\text{n,w}}D} = 10 \Leftrightarrow U = 10D\frac{1}{2\pi}\sqrt{\frac{K}{(m + m_{\text{a}})}} . \tag{47.16}$$

That is, the end of the VIV synchronization range increases proportionally with the square root of the spring stiffness K. Obviously, the onset of synchronization will also follow the same rule.

On the other hand, galloping initiates at an absolute value of velocity $U = U_{\text{g}}$, which is not affected by the spring constant K [47.43].

$$U_{\text{g}} = \frac{2cDm^*}{a} , \tag{47.17}$$

where c is the linear viscous damping coefficient, a is the geometry-dependent constant, and

$$m^* = \frac{m_{\text{osc}}}{m_{\text{d}}} . \tag{47.18}$$

That is, initiation of galloping does not depend on K but only on the absolute flow velocity and geometric and dynamic particulars of the oscillator. Higher damping would require a higher velocity to initiate galloping.

Principle 5 – Transition from VIV to Galloping. Typically, VIV occurs before galloping in the U^* scale, where galloping starts at $U^* \approx 20$. Then, a gap will

exist between the ending of VIV and the onset of galloping. This is discussed further in Principle 9 and in Fig. 47.29a below. In that gap, the VIVACE converter will remain idle or its parameters would require adjustment to either shift the VIV range to higher speeds, or initiate galloping earlier. By comparing (47.16) and (47.17), it is easy to see that it is feasible to bridge the gap and make VIV and galloping overlap. What happens during such transition given that VIV and galloping differ at least in the five points (1–5) stated earlier in Sect. 47.2.3, *The Underlying Principles*:

1. The amplitude of oscillation increases sharply over a very short range of U^*.
2. The two hydrodynamic driving mechanisms of VIV and galloping coexist. This is shown in Fig. 47.10a, where vortices still push the cylinder in the direction of its motion.
3. The amplitude of oscillation increases to the point that the VIV mechanism of wake synchronization cannot follow and fully developed galloping takes over. Figure 47.10b shows that vortices shedding out of synchronization and pushing the cylinder against its motion.

Principle 6 – Enhancement of FIM. ALTs, such as the VIVACE converter, take advantage of catastrophic phenomena such as FIMs, control them, and in the process harness energy from fluid flows using an appropriate damping mechanism. Enhancement of FIM is desirable in order to convert more MHK energy to mechanical in the oscillator; as long as the enhanced response of the oscillator can be controlled.

There are several flow regimes and configurations where FIM enhancement is desirable. The following have been pursued and successfully enhanced in VIVACE converter models and prototypes using properly designed turbulence stimulation – called PTC – which is discussed under Principle 7:

1. In the critical flow regime, at the transition from the laminar boundary layer to turbulent boundary layer, VIV is fully suppressed, the lift coefficient is nearly zero as shown in Fig. 47.16. In that flow regime there is no predominant Strouhal frequency f_s. The Strouhal number is defined as in (47.1), where f_s is the vortex-shedding frequency for a stationary circular cylinder. This regime is important for Scale-2 and Scale-3 because a cylinder with $D = 0.30\,\text{m}$ in a flow speed of about $U = 2.5\,\text{kn}$ results in Reynolds number $\text{Re} = 327\,000$ placing it in the critical flow regime.
2. The lift coefficient, and consequently the amplitude in VIV, is relatively low in the TrSL2 flow regime (Fig. 47.16) [47.56]. Using properly designed turbulence stimulation, the effective Re can be pushed to higher values to move the cylinder flow into the TrSL3 regime where the lift and VIV responses are significantly higher.
3. VIV is a broad range, high-response phenomenon but has a finite range as defined by the double inequality (47.3). Past the end of the VIV synchronization range the response of ALT would be zero leaving a range of velocities with no response from the ALT. Using relations (47.16) and (47.17), in terms of absolute flow velocity U, the VIVACE converter can be redesigned to close the gap between VIV and galloping. This is also achieved by using PTC defined in Principle 7.
4. In case of multiple cylinders in FIM, it is possible to adjust the in-flow and transverse spacing between PTC cylinders to achieve gap flow that can enhance the interaction between cylinders in a school. This is further discussed in Principle 9.

Enhancement of MHK energy production can be achieved by several different means. PTC though, can be applied in the four flow regimes and configurations of FIM enhancement listed above. In all of those the passive enhancement was achieved by affecting the hydrodynamics directly. In addition though, there are ways to enhance the final output of an ALT by affecting the interaction between fluid and structure. Means that are still under development in the MRELab and VHE include:

1. Most of the information on FIM available in the literature uses linear restoring springs. In field tests, VHE has achieved maximum power output using strongly nonlinear restoring force as discussed in Sect. 47.2.1, *Description of the VIVACE Converter* (springs).
2. In the traditional linear time invariant (LTI) mathematical model of oscillators (Sect. 47.3.6), the term that generates power is the damping term. Typical LTI models in textbooks and papers assume that the linear viscous model is representative of one degree-of-freedom LTI oscillators. Papers by *Lee* et al. [47.98] and *Sun*et al. [47.142], prove that damping in real mechanical oscillators is strongly nonlinear and may exhibit memory and hysteresis. In the process of system identifying damping, in VIVACE laboratory models, nonlinear forms of damping have proven to be more effective in affecting the Fluid-Structure Interaction and generating MHK power.
3. The circular cross-section of cylinders in an oscillator provides many advantages from the hydrodynamic and fabrication points of view. Other cross-sectional shapes have been studied experi-

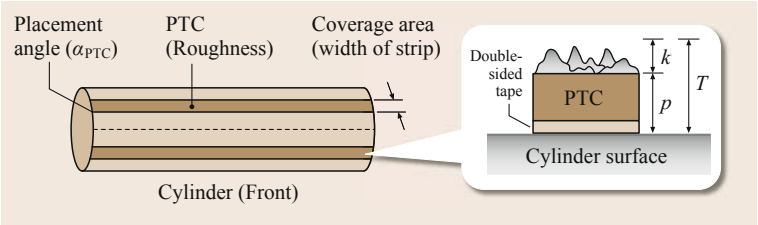

Fig. 47.23 Passive turbulence control (PTC) parameters

mentally and computationally as discussed under Principle 11.

Principle 7 – Passive Turbulence Control (PTC). In the MRELab, a method was developed and patented to induce the FIM of a circular cylinder by designing and applying turbulence stimulation in a passive way [47.67, 70, 96]. This method, named PTC, is based on the selective distribution of surface roughness on a circular cylinder. PTC induces several different FIMs.

The design parameters of PTC are listed below and shown in Fig. 47.23:

1. α_{PTC}, placement angle
2. Area coverage in degrees
3. k, roughness grit size
4. $T = k + p$, PTC total height.

The mechanics of PTC affect the flow around the cylinder and consequently its FIM in the following ways:

1. It trips the boundary layer
2. It may or may not allow reattachment
3. It introduces turbulence into the flow
4. It reorganizes the flow in downstream cylinders and affects the correlation length
5. It introduces rotational asymmetry which may initiate galloping instability.

This four-parameter problem was solved over a period of two years. The results are shown for the TrSL3 flow regime in the PTC-to-FIM map in Fig. 47.24 [47.70]. The following FIM zones were established as a function of the starting point of the PTC location angle in the clock-wise direction from the forward stagnation point:

1. Weak suppression zone 1, WS1
2. Hard galloping zone 1, HG1
3. Soft or regular galloping zone, SG
4. Hard galloping zone 2, HG2
5. Weak suppression zone 2, WS2
6. Strong suppression zone, SS.

Obviously, PTC can act as an FIM amplifier (HG1, HG2 and SG) and an FIM suppressor (WS1, WS2, and SS).

Additional information that is useful in terms of the PTC and its impact on the developed *PTC-to-FIM map* are the following:

1. Several types of commercial sandpaper were used in the experimental investigation. Their properties are shown in Table 47.3.
2. The two maps developed, for two commercial grade sandpapers P60 and P180, exhibit minor variations in each zonal range. Response features within each zone remain nearly independent of the height of the PTC.
3. The thickness of the PTC should be compared to the thickness of the boundary layer where the effect of the PTC is initiated (Fig. 47.25 and Table 47.5).

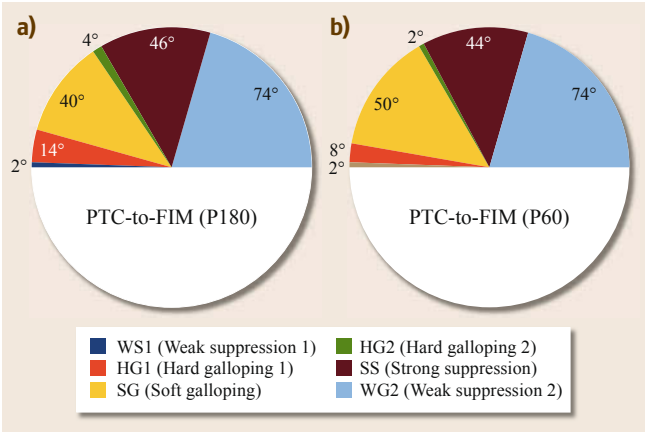

Fig. 47.24a,b PTC-to-FIM map for two different roughness values: **(a)** P180, **(b)** P60. Roughness strip width covers 16° on each side of the cylinder as shown in Fig. 47.23 (after [47.149])

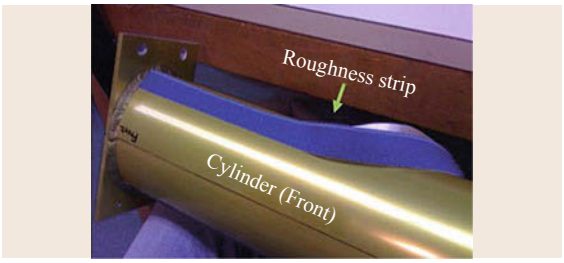

Fig. 47.25 PTC application on cylinder (after [47.101])

Table 47.5 Boundary-layer thickness δ(mm) for various Re and α_{TC}. Calculation of boundary layer thickness for smooth cylinder by the approximate method of Pohlhausen (after [47.150]); $D = 3.5''$ (0.0889 m)

α_{PTC}	Re 10 000	40 000	70 000	80 000	90 000	100 000	118 000
20	1.283	0.6416	0.48500	0.4537	0.4277	0.4058	0.3735
25	1.247	0.6234	0.4712	0.4408	0.4156	0.3943	0.3629
30	1.219	0.6092	0.4605	0.4308	0.4062	0.3853	0.3547
35	1.249	0.6246	0.4721	0.4417	0.4164	0.3950	0.3637

With the application of PTC, the following results have been achieved:

1. Even with a smooth PTC strip of total thickness $T = 0.192$ mm on a $D = 0.0889$ m cylinder, amplitude of three diameter was reached. That is, such a small geometric asymmetry-induced fully developed galloping.
2. By introducing PTC with total thickness of the order of magnitude of the boundary layer, and positioning it properly along the boundary layer (before the separation point) several different forms of FIM were achieved.
3. By placing the PTC in the SS zone, the separation point is covered, which oscillates around 81° in laminar flow for a smooth stationary cylinder.
4. With PTC, galloping was initiated earlier which is an important step toward achieving back-to-back VIV and galloping on a single-circular cylinder [47.70]. See also Principle 9.
5. FIM of multiple cylinders in tandem was studied by *Kim* et al. [47.68, 69, 76, 84, 113, 114, 117] using PTC. Smooth cylinders down stream from the lead cylinder would not move without PTC. The oscillatory amplitudes of all cylinders (up to four tested) reached the limitation of the facility at a flow speed

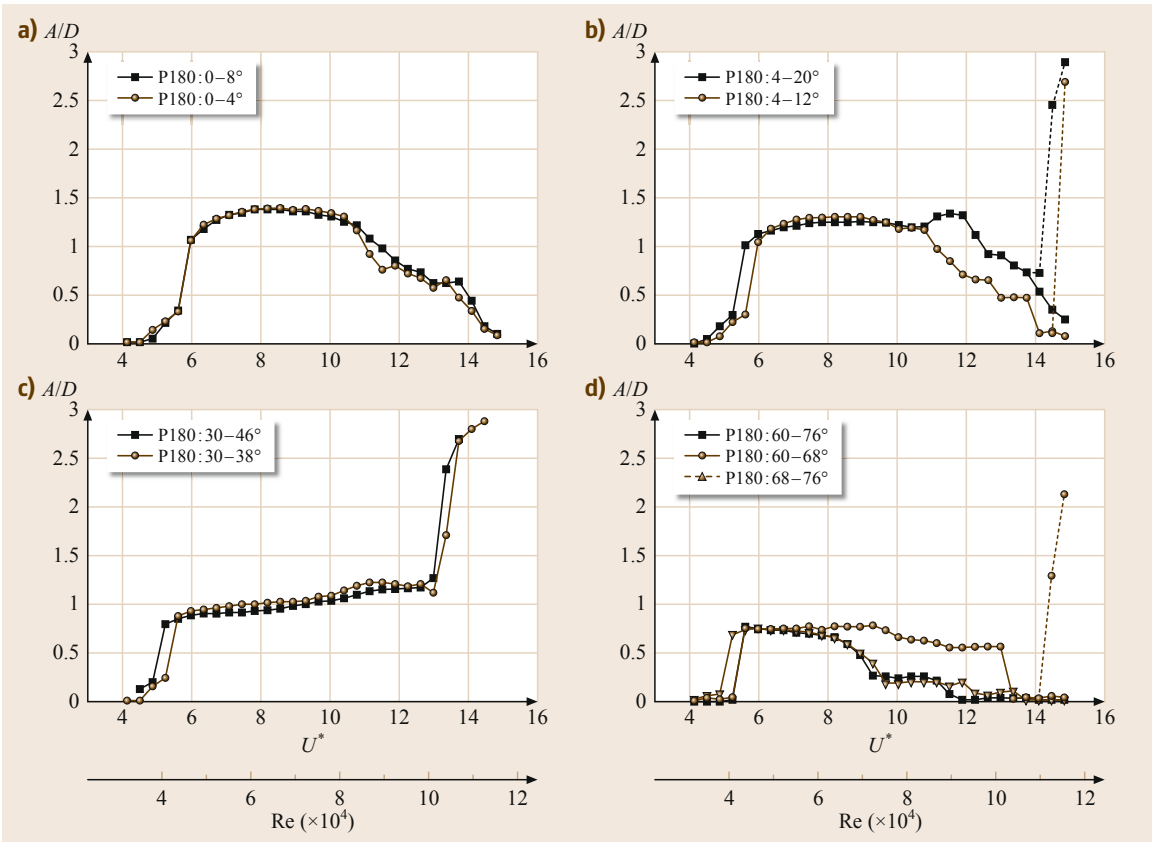

Fig. 47.26a–d Amplitude response A/D for cylinder, with $D = 3.5''$ (0.0889 m), with half-width strip P180. Zones: **(a)** WS1, **(b)** HG1, **(c)** SG, **(d)** SS (after [47.70])

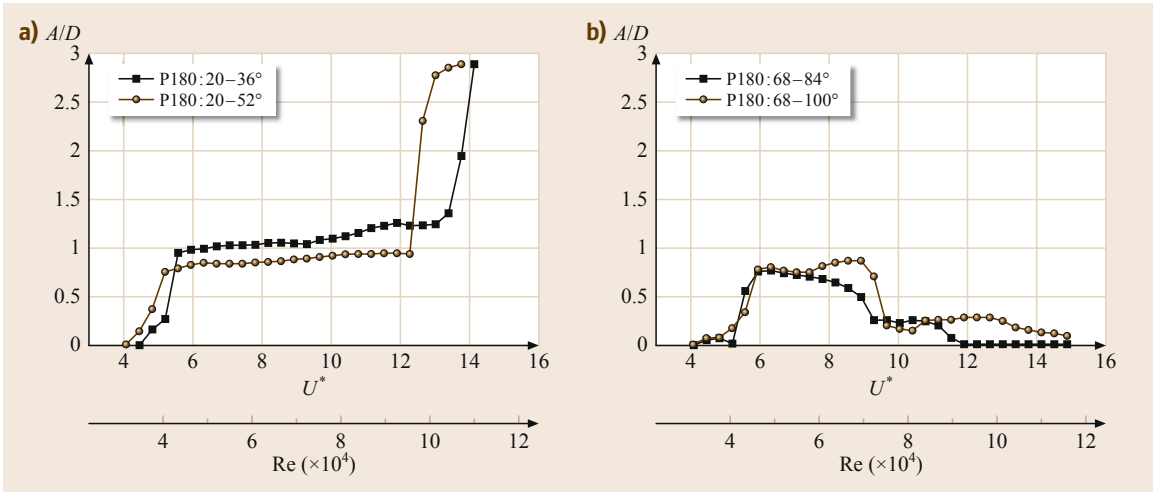

Fig. 47.27a,b Amplitude response A/D for cylinder, with $D = 3.5''$ (0.0889 m), with double-width strip P180. Zones: **(a)** SG, **(b)** SS (after [47.70])

of $1.5\,\mathrm{m\,s^{-1}}$, which is below the maximum flow speed of the water channel.

The final issue raised about the effectiveness of the *PTC-to-FIM map* relates to its robustness. The conclusions of this investigation follow supported by Figs. 47.26–47.28 [47.70]:

1. The zones specified in the *PTC-to-FIM map* are robust (insensitive) to width and configuration of the PTC. That is, if the roughness strips are located in their entirety inside a single zone, the cylinder response will be the same regardless of covering (8, 16, 32°) or design.
2. The SS zone is the most dominant zone in the *PTC-to-FIM map*. When the SS zone is covered by PTC along with other adjacent zone(s), the amplitude response of the PTC cylinder corresponds always to strong suppression.
3. The soft (regular) galloping (SG) zone is the second most dominant zone in the map. It has stronger effects than the WS1, HG1, and HG2 zones. When the four zones WS1, HG1, HG2, and SG are covered by roughness, the resulting FIM was soft galloping as long as the SS zone was not covered.
4. A staggered configuration covering all zones is an effective means of suppression. The range of the

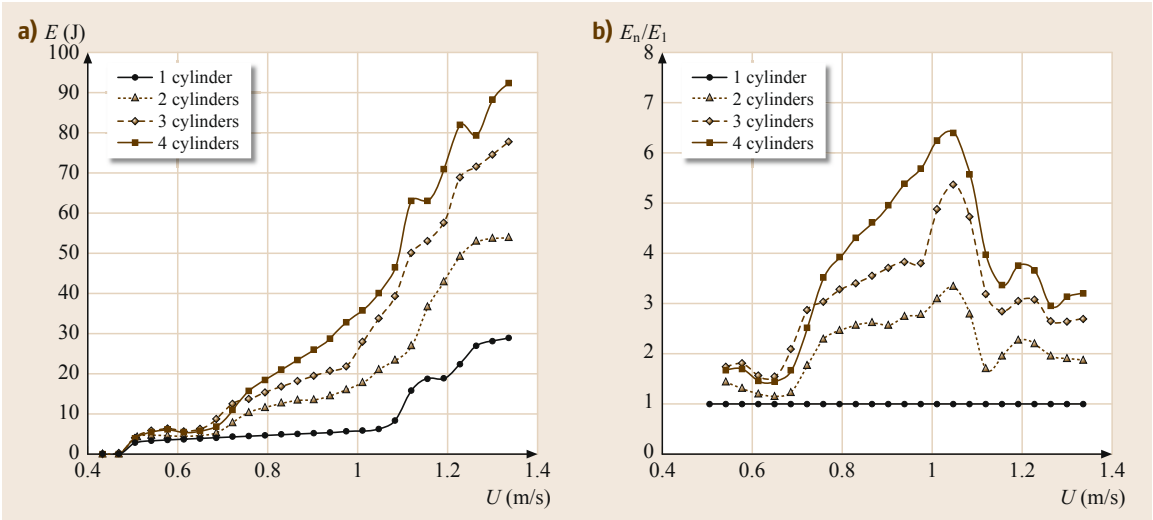

Fig. 47.29a,b Synergistic operation of 2, 3, 4 PTC cylinders for $d/D = 2.5$ (after [47.68, 84]). Smallest spacing is $d/D = 2.5$ for 3 or 4 cylinder tests. For $0.8\,\mathrm{m\,s^{-1}} \le U \le 1.1\,\mathrm{m\,s^{-1}}$, multiple cylinders in synergistic operation harness 60–80% more energy than acting in isolation. **(a)** Total converted energy. **(b)** Normalized converted energy

upper branch is about half that of the smooth cylinder and its maximum amplitude is about 56% of that of the smooth cylinder. Also, the desycnhronization region starts at much lower U^* compared to the smooth cylinder.

Principle 8 – Multi-Body Interaction. A single-cylinder converter cannot achieve high enough power-to-volume/weight ratio. That would correspond to a single-blade propeller or turbine. Placing cylinders far apart, either in tandem or side-by-side, would require significant spacing to minimize interference. To achieve high enough power-to-volume/weight ratio to overcome this Achilles heal of renewable energy technologies, multiple cylinders should be placed in close proximity and made to work efficiently. That would be the equivalent to a multiblade propeller/turbine. The additional challenge in an ALT is that unlike for a propeller, for which all blades have equivalent position as they span the same space and are hydrodynamically equivalent, in a school of cylinders:

1. The lead cylinder is not in the wake of any other cylinder.
2. Each cylinder following the lead cylinder is in the wake of a different number of upstream cylinders.
3. The flow velocity may be reduced due to power harnessing by upstream cylinders.
4. In an unconfined space, the flow may be diverted by the reaction of the oscillating cylinders on the fluid.

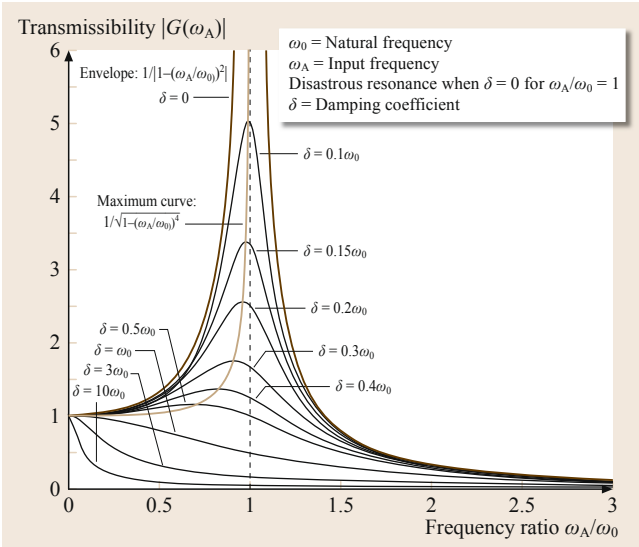

Fig. 47.30 Linear oscillator

Actually, the average drag coefficient in the direction of the flow may increase from $C_D = 1.05$ for a stationary cylinder in steady uniform flow in the laminar regime (Fig. 47.16) to for a cylinder oscillating transversely to a uniform flow for the same Reynolds number [47.151].

The only solution to this problem is that cylinders are placed in close proximity in a school and work synergistically. This has been achieved in the MRELab with up to four cylinders by taking advantage of PTC and interference phenomena such as gap flow. This is

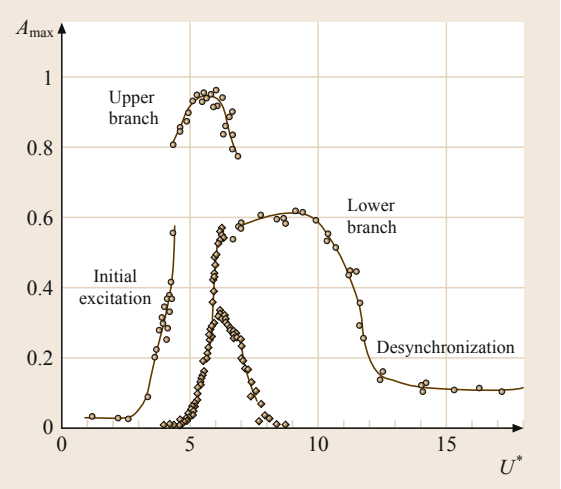

Fig. 47.31 Nonlinear oscillator: low-Re (< 10 000) VIV (after [47.154])

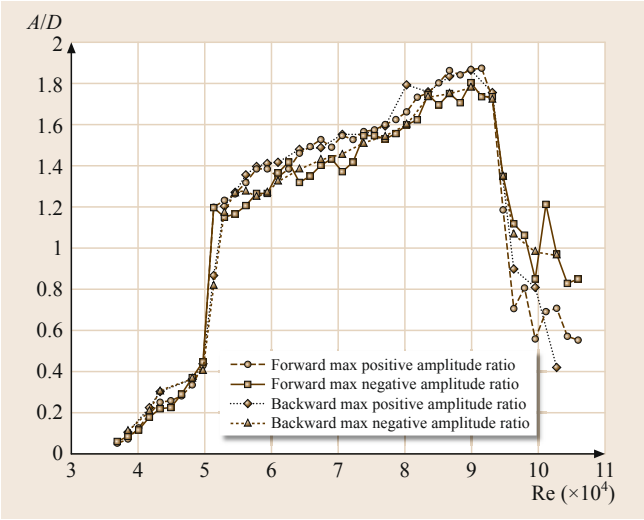

Fig. 47.32 Nonlinear oscillator: higher Re (≈ 30 000–150 000) VIV (after [47.107])

further discussed in the research (Sect. 47.3.5). At this point, it is sufficient to introduce two results:

1. A four-cylinder VIVACE converter has been designed and built in the MRELab, where the cylinders work synergistically and are all in vigorous FIM as shown in the two 30 s videos [47.152, 153]. The converter operates like a 4-cylinder reciprocating engine driven by water. There are no mechanical connections between the cylinders.
2. Figures 47.28 and 47.29 show that two, three, four cylinders placed in a school properly can harness up to 60–80% more MHK energy that the same number of cylinders operating in isolation.

Mechanical Principles

Principles involved in an FSI system cannot rationally be separated into fluid and mechanical principles. Nevertheless, they are separated in Sect. 47.2 for more efficient presentation.

Principle 9 – Nonlinear Oscillator. A one degree-of-freedom linear oscillator has a response amplitude operator like the one shown in Fig. 47.30. It has high response, at low damping, with small bandwidth near the natural frequency f_n. Figure 47.31 shows the response of a cylinder in VIV in the TrSL2 flow regime. It is broad banded but self-limiting with a maximum amplitude of one diameter. Figure 47.32 shows the response of a cylinder in VIV in the TrSL3 flow regime. It is broad banded but self-limiting with a maximum amplitude $A = 1.8D$. The VIVACE oscillator in Fig. 47.33 has open-ended bandwidth to the right, with high response even at high damping, only limited by the experimental facility limitations.

As explained in Principle 5, with PTC (Principle 7) back-to-back VIV and galloping have been achieved resulting in an open-ended range of high-amplitude response. By increasing damping to harness more energy, the gap between VIV and galloping may reappear. This gap can be bridged again by increasing the spring constant K as shown by *Chang* et al. [47.67].

Thus, the VIVACE converter is a nonlinear oscillator, which initiates at low velocities with VIV and continues with galloping. The latter – being an instability – increases in amplitude with increasing velocity unless post-instability nonlinearities introduce additional strength. That makes the VIVACE converter operate in FIM at a very broad range of synchronization and therefore broad range of velocities.

Principle 10 – Viscous Damping for Energy Harnessing. High-amplitude response of the nonlinear VIVACE oscillator is maintained even at high damping as shown in Fig. 47.33. High damping is used to harness energy and lower the oscillator response tending to separate VIV from galloping. High-damping FIM is very different from low mass and damping VIV [47.155], With increased spring stiffness, the back-to-back VIV and galloping feature of the VIVACE oscillator is restored. Nonlinear forms of damping have proven to be more effective in affecting the FSI and generating more MHK power. This concept is still at the research stage in the MRELab and VHE (Vortex Hydro Energy).

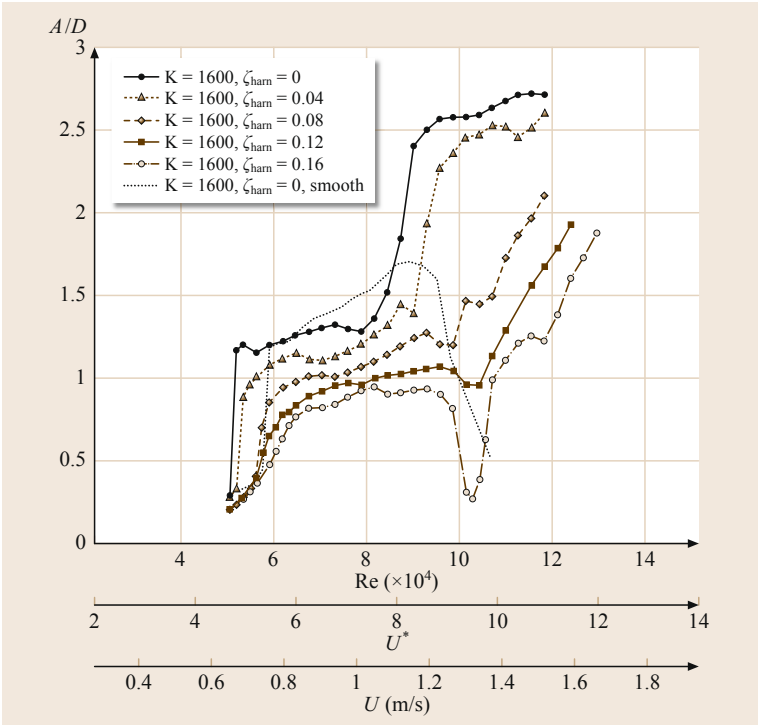

Fig. 47.33 Nonlinear oscillator: higher Re($\approx$ 30 000–150 000) with back-to-back VIV and galloping and variable damping (after [47.96])

Principle 11 – Shape Optimization. Fish in schools glide between vortices of preceding fish to move effortlessly through water. They take advantage of the thrust wake shown in Fig. 47.7c. Testing has shown that fish placed in the wake of a stationary cylinder in a steady flow can maintain their position by gliding between the cylinder alternating wake vortices. That leads to the conclusion that a cross-section of different shape may have some advantages over the simple-to-fabricate, circular cylinder. Figures 47.34 and 47.35 show parallel efforts to optimize the cylinder cross-section for the maximum oscillatory lift-to-drag ratio [47.118]. The early conclusion of this research is that there are shapes, which in some reduced velocity range may perform better than a circular cylinder but not over the entire range of velocities of interest. An important factor in this outcome is the difference in the location of vortex shedding as well as the shape of the vortex in the wake of circular and noncircular cylinders as can be seen in comparison of Figs. 47.34–47.36.

Electro-Mechanical Principles

A converter, regardless of its scale and whether used as a model or as a prototype, would not be complete without an integrated controller with the PTO system. As part of this case study, only the advanced features of the system developed in the MRELab are discussed. The PTO is conventional and will not be presented here. Suffice to say that the power generated is either burned in a heat bank or used to light a device for demonstration purposes. The advancement in the MRELab converter is in the V_{ck} (Virtual damping–spring) system,

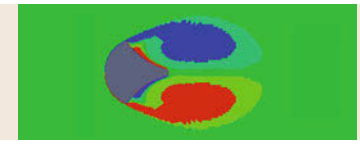

Fig. 47.34 CFD for fish-shaped after-body

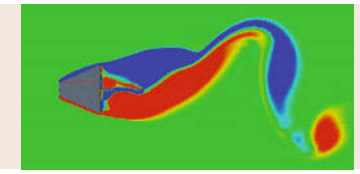

Fig. 47.35 CFD for wedge-shaped fore-body

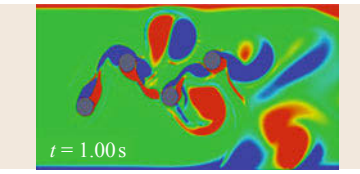

Fig. 47.36 Channel CFD for four circular cylinders in FIM

which enables efficient and fast changing of parameter values with little to no downtime between experiments.

Principle 12 – Virtual c-k Control-Law (V_{ck}). As mentioned in Sect. 47.2.1, *Description of the VIVACE Converter* in spite of the slow nature of oscillations – about a cycle a second – there are 32 million seconds in a year making the fatigue life of springs a challenge. In a laboratory setting, changing physical springs and dampers in order to change values of experimental parameters is time consuming requiring ordering of new physical components, calibrating them, mounting them, and retesting them periodically to ensure that their values have not changed with time. In the MRELab, to overcome this problem, a real-time controller with feedback force $-ky - c\mathrm{d}y/\mathrm{d}t$ emulating spring and damper has been developed [47.156]. It does not include the hydrodynamic forces in the closed loop. That is, it simulates only the mechanical part of the oscillator. The V_{ck} system requires extensive calibration and system identification as well as comparison with real springs and damping devices as shown in Fig. 47.39. V_{ck}, though, enables performing hundreds of tests in a few days and generating power envelopes (Fig. 47.38) by just adjusting the parameters c and k in the feedback force. Figures 47.37 and 47.38 show the results from the development of the first generation of the V_{ck} system [47.97, 98].

The mathematical model of the V_{ck} system and its practical implementation in the MRELab converter are presented next.

Oscillator simulated by the V_{ck} system: V_{ck} is a feedback loop that uses the servomotor encoder to keep track of the position and velocity of the cylinder and provide the necessary torque to simulate the spring stiffness and provide the linear viscous damping required. This logic keeps the hydrodynamics out of the control loop making it possible to simulate the mechanical part of the oscillator only without affecting the hydrodynamic excitation. The V_{ck} end product provides to the experimental setup the flexibility to input the values of spring stiffness and linear viscous damping into the controller and continue the experiments without interruption. This huge advantage comes at the expense of extensive time in V_{ck} system development.

It is critical to compare the accuracy of the V_{ck} system to implement a mechanical oscillator with the damping and spring constants desired. That requires systematic calibration followed by comparison of V_{ck} to an oscillator with real springs and dampers. The process requires performing repeated experiments in free air and in the LTFSW channel of the MRELab for system identification (SI). A nonlinear model for damping has been defined after many trials. The resulting damping model is subtracted by the controller in the V_{ck} system. That results in a zero damping system. Then, a linear viscous damping model is imposed by the controller, thus, producing a perfectly linear viscous damping matching the textbook oscillator models.

The first generation of V_{ck} [47.97] used the National Instruments data acquisition system for reading the position and completing the force feedback. This system was a success and showed improvements in the opera-

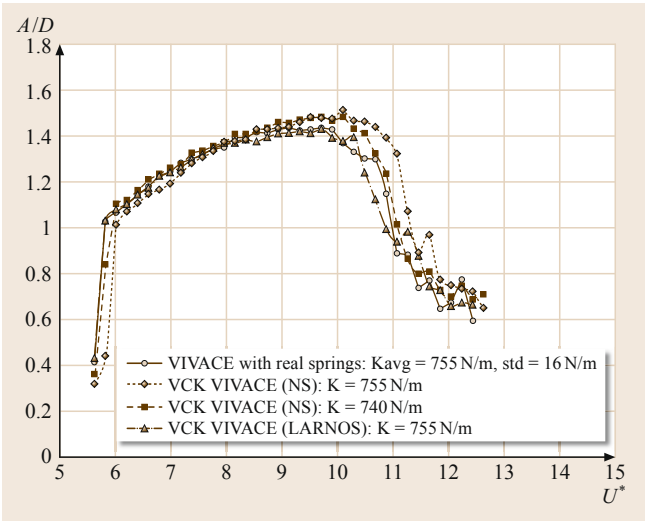

Fig. 47.37 Comparison between real spring damper and V_{ck} experiments for a single cylinder in VIV (after [47.100])

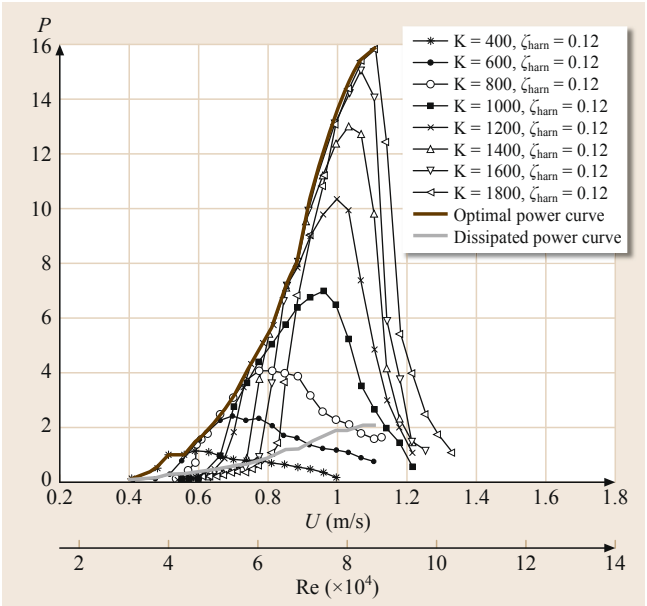

Fig. 47.38 Power envelope of converter with a single smooth cylinder (after [47.100])

tional efficiency but it had its own disadvantages as it introduced a significant amount of phase lag between force feedback and displacement into the system. The phase lag was due to the data acquisition system where the analog-to-digital conversion (ADC) and digital-to-analog conversion (DAC) ran through a digital filter. The phase lag was clocked between 30 and 50 ms, which was not desirable for FIM measurements or energy harnessing. The phase lag was compensated by introducing four dynamic terms with memory to model the hysteresis effects [47.98].

In the second generation of V_{ck}, a controller-embedded virtual spring-damping system (V_{ck})) for FIM experiments was developed for each oscillator [47.142]. The controller simulates the mechanical part of the oscillator by providing the feedback through belts and pulleys (Figs. 47.39 and 47.40). An Arduino-embedded board controls the servomotor, which has an optical encoder. Digital signal is used, making the system more responsive, theoretically with no lag except for that due to the CPU operation clocked to 10 µs. This approach enables real-time position/speed measurement.

Physical V_{ck} VIVACE System. Extensive experimentation has been completed on FIM with PTC with all the bearings and shafts outside the water (Figs. 47.5a, 47.17a, and 47.18a). The end conditions of the experimental oscillator reduced the two-dimensional flow along the cylinder length only by 3%. That is 97% of the length of the cylinder provided lift resulting in FIM. In 2011, in order to investigate further the FIM of cylinders with fewer restrictions, both the channel and the VIVACE converter were rebuilt. This allowed for amplitudes of oscillation reaching 5.5 diameters for $D = 3.5''$ (0.0889 m). The new test models were de-

signed and built as shown in Figs. 47.14 and 47.15 and were described in Sect. 47.2.1, *Description of the VIVACE Converter*.

Math Model for a V_{ck} VIVACE System. The physical model (Fig. 47.39) is assumed to have structural symmetry and the gravitational force is ignored assuming that the cylinder oscillates around its equilibrium position after the virtual springs and damper have been implemented.

The equations of motion of the new VIVACE system with the embedded V_{ck} are (47.19)–(47.23) where the symbols are defined in Table 47.6 and Fig. 47.40

$$(J_{motor} + J_{pulley})\ddot{\theta}_1 = T_{motor} - t_{motor} + r_{pulley}(F_1 - F_2)\,, \tag{47.19}$$

$$J_{pulley}\ddot{\theta}_2 = -t_{pulley\,3} + r_{pulley}(F_1 - F_2) - 2t_{pulley\,2}\,, \tag{47.20}$$

$$J_{pulley}\ddot{\theta}_3 = 2t_{pulley\,2} + r_{pulley}(F_3 - F_5) - t_{pulley\,3}\,, \tag{47.21}$$

$$J_{pulley}\ddot{\theta}_4 = -t_{pulley\,1} + r_{pulley}(F_5 - F_4)\,, \tag{47.22}$$

$$M_{OSC}\ddot{y} = -f_{bearing} + 2(F_4 - F_3)\,. \tag{47.23}$$

Assuming that the timing belts are inelastic, the kinematic relations among θ_i and y are

$$\theta_1 = \theta_2 = \theta_3 = \theta\,, \tag{47.24}$$

$$y = r_{pulley}\theta\,. \tag{47.25}$$

Thus, (47.19)–(47.23) are simplified to (47.26), by utilizing (47.24) and (47.25)

$$(J_{motor} + 6J_{pulley} + M_{osc}r_{pulley}^2)\ddot{\theta} = T_{motor} - t_{motor} - 6t_{pulley2} - 3t_{pulley3} - 2t_{pulley1} - f_{bearing}r_{pulley}\,. \tag{47.26}$$

$$\begin{aligned}(J_{motor} + 6J_{pulley} + M_{osc}r_{pulley}^2)\ddot{\theta} &= T_{motor} - (t_{motor} - 2t_{pulley} + 6t_{pulley2} - 3t_{pulley3} + f_{bearing}r_{pulley})\,.\\ \left(\frac{J_{motor}}{r_{pulley}} + \frac{6J_{pulley}}{r_{pulley}^2} + M_{OSC}\right)\ddot{y} &= \frac{T_{motor}}{r_{pulley}} - \left(\frac{t_{motor}}{r_{pulley}} + \frac{2t_{pulley}}{r_{pulley}} + \frac{6t_{pulley2}}{r_{pulley}} + \frac{3t_{pulley3}}{r_{pulley}} + f_{bearing}\right)\,.\end{aligned}$$

Assuming that $F_{motor} = T_{motor}/r_{pulley}$, the above equation can be simplified for convenience as

$$m\ddot{y} = F_{motor} - f\,, \tag{47.27}$$

where

$$m = \frac{J_{motor}}{r_{pulley}^2} + \frac{6J_{pulley}}{r_{pulley}^2} + M_{OSC}\,, \tag{47.28}$$

$$f = \frac{t_{motor}}{r_{pulley}} + \frac{2t_{pulley}}{r_{pulley}} + \frac{6t_{pulley\,2}}{r_{pulley}} + \frac{3t_{pulley3}}{r_{pulley}} + f_{bearing}\,. \tag{47.29}$$

Virtual, nonlinear, viscous damping model: First, the system calibration for stiffness k is performed. The results are shown in Fig. 47.40. Next the system identification process can be performed. One of the functions of the V_{ck} system is adding linear adjustable damping to the system to harness MHK energy. To develop the sought power envelope, systematic tests need to be conducted. Prior to adding prescribed damping, the physical system damping needs to be identified and subtracted. The latter is due to all moving parts, especially the timing belts and pulleys, which bring undesirable/excessive amount of nonlinear damping to V_{ck}. The mechanical oscillator equation of the V_{ck} system is

$$m\ddot{y} + c(\dot{y}) + ky = F_{total}\,, \tag{47.30}$$

where F_{total} is the total hydrodynamic transverse force acting on the cylinder. Thus, the damping model can be obtained through

$$c(\dot{y}) = F_{total} - m\ddot{y} - ky\,. \tag{47.31}$$

In order to find the nonlinear viscous damping and static friction, the total damping force f, which contains motor, pulleys, and bearings, can be expressed as

$$f = f_{motor} + f_{pulley}f_{bearing} \tag{47.32}$$

which can also be expressed as a function of dy/dt. Here, all the damping force is assumed to be be modeled adequately by a third-order polynomial as

$$c(\dot{y}) = c_3\dot{y}^3 + c_2\dot{y}^2 + c_1\dot{y}^1 + c_c\,\mathrm{sign}(\dot{y})\,. \tag{47.33}$$

c_1, c_2, and c_3 are the first, second, and third-order coefficients, respectively, and c_c, is the Coulomb friction coefficient.

The first generation of V_{ck} system [47.98] had a closed loop of the vibration components and the cylinder could be detached from the belt. Constant forces were applied continuously to the timing belt to achieve sufficient speed. The current V_{ck} system has sliding blocks and timing belts inside the structure and, thus, they cannot be disconnected (Fig. 47.14a). To achieve sufficient speed and acceleration, various single direction forces are fed to the system by the mo-

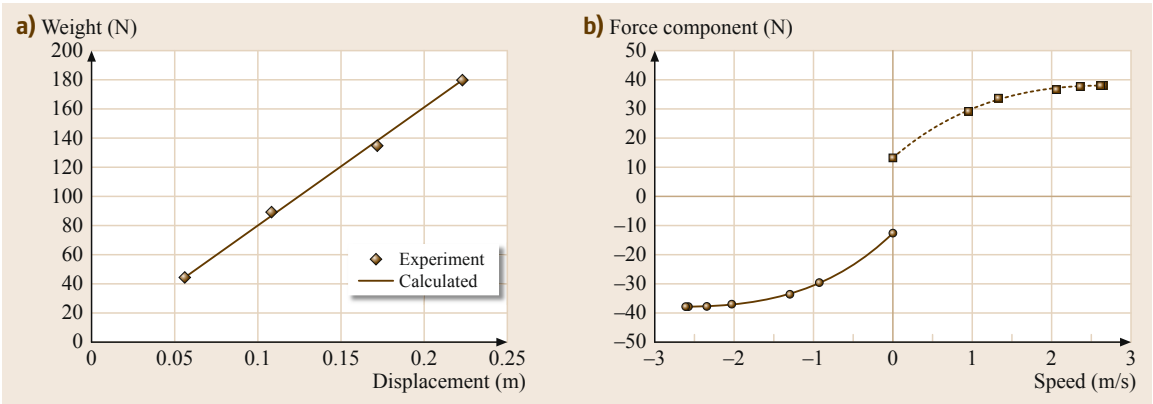

Fig. 47.41a,b System identification of second generation V_{ck} system (after [47.142]). **(a)** Virtual spring test curve fitting. **(b)** Nonlinear static damping

tor during the system-identification process [47.142]. Programmed safety stoppers are activated when the cylinder reaches the upper and lower ends of the travel to prevent collision with the plexiglass bottom of the LTFSW channel. The regression equations derived from the system identification process are (Fig. 47.41b)

$$c(\dot{y}) = 0.8793\dot{y}^3 - 7.7678\dot{y}^2 + 23.736\dot{y} + 13.439, \quad \text{for } \dot{y} > 0\,, \tag{47.34}$$

$$c(\dot{y}) = 1.1544\dot{y}^3 + 9.2064\dot{y}^2 + 25.992\dot{y} - 12.484, \quad \text{for } \dot{y} < 0\,. \tag{47.35}$$

Controller design: Based on this nonlinear viscous damping model, the controller force can be expressed as

$$F_{\text{controller}} = F_{\text{nonlinear damping}} - c_{\text{virtual}}\dot{y} - k_{\text{virtual}}y\,, \tag{47.36}$$

where, $F_{\text{controller}}$ is the force applied by the virtual system, F_{fluid} is the total hydrodynamic force acting on the cylinder, k_{virtual} is the virtual spring constant, c_{virtual} is the virtual linear viscous damping. c_{virtual} is added after subtracting the nonlinear viscous damping defined by (47.34) and (47.35). That results in a textbook case of linear viscous damping.

It should be noted that following this procedure, the V_{ck} system can be readily used to apply nonlinear springs functions or nonlinear damping.

The major conclusions that can be drawn from the analysis of underlying principles of the case study of the VIVACE converter are the following:

- Enhancing naturally occurring FIMs and altering their onset through PTC have made it possible to develop an ALT that has a high-response amplitude operator starting at low flow speeds and having no upper limit.

47.3 Methodology and Tools in Support of Development

The MRELab has pioneered several areas of research in support of the development of ALT and particularly the VIVACE converter. The outcome is implemented immediately in the design and field tests conducted by VHE for the product development. Research conducted in several labs worldwide citing the pioneering work of the MRELab and further developing these areas has been most valuable in this pursuit; *Vandiver* [47.157], *Konstantinidis* [47.158], *Vinod* and *Banerjee* [47.159], *Huynh* et al. [47.160]. These research areas include:

1. Energy harnessing by enhancing FIMs using alternating lift like fish, rather than steady lift like birds [47.48, 49].
2. Use of cylinder interference to improve synergistic operation of multicylinder arrays. It has been shown in the lab, for up to two/three/four cylinders, that an array of cylinders can actually harness more energy when cylinders work synergistically rather than in isolation (Figs. 47.28 and 47.29a) [47.68, 69, 77].
3. Cylinder cross-section shape optimization to maximize their oscillatory lift-to-drag ratio. This is the counterpart research conducted for decades on steady lift-to-drag ratio for airfoils (Figs. 47.33 and 47.34) [47.118].
4. Achieve three-dimensional distribution of cylinders in a flow so that the VIVACE converter may harnesses energy from the entire flow domain rather

than being a point absorber like buoys, line absorber like Pelamis, surface absorber like oscillating water columns, or area absorber like turbines and watermills.
5. Establish nonlinear spring constant for cylinder motion reversal and energy harnessing (Figs. 47.17b and 47.19a).
6. Build a virtual damping–spring system, V_{ck}, that does not include the hydrodynamic force in the loop to enable fast experimental change of parameters for testing [47.98, 142].
7. Implement different nonlinear models of damping and spring stiffness using the virtual system V_{ck} (Figs. 47.40 and 47.41).

To be effective in all these areas needed in support of ALT development, several research tools are used and/or being developed by MRELab and VHE. These include experimental facilities, flow visualization, field tests, mathematical models, and CFD codes. These are described briefly in the following sections.

47.3.1 Experimental Facilities

The experimental facilities used in the development of the VIVACE converter include two towing tanks and two recirculating channels providing complementary information through testing and data processing.

First Low-Turbulence Free-Surface Water (LTFSW) Channel

FIM experiments were conducted in the first LTFSW channel between 2005 and 2012 in support of the VIVACE converter development. Some of the outcomes and limitations of research and testing in this first channel are summarized below.

The first LTFSW channel was built in 1992 that proved to be a very valuable facility till its decommission in 2012. The purpose of the LTFSW channel was to facilitate the study of the fundamental structural aspects of turbulent flows near boundaries (solid walls, free surfaces, or both). The two-story high water channel was recirculating approximately 8000 gal of water. Its maximum flow speed was 2 ms^{-1}. The test section was 2.44 m long, 1 m across and 0.8 m deep. All walls of the test section were acrylic to allow for flow visualization experiments and to facilitate measurements with optical instrumentation. The measured background turbulence level at the test section was less than 0.1% of the free-stream velocity. Velocity and turbulence measurements are accomplished by utilizing a three-component, fiber optic, laser-Doppler velocimetry (LDV) system. The LDV system was specifically designed to allow for simultaneous laser-induced fluorescence concentration measurements. A three-axis traverse system allows movement of the LDV crossing point across the test section [47.161].

The tests conducted in this first LTFSW channel were FIM tests, not VIVACE model tests. The qualifying difference is very important. Specifically, in the FIM tests, only the cylinder and the supporting struts are submerged making it possible to bring the cylinder very close to the channel walls, thus, limiting the tip flow (three dimensionality) effects to 3% of the lift force (Fig. 47.17a). In VIVACE model tests, conducted in the second LTFSW channel (Sect. 47.3.1, *Second Low Turbulence Free Surface Water (LTFSW) Channel*) roller carts, bearings, belts, springs, and safety stops are placed in the channel creating a strong tip-flow effect of 43% (Fig. 47.17c). This is further discussed in Sect. 47.3.8. As a result, neither FIM test results can be used for VIVACE predictions nor VIVACE model-test measurements can be used as pure FIM experimental results. The mathematical post-processing for the reduction of data to a common equivalent has been developed in the MRELab and is introduced in Sect. 47.3.8. It will appear in a journal publication shortly after this work is published.

The first contribution of FIM testing by MRELab in the LTFSW channel has been tested in the TrSL3 flow regime [47.48, 49, 67, 107]. Typical VIV tests until then were conducted in the TrSL2 flow regime [47.55, 162–164]. The resulting response amplitude operators differ dramatically as shown in Fig. 47.30 for TrSL2 and Fig. 47.31 for TrSL3.

There are several fundamental differences in the flow dynamics past a circular cylinder between the TrSL3 ($1000 < Re < 300\,000$) and TrSL2 ($1000 < Re < 20\,000$) flow regimes as defined by *Zdravkovich* [47.56]. Most notably, the shear layers on either side of the cylinder are saturated in TrSL3 carrying more vorticity to the von Kármán vortices. As a result, the shear layers have a stronger roll-up much closer to the cylinder. The circulation in the von Kármán vortices reaches shedding strength faster based on the fact that the Strouhal number (47.1) is about constant ($St = 0.20 - 0.21$) practically over the entire laminar flow regime for $400 < Re < 300\,000$. Thus, the frequency of vortex shedding increases proportionally to the velocity. Further, the formation length is shorter [47.165]. At the moment of shedding, the combination of a shorter formation length with strong roll-up and higher circulation closer to the afterbody of the cylinder cross-section induces higher lift force. Thus, as shown in Fig. 47.16, the lift coefficient in TrSL3 is several times higher than that in the TrSL2 regime.

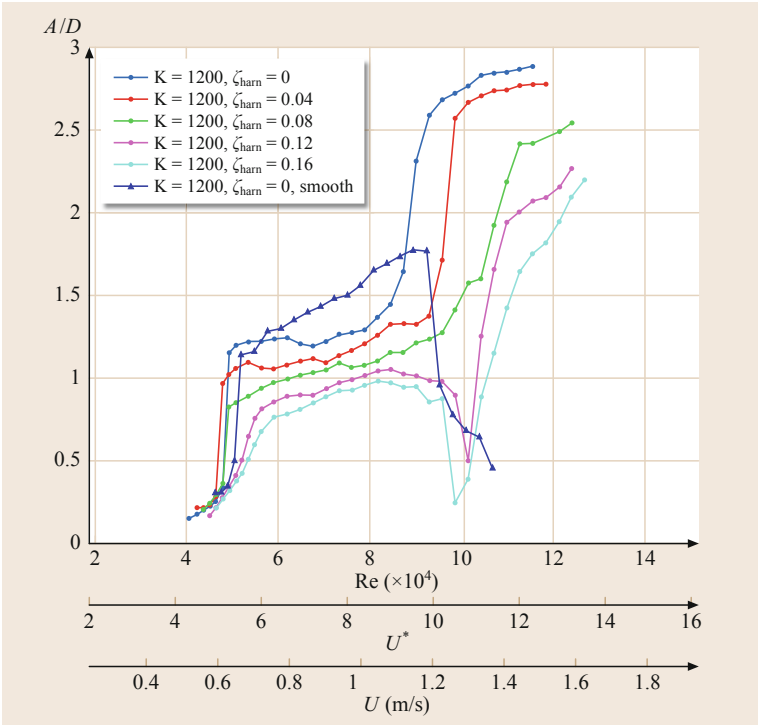

Fig. 47.42 The effect of Reynolds number is strong in the TrSL3 flow regime (after [47.105])

The following observations can be made comparing the response amplitude operators in TrSL2 (Fig. 47.30) and TrSL3 (Fig. 47.31):

1. Both exhibit the initial branch, the upper branch, the lower branch, and desynchronization.
2. In TrSL2, the upper branch shows constant response around $A/D = 1$, which led for years to the incorrect conclusion that VIV response depends only on the reduced velocity U^* (47.3) and not on Reynolds number.
3. In TrSL3, the upper branch constantly increases and overtakes the lower branch. The response A/D starts around 1.2 and increases up to 1.9 depending on the Reynolds number as shown in Figs. 47.41b, 47.42, 47.43, and 47.85 [47.48, 49, 73, 105]. This high response and Reynolds dependence were confirmed by a single data point at even higher Reynolds number, around 10^6, by *Ding* et al. [47.148].
4. Placing the MRELab measurements [47.48, 49] on the modified *Griffin* [47.166] plot shows that the extrapolation performed by *Govardhan* and *Williamson* [47.167] does not capture correctly the dependence of VIV on Reynolds number.
5. The measurements performed by *Bernitsas* et al. [47.48, 49, 67, 70, 105] show that VIV can be maintained in the TrSL3 flow regime even when values of damping are high for energy harnessing (Fig. 47.44).

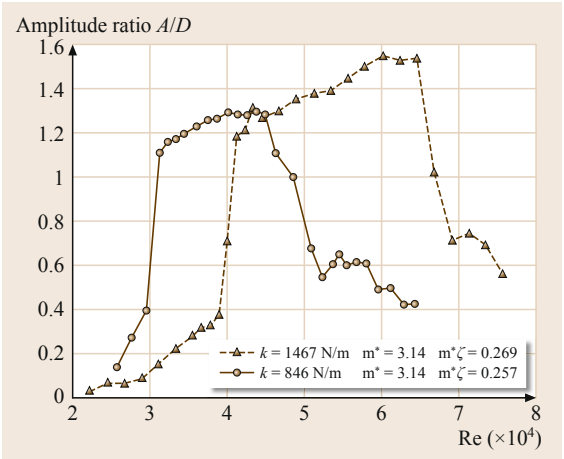

Fig. 47.43 Re has a stronger influence than m^* and $m^*\zeta$ on A/D (after [47.105])

Enhancing FIM through PTC: This was the second major contribution of the MRELab tests in the first LTFSW channel. Enhancement of FIM was introduced in Principle 6 and PTC in Principle 7 in Sect. 47.2. The PTC-to-FIM map was presented in Fig. 47.24 along with its robustness and showed how the motion of a cylinder can be enhanced or partially suppressed us-

ing PTC. Suffice to mention here that the ways in which our understanding of PTC have been implemented to improve the performance of this ALT converter:

1. Figures 47.45 and 47.46, when combined with the boundary-layer thickness in Fig. 47.25 provide guidance on the size of the PTC to be used for a specific size cylinder.
2. PTC has the following effects on VIV: It starts the TrSL3 flow regime earlier with the turbulators; it maintains the TrSL3 regime with the turbulators longer; it eliminates the transition region, thus, maintaining VIV without allowing its suppression in transition from laminar to turbulent boundary layer as is the case with smooth cylinders.
3. PTC increases the synchronization range in VIV.
4. PTC partially suppresses VIV amplitude. No significant influence from PTC roughness was found. For larger PTC coverage area, more amplitude reduction is observed.
5. PTC causes higher oscillation frequency in the VIV synchronization range as it induces more vorticity.
6. PTC induces galloping at smaller velocities, thus, enabling back-to-back VIV and galloping as shown in Fig. 47.32, which is the major advantage of the VIVACE converter, that is, an open-ended large amplitude response amplitude operator.
7. Galloping instability depends on PTC location mostly. PTC is more effective in galloping when placed at α_{PTC} of 20–64° (Fig. 47.23).
8. Effective PTC thickness for galloping is $T \geq 0.19$ mm.
9. Rougher PTC surface and larger PTC coverage promote early fully developed galloping. Surface roughness enhances maximum amplitude in galloping branch.

Blockage effects are a concern with all the experiments and thus the following assessment is offered. In both LTFSW channels, most experiments were conducted with a smooth circular cylinder or a PTC circular cylinder made of anodized aluminum with diameter $D = 3.5''$ (0.0889 m) and length $L = 36''$ (0.914 m). The corresponding aspect ratio (L/D) is 10.29. Tests are subject to blockage, free surface, and bottom effects. The ratio of cross-section of cylinder over water depth was about 12% ($D/d = 3.5/29$) for the first channel and about 7% for the second channel (Sect. 47.3.1, *Second Low-Turbulence Free-Surface Water (LTFSW) Channel*. The cylinder was suspended by two tension/compression coil springs and attached to the supporting struts. The test cylinder was constrained to move in the vertical direction (perpendicular

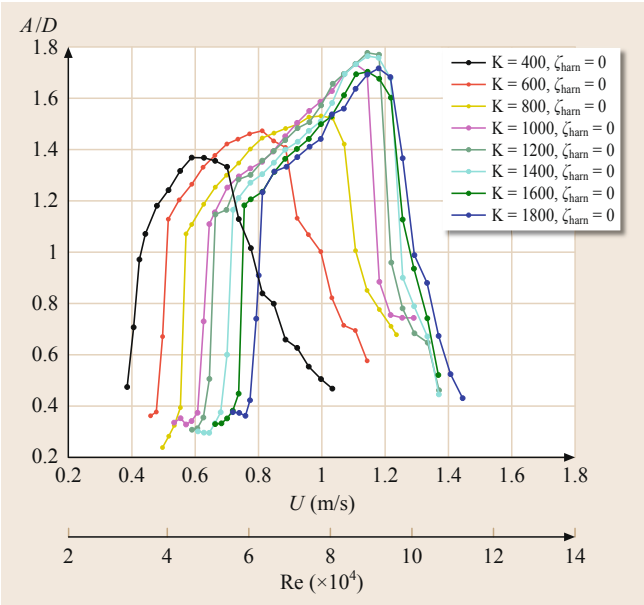

Fig. 47.44 VIV synchronization vs Reynolds number shows an increase of A/D with Reynolds number in the TrSL3 and TrBL regimes (after [47.100])

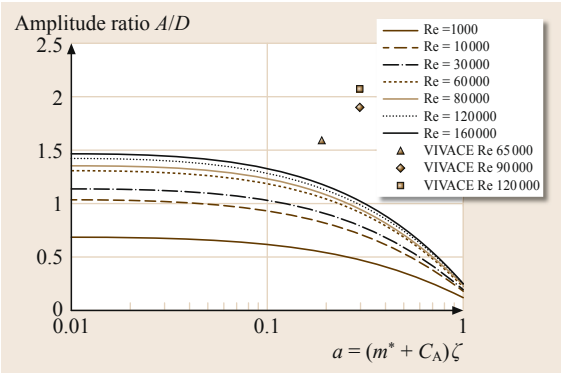

Fig. 47.45 Modified Griffin plot (after [47.167]) with VIVACE tests (after [47.49, 107]). TrSL3 tests revealed much stronger Re number dependence than predictions by extrapolation

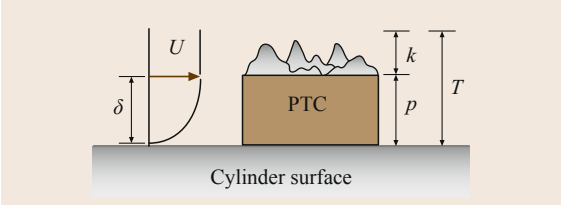

Fig. 47.46 Definition of PTC roughness strip parameters

to the flow direction) as shown in Fig. 47.17a. The ratio of cylinder length L over channel width w is nearly 1 ($L/w = 36/38$). All the experiments were conducted in the Reynolds number (Re=UD/ v) range of 10 000–118 000.

Four different boundary effects need to be discussed:

1. Side-to-side blockage
2. Top-to-bottom blockage
3. Free-surface effect
4. Bottom-boundary effect.

Boundary effects are expected to influence amplitude response particularly when the cylinder approaches the free surface or bottom boundary. There is limited information in the literature. For a stationary circular cylinder, with increase in blockage ratio but in the absence of free surface, vortices possibly become stronger [47.56] and span-wise correlation increases [47.168]. Both these factors, that is, increase in vortex strength and span-wise correlation of vortex shedding, are conducive for enhancement of lift force and consequent higher amplitudes of oscillation. In the FIM channel experiments, the testing arrangement was very different. Side-to-side blockage effects were eliminated by taking special care to maintain a two-dimensional flow side-to-side (Sect. 47.3.8, *Tip-Flow Effect*). The cylinder along with its end brackets occupied practically the entire width of the channel. Thus, there was no room for flow acceleration due to side-to-side restrictions. Hence, in the present case, boundary effects from flow restrictions were limited only to the vertical direction.

For nonstationary, smooth cylinders, free-surface effects have been studied by *Raghavan* and *Bernitsas* [47.73] and bottom-boundary effects by *Roshko* and *Chattoorgoon* [47.169] and *Raghavan* et al. [47.108–110]. Typically, free surface and bottom boundary partially suppress VIV. For the cylinders with PTC used, these effects can be surmised only by comparison to the smooth cylinder effects as presented in these references and by observing change in behavior as the cylinder approaches the boundaries. Corrections for free surface and bottom boundary were not carried out.

When the cylinder comes close to a wall, significant lift force is produced repelling the cylinder away from the wall according to the results by *Rosko* and *Chattoorgoon* [47.169]. Hence, applying that conclusion to this study, this implies a negative hydrodynamic force tending to reduce the amplitude of oscillation of the cylinder. This agrees with the results by *Raghavan* et al. [47.109, 110] confirming the effect of bottom boundary suppressing the oscillatory amplitudes.

In galloping, there will always be blockage in a channel since there is no limit to galloping amplitude. Even when there is no hydrodynamic blockage in very deep channels, there will always be mechanical constraints since galloping stops only with structural failure. Galloping is not self-limiting like VIV. This blockage is observed in Fig. 47.32, where the amplitude of oscillation reaches a plateau; actually at a different U^* depending on the system damping. Until that point, the results are not affected by blockage and, in an unbounded flow, galloping amplitude will increase until structural failure.

The following observations are useful. In the tests by *Chang* et al. [47.67], using smooth cylinder and thus being subjected only to VIV – not galloping $-A^* = A/D$ reached 1.65, which allows a gap ratio (ratio of gap between the top of the cylinder surface and the free surface) of about 2.0. For this gap ratio, results by *Raghavan* and *Bernitsas* [47.73] show that free-surface effects could bring an amplitude reduction for smooth cylinder in the range of 8–11%. It should be specifically noted that, for the corresponding stationary smooth cylinder, located midway between the free surface and the bottom boundary when mounted, the gap ratio comes to about 3.5. At that value, no free-surface effects are expected [47.170]. Furthermore, for the same gap ratio (2.0) with respect to the bottom boundary of the channel, there is an amplitude reduction of about 20% [47.108–110]. So, effects due to bottom boundary and free surface may have jointly contributed to an amplitude reduction of up to 30% for the smooth cylinder. In other words, without these effects, amplitude would have been up to 30% higher for smooth cylinders.

Second Low-Turbulence Free-Surface Water (LTFSW) Channel

After several years of testing in the first LTFSW channel, researching a variety of new phenomena regarding enhancement of FIM and synergistic operation between cylinders in arrays of up to four cylinders in tandem, it became clear that there were limitations in amplitude of oscillation in galloping. Thus, the channel was decommissioned and rebuilt out of stainless steel with bigger depth allowing for A/D of up to 5–7. At the same time, MRELab turned its attention to VIVACE tests as opposed to FIM tests. The relation between these two types of tests is discussed in Sect. 47.3.8.

The second LTFSW channel was built in 2012–2013. All stainless steel sections of the first two-story channel [47.161] were maintained and adapted to the new design. The section of the channel above the working level (second story) made originally by PVC was replaced by stainless steel and was made deeper. The depth increased from 80 to 140 cm allowing up

Table 47.7 Dimensions of PTC roughness strips. For $\mathrm{Re} > 7\times10^4$, $T/\delta > 1$ (after [47.102])

	P60	P80	P120	P150
K: Avg. grit size [mm]	0.26	0.195	0.127	0.097

T/D (10^{-3})	9.53	8.43	6.40	6.63

to 7 diameters amplitude, depending on the design of the oscillator model. The recirculating water increased from 8000 to 10 000 gal. The impeller and motor were maintained resulting in a reduced maximum velocity (from 2 to about 1.5 m s^{-1}) for the same level of turbulence intensity. Additional vanes were installed to reduce air entrapment at high speeds. On the other hand, increased speed is used and air entrapment is allowed when realistic conditions are tested for converter models. Figure. 47.17c and Table 47.7 show pictures of the test section of the new channel. Systematic tests are being conducted with up to four oscillators in synergistic operation. The objective of the MRELab is to optimize the multicylinder design of converters with systematic tests enabled by the V_{ck} systems [47.142].

The VIVACE models for the new channel were designed and built in 2012. They are described in detail as shown in Sect. 47.2.1, *Description of the VIVACE Converter* (Figs. 47.17c, 47.38, 47.39, 47.47).

Towing Tank at the University of Michigan

The need to test bigger models used in field tests, measure FIM response with no blockage effects, conduct measurements at larger Reynolds numbers and particularly in flow transition which suppresses VIV, led to experimentation in two towing tanks starting with the one at the University of Michigan, Ann Arbor.

The tank is a carriage-drive system with power provided by four 5 kW brushless servo motors using computer control for optimum speed regulation. Tank length is 109.7 m (360.0 ft), width is 6.7 m (22 ft), and depth (to edge of trough) is 3.05 m (10.0 ft). Typical water depth is 3.2 m (10.5 ft). Carriage type is a manned bridge with an unmanned trailer. Carriage speed is 0.08–6.10 m s^{-1} (0.25–20.0 ft s^{-1}).

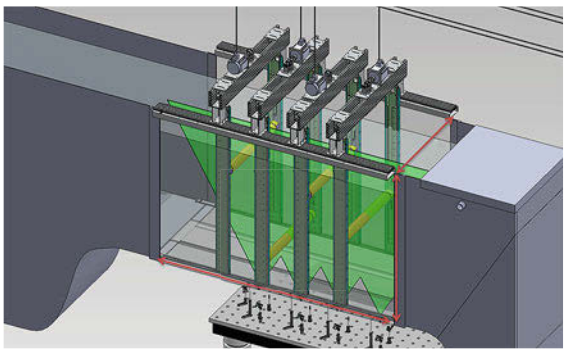

Fig. 47.47 Schematic of the mew LTFSW channel with four oscillators and laser visualization

Three different prototypes were tested in towing tank:

1. The prototype deployed in the St. Clair river in August 2010 consisting of two, horizontal, PTC cylinders with $D = 10''$ (0.254 m) and $L = 106''$ (2.70 m) shown during testing in the towing tank in Fig. 47.18a, in field deployment in Fig. 47.18b, and in river operation.
2. The prototype deployed in the St. Clair river in September–November of 2012 consisting of one, vertical, cylinder with $D = 8''$ (0.203 m) and $L = 60''$ (1.52 m) shown during testing in the towing tank in Fig. 47.17b, at the OHMSETT towing tank in Fig. 47.19a, in field deployment in Fig. 47.19b, and in river operation.
3. The small prototype built for canals in the Netherlands consisting of one, vertical, short cylinder with $D = 10''$ (0.254 m) and $L = 39.4''$ (1.00 m) shown during model tests at the University of Michigan in Fig. 47.20a, and deployment in Fig. 47.20b.

Flow Transition. Testing of larger models and prototypes is required in the development of any marine structure. For MHK energy devices, a procedure of gradually increasing size models and testing components is described by *Bahaj*et al. [47.144]. Figure 47.48 shows results of four towing tank tests at the University of Michigan with two different prototypes both of length $L = 106''$ (2.70 m) and with diameters $D = 10''$ (0.254 m) and $D = 6''$ (0.152 m). The objective of those tests performed over a period of 8 months (2009–2010) was to advance the design of the converter to maintain FIM though flow transition from laminar to turbulent. The amplitude gradually increased with each test. The first test was performed with the $D = 10''$ (0.254 m) smooth cylinder and VIV shut down at the onset of transition. In the second test, PTC was added to the same cylinder initiating VIV earlier, inducing higher response in VIV, and triggering galloping before the onset

Fig. 47.48 Two oscillators in the new LTFSW channel (photo courtesy of MRELab)

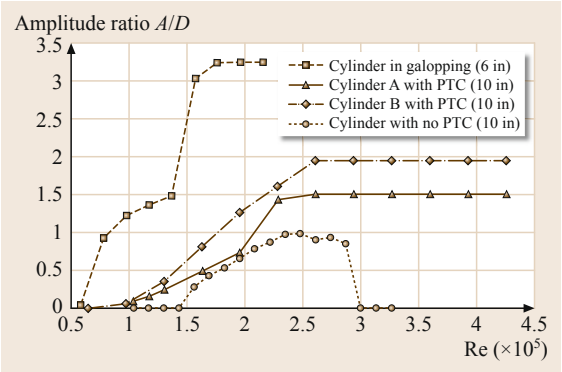

Fig. 47.49 Transition from laminar to turbulent boundary layer shuts down VIV at $\mathrm{Re} = 3 \times 10^5$. With turbulence stimulation placed as per Fig. 47.24, galloping was initiated prior to VIV desynchronization (courtesy of VHE)

of flow transition. The safety stops set at $A/D = 1.5''$ were hit through $\mathrm{Re} \cong 500\,000$. In the third test, the converter frame was redesigned to allow $A/D = 1.9$ for the $D = 10''$ (0.254 m) PTC cylinder. Due to towing tank limitations, the frame could not be redesigned to allow for higher A/D for the $D = 10''$ (0.254 m) cylinder. Thus, in the fourth test, the $D = 6''$ (0.152 m) cylinder was used resulting in the earlier onset of galloping in the middle of the upper branch and amplitudes limited again by the safety stops at $A/D = 3.25$. A similar effect is shown in Fig. 47.49 for a $3.5''$ diameter cylinder in the first LTFSW channel.

Amplitude Limits. Figure 47.48 made it clear that it would be important to conduct tests allowing for yet higher amplitude of oscillation. This led to testing of a smaller converter model in the towing tank of the University of Michigan (Fig. 47.17b). Amplitudes exceeded 4.5 diameters.

Towing Tank at OHMSETT

Limitation in amplitudes as well as concerns about blockage effects led VHE and MRELab to conduct testing in the towing tank of OHMSETT [47.147], which is a much larger, sea-water facility.

OHMSETT's above ground concrete test tank is one of the largest of its kind, measuring 203 m long by 20 m wide by 3.4 m deep. The tank is filled with 2.6 million gallons of crystal-clear saltwater. The OHMSETT test tank allows testing of full-scale equipment. The tank's wave generator creates realistic sea environments, while state-of-the-art data collection and video systems record test results.

In this tank, testing of vertical cylinders without horizontal or vertical blockage effects was made possible. Measurements conducted in the LTFSW channel and the towing tank of the University of Michigan were validated by comparison.

Linear or Nonlinear Springs or no Springs at all? The ever-increasing amplitude of oscillation recorded in FIM tests by MRELab and VHE resulted in continuously higher energy generation. This observation naturally led to the conclusion that a cylinder in galloping could convert more MHK energy to mechanical if it were allowed to move in one direction without frame and/or facility limitations. Several nonlinear springs were tested in 2009–2010, leading to the surprising conclusion that the optimal arrangement was for no springs at all. Short and stiff jounce bumpers were introduced at the end of the frame to reverse the direction of oscillation.

The major conclusions to be drawn from this discussion on the tests conducted in two channels and two towing tanks with various size models and prototypes of the VIVACE converter are the following:

- In the development of novel MHK-energy converters, as with all marine structures, model tests need to be conducted at several scales providing complementary information on the system performance.
- Among MHK-energy converters, an advantage that ALTs may have is that the underlying phenomena may be widely scalable and, thus, smaller models are prototypes of a smaller scale. This makes it possible to design multiple-scale converters in the process of developing a larger scale commercial converter.

- A V_{ck} (virtual damping–spring) system, which does not involve the hydrodynamic force in the loop, enables systematic change of the spring not only in value but also in functional form. The optimization process complexity increases dramatically as it becomes the counterpart of a variational calculus problem rather than a size optimization problem.
- In the design of the VIVACE converter, it has already been established that the optimal energy harnessing ALT requires strongly nonlinear springs.

47.3.2 Damping Model

The system identification process developed by *Lee* et al. [47.98] and *Sun* et al. [47.53] has established that the classical, linear viscous damping model does not represent reality in actual real-life oscillators. Consequently, comparison between experiments, even at the same scale, is of questionable validity. The V_{ck} simulator of the mechanical oscillator, which keeps the hydrodynamic force out of the controller loop, enables performing experiments even with high damping with mathematically accurate damping functional form and value. As explained in Sect. 47.2.3, *Electro-Mechanical Principals* under Principle 12, the following elaborate system identification, the system-damping model is removed from the oscillator making the system-damping zero before damping of specific form and value is added. That process, albeit tedious, enables accurate modeling of damping, systematic variation of damping values for a given damping model, and comparison of experimental results with different oscillators.

It is the author's opinion that the reduction of experimental results to a common equivalent even at the same scale is important for comparison of experiments from different laboratories. The process is not completed by the damping modeling and implementation established by the V_{ck} system by the MRELab. It is further discussed in Sect. 47.3.8.

The damping model of the VIVACE converter models established in Sect. 47.2.3, *Electro-Mechanical Principals* is specific to the oscillators used presently in the LTFSW channel experiments. Every oscillator tested in the MRELab undergoes this procedure. Then, all system damping is removed, before a specific damping model is implemented by the controller. The system-damping model identified by *Sun* et al. [47.142], given by (47.33) is

$$c(\dot{y}) = c_3\dot{y}^3 + c_2\dot{y}^2 + c_1\dot{y}^1 + c_c\text{sign}(\dot{y}) ,$$

where c_1, c_2, and c_3 are the first-, second-, and third-order coefficients, respectively, and c_c, is the Coulomb

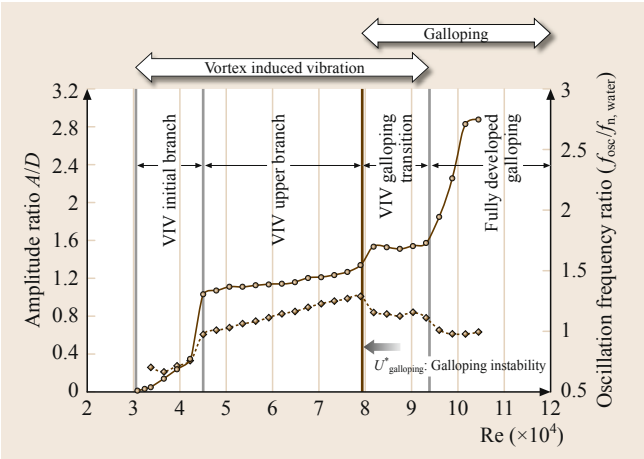

Fig. 47.50 Effect of turbulence stimulation on VIV and galloping using roughness strips (after [47.141])

friction coefficient. This model is generic enough but does not cover all systems encountered in testing in the MRELab. *Lee* et al. [47.98] identified a more complex damping system with hysteresis modeled with four dynamic terms; that is a total of eight coefficients. In both models, the values of the coefficients were different in the two halves of the periodic cycle; that is, when the oscillator was moving in one direction or the other. This is expressed by (47.34) and (47.35).

The following conclusions are worth noting from the preceding discussion on damping:

- A V_{ck} (virtual damping–spring) system, which does not involve the hydrodynamic force in the loop,

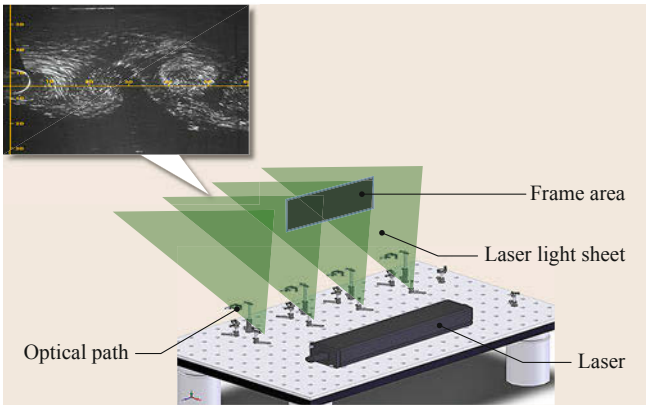

Fig. 47.51 Laser visualization arrangement to span the wake of all four oscillators. Lighting source: argon Laser, continuous laser. Maximum power: 5 W. Particles: AlO_2, ($D_{avg} = 100$ nm), fluorescent particles. Digital camera: Kodak 1000×1050, video; and Imprex 1500×3000, video. Nikon: 1800×2400, snap-shot image (after [47.104])

enables elimination of the system damping and implementation of a mathematically accurate damping model. The actual process has shown that damping varies not only from model to model even in the same laboratory, but also in a given period depending on the location of the oscillator. This is neglected in the MRELab system identification process [47.142].

- Implementation of a specific damping model with mathematical/controller accuracy is a solid step toward reduction of experimental data to a common equivalent model that would enable data comparison across models and labs at the same hydrodynamic scale.

47.3.3 Flow Visualization and Vortex Tracking

Amplitude and frequency response are not the only important information in FIM testing. Vortex shedding, timing and phase of vortex shedding, vortex structures, vortex strength, shear layer motion, and vortex formation length are also important at the scale of the cylinder diameter.

Broad-field visualization of the FIM properties listed above, at the cylinder diameter scale, is achieved as explained in Fig. 47.51. The result is vortex tracking images like those shown in Figs. 47.51–47.54, which show clearly the information needed at this scale in

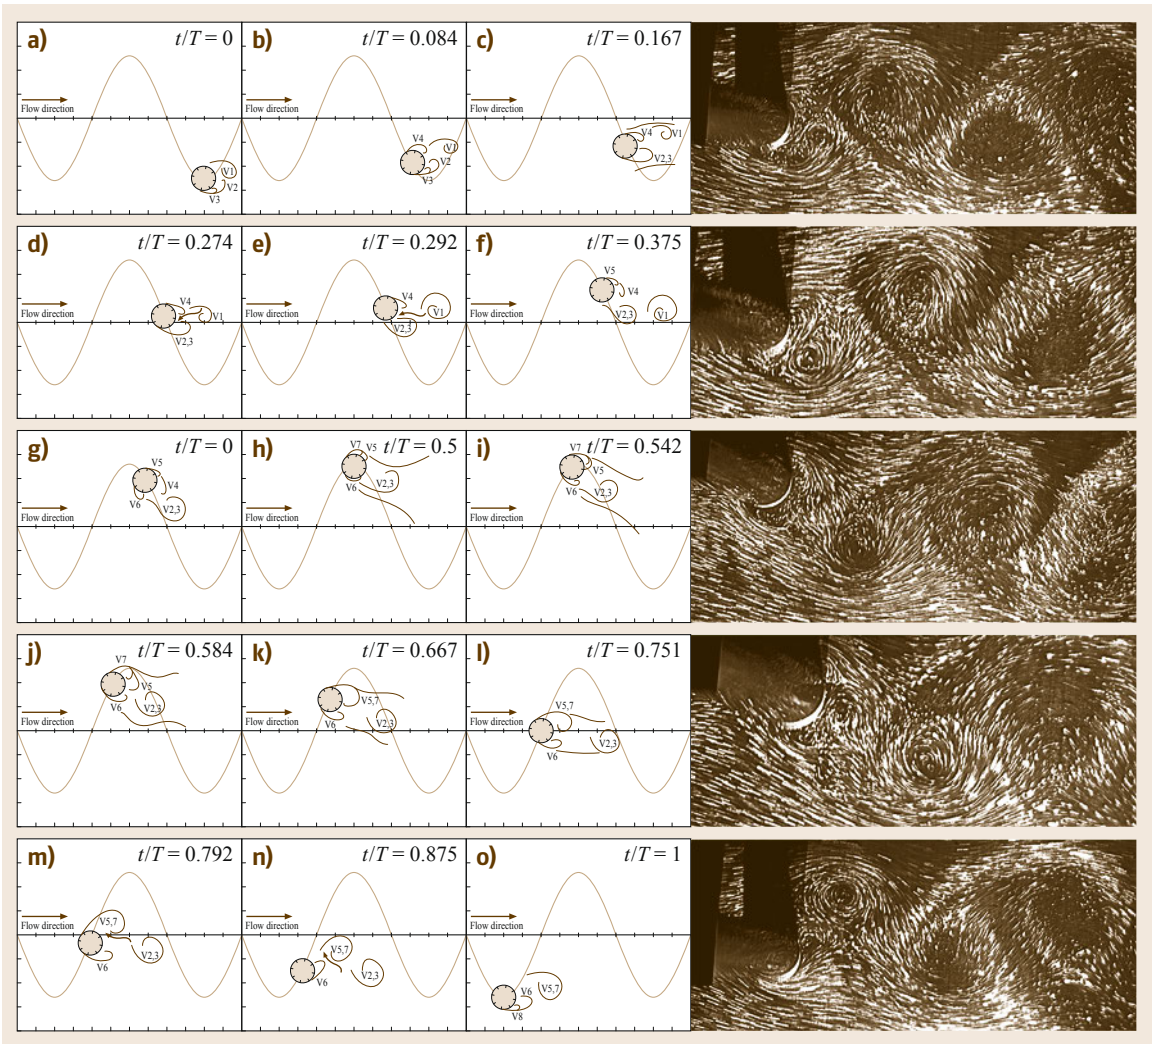

Fig. 47.52a–o Wake vortex structure of smooth cylinder over a cycle: $U^* = 5.58$ (upper end of initial branch), Re$= 4.33 \times 10^4$, $A^* = 0.404$, $f_{osc}/f_s = 0.64$. (after [47.104])

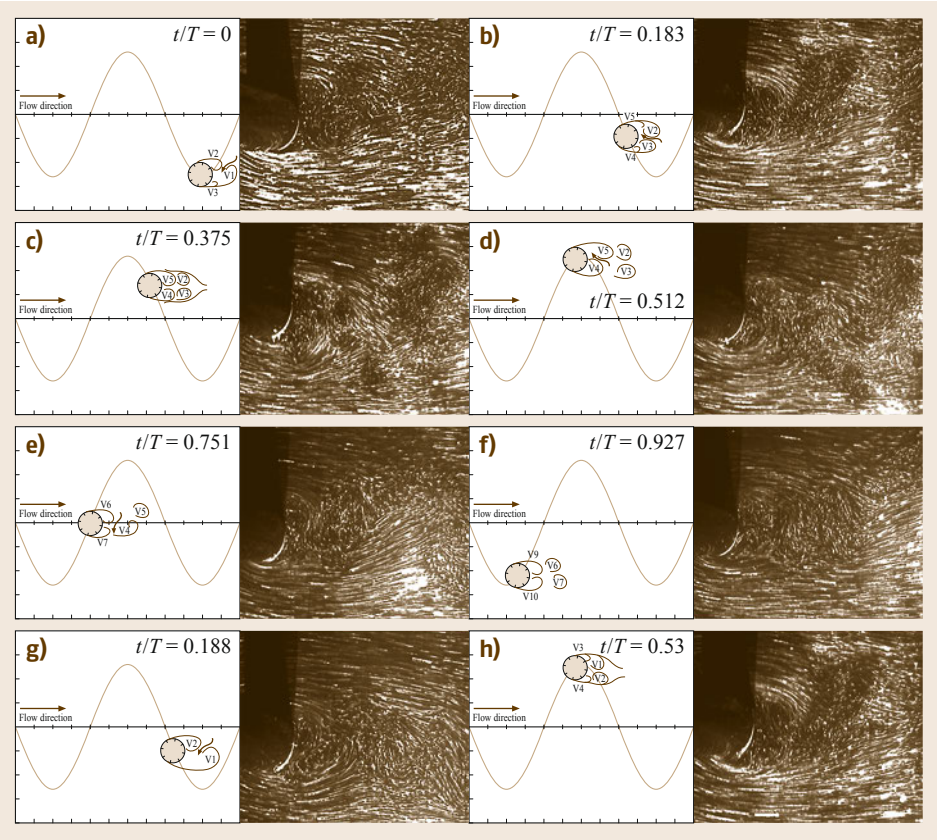

Fig. 47.53a–h Wake vortex structure of smooth cylinder in lower branch, $U^* = 12.28$, $\mathrm{Re} = 9.53 \times 10^4$, $A^* = 0.76$. Sketches **(a–f)** show the cycle with seven shed vortices. Variations exist. Sketch **(g)** is a variation of **(b)** and sketch **(h)** is a variation of **(d)** (after [47.104])

three different tests. Nevertheless, tedious post processing is needed to track vortices and reveal properties of vortex structures in the cylinder wake.

Figure 47.52 shows vortex tracking over a complete period for $U^* = 5.58$, which is close to the end of the upper branch. Figure 47.53 shows vortex tracking over more than a cycle for $U^* = 12.28$ which is in the lower branch. Figure 47.54 shows typical wake structures in desynchronization, for $U^* = 12.28$, which does not form von Kármán vortices. Finally, Fig. 47.55 shows how PTC can suppress VIV creating a narrow escape path for vortices. The cylinder plus its immediate wake form a hydrofoil shape which does not generate a von Kármán street and therefore it does not induce VIV.

Boundary-layer scale information is also important in FIM, when trying to understand the nature of the phenomenon under study, but that is retrieved in the MRELab using validated and verified CFD codes. The alternative of a high-speed camera tracking the motion of the cylinder at high amplitudes or using PIV (particle image velocimetry) at high Reynolds numbers would be desirable but impractical. As explained in Sect. 47.3.5, due to CFD limitations the diameter-scale information collected in visualization and vortex tracking is most important in verification of CFD codes before trusting CFD results at the boundary-layer scale.

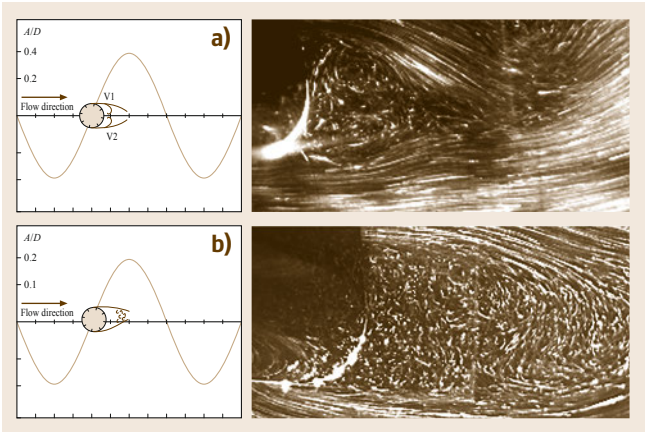

Fig. 47.54a,b Typical wake vortex structure of smooth cylinder at $U^* = 14.51$ (desynchronization), $\mathrm{Re} = 1.12 \times 10^5$, $A^* = 0.06$. **(a)** V1 and V2 shed nearly simultaneously, **(b)** irregularly shed-turbulent eddies (after [47.104])

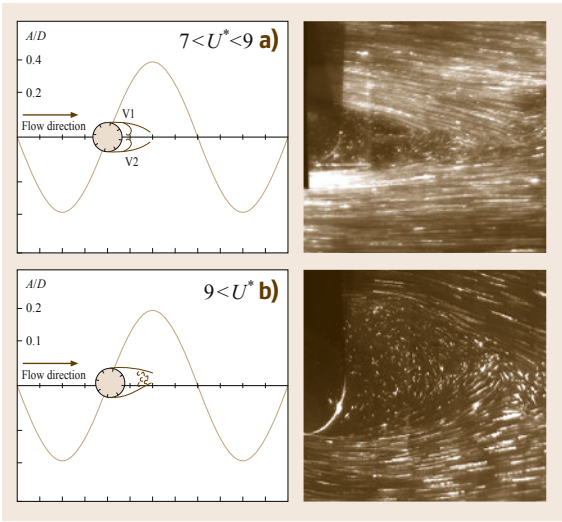

Fig. 47.55a,b Flow structures around a circular PTC cylinder in FIM suppression. Near-wake demonstrates absence of stable vortex shedding when PTC is placed in the SS zone. **(a)** V1 and V2 shed nearly simultaneously, **(b)** irregularly shed-turbulent eddies (after [47.104])

In conclusion it should be noted that:

- Broad-field visualization of FIM and vortex tracking is needed to understand the diameter scale for FIM dynamics as well as interaction of wakes with additional oscillators operating in the wake of other cylinders.
- Broad-field visualization of FIM is also needed for verification of CFD codes so that information at the boundary-layer scale can be trusted.

47.3.4 Field Tests

Field tests, regardless of the model or prototype scale, provide the ultimate environment for testing a technology in real life. Among the conditions that can be tested in field tests but not in a laboratory are the following:

1. Realistic flow conditions, including nonuniformity of flow caused by shear flows, boundary layers from the cite bed or walls, or variation along the cylinder length; variation of flow velocity and direction in time.
2. Data and power transmission to shore.
3. Hazards caused by other uses of the cite for navigation, recreation, fishing, etc.
4. Extended exposure to the marine environment including floating debris.
5. Recording of data for possible impact on the environment.
6. Deployment, retrieval, and decommissioning.

In the process of developing the ALT for the VIVACE converter, two river and two canal deployments have been conducted briefly described below along with some lessons learnt.

River Tests

The first field test was conducted in the St. Clair River in August 2010 with the two horizontal-cylinder converter shown in Fig. 47.18 in lab tests, during the deployment, and in underwater operation, respectively. In spite of the variation of flow from one end of the cylinder to the other by about 15% both cylinders operated in FIM and video and response were recorded for a short period of time.

The second field test tool place in September 2012 at the same location with a smaller, one-cylinder, horizontal-cylinder converter shown in Fig. 47.19 in towing tank testing, deployment, and underwater operation. The converter stayed in place for three months.

Canal Tests

In January 2013, two tests were conducted in canals in the Netherlands under the lead of *TAUW* [47.146]. Figure 47.20 shows the small model tested in the University of Michigan towing tank, and at location, respectively. The modelas small to fit in the available opening allowing for no more than 1.5 diameters amplitude. The testing took place under the most adverse conditions and had limited success. Specifically, the flow was nonuniform because it was coming into a small flat opening from a wider area (Fig. 47.20b). As a result, just as CFD conducted by TAUW showed, there was uniform flow only over one-third of the length of the cylinder while the rest was providing drag instead of lift. That means, that the generated lift power was only $(\frac{1}{3})^2$ of what that VIVACE model produced in the towing tank. In addition, the drag power in the same (transverse=lift) direction due to the two-thirds of the cylinder length was overcome by the lift. That is, the power capacity of the VIVACE canal model tested by TAUW was well over 10 times higher that what was actually produced in the field tests in the canals.

The conclusion to be drawn from field tests in the river and in the canals is:

- Flow uniformity is mandatory for success of the converter. At a 15% velocity variation from one end of the cylinder to the other, the oscillators performed very well. At the other extreme of field conditions, lift was generated by only one-third of the cylinder length. The converter still generated power, albeit about one-tenth of its capacity.

47.3.5 Computational Fluid Dynamics

Design of an ALT by CFD simulations can be a very time consuming and expensive process particularly as the geometry of the oscillator in FIM becomes more complex. The circular cross-section of a PTC cylinder or even a smooth cylinder is deceivingly simple. The complexity lies in the fact that CFD codes have difficulty predicting accurately the flow separation points one on each side of the cylinder. In simulation of flat plates or slender bodies, the location of the separation point is easily identifiable as it is expected to be at $\mathrm{Re} \cong 300\,000$ and can be set at that point in a CFD code. In flows past a stationary circular cylinder, the flow separation point is known experimentally to oscillate $\pm 5{-}10^\circ$ due to the von Kármán vortices. Finding the exact location of the separation point is critical in cylinder fluid dynamics as it affects all the important properties of vortex shedding, such as the beginning of the shear layer, the formation length, the circulation of the von Kármán vortices, and thus the alternating lift on the cylinder, the vortex structures, the width of the immediate wake, and thus, the interference with following cylinders in tandem. The problem becomes even more challenging when the cylinder is in FIM with large amplitude.

Another consideration in design by CFD is the need for a computational tool that can perform simulations fast. For four cylinders in FIM, simulation of 15 s real time may require 100 h of computational time converted to equivalent single-processor time. Most of this time is consumed in dynamic remeshing due to the finite fluid domain in the channel and the interface between the computational subdomains in the vicinity of each cylinder. DNS, DES, DNS three-dimensional computations would be too time consuming and do not resolve the separation point to a satisfactory degree.

In the MRELab, 2-D-URANS (two-dimensional Unsteady, Reynolds-averaged, Navier–Stokes) solvers in commercial codes are used for simulation. Specifically, OpenFOAM and Fluent/ANSYS are used. For a smooth cylinder, for $\mathrm{Re} > 10\,000$, CFD codes do not work well because of their inability to identify the exact location of the separation point even for a stationary cylinder. The separation point is calculated to be stationary at 90° which is incorrect and leads to poor predictions [47.139, 140]. Up to $\mathrm{Re} \cong 10\,000$, agreement between experiments and CFD for a smooth cylinder in VIV is acceptable (Fig. 47.56). *Wanderley* et al. [47.172, 173], achieved agreement between CFD and smooth cylinder VIV for Re up to 12 000.

On the other hand, when the separation point is forced to occur at the correct point on the cylinder, CFD predictions match remarkably well with experimental results. This is the case of PTC cylinders where separation occurs at the leading edge of the PTC both experimentally and computationally [47.139, 140]. Following that discovery, CFD tools have become very useful in the research of FIM of multicylinder VIVACE converters.

Next CFD modeling and simulation results are presented for two cylinders in tandem in FIM. Results are compared to experimental measurements. Few ad-

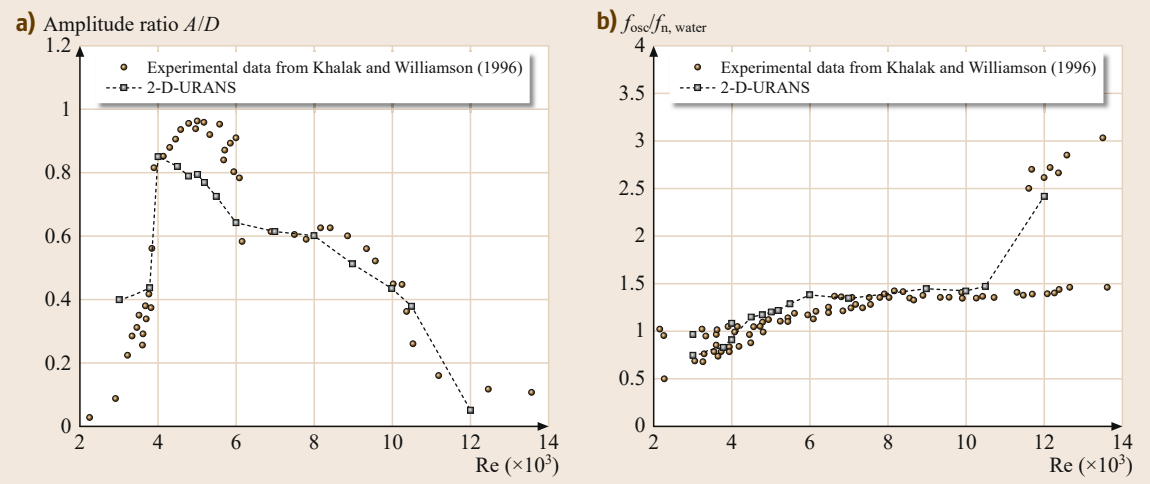

Fig. 47.56a,b For $\mathrm{Re} > 10\,000$, 2-D-URANS fails to predict cylinder forces and motion due to poor prediction of the oscillation of the separation point. For PTC cylinders, separation point is forced and agreement of CFD with experiments is excellent (after [47.112, 139, 140, 171]). **(a)** Smooth-cylinder comparison of A/D between experiments and VIV. **(b)** Smooth-cylinder comparison of $f_{\mathrm{osc}}/f_{\mathrm{n}}$, water between experiments and VIV

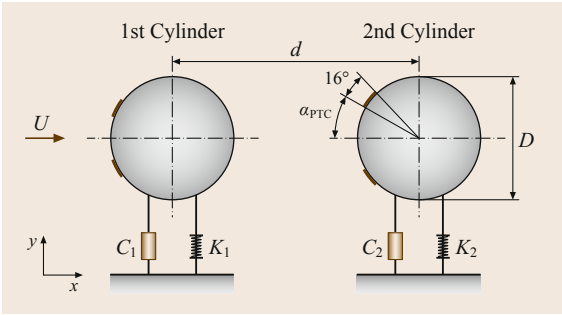

Fig. 47.57 Schematic of two PTC-cylinder physical model

ditional results are presented for three and four cylinder oscillators.

Physical Model

The first physical model consists of two oscillatory systems as shown in Fig. 47.57. Their properties are listed in Table 47.8. The other physical systems consist of two, three, or four oscillators shown in Fig. 47.58 with their properties summarized in Table 47.9. The elements of each oscillatory system are a rigid circular cylinder with diameter D and length L, two end-supporting linear-springs of stiffness K, and the system linear viscous damping C due to friction. Cylinders are arranged in tandem and constrained to oscillate in the y-direction, which is perpendicular to the flow velocity direction. The center-to-center distance d, between two cylinders is varied from $2D$ to $6D$. Two straight roughness strips are attached to the surface of each cylinder symmetrically, one on each side of the cylinder. The angle α_{ptc}, is measured in degrees from the forward stagnation point in the corresponding ideal flow (Fig. 47.23). The type and positions of the roughness strips are determined based on the PTC-to-FIM map (Fig. 47.24). The coverage provided by each sand strip is 16°. For the two cylinders in tandem configuration, $\alpha_{ptc} = \pm 20°$ is applied for the 1st cylinder and $\alpha_{ptc} = \pm 30°$ for the 2nd cylinder.

Simulations are always verified by comparison to experimental measurements on FIM of two PTC cylinders in tandem. The system parameters in the numerical simulations are the same as those used in the corresponding experiments.

Mathematical Models

Flow simulations are performed by a code developed in the MRELab based on the open source CFD tool OpenFOAM, which is composed of C++ libraries solving continuum mechanics problems with a finite-volume discretization method. In addition, code was developed:

1. For the dynamics of the multiple oscillators
2. For dynamic adjustment of the grid near a cylinder as it approaches a boundary.

Fig. 47.58 Four cylinders with PTC in tandem in the first LTFSW channel (photo courtesy of MRELab)

The time-dependent viscous flow solutions are obtained by numerical approximation of the incompressible 2-D-URANS equations in conjunction with the one-equation *Spalart–Allmaras* [47.174] turbulence model. The model is as follows

$$\frac{\partial \boldsymbol{U}_j}{\partial x_i} = 0\,, \tag{47.37}$$

$$\frac{\partial \boldsymbol{U}_i}{\partial t} + \boldsymbol{U}_j \frac{\partial \boldsymbol{U}_i}{\partial x_j} = -\frac{1}{\rho}\frac{\partial P}{\partial x_i} + \frac{\partial}{\partial x_j}\left(2\upsilon \mathbf{S}_{ij} - \overline{u_j' u_i'}\right), \tag{47.38}$$

where υ is the molecular kinematic viscosity and S_{ij} is the mean strain-rate tensor

$$\mathbf{S}_{ij} = \frac{1}{2}\left(\frac{\partial \boldsymbol{U}_i}{\partial x_j} + \frac{\partial \boldsymbol{U}_j}{\partial x_i}\right), \tag{47.39}$$

where $\boldsymbol{U}_i$ is the mean flow velocity vector. The quantity $\boldsymbol{\tau}_{ij} = -\overline{u_i' u_j'}$ is known as the Reynolds stress tensor, which is symmetric. In the Spalart–Allmaras model, a common method employs the Boussinesq approximation to relate the Reynolds stresses to the mean velocity gradient as

$$\boldsymbol{\tau}_{ij} = 2\nu_\mathrm{T}\mathbf{S}_{ij}\,, \tag{47.40}$$

where υ_T is the kinetic eddy viscosity and the related defining equations are as follows

$$\mu_t = \rho\tilde{\nu} f_{\nu 1},\; f_{\nu 1} = \frac{\chi^3}{\chi^3 + c_{\nu 1}^3},\; \chi = \frac{\tilde{\nu}}{\nu}\chi = \frac{\tilde{\nu}}{\nu}\,.$$

$\tilde{\nu}$ is an intermediate working variable of the turbulence model and obeys the following transport equation

$$\frac{\partial \tilde{\nu}}{\partial t} + u_j \frac{\partial \tilde{\nu}}{\partial x_j} = c_{\mathrm{b}1}\tilde{S}\tilde{\nu} - c_{\mathrm{w}1} f_\mathrm{w}\left(\frac{\tilde{\nu}}{d}\right)^2 + \frac{1}{\sigma}\left\{\frac{\partial}{\partial x_j}\left[(\nu + \tilde{\nu})\frac{\partial \tilde{\nu}}{\partial x_j}\right] + c_{\mathrm{b}2}\frac{\partial \tilde{\nu}}{\partial x_i}\frac{\partial \tilde{\nu}}{\partial x_i}\right\}. \tag{47.41}$$

Additional definitions of functions and constants are given by *Spalart* and *Allmaras* [47.174]. In this study, the trip terms $f_{\mathrm{t}1}$, $f_{\mathrm{t}1}$, and $f_{\mathrm{t}2}$ are turned off, and the *trip-less* initial condition for ν is used following *Travin* et al. [47.175].

The classical mass-damper-spring oscillator model is used to describe the cylinder dynamics in FIM. The one-degree of freedom equation of motion can be expressed as

$$m\ddot{y} + C\dot{y} + Ky = f(t)\,, \tag{47.42}$$

where m is the total oscillating mass of the cylinder and attachments including one-third of the spring mass and $f(t)$ is the total hydrodynamic excitation.

In the numerical simulations, a second-order Gauss integration scheme with a linear interpolation for the face-centered value of the unknown are used for the divergence, gradient, and Laplacian terms in the governing equations. The second-order backward Euler method is adopted for time integration. Thus, the numerical discretization scheme gives second-order accuracy in space and time. A pressure implicit with splitting of operators (PISO) algorithm is employed to solve the momentum and continuity equations together in a segregated way. The equation of motion for the cylinder in FIM is solved using a second-order mixed implicit and explicit time integration method.

Numerical Model

The computational domain size is different in the stream direction depending on the tandem spacing between the two cylinders. The domain length in the y-direction is $9D$ for all cases. As shown in Figs. 47.59 and 47.60, the entire domain includes five boundaries: inflow, outflow, top, bottom, and the cylinder walls. The distance between the inlet boundary and the center of the 1st cylinder, l_up, is set at $25D$. The downstream length of the domain, l_down, is also set at $25D$. The spacing d is varied from $2d$ to $6d$. The inflow velocity is considered as uniform and constant. At the outflow boundary, a zero gradient condition is specified for velocity. The bottom condition is defined as a wall boundary to match the experimental conditions. In the present numerical study, the free surface is simplified

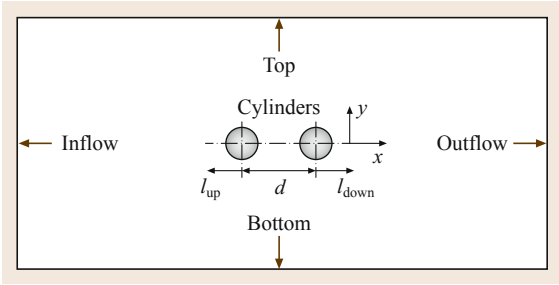

Fig. 47.59 Computational domain (after [47.113])

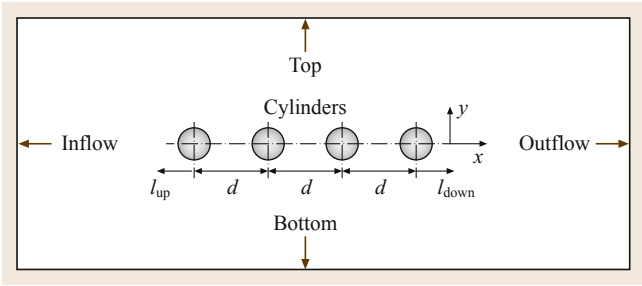

Fig. 47.60 Computational domain for four cylinders (after [47.114])

by modeling it as a wall. A moving wall boundary condition is applied for the cylinder surface when the cylinders are in FIM.

Two-dimensional, structured, computational grids were generated for all cases. A dynamic mesh technique of topological change is used to minimize the mesh deformation. A $2D \times 2D$ square subdomain for the near-wall region of each cylinder moves up and down when the cylinder is in motion. The cell layers at the top and bottom of the subdomain are removed or generated when the mesh is compressed or expanded during the simulation. Due to the specifically modified surface geometry of a PTC cylinder, a wall-function-type boundary condition is implemented to account for the effect of surface roughness. The near-wall grid spacing was selected to produce a $y+$ between 30 and 70, depending on Reynolds number. The medium grid resolution for the two PTC cylinders was selected and is identical to the density used in earlier work for CFD of one cylinder in FIM [47.139, 140] or two cylinders in FIM [47.113]. A close-up of the medium grid for the two PTC cylinders when $d = 2.5D$ is shown in Fig. 47.61. Figure 47.62 shows the grid configuration for four cylinders.

FIM of Two PTC Cylinders in Tandem

A series of simulations are conducted for investigation of the effect of tandem spacing on FIM of two cylinders with PTC. The Reynolds number range is $30\,000 < \mathrm{Re} < 100\,000$ which is in the high lift TrSL3

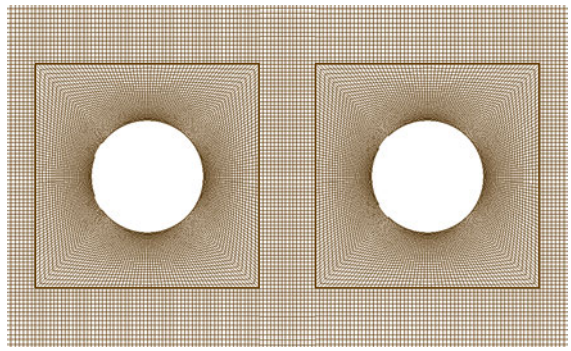

Fig. 47.61 Close-up of medium resolution grid (after [47.113])

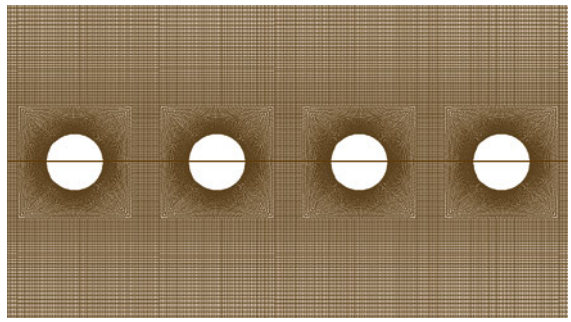

Fig. 47.62 Close-up of the medium grid for four PTC cylinders (after [47.114])

regime (Fig. 47.16). The corresponding reduced velocity ranges are $3.84 < U^*_{\mathrm{water}} < 12.81$ for the 1st cylinder and $3.93 < U^*_{\mathrm{water}} < 13.11$ for the 2nd cylinder. The simulation results are compared with the experimental data derived in the LTFSW channel of the MRELab. The two PTC cylinders start from the neutral position with zero initial velocity and displacement. In this study, the amplitude A_{peaks} of each PTC cylinder is calculated by averaging the absolute values of the 60 largest amplitude (negative and positive). The oscillation frequency f_{osc} of each cylinder is calculated by fast Fourier transform (FFT) over the recorded, steady-state, displacement history of the cylinder.

FIM of First Cylinder. Figure 47.63 shows the variation of amplitude and frequency response of the 1st cylinder with respect to Reynolds number (Re), free stream velocity (U), and reduced velocity (U^*_{water}) defined as in (47.3) $U^*_{\mathrm{water}} = U/(f_{\mathrm{n,water}}D)$. Within the test range of simulations and experiments, four regions can be clearly observed, including the VIV initial branch ($30\,000 < \mathrm{Re} < 40\,000$, $3.84 < U^*_{\mathrm{water}} < 5.12$), the VIV upper branch ($40\,000 < \mathrm{Re} < 80\,000$, $5.12 < U^*_{\mathrm{water}} 10.25$), transition from VIV to galloping ($80\,000 < \mathrm{Re} < 95\,000$, $10.25 < U^*\mathrm{water} <$

12.17), and galloping (Re > 95 000, U^*_{water}12.17). The experimental tests show that the oscillatory trends in A_{peaks}/D and f_{osc}/f_n, water of the 1st cylinder are not significantly influenced by the value of the center-to-center distance between the two PTC cylinders. For the simulation results, however, the VIV initial branch is initiated numerically earlier than in the experiments for all cases. This is attributed to the fact that the classical linear-viscous damping model used in the numerical simulations is different from the physical damping model in the experimental apparatus, which is more accurate but extremely complex [47.98, 100, 142]. When Re> 40 000 (U^*water > 5.12), the amplitude ratio follows closely the experimental data except for the case of $d = 2.5D$. Specifically, the amplitude of the 1st cylinder is slightly lower than other cases at Re = 50 000 ($U^*_{water} = 6.40$), and higher at Re = 80 000 ($U^*_{water} = 10.25$) when $d = 2.5D$. In all cases, Fig. 47.63 shows the rapid rise in amplitude, which is accompanied by a decrease in frequency for Re > 80 000 ($U^*_{water} > 10.25$). This phenomenon indicates that transition from the VIV upper branch to galloping is successfully initiated at $U^*_{water} = 10.25$ (Re = 80 000) instead of the typical $U^*_{water} \approx 20$, resulting in back-to-back VIV and galloping [47.67]. It should be noted that, for the smallest spacing ($d = 2.0D$), both the amplitude and frequency ratios of the 1st cylinder are lower than that in the other cases in the galloping region when Re > 95 000 ($U^*_{water} > 12.17$).

FIM of Second Cylinder. The amplitude and frequency ratios of the 2nd cylinder are plotted in Fig. 47.64. The motion of the 2nd cylinder is affected by the 1st cylinder and the response trend is quite different from that of the 1st cylinder. As shown in Fig. 47.64, during the VIV initial branch (30 000 < Re < 40 000, 3.93 < U^*_{water} < 5.24), the motion of the 2nd cylinder is almost suppressed in all the experimental tests. Similar phenomenon can be observed for the cases of $d < 3D$ in the numerical results. The major harmonic frequency is higher in the numerical simulations than the experiments in the initial-branch due to the difference in the viscous damping models between CFD and experiments. With increasing Re, the experimental results show that the amplitude bumps appear before the occurrence of the upshot of the initial-branch at Re ≈ 55 000 ($U^*_{water} \approx 7.21$) for all cases. The frequency trends also show a drop around Re ≈ 55 000 ($U^*_{water} \approx 7.21$) for the 2nd cylinder. Simulation cannot predict the phenomenon of decreasing in amplitude response at the start point of the upper branch. In the range of 60 000 < Re < 80 000 (7.87 < U^*_{water}10.49) in the VIV upper branch, the amplitude of the second cylinder shows a rising trend for all cases, and the oscillatory frequencies are not affected by the tandem spacing.

For $d = 2D$, the amplitude ratio is higher than other cases in the VIV upper branch. Similar bump in FIM response can also be observed in the transition region from the VIV upper branch to galloping at Re ≈ 95 000 ($U^*_{water} \approx 12.46$) when the tandem spacing d is smaller than $3D$. Thus, the galloping region is distinctly separated from the VIV upper branch for $d \le 3D$. However, with the increase in d, the VIV upper branch merges with the galloping branch. For the cases of $d > 3D$, it

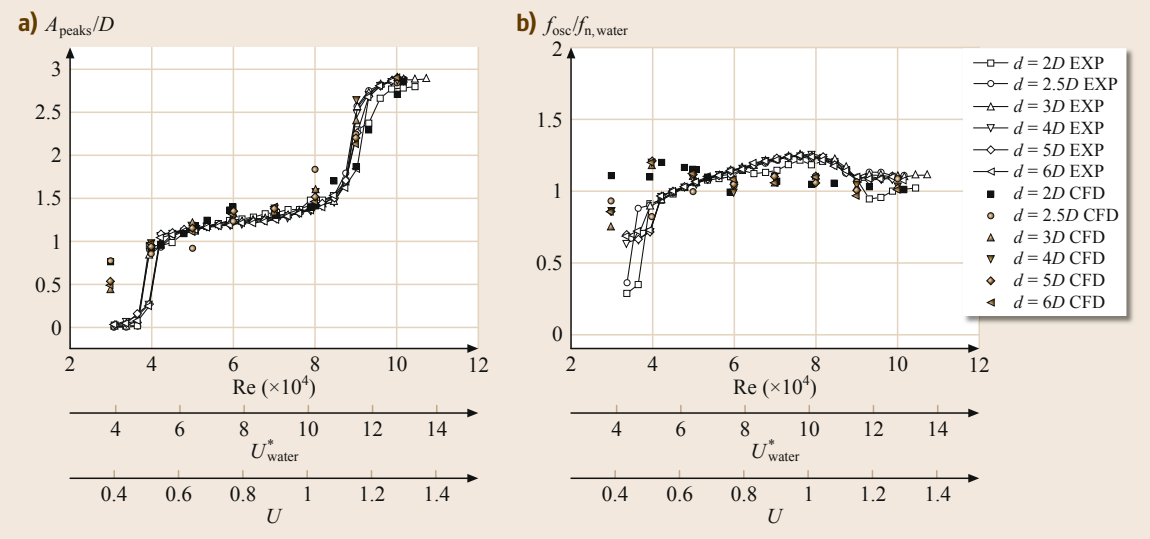

Fig. 47.63a,b Amplitude and frequency ratios of the 1st cylinder at different spacing values (after [47.113]) **(a)** A_{peaks}/D **(b)** $f_{osc}/f_{n,water}$

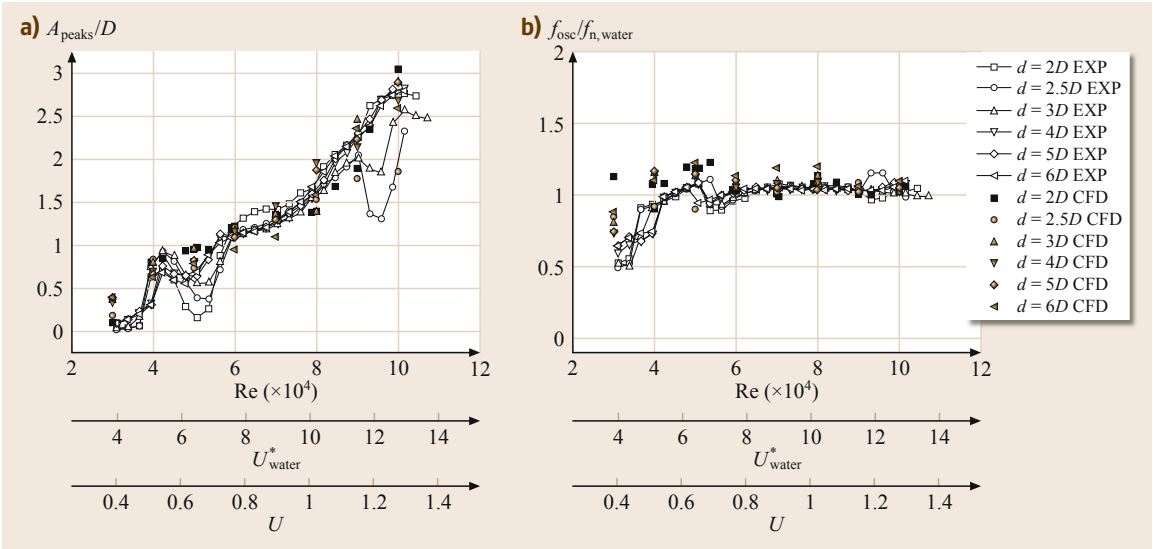

Fig. 47.64a,b Amplitude and frequency ratios of the 2nd cylinder at different spacing values **(a)** A_{peaks}/D **(b)** $f_{osc}/f_{n,water}$ (after [47.113])

is difficult to separate them. In addition, as shown in Fig. 47.63 102, the frequency of the 1st cylinder is not affected by the tandem spacing over the majority of the U^*_{water} range except for $d = 2D$. Similar is the case of the 2nd cylinder as well, but with minor deviations observed at very low and very high Re values.

Near-Wake Structures. For the two PTC cylinders in tandem, the 1st cylinder has great influence on the motion and vortex formation of the 2nd cylinder. To investigate the effect of tandem spacing on the FIM response of the two PTC cylinders, the vortex structures are discussed at four typical Reynolds numbers, as shown in Figs. 47.65 and 47.66 Re = 30 000, Re = 59 229, Re = 93 074, and Re = 10 000:

1. Re = 30 000. The wake vortex structures of two PTC cylinders with tandem spacing $d = 2D$ Re = 30 000 are illustrated in Fig. 47.65. The 2S mode of the vortex shedding can be clearly observed for the 1st cylinder. Two vortices are shed from the 1st cylinder per cycle of oscillation.
However, the vortex formation of the 2nd cylinder is affected by the vortices from the 1st cylinder, especially for the case of $d = 2D$. The motion of the 2nd cylinder is suppressed as the vortices from the 1st cylinder grab away the same rotation vortices of the second cylinder depriving it of circulation and consequently lift. For $d = 2.5D$, the shed vortices of the 1st cylinder allow only generation of weak vortices in the 2nd cylinder resulting in very small displacement of the 2nd cylinder (Fig. 47.64). When $d = 2.5D$, despite the formation of vortices behind the 2nd cylinder is affected by the 1st cylinder, the shed vortices can be clearly identified as 2S for the 2nd cylinder.

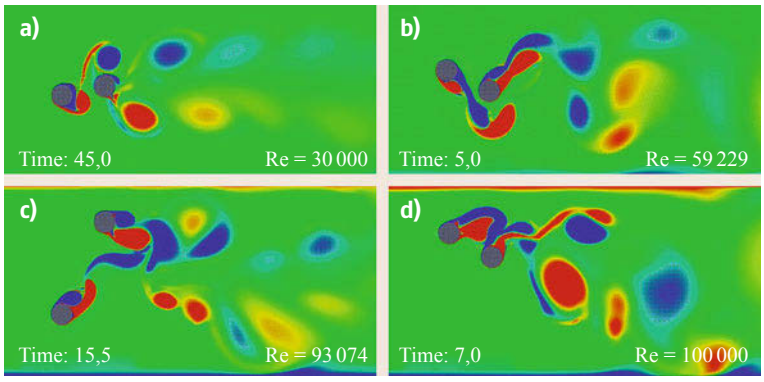

Fig. 47.65 Vorticity showing vortex structures of two PTC cylinders at various Re numbers at specific times; $d = 2D$ (after [47.113])

2. Re = 59 229. The two PTC cylinders oscillate in the VIV upper branch. Figure 47.65b shows the vortex structures of two PTC cylinders with $d = 2D$ center-to-center spacing. For the 1st cylinder, four vortices are shed per cycle of oscillation and the vortex patterns are 2P. When $d < 3D$, the upstream vortices directly and closely interact with the downstream cylinder. The shed vortices of the 2nd cylinder merge with the vortices from upstream as shown in Fig. 47.65b. The vortex pattern of the 2nd cylinder is hard to identify. It should be noted that the FIM of the 2nd cylinder is stimulated by the alternating vortices shed from the 1st cylinder at Re = 59 229. This means that the effect of the 1st cylinder on the motion of the 2nd cylinder in the VIV upper branch is different from the suppression results of the VIV initial-branch when $d < 3D$ for Re = 30 000. For $d \geq 3D$, 2P mode of vortex shedding can be observed for the 2nd cylinder.
3. Re = 93 074. As Re exceeds 90 000 the transition to galloping is initiated for the cylinders. There is variation in the vortex-shedding structure for the 1st cylinder, but the 2P+2S mode is observed in most cycles, such as the cases shown in Fig. 47.65c.

Figure 47.66 is very useful because it shows the pressure distribution on the cylinders at the same time as the corresponding picture in Fig. 47.65. This confirms the understanding that a shed vortex pushes the cylinder away.

The effect of spacing is shown in Fig. 47.67 for six values of center-to-center spacing for Re = 90 000. As expected, increased spacing reduces the impact on the second cylinder.

Several observations were made based on the numerical simulations and the experimental results regarding FIM of two PTC cylinders in tandem. The major conclusions are summarized below:

1. Simulation results are similar to experiments in VIV and galloping for PTC cylinders, capturing the most important features of amplitude, frequency, and vortex structures. Thus, the developed numerical tool can be powerful in understanding the FIM of two PTC cylinders in tandem.
2. For the upstream cylinder, the amplitude and frequency responses are not significantly influenced by the downstream cylinder when the spacing is greater than $2D$.
3. For the downstream cylinder, a rising amplitude trend in the VIV upper branch can be observed in all cases. The galloping region merges with the VIV upper branch for spacing greater than $3D$.

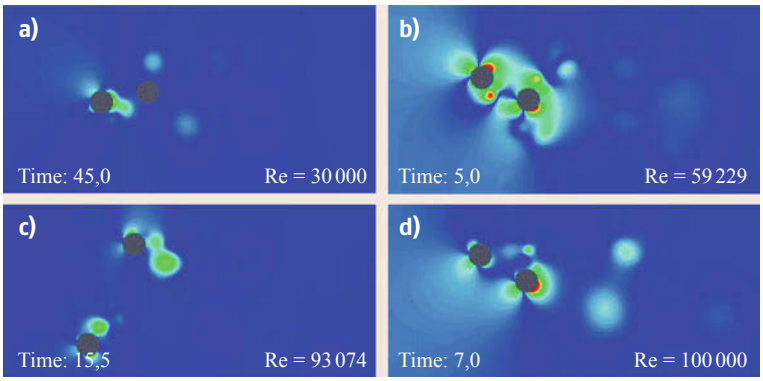

Fig. 47.66 Corresponding pressure distribution at the same Reynolds number and timing as in Fig. 47.65

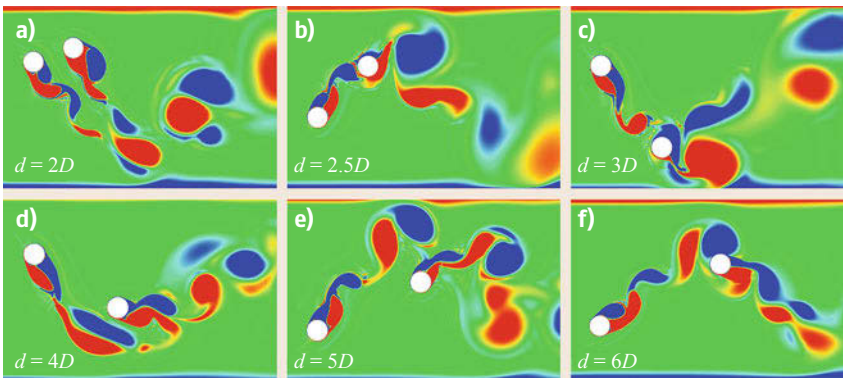

Fig. 47.67 Vortex structures of two PTC cylinders with different spacing at Re = 90 000 (after [47.113])

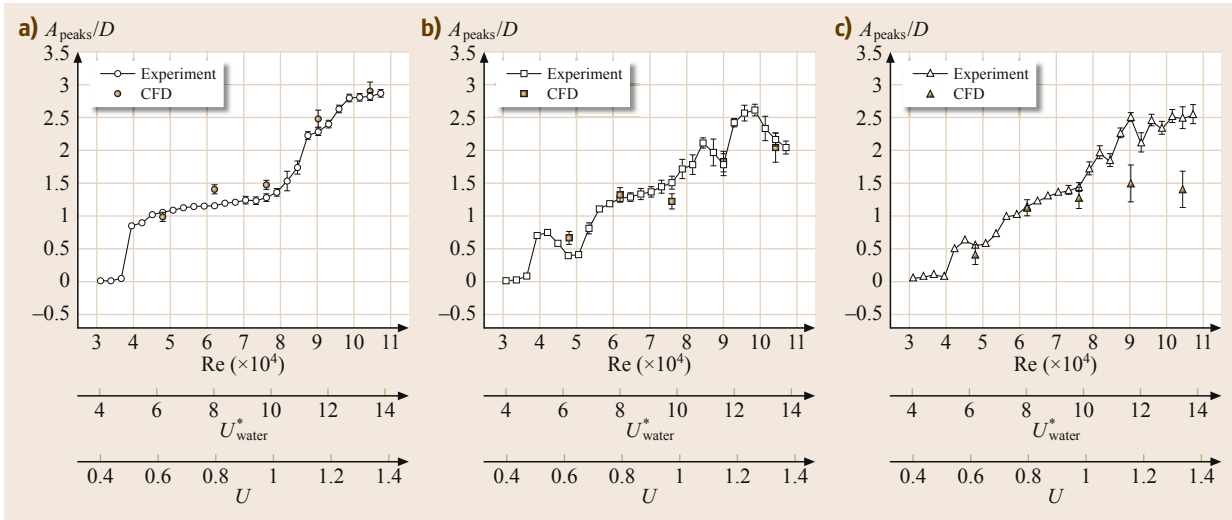

Fig. 47.68a–c Amplitude ratios comparison for three PTC cylinders: **(a)** 1st cylinder, **(b)** 2nd cylinder, **(c)** 3rd cylinder $d = 2.5D$ (after [47.113])

4. For Re = 30 000, the 2S mode of the vortex shedding can be clearly observed for the 1st cylinder in all cases. For the 2nd cylinder, vortex shedding is suppressed for $d = 2D$.
5. For Re = 60 000, the vortex patterns of the 1st cylinder are 2P for all cases. The vortex pattern of the 2nd cylinder is hard to identify for $d < 3D$. The 2P mode can be observed for the 2nd cylinder for $d \geq 3D$.
6. For Re = 90 000, the $2P + 2S$ mode is observed in most cycles for the 1st cylinder.
7. For Re > 90 000, the cycle-to-cycle variation phenomenon in vortex shedding occurs.

FIM of Three PTC Cylinders in Tandem

A few cases are presented here where the in-flow center-to-center distances between cylinders are kept equal to $d = 2.5D$. The angles of the PTC are $\alpha_{PTC} = \pm 30°$ for all the three cylinders. Results of three PTC cylinders are shown in Figs. 47.68–47.70. The different oscillating branches can be clearly observed in the curves of amplitude and frequency ratios. The dynamic response of the cylinders placed downstream of the 1st cylinder is affected by the 1st one. Comparing the results of the single PTC cylinder and two PTC cylinders, we observe that the downstream cylinders have an influence on the FIM for the 1st cylinder as well. As shown in Fig. 47.68, the amplitude ratios of the 1st cylinder rise from the VIV upper branch to galloping by an easy gradient instead of a sharp jump. For the 2nd and 3rd cylinders, similar to the behavior of the downstream cylinder of the 2-PTC cylinder case, the results show drops in the amplitude and frequency response around Re = 50 000 ($U^*_{water} = 6.47$). When galloping is fully developed, (Re > 95 000, $U^*_{water} > 12.29$), the response trends of the two downstream cylinders are profoundly affected by the upstream cylinder. Furthermore, the amplitude ratio for the 2nd and 3rd cylinders is lower than that of the 1st cylinder. Notably, $2.9D$ is obtained for the 1st cylinder in the simulation results.

For the three-cylinder cases, the motion of the downstream cylinders is strongly influenced by the vortices shed from the 1st cylinder. When Re =

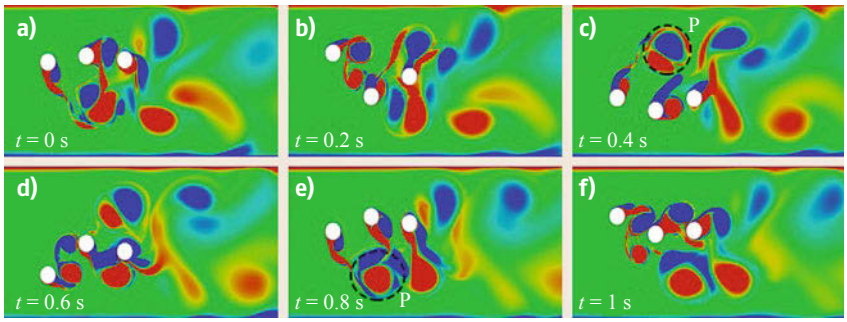

Fig. 47.69 Vortex pattern for three PTC cylinders at Re = 62 049; $d = 2.5D$ (after [47.113])

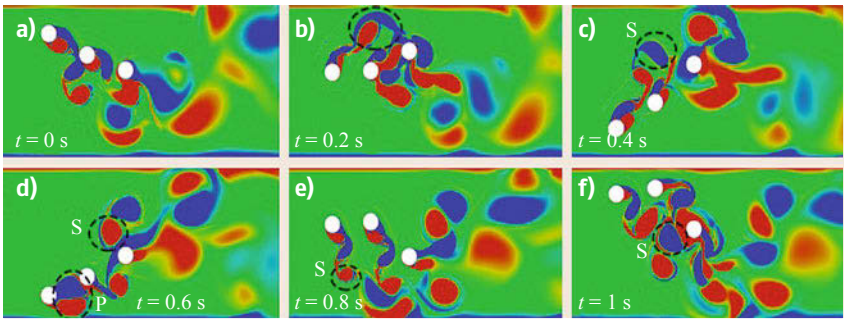

Fig. 47.70a–f Vortex pattern for three PTC cylinders at Re = 90 254; $d = 2.5D$ (after [47.113])

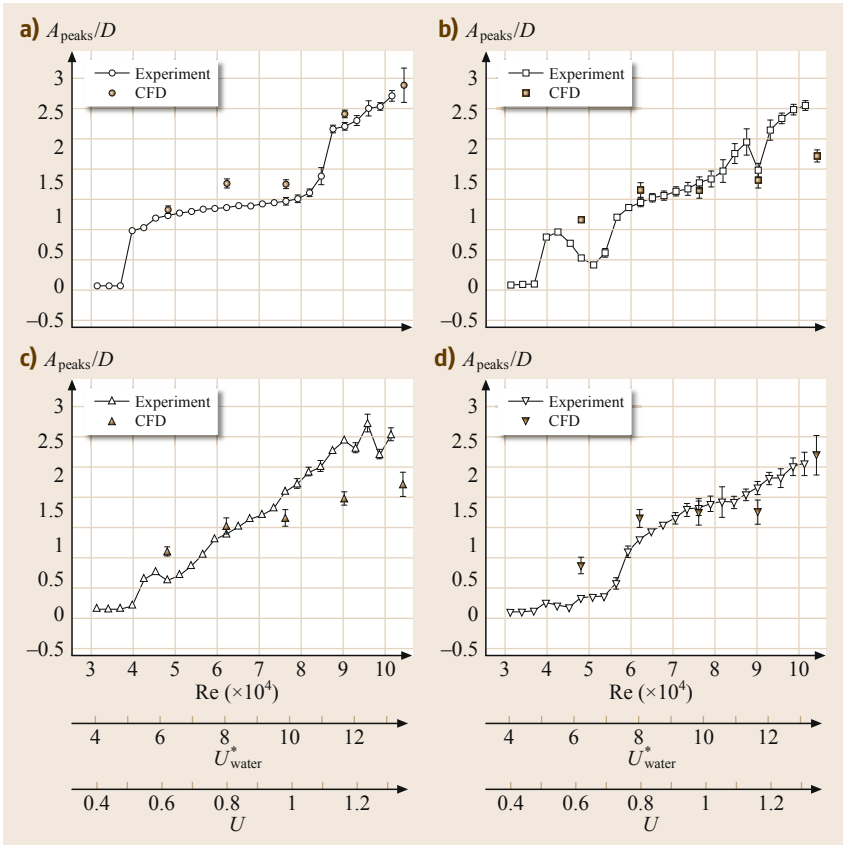

Fig. 47.71a–d Four PTC cylinders: **(a)** 1st cylinder, **(b)** 2nd cylinder, **(c)** 3rd cylinder, **(d)** 4th cylinder; A/D comparison between experiments and CFD in VIV, transition, and galloping; $d = 2.5D$ (after [47.113])

62 094($U^*_{water} = 8.03$), as presented in Fig. 47.69, the vortex pattern of the 1st cylinder is 2P and it is the same as that of the 1st cylinder for the two-cylinder case. The vortices developed by the 2nd and 3rd cylinders are taken away and absorbed by the upstream vortices. It is difficult to identify the vortex pattern for the 2nd and 3rd cylinders in animations due to the presence of the wake of the 1st cylinder. Moreover, the amplitude is higher for the upstream cylinder as shown in Fig. 47.68. Due to the specific spacing between the 1st and 2nd cylinder, the vortex pair from the 1st cylinder does not collide into the body of the 2nd one. Instead, the vortex pair from the first cylinder triggers the vortex shedding of the 2nd cylinder and can change the direction of movement. Therefore, the oscillatory frequency of the 2nd cylinder is approximately equal to the wake pattern (2P) frequency of the 1st cylinder. The 3rd cylinder follows the 2nd one. Thus, the frequencies of the three cylinders are close to each other.

In Fig. 47.70, the vortex pattern of three PTC cylinders for Re = 90 254 ($U^*_{water} = 11.67$) is plotted. Eight vortices are shed by the 1st cylinder in a 2P+4S vortex structure. The vortex patterns are not clear for the 2nd and 3rd cylinders due to the presence of the 1st

cylinder's wake. It should be noted that the 2nd cylinder follows the 1st cylinder and its vortex shedding is disturbed by upstream vortices. Thus, the displacement of the 2nd cylinder is influenced and small amplitude is obtained, as shown in Fig. 47.68. The amplitude ratio of $A_{peaks}/D = 2.49$ is reached for the 1st cylinder.

FIM of Four PTC Cylinders in Tandem

In all cases, the in-flow center-to-center distance between consecutive cylinders is fixed at $2.5D$ and PTC is placed symmetrically on cylinders at $\pm 30°$ from the front stagnation point of the corresponding ideal flow. The amplitude and frequency ratios are presented in Figs. 47.71 and 47.72, respectively. The maximum amplitude of $2.9D$ is achieved by the 1st cylinder in galloping. Compared with the results of the three PTC-cylinder cases, the amplitude and frequency responses are very similar for the three upstream cylinders. That means the 4th cylinder hardly affects the three upstream cylinders. But the FIM of the 4th cylinder is strongly disrupted by the vortices shed from the upstream cylinders. As shown in Fig. 47.71, four oscillating branches can be clearly observed and the VIV upper branch starts at Re$\approx 40\,000$ ($U^*_{water} \approx 5.17$) for the 1st cylinder. However, due to the presence of the upstream cylinders, the velocity corresponding to the start point of the VIV upper branch moves to higher velocities. Especially for the 4th cylinder, the VIV upper branch appears at Re $\approx 60\,000$ ($U^*_{water} \approx 7.76$).

For Re $= 62\,049$ ($U^*_{water} = 8.03$), the presence of the other three cylinders practically does not affect the oscillations of the 1st cylinder. In this case, the 1st cylinder experiences VIV and the 2P vortex pattern is observed in Fig. 47.73. It is worthwhile to note that significant phase difference exists between two adjacent cylinders. As shown in Fig. 47.73, there is a nearly 180° phase lag between the 3rd and 4th cylinders. The shear layers of the downstream cylinders are significantly affected by the wake of the upstream cylinders. The oscillating frequencies are very close for all four cylinders as can be seen in Fig. 47.71. The amplitude of the 1st cylinder is higher than the downstream cylinders and reaches $1.48D$.

As shown in Fig. 47.9b for Re $= 90\,254$ ($U^*_{water} = 11.67$), when the 1st cylinder moves down from the point of maximum displacement, a pair (P) of vortices sheds from the cylinder, followed closely by a single vortex (S). The same is observed in the upward journey of the cylinder. Thus, the vortex model is 2P+2S for the 1st cylinder. For the same Re as shown in Fig. 47.74, the downstream cylinders, the vortex pattern is hard to identify as the shed vortices are affected and modified by the vortices from the upstream cylinder wakes. In addition, the motion of the 1st cylinder has a regular form, which can be observed in the displacement ratio curve in Fig. 47.9c. The amplitude ratio $A_{peaks}/D = 2.49$ is achieved by the 1st cylinder which is much higher than those of the downstream cylinders.

Computational Visualization

Upon validation and experimental verification of the CFD code, it can become a very useful tool in investigating FIM of multiple PTC cylinders in tandem. To gain a greater insight into the flow details, the flow has to be visualized. It is difficult to visualize the flow experimentally at high Reynolds numbers using PIV. CFD can provide a unique tool to assist in understanding the underlying fluid dynamics. Most importantly, once the CFD code has been proven to predict correctly integral flow properties, such as amplitude and frequency responses, and nonintegral large-scale behavior – that is, von Kármán-scale vortex structures, it is expected to be able to predict with acceptable accuracy other properties difficult to measure experimentally and even smaller scale properties. Examples are the pressure distribution as in Fig. 47.66a–d, the separation points, and the interaction between shear layers and upstream wakes as in the significant discovery in Fig. 47.65a, which explained the experimentally observed suppression of the second cylinder's FIM.

A good case study is provided by *Kinaci* et al. [47.176] on computational and experimental assessment of turbulence stimulation on FIM of PTC cylinders. Different grades of commercial sandpaper were tested experimentally (P60 and P180 – Table 47.3). Figure 47.75 show vorticity contours to visualize wake structures. Pressure distributions, as in Fig. 47.76, are used to integrate pressure and calculate force. Velocity vector fields in the body vicinity in Fig. 47.77 are used to visualize separation of the flow. The following observations can be made based on Figs. 47.75–47.77:

1. The vorticity contours given in Fig. 47.75a,b are shown at the lowest position of the cylinder in oscillation. Both images are at the reduced velocity of $U^* = 7$ for the two PTC thicknesses defined in Table 47.3. The vorticity contours for the two roughness strips explain the difference in amplitude response as the thicker PTC induces higher amplitude when compared to the thinner PTC. The reason

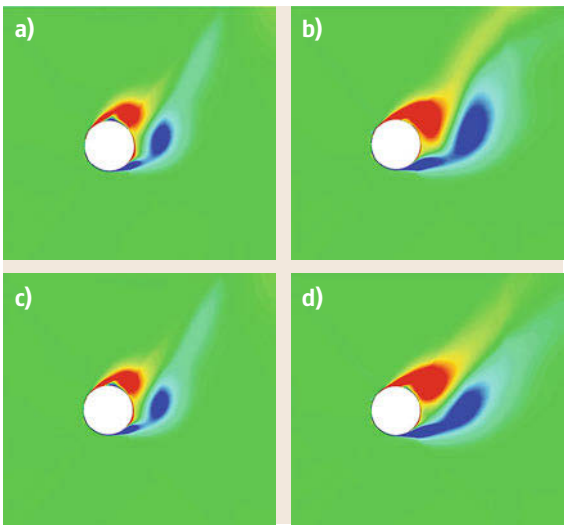

Fig. 47.75a–d Vorticity contours at the lowest position in vertical oscillation (after [47.176]). **(a)** PTC P60 at $U^* = 7$. **(b)** PTC P60 at $U^* = 14$. **(c)** PTC P180 at $U^* = 7$. **(d)** PTC P180 at $U^* = 14$

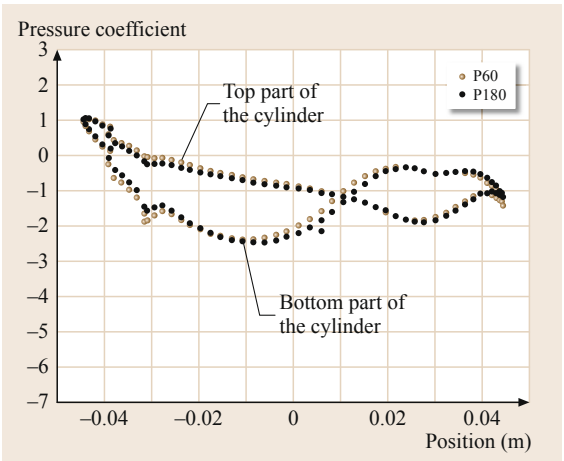

Fig. 47.76 Pressure coefficient around the cylinder with PTC P60 and P180 (after [47.176])

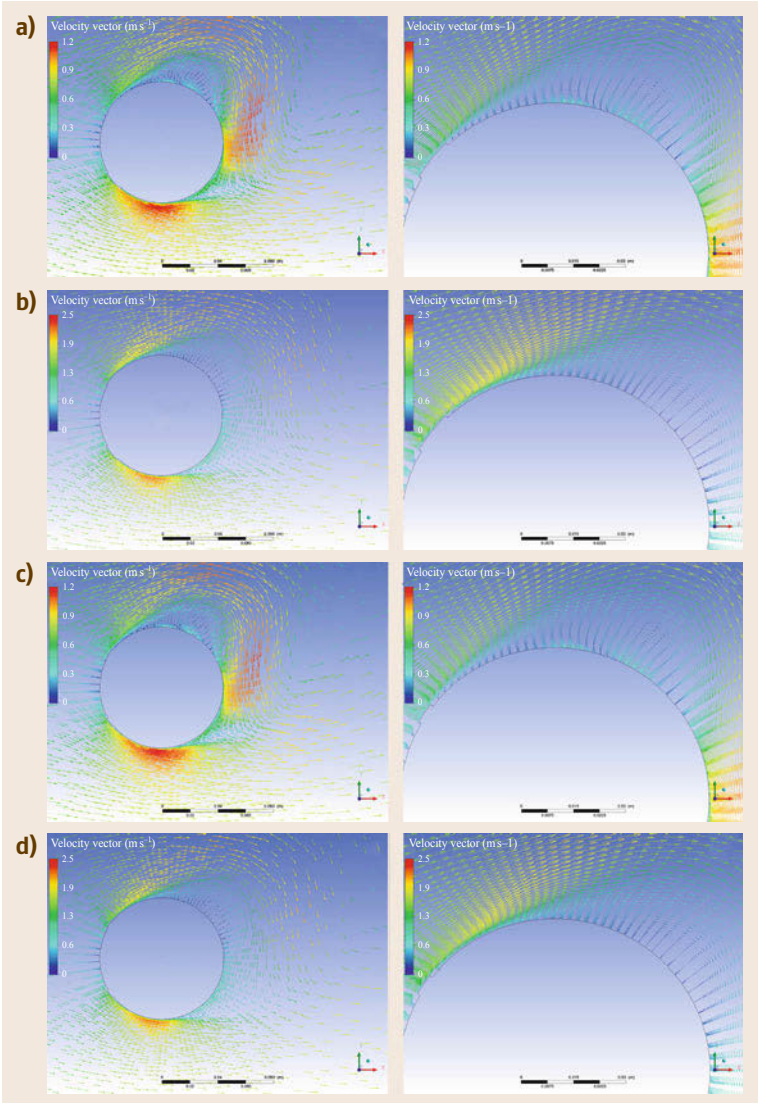

Fig. 47.77a–d Velocity vector round a stationary cylinder with PTC P60 and P180 (after [47.176]). **(a)** Velocity vectors at $U^* = 7$ for PTC P60 of 16° coverage. **(b)** Velocity vectors at $U^* = 14$ for PTC P60 of 16° coverage. **(c)** Velocity vectors at $U^* = 7$ for PTC P60 of 8° coverage. **(d)** Velocity vectors at $U^* = 14$ for PTC P60 of 8° coverage

for this is related to the vortex strength, which is proportional to the circulation and the resulting lift force per the Kutta–Joukowski theorem. Furthermore, shorter formation-length brings the shed vortex closer to the after body, where the pressure variation applies when the vortex sheds and thus induces lift.

2. The difference in amplitudes may be shown by the pressure differences at the upper and lower parts of the cylinders. The pressure coefficients at the lowest position of the cylinder for reduced velocity $U^* = 7$ for the cylinders with PTC P60 and P180 are given in Fig. 47.76. The pressure difference of the cylinder with PTC P60 is higher than that of the cylinder with PTC P180. It is clear that in Fig. 47.76 the difference in pressure coefficients is greater, which in return, creates higher amplitude.
3. Figure 47.77 presents the velocity vectors around the cylinder for 16° and 8° coverage at $U^* = 7$ and $U^* = 14$. These figures capture the flow-speed vector field at the lowest position of the cylinder oscillation. The boundary layer separation on the lower side of the cylinder occurs earlier at $U^* = 7$ when compared to the separation at $U^* = 14$.
4. There is a reattachment of the flow at the upper part of the cylinder which is not examined at the lower part independent of the flow speed. The formation of the flow characteristics given in Fig. 47.77 is periodic and at the upper end of the oscillation, they will approximately be reversed. The boundary layer

separation and flow reattachment at the upper part of the cylinder occurs later in galloping compared to the VIV range.
5. The trapped dead fluid in the VIV region ($U^* = 7$) is greater when compared to the galloping region ($U^* = 14$). The higher flow momentum in galloping, compared to VIV, pushes the trapped dead fluid zone to a later part of the cylinder.
6. In the VIV region, the trapped dead fluid restricts the amplitude of the cylinder when compared to the cylinder in the galloping region. In the galloping region, the dead-fluid zone is not carried with the cylinder in oscillation.
7. At $U^* = 7$, which is in the VIV region, the vortex that will be shed once the cylinder reaches its highest position, is built at the upper part of the cylinder and waits to be shed. At $U^* = 14$, which is in the galloping region, the vortex formed at the upper part of the cylinder is about to be shed. In the galloping region, the number of shed vortices per half cycle is higher when compared to the VIV region.
8. The trapped dead fluid in Fig. 47.77a,c increases the added mass at $U^* = 7$. This CFD result is consistent with the added mass curve by *Vikestad* et al. [47.60], showing that the added mass decreases with respect to increasing fluid velocity.

Numerous specific conclusions regarding CFD use in FIM of multiple cylinders were presented in this section. The conclusions to be retained are the following:

- 2-D-URANS CFD codes can be used to accurately model FIM of a single or multiple cylinders in tandem as long as turbulence stimulation is properly imposed both in CFD and experiments as specified in Fig. 47.24 and following the relevant robustness rules.
- CFD codes verified by experiments not only in predicting integral properties, such as amplitude and frequency, but also nonintegral properties at the von Kármán scale can provide valuable information at the small-scale level. Thus, separation points, pressure distribution, and wake interactions can be studied using such CFD codes.

47.3.6 Mathematical Model of Harnessed and Dissipated Power

FIM data collected experimentally in a lab, or in the field, or numerically can be post-processed to yield useful information. A mathematical model and a procedure are required and are presented in this section.

The motion of the cylinder in the y-direction (Fig. 47.78) is modeled by a second-order linear differential equation as

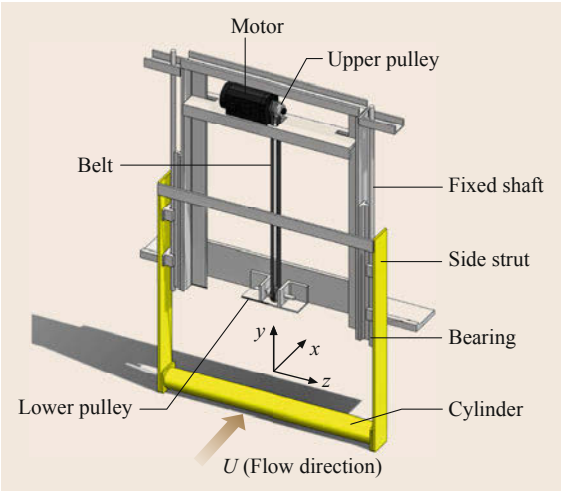

Fig. 47.78 Simple schematic of a VIVACE module with coordinate system (after [47.98])

$$m_{\text{osc}}\ddot{y} + C_{\text{total}}\dot{y} + Ky = F_{\text{fluid}}\,, \tag{47.43}$$

where y is the direction perpendicular to the flow and the cylinder axis, m_{osc} is the total oscillating system mass, which includes one-third of the spring mass, K is the spring stiffness, C_{total} is the total damping coefficient, and F_{fluid} is the force exerted by the fluid on the body in the y direction. This model differs from (47.6) in the sense that the added mass has not yet been separated from the total hydrodynamic force.

There are two approaches to the added mass issue:

1. The first approach separates the inviscid added mass from the total hydrodynamic force and is presented in this section. This assumes that VIV is a lock-in phenomenon resulting in synchronization between vortex shedding (excitation) and cylinder motion, which has a similar effect as resonance, albeit of self-limiting amplitude.
2. The second approach considers the added mass as part of the total lift force in the y direction and calculates it from experimental or numerical data from the force component in phase with the acceleration $\ddot{y}$ [47.61]. This is presented in Sect. 47.3.7 and leads to the conclusion that VIV is a resonance phenomenon with variable natural frequency in water due to variable added mass [47.60].

It is the author's opinion that this controversy is unnecessary as both are simple modeling methods that cannot account for the range of synchronization or the self-limiting nature of the amplitude of oscillation. Both just model the response of the cylinder in

FIM for a specific flow velocity and a given experiment. On the other hand, both approaches are useful in post-processing data and understanding this complex phenomenon better. For better understanding of the complexity of the added mass expression in forces and moments on a small body moving in a 3-D unsteady flow, the reader is referred to the detailed analysis by *Foulhoux* and *Bernitsas* [47.64]. The dependence of the inertia terms on absolute and/or relative velocity as well as the form of convective terms is explained thoroughly putting into perspective the simplicity of the inertia term used in Morison's equation.

Basic Mathematical Equations

The fluid force is separated into viscous and inviscid components as follows

$$m_{\text{osc}}\ddot{y} + C_{\text{total}}\dot{y} + Ky = F_{\text{viscous}} + F_{\text{inviscid}} \,. \tag{47.44}$$

The inviscid force may be defined in terms of the inviscid added mass m_{a} (this model) or may be measured experimentally or numerically (Sect. 47.3.7). Further,

$$F_{\text{inviscid}} = -m_{\text{a}}\ddot{y} \,, \tag{47.45}$$

$$F_{\text{viscous}} = \frac{1}{2}c_{\text{y}}(t)\rho U^2 DL \,. \tag{47.46}$$

The displaced fluid mass m_{d} for a circular cylinder is $\rho\frac{\pi}{4}D^2L$. This reduces the equation of motion to

$$(m_{\text{osc}} + m_{\text{a}})\ddot{y} + C_{\text{total}}\dot{y} + Ky = \frac{2}{\pi D}c_{\text{y}}(t)m_{\text{d}}U^2 \,. \tag{47.47}$$

Fluid Power Conversion

The power in the flowing fluid over the projected area of the cylinder in the direction perpendicular to the flow direction can be calculated as follows. The kinetic pressure head in the fluid form Bernoulli's equation is $\frac{1}{2}\rho U^2$. The force acting over the projected area DL of the cylinder in the direction y of the flow is $\frac{1}{2}\rho U^2 DL$. Then, the power in the fluid, being the product of the acting force times the velocity in that same direction x is

$$\text{Power in the fluid } = \frac{1}{2}\rho U^3 DL \,. \tag{47.48}$$

The work done by the fluid force acting on a VIVACE cylinder during a vibration cycle is the inner vector product of the force by the displacement vector $\mathrm{d}y$ integrated over one cycle of oscillation of the cylinder

$$W_{\text{VIVACE-Fluid}} = \int_0^{T_{\text{cyl}}} F_{\text{fluid}}\dot{y}\mathrm{d}t \,. \tag{47.49}$$

Then, the fluid power in VIVACE is

$$P_{\text{VIVACE-Fluid}} = \frac{W_{\text{VIVACE-Fluid}}}{T_{\text{cyl}}} \,. \tag{47.50}$$

The viscous force exerted by the fluid on the cylinder is given by the right-hand side of (47.47). Assuming a sinusoidal response which is accurate enough in all but the desynchronization zone of VIV, we multiply the force by the instantaneous velocity, integrate the right-hand side, and average it over the cycle period T_{cyl} to yield

$$P_{\text{VIVACE-Fluid}} = \frac{1}{T_{\text{cyl}}}\int_0^{T_{\text{cyl}}} \frac{2}{\pi D}c_{\text{y}}(t)m_{\text{d}} \times U^2 2\pi f_{\text{fluid}} y_{\max}\cos(2\pi f_{\text{fluid}})\mathrm{d}t \,. \tag{47.51}$$

In synchronization, we have $f_{\text{fluid}} = f_{\text{cyl}} = \frac{1}{T_{\text{cyl}}}$.

Therefore,

$$\begin{aligned} P_{\text{VIVACE-Fluid}} &= f_{\text{cyl}}\int_0^{\frac{1}{f_{\text{cyl}}}} \frac{2}{\pi D}C_{\text{y}}m_{\text{d}}U^2 2\pi f_{\text{cyl}} y_{\max} \\ &\quad \times \sin(2\pi f_{\text{cyl}}t + \emptyset)\cos(2\pi f_{\text{cyl}}t)\mathrm{d}t \\ &= \frac{4\pi}{D}C_{\text{y}}m_{\text{d}}U^2 f_{\text{cyl}} y_{\max}\sin\emptyset \,. \end{aligned} \tag{47.52}$$

Inserting the definition of $m_{\text{d}} = \frac{\pi}{4}\rho D^2 L$, yields

$$P_{\text{VIVACE-Fluid}} = \frac{1}{2}\rho\pi C_{\text{y}}U^2 f_{\text{cyl}} y_{\max} DL\sin\emptyset \,. \tag{47.53}$$

Mechanical Power

From (47.47), we integrate the left-hand side after multiplying it by the instantaneous velocity and we average it over the cycle period T_{cyl}. That yields the mechanical power in VIVACE [47.48, 49].

$$P_{\text{VIVACE-Mech}} = \frac{1}{T_{\text{cyl}}}\int_0^{T_{\text{cyl}}} [(m_{\text{osc}} + m_{\text{a}})\ddot{y} + C_{\text{total}}\dot{y} + Ky]\dot{y}\mathrm{d}t \,. \tag{47.54}$$

Only the term in phase with the velocity generates a nonzero energy term in sinusoidal response. In addition, we have

$$\zeta_{\text{total}} = \frac{C_{\text{total}}}{2\sqrt{(m_{\text{osc}} + m_{\text{a}}K)}} \,, \tag{47.55}$$

$$f_{\mathrm{n,water}} = \frac{1}{2\pi}\sqrt{\frac{K}{(m_{\mathrm{osc}} + m_{\mathrm{a}})}}\,. \tag{47.56}$$

Thus,

$$P_{\mathrm{VIVACE\text{-}Mech}} = \frac{1}{T_{\mathrm{cyl}}}\int_0^{T_{\mathrm{cyl}}} 4\pi(m_{\mathrm{osc}} + m_{\mathrm{a}})\zeta_{\mathrm{total}}\dot{y}^2 f_{\mathrm{n,water}}\mathrm{d}t\,. \tag{47.57}$$

Using the sinusoidal expression for

$$y = y_{\max}\sin(2\pi f_{\mathrm{cyl}}t)$$

in the above integral, we have

$$\begin{aligned}
&\frac{1}{T_{\mathrm{cyl}}}\int_0^{T_{\mathrm{cyl}}} 4\pi(m_{\mathrm{osc}} + m_{\mathrm{a}})\zeta_{\mathrm{total}}y_{\max}^2 \\
&\quad [\cos(2\pi f_{\mathrm{cylt}})]^2(2\pi f_{\mathrm{cyl}})^2 f_{\mathrm{n,water}}\mathrm{d}t \\
&= \frac{1}{T_{\mathrm{cyl}}}\int_0^{T_{\mathrm{cyl}}} 4\pi(m_{\mathrm{osc}} + m_{\mathrm{a}})\zeta_{\mathrm{total}}y_{\max}^2 \\
&\quad \frac{1+\cos(4\pi f_{\mathrm{cyl}}t)}{2}(2\pi f_{\mathrm{cyl}})^2 f_{\mathrm{n,water}}\mathrm{d}t \\
&= \frac{1}{T_{\mathrm{cyl}}}\int_0^{T_{\mathrm{cyl}}} 4\pi(m_{\mathrm{osc}} + m_{\mathrm{a}})\zeta_{\mathrm{total}}y_{\max}^2 \\
&\quad (2\pi f_{\mathrm{cyl}})^2 f_{\mathrm{n,water}}\mathrm{d}t \\
&= \left[\frac{T_{\mathrm{cyl}} + \frac{\sin(4\pi f_{\mathrm{cyl}}T_{\mathrm{cyl}})}{4\pi f_{\mathrm{cyl}}}}{2}\right] - \left[\frac{0 + \frac{\sin(4\pi f_{\mathrm{cyl}}0)}{4\pi f_{\mathrm{cyl}}}}{2}\right] \\
&= 2\pi(m_{\mathrm{osc}} + m_{\mathrm{a}})\zeta_{\mathrm{total}}y_{\max}^2(2\pi f_{\mathrm{cyl}})^2 f_{\mathrm{n,water}} \\
&= 8\pi^3(m_{\mathrm{osc}} + m_{\mathrm{a}})\zeta_{\mathrm{total}}(y_{\max}f_{\mathrm{cyl}})^2 f_{\mathrm{n,water}}\,.
\end{aligned} \tag{47.58}$$

Harnessed Power and Dissipated Power

In order to convert MHK energy to mechanical, additional damping is introduced into the system. The total damping (C_{total}) is defined as

$$C_{\mathrm{total}} = C_{\mathrm{stucture}} + C_{\mathrm{harness}}\,, \tag{47.59}$$

where $C_{\mathrm{structure}}$ is the existing damping due to frictional losses in the transmission system, C_{harness} is the damping added through the generator to convert the mechanical energy in the oscillating cylinder to electrical energy an in field prototypes.

From (47.55), we know that $C_{\mathrm{structure}}$ and C_{harness} can be expressed in dimensionless form using the damping ratios $\zeta_{\mathrm{structure}}$ and ζ_{harness}

$$\zeta_{\mathrm{structure}} = \frac{C_{\mathrm{structure}}}{2\sqrt{(m_{\mathrm{osc}} + m_{\mathrm{a}})K}}\,, \tag{47.60}$$

$$\zeta_{\mathrm{harness}} = \frac{C_{\mathrm{harness}}}{2\sqrt{(m_{\mathrm{osc}} + m_{\mathrm{a}})K}}\,. \tag{47.61}$$

Using (47.58), we obtain the harnessed power and the dissipated power as

$$P_{\mathrm{VIVACE\text{-}Dissipated}} = 8\pi^3(m_{\mathrm{osc}} + m_{\mathrm{a}})\zeta_{\mathrm{structure}}(y_{\max}f_{\mathrm{cyl}})^2 f_{\mathrm{n,water}}\,, \tag{47.62}$$

$$P_{\mathrm{VIVACE\text{-}Harness}} = 8\pi^3(m_{\mathrm{osc}} + m_{\mathrm{a}})\zeta_{\mathrm{harness}}(y_{\max}f_{\mathrm{cyl}})^2 f_{\mathrm{n,water}}\,. \tag{47.63}$$

Harnessed Power Calculation Using Experimental and Numerical Simulation Results

To calculate the harnessed power using (47.63), several parameters should be determined. Oscillating system mass m_{osc} and spring constant K can be measured directly. The ideal added mass m_{a} is equal to the displaced fluid mass. Using spring constant K, oscillating system mass m_{osc} and added mass m_{a}, the natural frequency of cylinder in water can be calculated using (47.11). Structural damping $C_{\mathrm{structure}}$ can be measured during the experiment and added damping C_{harness} is set by the V_{ck} system (virtual damping–spring system) developed by the MRELab (Sect. 47.2.3, *Electro-Mechanical Principles*) [47.98].

The remaining two parameters, $y_{\max}$ and f_{cyl}, are obtained through measured displacement history recorded in experiments or calculated displacement history based on numerical simulations. Next, the harnessed-power envelope for a single cylinder VIVACE converter is calculated using CFD simulations and compared to experimental results. *Lee* and *Bernitsas* [47.100] derived experimentally the power envelope in Fig. 47.38 for a smooth cylinder. *Chang* and *Bernitsas* [47.96] derived the power envelope in Fig. 47.33 for a PTC cylinder shown.

Liu and *Bernitsas* [47.177] derived numerically the power envelope for the same PTC cylinder and the results are presented in Table 47.10 and later in this section.

Amplitude Response. The amplitude ratio A/D graph obtained by numerical simulation is shown in Fig. 47.79 based on the optimal values in Table 47.10. The amplitude A of the PTC cylinder is calculated by averaging

Table 47.10 Power generated by single PTC cylinder VIVACE (after [47.177])

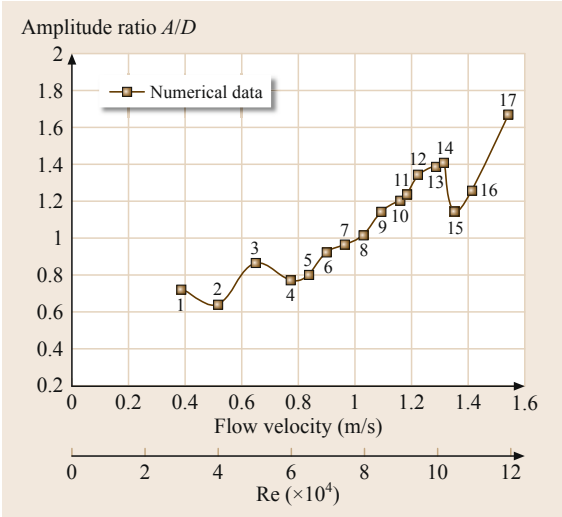

Fig. 47.79 Amplitude ratio of one cylinder with PTC for the power envelope points in Table 47.10 (after [47.177])

the absolute values of the 40 highest values negative and positive peaks in 30 s of simulation time. The maximum displacement of the oscillating cylinder reached in galloping is 1.67D with high damping as shown in Table 47.10 for each case. Figure 47.79 is not a typical VIV-galloping response graph as K and ζ are different for each point on the power envelope. Due to the variation of K and ζ on the envelope, it is not easy to identify the various branches of FIM from Fig. 47.79.

The various branches are easily identified for this application in Figs. 47.80 and 47.81:

1. Re $<$ 30 000: No FIM takes place in this range experimentally or numerically.
2. 30 000 $\le$ Re $\le$ 35 000: This is the VIV initial branch for $K = 600\,\mathrm{N\,m^{-1}}$ (Fig. 47.4c). The upper end of the range changes dramatically depending on K (Fig. 47.4b). Under the condition of constant spring stiffness K and damping ratio ζ, the amplitude ratio increases rapidly with increasing Re [47.88, 113, 114]. For optimal power though, *Liu* and *Bernitsas* [47.177] showed using 2-D-URANS that the amplitude ratio changes from 0.65–0.87. This is due to the effect of spring stiffness going up from $K = 400\,\mathrm{N\,m^{-1}}$ at Re = 30 000 ($U^* = 5.50$) to $K = 800\,\mathrm{N\,m^{-1}}$ at Re = 60 000 ($U^* = 7.78$) and system damping C rising from $18.28\,\mathrm{N\,s\,m^{-1}}$ at Re = 30 000 to $24.86\,\mathrm{N\,s\,m^{-1}}$ at Re = 60 000 used in the numerical simulation.
3. 35 000–55 000 $\le$ Re $\le$ 85 000–95 000: This is the upper branch in VIV for $K = 600\,\mathrm{N\,m^{-1}}$ (Fig. 47.81). But as Fig. 47.79 shows, the upper and lower ends change widely depending on K 35 000–55 000 $\le$ Re $\le$ 85 000–95 000. As far as power harnessing is concerned, the numerical results in Fig. 47.77d shows that the amplitude ratio increases approximately linearly from the starting point 0.78 to the end point 1.41 of the upper branch with the rising of spring stiffness from $K = 800\,\mathrm{N\,m^{-1}}$ at Re = 60 000 ($U^* = 7.78$) to $K = 1800\,\mathrm{N\,m^{-1}}$ at Re = 100 000 ($U^* = 8.65$). System damping rises from $\zeta = 24.86\,\mathrm{N\,s\,m^{-1}}$ at Re = 60 000 to $\zeta = 36.09\,\mathrm{N\,s\,m^{-1}}$ at Re = 100 000 per Table 47.10. This increase is a characteristic of VIV in the TrSL3 regime not in TrSL2 [47.107].

4. $85\,000–95\,000 \le \mathrm{Re} \le 95\,000–105\,000$: This is the transition region from the VIV upper branch to galloping. The amplitude of a single cylinder with PTC decreases dramatically while the spring stiffness and system damping are held at the level of $K = 1800\,\mathrm{N\,m^{-1}}$ and $36.09\,\mathrm{N\,s\,m^{-1}}$, respectively, with the Reynolds number increasing form $\mathrm{Re} = 100\,000$ ($U^* = 8.65$) to $\mathrm{Re} = 105\,000$ ($U^* = 9.08$). Here the transition region from the VIV upper branch to galloping is different from that in Ding's studies, which is $80\,000 \le \mathrm{Re} \le 95\,000$ [47.113, 114]. The reason is that the velocity range between VIV and galloping requires additional resolution to find out if the lower branch in VIV has been overtaken by the instigation of galloping as explained thoroughly by *Park* et al. [47.70–72, 149]. See also Sect. 47.2.3, *Hydrodynamic Principles* under Principle 4. In this application, of all the parameters that can affect the separation between VIV and galloping, D, a, and m^* in (47.17) are constant. Thus, the separation between VIV and galloping is influenced by the change in K, ζ, and flow velocity (Figs. 47.80 and 47.81).
5. $\mathrm{Re} \ge 105\,000$: This is the galloping region. Galloping is known to be a high-amplitude and low-frequency FIM. The maximum amplitude of the single cylinder with PTC reaches $1.67 * D$ at $\mathrm{Re} = 120\,000$ ($U^* = 9.85$) in the CFD numerical simulation results.

Frequency Response. In Fig. 47.82, the frequency ratio $f_{\mathrm{osc}}/f_{\mathrm{n}}$, water of the PTC cylinder is plotted versus Reynolds number Re and flow velocity U. The oscillation frequency f_{osc} is calculated by FFT of the displacement of the cylinder over the recorded period.

The following observations can be made based on Figs. 47.82 and 47.83:

1. Frequency increases from point 1 to 2, which have the same stiffness and system damping as in experiments in Fig. 47.83. The decreasing part – points 2,3,4 – is mainly caused by the difference in spring stiffness and system damping.
2. At $\mathrm{Re} = 60\,000$ ($U^* = 7.78$), the VIV upper branch begins. With increasing spring stiffness K, the system's natural frequency in water increases from 1.11–1.67 and the frequency of oscillation rises from 1.18–1.81. But the frequency ratio remains nearly constant around 1.07, which is typical in VIV. As Re approaches 100 000, the frequency drop indicates transition to galloping. The frequency drop is accompanied by a rapid fall in the amplitude of the cylinder in agreement with the experimental results in Fig. 47.83.

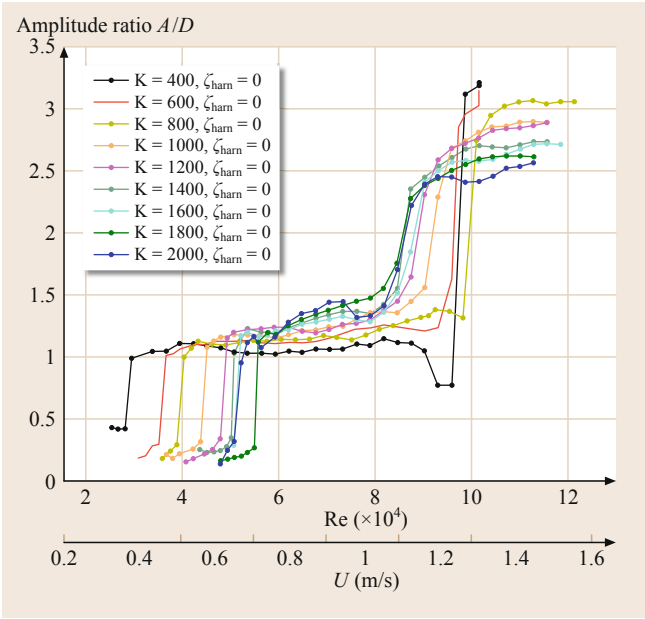

Fig. 47.80 Rough cylinder oscillatory responses at different stiffness values at no external damping (after [47.95])

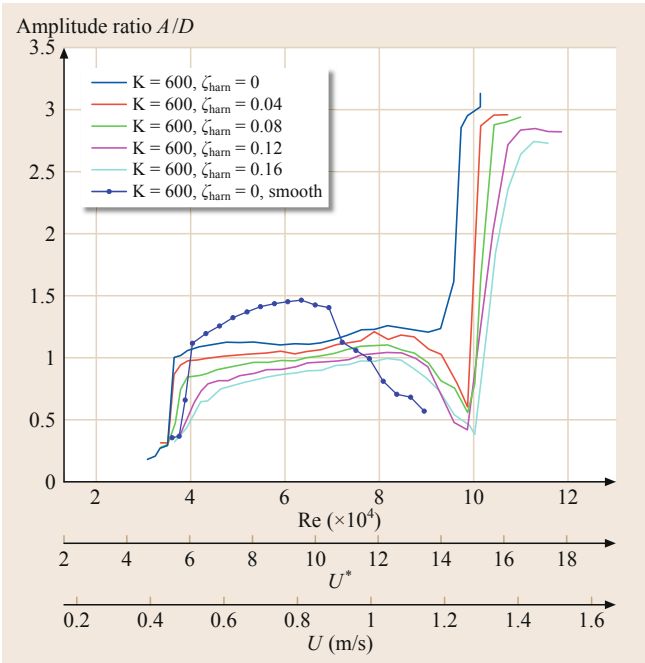

Fig. 47.81 Rough cylinder amplitude response at various damping values at $K = 600\,\mathrm{N\,m^{-1}}$ (after [47.95])

3. In the galloping branch for $\mathrm{Re} \ge 105\,000$ ($U^* = 9.08$), the frequency ratio reduction – characteristic of galloping – appears as a drop from 1.08–1.04. For the case of $\mathrm{Re} = 120\,000$ ($U^* =$

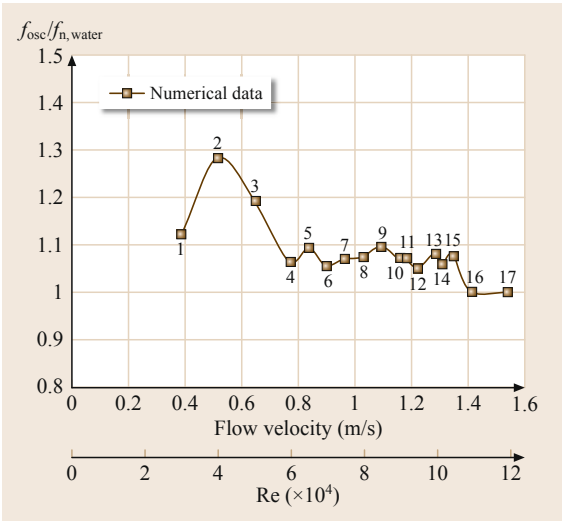

Fig. 47.82 Frequency ratio of one cylinder with PTC for the power envelope points in Table 47.10 (after [47.177])

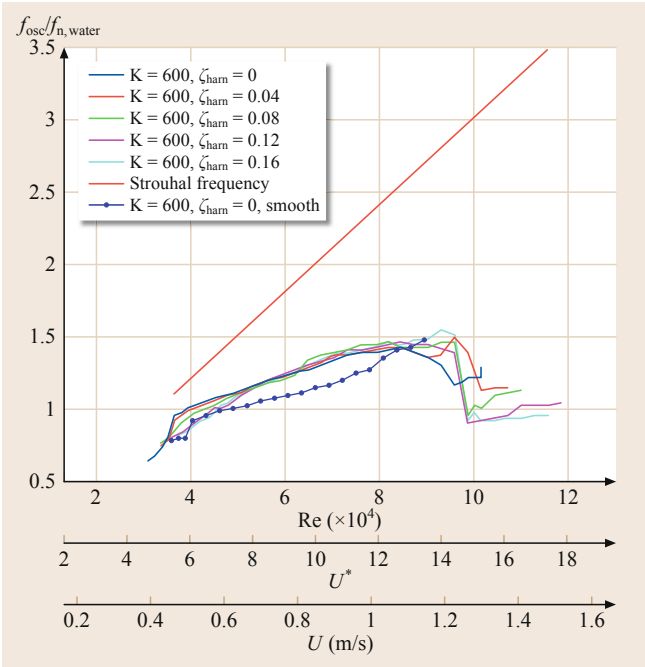

Fig. 47.83 Rough cylinder amplitude response at various damping values at $K = 600\,\mathrm{N\,m^{-1}}$ (after [47.95])

9.85) in CFD simulation and in the experiments the frequency of oscillation remains close to the system natural frequency; also a characteristic of galloping.

CFD versus Experimental Harnessed Power-Envelope. The power that can be harnessed by a single PTC-cylinder VIVACE converter is the power extracted by the generator, which is equal to the power that VIVACE extracts from the fluid minus the power dissipated by structural, transmission, and the internal generator losses. Based on the numerical results of amplitude and frequency response, the harnessed power P_w by the single PTC cylinder VIVACE system was calculated by *Liu* and *Bernitsas* [47.177] using the mathematical model presented above. The harnessed power envelope versus Reynolds number Re and flow speed (U), calculated by CFD, are depicted in Fig. 47.84, along with the experimental results by *Chang* [47.95]. The corresponding CFD results are presented in Table 47.10.

Power can be harnessed over a broad range of flow velocity from 0.38 to $1.54\,\mathrm{m\,s^{1-}}$. The upper limit is only due to limitations of the LTFSW channel. In the initial branch of VIV, the harnessed power of the single PTC cylinder VIVACE is very small and only 1.27 W is achieved at Re = 30 000 ($U^* = 5.50$). This is due not only to the fact that the available power in the fluid is small at such low speeds but also due to the low amplitude and frequency in the initial branch. With the increase in flow velocity, the power in the fluid increases by the cube of the velocity – as per (47.48) and at the same time the VIV upper branch begins, resulting in a steep increase in the energy conversion. This can be observed in the CFD calculations and the experimental measurements in Fig. 47.84. A second steep increase in converted power occurs at the beginning of galloping. In the present CFD results, it climbs from 35.53 W (Re = 105 000, $U^* = 9.08$) to 55.53 W (Re = 120 000, $U^* = 9.85$). In the experimen-

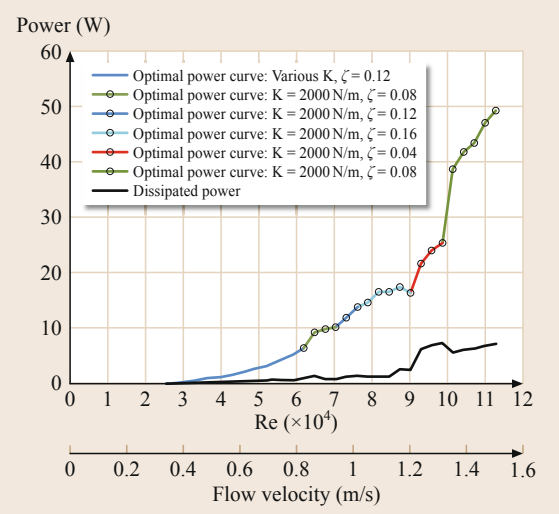

Fig. 47.85 Experimentally harnessed power envelope and corresponding dissipated power with information of system stiffness and damping (after [47.95])

tal measurements, converted power rises from 16.37 W (Re = 90 667, $U^* = 7.43$) to 49.35 W Re = 113 076, $U^* = 9.29$). The harnessed power envelope calculated by 2-D-URANS simulation is close to that obtained by experiments. The small discrepancy is mainly due to two reasons. First, the difference between the damping models used in the numerical simulation and the experimental apparatus (Sect. 47.3.5, *FIM of Two PTC Cylinders in Tandem*). Second, in the experiments conducted in the LTFSW channel in the MRELab, the cylinder would hit the safety stops limiting its travel in galloping, which leads to the smaller amplitude in the tests than in the simulations.

Even when the values differ a little, the slope of the two graphs in Fig. 47.84 are similar rendering the graphs to have the same trend and thus capturing the important variations in power conversion versus flow speed.

Based on the comparison of experimental and numerical results in Fig. 47.84, we can draw two conclusions:

1. The experimental measurements were conducted for variable spring stiffness K. The optimal points on the power envelope, though, were reached for $K = 2000\,\mathrm{N\,m^{-1}}$ and variable harnessed damping ratio from 0.04 to 0.14 corresponding to different Reynolds numbers or flow velocity (Fig. 47.85). The numerical results were acquired based on fixed harnessed damping ratio $\zeta = 0.12$ by changing spring stiffness K from 400 to $2000\,\mathrm{N\,m^{-1}}$ corresponding to different Reynolds numbers or flow velocity. The simulation results of the harnessed power envelope match very well with the experimental measurements. This demonstrates that optimal points – lying on the power envelope of single PTC-cylinder VIVACE converter – can be achieved in two different ways, for two different pairs of (K, ζ). For example, at Re = 75 000 ($U^* = 7.94$), the harnessed power is 10.49 W for ($K = 1200\,\mathrm{N\,m^{-1}}$, $C = 29.91\,\mathrm{N\,s\,m^{-1}}$), and 10.43 W for ($K = 1036\,\mathrm{N\,m^{-1}}$). The difference in harnessed power between these two pairs is only 0.57%.
2. The experimental results exhibit a local reduction at Re = 90 667 ($U^* = 7.43$). The numerical results exhibit a deep at Re = 105 000 ($U^* = 9.08$). This phenomenon indicates that transition between VIV and galloping can be changed by adjusting the spring stiffness and harnessed damping ratio of the PTC cylinder.

Post-Processing of Experimental or Numerical Simulation Results

In the MRELab, data collected through experimental measurements or CFD simulations are post-processed to extract useful information. Actually, five different mathematical models are used providing complementary information. All five are based on (47.43) and are differentiated based on the simplifying assumptions. They are defined as follows:

1. Math Model #1a [47.119]:
   - The ideal added mass cannot be separated from the hydrodynamic force
   - The response of the oscillator in FIM can be approximated by a sinusoidal function.
2. Math Model #1b [47.119]:
   - The ideal added mass can be separated from the hydrodynamic force
   - The response of the oscillator in FIM can be approximated by a sinusoidal function.
3. Math Model #2a [47.120]:
   - The ideal added mass cannot be separated from the hydrodynamic force
   - The response of the oscillator in FIM cannot be approximated by a sinusoidal function.
4. Math Model #2b [47.120]:
   - The ideal added mass can be separated from the hydrodynamic force
   - The response of the oscillator in FIM cannot be approximated by a sinusoidal function.
5. Math Model #3 [47.121]:
   - It is based on the approach by *Vikestad* et al. [47.60], where the added mass is calculated from the available data. It is further described in Sect. 47.3.7.

Reconstruction of the Lift Force. A key element in the mathematical post-processing of data with any of

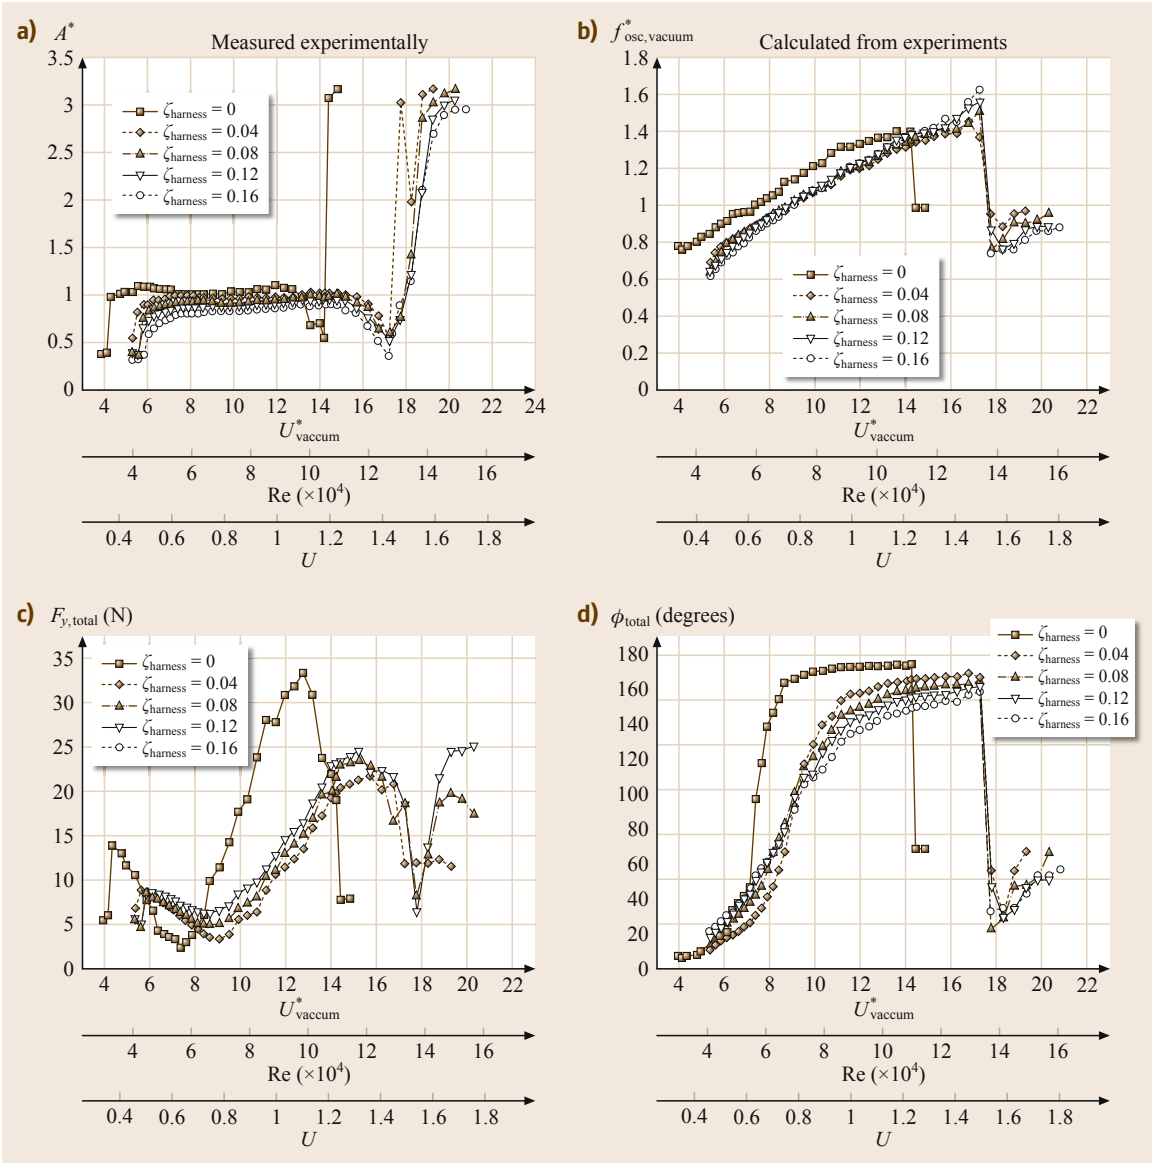

Fig. 47.86a–d Example of post-processing of experimental or CFD data for a given set of runs versus flow speed (after [47.119, 120]). **(a)** Amplitude ratio versus U^*, Re, U. **(b)** Frequency ratio versus U^*, Re, U. **(c)** Total reconstructed transverse force versus U^*, Re, U. **(d)** Total force phase lead over the displacement versus U^*, Re, U

the five mathematical models is the availability of the time history of the lift force. That can be obtained by a load cell or by reconstruction of the force from the displacement time history. Specifically the following steps are used at the MRELab to reconstruct the lift force time history:

1. The displacement is measured through the encoder of the motor of the V_{ck} controller.
2. The time derivative of the displacement is taken using the backward difference.
3. Low-pass filtering is used in MATLAB to eliminate the noise that typically comes with digital differentiation.
4. The phase shift induced by the filtering is eliminated by a MATLAB code.
5. The process is repeated for the second derivative. The accuracy of the methodology has been tested

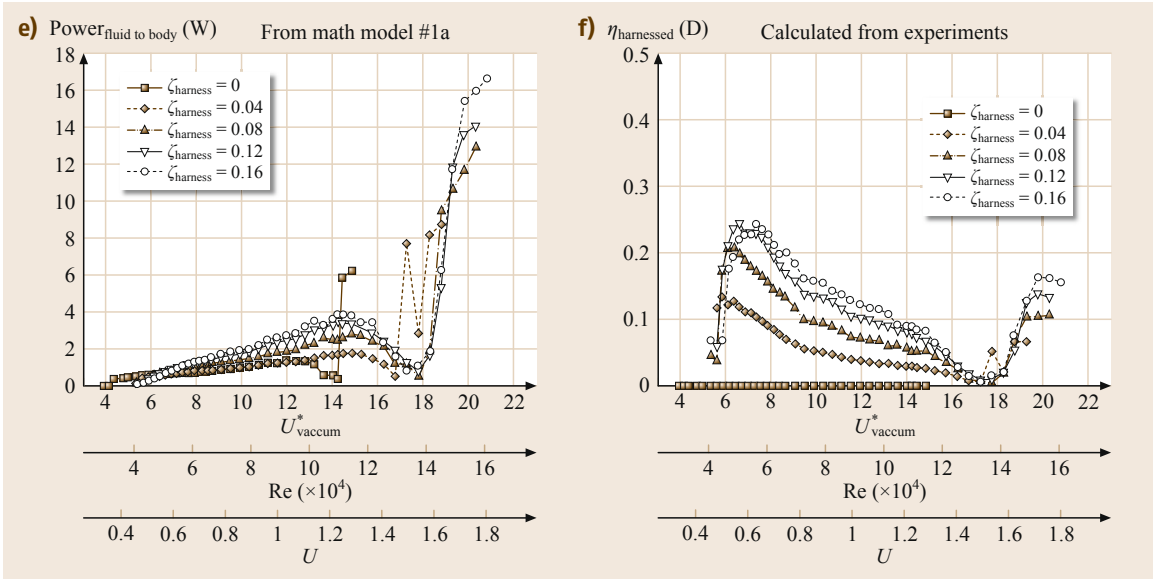

Fig. 47.86e,f **(e)** Power extracted from fluid to body versus U^*, Re, U. **(f)** Total hydrodynamic force versus U^*, Re, U

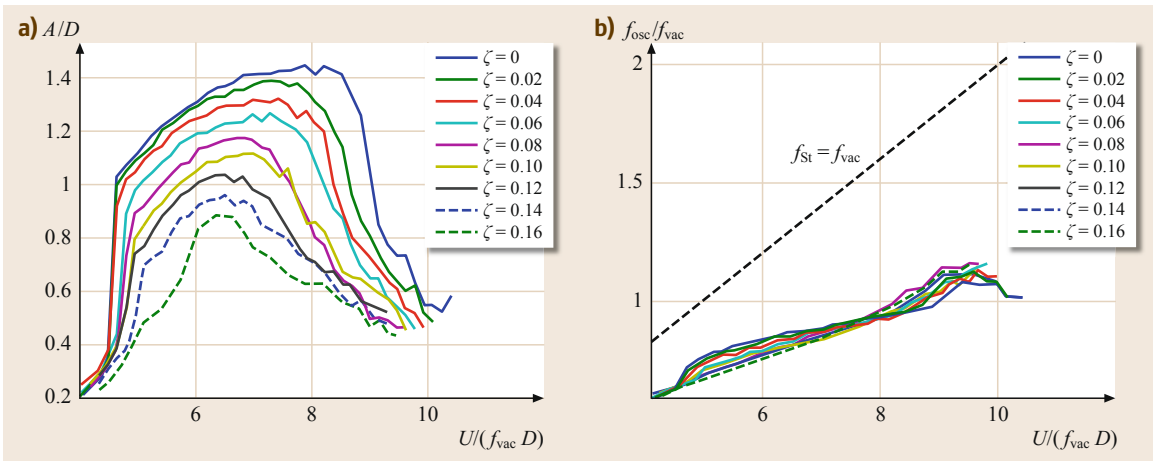

Fig. 47.87a,b Post-processing data by *Lee* and *Bernitsas* [47.100] using the variable added mass mathematical model [47.121]. **(a)** A/D for smooth cylinder in VIV versus **(b)** U^*. f_{osc}/f_{vacuum} for smooth cylinder in VIV versus U^*

repeatedly and the signal reproduction has been excellent.

6. The calculated derivatives along with the values of the coefficients in (47.43) are used to reconstruct the lift force at each time step.

Example of Post-Processing. Some of the results of this post-processing procedure are presented in Fig. 47.86. Specifically, in Fig. 47.86a, the peak amplitude ratio is calculated from the time history, for each velocity, by averaging the highest 40–60 peaks over a time interval of 60 s. Using FFT, the frequency is calculated in Fig. 47.86b. The lift force is reconstructed in Fig. 47.86c following the procedure outlined above. The force phase lead with respect to the displacement is shown in Fig. 47.86d. Generated power and efficiency are shown in Fig. 47.86e,f respectively.

47.3.7 Variable Added Mass Mathematical Model

Based on the procedure presented in Sect. 47.3.6, *Post-Processing of Experimental or Numerical Simulation Results* the lift-force time history can be reconstructed.

A time-averaged variable added mass is then calculated by averaging all periods of oscillation for a given data set. Starting with (47.43) for a cylinder oscillatory system in FIM, VIV or galloping, the following procedure can be used to post-process numerical or experimental data in yet another way.

If the lift force F_{fluid} in (47.43) is assumed to be sinusoidal, shifted in phase from the response of the body in VIV, the following substitutions can be made for $F_{\text{fluid}}(t)$ and $y(t)$

$$F_{\text{fluid}}(t) = F_{\text{o}} \sin(\omega t + \phi) \,, \tag{47.64}$$

$$y(t) = y_{\text{o}} \sin(\omega t) \,. \tag{47.65}$$

This allows (47.43) to be written as

$$\left(m_{\text{osc}} + \frac{F_{\text{o}} \cos\phi}{\omega^2 y_{\text{o}}}\right) \ddot{y} + \left(C_{\text{total}} - \frac{F_{\text{o}} \sin\phi}{\omega y_{\text{o}}}\right) \dot{y} + ky = 0 \,. \tag{47.66}$$

The added mass coefficient C_{a} can be calculated then based on the forcing function as

$$C_{\text{a}} = -\frac{8}{nTm_{\text{d}}(\omega^2 y_{\text{o}})^2} \int_{t}^{t+nt} F_{\text{fluid}}(t)\ddot{y}\mathrm{d}t \,. \tag{47.67}$$

The corresponding natural frequency in water can be calculated, then, as

$$f_{\text{n,water}} = \frac{1}{2\pi} \sqrt{\frac{K}{m_{\text{osc}} + m_{\text{d}} C_{\text{a}}}} \,. \tag{47.68}$$

This analysis is straightforward and was presented by *Vikestad* et al. [47.60].

In order to test the idea that a time-averaged variable added mass coefficient better captures VIV with the resonance model, previously collected VIV data by *Lee* et al. [47.98] are post-processed below and plotted in Figs. 47.87–47.89. The particulars of the VIVACE system used for analysis are given in Table 47.11. Figure 47.88 shows that the added mass coefficient may take negative values. On the other hand, the frequency of oscillation becomes equal to the calculated natural frequency in water over the entire range of VIV synchronization.

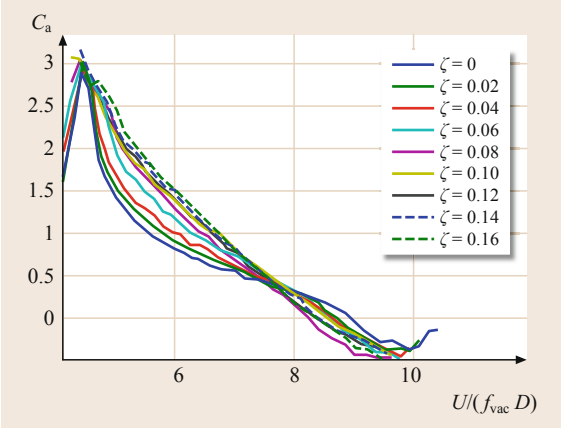

Fig. 47.88 Calculated added mass coefficient for smooth cylinder in VIV versus U^*

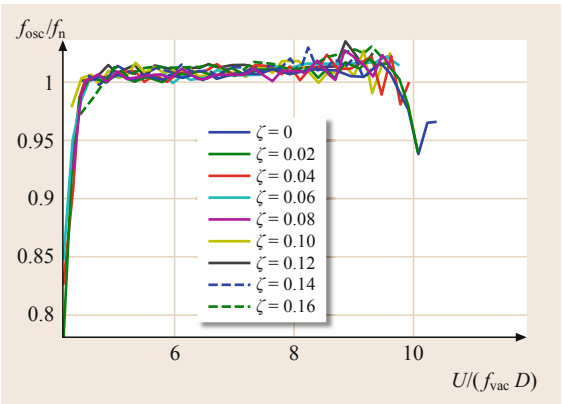

Fig. 47.89 Calculated $f_{\text{osc}}/f_{\text{n}}$, water for smooth cylinder in VIV versus U^*

Table 47.11 Properties of oscillator

Parameter	Value

K [N m^{-1}]	400–1800
ζ	0–0.16

47.3.8 Physical Models and Model Equivalence

A major challenge that the MRELab has been addressing in its research on MHK energy conversion using FIM is the reduction of data and models to a common equivalence. That is a challenge within the models in the same laboratory and of course it becomes even more of a challenge when processing data from different laboratories. This challenge has multiple facets:

1. Springs are not necessarily linear even when they are used for the first time
2. Viscous damping is by no means linear
3. Flows perpendicular to the cylinder may not be fully two-dimensional even in VIV due to tip-flow effects

Table 47.12 Experimental parameters of two models

Device parameter	VIV oscillator	VIVACE converter
$m*$	1.725	1.67
$f_{n,water}$	1.1183	1.0141
ζ	0.0158	0.02

4. FIM models are designed totally different from MHK-energy converters and thus results would not be comparable.

The first two cases have been handled in the MRELab using the V_{ck} controller, which simulates a mathematically accurate oscillator with whatever linear or nonlinear function for damping and spring stiffness desired. The third challenge is assessed next in Sect. 47.3.8, *Tip-Flow Effect*. The last challenge is major and is only stated in Sect. 47.3.8, *Experimental Model Equivalence*.

Tip-Flow Effect

Tip flow limits the cylinder length over which positive lift is exerted in the transverse direction when the cylinder is in FIM. Negative lift is typically exerted on the rest of the cylinder length, which is affected by the tip flow. Figure 47.90 shows schematically the first LTFSW channel setup with the VIV oscillator and the VIVACE converter as set in the new LTFSW channel. The parameters of the oscillators used in the experiments in both setups are summarized in Table 47.12. Although the parameters are not exactly equal, it is believed that they are sufficiently close to illustrate quantitatively the effect of the tip flow.

Figure 47.91 compares the results of tests of the VIV oscillator versus the VIVACE converter. The maximum amplitude and the range of synchronization obtained with the converter setup are significantly smaller than those obtained by *Park* et al. [47.70, 71, 149] for the VIV oscillator. This is attributed to the tip-flow effects evaluated by *Kinaci* et al. [47.178].

This effect is different in each oscillator and has to be evaluated before FIM data can be considered comparable. The tip-flow effects may become dramatic as in the field tests in canals in the Netherlands with the converter shown in Fig. 47.20.

The VIVACE converter model for energy extraction includes all the conversion equipment and the supporting struts underwater resulting in high tip-flow effects. It allows, though, for up to seven-diameter amplitude due to the bigger depth of the test section of the new channel (Fig. 47.92). Measurements of the setup are provided in the same figure. The struts are inside the water and take a considerable amount of space of the test cross-section. The width of the channel is $w_c =$ 100.8 cm with 3.8 cm wide struts at each side. The struts

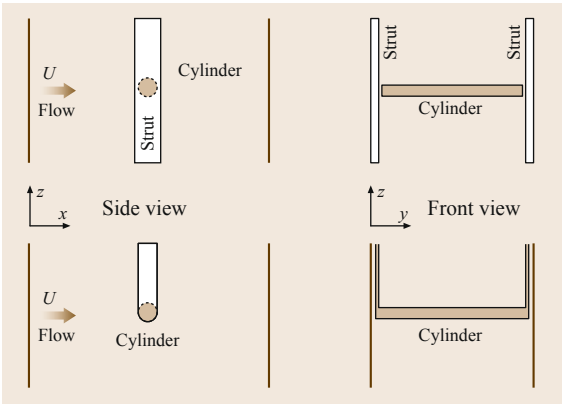

Fig. 47.90 Schematic view of the VIVACE converter used in the new channel and the VIV oscillator used in the first LTFSW channel (after [47.178])

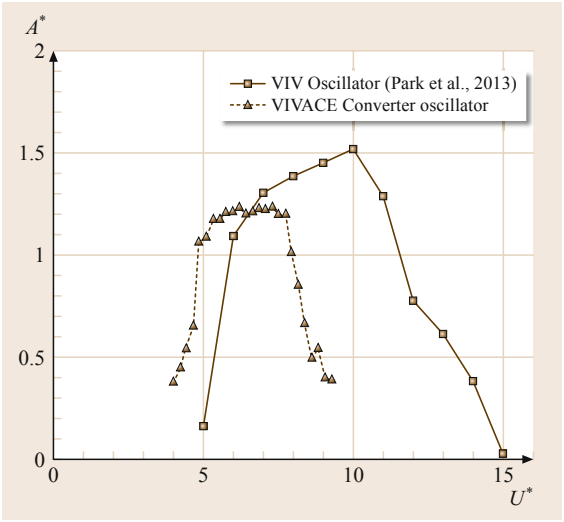

Fig. 47.91 Comparison of VIV response of VIV oscillator and converter oscillator with parameters shown in Table 47.1 (after [47.71, 72, 178])

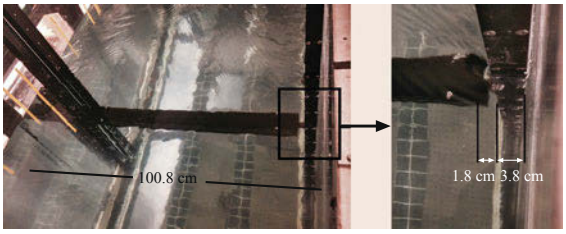

Fig. 47.92 VIVACE converter model in the new LTFSW channel (photo courtesy of MRELab)

are attached to the plexiglass side-walls of the channel. There is 1.8 cm of free space between the strut and the cylinder at each side. The length of the cylinder is

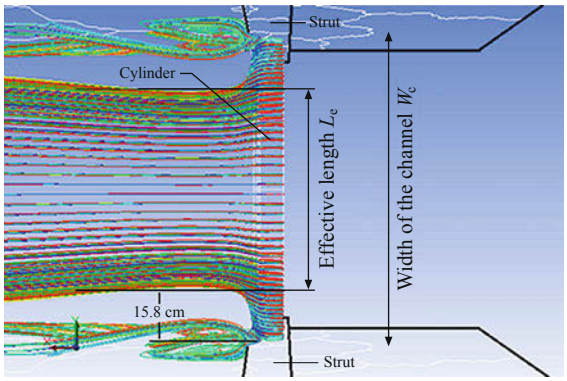

Fig. 47.93 Effective cylinder length from 3-D-URANS simulations for the new LTFSW channel at Re = 75 000 (after [47.176])

89.6 cm. That is, the converter oscillators serve a different purpose than the VIV oscillators in the first channel. Comparison between these two extreme cases of tip-flow effect provides valuable information on tip flow.

The effective length of the cylinder, which is generating lift, can be detected by studying the streamlines produced by the 3-D steady CFD analysis (Fig. 47.93). It is concluded that 15.8 cm of the cylinder at each end do not contribute to generating lift, reducing the effective length of the cylinder. So the effective length, L_e becomes

$$L_e = 100.8\,\text{cm} - 2(3.8\,\text{cm} + 1.8\,\text{cm} + 15.8\,\text{cm}) = 58\,\text{cm}\,. \quad (47.69)$$

Substituting the effective length of the cylinder L_e and the channel width w_c into (47.17), a tip-flow effect factor α, for this experimental setup, can be calculated as

$$\alpha = 0.5752\,. \quad (47.70)$$

Experimental Model Equivalence

The five blockage effects discussed in Sect. 47.3.1, *First Low-Turbulence Free-Surface Wake (LTFSW) Channel* and the four factors listed at the beginning of Sect. 47.3.8 result in sources of variability in the data collected about FIM. For proper comparison of data collected from different labs, different experimental devices, and particularly from diverse sources, such as FIM oscillators, ALT converters, or flexible risers, a major research effort would be required, which is beyond the scope of this review study.

47.3.9 Benchmarking

Benchmarking is difficult at best given that different technologies, and particularly MHK energy devices, have different ways of assessing their performance. More recently instead of efficiency data, comparisons have been based on power density ratios, such as power-to-weight or power-to-volume data. Table 47.13 shows data from wave-energy devices and data from recent VIVACE converter calculations. Conditions of course are very different between wave fields and ocean currents. In addition, it is debatable whether ballast should be part of the weight considered or volume includes space occupied by the structure only or its anchoring or mooring system as well since those do not allow alternative use of their space.

The advantage that the VIVACE converter has besides being able to operate efficiently even in low speed flows is the ability of cylinders to work synergistically generating more power in a properly deigned compact array rather than in isolation (Fig. 47.29). The gain from the hydrodynamic interaction is significant but the weight reduction due to the compact size of the converter has a bigger positive effect on the power density of VIVACE.

Closing Remarks

Horizontal MHK energy, encountered in rivers, ocean currents, and tides, is an abundant resource. Current technology is not capable of accessing efficiently and at a competitive cost the vast majority of the horizontal MHK energy because ocean currents are typically slower than 3 kn and rivers are slower than 2 kn. The MHK-energy industry has to overcome several challenges in technology development, market, and regulatory challenges before it can reach maturity. MHK energy harnessing technologies need research breakthroughs to improve their power-to-weight ratio before they can become competitive with other renewable energy technologies. Steady-lift technologies (SLT) are turbines and dominate the efforts to harness horizontal hydrokinetic energy. They are in need of a breakthrough to reduce their minimum flow speed threshold of $2\,\mathrm{m\,s^{-1}}$.

Alternating-lift technologies (ALTs) provide an alternative means to harness horizontal MHK energy. ALTs are in the form of an oscillator taking advantage of fluid–structure interaction instabilities. They come in two forms: hydrofoils in flutter instability or bluff bodies in vortex-induced oscillations, galloping, or coexistence of the two. In multiple body ALTs, gap flow may be used to further enhance the oscillator dynamics. Vortex streets and multibody interactions provide alternating lift and are used by fish to propel efficiently in water. Thus, ALT dynamics is natural in the marine environment. Both mechanisms are highly scalable occurring practically over the entire range of Reynolds numbers. By employing vortex streets, triggering galloping instability, and even superposition of VIV and galloping, nonlinear oscillators can be built using the naturally occurring alternating lift in all steady flows from very slow to very fast. Interference between two-dimensional bodies with bluff cross-section in close proximity can induce much more vigorous FIM response of the same bodies in isolation. That enables increased hydrokinetic energy conversion to mechanical energy in an oscillator, while at the same time reducing the space occupied by the MHK energy conversion device.

The VIVACE converter is probably closest to commercialization among ALTs and has the following properties:

1. It is based on alternating lift naturally occurring in the marine environment
2. The underlying physical mechanisms are highly scalable enabling the conversion of MHK energy to mechanical even at very slow flows
3. Multiple body interference enables higher conversion of MHK energy to mechanical in an oscillator
4. Proximity of bodies reduces occupied space by VIVACE resulting in higher power density of conversion
5. By properly configuring multiple cylindrical oscillators in close formation, a three-dimensional converter can be designed to have a positive impact on the power-to-volume ratio, which is the Achilles heel of all renewable energy devices.

Development of new MHK energy technologies requires extensive basic research using large experimental facilities like towing tanks, recirculating channels, control mechanisms to ensure a mathematically accurate oscillator model without including the hydrodynamic force in the closed loop, flow visualization, and computational fluid dynamics.

The MHK-energy industry has not reached the maturity level, where it can contribute to a national or international renewable energy portfolio. The next 5–10 years will be a critical period for development of new MHK energy technologies. If the industry does not succeed in demonstrating a robust and reliable SLT or ALT, which can compete with other renewable and conventional energy technologies on the basis of LCOE, governments and private investors alike may lose interest in this vast source of energy.

47.4 Nomenclature

Latin symbols:

- A: Amplitude value of the transverse displacement
- A^*: Amplitude ratio A/D, average of the 60 highest peaks
- ALT: alternating-lift technology
- c, C_{total}: Total damping
- c_{bearing}: Friction damping
- c_{harness}: Harnessing damping
- C_{a}: Potential flow added-mass coefficient of a circular cylinder ($C_{\mathrm{a}} = 1.0$)
- $C_{\mathrm{Y,total}}(t)$: Instantaneous lift force coefficient
- $C_{\mathrm{y,total}}$: Lift force coefficient
- $C_{\mathrm{Y,vortex}}(t)$: Instantaneous vortex force coefficient
- $C_{\mathrm{y,vortex}}$: Vortex force coefficient
- d: Spacing between cylinders in tandem
- D: Diameter of cylinder
- $f_{\mathrm{n,vacuum}}$: Natural frequency in vacuum $= f_{\mathrm{n,vacuum}} = 1/(2\pi)\sqrt{k/m_{\mathrm{osc}}}$
- $f_{\mathrm{n,water}}$: Natural frequency in water $= f_{\mathrm{n,water}} = 1/(2\pi)\sqrt{k/(m_{\mathrm{osc}} + m_{\mathrm{a}})}$
- f_{osc}: Body oscillation frequency

- $f^*_{\mathrm{osc,vacuum}}$: Vacuum oscillation frequency ratio $= f^*_{\mathrm{osc,vacuum}} = f_{\mathrm{osc}}/f_{\mathrm{n,vacuum}}$
- $f^*_{\mathrm{osc,water}}$: Water oscillation frequency ratio $= f^*_{\mathrm{osc,water}} = f_{\mathrm{osc}}/f_{\mathrm{n,water}}$
- $F_{\mathrm{Y,potential}}$: Instantaneous potential force in transverse direction
- $F_{\mathrm{Y,total}}$: Instantaneous total force in transverse direction
- $F_{\mathrm{Y,vortex}}$: Instantaneous vortex force in transverse direction
- k: Average grit height
- k, K, K_{virtual}: Spring constant
- L: Cylinder length
- m_{osc}: Oscillating mass
- m_{a}: Added mass
- m_{d}: Displaced fluid mass
- m^*: Mass ratio $m^* = m_{\mathrm{osc}} m_{\mathrm{d}}$
- P: Thickness of sand paper
- $P_{\mathrm{F-B}}$: Hydrokinetic power converted to body mechanical power
- $P_{\mathrm{F(D)}}$: Hydrokinetic power in fluid through height D
- $P_{\mathrm{F(2A+D)}}$: Hydrokinetic power in fluid through height $2A + D$
- $P_{\mathrm{dissipated}}$: Dissipated power P_{fluid} power in the fluid
- $P_{\mathrm{harnessed}}$: Harnessed hydrokinetic power converted to body mechanical power
- PTC: passive turbulence control
- Re: $= UD/\nu$ Reynolds number
- S_{ij}: Mean strain-rate tensor
- St: Strouhal number
- t: Time
- T: Total thickness of strip
- T_{osc} : A period of cylinder oscillation
- U: Flow velocity
- U^*_{vacuum} : Reduced velocity $= U/(f_{\mathrm{n,vacuum}} D)$
- U^*_{water}: Reduced velocity $= U/(f_{\mathrm{n,water}} D)$
- $y(t)$: Instantaneous cylinder motion in transvers direction.

Greek symbols:

- ζ_{vacuum}: $c/(2\sqrt{m_{\mathrm{osc}} k})$ Total damping ratio including friction and power harnessing
- ζ_{water}: $c/(2\sqrt{k(m + m_{\mathrm{a}})})$ Total damping ratio including friction and power harnessing considering added mass
- $\eta_{(\mathrm{D})}$: $\eta_{\mathrm{D}} = P_{\mathrm{F-B}}/P_{\mathrm{F(D)}}$ Efficiency with respect to fluid of height D
- $\eta_{(2A+D)}$: $\eta(2A + D) = P_{\mathrm{F-B}}/P_{\mathrm{F(2A+D)}}$ Efficiency with respect to fluid of height $2A + D$
- $\eta_{\mathrm{harnessed}(D)}$: $\eta_{\mathrm{harnessed}(D)} = P_{\mathrm{harnessed}}/P_{\mathrm{F(D)}}$ efficiency with respect to fluid of height D
- $\eta_{\mathrm{harnessed}(2A+D)}$: $\eta_{\mathrm{harnessed}(2A+D)} = P_{\mathrm{harnessed}}/P_{\mathrm{F(2A+D)}}$ efficiency with respect to fluid of height $2A + D$
- μ: Dynamic viscosity of water
- μ_{t}: Turbulence eddy viscosity
- ν: Fluid kinematic viscosity
- ρ: Water density
- τ_{ij}: Reynolds-stress tensor
- ϕ_{total}: Phase angle between total lift force and cylinder motion
- ϕ_{vortex}: Phase angle between vortex lift force and cylinder motion
- $\omega_{\mathrm{n,vacuum}}$: Undamped natural frequency of the system in vacuum
- $\omega_{\mathrm{n,water}}$: Undamped natural frequency of the system in water
- ω_{osc}: Angular frequency of oscillation.

48. Ocean Thermal Energy Conversion

Muthukamatchi Ravindran, Raju Abraham

Ocean thermal energy conversion (OTEC) utilizes the thermal gradient available in the ocean to operate a heat engine to produce work output. Even though the concept is simple and old for almost one century, during last three decades, it has gained momentum due to worldwide search for a clean, continuous energy source to replace the fossil fuels. There are technological hurdles to overcome to tap the immense potential of OTEC. But still the technology is mature enough to establish commercial power plants. This chapter presents the technological and economical aspects of the OTEC with an overview of the current status. It also suggests some further research and technological guidance based on the Indian OTEC experiences for this promising technology for future.

Sun warms the oceans at the surface and wave motion mixes the warmed water downward to depths of about 100 m. This mixed layer is separated from the deep cold water, formed at high latitudes, by a thermocline. This boundary is sometimes marked by an abrupt change in temperature, but more often the change is gradual. The resulting vertical temperature distribution, therefore, consists of two layers separated by an interface with temperature differences between them ranging from 10–25 °C. Higher values are found in equatorial waters. This simplistic description implies that there are two enormous reservoirs, in some oceanic regions, providing the heat source and sink required to operate a heat engine. The concept of utilizing the ocean temperature difference is referred to as OTEC or ocean thermal energy conversion.

48.1 OTEC Principles and Systems

OTEC is an energy technology that converts solar radiation to electric power. As long as the temperature between the warm surface water and the cold deep water differs by about 20 °C, an OTEC system can produce a significant amount of power which is economical. This potential is estimated to be about 10^{13} W of base load power generation. The cold deep seawater used in the OTEC process is also rich in nutrients, and it can be used to culture both marine organisms and plant life near the shore or on land.

The annual incidence of solar energy, in the form of short wavelength radiation, on the Earth is about 1.52×10^{18} kWh (1.73×10^{14} kW in units of power) of which as much as 70% is absorbed as heat by our ocean–land–atmosphere system to eventually be radiated back to space as long-wave radiation. This is

equivalent to an incidence of 240 W/m^2. The actual amount absorbed by the oceans corresponds to an incidence of 95 W/m^2 or 37×10^{12} kW over the surface of the oceans [48.1]. This incidence value represents an enormous amount of power compared to our human consumption. The amount of solar power absorbed by our oceans is equivalent to at least 4000 times the amount presently consumed by humans [48.2]. For a conversion efficiency of 3% from ocean energy to electricity as in the case of OTEC, we would need 1% of this renewable energy to meet the total demand of present requirement. The removal of such a relatively small value of ocean solar energy does not create an adverse environmental impact and technologies must be developed to transform it to a useful form and to transport it to the user.

In an OTEC plant, large quantity of water is to be transported to the surface from 800 to 1000 m depths, with temperatures ranging from 8 to 4 °C. Utilizing the warm surface water at 27–29 °C and the deep-sea cold water, energy is extracted. This concept is based in the thermodynamic Rankine cycle used in steam power plants. Figure 48.1 shows the distribution in the temperature difference between the surface seawater and

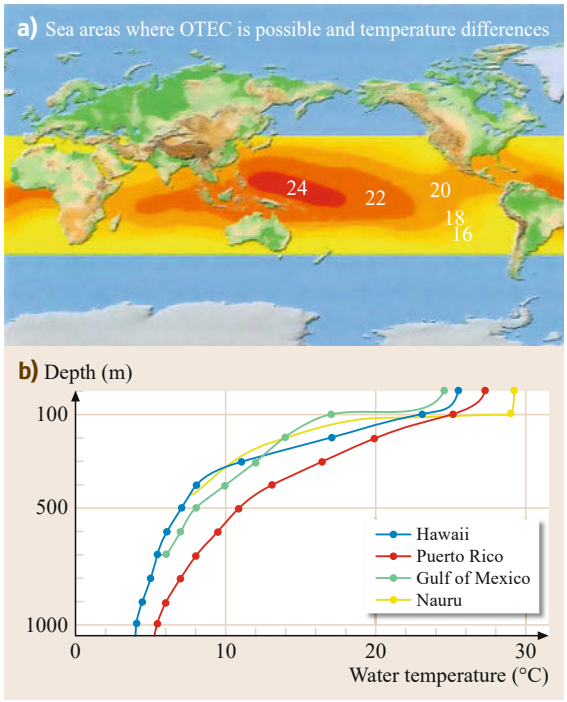

Fig. 48.1a,b Temperature variation with depth of the sea. **(a)** Ocean surface with the availability of different temperature differences in the tropical region; **(b)** vertical temperature distribution at four different locations (courtesy of Saga University, Japan)

1000 m depth across the world. The performance of OTEC power generating cycles is assessed with the same elementary concepts of thermodynamics used for conventional steam power plants. The major difference arises from the large quantities of warm and cold seawater required for heat transfer processes, resulting in the consumption of 20–40% of the power generated by the turbine-generator in the operation of pumps.

OTEC is capital intensive; however, improvements in technology and higher rated plants can bring down the unit cost considerably. For the mainland, the cost of power generation for plants upward of 25 MW is expected to be comparable to fossil fuel units. But for islands, an OTEC power plant of any size is cheaper than the conventional generation units. Countries like India are geographically well placed as far as the OTEC potential is concerned. Upwelling of deep sea cold water can be an answer to issues such as global warming and food scarcity.

48.1.1 Spin-Off Technologies

The primary benefit of OTEC system is to produce electricity. The turbine–generator system of the OTEC power cycle can generate electricity in a continuous mode compared to other renewable energy systems which are intermittent. There are spin-off technologies associated with OTEC which is of commercial interest. Larger OTEC plants can be used for producing electricity, water, and other spin-off benefits such as air conditioning and aquaculture (Fig. 48.2).

Desalination

A two-stage OTEC cycle, wherein electricity is produced in the first stage followed by water production in the second-stage, has also been proposed to maximize the use of the thermal resource available to produce both water and electricity [48.3]. In the second stage, the temperature difference available in the seawater effluents from an OTEC plant (i. e., about 10–12 °C) is used to produce desalinated water through a system consisting of a flash evaporator and a surface condenser. The simultaneous production of desalinated water and power has been considered to be economically attractive for the Island market. For example, a 50 MW hybrid cycle plant producing as much as 62 000 m^3 of water per day could be tailored to support a developing community of approximately 300 000 people or as many as 100 000 people in an industrialized nation.

Air-Conditioning

The use of the cold deep water as the chiller fluid in air-conditioning systems has a tremendous economic potential by providing significant energy conservation, in-

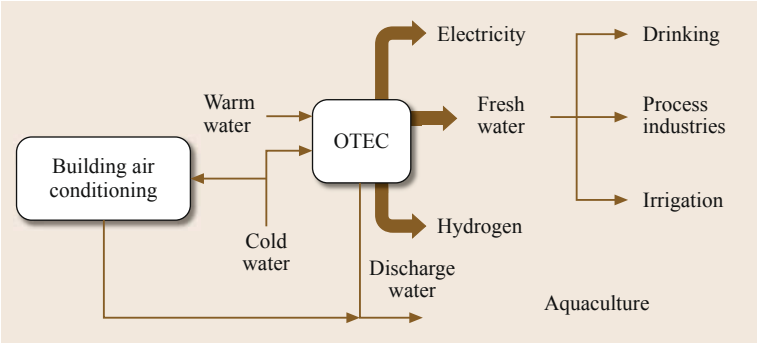

Fig. 48.2 OTEC spin-off technologies

dependent of OTEC. For example, only 1 m^3/s of 7 °C deep ocean water is required to produce 5800 t (roughly capable of cooling 5800 rooms) of air conditioning, consuming 360 kW, mostly in pumping seawater, while saving the equivalent of 5000 kWe with an investment payback period estimated at 3–4 years [48.4]. The same amount of seawater could only support a 500 kWe OTEC plant (1/10 of the power saved with the AC (air-conditioning) system).

Aqua-Culture

The deep-sea cold water is very rich (nearly 28 times) in inorganic nutrients such as nitrates, phosphates, silicates, and it can be commercially used for sea farming. There are several significant deep sea-water aquaculture research facilities in many countries such as Japan (Toyama Bay and Kochi) and US (Hawaii). The commercial utilization of deep sea water is already initiated in Hawaii. It has been estimated that the annual revenue from fish culture from a 10 MW OTEC mari-culture facility is $3.3 million/year [48.5]. The aquaculture of abalone, kelp, nori, micro algae, lobster, salmon, oysters sea urchins, etc. were successfully demonstrated at Hawaii. As the deep-sea cold water is comparatively pure, sensitive larval stages of species can thus be grown without expensive purification and filtration needed when surface water is used.

Production of Metals

Sea water contains metals such as uranium, lithium, etc. Large quantity of sea water is pumped through the OTEC system and discharged back into the sea. Deep sea water is having higher concentration of many of these metals. Extractions of these minerals are an additional benefit of the OTEC system and attempts are made in many research laboratories [48.6].

48.1.2 Types of OTEC Plants

OTEC plants are classified based on the location of the plant established as well the thermodynamic cycle used. The cost and size of the plant is determined by the thermodynamic cycle and the working fluid used.

OTEC Plants Based on Location

Depending upon the availability of deep sea near the coast for a depth of 600–1000 m, the OTEC system could be installed in three possible types of locations.

Floating Plants. When the distance of deep sea from coast is large, that is, 10–15 km or more from the shoreline the OTEC plant could be placed on a floating platform with a cold water pipe suspended vertically down. An underwater cable is needed for power transmission to shore. Alternately, the energy generated may be utilized to produce energy intensive materials like ammonia or hydrogen from the seawater. The products have to be transported to the main land by ships. Keeping the position of the floating platform under the action of waves, wind, and currents needs careful considerations during the design.

Shelf-Mounted Plants. The sea bed is shallow for some distance and then moves steep and the distance of 1000 m contour is around 10 km, the OTEC plant could be mounted on a platform at the end of shallow water area and the generated power can be transmitted to the mainland by underwater cables. A tower is built in a water depth at around 50–100 m where the bed starts sloping down.

Land Based Plants. If the deep-water conditions are available within 2–3 km of the coast, the entire plant could be situated on land with the cold-water pipeline running along the ocean bed to a depth of 800–1000 m. This eliminates the costly structures for floating platform or shelf-mounted platform.

OTEC Plants Based on Power Cycles

There are basically three types of OTEC processes: closed cycle, open cycle, and hybrid cycle based on the thermodynamic process. Much efforts were made in the

past for optimizing the cost of OTEC using power cycle analysis [48.7, 8].

Closed Cycle Plants. In the closed-cycle system, heat transferred from the warm surface seawater causes the low boiling point working fluid (such as ammonia), to evaporate. The expanding vapor drives a turbine attached to a generator, which produces electricity. Cold seawater passing through a condenser containing the vaporized working fluid turns the vapor back into liquid, which is then recycled through the system (Fig. 48.3). Technology for the manufacture of ammonia turbines with a low pressure ratio required for the closed-cycle plant is available. The heat exchangers having close temperature approach for OTEC applications can be of either titanium or aluminum plate heat exchangers. It is easy to scale up a closed cycle plant to 5, 25, or even 100 MW OTEC plant.

Open Cycle Plants. Open-cycle OTEC plant uses the warm surface water itself as the working fluid. The water vaporizes in a near vacuum at surface water temperatures. The expanding vapor drives a low-pressure turbine attached to a generator, which produces electricity. The vapor, which has lost its salt and is almost pure fresh water, is condensed back into a liquid by exposure to cold temperatures from deep ocean water. If the condenser keeps the vapor from direct contact with seawater, the condensed water can be used for drinking water, irrigation, or aquaculture. A direct contact condenser (DCC) instead of surface condenser produces more electricity, but the vapor is mixed with cold seawater and that mixture is returned to the ocean. The process is repeated with a continuous supply of warm surface seawater (Fig. 48.4).

Since the pressure drop across the turbine is the difference between the pressure at which the water vaporizes and the lower pressure remaining after condensation, open-cycle systems require very large turbines to capture relatively small amounts of energy. George Claude, the inventor of the open-cycle process, calculated that a 6 MW turbine would need to be about 10 m in diameter, and he could not design a realistic turbine larger than this. Recent re-evaluation of Claude's work indicates that modern technology cannot improve significantly on his design, so it appears that the open-cycle turbines are limited to about 6 MW. The multiple turbines required for a commercial-sized OTEC plant will significantly increase its complexity and reduce its efficiency. Also, a complicated vacuum system is required to create and maintain the vacuum up to 25 m bar.

In an ideal open-cycle plant, the vacuum pumps could be shut down after start-up, since all the water vaporized in the evaporator would be condensed in the condenser, leaving behind a vacuum. However, vacuum leaks and noncondensable gases dissolved in the surface and deep seawater necessitate continuous operation of the vacuum pumps. The overall thermal to electrical efficiency of these traditional open- and closed-cycle OTEC plants is very similar, approaching 2.5%. The following are the advantages of using an open cycle:

- Conventional surface heat exchanger is eliminated.
- Production of potable water is an additional benefit.
- Water itself is the working fluid and hence no environmental pollution.

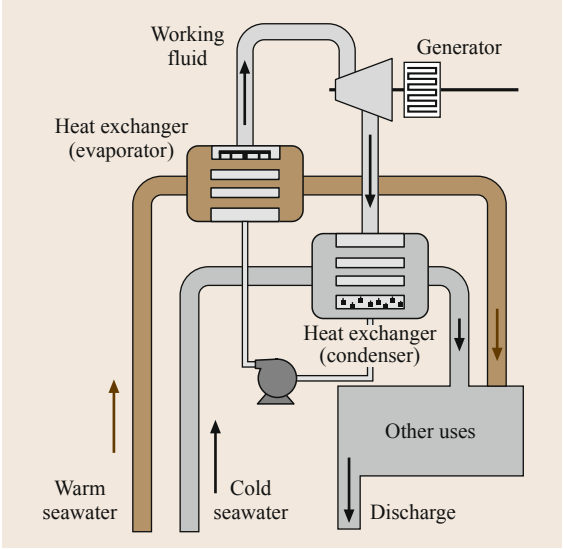

Fig. 48.3 Closed cycle OTEC plant

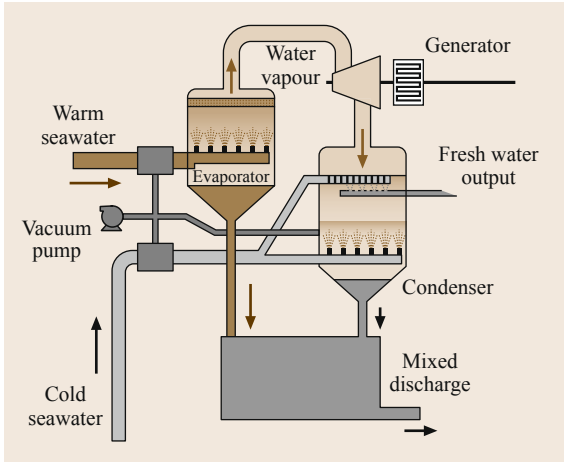

Fig. 48.4 Open cycle OTEC plant

Panchal–Bell Cycle. Panchal–Bell cycle is a combination of the closed and the open cycle. In the Panchal–Bell cycle, steam from flash evaporation of warm water is condensed on the surface of a heat exchanger containing liquid ammonia, which vaporizes to form the working fluid for the closed cycle. Condensed steam is discharged to the ocean or may be saved as a source of fresh water. The Panchal–Bell cycle has a number of potential advantages, compared to the closed and open cycles such as the elimination of low-pressure turbine, reduced heat exchanger area.

Hybrid Cycle Plants. Hybrid systems is similar to Panchal–Bell cycle in which parts of both open- and closed-cycle systems to optimize production of electricity and fresh water. The warm water discharge from the evaporator is sent to a flash chamber where it is flash evaporated. The vapor thus produced is condensed back to fresh water in a desalination condenser using the cold-water discharge from the closed-cycle condenser. The warm water enters a flash chamber under vacuum condition where it is flash-evaporated into steam, in a similar fashion to the open-cycle evaporation process. The vaporized working fluid in the evaporator would then drive a turbine to produce electricity and is condensed back to liquid in the condenser. A vacuum pump is connected to the desalination condenser to maintain the vacuum in the flash chamber and desalination condenser (Fig. 48.5). The simultaneous production of power and water is the great advantage and the quantity of power and water can be varied depending on the requirements.

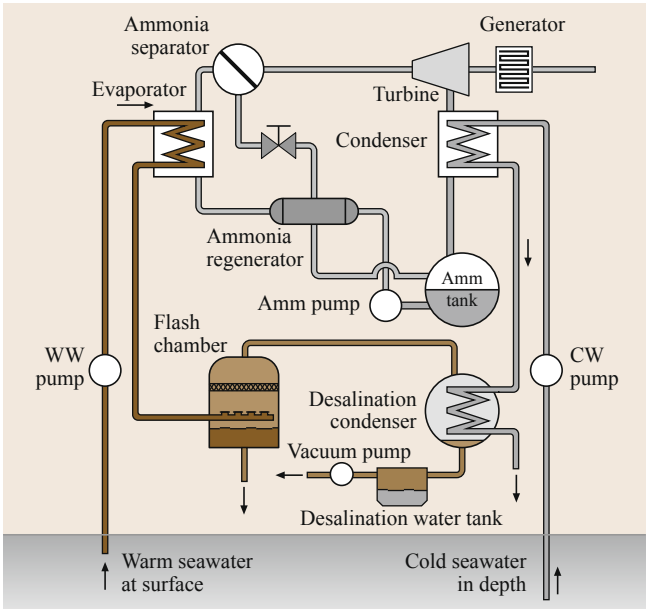

Fig. 48.5 Diagram of the hybrid OTEC process

Advanced Power Cycles

OTEC power cycle utilizes a major portion of net power for pumping the sea water and working fluid. As it work with a small temperature difference, the overall efficiency of the power cycle is very less. There are many attempts to improve the overall efficiency of the OTEC power cycle as discussed below.

Kalina Cycle. Among several OTEC systems developed, the leading ones are the Rankine cycle, Kalina cycle, and Uehara cycle. The working fluid used in the Rankine Cycle is pure ammonia where as other cycles use mixtures such as ammonia–water. American Scientist Dr. A. Kalina developed a system using ammonia–water mixture for the working fluid, providing a significant efficiency boost over the earlier Rankine cycle (Fig. 48.6). In the Kalina cycle, after the working fluid (vapor) expands through the turbine and in the phase before it goes into the condenser, it is liquefied using an absorber. Also, in the phase before the working fluid (liquid) goes in to the evaporator, the

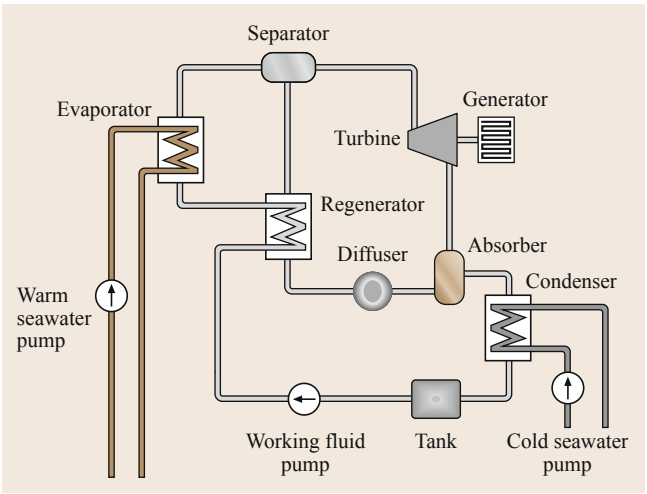

Fig. 48.6 Schematic diagram of the Kalina cycle

vapor that emerges from the evaporator and the liquid that was unable to evaporate is separated by a separator, and the liquid is mixed with the leftover liquid at the regenerator to improve efficiency. Kalina cycle uses a working fluid mixture which has the drawback of lower performance in the evaporator and condenser because some parts easily evaporates or condenses and others do not.

The heat efficiency of the Rankine cycle is about 3% under the conditions of 28 °C surface water and 4 °C deep-sea water, but the Kalina cycle showed astonishingly 5% under the same conditions. But there are

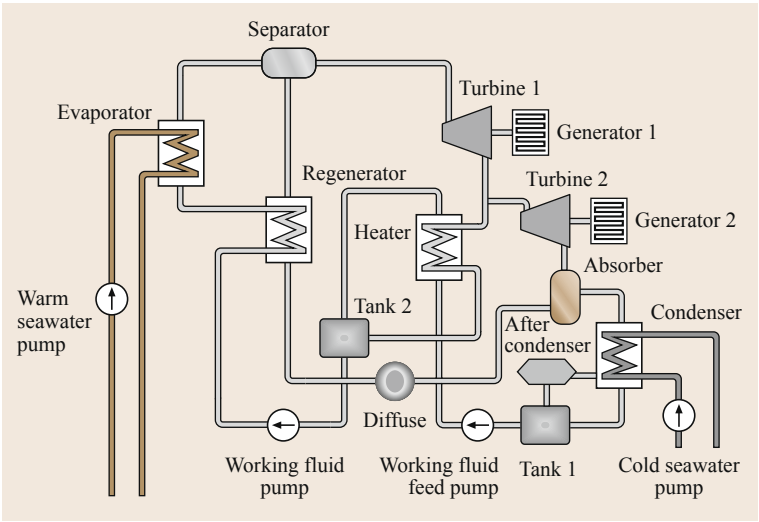

Fig. 48.7 Schematic diagram of Uehara cycle

problems too such as, as compared to the Rankine cycle, the fairly large loss of efficiency of both evaporator and condenser, which was due to the working fluid of ammonia–water mix.

Uehara Cycle. Uehara cycle provides an additional turbine and lessens the load on the condenser by extracting the vapor from the first turbine [48.9]. Extraction means drawing the vapor out of the turbine after it has done its work but has not completely expanded out of the turbine (drawing some of the vapor out of the turbine). In addition, the extracted fluid and the liquefied one by the condenser are heated by a heater in the phase before it enters the regenerator, thereby increasing efficiency. The cycle also has an *after condenser*, which liquefies the vapor that could not be liquefied in the condenser (Fig. 48.7).

Comparison of Cycles. The Kalina cycle has added a separator, a regenerator, and an absorber to improve its efficiency. Uehara cycle has added a second turbine, a heater, and an after-condenser to improve its efficiency much more. In the Kalina cycle, because of the heavy load on the evaporator and condenser, the intake volume of seawater could not be reduced. In the Uehara cycle, the intake volume could be reduced, making it possible to reduce the diameter and weight of the intake pipe. While the Kalina cycle has only one turbine Uehara cycle has two turbines. Vapor that comes out of the primary turbine is extracted to reduce the load of the condenser. The Uehara cycle shows an improvement in efficiency over the Kalina cycle, but the capital cost of the plant is higher due to the addition of another turbine and heater. Studies of Prof. Uehara show that the thermal efficiency of the Kalina cycle 4.9% and that of Uehara cycle 5.4%. This is 10% higher than that of the Kalina cycle and 30% higher than that of the Rankine cycle. The estimation is done under the operating conditions of 28 °C warm water inlet temperature and 6 °C cold-water inlet temperature.

48.2 History of OTEC Installations Worldwide

The overall research and developments of OTEC in the past are discussed by *Avery* [48.10]. The concept of OTEC was first recognized by the French engineer Arsene d' Arsonval in 1881. However, the first experimental system was designed and built by George Claude in 1929 and was field-tested in Matanzas Bay, Cuba. This OTEC plant generated 22 kW (gross) of power. In Claude's cycle, the surface water is flash-evaporated in a vacuum chamber. The resulting low-pressure steam is used to drive a turbine-generator and the relatively colder deep seawater is used to condense the steam downstream from the turbine. The plant failed to achieve net power production because of a poor site selection and a mismatch of the power and seawater systems. However, the plant did operate for several weeks. This was followed by the design of a 2.2 MW floating plant for the production of up to 2000 tons of ice for the city of Rio de Janeiro. Claude was able to deploy his plant, housed in a ship, about 100 km from the harbor, but unfortunately he failed in his numerous attempts to install the long vertical cold-water pipe required to transport the deep ocean water to the ship, and

Table 48.1 The major events in OTEC History

1881	French scientist J. D'Arsonval presented concept of OTEC
1926	Initial study for commercialization by French scientist Claude
1933	Claude built a floating 1200 kW OTEC plant, but it failed
1970	Research association of New Power Generation System started the experiment as one of the theme
1972	OTEC development program initiated in the USA
1973	Saga University started experiments
1974	OTEC was a priority subject for *Sunshine Project* USA launched their OTEC study under Energy Research and Development Association (ERDA) project First International OTEC Conference in USA
1977	Saga University succeeded in 1 kW OTEC experiment
1979	Mini-OTEC by USA succeeded in generating 50 kW OTEC
1980	The proposal of a 25 MW floating OTEC plant off Tamil Nadu
1981	OTEC-1 experiments to test 1 MWe heat exchangers
1981–1985	Long term bio fouling and corrosion experiments at STF, Hawaii
1981	Tokyo Electric Co. and others succeeded in 120 kW OTEC test in Nauru Republic
1982	Kyushu Electric Co. and others succeeded in generating 75 kW
1982	France proposed to build a 5 MWe shore based plant in Tahiti
1985	Saga University built 75 kW OTEC pilot plant
1990	IOA (International OTEC Association) was organized by Taiwan, USA, Japan and others
1993–1998	USA built 210 kW pilot plant, that is open cycle on Kona
1997	National Institute of Ocean Technology, India and Saga University signed memorandum on technical collaboration
1999	International OTEC/DOWA (Deep Ocean Water Associaton) Conference was held in Imari city, near Saga University
2001	1 MW floating OTEC plant was constructed by NIOT, but failure in cold water pipe deployment.
2002	Forum on desalination using renewable energy in Palau (FDE in Palau) was held in October
2003	New Pilot Hybrid OTEC plant is to be constructed in Saga and 3rd WWF in Kyoto was held in March
2010	10 MW proposed closed cycle OTEC plant by Lokheed Martin at Hawaii

had to abandon his enterprise in 1935. His failure can be attributed to the absence of an offshore industry, and of ocean engineering expertise, as it is today. His biggest technological challenge consisted in installing the required seawater pipes at sea. The situation is markedly different now in that there is a proven record for such operations.

In the 1950s, a French corporation planned the construction of an OTEC plant at Ivory Coast of Africa, generating 3.5 MW of electricity, but later it was dropped due to political reasons. The Gulf oil crisis of 1973, ignited the search for substitutes for petroleum, and re-examined, along with other options like wind energy, solar energy, bio-mass, etc. D'Arsonval's concept was successfully demonstrated in 1979, when a small plant mounted on a barge off Hawaii (Mini-OTEC) produced 50 kW of gross power for several months, with a net output of 18 kW.

This closed-cycle plant was sponsored by private industry and the State of Hawaii. Heat exchangers for a 1 MW OTEC plant, that is, with a thermal rating of about 35 MW, were successfully tested and known as OTEC-1. In OTEC-1, ammonia was used as a working fluid and a polyethylene pipe was used to pump cold water from 670 m depth. Subsequently, a 120 kW gross power, land-based plant was operated for 2 years in the island nation of Nauru by a consortium of Japanese companies. In 1982, a 50 kW closed-cycle land-based OTEC plant was established with plate heat exchangers on the Island of Tokunoshima for 2 years. These plants were primarily used to prove the concept, and were too small to be scaled to commercial size systems. The OTEC plant in a small OC-OTEC land-based

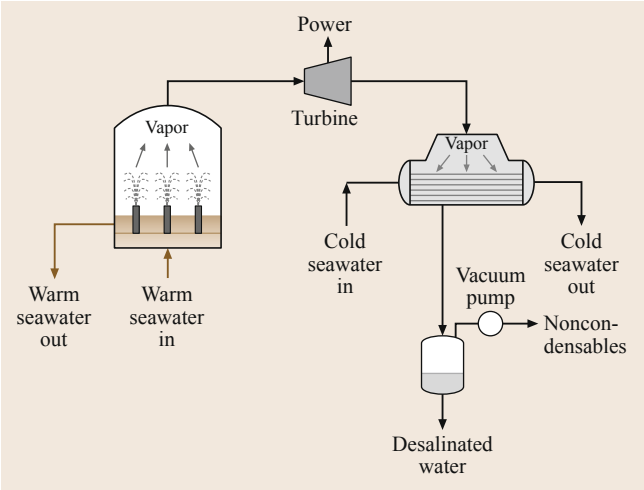

Fig. 48.8 The 210 kW open cycle OTEC plant (1993–98)

Table 48.2 Pilot-scale OTEC systems tests

Serial number	Major project	Salient features	Remarks
1	U.S. Mini-OTEC Program	A complete OTEC system, including a 670 m cold water pipe (CWP), was constructed, deployed, and tested in the Mini-OTEC program, in 1978–1979, The program was conducted with private funding by an industrial team headed by the Lockheed Missiles and Space Division. Mini-OTEC was constructed in 28 months, using off-the-shelf components.	Net power of 18 kW was produced, in close agreement with the predicted performance, The Mini-OTEC program demonstrated OTEC floating system feasibility in 4 months of at sea operation, including first time production of net OTEC power.
2	OTEC-1 Program This program was conducted by DOE to demonstrate OTEC heat exchanger operation at 35 MWt scale in an at sea environment.	A simulated OTEC power system was installed in which the turbine-generator was replaced by a throttle valve that simulated the pressure drop through the turbine. The equipment included a 35 MWt shell and tube heat exchanger, a 700 m-long, 2 m-diameter plastic CWP and pumps. Provision was made for testing bio fouling control methods such as Amertap and chlorine injection. The CWP was assembled on shore then towed to a site roughly 10 miles off-shore from Kailua-Kona, Hawaii, where it was upended and inserted into a gimbal on the ship. The gimbal allowed movement through an angle of 30°. Significant accomplishments demonstrated during the 4 month at sea operation.	(a) The system performed well with a maximum wave height of 4 m, maximum subsurface currents of 3 knots. Wind gusts up to 45 knots and ship roll angle of 18°. (b) The heat exchanger cycle operated in close accordance with predicted performance. Bio fouling control was accomplished with injection of 60 ppb of chlorine, 1 hr per day. (c) Deployment and operation of the CWP were successful. The pipe survived a sea state that caused the pipe to move to a 30° angle at the gimbal.
3.	Japanese Shore-Based 100 kW OTEC Pilot Plant in cooperation with the Republic of Nauru, Tokyo Electric Power Co. and the Toshiba Corpn in 1980 constructed a 100 kW (gross) OTEC plant at a site on the island of Nauru	Power-generating operation was performed from October 1981 to December 1981. Heat-loop operation was continued to July 1982. The Nauru test was designed to provide accurate experimental data on the performance of the complete power cycle as well as demonstrate total pilot-plant construction and operation. The goals were all successfully accomplished.	The plant provided the first demonstration of land based OTEC net power generation and established a record for total net power production, at 31.5 kW. It was also the first demonstration of OTEC power connection to a utility grid.
4	Japanese Mini-OTEC Program. A Mini-OTEC plant was constructed for at-sea tests off the coast of Shimane Prefecture (1979).	The tests included deployment of a steel CWP, 190 m long, made of 12 m-long tubular sections of 26.7 cm outer diameter (OD) and 0.45 cm wall thickness, joined by flanges. The pipe was supported by a float and held in place by a steel cable attached to the pipe and anchored at a depth of 300 m. The OTEC power plant and water pumps were mounted on the research vessel, which was attached to the float.	The program demonstrated successful deployment and operation of the system, including heat transfer measurements.

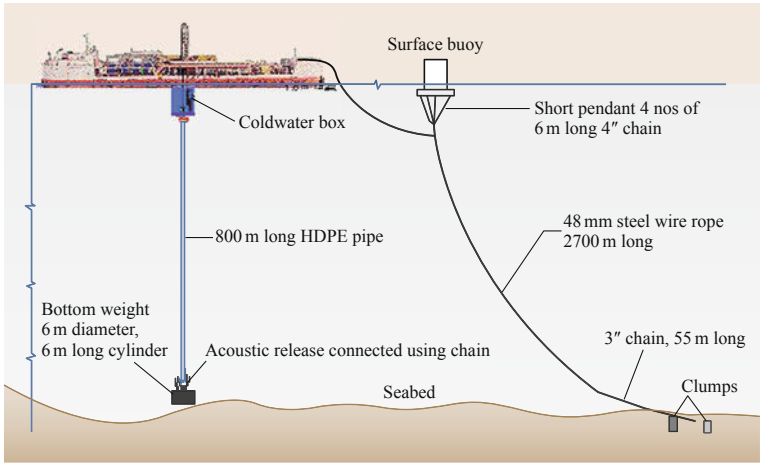

Fig. 48.9 1 MW floating OTEC plant

experimental facility, sponsored by the US Federal Government and the State of Hawaii, at NELHA used a turbine generator that was designed for an output of 210 kWe when the surface seawater temperature is 26 °C and the deep seawater temperature is 6 °C. As of September 1993, the highest surface temperature available was 27.5 °C and correspondingly, 255 kWe (gross) was produced, the largest OTEC output ever recorded (Fig. 48.8). The plant was operational until it was decommissioned in 1998. The major events in the OTEC history are summarized in Tables 48.1 and 48.2.

48.2.1 Indian Experiences

Research on OTEC was intimated in Indian Institute of Technology, Madras, during 1985 with site surveys, feasibility studies, etc. An active work on OTEC was started with the formation of National Institute of Ocean Technology (NIOT), Chennai, in 1993.

Ocean Thermal Energy Conversion

NIOT under the sponsorship of Ministry of Earth Sciences (MoES) designed and developed a 1 MW (gross) floating OTEC plant to be operated between 29 °C and 7 °C using ammonia as the working fluid. The power plant components were assembled on a barge which is to be moored at 1000 m depth using a high-density polyethylene (HDPE) pipe of 1.0 m diameter (Fig. 48.9). The HDPE pipe carries deep-sea cold water to the barge with specially designed moon pool systems. The power cycle of a closed Rankine cycle consists of components such as evaporator, turbine-generator, condenser, and pumps for seawater and working fluid. The warm sea water exchanges heat in the plate heat exchangers with the working fluid, which undergoes a phase change in to vapor and this vapor is allowed to expand in the four-stage axial turbine producing mechanical energy. This turbine drives an AC synchronous generator of 1 MW rating at 440 V and 50 Hz. The vapor from the turbine is allowed to condense in the plate condensers, which is again pumped back to the evaporator using the working fluid pump. Inside the condenser, the heat is exchanged with the cold seawater pumped from the deep sea at 1000 m water depth. The details of the research program are discussed and project could not be commissioned due to failures in the intake joint [48.11–13]. All the precommissioning tests were carried out satisfactorily during 2001–2004 [48.14].

Ocean Temperature Driven Desalination

As spin-off, desalination utilizing the ocean temperature difference was experimented and succeeded in 2004. In low-temperature thermal desalination, the sea surface water at about 28–29 °C is flash evaporated in a chamber under vacuum conditions. The deep sea

Fig. 48.10 100 m^3 per day desalination plant at Kavaratti Island (courtesy of National Institute of Ocean Technology)

water at about 12–14 °C is utilized to condense the evaporated vapor to generate the fresh water. The main attraction of this technology is the operational simplicity and the ease of maintenance. This was commissioning at Kavaratti Island, Lakshadweep group of islands with a capacity of 100 m^3/day as shown in Fig. 48.10. It is producing potable quality water since May 2005 and supplying to the islanders [48.15]. Similar two more plants were installed later in the islands, namely, Agatti and Minicoi during 2010–2011.

48.3 Current Status of OTEC Technologies

The recent trends and technological challenges on OTEC are discussed in the following sections.

48.3.1 Developing Technologies on OTEC

The oil crises in the 1970s gave a boost for OTEC research and there were many international attempts to demonstrate the technology. Many commercial plants were designed based on selected site conditions. After the 1980s, the primary aim was to develop OTEC technologies for commercialization such as new power cycles and new materials for the OTEC power plant. There are many institutions across the world pursuing OTEC research. Many Asian and African countries are interested in OTEC. The climatic conditions required for the operation of an OTEC plant are satisfied in about 100 countries. They are located in a range of 40° north and 40° south latitude. Pilot projects are underway for a 3–10 MW OTEC plant to be built in the Pacific Region. Countries like Korea, Philippines, Sri Lanka, New Guinea, are interested in OTEC.

48.3.2 Research on OTEC in International Scenario

Argonne National Laboratory (ANL) in USA proposed the hybrid OTEC system that has the advantages of both open and closed systems while eliminating the disadvantage of both. Tests of different types of heat exchangers such as shell and tube, plate-frame and plate-fin were conducted at ANL test facility. Vertical double-fluted-aluminum-tube evaporator, sprayed bundle, horizontal shell and tube evaporator, etc. were tested with different working fluids to evaluate the heat-transfer characteristics. ANL also tested an Alfa Laval, titanium-plate-type evaporator with chevron type passages. Special braced aluminum heat exchangers known as Trane heat exchangers were developed for OTEC application and tested up to a range of 1 MW.

Institute of Ocean Energy (IOES) has been continuing their work on OTEC research for more than 30 years. IOES is devoted to the areas of research such as experimental studies on superior power cycles, working fluids, heat-transfer studies by special coating, spray-flash desalination system, production of hydrogen and storage, extraction of lithium and storage, and experimental work on deep-sea water, etc.

USA and Japan are working on various large-scale research projects to develop cheaper and more compact OTEC power systems. Pacific International Center for High Technology Research (PICHTR) was established in 1986 in Hawaii for the US–Japan joint program on OTEC technology. Its main objective is to provide an operational testbed for OTEC system components. The products expected are electric power, fresh water, aquaculture products, and air-conditioning. They have installed a 1 m diameter pipeline at Natural Energy Laboratory of Hawaii (NELHA) for OTEC research.

48.3.3 Commercial Designs for OTEC Plants

Research and development in OTEC technology have been witnessed sporadically in several other countries such as France, Japan, Taiwan, and Indonesia, and also in India where several feasibility studies and preliminary design studies were carried out after eighties. There are site specific, detailed commercial designs available ranging from 25 to 200 MW OTEC plants. It includes land-based plant, shelf-mounted plant, and floating plants. The power utilization is also discussed in some of the reports. The consolidated list of the past designs for commercial OTEC plants is given in Table 48.3. The high cost of capital, coupled with the absence of operational data from a full-fledged pilot plant, has been the major deterrent hampering the commercialization of OTEC technology in the past.

48.3.4 Industrial Proposals for OTEC Commercialization

There are many international agencies available for the commercialization of OTEC technology. Most of them have contracts with international expertise in the field of power plant installation, power distribution, deep-sea operation, etc. Sea Solar Power (SSP), a government-supported consortium, was made up of many of America's most prominent industrial giants. SSP seeks long-term contracts to sell electricity, fresh water, and mari-culture products from OTEC plants

Table 48.3 Conceptual designs of OTEC systems

Serial Number	Major project	Salient features	Remarks
1.	Conceptual Designs of Japanese 100 MWe Floating OTEC Plants during the period 1974–1977, a program, named the *Sunshine Project*, was established in Japan (1980).	First-phase study of a 1 MWe, land-based plant and proceeded to a study of a 100 MWe floating plant. Design of platform structure, station keeping, riser cable design, and heat exchanger improvements. Ammonia as the working fluid. Plate heat exchangers are incorporated in 25 MWe power modules.	Estimated cost 3550 US$/kW (max.)
2	General Electric (GE) 40 MWe Shelf-Mounted Hawaii Plant (1982)	GE proposed a tower-mounted OTEC plant, which would be installed 2200 m offshore at a depth of 100 m, at Kahe Point, Oahu, Hawaii.	Power produced is to be carried by underwater cable to the Hawaiian Electric Company (HECO) plant for distribution to its customers. Total estimated cost – 320 M US$ (8000 $/kW)
3	Puerto Rico Electric Power Authority (PREPA) – a tower-mounted 50 MWe (net) OTEC plant (1985)	PREPA proposed a tower-mounted 40 MWe (net) OTEC plant to be sited at the edge of the continental shelf at 75 m depth approximately 200 m offshore from Punta Tuna, Puerto Rico. Electric power transmission by underwater cable.	Cold water is drawn from a depth of 1000 m at a distance of approximately 1500 m from the tower. Estimated cost – 378 M US$
4	Taiwan 50 MWe (net) shore-based OTEC plant by Taiwan Power Company (1985)	Three shore sites on the east cost of Taiwan were selected. Four 12.5 MWe (net) power modules using ammonia as working fluid. Shell and tube heat exchangers with titanium tubes. A 10 m dia 15 m long CWP made of concrete to be deployed.	Estimate of cost 4920–5690 $/kW
5	French 5 MWe OTEC Plants at Tahiti. Shore-based and floating OTEC plants to be sited in Tahiti. Sponsorship – French Centre National Pour l'Exploitation des Oceans (CNEXO) (1985)	Detailed site studies, evaluation of closed- and open-cycle options, methods of constructing and deploying the cold water pipe and estimates of costs of favored alternatives. Preliminary surveys led to selection of a site at the port of Papeete for the projected plant.	Plant layouts for closed-cycle and open-cycle systems were developed. Total cost Open cycle – 547 M FF Closed cycle – 523 M FF
6	OSEA 100 MWe OTEC Power Plant. A floating OTEC plant of the SSP design that would supply power to the Puerto Rico Water and Power Authority (PREPA). (1985)	(a) Design for submerged operation so that the major power plant components can be placed in the ocean outside the hull (b) A four-stage vapor cycle to improve the average temperature difference between the water flows and working fluid R.22 A *stockade* construction of the CWP with sections of steel pipe	Details of the construction, deployment, and operation are not available. Estimated cost 250 MUS$ (2500 $/kW)

Table 48.3 (continued)

Serial Number	Major project	Salient features	Remarks
7	SOLARAMCO Concept of OTEC 40 MWe (net) Grazing Ammonia Plant ship (1990) Working fluid ammonia	Location of Hawaii where a temperature difference of 22–23 °C would be available. The net OTEC electric power for water electrolysis to produce hydrogen for on-board ammonia synthesis (125 MT /day)	The proposal included provisions for testing four 10 MWe power modules equipped with different heat exchanger types. Estimated cost 250 MUS$ (6250 $/kW)
8	200 MWe (nom) OTEC floating plant Methanol. (1990)	Oxygen and hydrogen to be produced by water electrolysis in combination with low cost coal to produce a low-pollution liquid vehicle fuel. The power plant includes four power modules at each end of the barge. CWPs, 7–10 m diameter made of fiber reinforced plastic (FRP) or lightweight concrete, are supported by a universal joint or ball-and-socket mounting.	Energy transfer is done by production of 1750 tons/day of methanol. Estimated cost (Max.) 1313 MUS$ (6560 $/kW)

with 100 MW net electric power and 400 MLD capacity desalination plants. SSP claims that four independent engineering evaluations have been carried out and their OTEC design is technically sound and economically feasible. Xenesis is a Japanese-based company having technical collaboration with Saga University, Japan.

Makai Ocean Engg. was involved in the design, development of deployment plan, identification of materials, and fabrication in various sea water intake installations in the past. They were also involved in the engineering of sea–water system for Mini OTEC. Design and deployment of pipes ranging from 300 to 1400 mm were carried out. In 1987, Makai has deployed the 1000 mm HDPE pipe made of two sections of 915 m length and 610 m length to a depth of 701 m for Hawaii Ocean Science and Technology (HOST) Park. A pipe of 450 mm diameter was installed in the following year to replace a 300 mm pipe installed 6 years earlier. In 2001, Makai completed the installation of a 1.4 m diameter HDPE sea water supply system from a depth of 915 m with an approximate length of 3050 m to pump about 1705 kg/s seawater at 4 °C. This is the largest and deepest cold water intake system in the world and was installed for the State of Hawaii. These pipelines were for OTEC and aquaculture research. However, the Hawaii OTEC plant does not work for a number of sound reasons, but cold water is still being pumped up from the bottom of the ocean to support the businesses that flourish from the use of the cold water. The OTEC industrial park has grown from 300 acres to 547 acres because of this successful use of the cold nutrient-rich water (Fig. 48.11).

Fig. 48.11 Aqua-culture farm at the Natural Laboratory of Energy Hawaii (courtesy of NELHA)

48.4 Design Considerations for Future OTEC Plants

There are successful OTEC demonstration plants in the past and the commercialization of OTEC technology is expected in the nearby future. Research and development works are continuing and OTEC is mature enough to establish commercial plants. However, there are constraints and limitations which need further attention. The following discussion is on the selection of working fluids, equipment, materials on OTEC, and the utilization of power generated.

48.4.1 Choice of Working Fluids

The selection of the working fluid is important in an OTEC plant. The selection of the equipment, size of the pipe, working conditions, etc. depends on the selection of working fluid. The following are the important characteristics to be considered while choosing the working fluid:

1. Low-temperature boiling and condensation between 25 and 10 °C
2. High heat transfer coefficient for liquid fluids
3. Material compatibility: metals, oils, gaskets, etc.
4. Environmental friendly
5. Low-specific volume and high heat of vaporization
6. Safety: Nontoxic, nonflammable, and nonexplosive.

The following working fluids are commonly suggested:

1. Ammonia
2. Fluoro carbon (R-22)
3. Tetra fluoro ethane (HFC-134a)
4. Propane (C_3H_8)
5. Propylene (C_3H_6) (propane).

All fluoro carbons are ozone depleting and hence cannot be considered for any future OTEC projects. Ammonia is easily available with better thermodynamic properties; it is corrosive especially with copper and its alloys. Also, it is highly toxic for storage and handling. Ammonia cannot wash away any grease deposits on the pipeline and heat exchanger surface. Propane is combustible and each liters of propane contains 26.2 MJ energy. It is easy to detect for leak and its volume increases approximately 270 times when it is vaporized. There is no possibility of water or air pollution with propane.

Thermodynamic and physical properties of HFC-134a, coupled with its low toxicity and nonflammability makes it a very efficient and safe refrigerant. HFC-134a has long-time stability with copper, steel, and aluminum. It has the zero ozone depletion potential (ODP) and has the global warming potential (GWP) 1200. HFC-134a possesses no acute or chronic hazard when exposed below recommended exposure limits such as 1000 ppm, 8 or 12 hours' time. However, inhaling high concentration may cause temporary nervous system depression. HFC-134a in the liquid form can freeze skin or eyes on contact causing frostbite. However, it is not an eco-friendly refrigerant. Hence if safety is an important issue the choice is HFC-134a. But ammonia is less costly, easily available and has superior thermodynamic properties such as heat of vaporization, pressure ratio, etc. Experimental studies show that the contamination of ammonia by water adversely affects the performance of the plant. About 1% of water by weight can reduce the heat transfer coefficient by 8–10% and the resulting power loss. Hence, it is advisable to keep water concentration below 0.1% when ammonia is used as the working fluid [48.16]. A comparison of different working fluids is shown in Table 48.4.

Table 48.4 Properties for working fluids for OTEC

	Ammonia		Propane		HFC – 134a	
Chemical formula	NH_3		C_3H_8		CF_3CH_2F	
Molecular weight	17.03		44.09		102.0

Safety Consideration in the OTEC Plant

In an OTEC plant, large amount of working fluid is to be stored and handled (Fig. 48.12). At low concentration in air, ammonia vapor irritates the eyes, nose, and throat. Inhalation of high concentrations produces a sensation of suffocation, quickly causes burning in the respiratory tract, and may result in death. Liquid anhydrous ammonia causes severe burns on contact with the skin, while its effect on being inhaled would cause severe corrosive action in the mouth, throat, and stomach. Safety guidelines to be followed as large quantity of working fluid is to be handled in the OTEC plant during the following operations such as transfer to storage tank, venting and draining, testing the components, and plant operation. A detailed checklist should be prepared before each operations and the entire team is to be briefed about the operation in detail. Continuous monitoring of the pressure in the pipeline should be done. In the case of emergency, the operation personnel are required to evacuate through escape route marked on both sides of the platform to ensure the safety for them.

48.4.2 Choice of Materials

The material selection for OTEC heat exchangers is based on two criteria: (i) corrosion resistance to marine environment and (ii) compatibility with working fluid. Various materials are considered such as aluminum, cupro-nickel, stainless steel, and titanium. The following material combination can be considered for OTEC plant heat exchanger with the working fluids:

- Titanium – Ammonia
- Cu–Ni – Propane
- Cu–Ni – HFC-134a
- Aluminum – Propane
- Aluminum – HFC-134a

Fig. 48.12 Ammonia transfer to OTEC plant (courtesy of National Institute of Ocean Technology)

Aluminum and Aluminum Alloys

Aluminum grades 5052, 5083, 5086, and 6061 are suitable for seawater applications. This metal can be safely used with any working fluid considered for OTEC. It has a high thermal conductivity, low density, and good malleability but poor weldability. It is subjected to pitting corrosion at sea water velocities greater than 3 m/s, but is quite inert to seawater at velocities less than 2.2 m/s. This is because the passive protective layer on its surface, formed due to oxidation, is not stripped away by seawater at low velocities. Other metals, which may be used along with aluminum in a marine environment, are those that acquire a similarly oxidized surface condition in the course of time acquiring corrosion resistance. Special technologies are to be developed to control the galvanic corrosion. Titanium must be well insulated from aluminum if the latter is not to be destroyed by galvanic corrosion. Suitable cladding is to be done when aluminum is used. Heat-exchanger tubes can be made of aluminum with proper cladding. ANL carried out extensive studies for the use of aluminum as the heat-exchanger material. The special heat exchanger developed and tested at ANL is known as Trane heat exchanger [48.17]. Studies at IIT Madras showed that Al alloys requires 15% less tonnage compared to titanium and 2% less floor area. The cost of titanium is nearly 10 times that of Al alloys.

Stainless Steel

The oxygen content of seawater is sufficient to maintain a passive film of chromic oxide on the surface provided the seawater velocity is high enough to prevent debris settling on the surface. The recommended lower velocity limit is 1.5 m/s. If debris deposition or fouling occurs, differential aeration corrosion would set in causing pitting. It should be noted, however, that higher seawater side velocities would result in higher pressure drop in the exchanger, which should be avoided. Where stainless steel is employed, an alloy of greater chromium content, such as 355 S 80, should be used, since the behavior of lower percentage chromium alloys in marine environment is less reliable. Also, stainless steel containing molybdenum (326 S 16) has a greater resistance to corrosion at low seawater velocities. Steel belonging to the austenitic grade is used in marine application (Type 316 and 304). The mechanism of corrosion protection for stainless steels differs from that for carbon steels, alloys steels, and most other metals. In these cases, the formation of a barrier film of true oxide separates the metal from the surrounding atmosphere. Stainless steel grades AL-6XN and 29-4C are reported to be having excellent sea-water resistance compared to conventional duplex steels. The high nickel chromium

content provides a corrosion resistance against chloride stress-corrosion cracking.

Austenitic grades of steel are susceptible to pitting and crevice attack. These will be minimal if velocities are maintained below 1.5 m/s. The addition of molybdenum is usually used in high-velocity service systems such as pump impellers. 3% molybdenum has been used in the impellers of the OTEC plant. Molybdenum provides longer induction period before pitting or crevice attack. Deep-ocean experiences for these steels were varied with slight edge attack or tunneling. Stainless steel is compatible with any working fluid and has good machinability and weldability.

Cupro-Nickel

The most common alloy combination are the 90/10 and 70/30 cupro-nickels. All cupro-nickels are incompatible with ammonia. However, they have various other advantages. They are corrosion resistant below a seawater velocity of 4.5 m/s. The 90/10/1.5 copper–nickel–iron alloy is also very resistant to fouling by marine organisms. Chlorination of seawater, to prevent fouling, does not increase the corrosion rate of cupro-nickel. But seawater polluted with H_2S enhances the corrosion rate. Titanium and cupro-nickel can be used together without appreciable galvanic corrosion.

Titanium

It is virtually immune to seawater due to the self-healing ability of its protective film. Titanium cannot be used in conjunction with various copper alloys, mild steel, and aluminum as these undergo galvanic corrosion. Titanium is compatible with most working fluids. In most marine applications, a thin oxide film forms on titanium and provides complete protection. In spite of titanium's excellent corrosion behavior, some problems encountered in the marine environment are: (i) pitting at oxygen-starved crevices when seawater is heated at 250 °C (ii) stress-corrosion cracking in the presence of tensile stresses and surface flaw. These types of effects would not be encountered in the OTEC plant as the plant operates at ambient temperatures of 28 °C. Titanium has the ability to withstand high velocities with negligible attack. It is also the most expensive of the materials considered.

In conclusion the titanium and high-alloy stainless steel (AL-6XN and 29-4C) can have a life of 30 years. Cu-Ni 90/10 alloy is a good candidate for sea water but not compatible with ammonia. Aluminum alloys are suitable for OTEC applications but mechanical cleaning is to be limited to prevent erosion. Pitting corrosion was observed with deep-sea cold water in aluminum alloys. An average life expectancy of 12–15 years can be considered for aluminum.

Materials for the Structures

Carbon steel is the most commonly used material for marine structural applications. The most significant parameter that influences the behavior of this metal is the availability of oxygen needed to depolarize cathode regions, which can affect the rate of attack. Normally a rust coating, or a calcareous scale, or a layer of bio fouling will develop within a few months on the surface and will act as an interfering barrier. Deep ocean corrosion rates for carbon steels tend to be lower compared to surface seawater. The rate of attack tends to decrease with time because of the low temperatures. Additions of 0.1–0.5% nickel are effective in promoting increased resistance to the marine environment. Addition of 1–2% of chromium results in the decrease of corrosion rate by half. Proper epoxy-based coating suitable to marine environment should be provided for all marine structures made of carbon steel. Composite technology is being developed and this can be a good alternative for marine structures of the OTEC plant due to the light weight and corrosion resistance.

48.4.3 Selection of Equipment

Major cost of the OTEC project is on the power module components such as heat exchangers, turbine, seawater pumps, storage systems. The following section is a description on the principles of selection of these major components.

Selection of Heat Exchangers

Heat exchangers are the most critical components of the OTEC plant. Keeping in view the stringent requirements of low approach and maximum heat recovery, counter current type plate heat exchangers can be considered both for evaporators and condensers. OTEC heat exchangers work on large heavy duty due to the low thermal efficiency of power cycle even as low as ≈ 2.5%. Seawater on the one side and a two-phase mixture of ammonia on the other side makes the process complex. The capital cost of the heat exchangers is nearly 30–50% of the overall cost of the plant. The heat transfer surface required is 7–8 m^2/kW (net) for the evaporator and condenser. The conventional shell and tube heat exchanger design, with a low ratio of heat transfer to exchanger volume, would require very large volumes (1.7–1.9 times) of the plate heat exchanger. The heat transfer area for the double-fluted-type exchanger is about 1.5 times as large as when using the plate type one. This would increase the material inventory and the fabrication costs. A qualitative comparison between the shell-tube exchanger and the plate-fin exchanger on various points of interest is set out in the Table 48.5.

Table 48.5 Techno feasibility comparison of different heat exchangers

No.	Aspect	Shell-tube	Plate-fin	Plate heat exchanger
1.	Present level of technology in marine conditions	Well-developed	More developments/ work required	Developments are in progress
2.	Volume of heat exchanger	Large	Comparatively smaller	Least
3.	Material inventory	Large	Small	Least
4.	Seawater side heat transfer coefficient	Lower	Higher	Lower
5.	Seawater side fouling	Lower	Higher	Lower
6.	Frequency of use of cleaning procedures	Low	High	Medium
7.	Heat transfer area required	More	Less	Least
8.	Heat transfer area per unit volume of exchanger	Low, about 200 m^2/m^3	High, around 500 m^2/m^3	About 300 m^2/m^3
9.	Fabrication processes	Already existing	Need to be developed	Already existing
10.	Pressure drop in exchanger	Lower	Higher	Medium
11	Maximum working pressure	60 bar	25 bar	15 bar

More experimental data are required on fouling rates, fouling control measures, and development of more economical fabrication processes. Fabrication costs can be greatly minimized if a leak-tolerant system rather than a leak-intolerant one is adopted. In the former, costly and precise welded joints are replaced by rubber seals. Each plate is fitted with a gasket, which seals the channel and directs the fluids into alternate channels. The overall heat transfer coefficient for high-angle plates is about 33% greater than that of low-angle plates under the similar operating conditions. However, the water side pressure drop for high-angle plates is nearly four times greater because of the higher turbulence. The number and size of plates are determined by the flow rate, physical properties of the fluids, pressure drop, and temperature program. The test results of plate heat exchangers in Indian OTEC plant are as shown in Fig. 48.13. Some of the reported values of overall heat transfer coefficient (K) are listed in Table 48.6.

Experimental studies at ANL and Saga University proved that a special coating on the ammonia side can improve the K-value by 30–40% or more. The tiny cavities act as nucleation points and enhance the vaporization process. As OTEC heat exchangers work on low temperature of approach, coating makes appreciable difference. The coating is achieved by spraying molten stainless steel on the sand-blasted plate surface using compressed air (Fig. 48.14).

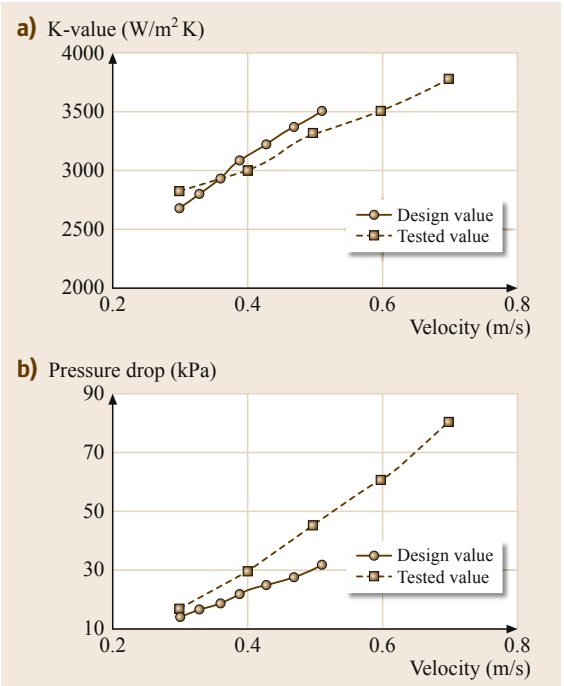

Fig. 48.13a,b The test results on plate heat exchanger. **(a)** Test results of overall heat transfer coefficient with varying flow channel velocity for the thermal spray coated plate heat exchanger; **(b)** pressure loss in the plate exchanger is measured for different channel velocities. These results are compared with design correlations

Selection of Turbine

The selection of the turbine depends on the type of the cycle chosen. Higher capacity plants are to be based on the closed cycle. Axial flow turbines will give a better adiabatic efficiency and part load efficiency compared with radial flow turbines. However the construction cost will be higher. The unit comprising of a turbine-gearbox-alternator is expected to give an overall efficiency of 80%. The main components namely the turbine disk and rotor blades can be made of a special material 17-4PH semi austenitic stainless steel. The 17-4PH SS is known for its resistance to corrosion. The possibility of crevice corrosion occurring in the assembly is ruled out because of the close fits. The material 17-4PH SS can be selected for the turbine disk can withstand high stresses, high resistance to crack propagation and proven resistance to stress-corrosion cracking in marine atmosphere. The shaft can also be made of 17-

Table 48.6 Reported values of overall heat transfer coefficients

Sea water Channel velocity [m/s]	K-value [W/m^{2}K]	Ammonia side of evaporator	Source of data [48.10, 11, 17]

4 PH Stainless steel H1025 39-42 HRc. The material for all the turbine rotor blades is 17-4PH stainless steel at H1025 condition, which provides greater transverse ductility, lower transition temperatures, and more useful levels of fracture toughness. By pass mode of governing can be adopted for the OTEC turbine. A quick shut-off valve can be provided to the inlet to the turbine as a safety measure.

Selection of Sea Water Pumps

For the OTEC application, the pump required should have characteristics so as to meet the demand of large discharge and low head, which limits the choice to mixed flow centrifugal pumps. Centrifugal pumps have also been considered for pumping ammonia in the working fluid cycle. Seawater pumps would consume about 30–40% of gross power produced by the plant. The choice of the material, strength, and endurance should be taken into consideration at the design stage due to ship motion (for floating plant), fluctuations in submergence, and seawater corrosion. Materials compatible in the marine environment such as stainless steel for impellers and shafts, Ni cast iron for casing are selected based on the superior corrosion resistance exhibited by these materials and their stability in chlorinated seawater adopted for fouling control. A special roller thrust bearing is to be provided to account for about 5% pitching motion of the ship for floating plants. Impellers of pumps are made of ASTM A351 grade materials. The inner walls of the pump casing can be coated with copper oxide and covered by a layer of epoxy. Chlorine is to be introduced into the caisson below each feed pump to prevent the buildup of fouling on the casing and the impellers. Certain steel like the Duplex steel show high pitting probabilities at high potentials and a significantly lower pitting probability as the potential is reduced.

48.4.4 Sea Water Intake System and Deployments

One of the critical components of an OTEC system is the pipe which will carry the cold water from a depth of 1000 m to the OTEC platform. These seawater intake pipes have to handle huge quantities of water and hence are generally large in diameter. The pipes must withstand forces of the ocean waves, currents as well as corrosion, and bio fouling over a long period of time say, 25–30 years. The pipes in general will have length from 1 to 4 to 5 km depending on the type of the plant. The design of the connection of the pipe to the floating platform and the study of the pipe's behavior under various environmental conditions is are challenging task. The sea–water systems of the land-based plants have special requirements for the discharge pipe and the surf zone transition for all the pipes of the system. In floating plants the pipe can be a part of mooring as in the mini-OTEC plant. In another way, the mooring is separated from the pipe and the pipe is vertically suspended from the barge itself. OTEC-1 experiments used this configuration.

Materials for Intake Pipe

The selection of most economic and technically suitable pipes with a desirable life expectancy is a problem by itself. The choice of pipes must be made with regard to its capacity to withstand load, resist pressure, min-

imum increase in temperature during the flow of cold water from intake to sump and corrosion, which may be caused, by the seawater. In addition to the conventional steel pipes, there are several other pipe materials like cast iron, concrete, HDPE, FRP. Most of the experimental plants, installed till date, have used either HDPE or polyethylene pipes. For the proposed plants, HDPE has been selected as the material for bringing cold and warm water. Table 48.7 gives the properties of various types of pipes available [48.18].

Station Keeping Systems

There are two alternatives to position: a floating platform at a point such as dynamic positioning system and the mooring system. The dynamic positioning system with a thruster is more costly than a mooring system. However, mooring system for deep waters is still a technical challenge. The selection of a suitable mooring system for offshore platforms depends on several factors such as water depth, environmental conditions, type and size of platform, platform motions, period of operation, whether temporary or permanent system is required, maximum allowable drift, cost. There are three types of mooring systems (Fig. 48.15):

1. Single-point mooring in which the platform is held by a single wire or a chain system. Mini OTEC proved that even the HDPE pipe can be used for mooring.
2. Vertical tension mooring in which some tension is introduced in the mooring lines.
3. Multi-leg catenary moorings in which different wires are used to keep the platform in position.

Single-Point Moorings. Single-point moorings have weather-vaning capability and are economical for deep-water conditions as they always try to minimize the environments loads on the structure by heading into the weather. A wide variety of designs are available for single-point mooring system even though all of them perform the same function. Figure 48.9 is an example of single-point mooring system.

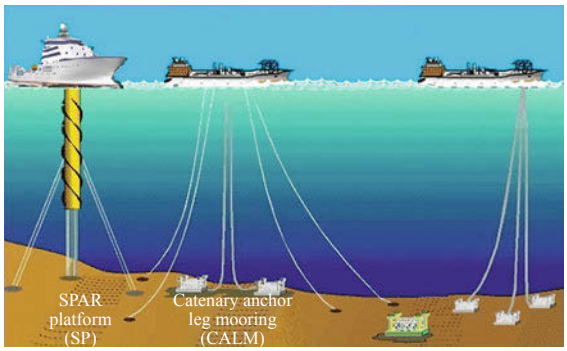

Fig. 48.15 Station keeping systems for OTEC barge

Turret Mooring. In this system, a number of catenary mooring legs are attached to a turret that is an essential part of the vessel/platform to be moored. The turret is provided with bearings to allow the vessel to rotate around the legs.

Catenary Anchor Leg Mooring (CALM). In this system, a large buoy is used to support a number of catenary chain legs anchored to the seabed. The flow lines coming from the sea (the cold water pipe lines in the case of OTEC plant) are connected to the bottom of the buoy and a hawser; typically, a synthetic rope connects the floating platform to the buoy. Since the response of the CALM buoy is totally different from that of the floating platform under the action of waves, this particular system has some limitations in withstanding severe environmental conditions. Hence provisions are made to disconnect the platform from the buoy during extreme environmental conditions. For cases where disconnection is not possible, rigid structural yokes with articulations are provided to tie the ship/platform to the top of buoy. The rigid yokes are designed in such a way that they totally eliminate the horizontal motion between the platform and the buoy.

Single-Anchor Leg Mooring (SALM). This system uses a vertical riser system that has a large amount of buoyancy near or on the surface and is held by pretensioned riser. A tubular articulated riser with a fixed yoke is employed. Chain risers with soft mooring connections can also be provided. The riser behaves like an inverted pendulum due to a large amount of vertical buoyancy available at the surface. Whenever the system is displaced from its original position, the pendulum action tends to bring back the riser to its old position. As mentioned in the earlier case the floating platform is connected to the top of the SALM buoy either by a rigid yoke or a flexible hose. The bottom portion of the riser is connected to a piled or dead weight concrete or steel structure on the seabed. In deep water, the SALM system usually has mid-span articulation (Fig. 48.16).

Dynamic Mooring Systems. Dynamic positioning (DP) is used either as a sole source of station keeping or used to assist a catenary mooring system. Dynamic positioning system consists of a position reference system with a thruster controlled using computer around the vessel. When dynamic positioning system is used, it is called as DP assisted mooring and thruster assisted mooring when thrusters are manually controlled. The use of dynamic position assisted mooring systems for

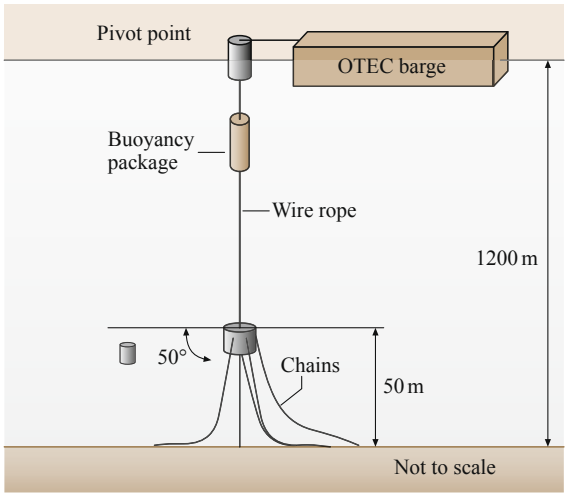

Fig. 48.16 Counter weight articulated mooring system

ship shaped vessels has drawn considerable attention in recent years. The ability to control vessel heading, damp vessel motions, and subsequently reduce mooring line loads, and improve operating efficiencies, are key factors for consideration.

For the economic design the realistic estimation of the load on the mooring system is to be carried out considering all wind, wave and current forces. The problem of fatigue and corrosion are major challenges in the mooring system for an OTEC plant.

Deployment of Pipe

The cold-water pipe is a critical component of an OTEC plant since it conveys the cold water to the power plant. Since the temperature of cold water required is around 6–7 °C, the pipe has to be about 1 km long. The long pipe has to be horizontally towed and vertically upended in a water depth of over 1000 m. This task, that is, the deployment of the cold water pipe is a complex operation. Fortunately, materials like HDPE floats in water hence an HDPE pipe will float by itself. Other materials may need flotation devices to make the pipe float. HDPE is flexible however it also has a limiting bend radius and during deployment it must be ensured that the bending stresses do not exceed the limiting values. After the pipe is towed to the site it has to be made vertical, for this a crane barge is required to lower the pipe at a slow rate and capable of handling all the weights attached to the pipe. The mooring has to be first deployed and subsequently after the pipe is made vertical, connection to the vessel need to be made. The upending of the pipe is a very delicate task and may involve air locks, which will lead to failure, and hence the entire procedure needs to be carefully planned and executed. Connections to vessel involve divers and several onboard equipment like winches and cranes are used for handling. Generally, a large barge fitted with handling equipment, a large vessel with positioning system for support and logistics, tugs, and several fishing craft are required for the deployment procedures.

48.4.5 Bio-Fouling and Control

Any solid surface in seawater begins to acquire a film of microbes in the form of detectable slime layer within a few hours. This film grows in thickness and impairs the performance of the heat exchanger by acting as a thermal insulator. The rate of micro fouling on a sur-

face is dependent on a number of factors such as the character of the surface, kind and amount of nutrients present near the surface, oxidizing capacity of the environment, pH of the seawater. With the fast flow of seawater past the heat exchanger walls, the loosely attached top parts of the film break away. However, with time the film becomes harder and dense decreasing the heat transfer coefficient even up to 60%. The resistance to heat flow is measured as the reciprocal of heat transfer coefficient and is designated as the fouling factor (R_f). The typical fouling factors generally considered for surface seawater is $0.00005\,m^2K/W$ and for deep water is $0.000015\,m^2K/W$. Experimental studies at NELHA over a period of 5 years showed that negligible bio-fouling of heat exchangers at deep-sea cold-water side [48.19]. Bio-fouling in the evaporator could be prevented by suitable chlorine dosing. The following are the general conclusions:

- Fouling characteristics of open seawater are comparable irrespective of site
- Fouling characteristics for near shore/coastal water and open seawater are different.
- A low level of intermittent chlorination may prevent fouling buildup of heat exchanger surfaces.

There are many bio-fouling control measures as discussed below.

Chlorination

In this system, chlorine is injected into the water intake in the form of NaOCl or with the help of a small electro-chlorine generator system. This injection can be continuous such that the concentration of chlorine never exceeds 0.5 ppm, or it can be intermittent at regular intervals with chlorine concentrations as high as 1.2 ppm.

Ultrasonic Cleaning

In ultrasonic cleaning, high-frequency sound waves remove the bio fouling from the heat exchanger surface. The power required to be transmitted is of the order $1\,W/cm^2$ of the heat exchanger surface area. Other methods such as Amertrap rubber sponges and mechanical cleaning using brushes have also been effective. Slurries of silica particles of various sizes and concentrations circulated past the heat exchanger surfaces were of limited effectiveness.

Tight control over heat exchanger cleanliness is required as the gap between successive plates in a plate exchanger is only 3–6 mm and hence fouling can easily impede flow. Based on preliminary evaluation liquid sodium hypochlorite was selected as a possible biocide for fouling control in OTEC operation based on its effectiveness, easy availability, low cost, and ease in mid sea replenishment of stock. Subsequently experiments were conducted in near-shore waters, at residuals of 0.2, 0.5, 0.8, 1.0, 1.2, and 1.5 mg/l in simulated flow chambers (Pederson device) and slime control was achieved at continuous residual levels of 1.2 mg/l. A log reduction 0.8 times in bacterial density between control and chlorinated plates was observed at this regime. Later on experiments were conducted at the OTEC site by changing the regime to an intermittent mode, with a view to reduce chlorine inventory on the OTEC barge. These studies showed an intermittent chlorination regime of 1.2 mg/l residuals (two hours interval) was effective for slime control. Since the control of fouling is critical for heat transfer efficiency, the dose and frequency evolved in coastal and oceanic waters using flow chambers were validated using a model plate heat exchanger at the oceanic site onboard a research vessel. A summarized result from the experimental studies is shown in Table 48.8.

An intermittent chlorination of 1.2 ppm with periodical mechanical cleaning would be the ideal method for bio-fouling control for the OTEC plant. However site specific bio fouling studies have to be carried out for establishing the chlorine dosing regime [48.20].

48.4.6 Power Transmission from Offshore OTEC Plants

The fact that OTEC plants, if built, would be stationed at sea, 4–100 km (or even more) off-shore, raises the question of how, and perhaps in what form, the energy produced by these plants will be made available to the user markets on land. The link between the OTEC plant and the land-based energy markets is an important part of the total system, as the overall credibility of the OTEC concept will depend upon the availability and economics of the transmission system. Power generated by OTEC plants moored less than 25 km off-shore may be transmitted through submarine cable as high-voltage AC ($\approx$ 150 kV). For longer distances, up to 200 km, high-voltage DC (direct current) ($\geq$ 250 kV) transmission has to be resorted to. Underwater bulk-power transmission at depths (1–2 km) and distances characteristic of OTEC conditions has not been attempted so far. This is bound to pose numerous engineering problems, particularly with regard to platform positioning

Table 48.8 Thickness of biofilm developed on the titanium

Chlorine dose regime	Biofilm thickness [μm]		
	1st day	3rd day	6th day
Continuous – 1.2 ppm	9	15	20
2 h interval – 1.2 ppm	12	18	32
4 h interval – 1.2 ppm	13	22	45

and cable-design and installation. The DC cable will have to be in one piece since no splices or joints are permissible in lengths exceeding 100 km.

For OTEC plants, which are more remotely sited than a few tens of kilometers from the coast, both engineering and economic considerations seem to favor strongly the conversion of the primary OTEC electrical energy to hydrogen by electrolysis of deionized seawater. The hydrogen thus produced could be transmitted as gas through submarine pipes if the distance is not large, or else converted in the OTEC plant itself to liquid hydrogen or liquid ammonia (NH_3), which could be shipped in special containers or tankers to the land terminals. The latter alternatives offer greater operational flexibility in the disposal of the energy product. Submarine cables are usually subject to much more onerous installation and service conditions than an equivalent land cable and it is necessary to design each cable to withstand the environmental conditions prevailing on the specific route. Subject to certain restrictions, paper insulated solid-type cables, oil-filled cables, gas-filled cables, and polymeric cables are all suitable for submarine power cable installations. There are under water cable installations up to a depth of 550 m to a length of 127 km (between Denmark and Norway).

48.5 Conclusion

The OTEC offers a great potential of energy for the generation of continuous power with renewable nature like conventional power plants. The ever-increasing energy demands combined with the alarming ozone layer depletion rate and the socio-environmental impact of fossil fuels necessitate focusing the attention to the ocean for the energy needs. There are many countries in the world, which are keenly interested in the development of OTEC. There are technological and economical hurdles to overcome. But building the confidence and reliability on the ocean energy technologies is the present challenge. For the main land applications rating of 25 MW and above the cost of power generation is expected to be comparable to the fossil fuel plants. However, OTEC power plants will be cost competitive to island communities, even today. In view of the enormous OTEC resource available in many countries and because of its renewable and pollution free nature, this technology development program of smaller power plants and generation of experimental data should be treated as investment for the future technologies and not expect to be cost competitive at present with conventional fuel plants.

49. Offshore Wind Energy

Mareike Strach-Sonsalla, Matthias Stammler, Jan Wenske, Jason Jonkman, Fabian Vorpahl

In 1991, the Vindeby Offshore Wind Farm, the first offshore wind farm in the world, started feeding electricity to the grid off the coast of Lolland, Denmark. Since then, offshore wind energy has developed from this early experiment to a multibillion dollar market and an important pillar of worldwide renewable energy production. Unit sizes grew from 450 kW at Vindeby to the 7.5 MW-class offshore wind turbines (OWT) that are currently (by October 2014) in the prototyping phase.

This chapter gives an overview of the state of the art in offshore wind turbine (OWT) technology and introduces the principles of modeling and simulating an OWT. The OWT components – including the rotor, nacelle, support structure, control system, and power electronics – are introduced, and current technological challenges are presented. The OWT system dynamics and the environment (wind and ocean waves) are described from the perspective of OWT modelers and designers. Finally, an outlook on future technology is provided.

The descriptions in this chapter are focused on a single OWT – more precisely, a horizontal-axis wind turbine – as a dynamic system. Offshore wind farms and wind farm effects are not described in detail in this chapter, but an introduction and further references are given.

The use of renewable energy sources increased rapidly since the middle of the last century. For example, the percentage of installed wind power in the European Union (EU) increased from 2.2% in 2000 to 11.4% in 2012 [49.1]. To foster this trend, the member states of the EU have agreed on the target of generating 20% of their energy consumption from renewable energy sources by the year 2020. There are mainly two reasons for this: independency from fossil energy sources, which have become more expensive in recent years, and environmental awareness.

Wind energy has a large share in energy transition. As of 2012, 282 430 MW of wind power capacity have been installed, of which 5410 MW are located offshore [49.2]. Although the installed offshore wind capacity corresponds to only 1.9% of the total installed wind capacity, it has to be stressed that the offshore wind industry is relatively young and has been growing rapidly only in the last decade; the installed offshore wind capacity rose from 4 MW in 2000 to 1188 MW in the member states of the EU in 2012 [49.3]. In several countries, both politics and industry are eager to push offshore wind energy. For example, [49.3] states that *31 companies have announced plans for 38 new offshore turbine models*, and the German government wants to install 25 000 MW of offshore wind capacity by 2030 [49.4].

In general, an offshore wind turbine (OWT) generates electricity from the power contained in the wind. The electricity produced is fed into the grid and transported to land where it is used by households and industry. In contrast to fossil energy sources, the electricity produced by an OWT cannot be controlled on demand; an OWT can only produce electricity based

on current wind conditions. The wind is random and cannot be collected and put aside for later use. For large penetrations of wind power, this is an issue when establishing grid stability and providing a continuous electricity supply. The problems arising from the intermittent electricity fed into today's grid is causing a shift in the way grids are thought of and how they need to be designed in the future. Currently, a lot of research is devoted to this field. However, the electricity grid is not the topic of this chapter, but it is referred to in the description of [49.5].

This chapter gives an overview of the state of the art in offshore wind turbine technology and introduces the principles of modeling and simulating an OWT. The OWT components are illustrated, along with how the wind is used to produce energy, how ocean waves and corresponding loads are described, and how an OWT can be modeled and simulated. The chapter is concluded with an outlook on future technology. The descriptions in this chapter are focused on a single OWT – more precisely, a horizontal-axis wind turbine (HAWT) – as a dynamic system. Offshore wind farms are not described in detail, as this would be beyond the scope of this chapter. An introduction and further references can be found in [49.5].

A last note regarding usage of *offshore wind turbine*s and/or OWTs: although not explicitly stated, most of the following explanations are valid for land-based wind turbines as well. However, to avoid confusion, OWT is used throughout the chapter.

49.1 Current Offshore Wind Turbine Technology

In this section, the technology of OWTs is described. The components of an OWT are introduced following the definition of the International Electrotechnical Commission (IEC) in [49.6] (shown in Fig. 49.1). Accordingly, the term *offshore wind turbine* describes a system consisting of a rotor-nacelle assembly (RNA) and support structure. The focus of this section is on bottom-fixed three-bladed horizontal-axis wind turbines like the ones shown in Fig. 49.2 as they are used in commercial offshore wind farms today. Examples of technologies that differ from this concept are introduced in Sect. 49.3. The RNA consists of the rotor, the hub and rotor blades, and the nacelle, containing the generator and the drivetrain with a corresponding support frame. The RNA is described in Sect. 49.1.1 (rotor) and 49.1.2 (nacelle). The term *support structure* includes the foundation, the substructure, and the tower (Fig. 49.1) and is described in Sect. 49.1.3. The control system and the power electronics are an important part of a wind turbine and their location varies among OWT concepts, which are described in Sect. 49.1.4 (control system) and Sect. 49.1.5 (power electronics).

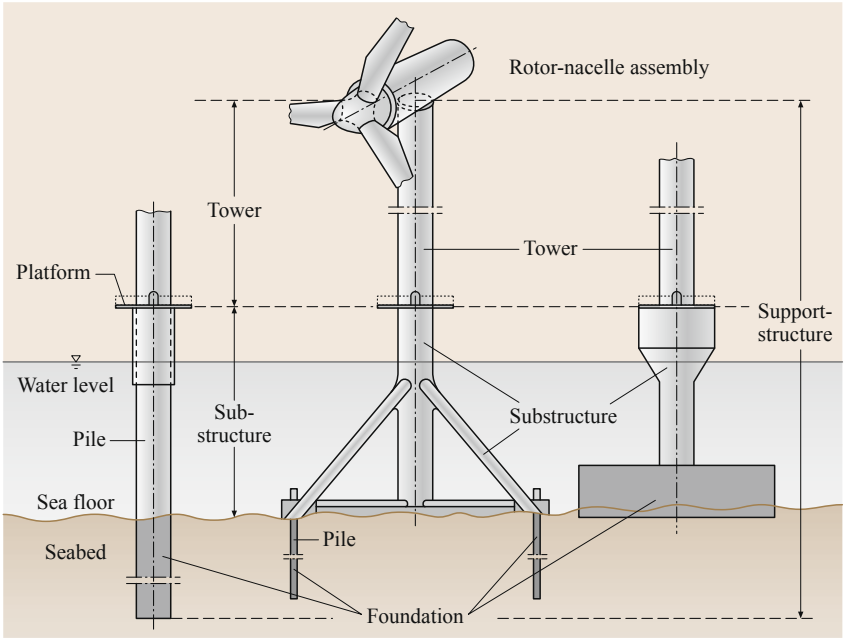

Fig. 49.1 Offshore wind turbine components according to IEC (after [49.6])

49.1.1 Rotor

The rotor converts the kinetic energy in the wind to rotational energy of the rotor and drivetrain by utilizing aerodynamic lift. Based on the arrangement relative to the wind direction, rotors can be divided into upwind and downwind rotors. Most of today's wind turbines have an upwind rotor with three blades; the rotor faces the wind in front of the tower.

The ratio between blade tip speed, the product of rotational speed Ω and rotor radius R, and the undisturbed wind speed v_{wind} is denoted as tip-speed ratio λ and is given in (49.1). The tip-speed ratio is a key parameter for the aerodynamic design of a rotor that is explained in standard wind energy textbooks like [49.5] or [49.7].

$$\lambda = \frac{\Omega R}{v_{\text{wind}}} \,. \tag{49.1}$$

Currently used OWTs are designed for tip-speed ratios of about 5–8 [49.8] and thus, deliver high generator speeds through a low torque. Also, most OWTs are variable speed, they can change the rotational speed of the rotor and can, therefore, operate at the optimal tip-speed ratio in a range of wind speeds. However, for variable-speed turbines, the electricity generated does not meet the grid frequency and has to be converted to be fed into the grid.

The power that is produced by the rotor has to be controlled to avoid violating limits like rated power. This approach protects the machinery and prevents overloading of the generator. A generic power output curve of a variable-pitch controlled wind turbine is shown in Fig. 49.3; the power produced is zero below the cut-in wind speed, increases cubically for wind speeds between cut-in and rated wind speed, is constant above rated wind speed, and becomes zero again after reaching the cut-out wind speed.

For the aerodynamic control of a rotor, variable-pitch-to-feather control is most common. For these rotors, the rotor blades are rotated around their longitudinal axis according to the wind conditions. In above-rated wind speed, the rotor speed is fixed and the pitch angle of the blades is increased to decrease the resulting inflow velocity's angle of attack and to keep the produced power constant. For variable-pitch-to-feather rotors, the connection between rotor blades and hub is rather complicated because of the necessary bearings and actuator systems.

Another possibility to aerodynamically control the power produced by the rotor is to utilize the stall effect, which can be done actively or passively. For passive-stall controlled rotors, the rotor is kept at a fixed rotational speed over a range of wind speeds. Furthermore, the rotor blades are fixed at a certain pitch setting angle and cannot rotate along their longitudinal axis. For an active-stall controlled rotor, the rotation speed of the rotor is varying and the rotor blades are pitched actively to stall. In both cases, the resulting inflow velocity's angle of attack is increased. This increase causes the flow on the blade to detach and thus decreases the lift on the blade and reduces the power produced. It is not easy to predict stall behavior. Furthermore, the damping and fatigue behavior is less favorable than that of variable-

Fig. 49.2 Wind turbines in the German offshore wind farm Alpha Ventus (courtesy of Urs Wihlfahrt)

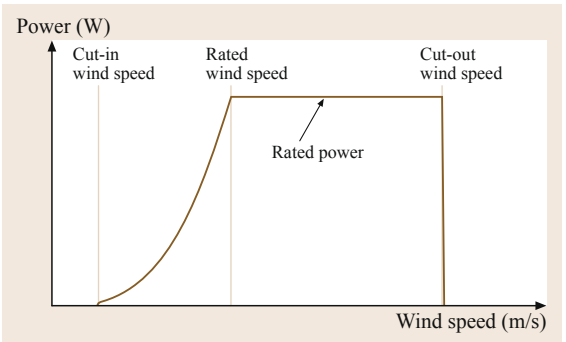

Fig. 49.3 Power output curve for a wind turbine

pitch rotors, resulting in higher blade costs than for variable-pitch-to-feather rotors [49.5], which is why the latter are more commonly used in current OWTs.

A typical OWT has three rotor blades. This configuration results in a constant moment of inertia with respect to the yaw axis (Sect. 49.1.2). More rotor blades would also result in this symmetry but would increase the weight of the rotor and, therefore, the cost of the whole turbine with very little gain in aerodynamic performance. Two or even one rotor blades result in more unfavorable dynamic properties of the rotor without sacrificing much aerodynamic performance [49.7]. Two-bladed rotors for OWTs are a topic of recent research projects.

Rotor Blades

The rotor blades are the most important components of a OWT as they actually extract the power from the wind. They are large flexible structures whose size is often underestimated when they are only seen up in the air as a part of the RNA. Rotor blades for a multimegawatt turbine compared to a truck are shown in Fig. 49.4. Both aerodynamic performance and structural strength are important for the design of a rotor blade.

An initial guess for the blade shape can be determined based purely on the aerodynamic performance following the optimal blade design according to Betz or Schmitz, which is explained in [49.5]. An example for an optimal blade design in terms of chord length, the width of the blade along its radius, is shown in Fig. 49.5. The cross-sections of a rotor blade are different airfoils that are *threaded* along the longitudinal axis. For rotors with high tip-speed ratios, i. e., for those of an OWT, the selection of these airfoils is of particular importance for the aerodynamic performance because the lift-to-drag ratio of the airfoils needs to be high. Also, the aerodynamic control of the rotor influences the choice of the airfoils.

The structural properties of a rotor blade are determined through a trade-off of dynamic properties against material usage. Thin, flexible blades might need less material but tower clearance has to be taken care of (the blades must not crash into the tower). Also, the shape of the blade root is often designed differently from the optimal aerodynamic design because of the loads that have to be transferred into the structure.

Fig. 49.4 Rotor blades for multimegawatt wind turbines compared to a truck (courtesy of Mareike Strach)

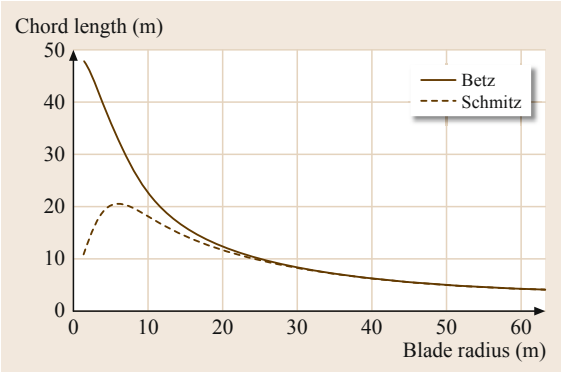

Fig. 49.5 Optimal blade chord length according to Betz and Schmitz [49.5] for a three-bladed rotor with a design tip-speed ratio of 8

Rotor blades are made from composite materials, mostly from glass-fiber-reinforced polyester. Large and flexible rotor blades, which are common for OWTs, also have carbon fibers. The most important processes in blade manufacturing are described in [49.7]. In addition, the automatization of the blade manufacturing process is a current research topic (Sect. 49.3).

Hub

The hub is the component that brings together the rotor blades and connects the rotor to the drivetrain. The most common form of hub for an OWT is rigid, which does not allow blade motions except for the pitch angle variation. That is, the hub and the rotor blades are connected through the pitch bearings and respective drives. There are other types of hubs that allow teetering of the rotor or hinging away of the rotor blades [49.7], but they are mainly used for rotors with two blades. Most hubs are made of steel and are either casted or welded structures.

49.1.2 Nacelle

The nacelle contains the drivetrain, generator, and other equipment such as hydraulic machinery, and protects all of it from the weather. It also provides the support frame for the drivetrain. To prevent salty air from corroding the components within the nacelle, most OWTs have a filtering system. For the commonly used upwind turbines and sometimes for downwind turbines, the nacelle needs to follow the current wind direc-

tion actively to allow power conversion and reduced loads on the support structure. This active control is achieved by a yaw system consisting of a yaw bearing that connects the nacelle with the tower and the yaw drives that turn the nacelle. Maintenance of OWTs is far more challenging than maintenance of land-based wind turbines (Sect. 49.1.6). Thus, some OWT nacelles are designed specifically to facilitate maintenance. For example, some designs ensure that there is enough spare space to store replacement components, or that the onboard cranes have sufficient capacity to unload transporting ships and lift heavy components, and workshops are placed within the nacelle. Additionally, maintenance personnel may have to stay in the nacelle for several days for bad weather or other reasons, therefore, survival packages, first aid boxes, and camp beds are stored there.

Drivetrain

The drivetrain is the rotating connection between the rotor and the generator. Currently, there are three major design philosophies for drivetrains: medium speed, high speed, and direct drive.

Early wind turbines had drivetrains with a three-stage gearbox that sped up the slow rotatory motion of the rotor. With such a gearbox, high-speed generators can be used. Standard high-speed generators work at rated speeds of 1500 rpm in a 50 Hz grid or 1800 rpm in a 60 Hz grid. Although this type of drivetrain has technical advantages, the main reason for combining the gearbox and high-speed generator in the early years of the wind energy industry was the availability of off-the-shelf industrial components.

As a result of several gearbox failures and the complexity of wind turbine gearbox design, German wind turbine manufacturer Enercon started to design directly driven, slowly turning multipole generators [49.9]. Although direct-drive nacelles are typically heavier than those with a classical drivetrain, they had superior reliability for several years.

With the emerging offshore wind energy industry, some companies sought to combine the advantages of the direct-drive and high-speed drivetrains by developing medium-speed drivetrains consisting of a two-stage gearbox and a medium-speed generator [49.10]. This design provides a relatively lightweight drivetrain without using the third (high-speed) stage of the gearbox. This is especially beneficial because the third stage is one of the main failure locations in common gearboxes.

In current OWTs, all three types of drivetrains are used. For several years, direct drives were said to be the dominating technology of the future; however advanced understanding of wind turbine gearboxes and the new medium-speed drivetrains made the race open again. Further insight on drivetrains is provided in [49.11] and [49.5]. A clear statement concerning the overall efficiency of the different wind turbine drivetrain concepts cannot easily be made. The annual yield for a given wind distribution at a particular site is a better benchmark value than the efficiency at the nominal operating point [49.12].

Bearings

Roller bearings are used in all drivetrain components, the pitch system, and the yaw system of an OWT. Bearing designers face several difficulties when developing bearings for wind turbine applications, and bearing failures were a main reason for reduced reliability of wind turbines in the early days of the industry [49.13].

In comparison to other industrial applications, wind turbine bearings face stochastic, varying loads. Within a high-speed drivetrain, rated speeds vary between 10 rpm on the rotor side and up to 1800 rpm on the generator side. Especially, in gearboxes that contain the entire range of speeds, a lubricant is always a compromise between the demands of the large low-speed and the small high-speed bearings. Only modern, synthetic lubricants with a powerful package of additives are able to fulfill these requirements.

Pitch and yaw bearings spend most of their life in standstill while experiencing huge bending moments. When they are turned, the rotating speed is rather low and the movement is short and sometimes oscillatory. This combination of loads prohibits the creation of a lubricating film that separates the different parts of a bearing. Wear instead of fatigue is the dominant damage mode. Bearing design for this application is especially challenging, and methods for testing and calculating the bearing lifetime are currently not available [49.13].

Generator

Today, three different kinds of main generators are used within OWTs: induction generators (IG), doubly-fed generators (DFIG), and electrically or permanent-magnet-excited-synchronous generators (EESG or PMSG). From a theoretical point of view, these types of generators can be combined with the three main drivetrain variants mentioned above. In practice, the whole bandwidth of application can only be found within the high-speed drivetrain designs. Induction generators have a higher weight than the other types and are, therefore, not used in medium-speed and direct-drive drivetrains.

The use of permanent-magnet material for field excitement seems to have the biggest advantages concerning efficiency, specific volume, and weight. However,

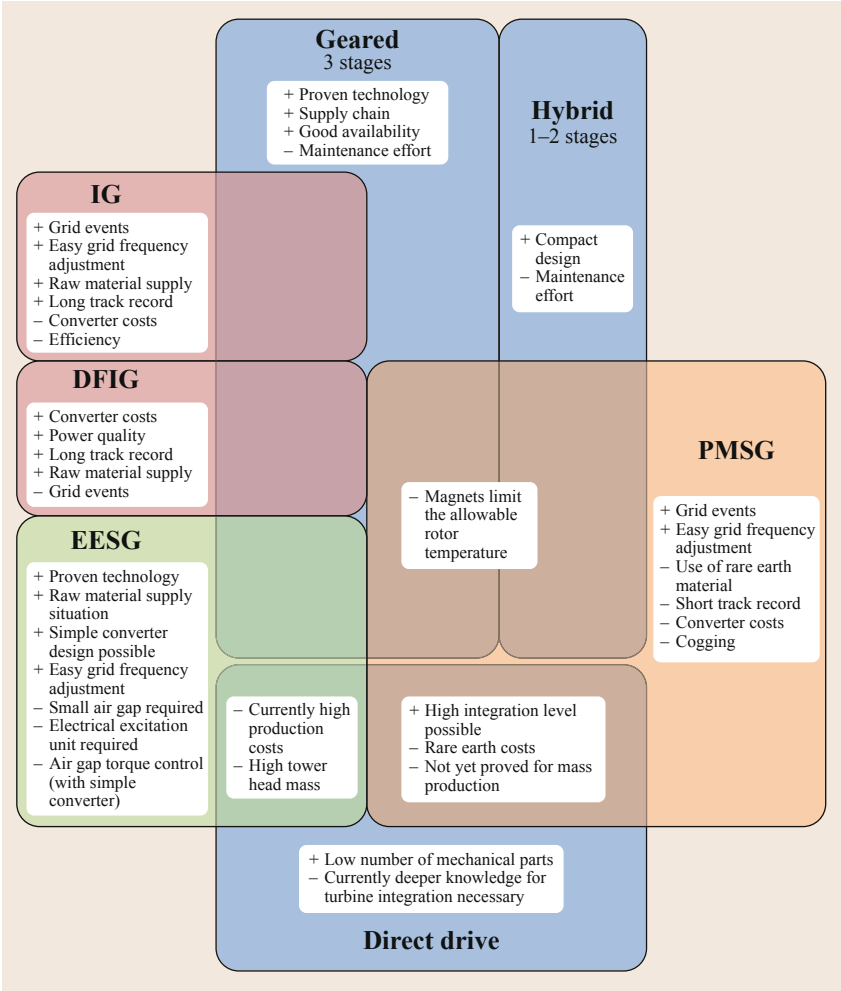

Fig. 49.6 Overview of drivetrain concepts and respective arguments

until now there has been no sufficient track record for direct-drive wind turbine applications, and volatile prices for rare earth materials can negatively influence costs. For example, in 2011, the price for 1 kg of raw neodymium started at 36 EUR, reached a top level of 195 EUR in July, and fell back to 110 EUR at the end of the year. In the same time span, the price for 1 kg of raw dysprosium varied between 243 EUR and 975 EUR, peaking at 1700 EUR. Current direct-drive generator designs need roughly 600–800 kg permanent-magnet material per megawatt of rated generator power, in which 30% of this weight is rare earth materials such as neodymium or dysprosium.

The EESG variants, which are based mainly on Enercon turbine technology, are generally very reliable, but have the disadvantage of a higher weight and a larger required installation space in comparison to the PMSG variants. The weight and size issue connected with various turbine concepts was much discussed in the past; however, it can be stated that modern direct-drive turbine developments by manufacturers such as Siemens are very close to achieving the latest benchmark-geared turbines (Vestas V90-3.0) in respect to their specific nacelle weight.

Among other things, the requirements for OWTs differ from the requirements for land-based wind turbines because of the different cost structure. Failures can lead to extensive downtime and cause high production losses. Consequently, ensuring high reliability and sophisticated service concepts are crucial (Sect. 49.1.6). As a result, direct-drive designs allow OWTs to get rid of gearbox reliability issues and gearbox maintenance. Most of the recently developed and announced offshore wind turbines by manufacturers such as Siemens, XEMC Darwind, and Alstom are direct-drive PMSG turbines. In contrast, other OWT manufacturers, like Sinovel and Repower, favor geared concepts with DFIG. Other companies, such as Ves-

tas and Gamesa, have developed OWTs with medium-speed PMSG. Nonetheless, a current trend towards direct-drive PMSG for OWTs is observable [49.12]. Figure 49.6 gives an overview of the above-mentioned concepts and the related technical arguments.

49.1.3 Support Structure

As mentioned earlier, the support structure represents the tower, substructure, and foundation of an OWT. In theory, all combinations of the different variations of each of these parts are possible [49.14]. Details on the substructure and foundation are provided below, with the focus on currently existing configurations. They are described together because the foundation and substructure cannot be separated uniquely for all configurations. An example of this would be a gravity-based substructure in which the substructure and foundation overlap to some extent.

Tower

Practically all of today's OWTs have tubular steel towers. Usually, they are built up from different tower segments (Fig. 49.7) that are bolted together at the site. A limiting factor for the tower segment diameter is a result of logistics (maximum height under bridges). For OWTs, this limitation can be avoided when the tower segments are manufactured close to the shore, making street transportation unnecessary. Towers usually have ladders and/or elevators as well as platforms on different levels inside to make the RNA accessible (for maintenance).

An important factor for the tower design is to prevent resonant vibrations by placing the first natural frequency of the tower far away from blade passing frequencies and/or rotational frequencies – typically once per revolution (1P) and three times per revolution (3P). The *tuning* of the first natural frequency is provided in greater detail in [49.5].

Fig. 49.7 Tower segments for multimegawatt offshore wind turbines (courtesy of Mareike Strach)

Substructures and Foundations

Offshore wind farms currently use monopiles, jackets, tripods, tripiles, and gravity-based substructures. They differ in appearance, how the loads are transferred to the soil, the way they are fixed to the seabed, and the water depths where they can be installed with respect to economic feasibility. So far, floating platforms for OWTs have not been used in commercial farms but in prototypes and are subject to research (Sect. 49.3). In general, when designing an OWT substructure, it is important to take into account the large overturning moment caused by the rotor thrust that is potentially much greater at rated wind speed than at cut-out or even the 50-year extreme wind speed. All substructures are equipped with so-called secondary steel, that is, with ladders, boat landings, j-tubes for cable guiding, and so on. Although secondary steel is essential for the operation and maintenance of an OWT and might induce vibrations and/or supplementary loads on the system, it is not primary, that is, load-carrying steel. Therefore, it is not discussed in detail here.

Monopiles. Monopiles are single steel tubes that are pile-driven or drilled into the seabed. A transition piece connects the monopile and the tower mainly to balance out possible inclinations in the pile and to provide possibilities for boat landing. The necessary diameter and mass of a monopile increases disproportionally with increasing water depth because the hydrodynamic loading dominates the overturning moment for great water depths [49.15]. Therefore, monopiles are usually uneconomic for water depths greater than about 30 m and are mainly used in shallow waters. Both vertical and horizontal loads are transferred to the soil through skin friction and shear forces, which requires a sufficient pile length and diameter.

Jackets. The jacket in offshore wind energy represents a three-dimensional (3-D) truss, usually with four inclined legs (the whole substructure is referred to as the jacket). Jacket designs for the German offshore wind farm Nordsee Ost are shown in Fig. 49.8. The spacing of the legs on the top of the jacket requires a transition piece to connect the tower and substructure. Just as for the monopile, this transition piece can also be used for boat landings. In theory, there is also the option of using a full-length jacket (without the transition piece and tower); however, this option has not been installed until now. There are two ways to fix a jacket

Fig. 49.8 Jacket substructures for the German offshore wind farm Nordsee Ost ready for transportation in the harbor of Bremerhaven, Germany (courtesy of Wolfhard Scheer)

Fig. 49.9 Tripod substructures for an offshore wind farm ready for transportation in the harbor of Bremerhaven, Germany (courtesy of Wolfhard Scheer)

to the sea bottom [49.5]: pile sleeves (piles are driven through tubes that are fixed at the bottom of the legs) and jacket stabs (plugs at the bottom of the legs are grouted into predriven piles). For a jacket, the loads are mainly transferred into the soil as axial loads in the legs. Also, a jacket has a higher resistance against overturning moments than a monopile because of the spacing of the legs at the sea bottom. Compared to monopiles, jackets can be considered as lightweight structures. Also, jackets can be assumed to be hydrodynamically transparent. Both load-bearing capacity and hydrodynamic properties make jackets suitable for greater water depths. However, as it is a large structure composed of multiple members that require a lot of welding, the manufacturing and logistics of jackets are more complicated and thus more expensive than for monopiles in shallower water.

Tripods. Currently installed tripod substructures are center-column tripods (Fig. 49.9). That is, they consist of a central tube that is supported by inclined tubes, which are connected through braces to provide sufficient stiffness. Transition pieces (Fig. 49.10) are used to connect the tripod and tower. Existing tripods are connected to the sea bottom using pile foundations. Because of the spacing of the legs, a tripod has a high resistance against overturning moments, similar to a jacket. However, the large central member can cause high hydrodynamic loads, and the geometry is even more complicated to weld than a jacket. In general, tripods can be used for the same water depths as jacket substructures.

Tripiles. Tripiles are patented by the BARD group and have only been used in the BARD Offshore 1 wind farm. Basically, a tripile consists of three piles that are

Fig. 49.10 Transition pieces for tripods used in combination with 5 MW OWTs in the German offshore wind farm Global Tech I (courtesy of Mareike Strach)

connected to the tower by a transition piece. For the installation, a concept similar to jackets is used: plugs at the bottom of the piles of the tripile are grouted in predriven hollow piles in the soil. The spacing of the piles provides the required stiffness and also makes the structure hydrodynamically transparent, as the piles have a relatively small diameter. Just like for the jacket, the loads are transferred to the soil through axial loads in the piles.

Gravity-Based Substructures. Gravity-based substructures (GBSs) are massive concrete structures in

which the distinction between the substructure and foundation is not as clear as it is for tripods or jackets. So far, two GBS concepts have been used for OWTs:

1. The base plate on the ground is tapered to meet the tower diameter at mean sea level.
2. A single pile is attached to a base caisson without a smooth transition.

The large weight and covered area of a GBS keep the OWT in place, and the loads are transferred to the soil through pressure on the underlying soil layers. Compared to branched structures like jackets and tripods, GBSs are very sensitive to overturning moments, which means that they are installed in shallower water.

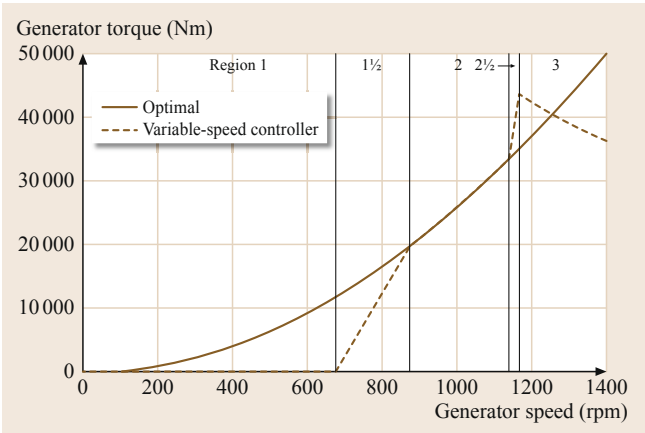

Fig. 49.11 Torque-speed-control curve for the National Renewable Energy Laboratory's 5 MW offshore reference turbine (after [49.16])

49.1.4 Control and Protection System

An OWT and its components include a large set of control systems and subsystems. Here, the term *control system* refers to the rotation speed and torque control as well as operating control. The latter is responsible for releasing and executing braking maneuvers, start-ups and shut-downs, and so on. In the following section, the focus is put on the former – the rotation speed and torque control for a pitch-controlled, variable-speed OWT.

The goals of the control system to maximize energy output while still working within operational limits like rated power, rated rotation speed, and cut-out wind speed, and to minimize static and dynamic loads on the OWT, as well to meet the grid requirements.

A pitch-controlled, variable-speed OWT has different operational modes. Above rated wind speed, the turbine is in fixed-speed mode; the pitch angle of the rotor blades is changed to keep the rotation speed of the rotor as constant as possible. Below rated wind speed, the OWT is in the variable-speed region with fixed pitch to ensure optimal energy production. Based on this principle, variations of control strategies are possible. The torque-speed-control curve of a generic 5 MW OWT is shown in Fig. 49.11. The solid line in the figure gives the aerodynamically optimal torque curve that would lead to an optimal energy output, which is a quadratic relationship between torque and generator speed. The dotted line in Fig. 49.11 represents the real torque-speed curve for the turbine. Region 1 is below the cut-in speed of the generator, i. e., the turbine is in an idling position, Region 1 1/2 is the start-up region, in Region 2 the controller follows the optimal torque-speed-curve, Region 2 1/2 is very steep and covers a wide range of wind speeds and is used to bring the turbine to generating the rated power (following the optimal curve would lead to too high rotation speeds that would cause too much noise), in Region 3 the turbine is in the variable-pitch operation mode.

Braking maneuvers, start-ups, and shut-downs are also controlled by varying the pitch angle and pitch rate of the rotor blades as well as the torque. Other control system functions include yaw control and safety and protection functions.

49.1.5 Power Electronics

Because current OWTs are variable-speed turbines, the electrical power (AC) produced by the generator is of variable frequency. In order for the frequency to be fed into the electrical grid, it needs to be within certain boundaries. For example, the target value would be 60 Hz, or 50 Hz for Europe. AC–DC–AC (AC: alternating current, DC: direct current) converters change the variable frequency power produced by the generator into DC and then back into AC power with the grid frequency.

For OWTs, usually insulated-gate bipolar transistor (IGBT) switches with reverse blocking voltage ability of 1200 V or 1700 V are used, with a DC-voltage level between 750 V and 1200 V and nominal AC-line voltages between 490 V and 690 V. Standard switching frequencies for those low-voltage converters are in the range of several kilohertz. Medium-voltage converters with a higher voltage blocking capability of 3.3 kV or 6 kV, respectively, and switching frequencies of several 100 Hz are increasingly used in OWTs. In general, this leads to lower current values at the same rated power with some inherent advantages such as lower losses, less copper, and higher reliability, but also higher investment costs [49.17].

In OWTs, converters are mostly placed within the nacelle for maintenance reasons and typically contain independent converters working in parallel. This quasi-redundancy allows for power production at a reduced level if one of the systems fail. Power converter reliability is crucial for the economically successful operation of OWTs [49.18]. As the circuit boards are very sensitive to even small interactions with the environment – for example, short circuits can be caused by flies landing on the boards – OWT converters are encased in a cabinet and have a water cooling circuit.

One aspect that is gaining importance with the increasing use of wind energy is the quality of the power fed into the grid and the wind turbine's reaction to grid events. Turbines using full converters have better capabilities in handling grid events than turbines with DFIG. Although the power delivered by the geared DFIG solution is of good quality, more sophisticated control effort and hardware protection systems are necessary to comply with most of today's grid codes. The biggest disadvantage of DFIG is the lack of a complete grid decoupling.

In general, high-speed and medium-speed PMSG/EESG have a higher efficiency than low-speed PMSG/EESG. This is mainly the result of design constraints like material usage, mechanical dimensions, air gap dimensions, and the cooling effort needed. However, the main advantage of the direct-drive concept is the mitigation of losses within the mechanical part of the drivetrain. On the other hand, gearbox turbines – especially those using DFIG technology – show slightly higher efficiency values in their optimal operating point. This is mainly caused by the significantly reduced installed power electronic (approximately 50–70% savings) compared to a full converter design (for PMSG applications).

49.1.6 Challenges of Current Technology

Although a lot of experience has been gained during the last years regarding installation and operation of OWTs, there are still challenges that need to be addressed in the future to reach the desired installed offshore capacity. One of the main challenges is the high cost of offshore wind energy compared to land-based wind energy.

Reasons for the increased cost can be found throughout the whole lifetime of an OWT. The planning and construction process takes more time and effort, mostly because of the substructure design and the grid connection. A big challenge is simply the resource management – that is, scheduling the arrival of parts to be assembled and installed at sea, given the delays in manufacturing or weather windows. The small number of suitable installation vessels can also be a reason for delays in offshore wind projects.

During the operation of an OWT, maintenance is more expensive than on land as the location can only be accessed by boat or helicopter. This limitation requires greater reliability of the condition monitoring system of an OWT [49.19]. There are also problems arising from *marinizing* existing land-based wind turbines (e.g., increased corrosion issues in the nacelle).

Despite these challenges, both research and industry have identified many bottlenecks and are working on ways to resolve them. Because there is already a solid sum of experiences from realized offshore wind projects, design standards are improving and design innovation is taking place (Sect. 49.3).

49.2 Fundamentals of Turbine Dynamics and the Offshore Environment

An OWT is a highly complex and dynamic system that is influenced by a number of linear and nonlinear effects. That is, an OWT is subject to static, cyclic, transient, and stochastic loads that originate from different meteorological, oceanographic, electrical, and structural sources [49.20]. Accordingly, both design and certification of OWTs heavily depend on accurate loads analysis with corresponding pre- and post-processing. Only with appropriate loads analysis can a reliable and cost-effective wind turbine design be achievable.

In addition, an OWT is subject to environmental conditions like turbulent wind, gusts, wind direction changes, wake effects, and ocean waves and currents. Apart from the environmental loading, the rotor of the OWT applies up to 10^9 load cycles of significant amplitude to the system during the lifetime – usually 20 years or more – of the OWT. The effects of these load cycles can be amplified by aerodynamic or structural imbalances of the rotor. Furthermore, the yaw and pitch systems, the mechanical brake, and the generator torque control system cause loads on the components of the turbine that must not be neglected when performing loads analysis.

The complexity of an OWT differs from conventional offshore structures used in the offshore oil and gas industry. For example, oil and gas structures are rather passive and high risk, because they are manned and carry a high pollution hazard. In contrast, OWTs can be considered as highly active structures because of their control system and the spinning ro-

tor, as well as low-risk structures concerning hazards for human life and the environment. Also, the design limit states for offshore oil and gas structures and OWTs are different; although conventional offshore structures are mainly designed against the ultimate and accidental limit state, the fatigue limit state is of higher importance for OWTs. Another goal is to achieve cost-effectiveness during design, manufacturing, and operation. For the latter, that means that an OWT has to withstand the before-mentioned combination of environmental and cyclic loading over its lifetime without causing high operation and maintenance costs. Furthermore, the natural frequencies of the support structures of OWTs have stricter requirements as they must not meet the rotational frequencies of the rotor or the blade passing frequency of the tower (and higher harmonics) to avoid resonance effects.

The extensive experience that exists for land-based wind turbines and for offshore oil and gas structures needs to be combined when designing OWTs; simply mounting a land-based turbine on an offshore structure is not sufficient, as this would neglect the load effects mentioned above and would not lead to a reliable and cost-effective design.

In the following sections, the main sources of environmental loading on an OWT, wind (Sect. 49.2.1) and waves (Sect. 49.2.2) are described. The inclusion of other sources of external loading (currents, ice loads, and seismic loads) are beyond the scope of this chapter. Instead, the reader is referred to the listing of the respective references in [49.20] and to the descriptions of the marine environment in [49.14] or [49.21], respectively. Furthermore, the aero-hydro-servo-elastic approach for modeling and simulating OWTs (for performing loads analysis) is introduced in Sect. 49.2.3.

49.2.1 Wind

Wind is both a source of energy and mechanical loading for an OWT. Stronger wind contains higher energy but also applies higher loading. Furthermore, the wind resources available are crucial for assessing possible locations for an OWT. An important characteristic of wind is its high variability; both wind speed and direction may change rapidly with time and position. It is, therefore, crucial to describe the wind in an appropriate way when performing loads analysis.

Nature of Wind

Wind itself is of a random nature because it varies greatly in both time and space. Following the categorization pattern of [49.7], variations in wind speed and direction can be categorized into *interannual* variations over time scales greater than 1 year, *annual* variations caused by seasonal changes (the wind is usually stronger in autumn and winter than in summer), *diurnal* variations depending on the time of the day, and *short-term* variations that describe changes within 10 min or less (gusts and turbulence).

Figure 49.12 visualizes an example for a wind speed spectrum that shows peaks corresponding to these variations. The so-called *spectral gap* between the diurnal and turbulent peak where the energy density is quite low indicates that short-term variations may be treated independently from variations on a larger time scale. However, in [49.5] it is argued that the wind spectrum shown in Fig. 49.12 is not *universally applicable*. Regardless of this, the *spectral gap* is the main reason for treating mean wind speed and turbulence separately in loads analysis (below).

In general, interannual variations are difficult to predict. For annual variations, however, the occurrence

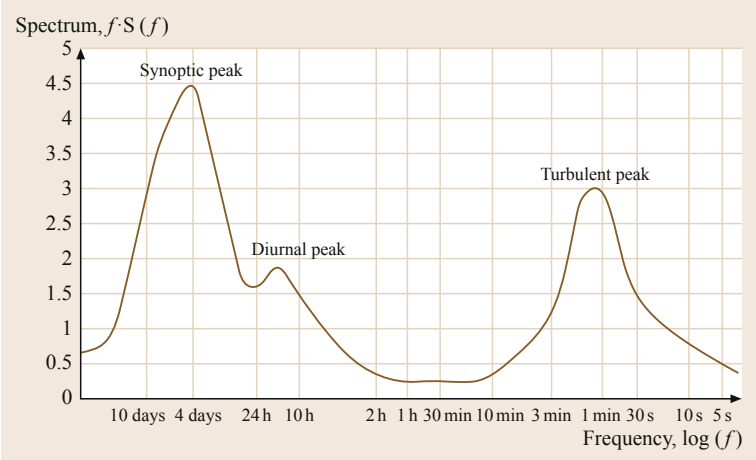

Fig. 49.12 Wind spectrum from Brookhaven, New York, USA (modified from [49.5], originally published in [49.22]. Modified with permission from [49.22]; courtesy of American Meteorology Society 1957)

probability of mean wind speeds can often be displayed by a Weibull distribution. The Weibull probability density function for a wind speed v depends on the two parameters A and k, where A is a scaling factor that determines the mean value of the probability density and k is a shape parameter that determines the width of the density.

$$p(v) = \frac{k v^{k-1}}{A^k} \exp\left(-\left(\frac{v}{A}\right)^k\right) \tag{49.2}$$

Examples of the dependency of (49.2) on different values for A and k are shown in Fig. 49.13.

With shorter time scales, the variation of wind speed is random and harder to predict. The probability distribution of turbulence can be assumed to be mainly Gaussian. This leads to the definition of a three-dimensional turbulence intensity I, which is the ratio between the standard deviation σ of the wind speed and the mean wind speed over 10 minutes, $\bar{v}$.

$$I = \frac{\sigma}{\bar{v}} \tag{49.3}$$

Turbulence is greatly influenced by terrain, with trees, bushes, and hills causing higher turbulence intensities; however, terrain-induced turbulence is of less importance for OWTs. A more important issue for wind turbines in an offshore wind farm are wake effects, in which the wake behind one turbine influences the flow of another turbine. An introduction to this topic can be found in [49.5].

Equation (49.3) is not valid for large changes in wind speed over a short time (for gusts). Therefore, for the loads analysis of OWTs, approximations of gusts according to different models are used (see below).

The wind speed also depends on the location. In general, wind speeds are higher and less turbulent offshore than onshore due to smaller surface roughnesses. The change in wind direction with height and atmospheric stability are also important factors when determining the wind speed, as well as the change in wind speed with height due to the atmospheric boundary layer, which is called wind shear. Examples of wind speed profiles based on logarithmic and power laws are shown in Fig. 49.14, and the corresponding equations can be found in standards and guidelines like [49.6, 23]. In addition, the shape of the wind speed profile over height depends on the surface roughness and the temperature distribution.

Energy in the Wind

Considering an idealized flow and constant air density ρ, the wind passing through a rotor disk with cross-sectional area A has a kinetic energy E, where m is the air mass moving with wind speed v_{wind}

$$E = \frac{1}{2} m v_{\text{wind}}^2 \,. \tag{49.4}$$

Differentiating the kinetic energy with respect to time yields the power P_{wind} that is contained in the wind

$$P_{\text{wind}} = \frac{1}{2} \rho_{\text{air}} A v_{\text{wind}}^3 \,. \tag{49.5}$$

The wind is slowed down when passing through the rotor disk, i. e., the rotor extracts energy from the wind; however, it cannot be stopped completely, as this would mean that the rotor disk is *blocked*, which would violate the continuity assumption in the flow. Thus, not all power contained in the wind can be used for energy production by a wind turbine. The maximum power that can be extracted from the wind theoretically, P_{Betz}, was derived by *Betz* in [49.24],

$$P_{\text{Betz}} = c_{\text{p,Betz}} \frac{1}{2} \rho A v^3 \,. \tag{49.6}$$

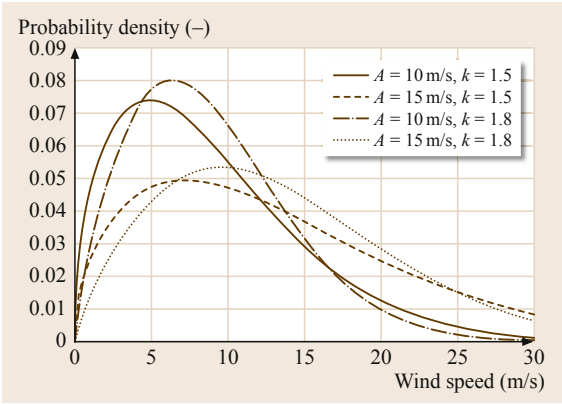

Fig. 49.13 Weibull probability density function for different values of k and A

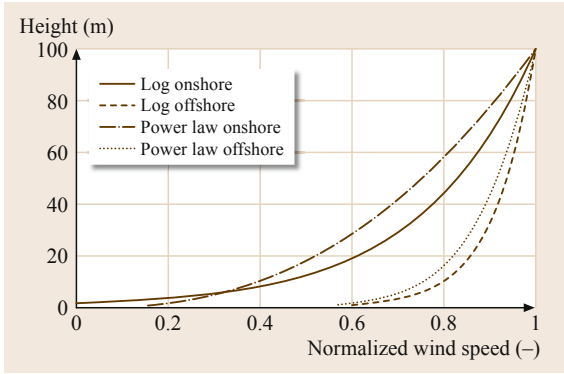

Fig. 49.14 Examples of land-based and offshore wind shear profiles according to logarithmic and power law

The Betz power coefficient $c_{p,Betz}$ equals $\frac{16}{27}$ or 0.59, which means that a maximum of 59% of the energy contained in the wind can be extracted. Practically, this value can not be reached, as friction and other losses reduce the power that is possible to extract.

Description of Wind in Loads Analysis

In loads analysis, standards and guidelines like [49.6] or [49.23] give recommendations on how to produce time series of wind velocities that can be used for the simulation of an OWT. Usually, 10 min time series are needed, for which a mean wind speed is assumed.

To choose an appropriate range for the mean wind speeds, measurements from a chosen site should be available. If this is the case, the measured mean wind speeds are sorted into bins of usually 2 m s^{-1} width and a Weibull distribution is fitted to the occurrence probabilities of the bins. In Fig. 49.15, an example of a wind speed histogram with corresponding Weibull distribution is shown. The Weibull probability density is needed for fatigue load calculation to obtain weighting factors that can be used to estimate the importance of simulated load time series.

To obtain values for the turbulence intensity in each spatial direction, either measurements or recommendations from standards and guidelines are used. The variations caused by turbulence are then added to the mean wind speed so that the wind time series fluctuates around the mean wind speed. These turbulent wind time series are produced numerically using stochastic methods. The turbulence is derived from a wind spectrum for all three directions of wind speed at many points across the rotor plane, ensuring proper discretization and spatial coherence. Therefore, a turbulent wind field is random and different in each realization. The boundary conditions to obtain these random wind fields are given in the standards. Typically used models are the *Kaimal* spectrum [49.25] or the *Mann* model [49.26].

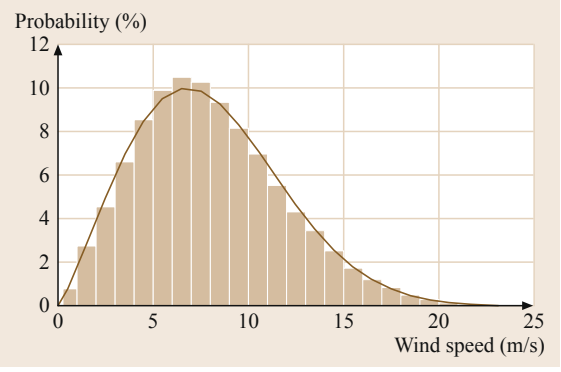

Fig. 49.15 Example of a wind speed histogram with fitted Weibull distribution

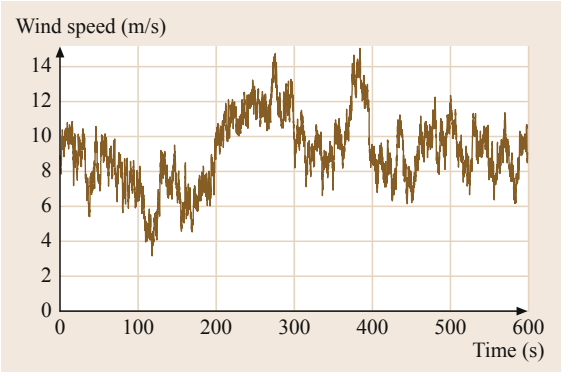

Fig. 49.16 Example of a turbulent 10 min wind speed time series with a mean wind speed of 9 m/s and 20% turbulence intensity

Based on these models, the wind field is generated. An example for a turbulent 10 min wind speed time series for the principle wind direction and a mean wind speed of 9 m s^{-1} and 20% turbulence intensity is shown in Fig. 49.16.

To display extreme wind speeds and gusts, a turbulent wind field is not sufficient. For extreme wind speeds, usually the 1 and 50-year wind speeds, that is, the maximum mean wind speed over a given time interval that statistically is exceeded only once in 1 and/or 50 years, is taken into consideration. Measurements over a long time are usually not available, such that the 1 and 50-year wind speeds can be determined using extreme value extrapolation or based on recommendations in guidelines like [49.23].

As mentioned above, gusts are commonly displayed using a predefined shape. Examples are the *one-minus-cosine* or the *Mexican hat* gust shapes [49.20]. Other shapes can be found in the respective standards and guidelines, like [49.6] and [49.23].

49.2.2 Waves

The description of ocean waves given in this section is purely focused on how waves are represented in offshore wind energy, particularly during loads analysis of OWTs. For more detailed descriptions of the different theories and methodologies that offer a wider focus, see other chapters of this book and/or standard offshore engineering textbooks like [49.27–29]. The basis for modeling ocean waves is sufficient long-term meteorological and oceanographical data. Usually, a joint probability distribution of significant wave height H_s, spectral peak period T_p, and wind speed v_{wind} is provided to select appropriate sea states for a mean wind speed. Such a distribution can be derived based on three-dimensional scatter diagrams for a given location.

Wind speed bin v_{wind} (m/s)		T_p (s)												Probability
		<0.5	1	2	3	4	5	6	7	8	9	10	11

An example of the format of a scatter diagram is shown in Fig. 49.17.

The theories used for modeling ocean waves in the context of loads analysis are given in standards and guidelines. According to [49.23], for almost every design load case (for almost every simulation) waves should be modeled as long-crested irregular waves. That is, a number of wave components with different frequencies and phase angles based on linear wave theory [49.27] are superposed to obtain an irregularly shaped wave elevation. This approach is no different to how turbulence at a location is derived from a wind spectrum; the wave kinematics are derived based on this irregular wave elevation. Wave spectra, which represent the energy density of a sea state depending on the wave frequency, are the basis for this description. For loads analysis of OWTs, two spectra are commonly used: the Pierson–Moskowitz spectrum [49.30] for fully developed sea states as well as the JONSWAP spectrum [49.31] for storms, which is derived from the Pierson–Moskowitz spectrum. Discretizing the wave spectrum gives the wave frequencies for the wavelets that are superposed. The phase angles are assumed to be uniformly distributed and are, therefore, of random nature. This approach makes each realization of a sea state different from another.

To display short-term events, such as extreme waves, the design wave method is commonly used, as described in [49.23]. Similarly to the n-year wind speeds, the n-year wave height with corresponding wave period is used to model the design wave. Using the 50-year wave height is recommended when modeling OWTs [49.6]. It is also common to use higher order wave theories to describe the wave kinematics for the design wave (wave theories that are based on Dean's stream function). In this way, the wave crest can be modeled larger than the wave trough, which is more realistic for high and extreme waves.

49.2.3 Aero-Hydro-Servo-Elastic Models for Horizontal-Axis Wind Turbines

The assessment of OWTs is based on aero-hydro-servo-elastic simulation models. Simulations of OWTs are performed in the time domain to capture the nonlinear dynamic effects and time-dependent events that are described in the introduction of this section can be accounted for. Aero-hydro-servo-elastic models display the complex interaction between aerodynamics (*aero*), hydrodynamics (*hydro*), the control system (*servo*), and structural dynamics (*elastic*) under the influence of external loads from the wind (including wake effects), waves, soil, electrical grid, and – where applicable – ice. This coupled approach is required by standards and guidelines to predict the dynamic response as well as extreme and fatigue loads of the OWT. The importance of the coupled models can be seen, for example, in the aerodynamic damping of the rotor, which can reduce the loads on the substructure significantly [49.14]. This effect would be lost when the wave loads are calculated separately from the wind loads in a so-called sequential approach.

To base an OWT design on simulations, the aero-hydro-servo-elastic models need to be detailed enough to predict load effects and dynamic response; however, because a large number of simulations need to be run, the time needed to run a simulation has to be considered when choosing the level of detail for the model.

Rotor Aerodynamics

Methodologies with different levels of detail that are used to calculate the aerodynamic loads on the rotor of an OWT are introduced below. The commonly used

blade-element-momentum (BEM) theory and the generalized dynamic wake (GDW) method are described. For a broader description of OWT rotor aerodynamics of OWT see [49.5] and [49.32].

Blade Element Momentum Theory. The BEM theory is the state-of-the-art method for calculating aerodynamic loads in OWT loads analysis. This method is fast and gives good results – assuming that appropriate aerodynamic airfoil data are available. Therefore, it is very common to use BEM theory with corrections in the wind industry.

In BEM theory, the rotor blade is divided into elements for which induction factors are determined. The induction factors describe how much the wind speed is reduced and redirected by each blade element. Based on the induction factors, the resultant velocities and angles of attack for the aerodynamic loads can be derived for each blade element. Each blade element is associated with aerodynamic airfoil data that are used to determine the aerodynamic loads. The aerodynamic loads influence the induction factors, which makes BEM theory an iterative method that is repeated until the induction factors converge. The calculations are based on the following principles:

- *Newton's law*: The calculation of the wind speed through the rotor disk is based on the equilibrium between aerodynamic loads on the blade elements and the change of momentum of the moving air. The change of momentum equals the change in velocity multiplied by the mass flow.
- *Bernoulli's theorem*: The loads at each blade element equal the average pressure difference on the rotor disk multiplied by the area swept by the rotor.
- *Airfoil theory*: The loads at each blade element can be determined using airfoil theory in which the loads are calculated using the angle of incidence of the wind speed.

BEM theory is based on assumptions that are often violated in reality. The method is, therefore, corrected to make up for these violations – for example, the flow is assumed to be stationary. This assumption requires a correction for instationary and skewed flow. Additionally, airfoil theory has to be modified using unsteady aerodynamic models, including dynamic stall (one possibility is the *Beddoes–Leishman* method [49.33]). It is further assumed that the flow is two-dimensional, which means that adjacent blade elements do not influence each other. This assumption requires the aerodynamic airfoil data to be corrected for 3-D effects. Moreover, the rotor is assumed to be a disk with an infinite number of blades, which makes a correction necessary that accounts for hub and tip losses (tip-loss correction according to Prandtl). Another correction that is often employed is a time filter to *pseudo dynamic wake.* Additionally, the flow reversion around the rotor is neglected. Therefore, for heavily loaded rotors, i. e., mostly for large axial induction factors, a correction according to Glauert is applied. Both BEM theory and the mentioned corrections are described in standard wind energy textbooks like [49.5].

Generalized Dynamic Wake Method. Similarly to the BEM theory, the GDW method provides fast results. The GDW method is a dynamic inflow method and is based on obtaining the pressure by solving the Laplace equation. Originally, it was developed for helicopters in [49.34].

The pressure and velocity field are described as superpositions of functions whose coefficients are obtained by solving a system of differential equations. The calculation of aerodynamic loads is done by applying airfoil theory. In contrast to BEM theory, which is based on a rotor disk, the GDW method allows for the localization of the position of the rotor blade within the velocity field. In this way, most of the above-mentioned corrections for BEM theory are obsolete for the GDW method. However, the dynamic stall method must still be applied.

Hydrodynamics

Similarly to the description of the waves in Sect. 49.2.2, this section focuses on the calculation of hydrodynamic loads for OWTs. For a general description of (moving) bodies in waves and the forces exerted from waves on offshore structures, the reader is referred to other chapters of this book or to standard offshore engineering textbooks like [49.27–29].

For aero-hydro-servo-elastic simulations of OWTs, the *Morison* equation [49.35] is commonly used to determine the loads applied from waves on the substructure. That is, the hydrodynamic forces are assumed to be a sum of inertia and drag loads. The inertia part consists of Froude–Krylov and the scattering term characterized by an added mass multiplied by the water particle acceleration based on the long wave-length approximation of the diffraction problem. Added mass based on member acceleration is typically included separately. The drag part accounts for viscous drag and is proportional to the squared water particle velocity, including structural motions. Other loads on an OWT result from the surrounding water include buoyancy, dynamic pressure, and slap and slam loads.

An obvious drawback of the Morison equation is the assumption of hydrodynamic transparency; it can only be used if the ratio between characteristic dimension and wave length is smaller than 0.2. That means

that radiation, reflection, and diffraction effects (the influence of the body on the wave field) are not accounted for. With the currently used substructures and water depths (Sect. 49.1.3), this is a reasonable assumption. However, with new technology arising (Sect. 49.3), the assumption of hydrodynamic transparency may no longer be applicable. Therefore, some OWT simulation tools already have the ability to account for the influence of the OWT substructure on the wave field. For example, this is done by using the *MacCamy–Fuchs* approximation [49.36] or by using the results from the frequency-domain analysis of the substructure in waves in the time domain, as described in [49.37].

Control System

In general, the control system is of high importance for the modeling of large and flexible wind turbines as it has a large influence on the magnitude of the loads. Without proper representation of the control system in the OWT model, it is not possible to achieve correct estimates of performance and loads. However, the control system is often also the most *secretive* part of the OWT, for which realistic parameters are hard to come by.

Using the example of a variable-pitch controlled OWT, it is necessary to display the time of activation, pitch rate, and maximum angle of pitch. Furthermore, the frequency of the control system must be included to display the time needed for a full control cycle (looking up the generator speed and returning the correct pitch angle). Safety functions of the control system also need to be implemented.

Structural Models

When conducting loads analysis of OWTs, structural models are used to determine load effects depending on the time for various components and positions of the turbine. Nonlinear effects like large deflections, nonlinear aeroelastic effects, nonlinear dynamic properties, and time-varying loads have to be accounted for [49.20]. In short, the structural model has to be coupled to the aerodynamics, hydrodynamics, and the control system model (introduction of this section). Furthermore, components of a wind turbine are coupled to each other, which has to be displayed in the model. For example, the wind-induced movement of the rotor blades can influence the drivetrain vibrations.

Usually, the rotor blades, tower, and drivetrain are modeled as flexible beam components. The nacelle, hub, gear box, and generator are often assumed to be rigid. The main bearing, yaw bearing, and clutches are usually modeled as connections between the respective components.

Choosing an approach for the structural models means doing a trade-off between accuracy of results and simulation time. Therefore, there are three approaches for modeling the structure of an OWT: multibody simulation (MBS), modal reduction approaches, and the finite-element method (FEM). However, combinations of these approaches are even more commonly used (e.g., a combination of MBS and modal reduction or a combination of MBS and FEM). Each approach and respective combinations are introduced below.

Multibody Simulations. In the time domain, the components of an OWT are displayed as rigid bodies that have a mass and are connected by massless joints. The joints can restrain the degrees of freedom (DOFs) of the bodies and elasticity of the joints can be modeled through spring–damper elements. The motion of the coupled bodies can be obtained using Lagrange formalism with generalized coordinates and masses.

Components for which a single rigid body is not sufficient – such as for the rotor blades and the tower – can be modeled through multiple bodies that are connected through springs and dampers. This approach increases the number of DOFs and, therefore, the simulation time. A modal reduction is often performed for these components.

Modal Reduction. It can be said that the higher the number of DOFs in a system, the more time is needed to solve the equations of motion. In a modal reduction approach, the number of DOFs is reduced and, therefore, the simulation time decreases. When simulating OWTs, the equations of motion are solved using an MBS approach; however, components like the rotor blades, tower, and drivetrain are modeled using a modal reduction approach.

Before simulating the whole system, the respective components are modeled using appropriate beam theories based on the geometry and material properties. The mode shapes of the OWT components are determined to be used as shape functions in the (often nonlinear) beam element formulation. The vibrations of the components in the OWT system are then modeled through superposition of a finite number of mode shapes. This method can reduce the number of DOFs drastically, although there is also a loss in accuracy. In loads simulation tools for OWTs, the following configurations are typically used for a modal-reduced model:

- The first three or four mode shapes are used for the rotor blades (two in flapwise, one or two in edgewise direction).
- Four mode shapes are used for the tower (two for bending out of the rotor-plane, two for bending in the rotor-plane).

- Three mode shapes are used for the drivetrain (one for torsion, two for bending).

Although there is a loss of accuracy with respect to the solution of the full system of equations, modal-reduced models agree with measurements. Therefore, they are validated and are used in a number of OWT loads analysis tools.

It should be clarified that modal methods in OWT simulation tools include many nonlinear terms that are important for modeling the dynamic response, such as axial shortening, coriolis and gyroscopic loads, and so on. A possibility is to model the rotor blades and the tower with a nonlinear beam formulation based on a limited number of shape functions. Because there is a limited number of shape functions, it is good to use mode shapes for the shape functions. This is often called a modal method, but it is not a linear approach.

Finite-Element Methods. Modal-reduction methods are efficient when it comes to simulation time. However, large deflections, as they become more important for sizeable and very flexible turbines, often cannot be displayed accurately enough with this approach. Instead, a FEM-based multibody approach can be used, which allows for the simulation of more complex deformation states of the OWT.

Similar to the modal-reduction approaches, the equations of motions of the OWT are solved using an MBS approach, but components like the rotor blades and tower are modeled through beam finite elements. Usually, beam elements are used for the components so that torsional, bending, extensional, and shear stiffness can be considered. This system of FEM-based dynamic MBS-equations can be solved iteratively for the combination of *elastic* DOF (coming from the finite elements) and *rigid* DOF (coming from the multibody connections).

FEM-based methods are slower than modal-reduction approaches in terms of the simulation time; however, they are already being used in some of the loads simulation tools for OWTs.

49.3 Outlook on Future Technology

The state of the art of OWT technology has been described in the previous sections. This section describes the technology that is in the early design stage, only exists in prototypes, and/or is currently subject to research. Technology types include floating offshore wind turbines and rotor configurations that differ from the previously described three-bladed horizontal-axis upwind rotors, new blade technology, and further developments related to analyzing OWTs through loads simulations.

A significant amount of research is currently being done to develop cost-effective and reliable floating OWTs. In these systems, the wind turbine is mounted on a floating platform with an appropriate station-keeping system instead of on bottom-fixed substructures (described in Sect. 49.1.3). It was shown by *Musial* et al. in [49.38] that floating OWTs could become economically feasible. As of today, there are four floating prototypes with multimegawatt turbines in operation. Two are installed in European waters (Norway and Portugal, shown in Figs. 49.18 and 49.19), while the other two are Japanese designs that are installed off Fukushima.

Both the design and modeling of floating OWTs are challenging. The prototypes that have been installed thus far use a traditional three-bladed horizontal-axis wind turbine, as described in Sect. 49.1, mounted on floating platforms that were designed based on experience from the offshore oil and gas industry. This approach has been adopted in many research projects. In contrast, the heavy weight of the RNA high above the floating platform may imply complications in terms of stability, therefore additional research projects are being conducted on vertical-axis floating OWTs. Another research possibility is to study the use of downwind rotors.

For the simulation of floating wind turbines, there are already a number of sophisticated tools available; these are described in [49.39]. However, there are also challenges to developing appropriate simulation tools; these are summarized in [49.40], such as the use of

Fig. 49.18 Hywind prototype: 2.3 MW wind turbine on a spar buoy platform (courtesy of Lars Christopher)

Fig. 49.19 WindFloat prototype: 2.0 MW wind turbine on a semisubmersible platform (courtesy of Untrakdrover, Wikimedia Commons)

more advanced hydrodynamics including second-order effects. Another current research interest is the validation of simulation models through model test data. Yet, this is a difficult area to study because of scaling issues and the generation of both wind and waves at the same time. Field data is rarely available because of the small number of available prototypes and their proprietary nature.

As mentioned in Sect. 49.1.6, the experience gained with OWTs has led to improvements in the certification guidelines. This is also the case for floating OWTs; both the IEC and certification bodies are developing guidelines dedicated to floating OWTs, see [49.23] or [49.41].

Restrictions in the development of land-based turbines do not necessarily apply to OWTs. For example, noise emissions are less of an issue offshore than on land, which makes higher tip speeds possible for OWTs. Furthermore, the ease of transportation offshore and the cost of the support structure, which has a large share of the overall OWT cost, leads to developments with higher rated power – possibly up to 10 MW. For this, larger blades are necessary, which leads to new developments in terms of materials and load reduction methods. A possibility for larger blades would be the use of so-called *smart blades* – blades with sensors and actuators and/or structural properties that allow for load reduction. Another possibility is the individual pitch control of each blade [49.42].

The challenge of making offshore wind energy more cost effective is being addressed by research dedicated to the automated manufacturing of components, such as the rotor blades and simplified logistics (self-installing substructures).

In summary, there is a lot of research dedicated to making offshore wind energy more reliable and cost effective in the future. This is done through the development of new concepts for the overall turbine layout as well as modifying components based on offshore requirements. Furthermore, logistics, guidelines, and aero-hydro-servo-elastic models are constantly being adapted and improved to meet the growth of the offshore wind industry.

Acknowledgements

A.6 Principles of Marine Corrosion

by Robert Melchers

The author acknowledges the continued provided by Australian Research Council Professorial Fellowship scheme (2004–2008, 2009–2013). He also acknowledges with gratitude the support he receives from a great team of co-researchers and from many in industry.

B.11 Highly Maneuverable Biorobotic Underwater Vehicles

by Promode Bandyopadhyay

The author's various works described in this review have been sponsored by the Bio-inspired Autonomous Systems Programs of the Office of Naval Research (ONR), Dr. Thomas McKenna (ONR 341), and also by ONR341 (Dr. Teresa McMullen, Dr. Harold Bright, and Dr. Linda Chrisey), and ONR33 (Mr. James Fein, and Dr. Kam Ng). The author's exposure to olivocerebellar dynamics owes a great deal to the fruitful interactions with neuroscientists Dr. Thomas McKenna of ONR, Professor Rodolfo Llinas of the Department of Neuroscience of the New York University Medical School, and Professor James Simmons of the Bat Laboratory of the Brown University Neuroscience Department. The author thanks his many co-workers who made the demonstrations described in the article possible over the last two decades.

B.20 Nested Autonomy for Distributed Ocean Sensing

by Henrik Schmidt, Michael Benjamin, Stephanie Petillo, Toby Schneider, Raymond Lum

The development of the fundamentals of the nested autonomy concept, and the MOOS autonomy system were performed at MIT with support from the Office of Naval Research Code 32 under the GOATS program (Thomas B. Curtin, Jeffrey Simmen, Randy Jacobson and Tom Swean, Program Managers) and the IvP extension was performed at MIT and NUWC under support from Dr. Don Wagner and Dr. Behzad Kamgar-Parsi from ONR Code 31. The operational paradigm and the associated MOOS-IvP configuration have subsequently been further developed and applied in several major field experiments under the ONR GOATS (Thomas B. Curtin, Ellen Livingston, and Bob Headrick, Program Managers), SWAMSI (Bob Headrick, Program Manager), and PLUSNet Undersea Persistent Surveillance (Thomas B. Curtin, Program Manager) programs, and most recently the DARPA DSOP Program (Andy Coon, Program Manager). The specific application of the concept to the adaptive tracking of the thermocline was performed under the ONR Adaptive Sampling and Prediction (ASAP) MURI (Thomas B. Curtin, Program Manager) and supported by the U.S. Department of Defense (DoD), U.S. Air Force Office of Scientific Research, and National Defense Science and Engineering Graduate (NDSEG) Fellowship 32 CFR 168a.

The first field demonstration of MOOS and the early version of the nested autonomy control paradigm were performed in the BP02 experiment in La Spezia, Italy, carried out jointly with the NATO Undersea Research Centre (NURC), who supplied engineering and operational support. The GLINT'08-'10 experiments were also carried out in collaboration with NURC, and the authors appreciate the assistance from NURC for their exceptional engineering and operational support, and the use of their OEX AUV for the thermocline mapping and multistatic acoustic experiments described here. The collaboration with Naval Undersea Warfare Center (Michael Incze, Scott Sideleau, and Dr. Don Eickstedt) Code 25 & the ONR Lightweight NSW UUV program in the Lake Champlain'09 experiment is highly appreciated.

B.21 Science of Autonomy: Time-Optimal Path Planning and Adaptive Sampling for Swarms of Ocean Vehicles

by Pierre Lermusiaux, Tapovan Lolla, Patrick Haley Jr., Konuralp Yigit, Mattheus Ueckermann, Thomas Sondergaard, Wayne Leslie

PFJL dedicates the results presented to Dr. Tom Curtin. Tom Curtin's vision and questions in the early 2000s on how to utilize the ocean currents as dynamic highways for autonomous vehicles were early seeds for our theoretical and applied research in marine autonomy. We are also very thankful to all members of the MSEAS group, past and present, for the many useful discussions. PFJL also thanks Drs. Tim Duda and Kevin Heaney, as well as Drs. Jim Bellingham, Russ Davis, Constanti-

nos Evangelinos, Dave Fratantoni, Glen Gawarkiewicz, Naomi Leonard, John Leonard, Sharan Majumdar, Nick Patrikalakis, Steve Ramp, and Henrik Schmidt for their collaborations on autonomy. We are grateful to the Office of Naval Research for support under grants N00014-09-1-0676 (Science of Autonomy, A-MISSION) and N00014-12-1-0944 (ONR6.2) to the Massachusetts Institute of Technology (MIT). We especially thank Dr. Marc Steinberg, as well as Drs. T. Paluszkiewicz and S. Harper, for their support and interactions. KY is very thankful to the Turkish Navy for support. MPU and PFJL thank the Natural Sciences and Engineering Research Council (NSERC) of Canada for the postgraduate scholarship partially supporting the graduate studies and research of MPU at MIT.

C.25 Physical Characteristics of Coastal Hazards

by Jennifer Irish, Robert Weiss, Donald Resio

This effort was supported by Virginia Tech and the University of North Florida. The authors wish to thank Dr. Celso Ferreira and Mr. Antonne Taylor for providing literature review materials on environmental impacts and storm waves, respectively.

C.26 Statistical Characterization of Hazards and Risk in Coastal Areas

by Donald Resio, Mark Tumeo, Jennifer Irish

This effort was supported by the University of North Florida and Virginia Tech.

D.36 Vortex-Induced Vibrations

by Michael Triantafyllou, Rémi Bourguet, Jason Dahl, Yahya Modarres-Sadeghi

The authors wish to acknowledge support by ONR, monitored by Dr. Thomas Swean, Jr., by the BP Major Projects Programme monitored by Dr. Michael Tognarelli and Mr. Pierre Beynet, and by Chevron's University Partnership Program, monitored by Mr. Yiannis Constantinides and Dr. Owen Oakley.

E.46 Ocean Current Energy Conversion

by Howard Hanson, James VanZwieten, Gabriel Alsenas

The Southeast National Marine Renewable Energy Center at Florida Atlantic University is supported by the State of Florida and by the US Department of Energy. The views expressed in this chapter are those of the authors and are not meant to represent the views of these public entities.

E.47 Harvesting Energy by Flow Included Motions

by Michael Bernitsas

The effort for the basic research and development of the VIVACE converter started in 2005 and several Federal, State, and private sponsors supported it. The following support is gratefully acknowledged:

1. DOE contract DE-EE0003644 to Vortex Hydro Energy with subcontract to the University of Michigan
2. DOE contract DE-EE0006780 to Vortex Hydro Energy with subcontract to the University of Michigan.

Besides DOE, present supporters include the University of Michigan, the State of Michigan, Vortex Hydro Energy, SPARK of Ann Arbor, and private investors to VHE. Previous supporters (2005–2014) include DOE (DE-SC-0010091), the National Science Foundation (IIP-0810426, IIP-1026367), the Office of Naval Research (N00014-03-1-0983, N00014-08-1-0601), the US Navy (N62583-09-C-0091), MUCI – Michigan University Commercialization Initiative, TAUW BV Deventer, The Netherlands, DTE Foundation, Wayne County Detroit Port Authority. The support of Mr. David Haynes of the Economic Development Alliance of St. Clair County has been most helpful in collaborating with the local authorities for field deployments.

The author would like to express his sincere thanks to the Editors of this Handbook, Drs. Manhar Dhanak and Nikolas Xiros for their thorough review of the manuscript. Since 2005, more than 100 students have been educated and trained in the MRELab including UROP, BSE, MSE, Ph.D. students, postdoctoral fellows, and international visitors. Their engineering innovative thinking has been a continuous source of challenge in pioneering a multifaceted research effort and developing a unique technology. In chronological order, the following collaborators, whose papers are cited in this chapter, have been major contributors in the research and development of the VIVACE converter: Kamal Raghavan Ph.D., Yaron Ben Simon P.E., Prof. Elisha M.H. Garcia Ph.D., Prof. R. Ajith Kumar Ph.D., Gustavo Simiao, Rebecca Macklem-Alter, Prof. Nikolas Xiros Ph.D., Jonghun Lee Ph.D., Che Chun Chang Ph.D., Wei Wu Ph.D., Hongrae Park Ph.D., Eun Soo Kim Ph.D., Austin Kana, Prof. Hai Sun Ph.D., Lin Ding Ph.D., Jianhui Liu Ph.D., Prof. O. Kemal Kinaci Ph.D. Undergraduate Research Opportunity (UROP) students George M. Hadjicharalambous and Ryan Ouderkirk contributed to the clarity of the document and referencing, respectively.

About the Authors

Raju Abraham

Naval Research Board
Pallickaranai Campus
Chennai, India
abraham@niot.res.in

Chapter E.48

Raju Abraham has worked at the National Institute of Ocean Technology, Chennai, on design, development, and operation of OTEC systems, desalination systems, and deep sea mining systems for 17 years. He worked on the installation of one MW OTEC plant in India, which was tested on a floating barge (1998–2003) and on a low temperature thermal desalination plant utilizing ocean temperature difference (2004–2007).

Gabriel M. Alsenas

Florida Atlantic University
Southeast National Marine Renewable Energy Center
Boca Raton, USA
galsenas@fau.edu

Chapter E.46

A founding member of FAU's SNMREC, Gabriel Alsenas' previous work focused on US Navy future projects and sensor systems. He earned BSc and MSc degrees in Ocean Engineering at FAU. He is Convenor of IEC/ISO's TC-114 AHG04 (tidal performance assessment), Chief US delegate for IECRE's certification and conformity ME-OMC, Treasurer for the USNC/IECRE, and a Judge at FIRST Robotics FRC competitions.

Pak-Cheung Edgar An

Florida Atlantic University
Dep. Ocean and Mechanical Engineering
Boca Raton, USA
pan@fau.edu

Chapter A.10

Dr Edgar An received his BS degree from the University of Mississippi in 1985, and his MS and PhD degrees from the University of New Hampshire in 1988 and 1991. He joined the Department of Ocean Engineering at Florida Atlantic University in 1995. His areas of interest are autonomous underwater vehicles, navigation, control, robotics, modeling and simulation, and neuro-fuzzy systems.

Palaniswamy Ananthakrishnan

Florida Atlantic University
Dep. Ocean and Mechanical Engineering
Boca Raton, USA
panantha@fau.edu

Chapter A.4

Dr P. Ananthakrishnan received his PhD in Naval Architecture and Offshore Engineering from the University of California at Berkeley. He joined Florida Atlantic University where he taught fluid mechanics, water wave mechanics, ship hydrodynamics, physical oceanography and computational methods. He has served as a visiting faculty member at the Indian Institute of Technology Madras, India and at Ecole Centrale de Nantes, France.

Alexia Aubault

Principle Power Inc.
Berkeley, USA
aaubault@principlepowerinc.com

Chapter D.34

Alexia Aubault attended Ecole Nationale Supérieure de Techniques Avancées, a Technology Institute of ParisTech, France. She earned a Master's degree in Ocean Engineering at the University of California, Berkeley. She is a Lead Engineer at Principle Power Inc., a renewable energy firm dedicated to offshore wind technology. A naval architect, Alexia has focused on global design of floating structures, complex hydrodynamic modeling, and hull loading.

Alexander Bahr

Ecole Polytechnique Fédérale de Lausanne
ENAC IIE DISAL
Lausanne, Switzerland
alexander.bahr@epfl.ch

Chapter B.14

Alexander Bahr is a Postdoctoral Associate at Ecole Polytechnique Federale de Lausanne. He holds the degrees of Diploma in Electrical Engineering from the Technical University Aachen and a PhD from the MIT/Woods Hole Joint Program in Applied Ocean Science and Engineering. His research interests include navigation, communications, and cooperation for autonomous underwater vehicles, and wireless sensor networks.

Promode R. Bandyopadhyay

Naval Undersea Warfare Center
Undersea Warfare Weapons, Vehicles, and Defensive Systems Dep.
Newport, USA
promode.bandyopadhya@navy.mil

Chapter B.11

Promode Bandyopadhyay's current research focuses on developing autonomous biorobotic technologies. Areas of recent research have been neuroscience-based control of unmanned underwater vehicles, microbial fuel cells, flapping fin propulsion technology, and analytical theories of wall-turbulence and control. His activities also include the mentoring of new and prospective hires and teaming with national and international performers.

David R. Basco

Old Dominion University
Dep. Civil and Environmental Engineering
Norfolk, USA
dbasco@odu.edu

Chapter C.30

Dr Basco is Professor of Civil Engineering and Director of the Coastal Engineering Centre at Old Dominion University, Norfolk, VA, USA.

Pierre-Philippe J. Beaujean

Florida Atlantic University
Dep. Ocean and Mechanical Engineering
Boca Raton, USA
pbeaujea@fau.edu

Chapter B.15

Pierre-Philippe J. Beaujean is an Associate Professor in the Department of Ocean and Mechanical Engineering, Florida Atlantic University. He specializes in underwater acoustics, with a particular interest in acoustic telemetry and networking, acoustic imagery, sediment acoustics, detection and classification of subsea objects, and machine reliability. Dr Beaujean is an active member of the Acoustical Society of America and a Marine Technology Society member.

James G. Bellingham

Woods Hole Oceanographic Institution
Woods Hole, USA
jbellingham@whoi.edu

Chapter B.16

Dr Bellingham received his PhD in Physics from MIT in 1988. He is a leader in the field of marine autonomous robotics, having created a large number of robotic systems and pioneered their use at sea. After 7 years as the Chief Technologist at MBARI, he joined WHOI as the founding Director of the Center for Marine Robotics.

Michael R. Benjamin

Massachusetts Inst. of Technology
Laboratory for Autonomous Marine Sensing Systems
Cambridge, USA
mikerb@mit.edu

Chapter B.20

Michael Benjamin is a Research Scientist at MIT in the Department of Mechanical Engineering and the Computer Science and Artificial Intelligence Lab. His research focus is on autonomy algorithms for unmanned marine vehicles. Dr Benjamin received BS and MS degrees in Computer Science and Cognitive Science from Rensselaer and MS and PhD degrees in Computer Science from Brown University.

Michael M. Bernitsas

University of Michigan
Dep. Naval Architecture & Marine Engineering
Ann Arbor, USA
michaelb@umich.edu

Chapter E.47

Michael M. Bernitsas, received his PhD in Ocean Engineering from MIT. He is the Mortimer E. Cooley Collegiate Professor of Engineering at the University of Michigan and the Director, of the Marine Renewable Energy Laboratory. He is a fellow of ASME and SNAME 1998. He is the founder and CTO of Vortex Hydro Energy, a company commercializing the VIVACE Converter.

Rémi Bourguet

University of Toulouse, CNRS
Inst. Fluid Mechanics
Toulouse, France
remi.bourguet@imft.fr

Chapter D.36

Rémi Bourguet received his PhD degree in Fluid Dynamics from the Université de Toulouse in 2008. He worked at MIT as a postdoctoral researcher. He has been a CNRS Research Associate at the Institut de Mécanique des Fluides de Toulouse since 2011. His research interests include fluid–structure interactions, turbulent flows, and their modeling and numerical simulation.

Mario P. Brito

University of Southampton
Centre for Risk Research
Southampton, UK
m.p.brito@soton.ac.uk

Chapter B.24

Dr Mario Paulo Brito is a Lecturer in Risk Analysis and Risk Management at the University of Southampton. He has worked as a risk and reliability analyst for several marine autonomous systems deployment projects. His main research interest is in the development of novel risk and reliability methods, particularly in exploring extreme environments.

Robert A. Brizzolara

Office of Naval Research
Sea Platforms and Weapons Division
Arlington, USA
robert.brizzolara@navy.mil

Chapter B.13

Dr Robert A. Brizzolara manages science and technology at the Office of Naval Research supporting small combatant craft. The program includes basic and applied research and technology development. He was previously Group Leader at the NSWC-Carderock Division, received his PhD degree in Physics from the University of Delaware, and performed his postdoctoral work at the Naval Research Laboratory.

Stefano Brizzolara

Massachusetts Institute of Technology
MIT Innovative Ship Design Lab
Cambridge, USA
stebriz@mit.edu

Chapter B.13

Stefano Brizzolara holds an MSc in Naval Architecture and Marine Engineering and a PhD in Numerical Hydrodynamics for Ship Design. He started his academic career in the Department of Naval Architecture of the University of Genova. In 2013 he joined MIT Sea Grant as Assistant Director for Research and MIT iShip, which researches the functional design of innovative high performance marine vehicles, fast ships, and offshore technologies.

Wendell S. Brown

University of Massachusetts – Dartmouth
School for Marine Science and Technology
New Bedford, USA
wbrown@umassd.edu

Chapters A.2, A.5

Wendell Brown received his ScM in Engineering from Brown University in 1967 and his PhD in Oceanography from MIT in 1971. After a post-doc at Scripps Institution of Oceanography, he became a faculty member at the University of New Hampshire. In 2000, he joined the newly-established School for Marine Science and Technology at the University of Massachusetts-Dartmouth. His area of expertise is coastal ocean physical oceanography and observing systems.

Andrew Cairns

AECOM
New York, USA
Andrew.cairns@aecom.com

Chapter C.31

Andrew Cairns is a professional engineer and leads AECOM's port and marine engineering practice in the Northeast United States. He began his port and harbor engineering career as an engineer diver, performing underwater investigations around the world. His experience includes planning, inspection, design, and construction supervision of port and marine projects worldwide, including industrial and military marine terminals, bulkheads, marinas, and shore side civil works.

Thomas J. Campbell

The Shaw Group
Coastal Planning and Engineering Inc.
Boca Raton, USA
sanddiver@icloud.com

Chapter C.29

Thomas J. Campbell is the President of Coastal Planning & Engineering. He has directed coastal engineering analysis, design, geotechnical and physical surveys, and numerical modeling for 75 beach restoration projects throughout the United States. He is a registered professional engineer in seven states, Vice President of the American Shore and Beach Preservation Association (ASBPA), and serves as the Co-Chair of the Science and Technology Committee.

John M. Carel

Estero, USA
johnmcarel@gmail.com

Chapter C.31

John Carel, a professional engineer and Vice President with AECOM ports and marine practice, received a Master's degree from Michigan State and has 40 years of marine and coastal experience, specializing instructural and geotechnical design of maritime structures. He has extensive experience throughout the metropolitan New York area, as well as the US East and Gulf Coasts, the Caribbean, and the Middle East.

Bruce Cathers

University of New South Wales
Water Research Laboratory
Manly Vale, Australia
b.cathers@unsw.edu.au

Chapter C.32

Bruce Cathers has more than 35 years of experience in the fields of coastal, estuarine and river engineering, and physical and numerical modeling. In particular, he has worked on ocean outfalls, water quality and hydrodynamic modeling, sediment transport simulations, breakwaters, and hydraulic structures. His teaching areas include fluid mechanics, hydraulics, air and water quality, and computational hydraulics

Ioannis K. Chatjigeorgiou

National Technical University of Athens
School of Naval Architecture and Marine Engineering
Athens, Greece
chatzi@naval.ntua.gr

Chapter D.38

Professor Chatjigeorgiou received his diploma and PhD from the National Technical University of Athens in 1990 and 1997, respectively. His research interests include linear and nonlinear hydrodynamics, wave resistance, violent slamming, hydroelasticity, and dynamics of slender structures with internal flow for marine applications. He has also been involved in the scientific computing of special functions and their applications to boundary value problems associated with Laplace, Helmholtz, and Stokes domains.

Cortis K. Cooper Chapter A.3 For biographical profile, please see the section "About the Part Editors".

Joseph A. Curcio

Gray, USA
jacurcio@mit.edu

Chapter B.23

Joseph Curcio received his MEng and MS in Ocean Engineering and Ocean Systems Management from MIT. While at the MIT Autonomous Underwater Vehicles Laboratory, he participated in the design, development, and deployment of early Odyssey class autonomous underwater vehicles (AUVs) and led a team in the design and development of CETUS, the world's first production level AUV capable of hovering and station keeping.

Jason Dahl

University of Rhode Island
217 Sheets Laboratory
Narragansett, USA
dahl@egr.uri.edu

Chapter D.36

Jason Dahl received his PhD degree in Ocean Engineering from MIT in 2008. He worked as a postdoctoral researcher at both the SMART Centre in Singapore and at MIT. He has been an Assistant Professor at the University of Rhode Island since 2011. His research interests include flow-induced vibrations, offshore renewable energy systems, and experimental methods for studying fluid dynamics.

Michael S. Dean

Naval Sea Systems Command
Washington D.C., USA
michael.s.dean@navy.mil

Chapter D.42

Michael Dean is an ocean engineer from Florida Institute of Technology. He has participated in and led numerous salvage, deep ocean search and recovery and underwater repair operations. As the Deputy Director of Ocean Engineering, he is the Navy's technical authority for salvage and underwater ship repair where he leads an outstanding team of civilian and military personnel conducting salvage and diving operations worldwide.

Robert G. Dean (deceased) Chapter C.29

Manhar R. Dhanak Chapters 1, A.7, E.44, E.45 For biographical profile, please see the section "About the Editors".

Alana E.S. Duerr

New West Technologies LLC
Englewood, USA
a.e.smentek@gmail.com

Chapter E.44

Alana Duerr received her BS in Naval Architecture and Marine Engineering from the Webb Institute and a PhD in Ocean Engineering from Florida Atlantic University. At Florida Atlantic University she focused on ocean current resource assessment for marine hydrokinetic devices. She currently supports the US Department of Energy's Offshore Wind research, development, and deployment efforts.

Gerald D'Spain

University of California San Diego
Scripps Inst. of Oceanography
San Diego, USA
gdspain@ucsd.edu

Chapter B.12

Gerald D'Spain is the lead Principal Investigator in the ONR-sponsored Flying Wing Autonomous Underwater Glider program, a partnership with the Applied Physics Lab, the University of Washington (APL/UW), with Peter Brodsky as Principal Investigator. The lead engineer is Richard Zimmerman. Other key engineering personnel include Scott Jenkins, Dennis Rimington and Dave Price at Scripps, and Jim Luby and Sean McPeak at APL/UW.

Frank Ehlers

Bundeswehr Technical Center for Ships
and Naval Weapons (WTD 71)
Kiel, Germany
drfrank.ehlers@gmail.com

Chapter B.22

Dr Frank Ehlers obtained his Dr rer nat degree in Theoretical Physics (1998) from the University of Kiel, Germany. Working at the Research Department FWG at the Bundeswehr Technical Center WTD 71, Germany, and at the NURC/CMRE, Italy (2006–2011), he conducts both application-oriented and fundamental research in data fusion, collaborative signal processing, autonomic behaviors, and coordinated distributed sensor systems for maritime surveillance.

Naomi Ehrich Leonard

Princeton University
Mechanical and Aerospace Engineering
Princeton, USA
naomi@princeton.edu

Chapter B.19

Naomi Ehrich Leonard is Edwin S. Wilsey Professor of Mechanical and Aerospace Engineering at Princeton University. She received her BSE in Mechanical Engineering from Princeton and her PhD in Electrical Engineering from the University of Maryland. Leonard's research focuses on control and dynamics in multi-agent systems from cooperative vehicle sensing networks to social groups of animals to human decision-making teams.

Karl Dietrich von Ellenrieder

Florida Atlantic University
SeaTech Inst. for Ocean Systems
Engineering
Dania Beach, USA
ellenrie@fau.edu

Chapter A.7

Karl von Ellenrieder received MS and PhD degrees in Aeronautics and Astronautics from Stanford University, in 1992 and 1998, respectively. He is currently a Professor in the Department of Ocean and Mechanical Engineering at Florida Atlantic University. His research interests include the development of unmanned surface vehicles, marine hydrodynamics, and design and control systems engineering.

R. Cengiz Ertekin Chapters D.34, D.35 For biographical profile, please see the section "About the Part Editors".

Merv Fingas

Spill Science
Edmonton, Canada
fingasmerv@shaw.ca

Chapter D.43

Merv Fingas is a scientist working on oil and chemical spills. Dr Fingas has a PhD in Environmental Physics from McGill University. He has published more than 875 papers and publications in the field. Merv has prepared eight books on spill topics. His specialities are oil spill behavior and fate, remote sensing, and in-situ countermeasures.

George Z. Forristall

Forristall Ocean Engineering, Inc.
Camden, USA
george@forocean.com

Chapter A.3

Dr George Z. Forristall formed Forristall Ocean Engineering, Inc. in 2004 to provide metocean services to offshore industries. He previously spent many years in various Shell companies specifying oceanographic design conditions for offshore structures worldwide. His work has involved fundamental research into kinematics and statistics of storm waves and the structure of oceanic circulation, as well as site specific investigations. He has a PhD in Mechanical Engineering from Rice University.

David Fries

University of South Florida
Inst. for Research in Arts
Tampa, USA
dfries@usf.edu

Chapter B.18

David Fries is Head of the Integrative Creative Technology Group at USF College of Arts and CTO of Spyglass Technologies. He has 35 patents issued, licensed 12 technologies, and over 60 publications in oceanography, analytical chemistry, medical technology, biotechnology, chemistry, microtechnology, electronics, and robotics. He has held a past appointment at Sandia National Laboratories/Lockheed Martin and holds BS/MS degrees in Chemistry.

Gwyn Griffiths

Autonomous Analytics
Southampton, UK
gwyn@autonomousanalytics.com

Chapter B.24

Gwyn Griffiths is an ocean technologist whose career began in the mid 1970s developing instrumentation for measuring ocean currents. In the late 1980s he first became involved with autonomous underwater vehicles through the UK Autosub project, working with scientists to develop applications and research programs. His interests now include underwater gliders and autonomous surface vehicles, and, above all, their reliability.

Patrick J. Haley Jr.

Massachusetts Institute of Technology
Dep. Mechanical Engineering
Cambridge, USA
phaley@mit.edu

Chapter B.21

Patrick Haley received a BS in Physics from Siena College in 1984 and a PhD in Applied Mathematics from Northwestern University in 1991. From 1991 to 2006, he worked in ocean modeling at Harvard University. Since 2007, he has been a Research Scientist at the Massachusetts Institute of Technology. His research interests include multidisciplinary ocean modeling, uncertainty, and path planning.

Andrew Hamilton

Monterey Bay Aquarium Research Institute
Moss Landing, USA
hamilton@mbari.org

Chapter D.40

Andrew Hamilton is an engineer at the Monterey Bay Aquarium Research Institute; his research interests include marine hydrodynamics and ocean wave-energy for oceanographic applications. Dr Hamilton received his PhD in Mechanical Engineering from the University of California, Berkeley, and has been involved in the design of a wide variety of oceanographic buoy and mooring systems.

Howard P. Hanson

Florida Atlantic University
Southeast National Marine Renewable Energy Center
Boca Raton, USA
hphanson@fau.edu

Chapter E.46

Hanson's previous role as Chief Scientist of Florida Atlantic University's Southeast National Marine Renewable Energy Center provided opportunities for his variety of experience at the University of Colorado at Boulder and at the Los Alamos National Laboratory in air–sea interaction and its role in the climate system to converge on a topic of importance to the future of clean energy.

John J. Holmes

Naval Surface Warfare Center
Underwater Electromagnetic Signatures and Technology Division
West Bethesda, USA
john.j.holmes@navy.mil

Chapter A.8

John Holmes received the PhD degree in Electrical Engineering in 1977 from West Virginia University. Since then, he has been with the Naval Surface Warfare Center conducting research to reduce the underwater electromagnetic field signatures of ships and submarines.

Jennifer L. Irish Chapters C.25, C.26 For biographical profile, please see the section "About the Part Editors".

Dong-Sheng Jeng

Griffith University Gold Coast Campus
Griffith School of Engineering
Griffith, Australia
d.jeng@griffith.edu.au

Chapter D.39

Dong Jeng received his PhD degree from the University of Western Australia in 1997, and since then has been an academic at Griffith University, the University of Sydney, and the University of Dundee. His primary research area is offshore geotechnics, with a focus on fluid–soil–structure interactions. Further research interests cover coastal engineering, groundwater hydraulics, porous flow, and offshore wind energy.

Scott A. Jenkins

University of California San Diego
Scripps Inst. of Oceanography
San Diego, USA
sjenkins@ucsd.edu

Chapter B.12

Scott A. Jenkins received a BS from Yale University in 1972 and a PhD in Oceanography from UCSD in 1980. He is author of 80 scientific papers, including the first generalized speed-to-fly glide theory in 3-D wind fields. He holds the three *Soaring Diamonds* from *Fédération Aéronautique Internationale* and was Chair of the ONR Underwater Glider System Study in 2003.

Jason Jonkman

National Renewable Energy Laboratory
National Wind Technology Center
Golden, USA
jason.jonkman@nrel.gov

Chapter E.49

Jason Jonkman is a Senior Engineer at National Renewable Energy Laboratory (NREL), which he joined in 2000, and leads the wind turbine multi-physics engineering tools development activities. He works on a variety of projects focused on developing, verifying and validating, and applying tools for offshore wind turbines. Jason holds a PhD in Aerospace Engineering Sciences from the University of Colorado.

James M. Kaihatu Chapters A.4, C.27 For biographical profile, please see the section "About the Part Editors".

Tae Won Kim

FMC Technologies Schilling Robotics
Davis, USA
twon.kim@gmail.com

Chapter B.17

Dr Kim works for FMC Technologies Schilling Robotics where he develops underwater devices and ROV simulators. He has served as a Co-PI of the Semi-Autonomous Underwater Vehicle for Intervention Missions project at the University of Hawaii, and a senior research engineer at Samsung Aerospace Ind., Korea.

William Kirkwood

Monterey Bay Aquarium Research Institute
Moss Landing, USA
kiwi@mbari.org

Chapter B.18

William Kirkwood is Senior Research and Development Engineer for the Monterey Bay Aquarium Research Institute. As lead engineer, he has managed several remotely operated vehicles, autonomous underwater vehicles and in situ instruments. He is an Adjunct Professor at Santa Clara University and Treasurer for the IEEE Ocean Engineering Society. He has over 65 publications on vehicles/mechatronics, optics, and instrumentation.

John J. Leonard

Massachusetts Institute of Technology
Dep. Mechanical Engineering
Cambridge, USA
jleonard@mit.edu

Chapter B.14

John J. Leonard is the Collins Professor of Mechanical and Ocean Engineering in the MIT Department of Mechanical Engineering. His research addresses the problems of navigation and mapping for autonomous mobile robots. He holds the degrees of BSEE from the University of Pennsylvania and DPhil in Engineering Science from the University of Oxford. He is an IEEE Fellow.

Pierre F.J. Lermusiaux

Massachusetts Institute of Technology
Dep. Mechanical Engineering
Cambridge, USA
pierrel@mit.edu

Chapter B.21

Pierre Lermusiaux has made outstanding contributions in data assimilation, ocean modeling, and uncertainty predictions. His research thrusts include understanding and modeling complex ocean dynamics and processes. With his group, he creates, develops, and utilizes new mathematical models and computational methods for ocean predictions and dynamical diagnostics, for optimization and control of autonomous ocean systems, for uncertainty quantification, and for data assimilation.

Wayne G. Leslie

American Meteorological Society
Boston, USA
wgleslie@mit.edu

Chapter B.21

Wayne Leslie is a Technical Editor at the American Meteorological Society. He has more than 30 years of world-class experience in ocean data analysis, oceanography, ocean modeling, and real-time forecasting. He is an expert at observational program management; data analysis, management and software development; physical and interdisciplinary ocean forecasting and modeling; and web-based dissemination of analysis and forecast products.

Xiao Li

Livingston, USA
Steven.li@aecom.com

Chapter C.31

Steven Li is a professional engineer with over 25 years of coastal engineering experience. The solid theoretical foundation and the wide range of experience in Steven Li's engineering career have enabled him to attain a high level of technical expertise related to analysis and modeling of coastal processes, design of sea defense structures, port design, ship mooring, and maneuvering study.

Tapovan Lolla

Massachusetts Institute of Technology
Dep. Mechanical Engineering
Cambridge, USA
ltapovan@mit.edu

Chapter B.21

Tapovan Lolla is a PhD candidate in the Department of Mechanical Engineering at MIT. He earned his Bachelor's degree from IIT Bombay in 2010 and a Master's degree from MIT in 2012. His research interests include robotic path planning, control systems, uncertainty quantification, and high-dimensional inference.

Raymond Lum

DSO National Laboratories
Singapore, Singapore
raylum@alum.mit.edu

Chapter B.20

Raymond Lum received the BEng (First Class Honors) and MSc degrees from Nanyang Technological University, and the PhD degree from Massachusetts Institute of Technology (MIT). During his time at MIT, he worked in the Laboratory for Autonomous Marine Sensing Systems. He is presently a Program Manager with DSO National Laboratories, where he leads teams of engineers to develop sonar surveillance systems for the Republic of Singapore Navy.

Patrick J. Lynett

University of Southern California
Sonny Astani Dep. of Civil and Environmental Engineering
Los Angeles, USA
plynett@usc.edu

Chapter C.27

Patrick J. Lynett is a Professor of Civil Engineering at the University of Southern California. His research interests are directed towards a better understanding of coastal processes, such as nearshore circulations, wave evolution from generation to the shoreline, multi-scale hydrodynamic interactions, and sediment transport. Amongst other awards, Dr Lynett received the Department of the Army Commander's Award for Public Service for his post-Katrina work.

Giacomo Marani

West Virginia University
WV Robotic Technology Center
Fairmont, USA
gmarani@gmail.com

Chapter B.17

Dr Marani serves as lead research scientist at the WV Robotic Technology Center, affiliated with the NASA Space Servicing Capabilities Office. In the past decade he served as researcher at the University of Hawaii at Manoa. He is Chair of the IEEE Marine Robotics Technical Committee and a member of the Editorial Board of the journal of Intelligent Service Robotics.

Spyros A. Mavrakos

National Technical University of Athens
School of Naval Architecture and Marine Engineering
Athens, Greece
mavrakos@naval.ntua.gr

Chapter D.38

Spyros Mavrakos is Vice Rector of NTUA, Director of the Laboratory for Floating Structures and Mooring Systems, and Professor of Offshore Structures. He has degrees in Naval Architecture and Marine Engineering, and in Offshore Hydrodynamics. His research activities include offshore hydrodynamics, mooring systems' analysis and design, hydrodynamics of wave energy converters, design of floating wind turbines, and multi-purpose floating structures for offshore wind and wave energy sources exploitation.

Robert E. Melchers

The University of Newcastle
Centre for Infrastructure Performance and Reliability
Callaghan, Australia
Rob.Melchers@newcastle.edu.au

Chapter A.6

Rob Melchers is Professor of Civil Engineering and ARC DORA Research Fellow at the University of Newcastle, Australia. He holds a BE and MEngSc from Monash University, and a PhD from the University of Cambridge, UK. He is a Fellow of the Australian Academy of Technological Sciences and Engineering. He specializes in corrosion modeling and structural reliability analysis.

Yahya Modarres-Sadeghi

University of Massachusetts
Mechanical and Industrial Engineering
Amherst, USA
modarres@engin.umass.edu

Chapter D.36

Yahya Modarres-Sadeghi received his PhD degree in Mechanical Engineering from McGill University in 2006. He worked as a postdoctoral researcher at MIT for 3 years. He has been an Assistant Professor at the University of Massachusetts, Amherst since 2009. His research interests include fluid–structure interactions, nonlinear dynamics, offshore wind energy, and biomimetics.

Stephanie M. Petillo

Woods Hole Oceanographic Institution
Woods Hole, USA
spetillo@whoi.edu

Chapter B.20

Stephanie Petillo is an Oceanographic Engineering PhD candidate in the MIT/WHOI Joint Graduate Program with a BS in Aerospace Engineering from the University of Maryland – College Park (2008). Her research focuses on the use of autonomous underwater vehicles for autonomous and environmentally adaptive sampling of the ocean environment, to improve efficiency and synopticity of data collection.

Roshanka Ranasinghe

UNESCO-IHE Inst. for Water Education
Delft, The Netherlands
r.ranasinghe@unesco-ihe.org

Chapter C.28

Dr Roshanka Ranasinghe is Associate Professor of Coastal Engineering at UNESCO-IHE and at Delft University of Technology, The Netherlands. He is also Visiting Professor at the Australian National University, Canberra, and strategy advisor on morphodynamic modeling at Deltares, The Netherlands. He is regularly invited to provide expert advice on coastal management and climate change impacts by national governments and international agencies.

Muthukamatchi Ravindran

Naval Research Board
Pallickaranai Campus
Chennai, India
ravinmv@gmail.com

Chapter E.48

Muthukamatchi Ravindran graduated in Mechanical Engineering from IIT Madras and served at IIT as Head of Ocean Engineering. He was the Founding Director of the National Institute of Ocean Technology, and initiated major national programs on ocean energy, the Deep Sea Mining and Data Buoy Programs. He has served on the International Oceanographic Commission, ISBA, and the Naval Research Board.

Dronnadula V. Reddy

Florida Atlantic University
Dep. Civil, Environmental and Geomatics Engineering
Boca Raton, USA
dreddy@fau.edu

Chapter D.33

Dronnadula V. Reddy is a Professor of Civil, Environmental, and Geomatics Engineering at Florida Atlantic University. His numerous publications evidence his wide research interests, which include computational, experimental, and structural geomechanics, offshore and coastal structures, concrete technology with the focus on supplementary cementitious materials; and corrosion and fire resistant structural concrete.

Donald T. Resio

University of North Florida
Dep. Civil Engineering
Jacksonville, USA
don.resio@unf.edu

Chapters C.25, C.26

Dr Donald T. Resio is Professor of Ocean Engineering at the University of North Florida and has 40 years of experience in wind, wave and surge prediction, and hazard/risk estimation. He has served as senior scientist for coastal work at the Army Engineer Research and Development Center and has led their post-Katrina effort to improve methods for assessing hazards/risks along US coastlines.

H. Ronald Riggs

University of Hawaii at Manoa
Dep. Civil & Environmental Engineering
Honolulu, USA
riggs@hawaii.edu

Chapter D.37

H.R. Riggs received his PhD degree from the University of California, Berkeley, in Structural Engineering in 1981. After 6 years in industry, he joined the University of Hawaii in 1987. Over the years he has worked extensively on hydroelasticity and very large floating structures. He is currently focusing on structural dynamic response to fluid and other loading.

George Rodenbusch

Rodenbusch Consulting
Dripping Springs, USA
george@rodenbusch.net

Chapter D.35

Dr Rodenbusch has more than 35 years of experience with the engineering and management of deepwater offshore oil and gas developments around the world. He holds a BS and an MME in Mechanical Engineering from Rice University and a PhD in Oceanographic Engineering from Massachusetts Institute of Technology & Woods Hole Oceanographic Institution. He is a Licensed Professional Engineer in Texas.

J.A. Dano Roelvink

UNESCO-IHE Inst. for Water Education
Delft, The Netherlands
d.roelvink@unesco-ihe.org

Chapter C.28

Dano Roelvink has more than 25 years of experience in coastal engineering and research. He has managed and contributed much to the development of the Delft3D system and has been actively involved in many EU-sponsored research projects on coastal morphodynamics. He has set up collaborative projects with the USGS, ONR, and many international institutes and leads the development of XBeach, an open-source model for storm impacts.

Salvatore Scaturro

Expert Water Modelling
Sydney, Australia
sal.scaturro@ewmworld.com

Chapter C.32

Salvatore Scaturro is a water engineer specializing in the analysis and design of pipelines, pumping stations, distribution networks, hydraulic structures, and marine intake and outfall systems. He is an experienced user of water hammer and computational fluid dynamics (CFD) modeling software and has also programmed his own models for a range of hydraulics applications.

Henrik Schmidt

Massachusetts Institute of Technology
Center for Ocean Engineering
Cambridge, USA
henrik@mit.edu

Chapter B.20

Henrik Schmidt is a Professor of Mechanical Ocean Engineering at MIT. His research focuses on underwater acoustic propagation and signal processing. In recent years Professor Schmidt has been pioneering the development of new underwater acoustic sensing concepts for networks of small autonomous underwater vehicles. He is a Fellow of the Acoustical Society of America, and the 2005 recipient of the ASA *Pioneer of Underwater Acoustics* medal.

Robert Seah

Chevron Energy Technology Company
Facilities Engineering Dep.
Houston, USA
RSeah@Chevron.com

Chapter D.41

Dr Seah has been involved in hydrodynamic research since 1998, initially at the National University of Singapore and the University of California at Berkeley, finally joining the Chevron Energy Technology Company in 2007. His past and present research include vortex breakdowns, drag reduction, ship roll damping, sloshing of LNG, and multi-floater response in waves. He is currently leading research into integrity management of FPSOs.

Thomas Sondergaard

TrackMan A/S
Vedbæk, Denmark
tsondergaard@gmail.com

Chapter B.21

Thomas Sondergaard is currently working as a Research and Development Engineer at TrackMan A/S. He has a Master of Science degree in Mechanical Engineering from the Massachusetts Institute of Technology, USA. Prior to that, he earned a Master of Engineering degree from Imperial College, London. His research interests lie in the fields of acoustics, computational data analysis, statistics, uncertainty quantification, nonlinear data assimilation, estimation theory, and signal processing.

Matthias Stammler

Fraunhofer Institute for Wind Energy and Energy System Technology IWES
Hannover, Germany
matthias.stammler@iwes.fraunhofer.de

Chapter E.49

Matthias Stammler studied Automotive Engineering in Germany and Mexico. He started his professional career as a drivetrain test engineer with Porsche. In 2011 he joined PowerWind as gearbox engineer for wind turbines. In 2013 he joined the Fraunhofer IWES as a Research Fellow. He further specializes in bearing design for wind turbine applications, focusing on pitch systems.

Milica Stojanovic

Northeastern University
ECE Department
Boston, USA
millitsa@ece.neu.edu

Chapter B.15

Milica Stojanovic graduated from the University of Belgrade, Serbia, in 1988, and received the MS (1991) and PhD (1993) degrees from Northeastern University in Boston, MA, where she is currently Professor of Electrical and Computer Engineering. She is also a Guest Investigator at the Woods Hole Oceanographic Institution. Milica is an Associate Editor and a Fellow of the IEEE.

Mareike Strach-Sonsalla

Fraunhofer Institute for Wind Energy and Energy System Technology IWES
Bremerhaven, Germany
mareike.strach-sonsalla@outlook.com

Chapter E.49

Mareike Strach-Sonsalla is Group Manager for Loads Analysis and System Dynamics at Fraunhofer IWES. She specializes in offshore wind energy turbine dynamics and modeling, particularly floating offshore wind turbines. She joined Fraunhofer IWES as a research fellow in 2011, after studying naval architecture and offshore engineering in Berlin and Trondheim.

Arisi S.J. Swamidas

Memorial University of Newfoundland
Faculty of Engineering and Applied Science
St. John's, Canada
aswamidas@mun.ca

Chapter D.33

Arisi S.J. Swamidas is a retired Professor of Civil Engineering at the Faculty of Engineering and Applied Sciences, Memorial University, St. John's, NL, Canada. Until 2014 he was active in supervising graduate students in computational/experimental analysis and testing of offshore and onshore structures/elements subjected to wind, wave, ice, and accidental impact forces. His publications include 2 books and more than 215 articles.

Peter M. Tate

Sydney Water Corporation
Parramatta, Australia
peter.tate@sydneywater.com.au

Chapter C.32

Peter Tate has more than 30 years' experience studying physical processes in the marine environment, specializing in the interaction of wastewater plumes and internal waves. He has worked in research, consulting, and government organizations, providing him with a broad perspective on marine outfalls. His interests lie in the design and execution of interdisciplinary monitoring programs to assess the impacts of wastewater discharges on the marine environment.

Krish P. Thiagarajan

University of Maine
Dep. Mechanical Engineering
Orono, USA
Krish.Thiagarajan@maine.edu

Chapter D.41

Krish Thiagarajan is the Correll Presidential Chair in Energy and Professor of Mechanical Engineering at the University of Maine. His research spans design and analysis of energy generating systems located offshore in the deep oceans. In particular, his area of research is dynamics and global performance of floating offshore systems for oil and gas, as well as renewable energy production.

Michael S. Triantafyllou

Massachusetts Institute of Technology
Dep. Mechanical Engineering
Cambridge, USA
mistetri@mit.edu

Chapter D.36

Faculty member in the Ocean Engineering Department since 1979 and in the Mechanical Engineering Department since 2005 at MIT, currently William I. Koch is Professor of Marine Technology and Director of the Center for Ocean Engineering. He received his degree from NTU Athens (1974) and SM (1997) and ScD (1979) degrees from MIT. His research interests include biomimetic robots, flow–structure interaction, and dynamics and control of marine vehicles.

Mark A. Tumeo

University of North Florida
College of Computing, Engineering & Construction
Jacksonville, USA
m.tumeo@unf.edu

Chapter C.26

Dr Mark A. Tumeo is Dean of the College of Computing, Engineering, and Construction, and Professor of Civil Engineering at the University of North Florida. He has over 25 years of experience in environmental consulting and research, environmental risk assessment, policy, and regulation. He is actively involved in several professional organizations and currently serves as a Corresponding Editor for the ASCE Journal of Professional Issues in Engineering Education and Practice.

Mattheus P. Ueckermann

Creare
Hanover, USA
mpu@creare.com

Chapter B.21

Dr Ueckermann received his Bachelor's degree from the University of Waterloo, and his MS and PhD from Massachusetts Institute of Technology in Mechanical and Computational Engineering. For his research, he developed computational schemes for regional ocean models. Presently he is working as an engineer at Creare, where he develops mathematical models and algorithms for machine vision, weather prediction, and thermodynamic applications.

James H. VanZwieten

Florida Atlantic University
Southeast National Marine Renewable Energy Center
Boca Raton, USA
jvanzwi@fau.edu

Chapters E.44, E.46

James H. VanZwieten is an Assistant Research Professor at Florida Atlantic University's Southeast National Marine Renewable Energy Center. His research areas include numerical simulation, resource assessment, and controller development for applications related to the extraction of energy from ocean currents.

Fabian Vorpahl

Leading Expert Offshore Engineering
Tower & Substructure Senvion GmbH
Osnabrück, Germany
fabian.vorpahl@senvion.com

Chapter E.49

Fabian Vorpahl has a degree in Mechanical Engineering from Karlsruhe Institute of Technology and has worked as a project engineer, project manager, group manager, and Head of Department at Fraunhofer IWES. His work is focused on research and development of global dynamics, structural dynamics, coupled simulation, modeling, and loads of (offshore) wind turbines.

Dirk-Jan R. Walstra

Deltares
Unit Hydraulic Engineering
Delft, The Netherlands
Dirkjan.walstra@deltares.nl

Chapter C.28

Dirk-Jan Walstra is a coastal morphologist and is involved in numerous Dutch and international projects in the coastal zone. Due to his specialist coastal modeling expertise he plays a key role in the development of morphological models such as Delft3D and Unibest. He is also a Research Associate at Delft University of Technology and an invited Lecturer at Utrecht University and Twente University.

Mick van der Wegen

UNESCO-IHE Inst. for Water Education
Delft, The Netherlands
m.vanderwegen@unesco-ihe.org

Chapter C.28

Since 1996 Mick van der Wegen's position at UNESCO-IHE has been related to capacity building, education and research in the field of coastal engineering, and coastal zone management in an international context. Specific fields of interest include estuarine morphodynamics on decadal to millennial timescales, salt intrusion and density currents, and process-based modeling (Delft3D).

Robert Weiss

Virginia Tech
Dep. Geosciences
Blacksburg, USA
weiszr@vt.edu

Chapter C.25

Dr Robert Weiss is an Assistant Professor of Geosciences at Virginia Tech with more than 12 years of experience and 30 peer-reviewed papers. Dr Weiss is a tsunami expert with expertise in numerical simulations of tsunami evolution and dynamics, sediment transport, and field reconnaissance surveys.

Jan Wenske

Fraunhofer Institute for Wind Energy and Energy System Technology IWES
Bremerhaven, Germany
jan.wenske@iwes.fraunhofer.de

Chapter E.49

Jan Wenske studied engineering at the Technical University of Clausthal. He worked as a project manager with STILL GmbH and as Head of Power Electronics Development at ESW Jenoptik AG. He joined Fraunhofer-IWES in 2011 as the Head of the Wind Turbine and System Technology Department, specializing in power mechatronics, accelerated testing, and advanced drive train control. He has been a Professor at the University of Bremen since 2013.

Nikolaos I. Xiros Chapters 1, A.9, A.10, E.45 For biographical profile, please see the section "About the Editors".

Konuralp Yigit

University of Illinois at Urbana Champaign
Dep. Aerospace Engineering
Urbana, USA
yigit2@illinois.edu

Chapter B.21

Konuralp Yigit obtained his Bachelor of Science degree from the Turkish Naval Academy in 2005 and his Master of Science degree from Massachusetts Institute of Technology (MIT) in 2011. He is currently a PhD student at the University of Illinois at Urbana-Champaign. His current research is centered on parallel computing and algorithms.

Solomon Yim

Oregon State University
School of Civil and Construction Engineering
Corvallis, USA
solomon.yim@oregonstate.edu

Chapter D.37

Solomon Yim received his PhD degree from the University of California, Berkeley. He has been teaching at Oregon State University since 1987 and is the Glenn Willis Holcomb Professor of Structural Engineering. Dr Yim's work focuses on analytical, numerical, and experimental modeling, and simulation of coupled fluid–structure interaction systems, high-performance computing, with applications in civil, naval, offshore, and renewable-energy engineering.

Junku Yuh

Korea Institute of Science and Technology
National Agenda Research Division
Seoul, Korea
yuh.junku@gmail.com

Chapter B.17

Dr Yuh, IEEE Fellow, is currently Endowed Chair Researcher at Korea Institute of Science and Technology (KIST). He served as the 5th and 6th President of Korea Aerospace University, US National Science Foundation Program Director, Head of NSF Tokyo Regional Office, Professor of Mechanical Engineering and Information and Computer Science at the University of Hawaii, and Editor-in-Chief for the International Journal of Intelligent Service Robotics.

von Karman's constant 50
vortex
– shedding 132, 336, 828, 1174
– tracking 1210
– wake 281
Vortex Hydro Energy (VHE) 1179
vortex-induced
– motion (VIM) 820
– vibration (VIV) 132, 742, 802, 819, 842, 876, 1096, 1163
– vibrations for aquatic clean energy (VIVACE) 1165
vorticity 305, 603
– transport equation 158

W

wake
– capture 827
– defect 174
– displacement 1177
– effect propeller slip 145
– frequency 1175
– interference 845
– stiffness 845
wall-shear stress 285
WAMIT 956
wastewater 711–723, 732–737
water
– level 655–658, 662–667, 673
– particle trajectory 82
– retension from wave splashing and rain 778
– tightness 771
– tracing (WT) 720
wave 549–554, 556–561, 571, 573, 613, 1279
– (current)-induced soil response 922
– body interaction 78
– boundary condition 79
– breaking 91
– condition 655–658, 670
– current interaction 803
– current kinematics 804
– diffraction 96
– dominated system 628
– effect 617
– evolution 25
– exciting force 796, 865
– force 78, 94
– form 216
– frequency 51
– frontage 1117
– generation 25
– height 571
– induced liquefaction 929
– induced pore pressure 910
– induced residual liquefaction 921
– information study wave model 600

– instability 78
– load 777, 787
– long-crested 788
– model 600
– model (WAM) 59
– nonlinear 790
– number conservation 82
– pattern 327
– potential perturbation 871
– power density 1100
– radiation force 96
– resistance 81
– runup 133
– seabed–structure interactions 925
– shallow-water 791
– skewness 616
– spectra 867
– spectrum 792, 1100, 1280
– theory 78
– wave interaction 89
Wave Dragon 1143
wave energy 147
– conversion (WEC) 81, 798, 892, 1117
– conversion actuator (WECA) 1139
– flux 1100
– resource 1100
Wave Information Studies (WIS) 656
Wave Modeling Project 59
WaveRoller 1141
waypoint 446
weakly nonlinear deep water wave theory 83
wear 1271
weathertightness 771
Weber number 131, 812, 975
Weibull distribution 982, 1278
weight
– addition 765
– removal 765, 1054
– shift 765
well 630
western boundary current 1104
wharf 686
WHOI Micromodem 471
whole effluent toxicity (WET) 737
wide band/narrow band response 833
wide sense stationary (WSS) 217
