Editors

Springer

Springer Handbook of Ocean Engineering

Springer Handbooks provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Springer Handbook

# of Ocean Engineering

Manhar R. Dhanak, Nikolaos I. Xiros (Eds.)

With 1001 Figures and 150 Tables

Preface

It is our honor and pleasure to be part of this Springer Handbook that is intended to serve as a ready reference for ocean engineers, including practitioners in the maritime industry and government, as well as for researchers, educators, and students, providing a review of important fundamental and applied materials as well as updates of the contemporary topics in ocean engineering and ocean technologies. The handbook should be of interest to those involved in the many aspects of ocean engineering, including the design, development and operations of marine vehicles, coastal systems, and offshore technologies, as well as in the extraction of renewable ocean energy. At the same time, it will serve as a guide for anyone interested in the ocean and human activities in the ocean and the coastal environment. The handbook is divided into five parts comprising 49 chapters that cover ocean engineering basics and four important areas of application: *autonomous ocean vehicles, subsystems and control*; *coastal design*; *offshore technologies*; and *renewable ocean energy*. The coverage includes fundamental concepts, basic theories, methodologies, tools, and techniques involved in various aspects of the subject. The authors of the chapters of the handbook are specialists in their respective fields worldwide, and include well-accomplished individuals from academia, industry, and government. Each chapter has been peer reviewed. The participation of these select authors and peer reviewers has helped ensure that the handbook is an excellent and timely reference. The Springer editorial team has beautifully produced each chapter, including numerous custom drawings and figures. Keywords on each page are properly indexed for the convenience of the reader browsing through the handbook, enabling relatively easy location of material of interest in the handbook.

Our sincere gratitude are due, first of all, to the part editors for their efforts in scoping out the five parts, identifying and enlisting subject-matter experts as chapter authors, guiding the arrangement of the chapters in the parts, following up with authors, and finally seeking peer reviews of the chapters, thereby determining the scope and quality of the handbook. Second, our sincere thanks to all the authors for taking the time from their busy schedules to participate in this project, and devoting much time to carefully preparing their chapters. Further, we very much appreciate the selfless efforts of the peer reviewers for providing critical reviews of the chapters. Finally, we are significantly indebted to Springer's entire publishing team, including Werner Skolaut, Leontina Di Cecco, Veronika Hamm, Judith Hinterberg, and Constanze Ober for their knowledgeable advice, guidance, dedication, significant patience, and effective and efficient editing, which have been instrumental in ensuring timely and quality production of this handbook in support of the ocean engineering community. Part C on coastal design is dedicated to the late Professor Robert Dean for his many important contributions to coastal engineering.

Manhar R. Dhanak and Nikolaos I. Xiros

About the Editors

Manhar R. Dhanak, PhD, is Professor of Ocean Engineering and Director of the Institute for Ocean and Systems Engineering (SeaTech) at Florida Atlantic University (FAU). He is the past chair (2003–2009) of the Department of Ocean Engineering at FAU and a graduate of Imperial College, University of London. He served as a Research Associate at Imperial College, as a Research Scientist at Topexpress Ltd., Cambridge, UK, and as a Senior Research Associate at University of Cambridge before joining Florida Atlantic University. Dr. Dhanak has research interests in hydrodynamics, physical oceanography, autonomous underwater vehicles (AUV), and ocean energy. His sponsored research activities have included development of advanced energy-efficient autonomous surface vehicles and tools for assessment of advanced-hull ships, characterization of electromagnetic fields associated with oceanographic features in a coastal environment, and assessment of electromagnetic field emissions associated with live submarine cables.

Nikolaos I. Xiros is an Associate Professor of Naval Architecture and Marine Engineering at the University of New Orleans. His career spans more than 15 years in both industry and academia and his expertise lies within the fields of marine, electrical and ocean engineering. He holds an Electrical Engineer's degree and a Marine Engineering doctorate. His research interests are process modeling and simulation, system dynamics, identification and control, reliability, signal and data analysis. He is author of several technical papers and a Springer monograph. His current research encompasses projects within nonlinear process dynamics, applied mathematics, energy engineering and watercraft systems.

About the Part Editors

Manhar R. Dhanak Part A For biographical profile, please see the section "About the Editors".

Cortis K. Cooper

Chevron Energy Technology Corp.
San Ramon, CA 94583, USA
cortcooper@chevron.com

Part A

Cortis Cooper is a Chevron Fellow. His primary job is pollutant modeling and providing wind, wave, and current criteria for Chevron's worldwide operations. He received a BSc and an MSc in Engineering at MIT, followed by a PhD from the University of Maine. Outside the industry, he has served on seven National Academy of Sciences committees and boards, testified before Congress, and been a frequent advisor to government agencies.

Thomas B. Curtin

University of Washington
Applied Physics Laboratory
Arlington, VA 22205, USA
tbcurtin@verizon.net

Part B

Thomas Curtin has served as Chief Scientist at NURC in Italy, Chief Knowledge Officer at AUVSI, Program Manager at ONR, Assistant Professor at NCSU, and oceanographer at the Fisheries Research Institute in Malaysia. He received the BS degree in Physics from Boston College, MS and PhD degrees in Physical Oceanography from Oregon State University and the University of Miami, and the MBA degree from Massachusetts Institute of Technology.

Jennifer L. Irish

Virginia Tech
Dep. Civil and Environmental Engineering
Blacksburg, VA 24060, USA
jirish@vt.edu

Part C

Dr Jennifer L. Irish is an Associate Professor of Coastal Engineering at Virginia Tech. She is an expert in storm dynamics at the coast, vegetative effects, and coastal hazard risk assessment. She received the Department of the Army Superior Civilian Service Award and Texas A&M University's Civil Engineering Excellence in Research Award, and has served as Secretary of the Coasts, Oceans, Ports, and Rivers Institute Board of Governors of the ASCE.

James M. Kaihatu

Texas A&M University
Zachry Dep. of Civil Engineering
College Station, TX 77843-3136, USA
jkaihatu@civil.tamu.edu

Part C

James M. Kaihatu is an Associate Professor of Civil Engineering and of Ocean Engineering at Texas A&M University, where he has been since 2006. He has also previously held positions at the Naval Research Laboratory (1995–2006) and the Coastal Engineering Research Center, US Army Corps of Engineers (1987–1989). He received his PhD in Civil Engineering from the University of Delaware in 1994. His research interests include nearshore wave modeling, nearshore nonlinear wave dynamics, nearshore circulation, and wave propagation over cohesive sediments and vegetation.

R. Cengiz Ertekin

University of Hawaii at Manoa
Dep. Ocean & Resources Engineering
Honolulu, HI 96822, USA
Ertekin@hawaii.edu

Part D

R. Cengiz Ertekin has been Professor of Hydromechanics at the University of Hawaii's Department of Ocean and Resources Engineering since 1986. Before that he worked for Chevron and Shell oil companies. He holds a PhD degree from UC Berkeley. He has been teaching and doing research on marine renewable energy, hydroelasticity, nonlinear waves, wave loads on offshore structures and motions, among others. He is a fellow of SNAME and ASME.

Dominique Roddier

Principle Power
Berkeley, CA 94710, USA
droddier@principlepowerinc.com

Part D

Dr Dominique Roddier is a Naval Architect specializing in complex hydrodynamic problems. He serves as Principle Power CTO and is responsible for the WindFloat technology development and manages the company engineering team. He is actively involved in ASME OMAE conference management and in SNAME. He also serves as Associate Editor of multiple journals in the field of offshore engineering.

Part B Autonomous Ocean Vehicles, Subsystems and Control

11 **Highly Maneuverable Biorobotic Underwater Vehicles**
Promode R. Bandyopadhyay 281
11.1 Biorobotics 281
11.2 Theoretical Foundation of Animal-Inspired Hydrodynamics and Control 286
11.3 Description of Biology-Inspired Vehicles of Emergent Maturity 289
11.4 Reliability, Low Power Consumption, and Disturbance Rejection of Bio-Inspired Propulsion 296
11.5 Demonstrated Maneuverings of NUWC Bio-Inspired Vehicles 296
11.6 Discussion 297
11.7 Concluding Remarks 298
11.8 Nomenclature 298
References 299

12 **Autonomous Underwater Gliders**
Scott A. Jenkins, Gerald D'Spain 301
12.1 Concept 301
12.2 Hydrodynamics of Wings Versus Propellers 305
12.3 Underwater Glider Attributes and Limitations 306
12.4 Optimal Size and Shape for Horizontal Transport Efficiency 308
12.5 Thermal Glider 318
12.6 Discussion and Conclusions 319
References 320

13 **Autonomous Sea Surface Vehicles**
Stefano Brizzolara, Robert A. Brizzolara 323
13.1 Platforms 324
13.2 Autonomous Maneuvering and Navigation 326
13.3 Naval Architecture of AUSV Design 327

13.4 Optimized Class of Autonomous Unmanned Surface Vehicles 330
13.5 Conclusions 337
References 339

14 **Autonomous Underwater Vehicle Navigation**

List of Abbreviations

Symbols

1-D	one-dimensional
2-D	two-dimensional
2-D-URANS	two-dimensional unsteady, Reynolds-Averaged, Navier–Stokes
2.5-D	two-and-a-half-dimensional
3-D	three-dimensional
4-D	four-dimensional

A

A/D	analog-to-digital
A/R	asphaltenes and resins
ABE	autonomous benthic explorer
ACDP	acoustic current Doppler profiler
ACF	actual cubic feet
ACTUV	anti-submarine warfare unmanned surface vehicle
ACV	air cushion vehicle
ADCP	acoustic Doppler current profiler
ADV	acoustic Doppler velocimeter
AGV	automated guided vehicle
AHRS	attitude-heading reference system
AIS	automatic identification system
ALIVE	autonomous light intervention vehicle
ALT	alternating-lift technology
AM	analog modulation
AMOC	Atlantic meridional overturning circulation
AOP	apparent optical properties
AOSN	autonomous ocean sampling network
AOV	autonomous ocean vehicle
ARMA	Auto-Regressive Moving Average
ARQ	automatic repeat request
ASAP	adaptive sampling and prediction
ASC	autonomous surface craft
ASL	autonomous systems laboratory
ATA	absolute pressure in atmospheres
ATB	articulated tug barge
AUSV	autonomous USV
AUV	autonomous underwater vehicle
AWACS	autonomous wide aperture cluster for surveillance
AWM	added-weight method
Awp	areas of waterplane
AWS	Archimedes wave swing

B

BAUV	biorobotic autonomous underwater vehicle
Bbl	billion barrels
BCH	Bose-Chaudhuri-Hocquenghem
BENS	Broadband Environmental Networked Sensor
BHP	brake horsepower
BM	metacentric radius
BML	longitudinal metacentric radius
BOD	biochemical oxygen demand
BOG	boil-off gas
BOP	blow-out-preventer
BTEX	benzene, toluene, ethyl-benzene and xylenes
BTR	beam-time record

C

C3MR	air products propane precooled mixed refrigerant
CA	cellular automata
CAB	captured air bubble
CAD	computer-aided design
CALM	Catenary Anchor Leg Mooring
CARACaS	control architecture for robotic agent command and sensing
CBM	constant-buoyancy method
CCD	charge-coupled device
CCL	compact control language
CDF	cumulative distribution function
CDMA	code-division multiple access
CE	control and estimation
CEP	circular error probability
CF	cross-flow
CFD	computational fluid dynamics
CFL	Courant–Friedrichs–Lévy
CNG	compressed natural gas
COB	center of buoyancy
COBRAS	Cornell breaking wave and structure
COG	center of gravity
COM	center of mass
COMCOT	Cornell multi-grid coupled tsunami model
CONOPS	concept of operations
COSI	coastal storm impulse
COULWAVE	Cornell University long and intermediate wave model

CP	cathodic protection
CPC	characteristic current profile
CSM	computational structural mechanics
CSMA	carrier sensing multiple access
CT	inorganic carbon
CTD	conductivity, temperature and depth
CTS	clear-to-send
CWP	cold water pipe

D

D/A	digital-to-analog
DAB	digital audio broadcast
DAC	digital-to-analog conversion
DATS	digital acoustic telemetry system
DCC	direct contact condenser
DCCL	dynamic compact control language
DEC-POMDP	decentralized partially observable Markov decision process
DEMUS	deployable experimental multistatic undersea surveillance
DEPTHX	deep phreatic thermal explorer
DFE	decision-feedback equalizer
DFIG	doubly-fed generator
DFT	discrete Fourier transform
DGPS	differential global positioning system
DIDSON	dual-frequency identification sonar
DIF	decimation-in-frequency
DIT	decimation-in-time
DOC	dissolved organic compound
DOF	degree of freedom
DON	organic nitrogen compound
DP	dynamic positioning
DR	dead reckoning
DS-SS	direct-sequence spread-spectrum
DSL	demanded static load
DSP	Digital Signal Processor
DTFT	discrete-time Fourier transform
DTG	dynamically tuned gyroscope
DTN	delay-tolerant network
DVB	digital video broadcast
DVL	Doppler velocity log
DWT	deadweight tonnage

E

ECC	equatorial countercurrent
EDS	energy density spectrum
EESG	electrically-excited-synchronous generator
EHP	indicative effective horse power
EHS	erosional hot spot
EKF	extended Kalman filter
ELF	extremely low frequency
EMF	electromotive force
ENSO	El Nino-Southern Oscillation
EO	electro-optic
EOF	empirical orthogonal function
ER	echo-repeater
ERS1	Earth Resources Satellite
ESDU	Engineering Sciences Data Unit
ESP	environmental sampler processor
ESSE	error subspace statistical estimation
EST	empirical simulation technique
ETM	empirical track method
EUC	equatorial undercurrent

F

FDMA	frequency-division multiple access
FEC	forward error coding
FEM	finite element method
FFT	fast Fourier transform
FID	flame ionization detection
FIM	flow-induced motion
FIR	finite-duration impulse response
FLNG	floating liquefied natural gas
FMEA	failure model end effect analysis
FOG	fiber optic gyroscope
FOH	first-order hold
FORM	first-order reliability method
FOV	field of view
FPSO	floating production, storage and offloading
FR	Froude number
FRP	fiber reinforced plastic
FSI	flow–structure interaction
FSK	frequency shift keying
FSRU	floating regasification and storage unit
FSW	feet of seawater
FT	force–torque
FUNWAVE	fully nonlinear Boussinesq wave model
FVM	finite-volume method

G

GA	genetic algorithm
GBS	gravity-based substructure
GC	gas chromatograph
GC-MS	gas chromatography with mass spectrometric detection
GCCS	glider coordinated control system
GCT	glider coordinated trajectory
GDP	global drifter program
GDW	generalized dynamic wake
GFM	Green function method
GIS	geographic information system
GM	metacentric height

GML	longitudinal metacentric height
GMM	Gaussian Mixture Model
GMT	Greenwich mean time
GOOS	global ocean observing system
GPD	generalized Pareto distribution
GPS	global positioning system
GRP	glass-reinforced plastic
GTECCA	global tropical and extratropical cyclone climatic atlas
GWP	global warming potential

H

HAWT	horizontal-axis wind turbine
HDPE	high-density polyethylene
HED	horizontal electric dipole
HF	high frequency
HFR	high frequency radar
HMD	horizontal magnetic dipole
HMI	human–machine interface
HOPS	Harvard Ocean Prediction System
HOV	high-occupancy vehicle
HP	high pressure
HSLA	high strength low alloy
HTF	high tow force
HWM	high water mark
HYCOM	hybrid coordinate ocean model
HYSWAS	hydrofoil small water area ship

I

I-AUV	intervention-AUV
I/O	input–output
ICI	inter-carrier interference
ICON	Innovative Coastal Ocean Observing Network
ID	internal diameter
IFORM	inverse first-order reliability methods
IG	induction generator
IGBT	insulated-gate bipolar transistor
IHI	Ishikawajima–Harima heavy industries
IIR	infinite-duration impulse response
IMU	inertial measurement unit
INS	inertial navigation system
IO	inferior-olive
IOOS	Integrated Ocean Observing System
IPTS	international practical temperature scale
IR	infrared
IRM	inspection, repair, and maintenance
IRPA	individual risk per annum
ISI	inter-symbol interference
IT	inertia of the waterplane
ITB	integrated tug barge
IvP	interval programming

J

JPM	joint probability method

K

KC	Keulegan–Carpenter
KdV	Korteweg–de Vries

L

L/D	lift-to-drag ratio
LBM	lost-buoyancy method
LC-MS	liquid chromatography mass spectrometry
LCB	longitudinal center of buoyancy
LCF	longitudinal center of flotation
LCG	longitudinal center of gravity
LCO	limit cycle oscillation
LCOE	levelized cost of energy
LDPC	low-density parity-check
LDV	laser-Doppler velocimetry
LED	light-emitting diode
LEL	lower explosive limit
LES	large eddy simulation
LEV	leading-edge vortex
LFCTT	low-frequency cooperative target tracking
LGPL	GNU Lesser General Public License
LIBS	laser-induced breakdown spectroscopy
LIMPET	land-installed marine power energy transmitter
LISST	laser in-situ scattering and transmissometry
LNG	liquefied natural gas
LNGC	liquefied natural gas carrier
LOA	length overall
LOPC	laser optical particle counter
LPD	low probability of detection
LPG	liquefied petroleum gas
LTFSW	low-turbulence free-surface water
LTI	linear time invariant
LWL	length on waterline

M

MAC	medium access control
MACA	multiple-access collision avoidance
MAS	multiagent system
MBM	multi-buoy mooring
MBS	multibody simulation
MCTC	moment to change trim by one centimeter
MDOF	multiple degrees-of-freedom

MEG3	mooring equipment guideline
MEL	mixed Eulerian–Lagrangian
MEMS	micro-electro-mechanical system
MF	momentum flux
MFC	multi fluid cascade
MGSVA	Mariano Global Surface Velocity Analysis
MHK	marine hydrokinetic
MHW	mean high water
MIC	microbially induced corrosion
MILP	mixed integer linear programming
MIMO	multi-input multi-output
MIMS	membrane inlet mass spectrometry
MIP	mixed integer programming
MODU	mobile offshore drilling unit
MOOS	mission oriented operating suite
MOST	method of splitting tsunami
MPI	maximum possible intensity
MRE	marine renewable energy
MS	mass spectrometry
MSE	mean squared error
MSEAS	multidisciplinary simulation, estimation and assimilation system
MSL	mean sea level
MSP	marine spatial planning
MTBF	mean time between failure
MVC	main vehicle computer
MWL	mean-water level

N

NA	navigation aid
NCOM	Navy Coastal Ocean Model
NCV	nearly constant velocity
NEC	north equatorial current
NG	natural gas
NIP	net inlet pressure
NP	neutral loading point
NPSH	net positive suction head
NRV	NATO research vessel
NSE	Navier–Stokes equation
NSW	nonlinear shallow water
NTE	net transport economy

O

OA	objective analysis
OCT	ocean current turbine
OD	outer diameter
ODP	ozone depletion potential
OEX	Ocean Explorer
OFDM	orthogonal frequency division multiplexing
OHMSETT	oil and hazardous materials simulated environmental test tank
OHS	oil and hazardous substance
OM	operations and maintenance
ORQ	oil rig quality
OS	optimal sampling
OTEC	ocean thermal energy conversion
OTFT	organic thin-film transistor
OTM	overturning moment
OWC	oscillating water column
OWSC	oscillating wave surge converter
OWT	offshore wind turbine
OWTT	one-way travel-time

P

P–M	Pierson–Moskowitz
P-C	Pelnard Considère
PBL	planetary boundary layer
PCR	polymerase chain reaction
PDE	partial differential equation
PDF	probability density function
PDMS	polydimethylsiloxane
PGM	probabilistic graphical model
PHINS	photonic inertial navigation system
PISO	pressure implicit with splitting of operators
PIV	particle image velocimetry
PLL	phase-locked loop
PMH	probable maximum hurricane
PMSG	permanent-magnet-excited-synchronous generator
PMT	photomultiplier tube
POL	petroleum, oil and lubricants
POM	Princeton Ocean Model
POMDP	partially observable Markov decision process
POSG	partially observable stochastic games
PPP	point-to-point protocol
PROVERBS	probabilistic design tools for vertical breakwaters
PSD	power spectral density
PSK	phase shift keying
PSS	practical salinity scale
PTC	passive turbulence control
PU	polyurethane
PVC	polyvinyl chloride

Q

QAM	quadrature amplitude modulation
QPSK	quadrature amplitude modulation
QTF	quadratic transfer function

R

RANS	Reynolds-averaged Navier–Stokes equation
RAO	response amplitude operator
RC	Resistor and Capacitor
REF/DIF	refraction/diffraction model
REFLICS	real-time flow imaging and classification
REMUS	remote environmental monitoring units
RF	radio frequency
RHIB	rigid hull inflatable boat
RIB	rigid inflatable boat
RLG	ring laser gyroscope
RLS	recursive least square
RM	red muscle
RMG	rail mounted gantrie
RMMV	remote multi-mission vehicle
RMS	root mean square
RNA	rotor-nacelle assembly
ROMS	Regional Oceanic Modeling System
ROV	remotely operated vehicle
RPS	renewable portfolio standard
RS	Reed–Solomon
RSLR	relative sea level rise
RTG	rubber tire gantrie
RTS	request-to-send

S

SALM	single anchor leg mooring
SAR	synthetic aperture radar
SARUMS	Safety and Regulations for European Unmanned Maritime System
SAT	satellite communication
SAUVIM	semiautonomous underwater vehicle for intervention mission
SBL	short baseline
SCADA	supervisory control and data acquisition system
SCF	standard cubic feet
SCFM	standard cubic feet per minute
SCOUT	surface craft for oceanographic and unmanned testing
SDOF	single-degree-of-freedom
SDV	swimmer delivery vehicle
SEAS	spectrophotometric elemental analysis system
SEC	south equatorial current
SHP	shaft horsepower
SISO	single-input single-output
SLAM	simultaneous localization and mapping
SLR	sea-level rise
SLT	steady-lift technology
SNR	signal-to-noise ratio
SODAR	sonic detection and ranging
SOFAR	sound fixing and ranging
SOM	self-organizing map
SPH	Standard Project Hurricane
SPLINE	self-propelled line array
SPM	single point mooring
SPR	self-referential phase reset
SS	strong suppression
SSC	suspended sediment concentration
SSF	Saybolt furol second
SSP	Sea Solar Power
SST	sea-surface-temperature
SSU	Saybolt universal second
St	Strouhal number
STS	ship-to-ship
STWAVE	steady state spectral wave model
SWA	small waterplane area
SWAN	simulating waves nearshore
SWATH	small waterplane area twin hull

T

TA	total alkalinity
TAT	turn around time
TCB	transverse center of buoyancy
Tcf	trillion cubic feet
TCG	transverse center of gravity
TCXO	temperature compensated crystal oscillator
TDD	time division duplexing
TDHA	total dynamic head available
TDHR	total dynamic head required
TDMA	time division multiple access
TDP	touch down point
TDZ	touch down zone
TEF	transportation efficiency factor
TEU	twenty-foot equivalent unit
TLP	tension leg platform
TOF	time-of-flight
TPH	total petroleum hydrocarbon
TPI	tons per inch immersion
TRL	technology readiness level
TSL	tunnel sea lion
TSR	tip-speed ratio
TWh	terawatt-hours

U

UAV	unmanned aerial vehicle
UBAT	underwater bioluminescence assessment tool
UEL	upper explosive limit
UFC	Unified Facilities Criteria
UGV	unmanned ground vehicles

UHF	ultra high frequency
ULCC	ultra large crude carrier
ULCS	ultra large container ship
ULF	ultralow frequency
UMV	unmanned marine vehicle
UMVS	unmanned maritime vehicle system
UPS	uninterruptable power supply
USBL	ultrashort baseline
USSV	unmanned sea surface vehicle
UUV	unmanned underwater vehicle
UV	ultraviolet

V

VARANS	volume-averaged Reynolds-averaged Navier–Stokes equations
VBAP	virtual body and artificial potential methodology
VCB	vertical center of buoyancy
VCG	vertical center of gravity
VCR	virtual control room
VED	vertical electric dipole
VFD	variable frequency drive
VHE	Vortex Hydro Energy
VHF	very high frequency
vi	virtual instrument
VIM	vortex-induced motion
VIV	vortex-induced vibration
VIVACE	vortex-induced vibrations for aquatic clean energy
VLCC	very large crude carrier
VLFS	very large floating structure
VLSI	Very Large Scale Integration
VMD	vertical magnetic dipole
VO	velocity obstacle
VOC	volatile organic compound
VOF	volume of fluid
VS	Varley-Seymour
VSF	volume scattering function

W

WEC	wave energy conversion
WECA	wave energy conversion actuator
WET	whole effluent toxicity
WIG	wing in ground-effect
WIS	Wave Information Studies
WSS	wide sense stationary
WSSI	wave–seabed–structure interactions
WT	water tracing
WWC	winds, waves, and currents

Z

ZOH	zero order hold

1. Introduction

Manhar R. Dhanak, Nikolaos I. Xiros

This brief introduction is aimed to make the reader aware of the many interesting topics involved in ocean engineering, from basic engineering science to engineering applications, in support of enabling a host of commercial, naval, and recreational activities in the ocean and in the coastal zones. It is not possible to cover all the topics in detail in a single book. Instead, in this Handbook we aim to provide an updated account of key topics in ocean engineering and ocean technologies, including a review of important fundamental and applied subject matter as well as contemporary developments in leading-edge ocean technologies.

Ocean engineering is an engineering discipline that includes elements of multiple traditional engineering disciplines and is specialized to provide the engineer with the required background to effectively undertake engineering projects in the marine environment. It is a study of science, technology, engineering, and mathematics, including ocean sciences, mechanical, electrical, civil and computer engineering, and naval architecture. Professional ocean engineers are involved in the design, development, and operation of ocean systems, technologies, and structures as well as in enabling a host of endeavors in the marine environment. New demands in commerce, national defence, climate change, and renewable energy, coupled with advances in electronics and marine materials drive innovations.

1.1 Enabling Maritime Design and Development

Covering over 70% of the surface area of the earth, the oceans are integral to life on the planet, to its atmosphere, weather and climate, and to carbon and other biogeochemical cycles. Maritime commerce and transportation are vital to the economy and security of many nations and the coasts support significant professional and recreational maritime activities while serving as living interfaces between land and the oceans. Further, the oceans represent rich sources of food, renewable energy, oil, and minerals. Engineering expertise and requisite ocean technologies enable responsible maintenance of the health, productivity and resiliency of the oceans and the coasts, safe navigation and exploration of the oceans, and environmentally sustainable tapping of their resources. Smart and innovative solutions are critical in developing robust and resilient coastal and offshore structures and platforms, in mitigating the impact of storms and global climate change, in managing the coasts and beaches, and in meeting commercial, energy, defense, security, and other needs of nations. With emerging advances in both land and ocean based technologies, and expanding anthropogenic activities in the oceans and coastal waters, the need to understand the oceans and to exercise care and wisdom in conducting these activities has never been greater. A US Commission on Ocean Policy [1.1] suggests that this expansion of activities coupled with the advances in technologies is threatening the quality of the oceans and their marine life. At the same time, the Commission regards the technological advances as also offering hope for us to

change course to achieve a vision of a future in which the world's oceans and coasts are clean, safe, and sustainably managed.

Ocean engineering is a multidisciplinary engineering field aimed at wisely and innovatively solving problems associated with working in the ocean environment, exploring the oceans, and harnessing its resources. It is a study of civil, computer, electrical, and mechanical aspects of engineering in combination with fundamentals of mathematics, physics, material science, naval architecture, and the ocean sciences. Today's professional ocean engineers are involved in the design, development, and operation of commercial and naval ships, submarines, and autonomous marine vehicles and systems, offshore and coastal structures, ocean energy converters, underwater sensor systems and technologies, and in meeting a host of other challenges associated with our endeavors in the ocean.

This Handbook aims to provide an updated account of key topics in ocean engineering and ocean technologies, including a review of important fundamental and applied subject matter as well as contemporary developments in ocean technologies. The intended readers include practitioners in a range of maritime industries as well as academic researchers and students in ocean engineering and areas related to ocean technologies. At the same time, the Handbook aims to serve as an important guide for anyone interested in the ocean and human activities in the maritime environment. The chapters in the Handbook are grouped into five parts. In Part A, the focus is on fundamental topics of ocean engineering; in Part B, it is on topics in marine transport and automation; in Part C the focus is on topics in coastal design; in Part D it is on topics in offshore systems; and in Part E the focus is on renewable ocean energy.

1.2 History

Although engineers have been involved in working in the ocean environment and in design and development of ships and submarines over centuries, ocean engineering as a recognized formal discipline is relatively new, dating back to 1960s. In the United States, concerns were expressed that engineers involved with design and construction of ships, submarines and other ocean systems lacked the necessary experience of the ocean environment. In 1963, the loss of the submarine USS Thresher [1.2] heightened these concerns and led to the development of this new engineering discipline at the undergraduate level; the Merriam-Webster dictionary notes the first known use of the term *ocean engineering* to be in 1964. Whereas *naval architecture* traditionally deals with design and construction of ships and offshore structures, and *marine engineering* deals with the construction and operation of power plants on ships, at docks, and harbors, *ocean engineering* is associated with operations in the ocean environment and deals with the application of engineering principles and techniques of design, construction, and maintenance to working in the ocean environment and to development and use of requisite ocean technologies. Today's ocean systems and operations are complex and require multidisciplinary approaches. Therefore, increasingly these disciplines overlap. *Naval engineering* and *offshore engineering* draw from all of these disciplines in design, construction, and maintenance of naval ships and submarines, and offshore platforms, respectively.

1.3 Basics

Besides mathematics, physics, chemistry, and oceanography, a typical core ocean engineering curriculum at an undergraduate level covers the topics of statics, dynamics, thermodynamics, heat transfer, graphics, electronics, programming, probability and statistics, data analysis, hydromechanics, wave mechanics, materials, structures, underwater acoustics, and control and dynamics systems. The curriculum culminates in design of ocean systems. The topics covered aim to develop an understanding of the ocean environment and its resources as well as fundamentals of engineering, and provide the knowledge, the principles, and techniques in:

1. Design, construction, maintenance, and survivability of ships, submarines and ocean structures
2. Understanding natural and anthropogenic signatures in the ocean
3. Performance enhancement of ocean systems
4. Control and automation and
5. System integration.

The coverage of the ocean environment encompasses characteristics of seawater and geochemical properties, and such physical processes as surface and internal waves, ocean and tidal currents, thermal gradients, and air–sea interaction. The engineering topics

aim to provide skills for determining stability and hydrodynamics of ships and submarines; for evaluating strength and integrity of marine materials and structures; for protecting ocean systems against corrosion and biofouling; for characterizing generation, propagation, and reception of underwater sound; for processing and analyzing ocean data; for developing algorithms for control and automation of marine vehicles; and for designing, developing, testing, and demonstrating ocean systems.

An understanding of the physics of oceanographic processes enables modeling and prediction of at-sea conditions and their variability. It develops an awareness of various phenomena in the water column, including such processes as the thermocline, and wind-driven and geostrophic currents. Winds, waves, and currents with random characteristics lead to dynamic *sea states* that range from states corresponding to routine operational conditions to those associated with extreme events. The forces associated with such meteorological and oceanic (metocean) conditions are correspondingly dynamic, random, and range from routine to extreme. They have to be accounted for in designing robust ocean and coastal structures and in planning and conducting offshore operations. Oceanographic and metocean processes are described in Chaps. 2–4.

Subsurface pressure, temperature, and salinity are physical properties of some importance in the deep ocean environment. Pressure ordinarily increases linearly with water depth, but is also a function of temperature and salinity. Submarines and housings for electronics of deep-water systems have to be designed so that they can withstand such pressures and require specially designed gaskets to prevent high-pressure water leaking into compartments of the systems. It is believed that Woods Hole Oceanographic Institution's unmanned deep-sea research submarine Nereus was lost in 2014 off New Zealand at a depth of nearly 10 km, where the pressure exceeds 1000 times the atmospheric pressure, due to an implosion of one of its components. While the temperature in the ocean below a mixed layer drops rapidly in a thermocline, it typically does not drop below approximately 2 °C. Properties of seawater are described in detail in Chap. 5.

Damage due to marine corrosion that arises through contact with seawater or through exposure to the atmosphere in coastal areas continues to be a major problem; this includes corrosion in engines operating at sea or exposed to salt-laden air. It typically accounts for 30% of failures on ships and other marine equipment. A World Corrosion Organization report [1.3] estimates that the annual cost of damage due to marine corrosion worldwide is over $1.8 trillion. Corrosion destroys materials through chemical reaction with its environment and the rate at which it impacts structures depends on the type of metal or metal alloys, and the design of the structures as well as the environmental conditions; presence of microbial organisms; and processes such as cavitation that can damage material surfaces [1.4]. Corrosion is typically controlled through use of coatings, cathodic protection, use of inhibitors, chemical dosing of the local environment, or use of less corrosive materials, including composites, in structures. Properties of marine corrosion are discussed in Chap. 6.

Maximizing the operational efficiency of ships and submarines continues to be an important goal in marine transportation. In hydromechanics, fundamentals of drag, lift, and propulsion as well as such features as turbulence, boundary layers, jets, shear layers and wake resistance, and vortex-induced vibrations and galloping carry over from aerodynamics with the difference that the density of seawater is over 800 times greater than that of air. However, phenomena such as cavitation and bubble generation, and wave-induced forces on vehicles and offshore structures require special consideration in hydromechanics. In addition, for vehicles operating on or near the free surface, an additional contribution to vehicle drag or resistance arises that is associated with waves generated by the vehicle. Correspondingly, for vehicles operating on or near the free surface, in addition to Reynolds number, a dimensionless parameter, the Froude number, $\mathrm{Fr} = U/\sqrt{gl}$, where U and l are, respectively, the characteristic speed and length, and g is the acceleration due to gravity, governs the flow characteristics. The wave-making resistance of ships is typically characterized by the Froude number. Hydromechanics is discussed in Chap. 7.

Acoustics, electromagnetics, and optics are important sensing mechanisms in underwater operations and have led to significant efforts in development of associated sensor and sensor platform technologies and operations. Underwater sound is generated through vibrational activities as a pressure pulse in the water that propagates at speeds in the range of 1400–1600 m/s at frequencies typically in the band 1 Hz–1 MHz with corresponding wavelengths in the range of 1.5 km–1.5 mm. The sound undergoes transmission losses through absorption and scattering through refraction, reflection, and destructive interference of sound waves. The speed of sound decreases with decrease in temperature and increases with depth. This gives rise to existence of a minimum at mid-depth and the variability in sound speed with depth leads to bending or refraction of sound waves toward region of lower speed. A sound wave generated in the thermocline bends downward at first toward region of lower speed and then upward as the speed increases with depth. This leads to a particularly interesting phenomenon called the SOFAR (sound

fixing and ranging) channel, existing at 600–1200 m depth in mid-latitudes, through which sound travels long distances without attenuation [1.5]. Distances traveled by sound waves satisfy the inverse-square law and decrease with increase in frequency – low-frequency waves may travel tens of thousands of kilometers without significant attenuation, while very high frequency waves typically penetrate distances of order 1 m. Hydrophones measure pressure fluctuations induced by sound in μPa (micro Pascal), and the amplitude or the loudness of the underwater sound is measured in decibel with reference to a standard pressure level at a standard distance, written dB re 1 μPa at 1 m. As a reference, blue whales vocalize at 10–40 Hz at source sound levels of 155–188 dB re 1 μPa at 1 m [1.6, 7], whereas large ships and fast-moving small boats can produce broadband (20–1000 Hz) sound levels with source levels of 150–200 dB re 1 μPa at 1 m. An excellent description of underwater acoustics is provided in a sister handbook [1.5].

Since seawater is a conducting fluid, with conductivity in the range 2.5–6 S/m, electric fields in the ocean maybe generated through induction by time varying external fields or by motion of the seawater through the Earth's magnetic field. Strong temporal variations in the magnetic fields in the ionosphere and the magnetosphere induce electric fields in the ocean and generate secondary magnetic fields. Further, the dynamo effect of currents in the ocean, involving motion of conducting seawater through the Earth's magnetic field, induce electric fields, and, in turn, give rise to secondary magnetic fields in the water column [1.8]. Whereas the electromagnetic waves in air propagate at the speed of light (3×10^8 m/s), in the ocean the speed depends on the wave frequency. At 1 Hz, it is approximately 1600 m/s, several orders of magnitude lower than in air, while at 10 kHz, it is 100 times faster. The waves undergo transmission losses, the rate of attenuation increasing with frequency; a 10 kHz electromagnetic wave is attenuated at a rate over 80 times faster than a 1 Hz wave. Finally, at frequencies of order 10^{14} s^{-1}, with corresponding wavelengths of 400–700 nm (in air), is the visible part of the electromagnetic spectrum. Light waves propagate at the speed of 2.24×10^8 m/s in seawater compared with 3×10^8 m/s in air. The attenuation of light is wavelength-selective, leading underwater objects having bluish or greenish tints [1.9]. Ocean electromagnetics are discussed in Chap. 8.

Ocean signals are typically noisy and have to be processed to discern the underlying signatures that enable detection, identification, and location of objects underwater. Typical processing is in terms of spectral analysis of time series of signals, using for example Fast Fourier transforms. Sophisticated algorithms are required to extract underlying signatures from excessively noisy signals. The science of signal processing enables development of the algorithms that facilitate such extraction. It is discussed in Chap. 9.

In the past decade, significant effort has gone into shipboard automation and development of unmanned ocean systems. Underlying this effort are major advances in microelectronics and computer technologies. Unmanned systems typically involve sensors and actuators that may be linked via a computer that acquires and stores data from the sensors, formulates a response using onboard control algorithms and sends out an actuation control signal, in support of achieving a desired state. The error between the outcome of the actuation, determined via an appropriate sensor measurement, and the desired state is continuously monitored in a feedback loop and used to improve the control signal in an iterative process. A simple proportional-integral-derivative (PID) controller is based on using the present values of the error, accumulated past values of the error, and predicted future values of the error in developing an improved actuation control signal. The control theories and case studies illustrating the theories are discussed in Chap. 10.

1.4 Applications

Human activities offshore and in coastal regions span across a range of sectors, including shipping and maritime transport, offshore energy, security and defense, development of ports, harbors and other coastal structures, fisheries and aquaculture, recreational activities and activities related to mitigating environmental impacts of these activities. Planning, design, and conduct of these activities as well as development of enabling technologies involve applications of ocean engineering at various levels through the maritime industry. In Parts B through E, we cover four major areas of applications of ocean engineering in the maritime domain: automated unmanned systems, coastal design and structures, offshore platforms, and offshore renewable energy.

1.4.1 Automated Unmanned Systems

Automated unmanned systems are systems that are pre-programmed to carry out desired tasks. Taking advantage of the advances in electronic and computer technologies, significant strides are being made in the

level of autonomy as well as in the diversity of applications in commercial activities in the maritime domain. The applications range from automated port container terminals with automated guided vehicles (AGVs), stacking cranes, gantry systems, and other automated systems that are significantly revolutionizing port and container shipment operations, to autonomous underwater and surface vehicles (AUVs and USVs) for commercial and military applications, including for hydrographic surveys, underwater pipeline inspections, surveillance, asset protection, and mine-counter measures. Typically several subsystems integrated together make up an unmanned automated system. Design and development of such systems utilize many of the basic elements of ocean engineering. In the case of an AUV, while the size of the vehicle may be determined by the payload requirements, the shape of its hull and the designs of its propulsion and control surfaces, for stable and efficient motion and maneuverability, are determined through application of the principles of hydromechanics. Selection of materials and structures for operations at given water depths and for durability and reduced maintenance is based on principles of materials engineering and on corrosion science, as well as on expected hydrodynamic loads on the structures. Batteries and powering systems are selected for long endurance and together with other electronic elements require appropriately designed cooling systems. Designs of vehicle navigation, obstacle avoidance, and underwater communication systems are based on application of the principles of underwater acoustics as well as optics. Typically, an AUV may act as a mobile sensor platform carrying a range of mission-based acoustic and nonacoustic sensors. The acoustic sensors operate over a range of mission-specific frequencies that encompass human hearing range (20–20 000 Hz) and beyond. They include the well-known sidescan sonar for detection, classification and location of targets in the water column, and high-frequency (kHz–MHz range) sonar for detection of buried objects, and for imaging subsurface objects. Nonacoustic sensors include electromagnetic sensors, with important applications in the areas of geophysical surveys and searches of the seafloor and sub-bottom, communication across the sea–air boundary, and high data transfer rate at short ranges; optical sensors, including flashing light-emitting diode (LED) and laser, for sensing, detection and communication; electrochemical sensors for environmental monitoring [1.10]; and other bio-geo-chemical sensors with a host of applications in marine science and environmental monitoring. States of the art in key areas of autonomous marine vehicles are presented in Part B.

1.4.2 Coastal Design

Coastlines are interfaces between the challenging ocean environment and densely populated coastal areas and associated human activities. It is estimated that over 1.2 billion people worldwide live within 100 km of the coast [1.11]. Significant effort is therefore involved in taking measures to protect the coastline from storm surges, winds, waves, flooding, and erosion as well as in accommodating, sometime conflicting, needs of the coastal population and associated human activities, while maintaining a healthy coastal environment. Shore protection against beach erosion and storm damage, which fall under coastal management, involves construction of hard structures such as sea walls, breakwaters and revetments as coastal armor, and groins as sand-trapping devices, as well as methods for periodic beach nourishment and stabilization as measures for mitigation of beach erosion. Structures that accommodate human needs include ports and harbors, piers, and marine outfalls. Designing robust coastal structures and measures for maintaining a healthy shoreline, as well as assessing risks of damage due to coastal hazards, involve estimating and predicting the forces associated with coastal waves and extreme storms through modeling and simulation. Typically, the structures are designed to withstand a 100-year or 50-year wave, which are statistical projections of wave heights that on average would be exceeded once in 100 or 50 years, respectively, and are based on past observations. A harbor is defined as a protected place that offers safety to ships, whereas a port is defined as harbor with terminal facilities that accommodate intermodal transportation and storage of cargo, in support of commerce. The amount of cargo throughput and its cost-effective handling at a port are based on the number and size of the berths, storage capacity, cargo handling equipment and the size of ships that it can accommodate, as well as the impact of local environmental conditions [1.12]. Demands posed by new super-large cargo ships and move toward automation, in terms of channel depth and berth space and cargo handling, have provided new worldwide impetus to the process of planning and design of ports and harbors. Safety and efficiency of operations at a port are significantly based on the design of its approach channel, its berthing, anchoring and mooring systems, turning basins, and its terminal facilities. These and other considerations involved in coastal design and development, including, in quantification of the physical coastal environment, in practice of beach nourishment, in design of structures for protection against coastal hazards, and in design of ports, harbors, and marine outfalls are discussed in Part C, which is dedicated to Dr. Robert G. Dean in

recognition of his significant contributions to coastal engineering.

1.4.3 Offshore Systems

Offshore platforms have traditionally been critical in extracting, processing, and temporarily storing offshore oil and gas. The platforms can be fixed, bottom-supported structures that extend to the bottom or floating structures that are moored to the bottom. Design and construction of a robust offshore platform, buoy or other offshore system, as well as offshore operations in open water pose significant challenges, depending on the water depth, the local hydrodynamic conditions, and payload requirements. Major design considerations for an offshore platform includes the unsteady hydrodynamic loads that the platform would likely experience due to waves, winds, currents, and turbulent eddies, and the interaction of the platform with the flow, choice of materials and the design life of the system. The type of platform and its mooring and/or other support systems, as well as the condition of its foundation, characterize the fluid–structure interactions and the dynamic responses of the structure and its floating subsystems [1.13]. Consideration is also given to the damage and degradation resulting from corrosion, fatigue, biofouling, and wear and tear that play a significant role in determining the frequency of requirement for duty-cycle maintenance and the design life of the platform. Important elements of offshore systems and operations are cables or tethers for mooring platforms, for towing systems through the water, for securing instrument packages, and for meeting a host of other requirements. The cables or tethers in energetic ocean environments are typically subjected to random dynamic tension forces and the failure of a cable or tether can have costly consequences, possibly resulting in loss of a platform, instrument, or other system. Good estimates of these forces are required in designing and in selecting material for a marine cable or tether.

Large mobile offshore systems include floating production, storage, and offloading (FPSO) vessels used for production and processing of hydrocarbons, high-capacity crane vessels for offshore construction, commercial and naval ships for transport of goods and people across the oceans, and other purpose-built vessels for transporting large specialized subsystems. Among the latter category are container ships, bulk carriers, super tankers, liquefied natural gas (LNG) carriers, ocean liners, cruise ships, aircraft carriers and battleships. These vessels, which can be over 300 m long, call for special engineering requirements in terms of maritime technology and operations. For example, a LNG carrier, which is specifically discussed in Chap. 41 in Part D, is used for transporting flammable liquefied natural gas at cryogenic temperature of $-163\,^{\circ}\mathrm{C}$ and is designed to provide the necessary thermal isolation and operational safety.

Major offshore operations, such as oil-spill remediation and salvage of ships and submarines, require significant planning and preparation and merit special considerations. Major oil spills, such as in the Gulf of Mexico in 2010, pose significant environmental hazards and typically call for rapid responses. Complex physical, biological, and chemical weathering processes govern the fate of an oil spill in water, including interaction with suspended sediments, and the processes being dependent on the type of oil and prevailing local environmental conditions. As a result, following a major spill, there is large uncertainty in the portion of the oil that is at the water surface, where it may be subjected to significant evaporation, and the portions that remain suspended within the water column, at what depths, and in what form, as well as how much gets deposited on the seabed [1.14]. The state of the art in engineering expertise and technology critically governs the effectiveness and timeliness of the response to an oil spill, from detection of the spill, to identification of source location(s), to characterization of the extent of the spill, to surveillance and monitoring, to intervention, mitigation, and remediation. Salvage of ships and submarines lost at sea also entails major broad-based, interdisciplinary engineering operations. Salvage engineers apply the principles of naval architecture and ocean engineering in assessing the strength and stability of damaged vessels and in recovering them from the sea. Working knowledge of basic ocean engineering topics, maritime safety engineering, and the theory and practice associated with rigging offshore systems are essential for a practicing salvage engineer. Oil-spill remediation and salvage operations are considered in two major chapters in Part D.

1.4.4 Ocean Energy

Worldwide theoretical potential of ocean energy (in the forms of offshore wind, wave, ocean and tidal currents, and thermal and salinity gradients) as a renewable source for electricity is striking. It is estimated that this potential ranges from 20 000 to 80000 terawatt-hours (TWh) of electricity annually, which is 100–400% of current global demand [1.15]. Actual resources that can be harvested cost-effectively are currently much smaller. Ocean energy development is significantly behind in technical maturity, compared with other renewables such as onshore wind and photovoltaic solar. This is due to the technical, socioeconomic, environ-

mental, regulatory, and infrastructural challenges posed by the harsh, energetic ocean environment. The levelized cost of energy (LCOE) for ocean energy is currently uncertain or at best much higher than that of fossil fuels and other renewables [1.15] because capacity factor and design life of offshore systems, which are key drivers of LCOE, are generally not well understood. However, as has been demonstrated in the case of development of onshore wind and solar energy [1.16], the rate at which the challenges to ocean energy development are overcome and costs reduced will be driven by investment as well as by a concerted effort in learning, innovation, and deployment of prototypes that enables informed decision-making. The good news is that a number of studies, including proof of concepts, and computational and laboratory investigations, have been conducted [1.17, 18] and various breakthrough energy conversion devices have been designed and built, with over 150 global patents in ocean energy technologies filed annually between 2009 and 2013 [1.15]. Industry investment in ocean energy, having lagged in view of the risks involved, is being spurred in Europe and elsewhere with the help of government subsidies. Government regulators in Europe and the United States are increasingly looking to develop ecosystem-based coastal and marine spatial planning (MSP [1.19]), a process for making informed and coordinated decisions for multiple maritime activities while conserving biodiversity in the coastal environment, in support of reducing conflicts between commercial-scale development of ocean energy and other competing maritime activities. MSP aids in identifying a policy framework for siting, permitting, and developing ocean energy [1.20, 21]. MSP aims to site ocean energy development at ocean energy *hotspots* that have the lowest potential conflict with other maritime activities, such as fishing, shipping, and whale watching, for example, as well as with lowest impact on biodiversity. Topics in various forms of ocean energy, in terms of resource characterization, and requisite technologies for harvesting the energy are covered in six chapters in Part E.

1.5 Future Trends

Emerging new demands in commerce, national defense, and energy requirements on the one hand, and advances in electronics, computer chip industry, and marine materials on the other represent significant new challenges and great opportunities for practicing ocean engineers and educators in developing and implementing new ocean technologies and educating and training the next generation engineer workforce. Ocean engineering topics of interest in the 21st Century include:

- *Ocean exploration*: Vast regions of the oceans remain unexplored and a new era of ocean exploration, particularly in the Arctic is expected. Based on current progress, it will result in development and use of custom smart ships, submersibles, remotely operated vehicles, AUVs, and gliders that will carry smart sensor systems for navigation and ocean observation. AUVs and USVs will be used routinely with unmanned aerial vehicles (UAVs), and underwater robotics will become increasingly sophisticated.
- *Shipboard automation*: The drive to reduce manning onboard ships through automation has been in progress for several years and advances are being made utilizing developments in power electronics. It will result in highly automated, all electric ships that are highly reconfigurable for robust operation, and that will use new, efficient, low emission engines and fuels [1.22].
- *Coastline security technologies*: The new threats due to terrorism from the seas call for greater surveillance of our harbors, ports, and coastline and call for development of new sensor systems and small, automated sensor platforms.
- *Coastal structures*: Coastal hazards, compounded by the new significant threats associated with sea-level rise as well as rising populations in low-elevation coastal zones [1.23], will continue to require innovative engineering solutions for coastal structures and shoreline management, in support of sustainable management of coastal zones.
- *Offshore platforms*: Oil and gas exploration and extraction is being extended to deep waters. This will present new challenges in construction, implementation, and operation and maintenance of platforms far from shore. New concepts in multiuse offshore platforms that combine, for example, energy extraction, aquaculture, and platform-related transport are being explored [1.24]. Such platforms facilitate effective marine/ocean spatial planning as well as consolidate various offshore activities, and can be green platforms, benefiting from local renewable ocean energy.
- *Renewable ocean energy*: As discussed above and in Part E, reducing the cost of harnessing ocean energy in the forms of offshore wind, waves, ocean and tidal currents, and thermal gradients in a sustainable manner is a key factor in commercial-scale de-

velopment of ocean energy. Innovative engineering methods and ocean technologies will be required to achieve the required solutions.

- *Marine materials*: Lighter, stronger ship hulls, and ocean structures made of composites that exploit developments in nanotechnology show promise. At the same time, protection against corrosion and biofouling using safe, durable coatings and materials continue to drive new research. These materials and coatings will reduce duty cycle maintenance of maritime systems. Further, there is renewed interest in utilizing surface chemistry of nano- or microtextured polymer coatings for skin-friction drag reduction and improved hydrodynamic performance of ships and submarines; for streamlined vehicles, such as ships and submarines, skin-friction typically accounts for over 50% of the total drag so that its reduction provides a significant boost to the propulsive efficiency of the vehicle and can result in fuel saving or increased range.
- *At-sea operations*: The necessary science and technology for operating in high seas continues to present both significant ocean engineering challenges and opportunities for innovation in ship design, cargo transfer, sea-keeping, and hydrodynamic performance in high sea-states.

Educators are challenged to respond to future trends and improve ocean-related science and engineering education, in support of developing an educated engineering workforce with requisite knowledge of the ocean environment. Ocean engineering will continue to offer good career opportunities to young people, however challenging.

In Part A, a range of fundamental topics in ocean engineering that underlie practical engineering applications in the marine environment are covered in nine chapters, encompassing physical aspects of oceanography and marine meteorology, seawater properties, hydrodynamics, marine corrosion, marine electromagnetics, signal processing and control theory. These topics form part of a core ocean engineering curriculum aimed at providing an understanding of the marine environment together with basic concepts of engineering. These include design, development, and operation of ocean and coastal structures, marine vehicles, offshore platforms, ocean renewable energy in its various forms, and a host of other applications in support of commercial, naval, and recreational activities in the ocean and in the coastal zones, and in accommodating sustainable coastal communities and coastal management.

In Chap. 2, elements of physical oceanography, including surface and internal gravity waves, inertial motion and hurricane-driven storm surge are described. An outline of the wind generated surface waves, from generation to dissipation is provided. The roles of turbulence-derived oceanic friction in Ekman dynamics/upwelling-downwelling are described. The tides and geostrophic flow in wind- and thermohaline-driven circulations are discussed.

In Chap. 3 the ocean and atmosphere (metocean) conditions that govern the design and operation of man-made structures, facilities, and vessels are described. Metocean environments that allow routine operations and extreme *storm-related* environments are considered. Methods commonly used in the offshore oil and gas industry to quantify the most important metocean variables, associated with winds, waves, and currents that impact offshore facilities are outlined. Applications of the methods include the design and operation of vessels, coastal structures, offshore wind farms, navigational aids, coastal geomorphology, and pollution studies.

In Chap. 4, the mechanics of water waves and wave-body interactions pertaining to ocean and coastal engineering based on linear and weakly-nonlinear wave theories are reviewed. Numerical methods based on Green's theorem and mixed Eulerian–Lagrangian formulation for fully nonlinear wave and wave-body interaction problems are discussed, together with methods to determine the wave forces on fixed and floating structures, including the viscous drag force.

In Chap. 5, the principal physical properties of seawater, including pressure, temperature, salinity, density, density anomaly, specific heat, and thermal expansion are described. The typical global ocean profiles and distribution maps of surface temperature, salinity, and density anomaly are provided. Other oceanic properties, including stability of oceanic water columns, use of temperature-salinity diagrams in identifying water masses, seawater freezing, as well as oceanic sound transmission and light are described.

In Chap. 6, the corrosion processes due to exposure to marine environments over extended periods are reviewed. Mathematical models for the prediction of corrosion and pitting of structural steels are described. The effects of various influencing factors are considered, including that of seawater quality and the effect of microorganisms on corrosion. Corrosion of various materials, including stainless steels, aluminum, copper-nickels, and steel reinforcing bars in reinforced concrete is considered.

In Chap. 7, a reference source for concepts in hydromechanics is provided with the aim of providing the working knowledge for solving practical ocean engineering problems. A range of topics is covered, including dimensional analysis, static and dynamic flows, potential and viscous flows, laminar and turbulent flows, boundary layers, wakes, jets and shear layers, and drag and lift forces.

In Chap. 8, properties of electric and magnetic fields within the electrically conducting ocean are described. The mathematical descriptions, based on Maxwell's equations, of electromagnetic fields and dipole sources within a conducting media are developed. The differences between plane wave reflection and transmission at the surface of freshwater and seawater are used to highlight how electromagnetic propagation within the electrically conducting ocean is so very different to the more familiar radio frequency transmissions in air. A brief discussion of ocean electromagnetics at optical wavelengths is also provided.

In Chap. 9, an overview of digital signal processing is provided. The concept of discrete-time signals and sampled-data systems implemented on digital hardware vs. those of practical continuous-time signals driving analog systems and processes is discussed. The discrete Fourier transform and the Z-transform are introduced as tools for analysis of time series of data. A brief account of digital filter structures and types is provided. Random signals and stochastic processes are considered, together with concepts of optimal signal estimation.

In Chap. 10, the basics of control theory are described and its application to ocean engineering is illustrated by specific examples. Fundamentals of systems science and theory are discussed. Stability and controllability of linear, time invariant systems are presented.

Bode plots and the root locus technique are discussed. For single-input, single-output systems, proportional-integral-derivative (PID) control is introduced and pole placement design is discussed. A brief presentation of digital controller implementations is given. Applications from ocean engineering include control of autonomous underwater vehicles and autopilots for surface vessels.

2. Elements of Physical Oceanography

Wendell S. Brown

This chapter discusses the most important elements of physical oceanography in terms of the various oceanic responses to atmospheric and astronomical forcing – as mediated by earth rotation, including surface, and internal gravity waves; inertial motion and hurricane-driven storm surge. We include an outline of the history of wind-generated surface waves: generation to dissipation on the beaches. The roles of turbulence-derived oceanic friction in Ekman dynamics/upwelling-downwelling are outlined. There is a discussion of the elements of practical tidal sea level prediction. There is a review of the central role of geostrophic flow in wind- and thermohaline-driven circulations on ocean basin as well as continental shelf scales.

The ocean environment consists not only of the water column, but also the atmosphere above the water's surface and the seafloor and sediment and rocks of the subseafloor. A comprehensive study of the marine environment is enormous in scope and is thus often subdivided into disciplinary components, including biology, chemical, geology, physics, and meteorology. This chapter will focus on basic introductory information concerning aspects of the marine environment; however, it will also refer oceanographic literature for those seeking more comprehensive treatments.

Different aspects of ocean engineering design are influenced to varying degrees by one or more environmental factors. These factors comprise one of the several groups of the so-called external *design* constraints; or constraints that are independent of or external to the purpose on which the design is based. For example, submersibles encounter temperature, salinity, pressure, and density gradients as they move through the water column, irrespective of their individual missions. These *external constraints* may be subdivided into those which are fixed by mission requirements and those which are variable. For example, the design *maximum operating depth* of a submersible sets the maximum pressure that the submersible can encounter. However, this operating constraint is not usually linked to specific values of sea water temperature, salinity, and density which can be encountered; but rather only ranges of these variables.

While discussing different oceanic environmental factors, it is convenient to consider them in terms of the three basic regimes in a vertical profile that includes the atmosphere and the water column.

2.1 Atmospheric Processes

An instantaneous snapshot of the winds of the entire atmosphere would present an extremely chaotic view of the flow. Atmospheric circulations can be characterized as an enormously complex patterns of *eddies within eddies*. Thus, it is convenient to categorize the different features of atmospheric circulations according to their different sizes – or scales of motion.

The very small-scale eddies or whirls with time scales of only a few seconds can be eliminated by averaging the measured winds over periods of several minutes. Furthermore, observations are so widely spaced in time and area that most must be considered averages over horizontal distances of tens of kilometers, and vertical distances of tens of meters. Thus, even such relatively large circulation phenomena as thunderstorms and tornadoes often cannot be resolved by the usual weather station network of observations. Through this kind of averaging the range of atmospheric motions can be classified in terms of three general scales; microscale, mesoscale, and synoptic scales (Fig. 2.1).

On the microscale, we find small, short-lived eddies (or turbulence), that are strongly affected by local conditions of both surface roughness and temperature. These eddies are very significant as dispersers of pollutants. At the large end of the microscale are tornadoes and waterspouts. Because microscale motions have such short time scales, Earth rotation is not a significant factor.

Mesoscale phenomena of intermediate horizontal size include such processes as land–sea breezes, thunderstorms, and squall lines. Earth rotation can be an important factor affecting the larger mesoscale phenomena such as sea breezes.

Synoptic scale phenomena most notably represented by large-scale, low-pressure cyclones and high-pressure anticyclones that control our day-to-day weather changes – particularly at mid-latitudes. Historically these synoptic-scale features have been defined every 3 h by the large-scale weather network of simultaneous observations. Earth rotation-related forces are very important factors in the physics of synoptic-scale systems, which persist for days to weeks. Synoptic-scale features that persist for weeks to months tend to have planetary space scales and like jet stream loops play an important role in determining the seasonal characteristics of the weather.

The vertical displacements distinguish these different scales of atmospheric motion. For example, synoptic scale phenomena are dominated by horizontal motions; with vertical velocities generally only 1 to 2 cm/s. Even the great cyclonic storms in the middle and high latitudes, have vertical velocities of the order of 50 cm/s. In the smaller, more intense mesoscale circulations, horizontal and vertical velocities are more comparable; with thunderstorm vertical velocities are often of the order of 10 m/s. Microscale or turbulent phenomena, with nearly equal horizontal and vertical velocities, occur principally in a rather shallow layer adjacent to the Earth's surface and thus are important factors in air–sea interactions. A detailed description of the maritime atmosphere is provided in Chap. 3.

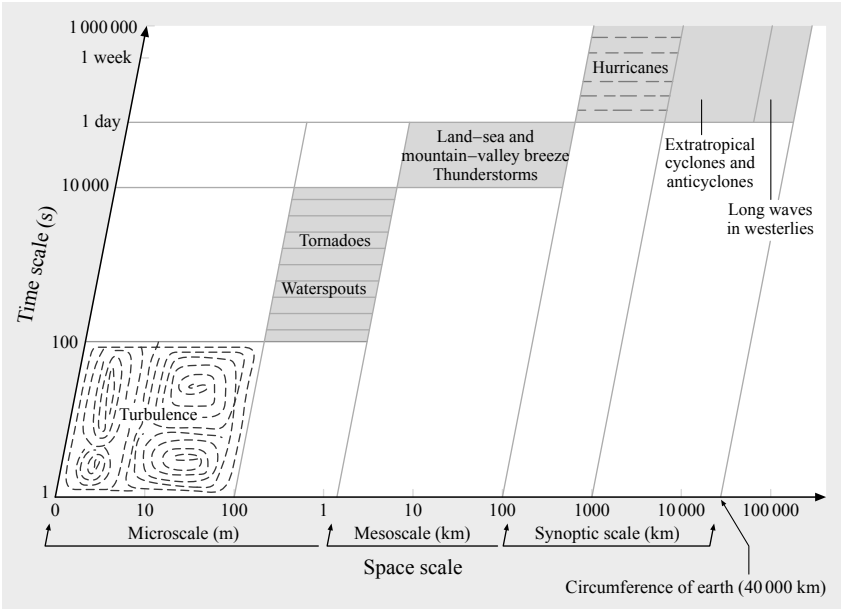

Fig. 2.1 Horizontal space and time scales of atmospheric circulations (after [2.1])

2.2 Ocean Structure

The global atmosphere and the ocean interact in ways that structure the ocean into fairly distinct *upper ocean layer*, which extends down to about 1000 m (3284 ft), and *deep ocean layer*, which extends to the bottom. On one hand, air–sea interactions create vast amounts of sinking cold, dense water in the polar oceans north and south of 40° latitude. On the other hand, in the subtropical and tropical regions between 40°S and 40°N, air–sea interactions warms a buoyant upper layer of the ocean that overlies a deep layer of cold, dense water throughout the world's oceans. The contoured-density section the Atlantic Ocean in Fig. 2.2 highlights the 2 layers. In particular, the region of closely packed of the isopycnals – the pycnocline – in the upper few 100 m represents a dynamical barrier to vertical mixing between upper and deep layer of the ocean.

The trio of oceanic water column density profiles in Fig. 2.3 demonstrates how the strength of the pynocline in the equatorial/tropical water column is much stronger than that in the high latitude polar regions. Density or specific weight of sea water is a function of temperature, salinity, and pressure. Variations in sea water temperature and salinity (which determine density) vary substantially in the upper layer water column forming their respective thermoclines and haloclines. These variations, in general, are due to the influences of heat exchange and precipitation/evaporation across the air–sea interface at a particular latitude and season. In the deep ocean layer, below 1000 m, these characteristics tend to be relatively constant. The upper ocean layer may be subdivided further into regions of seasonal and main pycnocline (and corresponding thermoclines and haloclines); particularly in the subtropics between 20° and 40° latitudes where density/temperature/salinity gradients are largest extending, respectively, from the surface to about 60 m and from this depth to about 1000 m (Fig. 2.4).

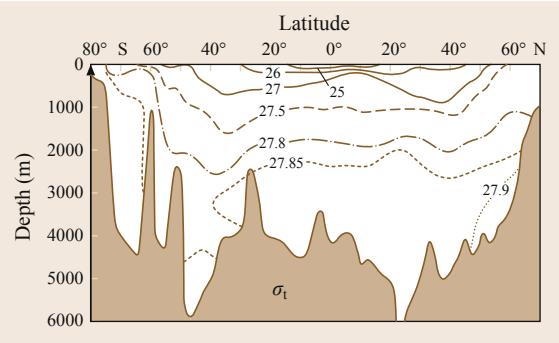

Fig. 2.2 A south–north section of contours of density anomaly (σ_t = water density − 1000) in the western Atlantic; showing how the upper and lower layers of the ocean between 50°S and 50°N are defined by closely packed isopycnals – a strong pycnocline or density stratification – at a depth of about 800 m (after [2.2])

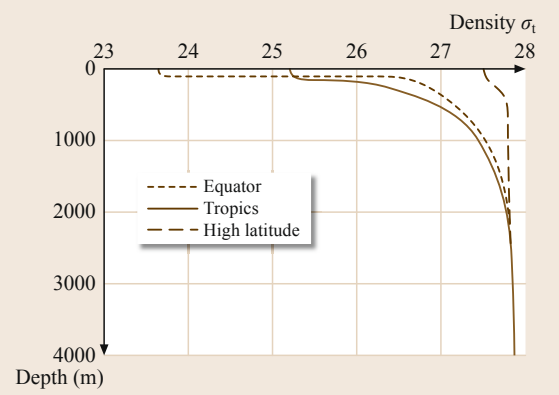

Fig. 2.3 Typical density anomaly versus depth profiles at low and high latitudes (after [2.2])

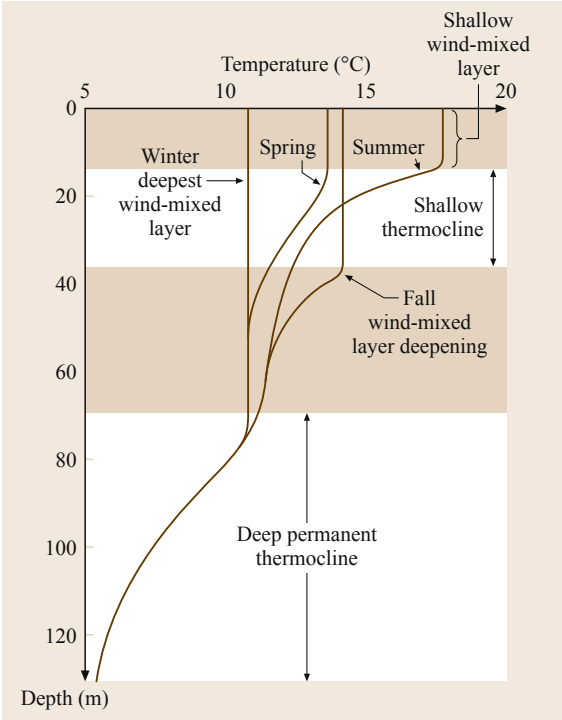

Fig. 2.4 The seasonal variability of a typical subtropical temperature profile (after [2.3])

2.3 Oceanic Processes

Like the atmospheric winds, ocean currents at a single place/time is a superposition of contributions from a complex set of processes many with different space-time scales. The following profiles many of the most important ocean processes in terms of their basic physical elements including forcing and restoring forces and relevance in the overall ocean system. The corresponding ranges of time and space scales of these processes are presented in Table 2.1 and in the dispersion diagram (Fig. 2.5) – a diagram that is particularly relevant to waves:

- Capillary waves. *Physics: surface tension, inertia, wind-driving* – First effect of winds in wave generation
- Surface gravity waves (short). *Physics: gravity, inertia, wind-driving* – Mid-ocean wind waves/surface chop, shipping, off-shore construction.
- Surface gravity waves (long). *Physics: gravity, inertia, bottom topography, wind-driving or earthquake* – Surf and breakers, storm surges, tsunamis, dangerous flooding.
- Internal gravity waves. *Physics: gravity or buoyancy, inertia, topography, indirect wind- driving* – Energy dissipation, mooring stresses, *dead water*.
- Turbulence, mixing. *Physics: inertia, buoyancy, nonlinear interaction, friction* – Dissipation of energy, mixing of momentum and dissolved chemicals including O_2.
- Upwelling (and downwelling). *Physics: buoyancy, local winds and currents* – Brings up nutrients/formation of water masses.
- Mid-Ocean mean flows. *Physics: buoyancy, Coriolis force, wind and heating driving, friction* – Maintaining climate, distributing chemicals, and heat for biology.
- Continental shelf currents. *Physics: buoyancy, Coriolis force, nonlinear inertia* – Transfer of heat and vorticity, climate and local weather, biology, chemistry.
- Tides. *Physics: gravity, inertia, sun and moon gravitational pull, Coriolis force* – Piloting and shipping, coastal construction.
- Internal tides. *Physics: gravity or buoyancy, inertia, topography, indirect wind-driving* – Internal waves at tidal periods with large vertical excursions.
- Estuary flows. *Physics: gravity-buoyancy, Coriolis, tidal, and wind forcing* – Pollutant dispersal, biological nutrient renewal, inflow of fresh water.

The energy distribution of these different oceanic processes tends to sort by time scale and can be conveniently presented in terms of frequency spectra in different forms. The energy density (i. e., energy per unit

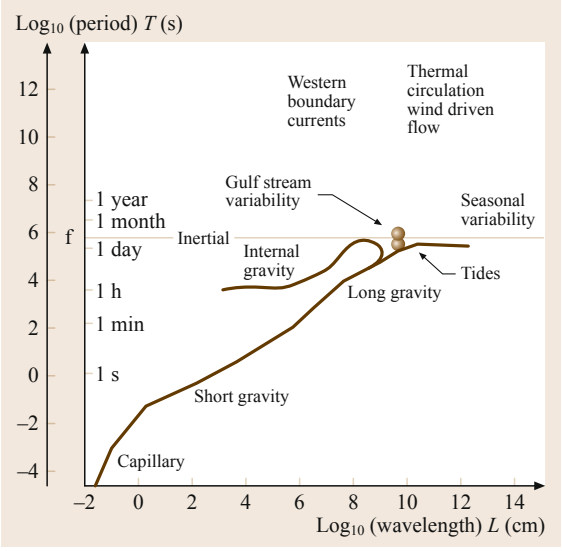

Fig. 2.5 Dispersion diagram for the principal oceanic processes

Table 2.1 Characteristic time and length scales associated with different ocean processes and currents

Type	Time Scales T	Length Scales L	Amplitude H
Capillary waves	< 0.1 s	< 1 cm	< 1 cm
Short surface gravity waves	0.1–60 s	cm–km	m
Long surface gravity waves	s/h	m–10's km	m
Internal gravity waves	min–h	m–10's km	m
Turbulence (Mixing)	s	cm–m	mm–cm/s
Upwelling/downwelling	Days–seasonal	100 km < 1	mm/day
Mid-ocean *mean* flow	1000km	1000 km	cm/s
Western boundary currents	Seasonal–decadal	100 km	≈ 200 cm/s
Continental shelf currents	Days–months	100 km	cm/s
Tides	Day	1000 km	m
Internal tides	Day	10–100 km	10 m
Estuarine currents	Day–seasonal	100 km	cm/sec

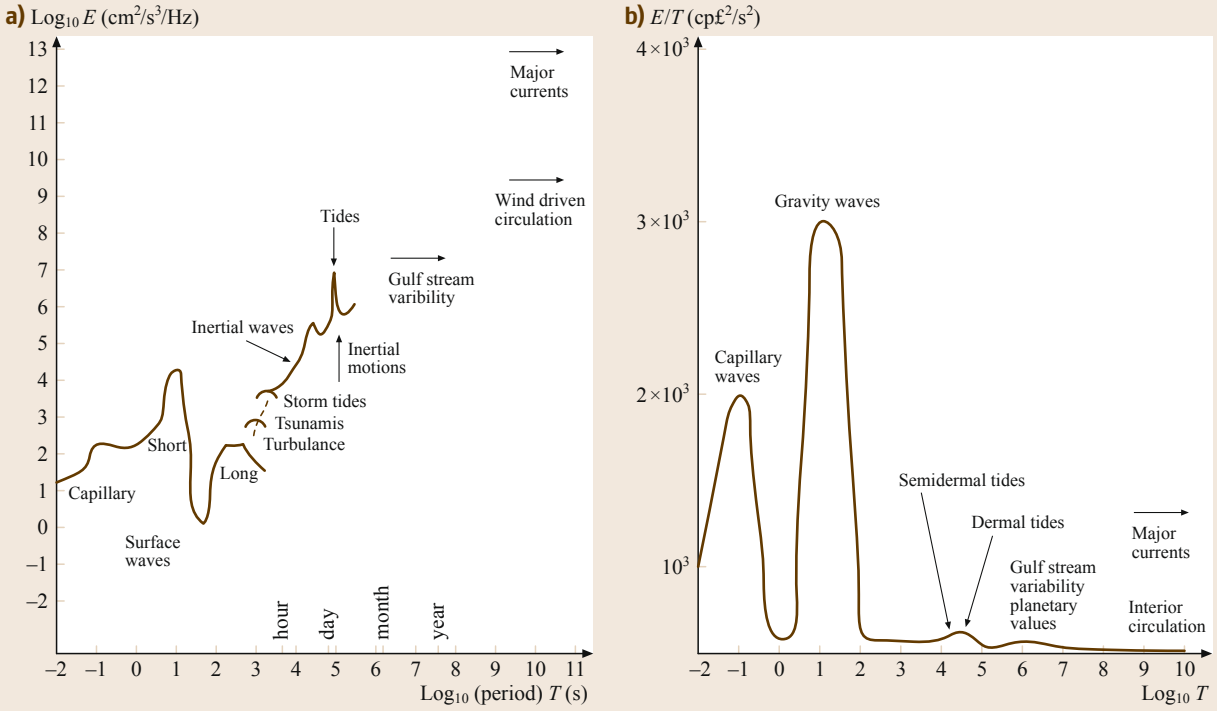

Fig. 2.6a,b **(a)** An *energy density spectrum* (EDS) of ocean current variability highlights the distinctive periodicities associated with many important oceanic processes. **(b)** The variance-preserving form of the corresponding EDS displays the period distribution of kinetic energy per unit ocean volume of these oceanic processes

frequency bandwidth) spectrum highlighting a range of principal ocean processes is presented in Fig. 2.6a. However, the corresponding *variance-preserving form* of the energy spectrum (Fig. 2.6b) is more useful for comparing the kinetic energy per unit volume of these different processes. Clearly energy concentration in physical space is greatest for surface gravity waves with capillary waves a close second. The next section treats the important class of surface gravity waves in more depth.

2.4 Surface Gravity Waves

Very often winds disturb the sea surface; leading to the generation a surface gravity waves with a broad range of wave periods. The gravitational interactions of the moon (and sun) with the Earth also disturb the sea surface in generating surface tidal waves. Tidal current interactions with bathymetry generate internal tides, which, if very nonlinear may spawn packets of internal solitons.

In all of these cases, as gravity acts to restore the sea surface distortion toward its equilibrium state, the potential energy of the original distortion is converted to kinetic energy in the form of a velocity field. The lowering sea surface then overshoots the equilibrium state as the gravity-related buoyancy forces reverse the process. As these surface gravity waves are generated, they with their energy propagate away from their generation site.

The wave periodogram in Fig. 2.7 shows how surface wave energy is distributed among many wave frequencies in the ocean. Wind-driven surface gravity waves of wind periods in the 1−30 s range are the most energetic, followed by tides. Note that short period (or high frequency) capillary wave motion is controlled by surface tension, while longer period (or low frequency) gravity waves, like storm surges and tides, are also influenced by earth rotation.

2.4.1 Surface Gravity Waves

The currents and pressures associated with surface gravity waves are attenuated with depth in accordance with their wavelength. The current and pressure amplitudes of surface waves become negligible (less than 5% of their surface values) at a depth of $L/2$, where L is the

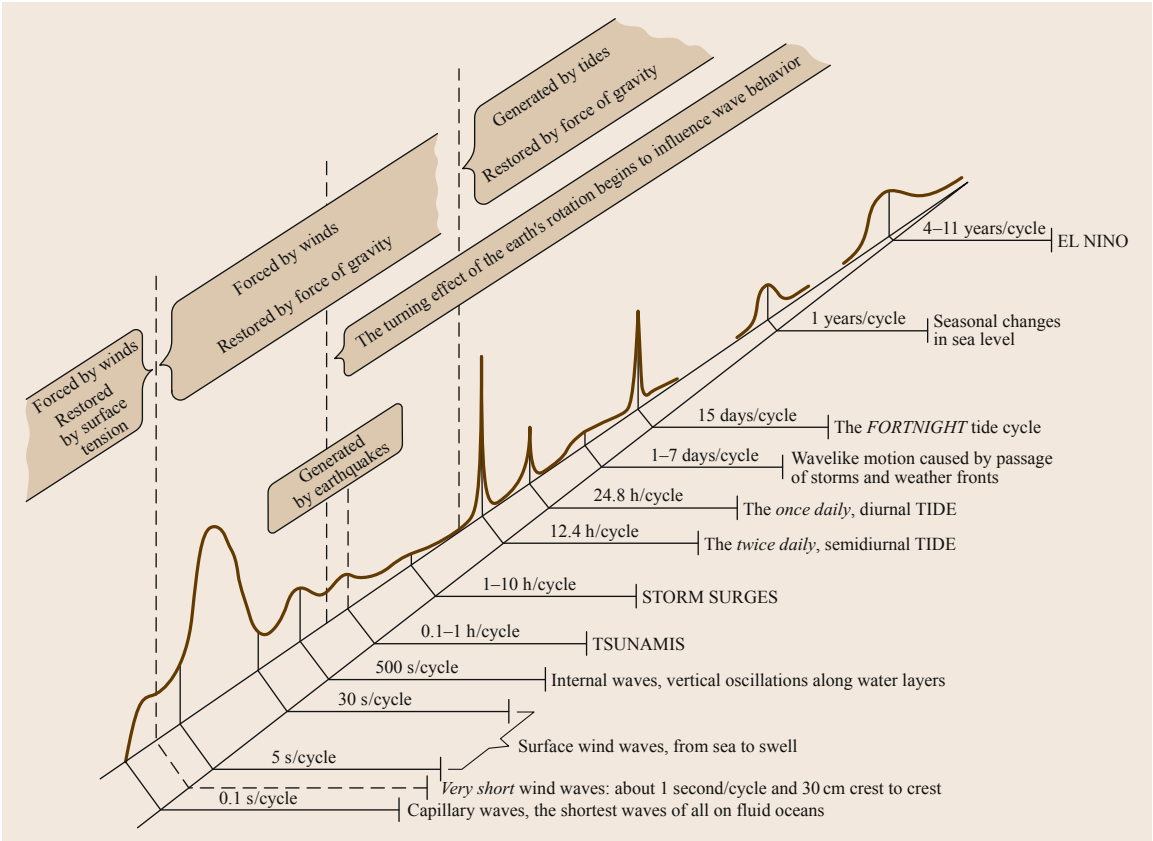

Fig. 2.7 This periodogram of sea level variability diagrams how energy of many different types of ocean gravity waves is distributed according to frequency. Waves are identified according to wave period and to the disturbing and restoring forces which act at different time scales (after [2.4])

wavelength. The currents associated with typical deep water wind waves (period of 20 s) are effectively attenuated at depths of about 300 m (984 ft) and are almost never felt at depths of 1000 m (3284 ft).

However, the longer period tides and tsunamis have such large wavelengths that their effects are virtually unattenuated throughout most of the world's oceans. However, because their periods are so much longer (minutes to a day) than typical wind waves, the water velocities associated with them are generally small. Tidal currents in coastal oceans settings are an important exception.

2.4.2 Definitions

Here we consider a simplified model for surface gravity waves. As we all have observed the sea surface at a particular location is a complicated superposition of waves with different characteristics propagating from different places where they were usually generated by the wind at different times. However, first we want to focus on the basic principles of wave motion, so we will explore a simple monochromatic (i. e., single frequency) wave model. Later, we will apply this understanding of the *essential physics* of wave motion to more realistic observed wave fields.

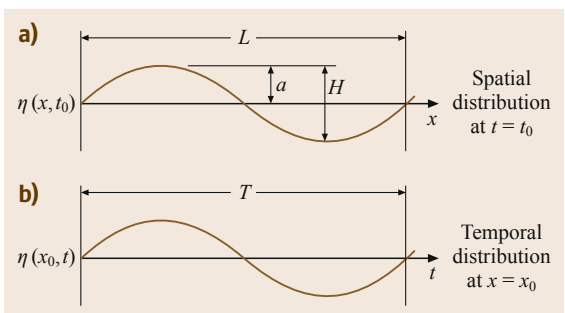

Fig. 2.8a,b The characteristics of a monochromatic sine wave $\eta(x, t)$ whose form is propagating with phase speed c in the x-direction is **(a)** *frozen* in space at time $t = t_0$; and **(b)** measured at a fixed station $x = x_0$

To start, we define the characteristics (with units indicated in [. . .]) of the monochromatic sine wave shown in Fig. 2.8:

- Elevation: $\eta(x, t)$ is the instantaneous vertical departure of the sea level from the undisturbed sea level.
- Wave height: H is the distance between the wave crest and trough. $[H] = (\text{unit length})^{-1}$
- Wave amplitude: $a = 1/2H$
- Wavelength: L is the distance between points of equal phase. $[L] = \text{length}$
- Wave number: $k = 2\pi/L$ is the number of times a wave can fit on the circumference of circle with a dimensionless radius = 1. $[k] = (\text{length})^{-1}$
- Wave period: T is the time between points of equal phase. $[T] = \text{unit time}$.
- Wave frequency: $f = 1/T$ is the number of complete cycles per unit time. $[f] = \text{cycles/time}$
- Angular frequency: $\omega = 2\pi/T = 2\pi f$ is the number of times a wave of period T can fit on the circumference of a circle with a dimensionless radius = 1. $[\omega] = (\text{time})^{-1}$
- Wave phase speed: $c \equiv L/T$ or $c \equiv \omega/k$ is the speed of a particular point on the waveform (or phase). $[c] = \text{length/time}$

The mathematical description of our monochromatic *right-traveling* waveform is

$$\eta(x,t) = a\cos\left(\frac{2\pi x}{L} - \frac{2\pi t}{T}\right)$$

or

$$= a\cos(kx - \omega t)\,. \tag{2.1}$$

Equation (2.1) can also be written in terms of phase speed as $\eta(x,t) = a\cos[k(x - ct)]$. The dynamical relation between wave period T and wavelength L can be defined by the solution to the two-dimensional (2-D) *Airy wave model* of a right-traveling wave at the surface of an ocean (mean depth $z = 0$) with a flat bottom at a depth of $-z = h$.

The solution to the approximate linearized Airy wave equations of motion and boundary conditions for small amplitude ($a/L \ll 1$) waves [2.5] yields the *dispersion relation*

$$\omega^2 = gk\tanh(kh)\,, \tag{2.2}$$

which describes the relation between wave frequency and wave number, and the dynamical variables of pressure p, and the x- and upward ($+z$)-directed velocity components u and w, respectively:

$$u = a\omega\frac{\cosh k(z+h)}{\sinh(kh)}\cos(kx - \omega t)\,, \tag{2.3a}$$

$$w = a\omega\frac{\sinh k(z+h)}{\sinh(kh)}\sin(kx - \omega t)\,, \tag{2.3b}$$

$$p = -\rho gz + \rho ga\frac{\cosh k(z+h)}{\cosh kh}\cos(kw - \omega t)\,. \tag{2.3c}$$

The dispersion relation given above can be rewritten as

$$c^2 = \frac{L^2}{T^2} = \frac{\omega^2}{k^2} = \frac{g}{k}\tanh(kh)\,,$$

which shows that, in general, Airy waves have phase speeds which depend upon wave number k (or wavelength L) (Fig. 2.9).

Two important approximations to the (2.2) and (2.3) wave solutions yield the classical *short* and *long* waves which are defined in terms of the wavelength to water depth ratio L/h.

For *short waves*, the water depth is greater than a half wavelength $h > L/2$ so that they are referred to as *deep water waves*. Mathematically, this means that kh is large (or $kh > \pi$) so that the *short wave* (deep water wave) dispersion relation (2.2) becomes

$$c^2 = \frac{\omega^2}{k^2} = \frac{g}{k} = g\frac{L}{2\pi}\,,$$

which reduces to

$$c = \sqrt{\frac{1}{2\pi}(gL)}\,,$$

so that short waves are dispersive, that is, the wave speed depends on wavelength. Since $L = cT$, the above

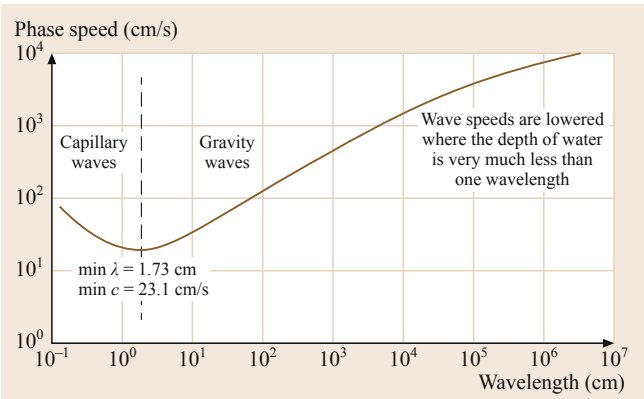

Fig. 2.9 The phase speed of gravity waves and capillary waves as a function of their wavelength (after [2.6])

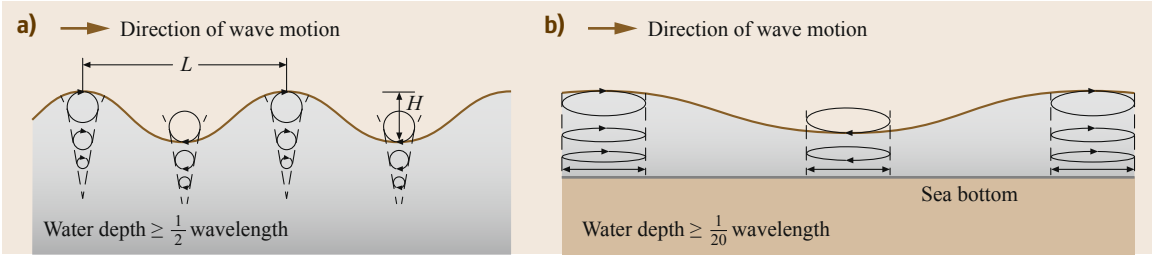

Fig. 2.10a,b **(a)** Progressive deep-water wave motion consists of near-circular water parcel orbits that become very small at water depths of $1/2$ wavelength. **(b)** Progressive shallow water wave motion ($h/L > 0.05$) is distinguished by water parcels that move in highly elliptical orbits, with widths that are constant with depth (after [2.7])

can also be written as

$$c = \frac{1}{2\pi}(\mathrm{g}T) \, .$$

For large kh, the *short wave solutions* to (2.3) for $\eta = a\cos(kx - \omega t)$ become

$$u = a\omega \mathrm{e}^{kz}\cos(kx - \omega t) \, ,$$

$$w = a\omega \mathrm{e}^{kz}\sin(kx - \omega t) \, ,$$

$$p = \rho g a \mathrm{e}^{kz}\cos(kx - \omega t) - \rho \mathrm{g} z \, .$$

The motions associated with short or deep water waves decreases with depth, such that amplitudes at a depth of $z = -L/2$ are $\mathrm{e}^{-\pi}$, or 4% of surface values. This is shown in the schematic of the water parcel trajectories as the wave passes (to the right in this case, Fig. 2.10a).

For *long waves*, the water depth is less than the wavelength or $h < L/20$ so that long waves *feel the bottom* and are called *shallow water waves* (Fig. 2.10b). Mathematically, this means that kh is small (or $kh > \pi/10$) so that the *long* (shallow water) *wave* dispersion relation (2.2) becomes

$$\tanh(kh) \approx kh \, ,$$

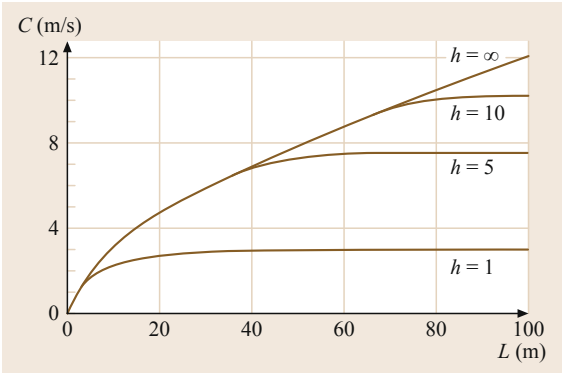

Fig. 2.11 Wave phase speed c versus wavelength L (m) – a dispersion diagram for Airy waves in different water depths h (m)

and the *long wave* (shallow water) dispersion relation becomes

$$c^2 = \frac{\omega^2}{k^2} = \frac{\mathrm{g}}{k}kh$$

or

$$c = \sqrt{\mathrm{g}h} \, .$$

Thus, long (or shallow water) waves are *nondispersive*, that is that their speed is independent of wavelength. This is demonstrated in Fig. 2.11 which depicts the relation of wave phase speed and wavelength for different water depths.

For small kh, the *long wave* (shallow water) pressure and horizontal velocity *solutions* to (2.3) for $\eta = a\cos(kx - \omega t)$ are undiminished with depth. The water parcel orbits during the passage of a *long water wave* in very shallow water are very elliptical as shown in Fig. 2.10b. Notice that most of the motion is horizontal, much like what scuba divers feel in shallow water with a long swell. Airy wave kinematics are shown schematically in Fig. 2.12 for different water depths. Note the relative phases of η, u, and w fields.

As Airy waves propagate from deep water through intermediate depth water into shallow water (Fig. 2.13), (2.2) and (2.3) describe their dynamics. As deep water waves propagate into shallow water, their orbital motions and pressure fields begin to interact with the bottom – they *feel the bottom*. Nearly circular water parcel orbits become more elliptical and wave velocities induce bottom stresses; which can have an effect on movable sediments.

However, while monochromatic Airy wave theory is very helpful in describing the basic dynamic characteristics of waves, the real ocean wave field is composed of contributions from waves with many wavelengths, wave periods and amplitudes. What are the consequences of the superposition of more than one Airy wave?

To answer the question, we increase the complexity of our model slightly by superposing two Airy waves η_1 and η_2 with the same amplitude but slightly different

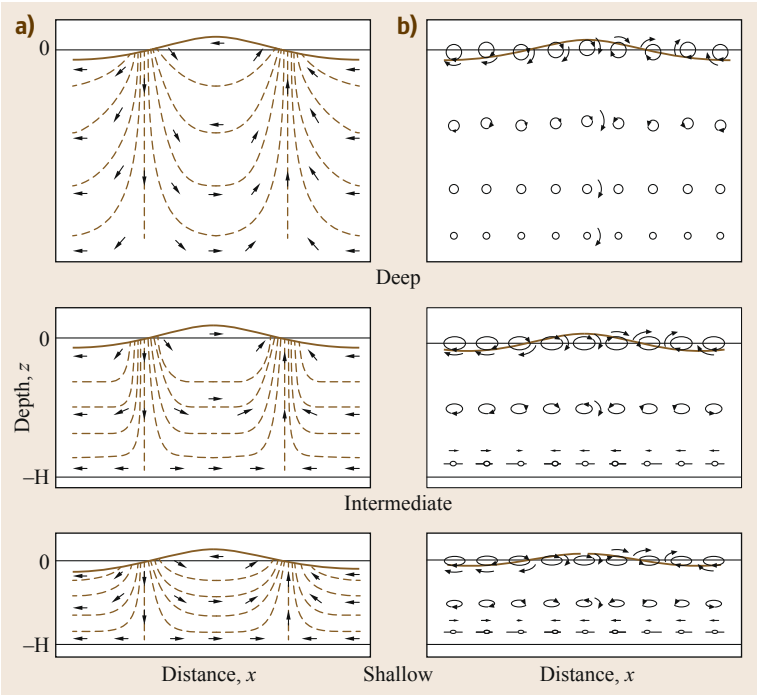

Fig. 2.12a,b Kinematics of waves propagating left to right in (top) deep; (middle) intermediate depth; and (bottom) shallow water – **(a)** instantaneous snapshots of the water parcel streamlines and **(b)** trajectories of selected water parcels over a full wave cycle (after [2.8])

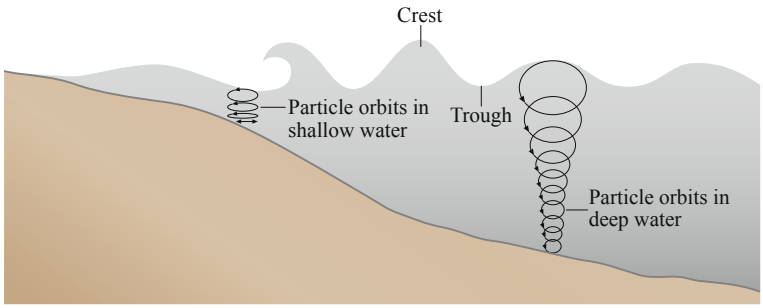

Fig. 2.13 Deep water waves propagating toward the left into *shallow water*. Note how the waves *feel the bottom* and water parcel orbits are squashed as the wave propagates into even shallower water

frequencies and wave numbers such that $\omega_2 > \omega_1$ and $k_2 > k_1$.

The amplitude of the resultant wave (shown in Fig. 2.14) is modulated according to

$$\eta = a\cos\left[\frac{\Delta k}{2}(x - c_g t)\right]\cos\left[\overline{k}(x - \overline{c}t)\right] , \qquad (2.4a)$$

where

$$\overline{k} = \frac{k_1 + k_2}{2}, \quad \overline{c} = \frac{\overline{w}}{\overline{k}} \quad \text{and} \quad \overline{\omega} = \frac{\omega_1 + \omega_2}{2} . \qquad (2.4b)$$

Note that on one hand, the cos[ ] term on the right in (2.4) represents a wave with intermediate frequency and wavelength and therefore is nearly indistinguishable from the parent waves. On the other hand, the cos[ ]

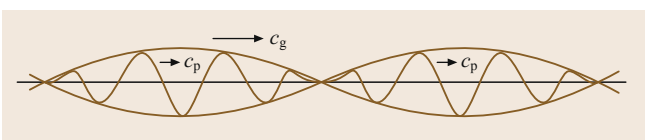

Fig. 2.14 The wave envelope – resulting from the superposition of a pair of surface gravity waves (with nearly identical phase speeds c_p) – travels at the wave group velocity c_g

term on the left represents a wave with much greater L (smaller k) that is traveling at the speed c_g given by

$$\frac{\Delta\omega}{\Delta k} = \frac{\omega_2 - \omega_1}{k_2 - k_1} = c_g .$$

In general, the superposition of multiple surface gravity waves form packets called *wave groups* whose energy travels at the *group speed* given by $c_g = \mathrm{d}\omega/\mathrm{d}k$. Thus the group velocity for general Airy waves is

$$c_g = \frac{1}{2}c\left(1 + \frac{2kh}{\sin h2kh}\right) ,$$

which for short waves (large kh) becomes

$$c_g = \frac{1}{2}c\,; \quad \text{deep water waves}$$

and for long waves (small kh) becomes

$$c_g = c; \quad \text{shallow water waves.}$$

Wave energy is composed of both the kinetic and potential energy components which can be computed explicitly for Airy waves [2.5]. In particular for shallow water waves, which are nondispersive, the wave energy travels at the same speed for all waves at $c = \sqrt{gh}$. The topic of wave generation and wave energy propagation is considered next.

2.4.3 Wave Generation and Evolution

Most ocean surface waves are produced by the wind. As the wind increases from near zero, it generates capillary waves, with short wavelengths (< 1.7 cm) and short periods (< 0.1 s). As the wind continues to blow, the

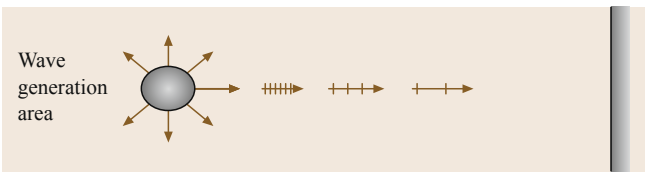

Fig. 2.18 Wave dispersion separates waves generated in the wave generation region

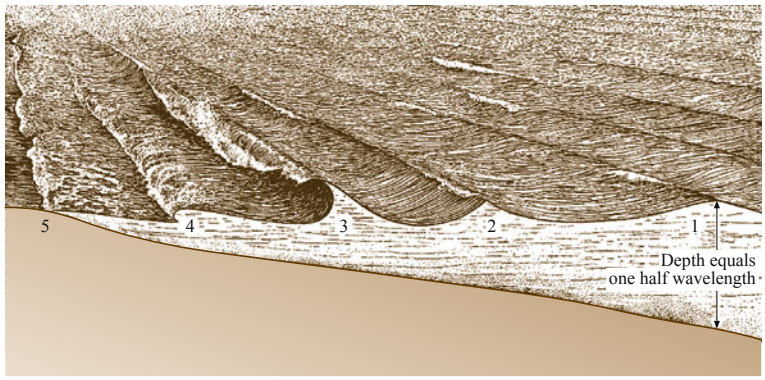

Fig. 2.19 (1) Deep water waves beginning to *feel the bottom*; (2) intermediate to shallow water wave transition; (3) shallow water waves begins to break; (4) fuel wave breaking; and (5) runup (after [2.10])

capillary waves can grow to become ripples and short choppy waves (Fig. 2.15). With increased wind velocity, duration, and fetch (length of the area over which the wind blows), more energetic (higher), longer waves are generated. The superposition of all of these waves in the wave generation region creates a fully developed sea with white capping. A fully developed sea appears chaotic because it is a superposition of waves with different wavelengths and corresponding wave periods (Fig. 2.16).

The spectral energy content of sea surface variability at the site can be analyzed in terms of their frequency content and displayed as energy density spectra (Fig. 2.17a) or a wave energy periodogram (Fig. 2.17b). These examples illustrate typical energy distribution as a function of wave frequency (or wave period) for a *fully developed sea* under different wind speeds. Both examples show generally that higher winds generate more energetic lower frequency waves. The wind strength, duration, and fetch determine the resulting range of wavelengths and wave amplitudes in the waves constituting the corresponding *fully developed* sea (Table 2.3).

Since weather systems move much faster than ocean wind waves, the storm winds will diminish over the immediate area of wave generation. Then this chaotic superposition of waves of different wave periods and wavelengths will propagate from the region in all directions at different speeds. Along a particular propagation trajectory, like that depicted in Fig. 2.18, groups of these deep ocean waves with the longer wavelengths (and thus the larger group velocities) will outrun the shorter wave groups. Because of deep water wave dispersion, wave energy spectra measured some distance from their generation site (e.g., a distant shore) will differ from those that are measured at a later time; as the slower, shorter wave groups arrive.

Eventually all of the deep water waves will propagate into water depths where they begin to *feel the bottom* (Fig. 2.19) and undergo significant changes. Once frictional contact begins, the wave changes in several ways simultaneously, namely the wave speed drops, its height increases, and its direction shoreward becomes more and more perpendicular to the beach line [2.4].

As these shallow water waves propagate shoreward both their phase and group speeds

$$c = c_g = \frac{L}{T} = \sqrt{gh}\,, \tag{2.5}$$

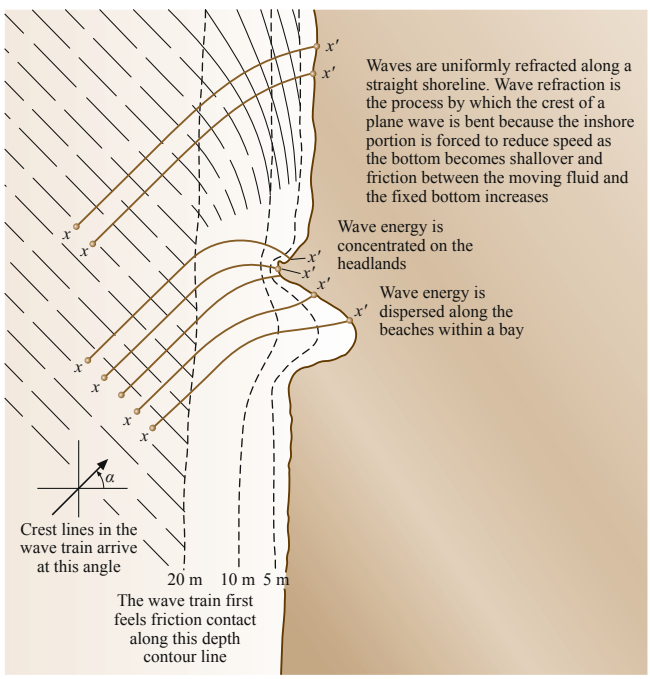

Fig. 2.20 Wave refraction or wavefront bending is due to the slowing of the part of the wavefront that shoals earliest. The pair of rays (or orthogonals that are perpendicular to the wavefront locally) mark the trajectory of equal amounts of wave energy (after [2.4]) ◄

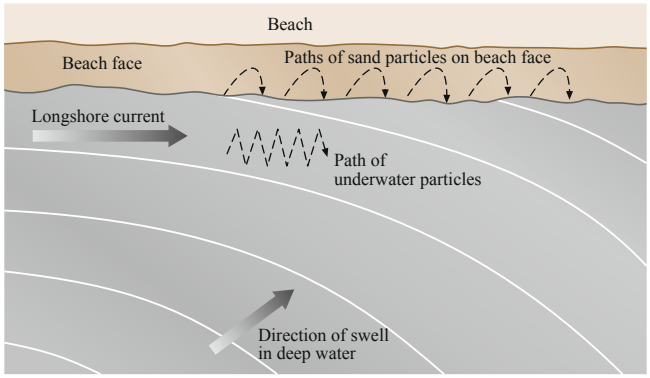

Fig. 2.21 Waves that approach the beach obliquely approach generates a longshore current in the surf zone. The wave-breaking suspends beach material (usually sand) that is transported in the surf zone by the longshore current; while the repeated wave run-up cycles also transport sand in the same longshore direction (after [2.10]) ►

decrease. Since the number of waves in the shoreward propagating wave train are conserved, the wave period T *remains constant*. Thus from a rearranged (2.5)

$$T = \frac{L}{\sqrt{gh}}\,, \tag{2.6}$$

the wavelength L must also decrease. For an idealized beach with straight coastline and parallel isobaths, the *wave power* per unit length of the shoreward propagating wavefront – given by

$$\overline{P} = \frac{1}{8}\rho g H^2 c_g = \frac{1}{8}\rho g H^2 \sqrt{gh} \tag{2.7}$$

is constant. Thus from a rearranged (2.7)

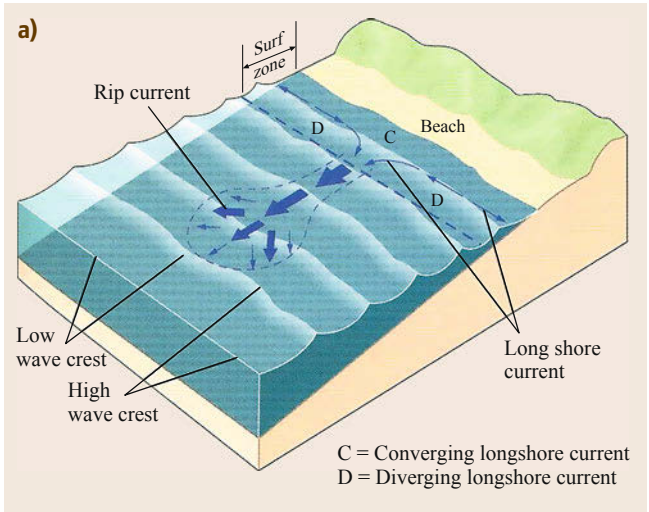
$$H^2 = \left(\frac{8\overline{P}}{\rho g^{3/2}}\right) h^{-1/2}\,, \tag{2.8}$$

we conclude that for shoreward propagating waves H must also increase! As a result, the wave slope which is proportional to H/L will increase to the point where Airy wave theory no longer applies.

At this stage, wave crests or fronts are generally propagating obliquely to the orientation of the beach (Fig. 2.20). The wavefronts are bent or refracted as the inshore end of the wavefront encounters even shallower water first and slows relative to the rest of the wave – bringing the wavefront into better alignment with the beach.

In the example of waves impinging on a straight beach (Fig. 2.20 – upper), by the refraction distorts the waves (and corresponding wave rays or orthogonals) so that the wave energy flux (energy/length/unit time) is reduced from its deep water value. Wave refraction near irregular coastlines (Fig. 2.20 – center) leads to distortion of the wavefronts. Thus the ray paths, or orthogonals indicating the direction of wave energy propagation, are also distorted. In the case of a *point of land* the equidistant rays in deep water are seen to converge on the point thereby concentrating wave energy there relative to other parts of the coastline. The opposite is true for a bay.

As the wave propagates shoreward, wave slopes generally increase and eventually lead to significant



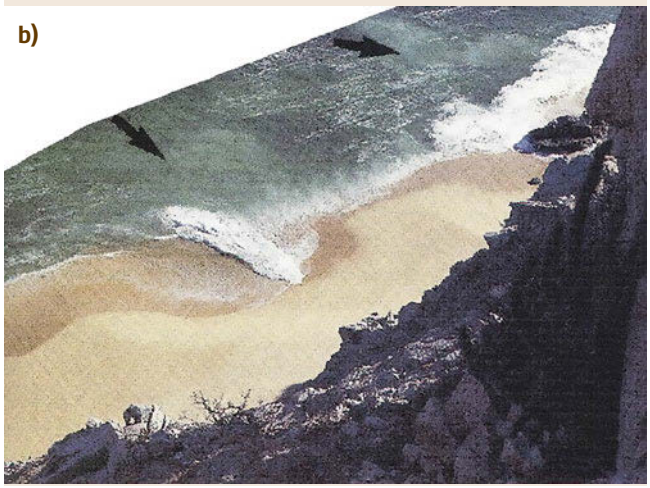


Fig. 2.22 **(a)** In this illustration, waves with crests parallel to the coast break and produce run-up that returns to the ocean via a system of longshore currents that feed narrow offshore rip currents. **(b)** narrow rapid rip current systems are observed frequently especially with large amplitude waves (after [2.7])

nonlinearities and subsequent *wave-breaking* as indicated at position 4 and *wave run-up* onto the beach front in position 5 in Fig. 2.19. It is noted that wave trains that approach the beach obliquely never fully align with the beach front. This asymmetry leads to the generation of an alongshore current in the direction indicated in Fig. 2.21. This alongshore current plus the zig–zag motion of the wave run-up transport beach material (sand in many situations) along shore as indicated. This is a dynamic longshore sand transport process under which a steady-state beach persists as long as the up-coast sand supply exists.

Of course, the wave run-up must return to the ocean. This return flow is concentrated in narrow rapidly moving offshore moving currents called rip currents (Fig. 2.22).

2.5 Wind-Forced Ocean Processes

2.5.1 Frictional Effects

Surface winds apply stress to the ocean surface to generate upper ocean currents and produce turbulent mixing. This process of transferring momentum to the ocean currents occurs through a complex process involving the generation of surface waves. In contrast, less complex stress-related processes remove momentum from near-bottom ocean flows and dissipate it as heat. Thus, ocean stress in the ocean mediates the vertical transport of horizontal momentum in the ocean.

The normal expression for fluid stress, in which horizontal stress τ is proportional to the local vertical gradient of horizontal velocity, is given by

$$\tau = \mu \frac{\partial u}{\partial z} , \tag{2.9}$$

in which μ is the coefficient of molecular viscosity. However, μ is too small for this relation to accurately define momentum transport (and thus stress and dissipation) in a turbulent ocean. Thus, we must incorporate turbulent eddy viscous effects into our consideration of momentum transfer in the ocean.

The nature of eddy viscous effects can be defined quantitatively by partitioning a variable eastward ocean flow into its temporal mean value $\overline{u}$ and eddy-induced fluctuating part u' (Fig. 2.23). A similar treatment defines the fluctuating *northward* and *upward* velocity components v' and w', respectively.

The time-average of the many random turbulent eddy events involving correlated fluctuations $\overline{u'w'}$ leads to an effective eastward stress S_x on a horizontal face of the fluid. The result is a turbulence-induced stress – called a Reynolds stress – that can be related to the shear of the mean flow via a coefficient of *eddy dynamic viscosity* A^e according to

$$S_x = A_z^e \frac{\partial \overline{u}}{\partial z} = -\rho \overline{u'w'} , \tag{2.10}$$

where $\nu_z^e = A_z^e/\rho$ is the *eddy kinematic viscosity*.

Similar relationships can be derived for stresses on other *faces* of a water parcel. Typical vertical eddy kinematic viscosities in the ocean range from 2 to $10^4\,\mathrm{cm^2\,s^{-1}}$. Lateral kinematic eddy viscosities are generally larger ranging from 10 to $10^8\,\mathrm{cm^2\,s^{-1}}$. The large difference between the vertical and lateral eddy coefficients relates to the fact that vertical turbulent momentum transport is considerably reduced relative to lateral momentum transport. This asymmetry is due to both the large geometrical aspect ratio or *thinness* of oceans; as well as the stabilizing effects of vertical stratification of the ocean.

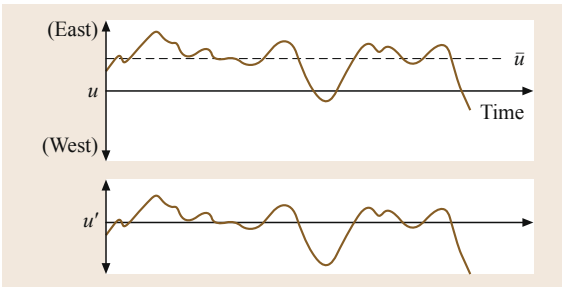

Fig. 2.23 The total time-varying of say an eastward flow is $u(t)$, which can be partitioned into its time-averaged component $\overline{u}$ and fluctuating component u'

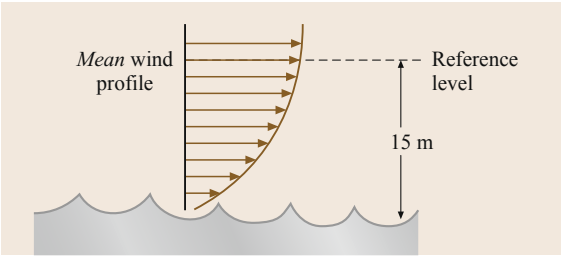

Fig. 2.24 Typical boundary layer air flow near a solid (or watery) horizontal boundary shows the effects of momentum extraction from the flow. The reference level of the wind at 15 m above the sea surface is used for estimating horizontal wind stress at the air-ocean interface

These considerations apply directly to oceanic stresses at the air–ocean and ocean–sediment interfaces. For example, dimensional considerations allows us to estimate sea surface stress according to is estimated as a function of the

$$\tau_w = \text{constant} \cdot \rho_a W_{15}^2 \,, \tag{2.11}$$

where W_{15} is the wind velocity at 15 m above the sea surface – the elevation of many ship and buoy anemometers.

To determine the constant in (2.11) we first define a friction velocity u^* such that $\tau = \rho_a u^{*2}$. Then consider the surface layer of turbulent winds near the sea surface – or *boundary layer* – with a time average wind profile that decreases from a maximum at the top of the boundary layer to near zero at the sea surface (Fig. 2.24).

It can be shown that the mean velocity profile $\overline{u(z)}$ in a constant stress turbulent boundary layer can be described in terms of a friction velocity u^* and Von Karman's constant $k_o = 0.4$ according to

$$\overline{u}(z) = \frac{u^*}{k_o} \ln \frac{z + z_o}{z_o} \,, \tag{2.12}$$

where z_o is a parameter related to ocean surface roughness. This form of the boundary layer mean velocity is the so-called Log Profile. This formulation permits us to compute u^* and z_o from the observations of $\overline{u}(z)$ so that the unknown constant in an expression for wind stress can be determined. Typically

$$\tau_w = 2.6 \times 10^{-3} \cdot \rho_a W_{15}^2 \tag{2.13}$$

for density units g cm^{-3} and wind units m s^{-1}.

The wind stress exerted on the sea surface can be expressed in terms of the direction of the wind vector $\boldsymbol{W}$ and is proportional to the square of the wind speed according to the relation

$$\boldsymbol{\tau}_w = \rho_a C_D |\boldsymbol{W}| \boldsymbol{W} \,, \tag{2.14}$$

where ρ_a is the air density and C_D is a drag coefficient.

2.5.2 Earth Rotation Effects

Earth rotation plays a central role in the physics (as viewed in our earthly rotating – hence accelerating frame of reference) of many of the most important atmospheric and ocean flows, (which have variability time scales exceeding 1/2 day). Earth rotation (rate $= \boldsymbol{\Omega}$) influences ocean flow through the effects of the Coriolis force which always acts to the right of the direction moving water (Fig. 2.25) according to

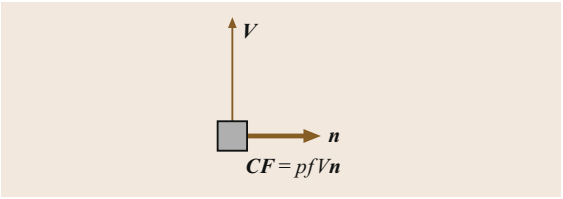

Fig. 2.25 An ocean water parcel is moving in an arbitrary direction with steady velocity $\boldsymbol{V}$ in the Northern Hemisphere. The Coriolis force $\boldsymbol{CF}$ acts on a moving water parcel to the right of the direction of $\boldsymbol{V}$ – or in the $\boldsymbol{n}$ direction

$$\boldsymbol{CF} = \rho f \boldsymbol{V} \boldsymbol{n} \,,$$

where ρ is the water density, $f = 2\Omega \sin(\text{latitude})$ is the Coriolis parameter, $\boldsymbol{n}$ is the unit vector in the direction perpendicular and to the right of the water parcel velocity $\boldsymbol{V}$ composed of an eastward u and northward v components.

In the Northern Hemisphere Cartesian coordinate system, the Coriolis force $\boldsymbol{CF}$ is given by $\boldsymbol{CF} = \rho f v \boldsymbol{i} - \rho f u \boldsymbol{j}$; where $i \neq j$ are the unit vectors in the eastward and northward directions, respectively.

2.5.3 Hurricane Wind-Forced Ocean Response

Tropical cyclones have a significant impact on coastal areas of the world. In the Atlantic Ocean they are called hurricanes, whereas similar storms in the Pacific Ocean are called typhoons. They are a significant part of global weather systems because they transfer large quantities of water and warm, moist air from equatorial regions to higher latitudes. In the Caribbean Sea, the Gulf of Mexico, and the southeastern United States, hurricanes have shaped low-lying coastal areas and, at times, have caused dramatic losses of life and property.

Historically, the hurricane season in the North Atlantic Ocean has extended from June 1 to November 30; when seawater temperatures in the equatorial oceans are warmest, usually above 25 °C (about 80 °F). Hurricanes begin as tropical waves, areas of organized clouds 200–500 km in diameter in the eastern equatorial Atlantic. Occasionally, the wave becomes a tropical depression, which when winds become 65–118 km/h (39–74 mph) becomes a tropical storm, which propagates generally westward. If winds exceed 118 km/h, the storm is called a hurricane (in the Atlantic and eastern Pacific oceans) or a typhoon (in the western Pacific Ocean) – powerful, self-sustaining atmospheric/oceanic heat engines.

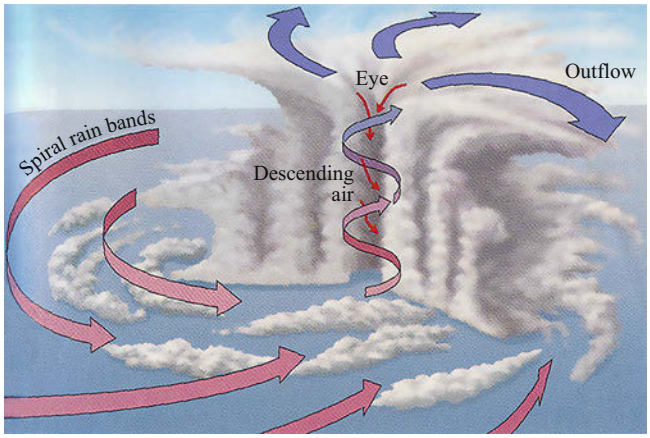

Fig. 2.26 Typical hurricane wind/cloud structure (after [2.11])

Tropical storms and hurricanes have cyclonic or counterclockwise circulation in the Northern Hemisphere because the Coriolis effect deflects the inward air flow toward to the right (Fig. 2.26). (In the Southern Hemisphere, the Coriolis deflection is to the left so that cyclones in the southern tropics have clockwise rotation). In a hurricane, inward flowing air spirals in an anticlockwise sense over the warm, wet ocean toward the eye, where it begins to spiral upward around the *eyewall* that surrounds the eye of the hurricane. As the air rises it cools and its water vapor condenses forming clouds and rain and releasing heat that propels the air even higher. At the top of the eyewall, most of this very cool, dry air begins to descend into the eye and the various spiral bands, warming and becoming even less humid (i. e., dryer) as it encounters the higher pressures at lower levels.Upon reaching the sea surface this very warm, dry air is able to absorb both heat and moisture from the ocean enabling it to rise again, thus re-energizing the hurricane which continues to propagate under its own power.

Table 2.4 The Saffir–Simpson hurricane scale is based on the minimum sustained wind speed criteria for each of the official categories. Typical minimum surface atmospheric pressures and storm surges are given along with more subjective damage descriptions (after [2.10])

Hurricane category	Maximum sustained wind speed		Storm surge [ft]	Minimum Surface pressure [mbar]	Damage
	kilometers/hour	miles/hour			
1	119–153	74–96	4–5	> 980	Minimal
2	154–178	97–111	6–8	979–965	Moderate
3	179–210	112–131	9–12	964–945	Extensive
4	211–250	132–155	13–18	944–920	Extreme
5	> 250	156+	18+	< 920	Catastrophic

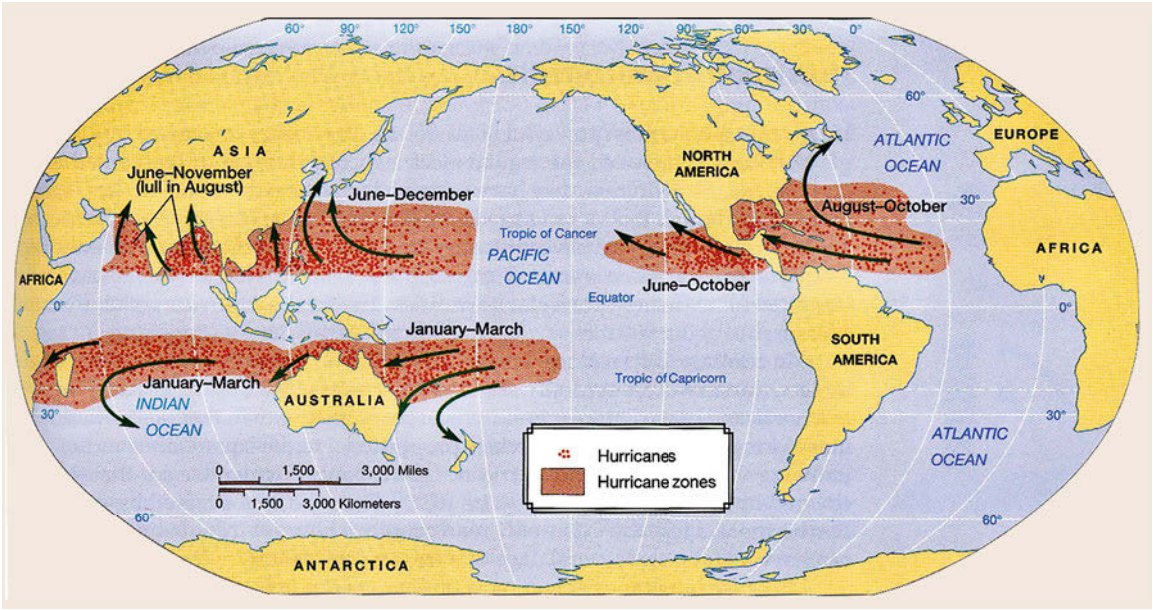

Fig. 2.27 Hurricane and typhoon locations around the globe (after [2.11])

The strength of hurricanes is measured by the Saffir–Simpson scale (Table 2.4), which uses minimum sustained wind speeds to categorize storms from Category 1, a minimal hurricane, to Category 5, the most intense hurricane. A list of the most intense US hurricanes appears in Table 2.5.

Hurricane trajectories are also influenced by larger scale meteorological forces – hence the uncertainty. Under certain conditions, the Atlantic hurricane trajectories tend toward the Caribbean, Florida and Gulf of Mexico; like hurricane Katrina in 2005 (Figs. 2.27 and 2.28). Under some conditions, the trajectories can take more northward paths along the eastern US seaboard; like hurricane Carol of 1954.

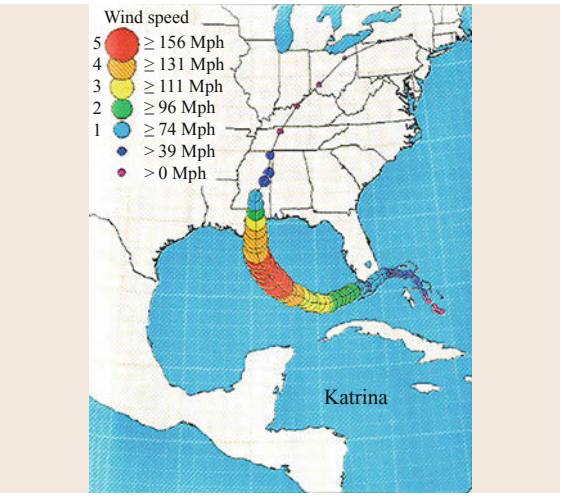

Fig. 2.28 The trajectory of hurricane Katrina showing the evolution in minimum sustained wind intensity and category (after [2.12])

The hurricane–ocean interaction also produces ocean surface waves, currents, and sea level changes or so-called storm surge. The group speeds of the most energetic (i. e., long) hurricane-generated surface waves are faster than typical hurricane propagation speeds and thus they speed out ahead of the hurricane. The local hurricane-generated ocean currents in the near-surface layer are intensified in the direction of the generating winds as the hurricane passes overhead. In the Northern Hemisphere, the highest hurricane winds are on the right hand side of the leading edge of the hurricane (the upper right quadrant in Fig. 2.29). This is because the forward speed of the hurricane itself adds to the speed of the wind around the storm on the right side of the storm.

As a hurricane approaches land, these ocean currents impinge on the land and thus can contribute to increased the sea level rise or storm surge. The storm surge is composed of contributions from the hurricane-generated current field and the elevated sea level that is induced by the very low sea level atmospheric pressure at the center of a hurricane. Thus the storm surge for a particular hurricane generally evolves in varying

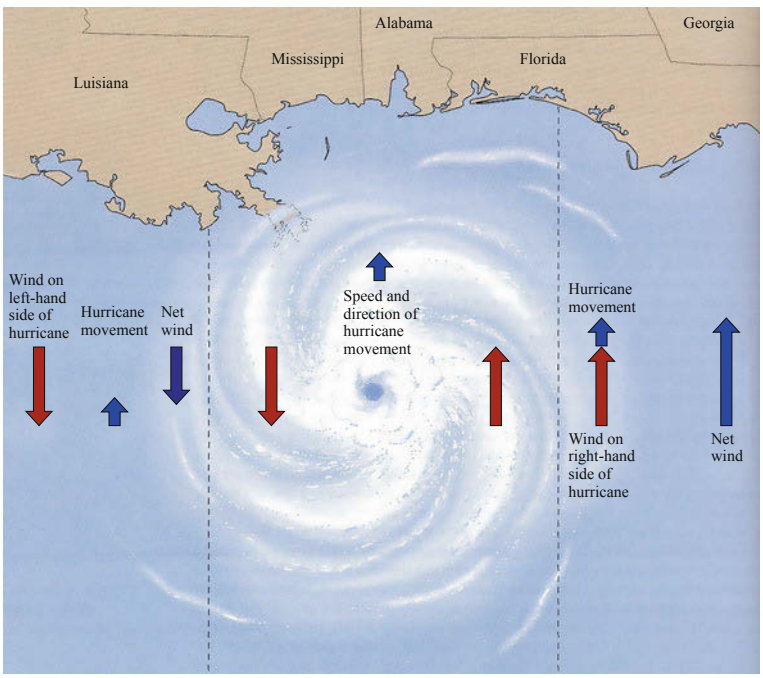

Fig. 2.29 Hurricane horizontal wind structure (after [2.7])

[a] Pressure exerted by the atmosphere at sea level is equal to 1 atmosphere, which is equal to 760 mm of mercury (760 mmHg), 1.01325 bar, 1013.25 mar, 29.92 inches of mercury (29.92 in Hg), and 14.7 pounds per square inch (14.7 psi)
[b] Hurricanses traveling more than 50 km/h.

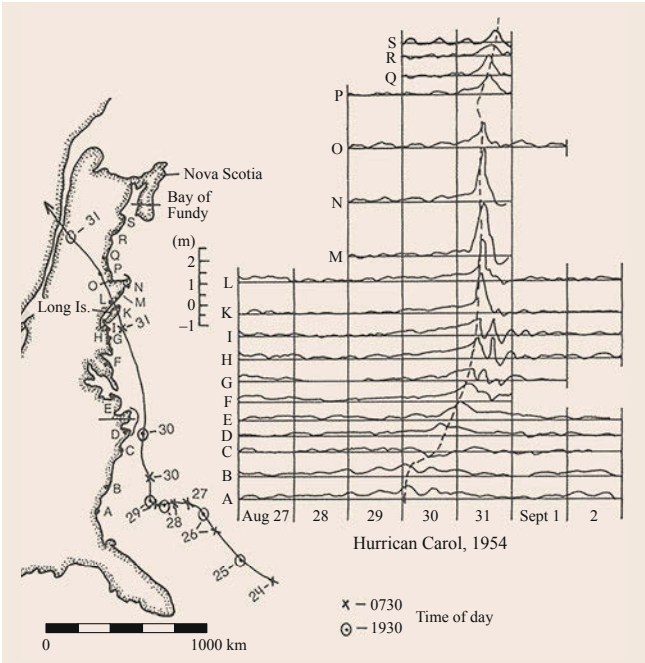

Fig. 2.30 The propagation of hurricane Carol along the US East Coast induced storm surge at coastal locations as hurricane Carol (after [2.13])

ways in tandem with the evolving hurricane (Hurricane Carol 1954, Fig. 2.30). Hurricane damage is caused by the combination of high winds, flooding, and storm surge. Surface winds can cause an abnormal (i. e., non-tidal) rise in sea level, reaching 1–6 m above normal sea level. Along the Gulf Coast, the estimated 330 km/h winds of Hurricane Camille in 1969 caused a maximum storm surge of 8 m, with 3-m-high wind-driven waves atop the surge. The end result was a l0-m-high wall of water approaching the Mississippi coastline. Failure to evacuate caused significant loss of life.

Hurricane-forced ocean currents are transient and intense in proportion to the wind intensity. The Integrated Ocean Observing System (IOOS) high frequency radar network along the US East Coast measured surface currents induced by 29 October 2012 *Superstorm* Sandy – the meteorological combination of a tropical hurricane and an extra-tropical storm that made landfall in New Jersey at about 2000 EDT 29 October 2012. The maps in Fig. 2.31 show that Sandy's winds overwhelmed the normal Mid-Atlantic 10–40 cm/s primarily wind-driven current patterns (e.g., 2000 EDT 27 October 2012) a full 24 h before landfall (2000 EDT 28 October 2012). The Sandy-induced intensifying southward currents that exceeded 1 kt (≈ 50 cm/s).

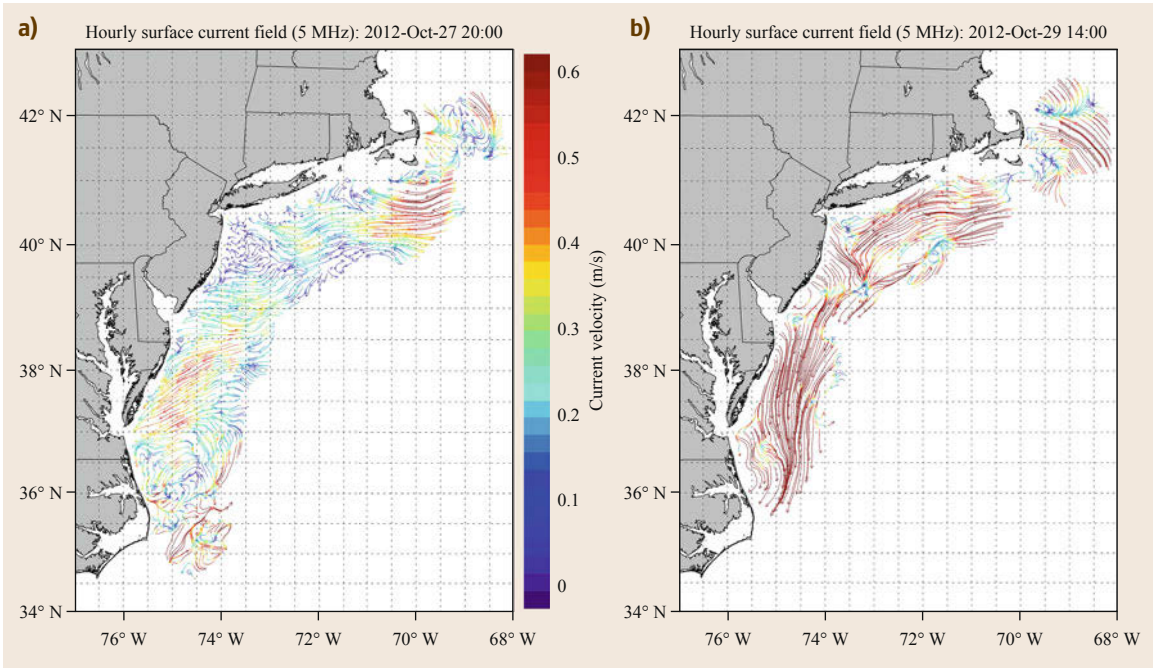

Fig. 2.31a,b Surface currents maps measured by a network of high frequency radar (HFR) sites in the coastal mid-Atlantic at: **(a)** 2000 EDT 27 October 2012 ... + 48 h before Superstorm Sandy landfall in New Jersey; and **(b)** 1400 EDT 29 October 2012 ... + 4 h – the last complete map before physical damage and power failures shut down the HFR network (after [2.14])

2.5.4 Wind-Forced Upper Ocean Response with Earth Rotation Effects

At time scale exceeding about one-half day, Earth rotation effects can become important. For example, in the aftermath of impulsive wind forcing, such as that associated with a weather front, the ocean often exhibits circular motion called inertial flow. More steady wind forcing of a frictional upper ocean often leads to Ekman flow. With larger scale wind shear, that forcing can induce Ekman divergence/convergence and associated upwelling and downwelling.

Inertial Flow

If there are no other significant horizontal forces present, then the Coriolis force will turn a moving water parcel into a clockwise (anticlockwise) circular inertial motion. The dynamics of *inertial motion* can be thought of as a dynamic balance between two pseudo-forces, namely the Coriolis force $\boldsymbol{CF}$ and the centrifugal force $\boldsymbol{f}_c$ that is associated with the acceleration of cir-

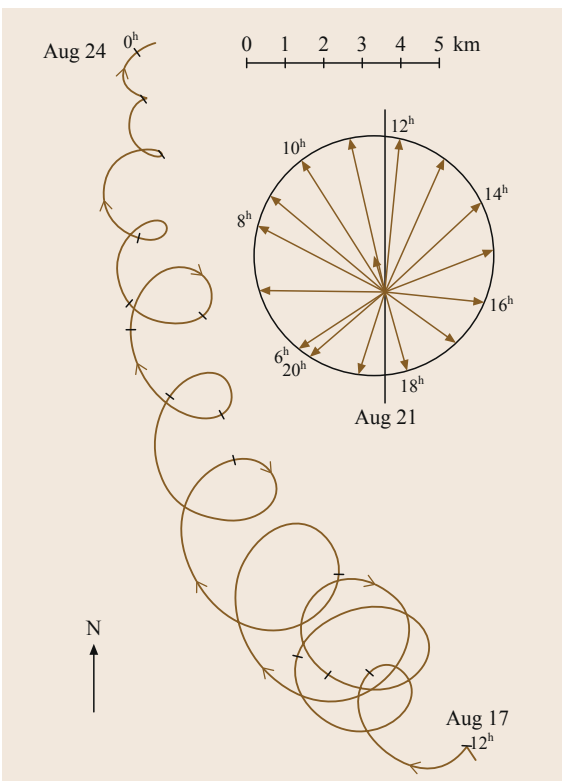

Fig. 2.32 A 7-day progressive vector diagram derived from moored current measurements time series, indicating clockwise circular inertial motion superposed on a northwestward flow (after [2.15]) ►

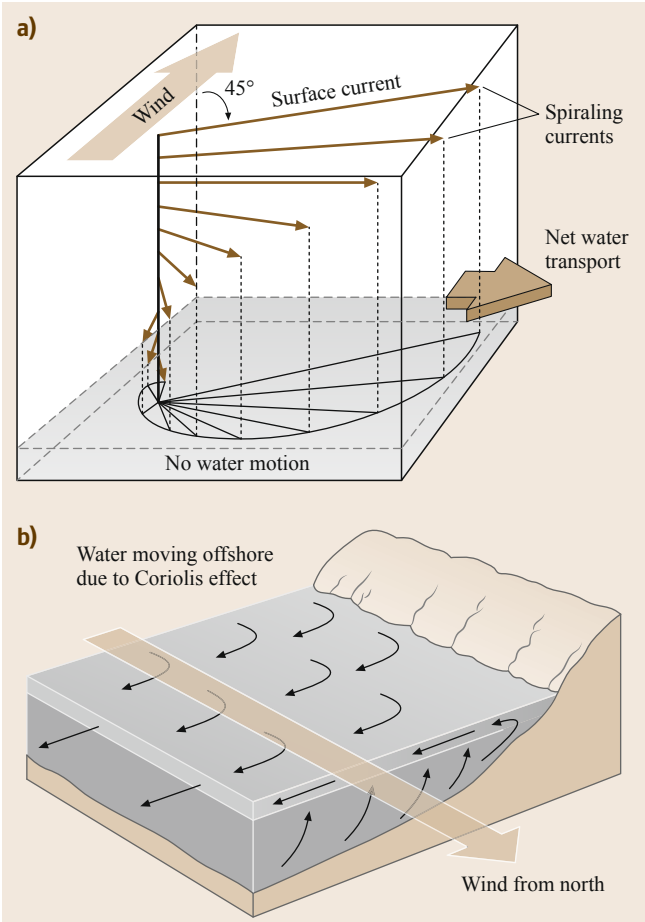

Fig. 2.33a,b Schematics of a Northern Hemisphere (NH) ocean being forced by a steady winds; showing **(a)** the surface velocity at 45° to the right of the surface wind stress and the downward spiral current structure – the vertical average of which yields a net Ekman transport to the right throughout the Ekman layer (after [2.7]). **(b)** Persistent winds along a NH coast produce a persistent Ekman transport *to the right* and an associated upwelling (after [2.10])

cular motion. Thus the force balance (per unit volume) for inertial motion is

$$\boldsymbol{CF} = \rho f \boldsymbol{V} = \rho \frac{\boldsymbol{V}^2}{R} = \boldsymbol{f}_c$$

so

$$f\boldsymbol{V} = \frac{\boldsymbol{V}^2}{R}$$

and the radius of the circle R

$$R = \frac{\boldsymbol{V}}{f} = \frac{\boldsymbol{V}}{2\Omega \sin\phi} .$$

The circular water parcel trajectory has an oscillation period called the inertial *period* T

$$T = \frac{2\pi R}{v} = \frac{2\pi}{f} = \frac{\pi}{\Omega \sin\phi}$$

which is independent of R! The inertial period is one half of a *pendulum day* which is defined as $2\pi/\Omega \sin\phi$. (A pendulum day is the time it takes for the vertical plane, in which pendulum swings, to rotate a full 360° (or 2π radians) relative to the Earth – a measure of the overhead Earth rotation rate at particular latitude). In practice, particularly after storm, it is not unusual to detect inertial motion (Fig. 2.32).

Ekman Flow

For wind stress-forced flow situations with times scales exceeding a half day, the effects of wind stress can be explored in terms a simplified form of the horizontal equations of motion in which Coriolis and frictional forces are balanced. The solution to these equations, assuming the application of a northward surface wind stress $\boldsymbol{\tau}_s = \tau_s \boldsymbol{j}$, is called *Ekman flow* whose respective eastward and northward components are

$$u^E = V_o e^{\pi z/D} \cos\left(\frac{\pi}{4} + \frac{\pi z}{D}\right) , \qquad (2.15a)$$

$$v^E = V_o e^{\pi z/D} \sin\left(\frac{\pi}{4} + \frac{\pi z}{D}\right) , \qquad (2.15b)$$

where $V_o = (\tau_s/\rho)/\sqrt{f\nu_z}$ is the surface velocity, $D = \pi\sqrt{2\nu_z/f}$ is the Ekman depth, and $\nu_z = A_z^e/\rho$ is the eddy kinematic viscosity.

While the detailed form of Ekman flow (Fig. 2.33) has only been recently verified experimentally, the existence of a vertically averaged flow to the right of the wind stress (Northern Hemisphere) called the Ekman transport has been observed for a long time. On ocean basin scales, as discussed below, Ekman transport convergence associated with the basin-scale wind fields create the conditions for large-scale ocean gyre currents. Near coasts, persistence along coast wind forcing generates offshore or onshore Ekman transports which lead to coastal upwelling/downwelling (Fig. 2.33). This process is particularly prominent along the US west coast during the summer when equatorward coastal winds persist.

2.5.5 Wind-Driven Currents: Ocean Basin Scale

Global-scale winds drive similar basin-scale gyre flows distinguished by intensified poleward flowing western boundary currents and less distinct equatorward flowing eastern boundary currents (Fig. 2.34). These mid-latitude gyre flows are connected by both tropical ocean current systems that straddle the equator in

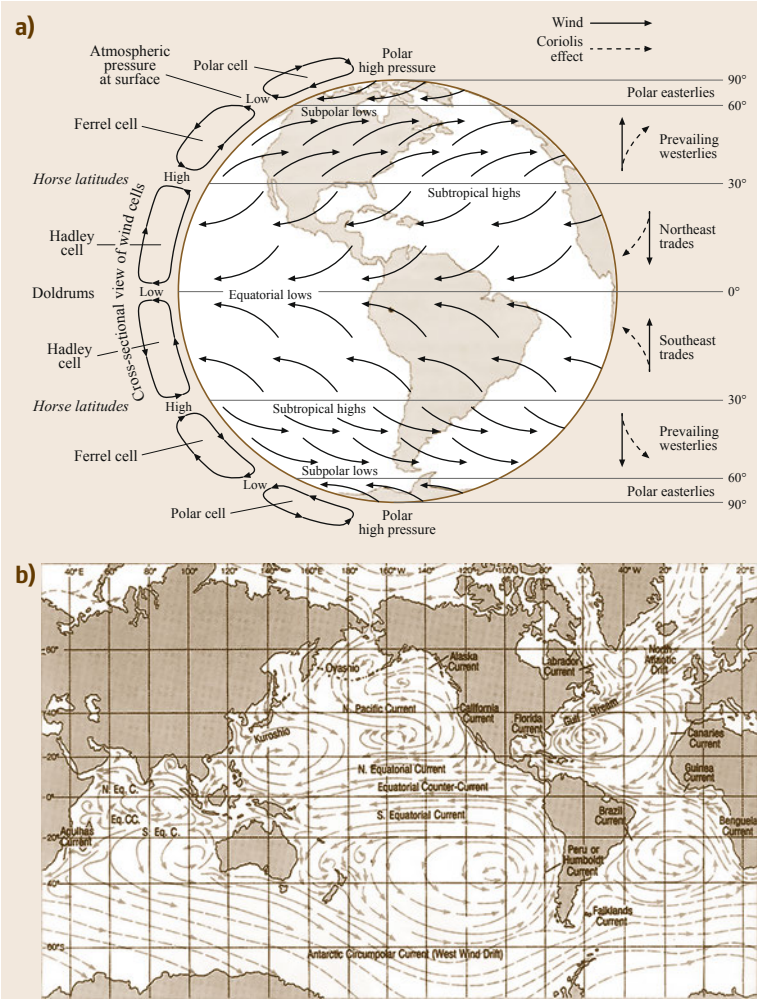

Fig. 2.34 **(a)** Average surface global winds divide into zonal bands due to Earth rotation effects. In both hemispheres, there are zones for the tropical easterly trade winds (equator–30°N and S), prevailing westerlies (30–60°N and S), and polar easterlies (60–90°N and S). **(b)** The major ocean basins feature gyre current systems that are interact through east–west equatorial current systems in the Atlantic and Pacific and the Antarctic Circumpolar Current in the Southern Ocean (after [2.7])

the Atlantic, Pacific, and Indian oceans and the Southern Ocean that circles Antarctica. The transports of the principal currents are presented in Table 2.6.

The dynamics of much of the open ocean flows is governed by one of the geostrophic force balances in which the Coriolis force balances the horizontal pressure gradient force for an arbitrary flow direction that is perpendicular to the force direction (Fig. 2.35).

The scalar form of the force balance is

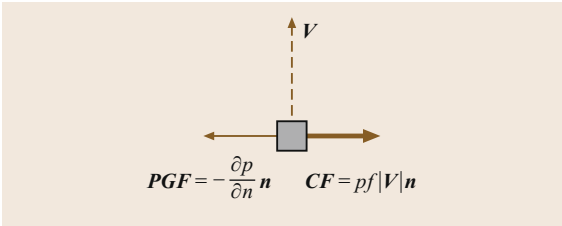
$$\rho f|\boldsymbol{V}| = \frac{\partial p}{\partial n}$$

So that the geostrophic flow magnitude is

$$V_{\mathrm{g}} = |\boldsymbol{V}| = \frac{1}{\rho f}\frac{\partial p}{\partial n}\,.$$

Table 2.6 Transport of major ocean surface currents

Location	Name	Maximum current [cm/s]	Volume transport [10^6 m^3/s]
Western Boundary Currents	Gulf Stream	200–300	400
	Kuroshio Current	> 200	50
	Brazil Current	50–100	10
Southern Ocean	Antarctic Circumpolar Current	15	150
Equatorial Currents	North Pacific Equatorial Current	20	45
	Equatorial Undercurrent	100–150	40
Eastern Ocean	Peru Current	10–50	20



The Cartesian representation of the velocity, Coriolis force, and pressure gradient force are

$$\boldsymbol{V} = u\boldsymbol{i} + v\boldsymbol{j}\,,$$
$$\boldsymbol{CF} = \rho f v\boldsymbol{i} - \rho f u\boldsymbol{j}\,,$$
$$-\partial p/\partial n = -\partial p/\partial x\boldsymbol{i} + -\partial p/\partial y\boldsymbol{j}\,.$$

Strictly speaking geostrophic flow is a steady-state, rectilinear flow that is perpendicular to the Coriolis/pressure gradient force balance which is to the right (left) in the Northern (Southern) Hemisphere as illustrated in Fig. 2.35. However, geostrophic flow is a practical model because much of the open ocean flows vary slowly compared to a pendulum day with very little curvature. The pair of diagrams in Fig. 2.36 show how the ocean has adjusted its internal mass structure (through seaward flows of warmer water and landward flows of cooler water) to generate the appropriate sea surface slope-induced pressure gradients that balance the Coriolis forces associated with what is a primarily wind-driven Gulf Stream flow.

Fig. 2.35 Generalized geostrophic flow force balance between the Coriolis force $\boldsymbol{CF} = \rho f|\boldsymbol{V}|\boldsymbol{n}$ and negative pressure gradient force $\boldsymbol{PGF} = -(\partial p/\partial n)\boldsymbol{n}$, which are acting on a water parcel with a velocity $\boldsymbol{V}$ in the orthogonal direction. The Cartesian components of different vectors are given ◄

The combined prevailing westerlies and easterly trade winds in the subtropical latitude band between 10° and 50° set up a poleward sheared surface wind stress field (Fig. 2.34a) that drives the basin-scale geostrophic gyre flows in the principal ocean basins. The Ekman transport generated by the westerlies and the trade winds converges in the vicinity of 30° in both the northern and southern Atlantic and Pacific Ocean basins. This situation creates the tendency for east–west zonal geostrophic flow perpendicular to Ekman transport-induced north/south pressure gradients and Coriolis force. However, in most ocean basins (the exception being the Southern Ocean around Antarctica), continents block the zonal ocean flow. So this wind-driven oceanic pressure field is a steady-state high pressure cell around which the geostrophic flow circulates. The combined effects of the geostrophic flow around the pressure cells and the earth's rotation lead to clockwise (or counterclockwise) basin scale *wind-driven* gyres in the Northern (or Southern) Hemisphere ocean basins (Fig. 2.34b). The gyroscopic interaction between the gyre motion and earth rotation leads to intensification of gyre currents along the western bound-

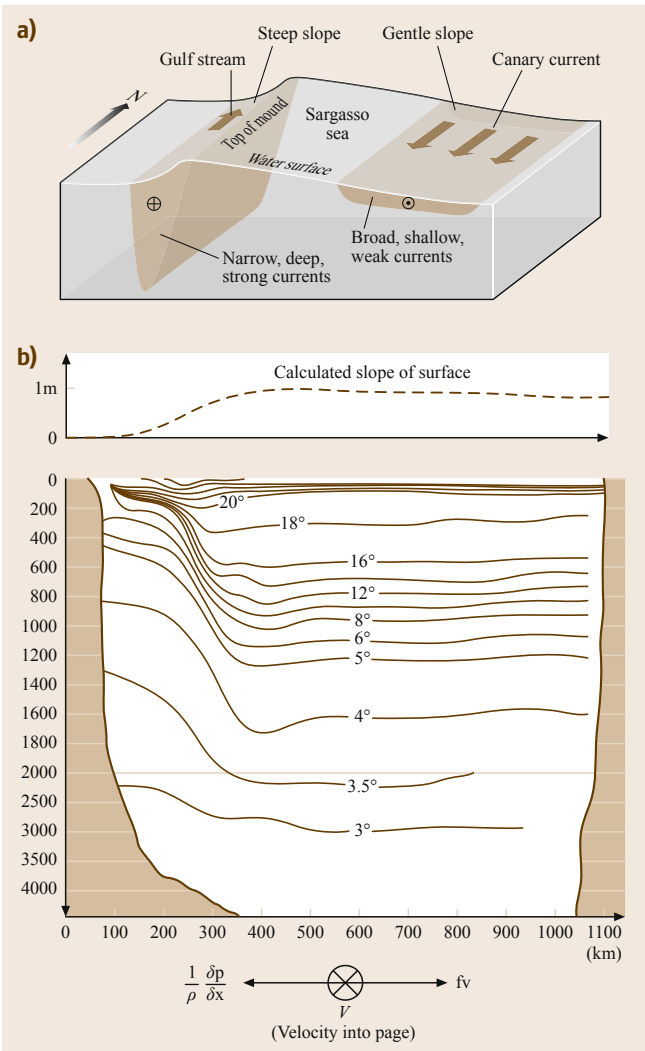


Fig. 2.36 **(a)** Schematic of the principal geostrophic flows in the North Atlantic basin. The exaggerated sea level distortions induce the pressure gradients that balance the Coriolis forces associated with the respective poleward Gulf Stream and equatorward Canary Current flows (after [2.7]). **(b)** A contoured temperature transect left-to-right across the Gulf Stream between Florida and Bermuda showing how the warm open ocean water raises sea level relative that associated with the cooler near-coast water and the relevant geostrophic flow force balance (after [2.6]) ◄

ary of all the ocean basins, exceeding 200 cm/s in the Gulf Stream of North Atlantic and in the Kuroshio of the North Pacific. The total transport of the Gulf Stream has been estimated to be in the range of 50–90 $\times 10^6$ m^3/s; with that of the Kuroshio being somewhat less (Table 2.6).

Despite the greater intensity of winds in the Southern Hemisphere, the intensity of the surface western boundary currents is less than that for either the Gulf Stream or Kuroshio. The Brazil current in the western South Atlantic has typical speeds of 50–100 cm/s and penetrates to depths of only about 400 m. in contrast to 800 m for the Gulf Stream. The reduced transport of the Brazil Current may be related to the presence of deeper western boundary undercurrents and their role in transporting heat poleward. The reduced intensity of the Australian current in the western Pacific and the Agulhas Current in the western Indian Ocean may be related to the lack of complete continental blockage of zonal flow.

The equatorward flow along the eastern boundaries of the wind-driven gyre as represented by the Canary and California Currents is generally less intense and less organized than the western boundary currents. The exception is the Benguela Current (Fig. 2.34b), which is an apparent extension of the Agulhas Current in the South Atlantic.

At tropical latitudes straddling the equator, significant trade winds can drive surface currents in the zonal circulation patterns shown in Figs. 2.34 and 2.37, patterns that exist in all major oceans. The wind-driven westward flow (Coriolis effects are weak near the equator) in a zone bracketing the equator is blocked by the presence of land masses. A resulting eastward pressure gradient force drives a return equatorial undercurrent jet along the equator and a seasonal countercurrent in the doldrum region. These countercurrents, while primarily zonal, are also very important connection between the major ocean basins.

The circulation at poleward latitudes greater than 50° differs greatly in the different oceans because of differences in the geography of the Northern and Southern Hemisphere ocean basins. The North Atlantic Ocean effectively ends at the sills at about 60°N and is weakly associated with the shallower Arctic Ocean, which has a circulation of its own. In the South Atlantic, there is a zonal ocean which circles the entire Antarctic continent. The winds are important in driving the broad Circumpolar Current (Fig. 2.34). Density adjustments in the interior produce pressure gradient forces which balance the Coriolis forces to produce a current profile which diminishes from about 15 cm/s at the surface to near zero at 3 km depth. So although Circumpolar Current speeds are considerably less than Gulf Stream speeds, the transports associated with the Circumpolar

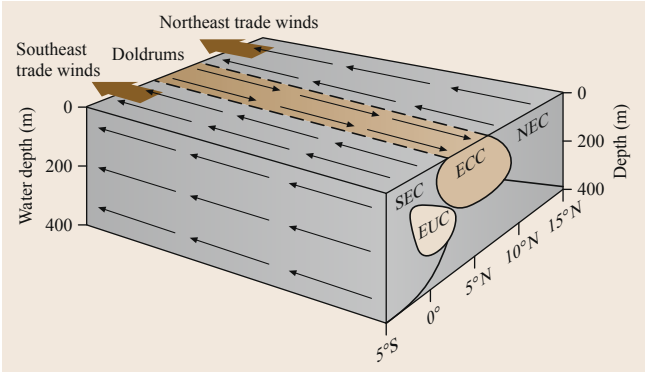

Fig. 2.37 Generalized Scheme of equatorial currents. Schematic of the westward trade wind-driven south (SEC) and north equatorial currents (NEC) bracketing the eastward flowing equatorial countercurrent (ECC) and equatorial undercurrent (EUC) (after [2.7])

Current are 130–190 $\times 10^6$ m^3/s and larger than Gulf Stream transports. As such, this current has the largest transport of any in the world's oceans and plays a crucial role in controlling the deep ocean circulation.

2.5.6 Gulf Stream Ring Flows

Before leaving the discussion of the wind-driven surface currents, it is important to note that western boundary currents are unstable leading to considerable changes on monthly time scales. For example, the Gulf Stream meanders and on occasion sheds pairs of eddies; warm core rings containing warm Sargasso Sea water or cold core rings (Fig. 2.38) containing colder waters with origins in the north. These rings are characterized by high currents – Gulf Stream-like currents of 50–100 cm/s. This eddy-shedding process enables effective poleward heat transport. Once these rings are shed, with the large Gulf Stream-like ocean currents, propagate affecting their local environments. Cold-core rings south of the Gulf Stream also propagate southwestward to be eventually entrained by the Gulf Stream in the region of Cape Hatteras. Warm-core rings with clockwise circulation are observed to propagate slowly southwestward along the continental margin on the northern side of the Gulf Stream. Satellite infrared imagery *is very* helpful in tracking these anomalously warm and cold eddies.

In reality, all of the upper oceans of the world are filled with eddy-like current structures embedded in the large-scale, wind-driven gyres described above. Typical currents in these eddies are about 10–20 cm/s. in contrast to the 1 cm/s gyre mean flow, and have lateral extents of about 100 km. Such eddies have been observed to propagate through a region in a period of months. The role of these eddies in the overall transport

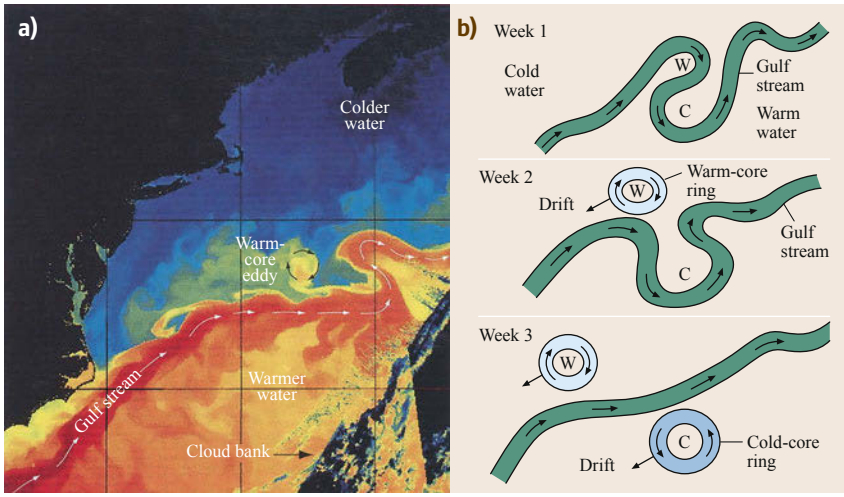

Fig. 2.38 **(a)** The warm Gulf Stream becomes unstable after leaving coast at Cape Hatteras, NC, and spawns both cold and warm core rings. **(b)** Gulf Stream ring formation begins with a meander that semienclosesses pockets of the warmer Sargasso sea water. and colder Slope Sea water. Every few months first a clockwise warm core ring and then an anticlockwise cold core ring will snap off. These rings will then drift equatorward on their respective side of the Gulf Stream – many times being reabsorbed by the Gulf Streams after several months of drifting (after [2.7])

of heat and other constituents is only just beginning to be understood.

The circulation in the tropical regions is likewise unsteady. A very important tropical ocean process is one in which warm equatorial waters in the western Pacific flow from west to east in response to moderating trade winds – with an uneven periodicity of 2 to 7 years. This anomalous flow of warm equatorial water has devastating effects on the fisheries along the Western Coast of South America. This ocean-centric process – called *El Nino* – is now known to be part of the larger scale atmospheric process called the Southern Oscillation. thus, the whole El Nino-Southern Oscillation process is referred to as ENSO.

2.6 Deep Ocean Currents

Superimposed on the wind-driven upper ocean circulation, which is mainly confined by the main pycnocline (or density gradient; Fig. 2.2) is a less intense thermohaline circulation. This global ocean scale overturning cell is driven primarily by atmospheric cooling-driven sinking of waters in the polar regions and closed through a poorly understood systems of vertical advections. The net effect of these vertical return flows (average vertical velocities of centimeters/day) is to maintain the depth of the main pycnocline against the downward heat diffusion in the upper ocean (Fig. 2.39).

Early ideas of deep ocean circulation were based on the ideas that water at polar latitudes – delivered primarily by western boundary currents – becomes relatively dense as it was cooled by the atmospheric winds and sank to depths in accordance with its density – with the coldest water sinking the deepest. As the water slowly warmed over hundreds if not thousands of years, it became less dense and rose to the surface distributed throughout the global oceans (Fig. 2.39).

The Stommel–Aron [2.16] dynamic theory of the thermohaline circulation of the world's oceans consisted of (a) polar region sinking – primarily North Atlantic and Antarctica – that (b) fed a network of deep western boundary currents (Fig. 2.40) that distributed the water to (c) a selected set upwelling zones from where (d) it returned to the upper ocean western boundary currents. Subsequent observations of the Atlantic deep western boundary current have verified one of the principal predictions of the Stommel–Aron theory.

Thus the overall picture of global ocean circulation is one that combines wind-driven and thermohaline flows in ways that transport enough heat poleward to

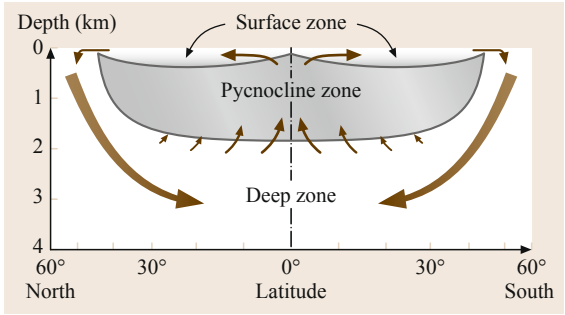

Fig. 2.39 Schematic of a three-zone global ocean in which thermohaline or meridional overturning circulation consists of poleward flow in the surface layers, sinking in the polar regions and upwelling through the very stable density gradient or pycnocline zone

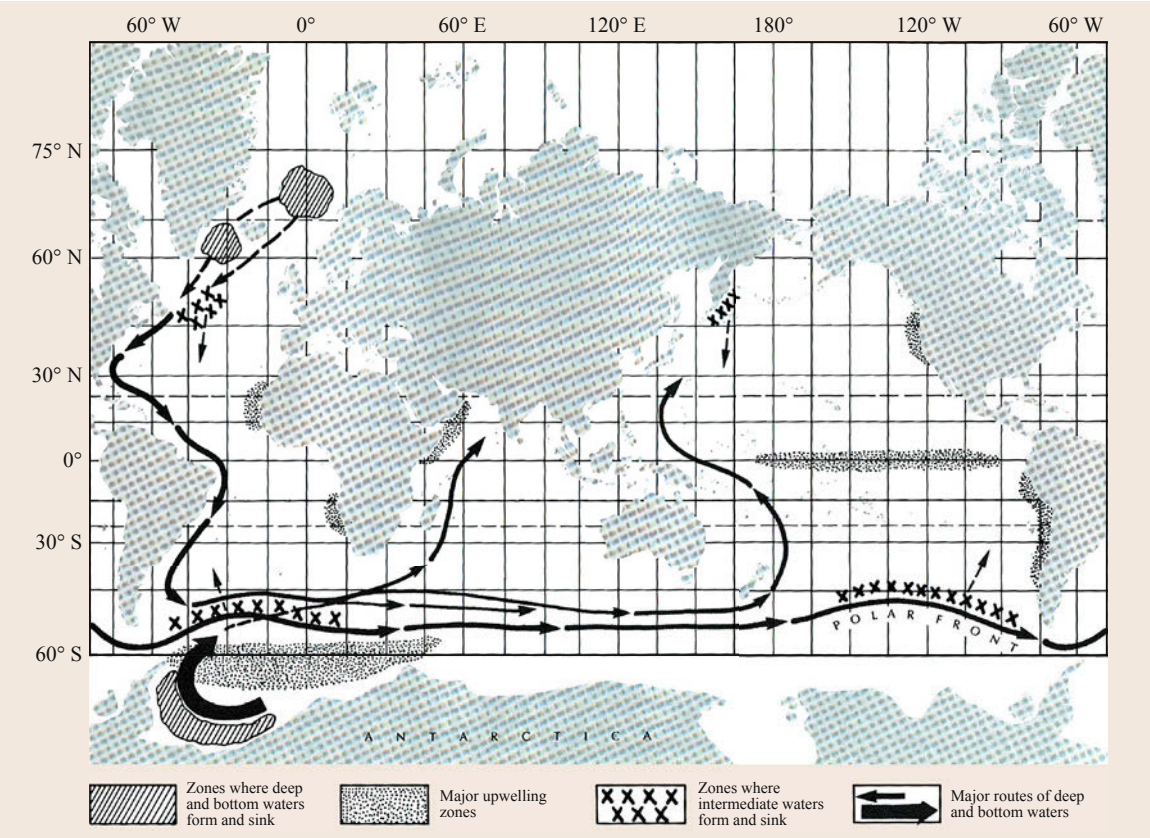

Fig. 2.40 The Stommel–Arons theory of deep ocean circulation consisting of a distributed set of deep western boundary currents that were connected via the Southern Ocean and to upwelling in the Southern, equatorial, and selected coastal oceans (after [2.4])

balance a polar hear deficit. The North Atlantic composite ocean circulation consists of an intense Gulf Stream that is opposed by the southward flowing deep western boundary currents composed of North Atlantic polar waters. The South Atlantic composite ocean circulation consists of a relatively weak Brazil current that is aided by a southward deep western boundary currents of North Atlantic polar waters. The medium intensity Kuroshio Current in the western Pacific is aided by deep underwater currents in transporting heat poleward.

2.7 Coastal Ocean Currents

The relative shallowness of the continental shelf and coastal regions of the world's oceans leads to a distinct current regime in which short term fluctuations are much larger than longer term mean flows. In general, the shallower coastal ocean waters respond more readily to wind forcing and exhibit important variability on the 2–10-day time scales of the mid-latitude synoptic weather systems which pass through the region. Density fronts caused in part by the proximity of the coastal ocean to significant fresh water river sources are associated with significant intensification of shelf and coastal currents. Of course, there are always tidal currents, which in many cases are as relatively weak (5 cm/s) as in the deep ocean. However, other places in the coastal ocean exhibit significantly stronger tidal currents that play a more important role in the mixing of shelf and coastal water masses (see next section for more on that).

Wind-forced shelf currents vary over longer time scales than tidal currents and thus are usually more effective in transporting nutrients, biota, pollutants, and other constituents on the shelf. Wind-forced

shelf fluctuations are usually most intense (typically 10–50 cm/s) in the along-shelf direction, with the maximum currents occurring at mid-shelf.

The presence of significant across-shelf density changes, such as those found along the East Coast of North America, leads to a modified current structure in which maximum along-shelf currents are concentrated in the density front along the outer shelf. These currents change over longer time scales in response to the more slowly changing density structures. Occasionally, deeper ocean currents in the form of Gulf Stream warm core rings penetrate onto the shelf and disturb the *normal* distribution of currents found there.

On many continental shelves, including the East Coast of North America, there is a more or less steady along-shelf flow superimposed on the fluctuating tidal, buoyancy-induced and wind-driven current field. Typical velocities of these steady flows are usually about 5–10 cm/s. Thus, while astronomical wind forcing plays an important role in shelf currents, their superimposition leads to complex and, as yet, unpredictable patterns crudely described by the characteristics discussed above.

2.8 Ocean Surface Tides

The astronomically forced surface gravitational tide has wavelengths that are long compared to the ocean depth and thus is a shallow water wave. Tidal waves are strongly forced by the motion of the earth relative to the moon and the sun and thus differ from *freely* propagating wind-generated surface gravity waves. Unlike most short period wind-driven waves, tidal waves have periods on the order of a day – enough to be influenced by the earth's rotation (Fig. 2.2).

The tidal response of the global oceans is complex because of the combined astronomical *tidal forcing* of the earth, moon and sun. The observed tides differ significantly from location to location because of the shallowness and geographical complexity of the global ocean basins. Observed tides throughout the world's ocean are composed of differing mixtures of both twice-a-day (semidiurnal) and once-a-day (diurnal) tidal variability. For example, the tides in Pakhoi, China (Fig. 2.41) are primarily once-a-day (or diurnal), while the tides in Port Adelaide, Australia are primarily twice-a-day or semidiurnal. Although the tides at both locations include both semidiurnal and diurnal tides, the minor tidal constituent is too small to detect except when the tidal range is small. Note that about every 14

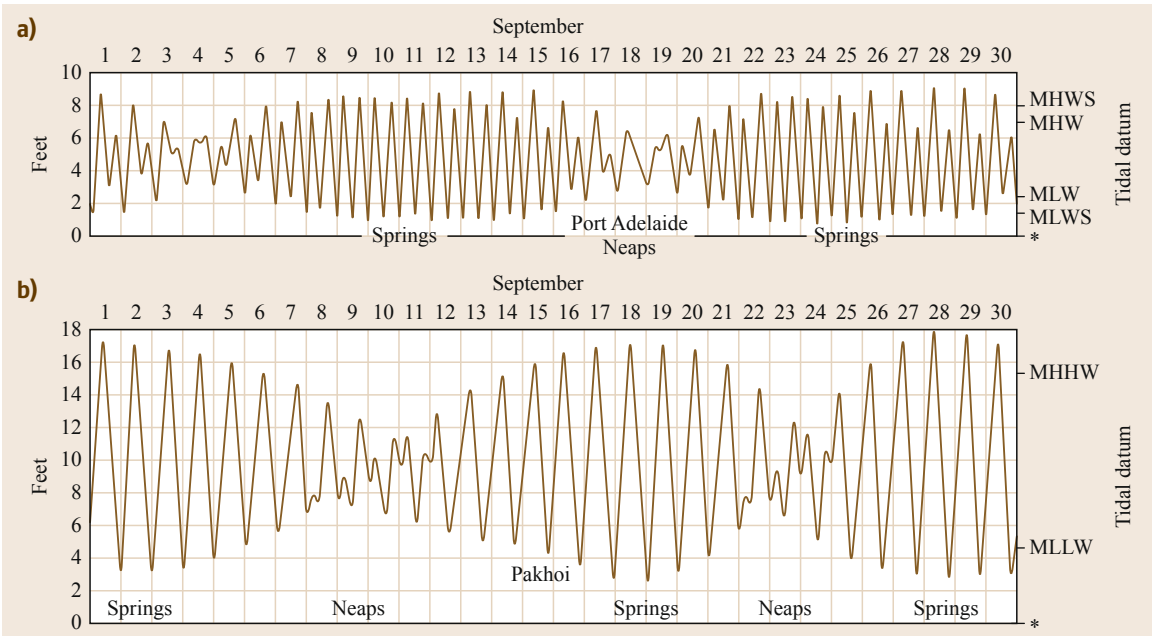

Fig. 2.41a,b Observed tides in **(a)** Port Adelaide are semidiurnal (twice-a-day) and in **(b)** Pakhoi diurnal (once-a-day). Tidal ranges in both locations exhibit a spring-neap cycles that are out of phase (after [2.15])

Table 2.7 The six basic astronomical tide-producing force frequencies are given in radians per unit time and degrees per solar day

Source	Angular frequency
Earth rotation	$\omega_\tau = \frac{2\pi}{\text{lunar day}} = 360° - 12.2°/d$
Lunar revolution	$\omega_s = \frac{2\pi}{\text{sidereal month}} = 13.176°/d$
Solar declination	$\omega_h = \frac{2\pi}{\text{solar year}} = 0.985/d$
Revolution of lunar perigee	$\omega_p = \frac{2\pi}{8.87\,\text{years}} = 0.111°/d$
Precession of lunar node	$\omega_N = \frac{2\pi}{18.6\,\text{years}} = 0.0529°/d$
Revolution of solar perigee	$\omega_{p1} = \frac{2\pi}{20\,000\,\text{years}} = 0.00005°/d$

days the range of the tidal sea level excursions and associated currents cycle through a maximum called spring tides and a minimum called neap tides (Fig. 2.41). This phenomenon occurs because the tide-producing forces associated with the moon and the sun reinforce (times of full and new moon) and oppose (times of half moons) each other twice a month.

As it turns out, there are five basic frequencies (Table 2.7) associated with astronomical tide- producing forces. Because the interaction of the astronomical tidal forcing and the oceanic response is highly nonlinear, the observed ocean tide anywhere on the earth can be decomposed into 400 *partial tides* (or *tidal species*). Each partial tides has a unique frequency ω_i that is determined by a set of integer weights a_j (for $j = 1, 2, 3, 4, 5,$ and 6) that multiply these six basic frequencies according to

$$\omega_i = a_1\omega_\tau + a_2\omega_s + a_3\omega_h + a_4\omega_p + a_5\omega_N + a_6\omega_{pl} \,.$$

Doodson [2.17] developed a shorthand notation for the weights called the Doodson number to define the different partial tides. (For example, the interaction of lunar declination changes and earth rotation leads to a pair of frequencies $\omega_\tau + 4\omega_s$ and $\omega_\tau - 4\omega_s$; which have Doodson number specifications (1 4 0 0 0 0) and (1 −4 0 0 0 0), respectively). The short list of the most important partial tides in Table 2.8 show equilibrium tidal forcing amplitude ratios relative to that of the M_2 tidal constituent – at many sites the most important constituent.

For practical purposes, the astronomical tide-producing forcing is fixed for all time. So the tidal response of the world's oceans, while it is complex spatially, is also fixed for all time. Thus to uniquely determine the tide at a particular location – say sea level $SL(t)$ – the task is to determine the amplitude (H_i) and

Table 2.8 List of the identities, periods, and relative equilibrium tidal amplitudes of the 19 of the most important partial tides (out of the 400)

Name of partial tides	Symbol	Speed (degrees per mean solar hour)	Period (solar hours)	Coefficient ratio $M_2 = 100$

phase (κ_i) for each of the partial tides (or *tidal constituents* η_i with its own ω_i) given by

$$\eta_i = H_i \cos(\omega_i t + \kappa_i) \; .$$

The harmonic constant H_i/κ_i pairs for each of the partial tides can be obtained by a harmonic analysis of a sufficiently long measured record – in this case sea level $SL(t)$ – from the site of interest. Modern harmonic analyses of measured records are based on a spectral analysis that has been modified to consider the variability at only the special partial tidal frequencies. Once determined, the partial tides can be constructed and summed to produce the total astronomically forced tidal sea level record according to

$$h(t) = \sum_i \eta_i = \sum_i H_i \cos(\omega_i t + \kappa_i) \; .$$

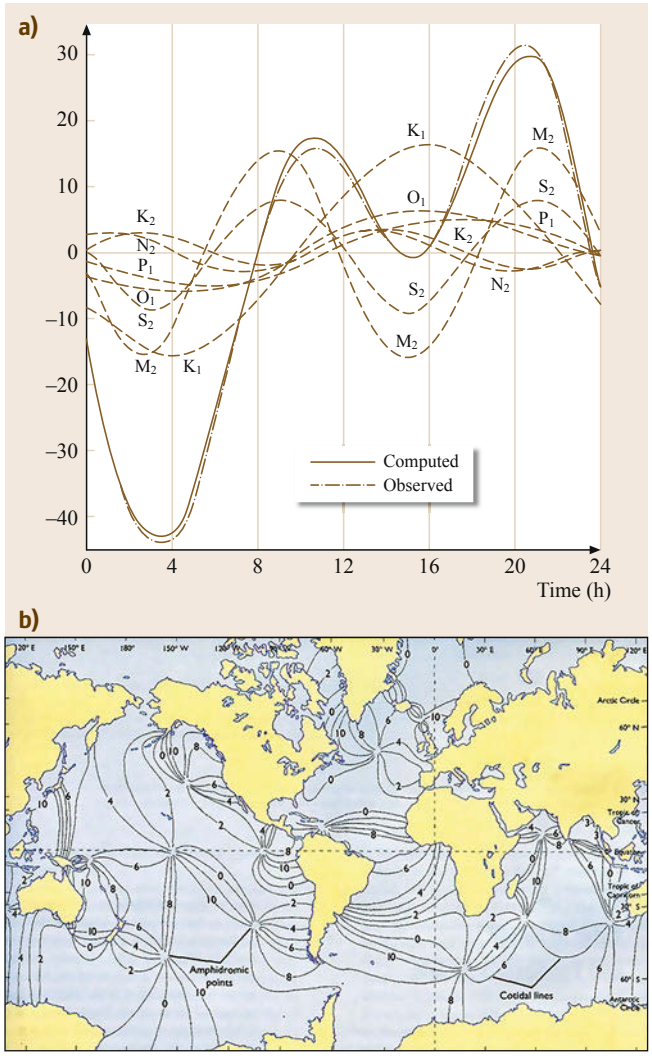

Fig. 2.42 (a) Harmonic decomposition of an observed sea level record (*dash-dot*) into several partial tidal constituents, which when added yield the computed tidal sea level (*solid*) part of the observed sea level record (after [2.10]). **(b)** The M_2 semidiurnal harmonic constants for an world's ocean array of sea level stations are used to construct a cotidal chart for the Atlantic Ocean tide. The solid cotidal lines mark the Greenwich times of high tide (after [2.7])

The harmonic constant H_i/κ_i pairs can be used to predict the future (present and past) tidal variability at the particular site. For most purposes, less than 10 tidal constituents are required to describe the tide adequately at a particular station. Figure 2.42a example shows the results of a tidal harmonic analysis of a sea level record in terms of seven tidal constituents. Note that this method is useful in predicting only that part of the measured sea level fluctuation which (2.1) occurs at astronomical frequencies and (2.2) is *phase locked* to the astronomical forcing.

Harmonic analysis results of a sea level record are widely useful because the principal contribution to sea level variability is usually at tidal frequencies. This helps to explain the relatively small difference between the observed sea level and the computed tidal sea level – a difference called the nontidal *residual sea level*. The residual or tidal signal *noise* can be of interest because it is due to other oceanic processes including weather forced phenomena, hydrodynamic nonlinearities, and wave phenomena at nontidal frequencies.

The maps of the harmonic constants can be used to define the patterns of the individual partial tides. The pattern of the very important M_2 semidiurnal tide is mapped for the Atlantic ocean in Fig. 2.42 – right in terms of its lines of constant tidal range (*cotidal lines*) and constant tidal phase (*copahse lines*). This *cotidal chart* for the M_2 semidiurnal tide reveals the classic signature of an *amphidromic system* in the North Atlantic; in which high tide, ranging from zero tidal range at its central *amphidromic point* to its maximum at its coastal extremes, marches around the basin in 12.42 h. The world's oceans consist of about six major interacting amphidromic systems.

The results of tidal harmonic analyses of ocean currents are more difficult to interpret than those from sea level because significant portions of ocean current variability (2.1) is due to wind – and not tidal forcing, and (2.2) even the tidal frequency variability is often are not phase locked to astronomical forcing. Internal gravity wave-generated currents can represent another major source of noise for the tidal harmonic analysis of currents. It is not unusual for internal wave currents with complex vertical structures to be superimposed on surface (or external) tidal currents with their more depth-

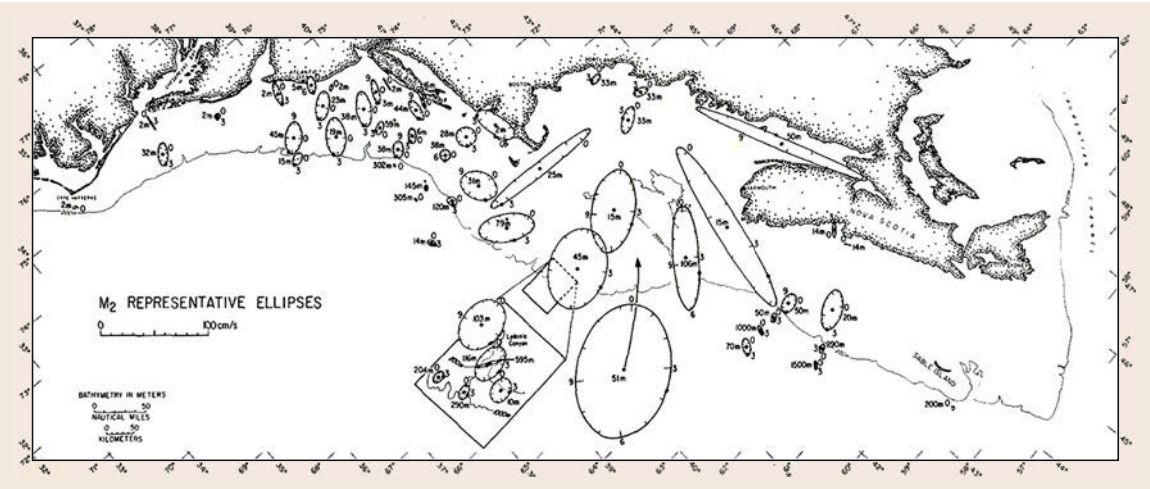

Fig. 2.43 Representative M_2 tidal current ellipses; representative of the mid-water column (water depths given). Ticks on ellipse edge indicated Greenwich hour, with the time of Boston high water indicated by the dot between hours 3 and 4. *Asterisks* identify currents 1 m above bottom, with bathymetry in meters (after [2.18])

independent structures. Therefore, relative to sea level records, current records need to be longer so that uncertainties in the tidal harmonic constants are comparable.

This guideline is less true for places like Georges Bank (at the entrance to the Gulf of Maine) where surface (or external) tidal currents forced by North Atlantic tidal variability dominate. This is because a large volume of water rushes into/out of the Gulf of Maine over the relatively shallow Bank during each semidiurnal tidal cycle. Because of earth rotation effects, semidiurnal tidal currents of more than 50 cm/s (≈ 1 nautical mile/hour or knot) rotate through a clockwise elliptical current vector pattern (for the M_2 semidiurnal ellipse see Fig. 2.43). Georges Bank tidal currents at are strongly sheared near the bottom, where their frictional effects transport sediments.

The amplitudes and ellipse characteristics of tidal currents vary greatly in the coastal ocean because of the effects of bathymetry and continental shelf configuration. The Gulf of Maine M_2 tidal current ellipses are larger than the rest of the northeast shelf region depicted in Fig. 2.43 because the Gulf of Maine length (Georges Bank – head of the Bay of Fundy) makes it is near-resonance with the semidiurnal tidal forcing.

2.9 Oceanic Internal Waves and Tides

With surface gravity waves, the air–sea density difference between air and water (ratio $\approx 1/800$) leads to the gravitational restoring force for fluid that has been displaced vertically (usually by wind). In the stably stratified water column, the similar, though weaker restoring force, makes *internal gravity waves* are possible. The surface expression of internal waves is very small, hence the name.

Consider the case depicted in Fig. 2.44a, where a thin layer (h') of less dense water ρ' overlies a thicker layer (h'') of slightly more dense water ρ''. Theory [2.19] indicates that an internal wave with wavelength L and phase speed of

$$c = \left[g h' \left(\frac{\rho'' - \rho'}{\rho''} \right) \right]^{1/2} ,$$

where $L/20 > h'$ and $L/2 < h''$ can arise. Thus the wave phase speed of a *shallow water* internal wave is considerably less than that of its surface gravity water counterpart because the reduced vertical density difference across the interface decreases the effect of gravity.

In contrast to the 2-layer example above, oceanic density and density gradients vary with depth or -z (Chap. 5). Internal gravity waves propagate in complicated ways throughout most of the ocean. Theory indicates that internal waves can occur at all depths in a stable water column between the frequencies of the inertial frequency $f(\phi) = 2\Omega \sin(\phi)$ (where ϕ is latitude) and the local buoyancy frequency that is given by

$$N(z) = \sqrt{-\frac{g}{\rho} \frac{\partial \rho_{pot}}{\partial z}} \quad \text{in radians/unit time} ,$$

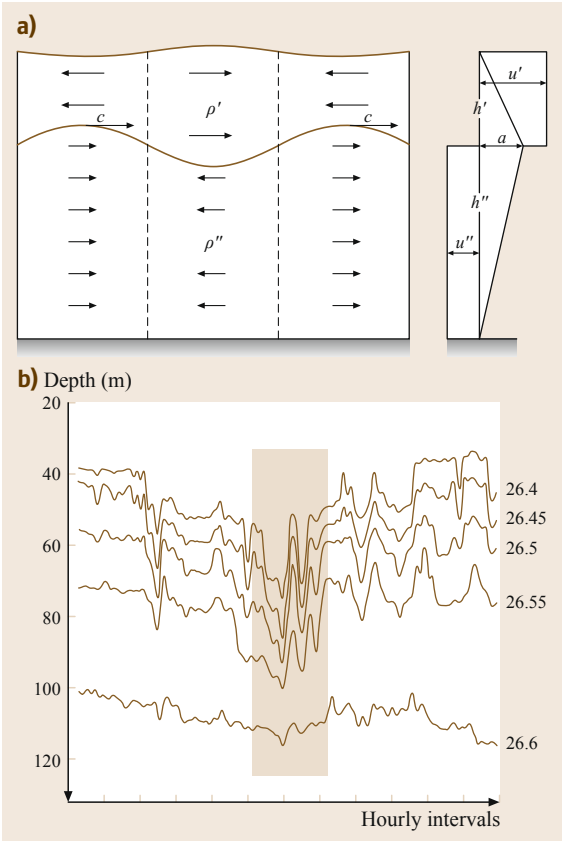

Fig. 2.44 **(a)** The configuration of an internal gravity wave in a 2-layer ocean with one layer of thickness h' and density ρ' overlying the deeper layer of thickness h'' and ρ'' supports an interfacial internal wave with a phase speed c that is independent of wave amplitude a (see text). Note the minor surface expression and that the opposed currents (u' and u'') in the respective layers do depend on the wave amplitude (after [2.8]). **(b)** Observed isopycnal depth time series define two rank-ordered oscillations on the trailing edge of an internal solitary wave of depression – estimated from moored observations on the northern California shelf in 133 m of water in April 21, 1981 (after [2.20])

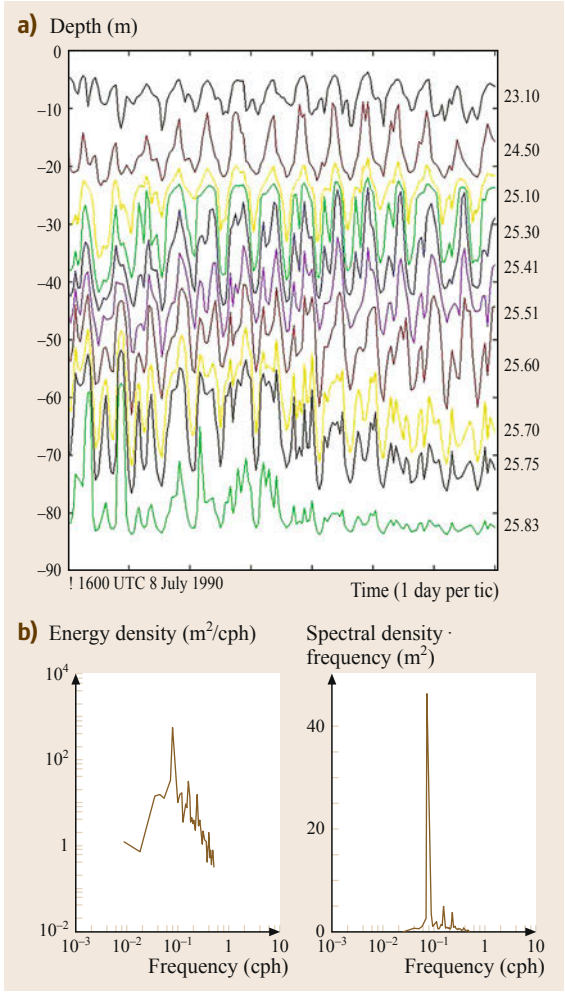

Fig. 2.45 **(a)** Massachusetts Bay isopycnal depth time series – inferred from density measurements – indicate strong internal tidal signatures throughout the water column. **(b)** Isopycnal displacement energy density spectrum. The prominent peak in the semidiurnal (≈ 12 h) frequency band is consistent with the proximity of the measurements to the internal tidal generation zone on Stellwagen Bank with 95% confidence limits indicated (b) Variance-preserving spectrum of the isopycnal displacement energy indicates the dominance of the semidiurnal internal tidal energy in the 12 h frequency band

where $-\partial\rho_{pot}/\partial z$ is the stable local gradient of potential density – a density that has been corrected for pressure effects (Chap. 5).

Intermittent interval wave events were observed by *Howell* and *Brown* [2.20] at a site in 133 m of water on the northern California continental shelf in April 1981. The water column at the site approximated a 2-layer ocean with an upper layer of 60 m. One of the observed events was a internal wave of depression with 29 m downward displacement of the mid-depth isopycnals (Fig. 2.44b), upper layer onshore velocity of 0.14 ± 0.02 m/s, lower layer offshore velocity of 0.14 ± 0.02 m/s, and time scale of 28 ± 4 min; all of which agreed well with internal soliton theory applied to the conditions of the observation site. They concluded that internal solitary waves, generated in the region of the continental slope, evolved into packets of solitons as they propagate shoreward before dissipating their energy of about 8.23×10^5 J per meter of wave crest.

The distribution of internal wave energy is determined by the nature of the different forcing mechanisms including winds and interactions between the surface tidal currents and bathymetry.

Temperature measurements made in the deep ocean (e.g., off Southern California and in the South China Sea) show significant concentrations of energy at semidiurnal frequencies. These temperature fluctuations were due to internal waves of tidal frequency (i. e., internal tides) with vertical displacement amplitudes of nearly 100 m and wavelengths of about 100 km. Evidence indicates that these energetic internal tides were generated at nearby bathymetric slopes.

Widespread evidence indicates that these internal tides represent an important component in the internal wave field many places in the world's oceans. In particular, subsequent interactions between (a) propagating internal tides from multiple generation sites, (b) the normally variable and heterogeneous oceanic density field, and (c) complex bottom bathymetry can lead to evolution and scattering that contribute to a general oceanic internal waves field with a range in periods that range between the local buoyancy (N) and inertial (f) frequencies. Other contributors to the oceanic internal wave field, include natural and well as ocean vehicle interactions with upper ocean stratification, with amplitudes that depend on the specific energetics of their generation processes.

The internal tide is an importantly energetic component of the internal wave field – particularly in the coastal ocean. One important and well-studied example of the internal wave being generated by surface (or external) tidal currents impinging on the bathymetric slopes is found on Stellwagen Bank in Massachusetts Bay. An array of moored measurements near Stellwagen Bank have been used to compute density time series at six levels; from which were produced the suite of isopycnal displacement time series shown in Fig. 2.45.

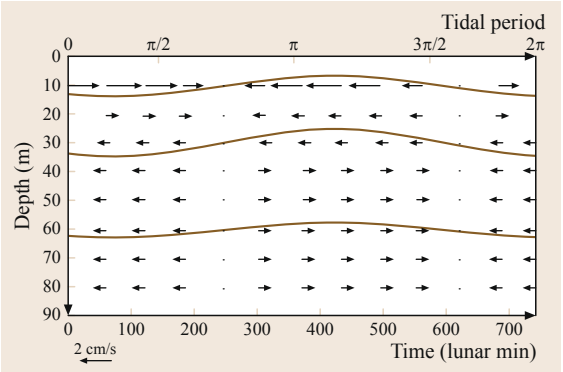

Fig. 2.46 Internal tidal kinematics: The spatial distribution of isopycnal displacement (−) and horizontal velocities associated with one cycle of an M_2 internal tidal wave in an ocean with exponentially decreasing buoyancy frequency

The energy spectra of these isopycnal time series clearly indicate the importance of the internal tide in the region (Fig. 2.45b). An analysis of these data has enabled us to construct the kinematical picture of the isopycnal displacement and current structure in Fig. 2.46. Note the zones of horizontal current convergence in the upper water column (strongest at the surface) and divergence at depth leading the isopycnal wave crest as it propagates from right to left. The current shear associated with such wave motion can become unstable leading to internal wave breaking and mixing.

3. Metocean Extreme and Operating Conditions

George Z. Forristall, Cortis K. Cooper

Metocean stands for *meteorology* and *oceanography*, an acronym that is commonly used in the offshore oil industry to encompass almost all topics involving the quantitative description of the ocean and atmosphere needed to design and operate man-made structures, facilities, and vessels in the ocean or on the coast. The metocean environment controls many aspects of facility design and operation, so errors in quantifying metocean conditions can cascade through the design and operational decisions. Errors can result in damage and lost lives. Conversely, if the variables are overestimated, costs will be overestimated perhaps to the point that the project becomes uneconomic and is never built.

Metocean criteria are typically broken into two categories: operating and extreme. The former involves quantification of metocean conditions in which the facility or vessel should be capable of achieving the routine functions of its primary purpose. Extreme conditions are typically associated with *storms*.

The approach taken by this chapter is to outline the methods commonly used in industry to quantify the most important metocean variables that impact offshore facilities. These methods are drawn largely from the offshore oil and gas industry but they are also readily applicable to other engineering applications involving the design and operation of vessels, coastal structures, offshore wind farms, navigational aids, coastal geomorphology, and pollution studies.

Of course there are a multitude of metocean variables which could be covered but this chapter focuses on winds, waves, and currents (WWC), since these are the variables that most often control extreme loads or operating conditions on man-made facilities. Because of space constraints it is necessary to only briefly cover some of the topics and to provide the reader with references for further reading.

After the introductory section, the next section reviews key physical processes: WWC spectra, wind and current profiles, wave growth and wave breaking. It is followed by two sections that briefly address some of the more important issues that can arise regarding measurements and models. Section 3.5 examines ways to calculate the marginal probability of WWC processes. Section 3.6 describes some of the analysis products that are typically used to quantify operating conditions. Finally, the last section covers the topic of extreme criteria.

3.1 Quantifying the Metocean Environment

Metocean is an acronym from *met*eorology and *ocean*ography and is commonly used in the offshore oil industry to encompass almost all topics involving the quantitative description of the ocean and atmosphere needed to design and operate man-made structures, facilities, and vessels in the ocean or on the coast. When engineers design a major facility or vessel to operate and survive in the sea, they must consider the loads and other constraints that may affect the structure. If those loads and constraints are underestimated, then damage can result and lives may be lost. Conversely, if loads and constraints are overestimated, then the costs will be overestimated perhaps to the point that the project becomes uneconomic and is never built.

The metocean environment controls so many aspects of facility design and operation that errors in quantifying metocean conditions can cascade though the design and operational decisions. For instance, overestimating a design wave height for a deepwater floating production platform could result in adding too many mooring lines. Since these additional lines would add tons of static load, a larger facility would be needed to provide the necessary buoyancy, thus generating additional capital cost well beyond the cost of the excess mooring lines. In short, the accurate quantification of metocean criteria can have far-reaching effects on the safety and profitability of offshore facilities. For this reason, metocean criteria are usually specified and described in a separate chapter or stand-alone document in a project's design documents. In 2005, the American Petroleum Institute (API) recognized the influence of metocean criteria and began publishing a stand-alone set of recommended practices for the offshore industry [3.1].

Metocean criteria are typically broken into two categories: operating and extreme. The former involves quantification of metocean conditions in which the facility or vessel should be capable of achieving the routine functions of its primary purpose. Examples of routine functions include pumping oil, drilling, receiving or pumping out natural gas, and generating wind energy. Typical products used to quantify operational conditions include a cumulative probability distribution of wave height and a table of wind speed persistence. These products are used in estimating the fatigue lives for components. In contrast, extreme conditions occur rarely and are often generated by episodic events (e.g., storms). During extreme conditions, normal operations are usually suspended – the vessel is slowed, oil or gas production is stopped, wind turbines are feathered, etc. A common example of an often used extreme condition parameter is the 100-year maximum wave height – the largest wave expected over a three-hour period once in 100 years.

With this background in mind, the goal of this chapter can now be stated: it is to outline the methods commonly used in industry to quantify the most important metocean variables that impact offshore facilities. These methods are drawn largely from the offshore oil and gas industry but they are also readily applicable to other engineering applications involving the design and operation of vessels, coastal structures, offshore wind farms, navigational aids, coastal geomorphology, and to some extent, pollution studies. While we attempt to provide some physical insights into the underlying metocean processes, this chapter focuses on the methodology for deriving the key variables, and the nuances of their correct application.

Of course there are a multitude of metocean variables that could be covered in this chapter. Potential topics include water temperature, tides, and salinity. While these variables can be important for some engineering applications such as acoustics, this chapter will focus on winds, waves, and currents (WWC), since these are the variables that most often control extreme loads or operating conditions on man-made facilities. However, even this narrowing leaves countless aspects of WWC that could be covered with far too little space to do them justice. Thus we again have chosen to narrow the frame further by specifically focusing on aspects of WWC that tend to drive capital or operating decisions in large offshore facilities. For those interested in coastal features where shallow-water effects are important, the Coastal Engineering Manual [3.2] serves as an excellent reference.

Much as we the authors have had to narrow the topics, a metocean design basis for a major project must narrow the variables that are covered. This is because the sea and atmosphere are filled with complicated processes, many of which are site specific and poorly understood. If aggressive filtering is not undertaken, then too much time can be spent quantifying variables

that make little difference to the design or operation of the facility. The first and best way to eliminate variables from investigation is to understand the basic responses of the *particular* facility. In other words to answer the question: which metocean variables impact this facility most and which have little or no impact? For example, squalls and their dynamic effects can be especially important in designing the moorings for floating production vessels near the equator, such as off Indonesia. Carefully quantifying squall intensity and its change over time scales of a few minutes and length scales of the order of 50 m is of highest importance. In contrast, quantifying water, storm surge, and air temperatures is not critical.

Section 3.2 is an overview of key processes, including a discussion of WWC spectra, wind and current profiles, and important though arguably tangential discussions of wave growth and wave breaking.

Sections 3.3 and 3.4 briefly address some of the more important issues that can arise regarding measurements and models. Since all metocean criteria are founded on one or both of these inputs, it is important to understand the various sources and databases, and their advantages and limitations. Otherwise one may well suffer the consequences of *garbage in, garbage out*.

Section 3.5 examines ways to calculate the marginal probability of WWC processes. One of the more interesting cases is when two variables are statistically independent (or nearly so) in time or space and yet there is often a non-negligible probability that the two can occur simultaneously and generate loads that exceed the load from an individual process at the same probability level.

Section 3.6 describes some of the analysis products that are typically used to quantify operating conditions. The discussion begins with the simplest approaches such as univariate probability density functions and then moves on to address more sophisticated products to characterize storm and calm persistence, directional dependence, and vertical space variations.

Finally, the last section covers the topic of extreme criteria. It is important because the economic and safety consequences of getting it right are so high. It is also important because there is no general and all encompassing methodology to estimate extremes so the topic is rich in subtleties, complexity, and potential traps.

3.2 Overview of WWC Processes

3.2.1 Winds

Most winds that are important for offshore design and operations come from extra-tropical or tropical storms. Extra-tropical storms are large-scale systems that are well represented on standard meteorological charts. The measurements used to produce these charts are discussed in Sect. 3.3. Tropical storms are relatively small features on common weather charts. Observations in them are scarce. Detailed wind fields in tropical storms are produced using dynamic or kinematic numerical models, which are discussed in Sect. 3.4.

Wind specification requires especially careful attention to definitions. *Richardson* [3.3] made an eloquent statement of the problem many years ago:

> *Does the wind possess a velocity? This question, at first sight foolish, improves on acquaintance . . . let us not think of velocity, but only of various hyphenated velocities.*

Richardson was concerned that $\Delta x/\Delta t$ might not have a limit in a turbulent fluid. Examples of *hyphenated velocities* which do have a clearly defined meaning are the one-hour or three-second wind. The one-hour wind is the wind velocity averaged over an hour. The three-second wind is the maximum three second average velocity in an hour interval unless another interval is stated. The three-second wind gust is about 30% higher than the one-hour average.

Wind speeds also vary with altitude. Friction at the water surface reduces the wind speed near the boundary. Wind speeds increase with height through the atmospheric boundary layer. The speed at 30 m height is about 15% higher than that at the common anemometer height of 10 m. Unless the averaging time and height of a wind measurement are given, that measurement is not very useful.

The standard offshore engineering method for converting wind speeds from one averaging period and height to another is given by Standards Norway (NORSOK) [3.4] and serves as the basis for the ANSI (American National Standards Institute)/API [3.1] recommended practices. These guidelines give the wind speed $u(z,t)_o$ at height z above mean sea level for averaging period t_o as

$$u\left(z,t_o\right)=U\left(z\right)\left[1-0.41I_u\left(z\right)\ln\left(\frac{t}{t_o}\right)\right], \qquad (3.1)$$

where the one-hour mean wind $U(z)$ is given by a modified logarithmic profile that depends on the one-hour

mean wind speed at 10 m elevation, $U(10)$, as given in (3.2) and (3.3)

$$U(z) = U(10)\left[1 - C\ln\left(\frac{z}{10}\right)\right], \tag{3.2}$$

$$C = 0.0573\sqrt{1 + 0.15U(10)}, \tag{3.3}$$

and the wind speed at other averaging periods given in (3.1) depends on the turbulence intensity $I_u(z)$ defined as the standard deviation of the wind speed at height z, $\sigma(z)$, divided by the one-hour mean wind speed at height z, $U(z)$. According to the API standard

$$I_u(z) = 0.06[1 + 0.043U(10)]\left(\frac{z}{10}\right)^{-0.22}. \tag{3.4}$$

Note that the equations use units of meters for height and m/s for velocity. Equations (3.1)–(3.4) are based on an extensive set of wind measurements made from a tower on a small islet off the coast of Norway. While all these measurements were made in extra-tropical storms, the equations are commonly used for tropical storms as well, e.g., [3.1]. However, recent work by *Vickery* et al. [3.5] shows that the equations from *ESDU* (Engineering Sciences Data Unit) [3.6, 7] fit the observations from tropical cyclones noticeably better than the *NORSOK Standards* [3.4] equations.

The original ESDU equations are more complicated than the *NORSOK Standards* [3.4] equations but *Vickery* et al. [3.5] found a number of simplifications which apply in cases of engineering interest and yield the following equations

$$U(z) = \frac{u_*}{k}\ln\left(\frac{z}{z_o}\right), \tag{3.5}$$

where U is the one-hour averaged velocity at a height of z above MSL (mean sea level), k is von Karman's constant (0.4), u_* is the friction velocity, and z_o is the roughness height. The latter two are defined as

$$u_* = U(10)\sqrt{C_d}, \tag{3.6}$$

$$z_o = 10e^{-k/\sqrt{C_d}}, \tag{3.7}$$

where C_d is the drag coefficient at 10 m above sea level. There are many expressions cited in the literature for the drag coefficient but *Vickery* et al. [3.5] chose *Large* and *Pond* [3.8]

$$C_d = 1.2 \quad 4 \le U(10) < 11\,\mathrm{m\,s^{-1}}, \tag{3.8}$$

$$C_d = [0.49 + 0.065U(10)]\,10^{-3} \quad 11 \le U(10) < 25\,\mathrm{m\,s^{-1}}, \tag{3.9}$$

where U must be in units of $\mathrm{m\,s^{-1}}$. For hurricanes, *Vickery* et al. [3.5] suggests restricting the maximum value of C_d based on *Vickery* et al. [3.9] to

$$C_{dMax} = (0.0881r + 17.66)10^{-4}, \tag{3.10}$$

where r is the horizontal distance from the storm center to the site. The value in (3.9) exceeds the value in (3.10) at about $22\,\mathrm{m\,s^{-1}}$ for $r = 20$ km. More will be said shortly about the cap on C_d.

The peak wind gusts for averaging time t_o can be calculated with

$$u(z, t_o) = U(z)\left[1 + g(\vartheta, t_o, z)\,I_u(z)\right], \tag{3.11}$$

where $I_u(z)$ is defined in [3.4]. Using the simplifications described by *Vickery* et al. [3.5]

$$\sigma(z) = \frac{7.5u_*\left[0.538 + 0.09\ln\left(\frac{z}{z_o}\right)\right]}{1 + 0.156\ln\left(\frac{u_*}{fz_o}\right)}, \tag{3.12}$$

where f is the Coriolis parameter.

The peak factor $g(\vartheta, t_o, z)$ is a function of the length of the record (typically 1 h), T_o, and the zero crossing period, ϑ, or

$$g(\vartheta, t_o, z) = \sqrt{2\ln(T_0\vartheta)} + \frac{0.577}{\sqrt{2\ln(T_0\vartheta)}}\frac{\sigma(z, t_o)}{\sigma(z)}, \tag{3.13}$$

where the variables are defined as

$$\sigma(z, t_o) = \sigma(z)\left[1 - 0.193\left(\frac{T_u}{t_o} + 0.1\right)^{-0.68}\right], \tag{3.14}$$

$$\vartheta = \frac{0.007 + 0.213\left(\frac{T_u}{t_o}\right)^{0.654}}{T_u}, \tag{3.15}$$

$$T_u = 3.12z^{0.2}. \tag{3.16}$$

Neither NORSOK or ESDU equations used to calculate wind at various time averages apply to short-lived squalls because the wind speed is not statistically stationary in them. Nor is it clear how well the wind profiles apply.

Squalls are important for engineering design and operations in low latitudes or where the wave fetch is limited by land. Squall lines often originate onshore where convection is strongest and then propagate with the mean winds. When a squall line passes a site, the wind speed rapidly increases and then decays over a few hours, perhaps with some oscillations. Squalls are generally modeled in design analyses as time series scaled up from actual measured squall records.

Compliant structures in deep water can have natural periods much longer than the vibration periods of fixed structures. Resonant oscillations of these structures can

be excited by long period variations in wind speeds. Knowledge of the wind spectrum is required in order to calculate the response. Again, the standard engineering wind spectrum is that given by NORSOK [3.4]. It is

$$S(f,z) = \frac{(320\,\mathrm{m^2\,s^{-1}})(U(10)/U_{\mathrm{ref}})^2(z/z_{\mathrm{ref}})^{0.45}}{\left(1+\tilde{f}^{0.468}\right)^{3.561}}\,, \tag{3.17}$$

where

$$\tilde{f} = (172\,\mathrm{s})f\left(\frac{z}{z_{\mathrm{ref}}}\right)^{2/3}\left(\frac{U(10)}{U_{\mathrm{ref}}}\right)^{-0.75}\,. \tag{3.18}$$

The reference elevation above the mean sea surface z_{ref} is 10 m, and the reference wind speed U_{ref} is $10\,\mathrm{m\,s^{-1}}$.

The drag of wind on the sea surface produces waves and currents, so accurate knowledge of the drag as a function of wind speed is important for modeling waves and currents. The drag coefficient depends on atmospheric stability, but in the high winds that interest us, the equations for neutral conditions usually apply. The wind stress τ is equal to $u_*^2\rho_{\mathrm{o}}$ where u_* is the so-called friction velocity given by (3.6) and ρ_{o} is the air density. The friction velocity is dependent on the drag coefficient, C_{d}. There are many formulations for C_{d} but one of the more popular is from *Large* and *Pond* [3.8] as shown in (3.8) and (3.9). For years, many metocean experts used (3.9) well above the maximum $25\,\mathrm{m\,s^{-1}}$ suggested by *Large* and *Pond* [3.8], but more recent hurricane measurements by *Powell* et al. [3.10] showed that the drag coefficient starts to level off around $30\,\mathrm{m\,s^{-1}}$. They conjecture that high wind speeds create a layer of sea foam and bubbles at the sea surface thus dropping the effective roughness of the sea. This reasoning was supported by the laboratory experiments by *Donelan* et al. [3.11]. *Powell* [3.12] provided additional support from field measurements. *Frolov* [3.13] showed that capping the drag coefficient at 0.0022 was essential to model currents measured in Hurricane Katrina in the Gulf of Mexico.

3.2.2 Waves

Waves grow because of the input of momentum from the wind, but knowledge of the exact mechanism by which this momentum is transferred has remained elusive. The fundamental mechanism, first proposed by *Miles* [3.14], seems to be a resonance interaction between wave-induced pressure fluctuations and the waves. As the waves propagate, they are modified by nonlinear interactions between different frequencies, frictional dissipation and wave breaking. A fuller discussion of wave generation and modeling is given in Sect. 3.4.

Ocean waves are a complex and irregular function of space and time. This complexity is best understood by considering the sea surface to be the superposition of many cosine waves, as shown in Fig. 3.1. Each of the cosine waves is characterized by a period T and an amplitude a. The height of a cosine wave $H = 2a$. Later we will see that this relation is not true for real waves. The wave frequency $f = 1/T$ is the inverse of the wave period. The wave length L between two crests is given by $L = gT^2/2\pi$ in deep water. The phase speed or celerity is given by $c = L/T$. A more detailed discussion of wave kinematics and dynamics is given in Chap. 2.

A wave record measured at a point can be analyzed into its component cosine waves using the Fourier transform. This transform gives the amplitude and phase of each component. It includes all of the information and irregularity of the original record. This is too much detail for most purposes because an individual wave record is a single realization of a random process. We would usually prefer to know the distribution of wave energy with frequency in the underlying process. If $F(f)$ is the Fourier transform of the wave record, its power

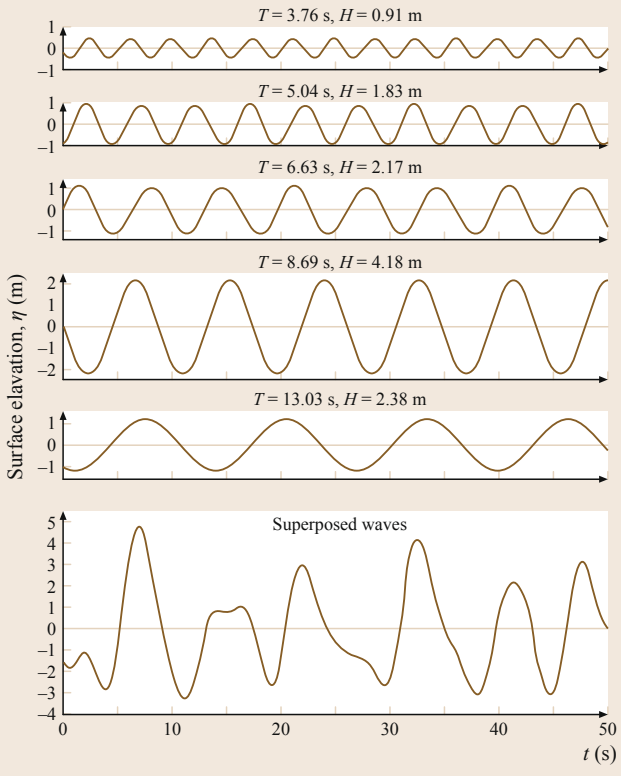

Fig. 3.1 Superposition of cosine waves to make regular waves

spectral density is given by

$$S(f) = 2\,|F(f)|\,/n\,, \tag{3.19}$$

where n is the number of points in the time series. Taking the square of the amplitude of the Fourier transform removes the phase information from the record, but the result is still a very irregular function of frequency. A smooth version of the spectrum is found by filtering $S(f)$ over frequency or averaging spectra from several ensembles. *Glover* et al. [3.15] give a good, practical guide to the details of calculating power spectra.

Once the spectrum is known, the significant wave height H_S is defined as

$$H_S = 4\int S(f)\mathrm{d}f = 4\sigma\,, \tag{3.20}$$

where σ is the variance of the wave record. The peak wave frequency is the frequency at the highest point in the power spectrum. The mean frequency f_m and zero-crossing frequency f_z are given by

$$\begin{aligned} f_m &= m_1/m_0\,,\\ f_z &= m_2/m_0\,. \end{aligned} \tag{3.21}$$

Where the spectral moments are calculated as

$$m_n = \int S(f) f^n \mathrm{d}f\,. \tag{3.22}$$

Wave spectra for design are generally specified in an analytic form. The most popular of these is the Joint North Sea Wave Observation Project (JONSWAP) spectral form. It is given by

$$S(f) = \beta f^{-5}\exp\left[-\frac{5}{4}\left(\frac{f}{f_p}\right)^{-4}\right]\gamma^{\exp\left[-\frac{(f-f_p)^2}{2\sigma^2 f_p^2}\right]}\,, \tag{3.23}$$

where

$$\sigma = \begin{cases}\sigma_a = 0.07 \text{ if } f \le f_p\,,\\ \sigma_b = 0.09 \text{ if } f > f_p\,.\end{cases} \tag{3.24}$$

The JONSWAP spectrum was originally proposed to describe fetch-limited waves, but by adjusting its parameters, it can give a reasonable fit to most single-peaked spectra. Given the significant wave height, peak period, and peak enhancement factor γ, *Goda* [3.16] showed that the scale factor is approximated by

$$\beta = \frac{5}{16}H_s^2 f_p^2\left(1.15 + 0.168\gamma - \frac{0.925}{1.909+\gamma}\right)^{-1}\,. \tag{3.25}$$

The JONSWAP spectrum can be used to describe most spectra with single peaks. However, combinations of sea and swell in storms can result in spectra with two or more peaks. The *Ochi–Hubble* [3.17] spectrum is often used to describe double-peaked spectra in areas subject to tropical storms. It is the sum of two Gamma distributions

$$S(f) = \sum_{j=1}^{2}\frac{H_{Sj}T_{Pj}(\lambda_j+0.25)^{\lambda_j}}{4\Gamma(\lambda_j)(T_{Pj}f)^{(4\lambda_j+1)}}\exp\left(-\frac{(\lambda_j+0.25)}{(T_{Pj}f)^4}\right)\,. \tag{3.26}$$

This spectrum has three parameters for each of the two wave systems, a significant wave height, a peak period, and a shape factor λ.

The *Torsethaugen* and *Haver* [3.18] double-peaked spectrum is also the sum of two Gamma functions. Their paper gives parameters which were fit to measurements made in the North and Norwegian seas.

The spectral representation of waves makes it natural to think of them as a Gaussian random process. The envelope of a Gaussian process has a Rayleigh distribution, and to first order, so do wave and crest heights. However, the trough preceding a large crest is likely to be on a lower part of the envelope. Trough to crest wave height differences are, therefore, slightly smaller than given by the Rayleigh distribution

$$P(h) = \exp\left[-2\left(\frac{h}{H_S}\right)^2\right]\,, \tag{3.27}$$

where H_S is four times the standard deviation of the wave trace.

The empirical distribution suggested by *Forristall* [3.19] accounts for the observed reduction in wave height and has been shown to agree with many observations, including measurements in water depths less than 30 m. It is given by

$$P(h) = \exp\left[-2.263\left(\frac{h}{H_S}\right)^{2.126}\right]\,. \tag{3.28}$$

Crest heights in steep waves are higher than those predicted by Gaussian theory because the waves are nonlinear. The distribution produced from simulations of second-order waves by *Forristall* [3.20] accounts for the most important nonlinearity. It is a Weibull distribution of the form

$$P(\eta_2) = \exp\left[-\left(\frac{\eta}{\alpha H_s}\right)^{\beta}\right]\,, \tag{3.29}$$

where

$$\alpha = \sqrt{\frac{1}{8}} + 0.2568 S_1 + 0.0800 Ur\,,$$
$$\beta = 2 - 1.7912 S_1 - 0.5302 Ur + 0.2824 Ur^2\,. \quad (3.30)$$

The mean steepness and Ursell number are given by

$$S_1 = \frac{2\pi}{g}\frac{H_s}{T_1^2}\,,$$
$$Ur = \frac{H_s}{k_1^2 d^3}\,. \quad (3.31)$$

The wave and crest height distributions in (3.27)–(3.29) do not take into account higher-order nonlinearities that may lead to rogue waves. The evidence for rogue waves and possible theoretical reasons for their existence are discussed in Sect. 3.7.9.

Representing waves as a Fourier series makes the tacit assumption that the waves do not break. A Fourier series, and most wave theories, cannot handle double-valued time series. Yet during a storm, the sea is covered with breaking waves [3.21]. Fortunately, almost all of these breaking events are spilling events that only affect a small portion of the wave crest. Because of this design calculations in deep water typically ignore breaking. Measured forces and the survival of structures in severe storms indicate that neglecting deep water breaking waves does not change wave forces significantly [3.22].

The situation is completely different near the shore. The transformation of wave spectra near the shore is modeled by specialized hindcasting tools such as SWAN (Simulating WAves Nearshore) [3.23]. Shoaling waves can steepen rapidly and form a plunging breaker. *Longuet-Higgins* and *Cokelet* [3.24] succeeded in integrating the equations of motion in a free surface flow past overturning many years ago. Such computations show that particle velocities in the crest of plunging breakers can exceed the phase velocity of the wave and are much higher than particle velocities in non-breaking waves. *Christou* et al. [3.25] used a boundary element method to calculate the particle kinematics in a shoaling wave shown in Fig 3.2. The velocities in the crest are about twice the velocities calculated before the wave breaks.

3.2.3 Currents

Knowledge of ocean currents is important when designing, building, or operating an offshore structure. Wind-driven currents are the most important consideration for structural design because their velocities add to wave particle velocities. Wind stress imparts momentum to the sea surface. Turbulent processes mix the momentum downward. The Coriolis force rotates the resulting currents (to the right in the northern hemisphere and to the left in the southern hemisphere). A fuller discussion of wind-driven current generation and modeling is given in Sect 3.4.

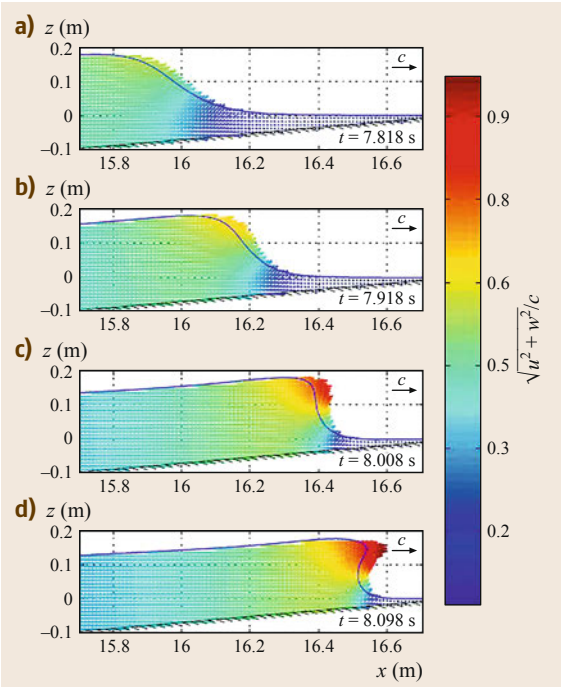

Fig. 3.2a–d Particle velocities in a shoaling breaking wave calculated using a boundary element method (after [3.25])

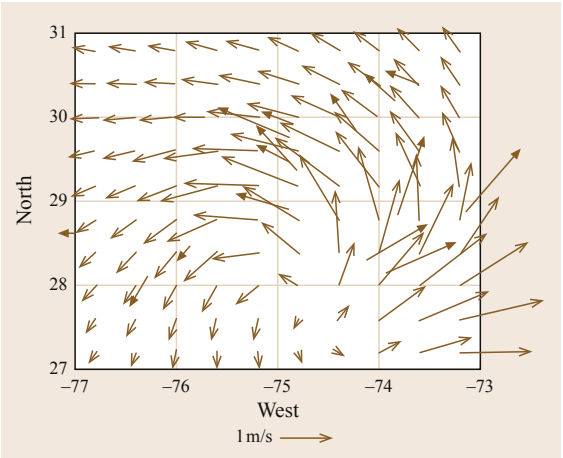

Fig. 3.3 Currents measured near the surface in Hurricane Gloria (1985). The *solid arrows* are measurements from air-dropped expendable current profilers and the *open arrows* are from a one-dimensional current model (after [3.26])

In the northern hemisphere, wind-driven currents are particularly strong on the right-hand side of a hurricane track. There, the current rotation due to Coriolis is often close to resonance with the turning of the wind stress as the hurricane passes, so near-surface currents can exceed 2 m s^{-1}. Figure 3.3 shows an example from Hurricane Gloria in 1985 [3.26]. At the time of the measurements, the hurricane center was at 28.75°N, 74.98°W and moving toward the north-northwest. The closed arrow heads show measurements made with air-dropped expendable current profilers and the open arrow heads show results from a one-dimensional (1-D) numerical model that used the turbulence closure model of *Kantha* and *Clayson* [3.27].

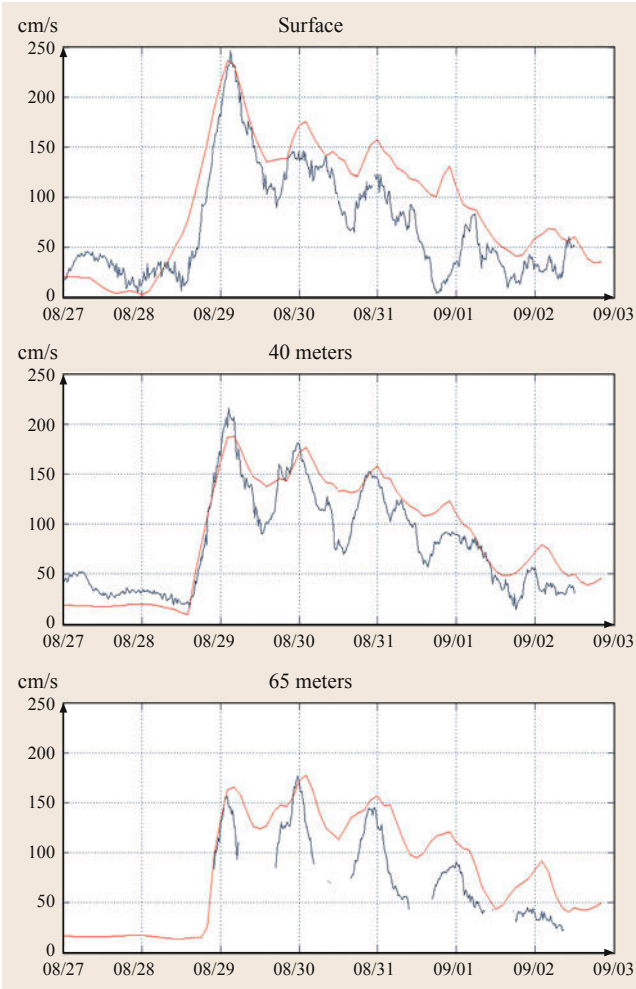

Fig. 3.4 Currents generated by Hurricane Katrina at the Telemark platform in the Gulf of Mexico. The *blue lines* are from the measurements and the *red lines* are from a three-dimensional (3-D) numerical model. The three panels show the current speeds at three depths

The downward propagation of wind-driven momentum is constrained to the upper water column by vertical stratification if it exists. Strong stratification is usually found at most sites in water depths greater than about 30–60 m during the summer months. *Kantha* and *Clayson* [3.28] give a detailed discussion of mixing in vertically stratified flows. Both measured and modeled currents are much stronger on the right-hand side of the storm because the Coriolis rotation is in the same direction as the wind stress rotation. The agreement between measured and modeled currents is good except for a direction difference to the east of the storm center.

Friction in deep water is extremely low, so wind-driven currents can persist as inertial currents for several days after the wind dies out. The rotation of the earth, through the Coriolis force, causes these inertial currents to rotate clockwise (in the northern hemisphere). The rotation period is $\pi/\Omega \sin \Phi$, where Φ is the latitude and Ω is the earth's rotation rate (2π/day). Figure 3.4 shows currents measured during and after Hurricane Katrina in the Gulf of Mexico [3.13]. The peak wind speed was at about the same time as the peak current early on August 29 2005, but the inertial currents persisted for 7 days after that when the wind was essentially calm.

Deep water structures must often contend with the permanent strong current systems that exist near the margins of the ocean. Examples include the Gulf Stream, the Loop Current, the Brazil Current, Kuroshio, and the Somali Current. Figure 3.5 shows these and many others. *Tomczak* and *Godfrey* [3.29] give a good descriptive introduction to these current systems.

Most of these currents are permanent features of the oceanic circulation. However, their position and strength can vary greatly. When they depart from the shelf break, they can often have large meanders and shed eddies than can persist for months [3.30]. Current speeds in these systems can exceed 2 m s^{-1} with speeds over 1 m s^{-1} down to 200 m.

The best design information for these current systems comes from combining remote sensing of the current positions with in situ measurements of current profiles. These techniques have been applied extensively in the Gulf of Mexico to study the Loop Current. The studies have led to the development of a kinematic hindcast model for Loop Current eddies that uses historical eddy positions and shapes as input [3.31].

The external astronomical tide generates weak currents in the deep ocean. Tidal currents are typically less than 10 cm s^{-1} in deep water. In shallower water tidal currents can exceed 2 m s^{-1} and must be considered in the design of facilities such as floating LNG (liquefied natural gas) terminals. Tides and tidal currents are predictable compared to other oceanographic phenomena,

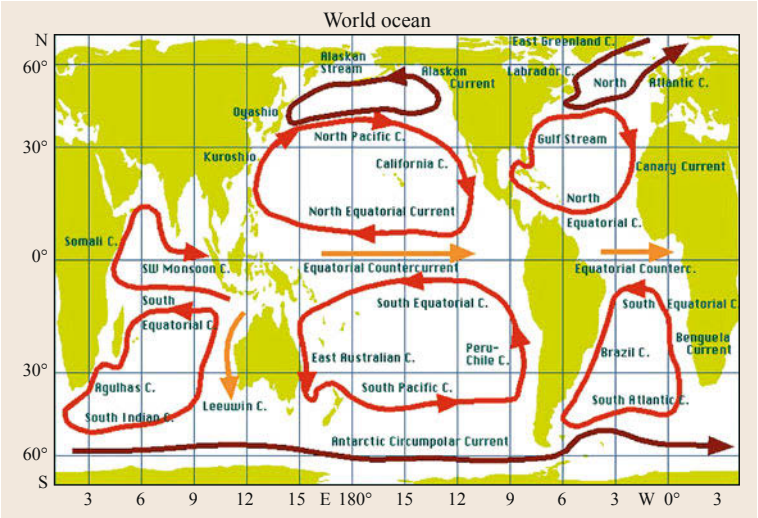

Fig. 3.5 Major current systems of the world

so it only takes a few weeks of measurements followed by harmonic analysis to enable multiyear prediction. The numerical models discussed in Sect. 3.4 also do well predicting tidal currents.

In waters that are strongly stratified in the vertical, the external tide in conjunction with sharp bathymetric features can generate a strong internal tide that is characterized by internal waves and possibly solitons with amplitudes of up to 40 m, phase speeds of about 50 cm s^{-1}, and wavelengths of several kilometers [3.32]. As these waves approach shallower water, they can break and cause high velocities and scouring of the seabed [3.33].

A power spectrum of current measurements typically shows a broad peak at periods of a few days corresponding to the motion of weather systems. There are then sharp peaks at the inertial period and any tidal periods that are important at that site. Measurements in laboratory flumes often show high frequency turbulence with amplitudes of as much as 5% of the mean flow speed. That turbulence strongly affects vortex-induced vibrations of cylinders, so it is important to understand whether such turbulence exists in open ocean currents. *Mitchell* et al. [3.34] made turbulence measurements in a Loop Current eddy using a towed body with a specially configured acoustic doppler current profiler (ADCP). The most energetic events had speed scales of only 1 cm s^{-1}. The typical and average values are more than ten times smaller. *Dhanak* and *Holappa* [3.35] made similar measurements using an autonomous underwater vehicle (AUV). These measurements of low turbulent intensity were made in deep water far from land. Turbulence is expected to be higher in shallow water and near the surface or bottom.

3.3 Measurements

Metocean criteria ultimately trace their roots to measurements or models. While models have become the predominant source data, measurements are still needed to provide boundary conditions and/or initial conditions and to validate or calibrate the model. In the case of small-scale ocean currents or atmospheric storm systems (e.g., squalls), modeling accuracy is problematic in large part because of a lack of understanding of the fundamental physics of geophysical fluids at small length and time scales. For these processes, measurements remain the dominant source of input data for metocean criteria.

Measurements can come from many different sources, including air or satellite-based sensors, vessel-mounted instruments, dedicated moorings, bottom-mounted instruments, Lagrangian drifters, and most recently, automated mobile platforms such as gliders or AUVs. Some of the more common and useful sources are described in further detail below.

3.3.1 Historical Storm Databases

Observations from ships formed the basis for the first database of winds and waves providing nearly global coverage. Wind speeds taken from ships are often measured with an anemometer, but waves are usually based on a sailor's visual observations. As one might expect, the primary challenge in using human observations is

to remove bias and reduce scatter. These wind measurements also have significant error because a ship's superstructure distorts wind flow patterns. *Thomas* et al. [3.36] discuss this issue in detail. Of particular concern with all ship observations is the so-called fair weather bias – the tendency for ships to avoid storms and thus underestimate the true probability of larger waves and winds. A number of attempts were made to remove bias and scatter [3.37] and these efforts eventually culminated in the work of *Hogben* et al. [3.38] who used observations from ships passing close to instrumented buoys to develop corrections that largely removed bias, at least in the North Atlantic. However, as *Hogben* et al. [3.38] point out, they were not nearly as successful in the southern hemisphere where there are far fewer offshore instruments. Nor could they do much about the scatter inherent in subjective human observations.

Another important historical dataset is the so-called HURDAT (National Hurricane Centers HURricane DATabases) best-track data maintained and distributed by NOAA (National Oceanic and Atmospheric Administration) [3.39] and documented by *Jarvinen* et al. [3.40]. It contains the time histories of tracks, peak winds, central pressure, and radius for historical North Atlantic tropical storms from 1851 to the present. NOAA provides similar information for the eastern North Pacific but only from 1949 to the present. The NOAA GTECCA (global tropical and extratropical cyclone climatic atlas) database contains historical track data for global storms up to 1995. For cyclones, the coverage starts as early as 1870 in the North Atlantic but not until 1945 for the other major basins of the world [3.41]. Coverage of Northern Hemisphere extratropical cyclones (winter storms) starts in 1965. Note that these datasets do not include detailed wind fields, just the basic intensity information that can be used to reconstruct the detailed wind fields using various methods such as parametric models [3.42]. Others have used the historical tracks to assimilate into much more sophisticated numerical models providing high resolution gridded wind velocity and pressure [3.43].

The accuracy of early storms in HURDAT have been questioned especially as climate scientists have tried to detect trends in historical storm severity. *Karl* et al. [3.44] provide a fairly recent summary of these findings. In part because of these questions, NOAA recently undertook a re-analysis of the data underlying HURDAT. These efforts have been documented in a series of publications, which are referenced in *Hagen* and *Landsea* [3.45]. Even after their reexamination, the researchers in this effort readily admit that large uncertainties remain in the storms prior to routine airborne observations which started in the early 1950s. *Emanuel* [3.46] and others have noted that there is even more uncertainty in basins outside the North Atlantic, and this uncertainty extends into the post-1950 era because of the lack of reconnaissance flights in most basins.

3.3.2 Satellite Databases

The study of the oceans and winds from space started in the 1970s with the launch of Skylab and Geos-3, which were equipped with a radar-altimeter, windscatterometer, radiometer, and infrared scanner. *Le Traon* [3.47] gives an overview of the state of operational satellites used in oceanography and to a lesser extent, meteorology.

One of the most useful sensors for ocean engineering has proven to be the altimeter. The first of many operational altimeters began with TOPEX (Ocean Topography Experiment)/Poseiden and ERS1 (Earth Resources Satellite) in 1991. Since 1998, there have been as many as four altimeters flying simultaneously because several altimeters are needed to properly resolve the length and time scales of energetic oceanographic phenomena such as mesoscale eddies, storm-driven waves, etc. The most used channels from the altimeter are wind velocity (speed and direction), wave height and period, and sea surface height.

Sea surface height from the operational altimeters is available in near real time and in historical archives from various sites [3.48–50]. Though accuracy varies by satellite, typical RMS (root mean square) errors are less than 3 cm [3.51]. These heights are useful in tracking geostrophic ocean currents and developing comprehensive maps of astronomical tides in deeper water, the latter being prohibitively expensive before the advent of satellite altimeters. *Shum* et al. [3.52] assessed 20 of these tidal models and found many to be accurate to better than 2 cm.

Wind speed and wave height and period measurements from the operational satellite altimeters are available over the web [3.53–55] but these are typically organized by individual tracks for each satellite or statistics from several satellites averaged over large areal blocks. The track data must typically be filtered to eliminate periods with heavy rainfall or close passage to land. Several companies offer commercial products with fully analyzed databases that can be accessed with their proprietary software [3.56, 57].

Numerous researchers have investigated the accuracy of altimeter-derived winds and waves, e.g., [3.58, 59]. These efforts show that there is a systemic bias unique to each satellite but it is easily corrected leaving an RMS difference with buoy current meter measure-

ment of about 30 cm for significant wave height and 1.5 m s^{-1} for wind speed. Some of this difference is due to buoy measurement error.

Synthetic aperture radar (SAR) has been sporadically deployed starting with Seasat. By far the most successful application was the QuikSCAT (quick scatterometer) satellite which launched in 1999 and continued to operate until late 2009. Unlike altimeters which only measure along their track, SARs measure over a wide swath. In the case of QuikSCAT the swath was 1800 km, resulting in the coverage of 90% of the Earth's surface in a single day. Results were widely used to improve forecast models, so archived model results are one of the best ways to use QuikSCAT since native measurements have many hours between samples. Archived QuikSCAT measurements are downloadable from the web [3.60].

SAR from various satellites has also been used to measure ice coverage, oil slicks, waves and currents as described in [3.47]. Unlike the altimeter, SAR measures wave direction in addition to wave height and period. Furthermore, it makes those measurements over a wide swath. Several commercial satellite wave databases include SAR measurements. SAR also has significant theoretical advantages over other sensors when it comes to identifying near-surface currents. Unlike the altimeter, SAR can identify non-geostrophic current fronts (i. e., currents that cause no detectable change in sea surface height). However, analysis of SAR images is complex in part because artifacts can be caused by natural surfactants, and also because a minimum wind threshold is needed. These disadvantages have limited the use of SAR for the measurement of waves and currents.

The wind velocity, wave height/period, sea surface temperature, and sea surface height measurements from satellites are routinely assimilated into ocean models to provide nowcast and forecast products [3.61–65]. It is probably in this form that the satellite results are the most valuable, since the models are able to interpolate between the large gaps in time and space that invariably appear in all sources of satellite measurements. Some of the more popular modeling products that are publicly available are described in Sect. 3.4.

3.3.3 In Situ Measurements

Instruments are commonly deployed at a fixed offshore location using quasi-permanent facilities like oil production jackets, moorings with subsurface or surface buoyancy, or quasi-permanent coastal facilities.

No matter how instruments are deployed, the ocean currents at a particular site are commonly measured by an acoustic doppler current profiler (ADCP). The accuracy and range of the instrument mostly depends on the transmission frequency, which ranges from 38 to 1200 kHz for commercially available instruments. ADCPs offer many advantages over earlier technologies. They are solid state instruments which are not easily fouled by marine growth. Perhaps most attractive of all is their ability to accurately measure at up to 1000 m from the instrument. That said, ADCPs can yield problematic results which may not be obvious to the untrained eye, especially in cases where the primary sources of scatter are mobile like plankton or fish scatterers or where the scatterer is fixed (i. e., risers on an offshore platform). *Hogg* and *Frye* [3.66] and *Magnell* and *Ivanov* [3.67] give some good examples of artifacts that can contaminate ADCP measurements.

High-frequency radar is a somewhat newer and more expensive technology than ADCPs but its use has grown rapidly in the past 5 years, largely because HF radar (High Frequency radar) can map surface currents over areas of the order of 1000 km^2 using only two coastal installations. Dozens of HF radars have been installed along most of the eastern and western coastlines of the US [3.68] and are available in real time from NODC [3.69]. *Paduan* and *Graber* [3.70] discuss the basic technology along with some of its limitations and provide numerous references.

Surface gravity waves can also be accurately measured with ADCPs [3.71] and HF radar [3.70]. However, most historical measurements have been taken with surface-following buoys equipped with accelerometers and perhaps augmented by roll sensors to measure directionality. Many developed countries with coastlines have deployed such instruments for several decades and the US results are available from the National Data Buoy Center (NDBC). *Pandian* et al. [3.72] summarize the limitations of accelerometer-based systems. The most noteworthy is the tendency of the smaller buoys to be pulled under water or be tossed about in larger waves.

Wind velocity has typically been measured with mechanical anemometers using some type of impeller. Most offshore buoys are still equipped with this type of sensor. While these measurements are useful most of the time, questions have been raised about their accuracy during large wave events, especially for the smaller buoys. Better sensors are needed to get detailed profiles. The least expensive of these better sensors are based on LIDAR (light detection and ranging; optical) or SODAR (sonic detection and ranging; sound). Both systems use a Doppler principle to determine velocity and are capable of measuring multiple bins over ranges of roughly 200 m above the sensor. Freeman et al. [3.73] compare a LIDAR profiler to more traditional anemometers and show excellent accuracy. In contrast, *de Noord* et al. [3.74] raise serious con-

cerns about the accuracy and consistency of SODAR measurements, especially in storm conditions or near obstructions.

Regardless of the variable being measured, interference from nearby man-made or natural features must always be considered. *Cooper* et al. [3.75] discuss some of the challenges of taking metocean measurements off of oil-industry facilities like jackets. Similar issues crop up with wind measurements from stations on the coast, and these have been well studied and codified into numerous recommended practices, e.g., ASCE (American Society of Civil Engineers) 7-05 [3.76] and EUROCODE [3.77].

Another issue that frequently arises is the *averaging interval*. As explained in Sect. 3.2, it is especially important for wind velocity because there is considerable wind energy at higher frequencies. Another important factor affecting winds is the elevation of the measurement above the sea or land, which is also explained further in Sect. 3.2. In short, specification of wind velocity should always include a minimum of four variables: speed, direction, averaging interval, and elevation. Similar issues arise with ocean currents, although they tend to be less pronounced because of the inherent difference in the turbulence spectra of winds and currents. In the case of waves, the issue of elevation is irrelevant. However, the temporal scale of the sampling is important when calculating statistical values like significant wave height. This issue will be discussed in more detail in Sect. 3.7.8. A good general rule is that the minimum sampling period for wave spectra should never be less than 20 min.

As indicated above, a great deal of in situ measurements, including wind velocity, are reported in real time and archived at the NDBC. Another good source for measurements from limited duration deployment is the National Oceanographic Data Center (NODC).

3.3.4 Mobile Measurements

Instrumented wind measurements have been taken from vessels for decades. In the 1980s, oceanographers began mounting ADCPs on ships [3.78]. In both cases, correcting for ship motion presents challenges but GPS (global positioning system) has largely resolved these. Vessel-based wind measurements remain susceptible to flow interference from the ship superstructure.

Starting in the 1980s there was a rapid increase in the use of semi-automated or fully automated mobile platforms, starting with Lagrangian drifting buoys whose paths are tracked by satellite, e.g., [3.79]. With the advent of GPS, the drifter position could be precisely tracked and accurate velocities estimated. *Coholan* et al. [3.80] describe the use of drifters to measure the strong currents associated with the Loop Current in the Gulf of Mexico.

Autonomous underwater vehicles (AUV) have not been used much for current measurements because of their cost and limited range. However, as mentioned in Sect. 3.2.3, *Dhanak* and *Holappa* [3.35] made good use of an AUV to measure turbulence.

In the late 1990s gliders became increasingly common thanks to their light weight (50–100 kg), small size (2 m), relatively low cost ($100 k), and lengthy deployment capability (several months). *Rudnick* et al. [3.81] describe the technology in some detail. Though gliders can only progress horizontally at about 1 knot, their long endurance and the ability to remotely pilot them make gliders highly cost effective and adaptable. The present crop of sophisticated gliders can reach 1000 m depth, though this will likely be extended in the near future. Gliders have limited payload and power capacities. They are typically equipped with CTD (conductivity-temperature-depth) sensors, although other sensors have been deployed, including fluorometers, dissolved oxygen, and pH. A time-mean, depth-averaged water velocity can be derived from the surfacing coordinates of a glider. Efforts are underway to incorporate ADCPs into a glider, though power consumption and obtaining an absolute velocity measurement in deeper water remain challenges.

The Global Drifter Program [3.82] began deploying large numbers of drifting buoys in 1999 as a fundamental component of the global ocean observing system (GOOS) and as of August 2011, nearly 11 000 buoys had been deployed worldwide and are available from the GDP website. Unfortunately, there is not yet an equivalent to NDBC for obtaining real-time or archived measurements from other mobile instruments.

3.4 Modeling

Since the advent of relatively cheap computing power in the past 30 years, numerical modeling has started to replace measurements as the primary feedstock for metocean criteria. There are many reasons for this change.

Models are typically much less expensive than measurements and can provide results at a specific site and for durations of many years. In contrast, one rarely has the luxury of having more than a year or two of

measurements at their site of interest. Calculating extreme criteria, say the 100-y event, from short duration measurements will give values with extremely large uncertainty and a high likelihood of major bias. Even 1–2 years of measurements are often inadequate to capture interannual variability.

3.4.1 Winds

Extratropical wind field calculations generally use pressure contours on archived meteorological analysis charts as input information. A balance between the pressure gradient and the Coriolis force gives the wind speed. That calculation must be modified using a boundary layer model to find the desired wind speed and direction at 10 m elevation.

An important modeling hindcast dataset is the NCEP (National Centers for Environmental Prediction) reanalysis product [3.83]. The first phase is documented in *Kalnay* et al. [3.84] and consists of a numerical model hindcast of wind and pressure fields from 1948 to the present. Observations from ships, satellites, and fixed sites have been assimilated into the model. A follow on effort, NCEP/DOE (Department of Energy) Reanalysis II, covered 1979–2010 [3.85] and included far more satellite observations, as well as bias correction and a more refined model. *Saha* et al. [3.86] describe the most recent model and processing.

The NCEP data is on a rather coarse grid, so for storm hindcasts it probably needs to be augmented with an analysis by an experienced meteorologist using all available data. Wind speeds derived from satellite scatterometers can be very helpful in this process.

Hurricanes offer a special challenge since they are small features relative to the scale of regular weather charts. To compensate for this, kinematic or dynamic hurricane models are often used to hindcast hurricane winds. The models typically begin with specification of the atmospheric pressure field. Winds due to that pressure field are found from the gradient wind balance equations. Then the wind is adjusted to 10 m elevation using a boundary layer model. *Holland* [3.42] introduced the radial pressure model

$$p(r) = p_c + \Delta p \exp\left[-\left(\frac{R_{max}}{r}\right)^B\right], \qquad (3.32)$$

where r is the distance from the center of the storm, R_{max} is the radius to maximum winds, Δp is the central pressure deficit, and the Holland B parameter modifies the exponential shape of the pressure curve. If enough data is available, different pressure curves may be used in different storm quadrants. A second exponential function is now often added to account for secondary wind speed maxima. *Cardone* et al. [3.87] give a good description of how the pressure gradient is transformed to boundary layer winds. The Hurricane Research Division HWIND model [3.88] uses these methods to produce wind fields for Atlantic Basin hurricanes.

3.4.2 Waves

Komen et al. [3.89] describe how wave hindcasts solve the transport equation directional wave spectrum $S(f,\theta)$

$$\frac{\partial S(f,\theta)}{\partial t} + v\nabla S(f,\theta) = S_{in} + S_{nl} + S_{ds}\,, \qquad (3.33)$$

where v is the group velocity of the waves, so the left-hand side of the equation represents the advection of wave energy. The right-hand side of the equation schematically lists the source terms for the spectrum: S_{in} represents the input of energy from the wind, S_{nl} represents the nonlinear interactions between wave frequencies, and S_{ds} represents dissipation terms such as bottom friction and wave breaking. Only the nonlinear term is known theoretically, but because its computation is formidable it is greatly simplified in operational models. The other two terms must be parameterized based on experimental data and tuned to observed wave growth. The directional spectrum calculated from the model is summarized as significant wave height, peak and average wave periods, mean wave direction, and wave directional spreading.

The standard wave model, WAM (Wave Modeling Project), was created by an international consortium of wave modelers called the WAMDI group. The development of WAM is thoroughly described by *Komen* et al. [3.89]. WAM has been continually modified, and versions have been installed at many national forecast offices. The NOAA version, WAVEWATCH III, is available for download at ftp://polar.ncep.noaa.gov/pub/wwatch3/v2.22. That site also maintains an archive of forecast and hindcast wave data for US waters.

The accuracy of wave modeling crucially depends on accurate specification of the wind fields. For severe storms, this often requires hand analysis by an experienced meteorologist. Given good wind fields, RMS wave height accuracies of less than 10% can be achieved for extratropical storms [3.90] and for hurricanes [3.91].

The various NCEP reanalysis products have been used to force wave models and generate 50+ year hindcast databases, e.g., [3.92]. The primary limitation of these products (other than NARR (North American Regional Reanalysis)) is the relatively coarse spatial grid (2.5°) and temporal resolution (6 h). *Cardone* et al. [3.93] discuss some of the implications of

this coarse resolution on modeling extreme waves and winds. In short, the reanalysis products suffer from poor resolution of areas of high winds in extratropical storms and in virtually all parts of tropical storms.

3.4.3 Currents, Surge, and Tides

With the advent of relatively fast and inexpensive computers in the 1970s, numerical models of ocean currents in *shallow* water began to proliferate. While the numerical discretization differs, all these models solve a similar set of differential equations conserving mass and momentum, which are often referred to as the shallow water equations. Model output includes the time series of depth-averaged velocity and surface elevation at discrete grid points in the horizontal domain. This class of model is now routinely used to accurately simulate astronomical tides and wind-induced currents and surge in coastal waters where stratification in the water column is not important, typically in 30 m of water or less and beyond the influence of substantial river inflow. *Johnsen* and *Lynch* [3.94] provide numerous examples of these so-called two-dimensional (2-D) models. Several models such as MIKE 21 HD [3.95, 96] and ADCIRC [3.97] have good user interfaces and can be successfully applied by users with modest familiarity with numerical ocean modeling. The accuracy of these models of course depends on the specifics but assuming that the bathymetry and the initial and boundary conditions are specified accurately, modeled currents and surface elevations can achieve a 15% RMS error when compared to measurements.

A similar story can be told for stratified deeper waters but only for some types of forcing such as winds and external tides. Some examples are given in [3.94]. An example for hurricane-generated currents is given by *Frolov* [3.13], who used a 3-D model to accurately simulate the ocean response from Katrina and Georges, both during the initial phase of direct wind forcing and the subsequent phase of inertial oscillations. It is worth noting that during the Katrina simulations, a storm marked by Category 4 winds, Frolov had to cap the surface drag coefficient, as discussed in Sect. 3.2.

Three-dimensional current models can also accurately simulate the longer time and length scales of quasi-geostrophic currents like the Gulf Stream, provided that they have accurate boundary and initial conditions, which are typically provided by satellite altimeters. While these models can achieve less than 20% RMS error on large length scale processes, they have difficulty simulating processes of approximately 100 km or less [3.98, 99]. That is because these processes often exhibit baroclinic instabilities with small length and timescales that are undersampled by the present altimeter array. These limitations can be circumvented to some degree by assimilating fine-scale measurements from ships, drifters, gliders, etc. [3.99]. A number of models are publicly or commercially available, but the skill needed to effectively apply these models is much higher than for the 2-D models, in large part because the underlying physics of a stratified ocean (3-D) are far more complex than an unstratified one (2-D). Examples of generally usable 3-D models include HYCOM [3.100], ROMS [3.101], and MIKE 3 HD. As in the case of 2-D models, the numerical methods employed by 3-D models differ greatly, but the better ones are capable of modeling similar real-world situations with equivalent accuracy.

That is the good news. The bad news is that there are a host of other processes, many of them energetic, where numerical models yield RMS errors of more than 100%. Published examples are hard to find because poor matches tend to go unpublished. However, the authors' experience suggests models have great difficulty simulating internal (baroclinic) tides and solitons, turbidity currents, and river outflows. In these cases, data assimilation is usually impractical because of the short length and time scales of the characteristic processes. In addition, since these cases are dominated by small length scales where turbulence and mixing play an important role, the physics are not well understood. CFD (Computational Fluid Dynamics) may someday be a viable tool but not until computer capacity increases substantially.

A number of extensive data sets of ocean currents have been generated in the last decade and are readily available over the web. These models assimilate data from satellite measurements and sometimes buoy and drifter measurements. Some noteworthy and useful data sets include:

NOAA's RTOFS global model [3.102] provides forecasts up to 7 days. The historical forecasts are *not* downloadable at this time, though that may change in the future (personal communication, Hendrik Tolman, NCEP, Environmental Modeling Center, 23 Aug 2012). The model is based on HYCOM and is composed of curvilinear grid points with variable horizontal sizes spanning 5−17 km. It uses 26 hybrid layers/levels in the vertical.

The HYCOM global model provides forecasts up to 7 days and archives back to 2003, though until 2013 the archive only saved the modeled fields at midnight. The model uses a $1/12^\circ$ grid.

NCOM (Navy Coastal Ocean Model) regional models [3.103] provide forecasts up to 4 days. The historical forecasts are *not* downloadable at this time, though that may change in the future. The models use a $1/36^\circ$ version of the global NCOM model, a version of the

Princeton Ocean Model (POM). Nowcasts have been archived back to 2010. Other regional models are also available: RTOFS for the North Atlantic, MERCATOR for Mediterranean [3.104], and BLUElink for Australia [3.105]. These models assimilate satellite observations within their domain and take their boundary conditions from larger-scale global models.

When utilizing the archive data sets from 3-D models, one must keep in mind the weaknesses described earlier in this section. More specifically, these archived products will not adequately resolve the peak current during tropical cyclones. Nor will they be able to reliably replicate historical mesoscale features, though they may be able to reproduce the statistics of those features (e.g., reproduce the histogram of speed). In summary, if there are energetic ocean current processes with length scales of less than 100 km affecting the site of interest, model archives should only be used with caution. At the very least, several months (preferably much more) of local measurements should be obtained and used to validate and calibrate the model before relying on model results.

3.5 Joint Events

Most ships and offshore facilities are designed to withstand a load with a specific return interval of n years, e.g., the 100-year event. For many decades, offshore designers assumed that the n-y event was created by the simultaneous occurrence of the n-y wind, n-y wave, and n-y current (i. e., the so-called *n-y independent events*), all aligned in the same direction. However, about 30 years ago, metocean researchers started collecting detailed measurements during major storm events and realized that the peaks of winds, waves, and currents, in fact, did not occur simultaneously in direction or time and they began developing various techniques to account for this fact. The more popular ones are described next.

3.5.1 Response-Based Analysis

The simplest and perhaps most accurate way of estimating the n-y response is to feed a time series of wind, wave, current into a response model of the facility and then do an extreme analysis of a key response variable. For example, if a structural engineer designing the legs in an offshore jacket for the 100-y overturning moment (OTM). In the response-based approach, the structural engineer would first develop a fairly simple response function whose input variables include wind, wave, and current and whose output is the OTM. Second, the metocean time series is fed into the response function resulting in a time series of OTM. Third, a peak over threshold (POT) analysis is done, as described in Sect. 3.7.2 and the n-y OTM calculated. Finally, a set of winds, waves and currents that produce the OTM is found and used for detailed analysis.

Ewans [3.106] describes the application of the response-based approach to pipeline stability. *Heideman* et al. [3.107] provide one of the earliest examples of the approach and show that for a jacket-type structure in the North Sea, one can combine the 100-y wind and wave with an *equivalent* current that is 0.25 times the 100-y current to reach the 100-y OTM. Their case is perhaps on the extreme end of potential savings as it is situated in the North Sea where storm winds and waves are weakly correlated to the extreme current. Nevertheless, even in regions dominated by hurricanes where the metocean variables are highly correlated, ANSI/API [3.1] recommends that the 100-y wave can be combined with 0.95 of the 100-y wind speed and 0.75 of the 100-y surface current speed. A further 3% reduction of the current and wind is allowed if directionality is considered.

The response-based approach is versatile and can apply to the calculation of extreme loads like base shear or OTM in a jacket, extreme responses like the n-y heave in a ship, or operating conditions like the marginal probability distribution of pitch and roll. ANSI/API [3.1] recommends the response-based analysis as the preferred alternative. Part of the reason for the rise in popularity of response-based analysis is the increase in computer power, which has made the repetitive solution of fairly complex response functions feasible. Another enabling technology has been the advent of long-duration hindcast datasets of simultaneous wind, wave, and current time series derived from numerical models.

That said, the downside of response-based analysis is the need for a response model with sufficient complexity to accurately reflect the critical response of the facility yet with sufficient computational efficiency to run many thousands of times. Developing such response models can be daunting for complex floating systems like TLPs (tension-leg platform) or spars. Of course there are shortcuts in the analysis that can reduce the computational requirement yet still preserve accurate results. For instance, in the case of calculating extreme loads, the metocean time series can be truncated into a much smaller set of events that only considers the stronger storms. Obviously this approach does not work as well for developing operational criteria.

3.5.2 Load Cases

As discussed in the previous section, a response-based analysis is generally the preferred approach in developing extreme criteria, but in practice the response function is often not easily simplified, so metocean specialists are requested to develop so-called *load cases*. These consist of likely combinations of wind, wave, and current that could cause the *n*-y load or response. For instance, one common load case would be the *n*-y wave and the *associated* wind (the most likely wind velocity to occur simultaneously with the *n*-y wave condition) and associated current. Another analogous case would be the *n*-y current and associated wind and wave. ANSI/API [3.1] makes routine use of load cases in their recommended practice.

There are two main questions to be answered when using load cases: *What combinations of wind, wave, and current can cause the n-y load/response? How is the* associated *value found?* Answering the first question is straightforward for well-studied facilities like offshore jackets. That is because previous work has shown that the *n*-y load for key global responses like base shear and overturning moment occurs during the *n*-y wave and associated wind/current. Other combinations such as the *n*-y wind and associated wave and current, come close but do not exceed the *n*-y wave case. However, for other facility types this may not be true and so there is a risk of missing load combinations with *n*-y recurrence that exceed traditional cases like the *n*-y wave and associated wind/current. One way to mitigate this risk is to provide a broad range of possible load cases, though a firm justification for those cases may be difficult to establish unless a response-based analysis is performed.

Several methods have been developed to answer the second question and these are discussed in the following sections.

Regression Analysis

Using a regression analysis to find the associated values can be straightforward, especially when the primary and secondary variables are well correlated. The analyst starts by estimating the *n*-y value of the primary variable using a peak-over-threshold (POT) method, as described in Sect. 3.7.2. Next, a scatter plot is made of the coincident (in time) primary and secondary variables. If there is some correlation evident in the plot, the data is fit with a curve to derive an equation expressing the secondary variable in terms of the primary one. The associated value can then be found by substituting the *n*-y primary variable into the equation.

Figure 3.6 illustrates this approach for the case where the primary variable is H_s, the significant wave height, and the secondary variable is W, the wind speed.

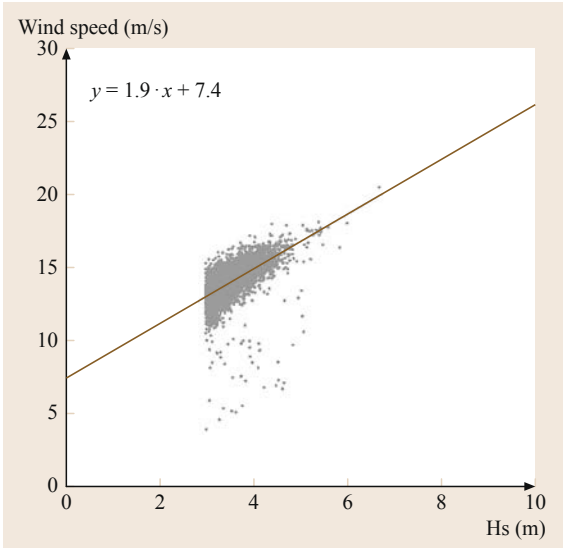

Fig. 3.6 Scatter plot of H_s vs W for all hurricane-generated waves with $H_s > 3$ m. The *red line* shows the least squares fit

The figure suggests that H_s is well correlated to W (correlation coefficient of 0.91) in a linear way. The red line shows the least squares fit with the resulting algebraic expression shown in the upper left-hand corner of the figure. A threshold of $H_s > 3$ m has been applied to remove the weaker winds and waves and make the best-fit curve linear. For this particular dataset, the 100-y H_s is about 9 m, so the red line suggests an associated wind speed of 24.5 m s^{-1}, well less than the 32 m s^{-1} suggested by an independent POT analysis of the 100-y W in this dataset. The 24.5 value represents a mean estimate with a 50% probability of being exceeded. Therefore, one might want to increase that value to reflect the scatter in the data and uncertainty in the fit.

The data shown in the figure was taken from a hurricane dataset, so the highly correlated relationship between the stronger waves and wind is not surprising. However, there are other situations in which the correlation may be weak or nonexistent, such as with currents and wind in deep water. In such cases, it is sometimes reasonable to set the associated value to the mean of the secondary variable. That said, there are subtleties that crop up in certain parts of the world. Consider the derivation of the 100-y wind speed and associated wave off Nigeria where the extreme winds are controlled by squalls that pass quickly and only generate small waves. It would be unconservative to use those squall-generated waves with the squall-generated winds, since much stronger waves are frequently found in the region originating from persistent southeasterlies and/or swell from the Roaring 40s. In this case, a reasonable estimate

of the associated wave for the *n*-y squall case would be the mean for the entire population of wave-producing events during the squall season.

Simulations

Numerical simulations are often one of the best ways of determining associated values. Take, for example, the challenge of estimating the astronomical tide and storm surge to associate with the peak wave crest height. Such a combined event is needed for setting the deck height on jackets. *Fox* [3.108] describes a Monte Carlo approach of numerical simulations to estimate the expected value of the three processes.

Simulations are often the only way to determine the associated value when there are strong nonlinear interactions between the two variables. *Cooper* and *Stear* [3.109] describe an example where the Loop Current and a hurricane simultaneously affected a site in the Gulf of Mexico. While both processes are statistically independent, a tropical cyclone crosses over the Loop or one of its eddies every 3 years, on average, in the deep water Gulf. Most crossings are glancing and of no consequence, but every few decades a hurricane will cross the western half of an eddy or the Loop, resulting in a strong nonlinear interaction that can magnify the subsurface ocean currents by four times the linear superposition of the hurricane-only and Loop-only currents [3.13]. *Cooper* and *Stear* [3.109] estimate the frequency of occurrence of the Loop and hurricane current by shuffling the years from a hindcast historical dataset with a hindcast Loop/eddy database. They then use a lookup table of hindcasted joint hurricane/Loop events to estimate the *n*-y combined current.

3.5.3 Environmental Contours

The largest structural responses may not come from the combination of the largest primary variable and the associated secondary variables. For example, the largest roll response of a floating structure may come from a lower wave height and a wave period that matches the roll period. Those cases can be systematically investigated using environmental contours.

Haver and *Winterstein* [3.110] give a good description of the method and its use. In their example, they fit an extreme value distribution to the significant wave height. Then they fit marginal distributions for peak wave period to ranges of wave height. Finally they fit the parameters of the marginal distributions so they can be extrapolated to low wave height probability levels. This process produces a functional form for the environmental contours of wave height and period.

It is also possible to produce non-parametric environmental contours using a kernel density estimator. In this method, each point in a scatter diagram is replaced by a probability density function. All of those density functions are added together to give a smooth probability density function for the entire data set. According to *Scott* [3.111], if we use a bivariate normal kernel, the optimum standard deviation of the kernel is given by

$$h_i = \sigma_i n^{-1/6} , \tag{3.34}$$

where σ_i is the standard deviation of the data in dimension i, and n is the number of data points.

The resulting probability density can be contoured using standard library functions like MATLAB's contourc.m. The probability levels of the contours are chosen so that the maximum wave heights on the contours equal the independent return period wave height. At low probability levels it may be necessary to limit the steepness of the waves to eliminate waves that are steeper than physically realistic. Figure 3.7 shows significant wave height and peak period contours based on NDBC buoy measurements during hurricanes from 1978–2010 in the Gulf of Mexico.

Similar contours can be calculated for other pairs of parameters such as wave height and wind speed.

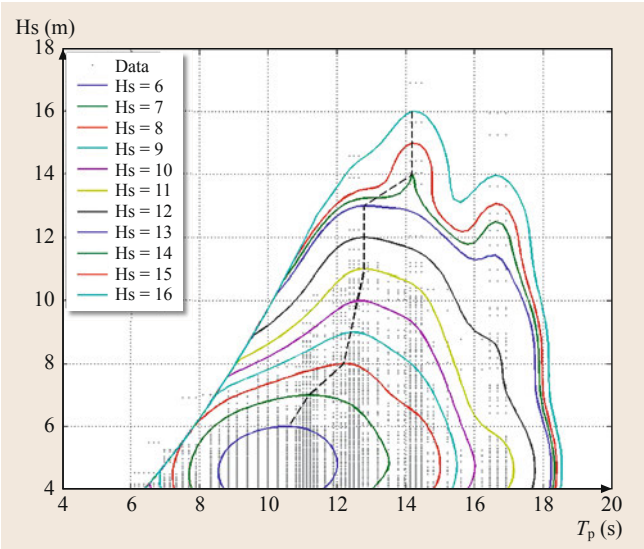

Fig. 3.7 Contours of significant wave height and peak period based on NDBC buoy measurements made in the Gulf of Mexico

3.5.4 Inverse FORM

Once equal probability contours of environmental parameters are calculated, inverse first-order reliability methods (IFORM) provide a general procedure for finding design conditions. The contours are searched for the point which maximizes some response function such

as the roll of a floating system. The environmental parameters at that point then become the design point. *Winterstein* et al. [3.112] give a good explanation of the method.

Inverse FORM maps the environmental contours to standard normal distributions. If the probabilities are expressed as annual extremes and the return period of interest is 100 years, then the probability of exceeding the 100 year value is $p = 1/100$, and the *reliability index* is

$$\beta = \Phi^{-1}(1-p) \,, \tag{3.35}$$

where Φ is the standard normal distribution. The design contour expressed in standard normal variables is then defined by

$$\beta^2 = \sum x_i^2 \,. \tag{3.36}$$

In two dimensions, (3.36) defines a circle. In three dimensions it is a sphere. Each point on the surface has the same probability. The theory extends to hyperspheres in higher dimensions, although the search for the maximum response then becomes much more time consuming.

Suppose the actual environmental parameters are wave height H and period T. If these distributions are independent, then each point on the contour given by (3.36) has the physical parameters

$$\begin{aligned} H &= F_{\mathrm{H}}^{-1}\left[\Phi(x_1)\right] \,, \\ T &= F_{\mathrm{T|H}}^{-1}\left[\Phi(x_2)\right] \,. \end{aligned} \tag{3.37}$$

where F_{H}^{-1} is the inverse wave height distribution and $F_{\mathrm{T|H}}^{-1}$ is the inverse distribution of T given H.

3.6 Operational Criteria

The *operating conditions* are the metocean conditions in which a facility or vessel should be capable of achieving its routine functions. Typical products used to quantify operational conditions include a cumulative probability distribution of wave height or a table of wind speed persistence. These products are used in estimating the fatigue lives for components for which this is a concern. In contrast, extreme conditions rarely occur and are often generated by *storms* of some kind. During extreme conditions, normal operations are usually suspended – the vessel is slowed, oil production may be stopped, windmills feathered, etc. The first two sections below describe several common methods for describing operational criteria of variables that have at least one, highly correlated associated variable, e.g., wind speed and direction. However, the methods are often used even when there are more than one correlated associated variable such as waves, e.g., wave height, wave period, and wave direction.

3.6.1 Probability Distributions

The simplest method for quantifying a variable with a single dimension like wave height is to provide a table or plot of the probability distribution (histogram) as shown in Fig. 3.8a. However, since virtually all metocean variables are vectors, such tables or graphs are typically expressed as joint probability distribution tables, as shown in Fig. 3.8b for the case of wind speed and direction. In this table, each cell shows the probability of the occurrence of wind speed for a given wind direction. A *wind rose* is another way of graphically displaying a vector like wind velocity (Fig. 3.8c). In this case, each *bar* shows the percent occurrence of the speed in discrete bins along the indicated heading. All three images are based on the same dataset, so Fig. 3.8a basically shows a plot of the first column of the table on the x-axis versus the tenth column on the y-axis, while Fig. 3.8c shows the percent occurrence of the speed (binned in $5\,\mathrm{m\,s^{-1}}$ increments) by direction.

One of the challenges in clearly quantifying the operational environment is dealing with variables that have multiple associated variables that are highly correlated. The section on currents below describes several ways of dealing with this issue for currents.

Waves are typically described by pairing of the associated variables. For instance, one can generate joint probability distribution tables of wave height versus wave period by direction sector. Alternatively, one could generate tables of wave height versus heading by period bin, e.g., a table like that shown in Table 3.1 for all wave periods between 10–12 s.

Many facilities are sensitive to wave fatigue, so designers need the probability distribution of the wave spectra. For regions dominated by single-mode spectra this is straightforward – one can use the tables described in the previous paragraph in conjunction with parametric spectra like JONSWAP. In other words, knowing the probability of a discrete bin of wave height, period, and direction, one can calculate the corresponding spectra at that probability level. Further refinements may be needed if the spectral width and/or directional spreading vary in the region.

Many regions of the world such as Brazil experience sea states characterized by spectra that have multiple peaks, several of which contain substantial en-

ergy. For floating facilities, the weaker secondary or tertiary peaks may be close to resonance of the facility and thus cause far larger forces than the primary peak. In these situations, it can be very unconservative to utilize single-peak spectra like JONSWAP. Perhaps the most widely used dual-peaked spectrum is that of *Ochi–Hubble* [3.17].

3.6.2 Persistence

Certain types of offshore operations require that the metocean environment not exceed a threshold for a specific period of time. If it does, the operation is suspended and there is *downtime*. While estimates of downtime can be made using the probability distributions described in the previous section, such an approach is an oversimplification that can distort the perceived risk. A more accurate method is to scan a time series of the variable of interest and characterize the periods when the variable lies above or below a specified threshold. For example, consider the case where a wind sensitive operation can be completed in 12 h, provided that the wind never exceeds 7.5 m s^{-1}. A simple frequency analysis shows that winds at this site exceed 7.5 m s^{-1} nearly 60% of the time, which at first glance might be discouraging. However, a persistence analysis of the

Table 3.1 Calm persistence for 1-y time series of wind gusts

CDF (% <)	0.00	1.03	41.75	88.72

Table 3.2 Storm persistence for a 1-y time series of wind gusts

Threshold [m s^{-1}]	2.50	5.00	7.50	10.00
# of Occur.	2.00	5.00	68.00	69.00
Avg. days	179.79	71.18	3.08	0.59
Max days	323.30	233.61	43.38	2.96
Min days	36.27	10.19	0.02	0.02
Std. dev.	202.96	92.48	6.01	0.71

events *below* 7.5 m s^{-1} (Table 3.1) indicates that there were 68 calm events in which the wind was less than 7.5 m s^{-1} and all of them lasted more than 12 h (minimum 0.54 days). A closer look at the events *exceeding* 7.5 m s^{-1} (Table 3.2) shows that when the winds did exceed 7.5 m s^{-1}, the events lasted an average of 3.08 days and roughly 85% (mean + standard deviation; 3.08 + 6.01) of these events lasted less than 9.09 days.

Thus by looking at persistence one could conclude that there is an expected downtime of about 3 days for the operation, which is a lot less onerous than might be concluded from looking at the 60% occurrence rate based on the frequency analysis.

While persistence analysis can provide valuable insights, it cannot easily incorporate multiple variables. This is especially limiting for floating systems, which are often dependent on wave height, period, direction, etc. For these cases, numerical simulations using a vessel response function are often preferred, e.g., *Beamsley* et al. [3.113].

3.6.3 Currents

Fatigue damage caused by currents is an important design consideration for oil drilling and production risers in deep water. Deep water current profiles have complicated shapes, and thousands of profiles are often now

available from models or measurements. All of that information must be condensed into a manageable number of cases for analysis. *Prevosto* et al. [3.114] discuss three methods for doing this and compare the results of using them with a full analysis of all profiles.

Empirical orthogonal functions (EOF) provide a method for capturing the important characteristics of current profiles in a few variables. *Forristall* and *Cooper* [3.115] outline the method and give examples. Singular value decomposition permits any matrix **A** to be decomposed as

$$\mathbf{A}_{ij} = \sum_{k=1}^{N} w_k \mathbf{U}_{ik} \mathbf{V}_{jk} \,. \tag{3.38}$$

Each current profile is written as a row in matrix **A** and each column represents the time series at one depth. The columns of **V** are called the EOFs. Each EOF is a vector with a value at each depth in the original data. There are the same number of functions as there are depths. They play the same role as cosine waves in a Fourier analysis. The diagonal elements of **W** are the magnitudes of the EOF modes. They give the relative importance of the modes. The matrix **U** gives the amplitudes of the modes in each current profile. There is one row in **U** for each profile. It gives the amplitudes of each mode at one time.

As it stands, (3.38) is not a more efficient representation of the data. The gain in efficiency comes from the fact that the magnitudes of the first few modes are often much larger than the rest. A good representation of the data can then come by summing over many fewer than N modes. The amplitudes of those modes can then fill a manageable scatter diagram.

There are, however, locations where a few EOF modes fail to describe all the dominant characteristics of the current profiles. The characteristic current profile (CPC) was developed by *Jeans* et al. [3.116] to work with those cases. For each current velocity time series, a number of possible states are defined at each selected depth level, and possible characteristic profiles are constructed from every permutation of these states. The number of measured profiles corresponding to each of these possible characteristic profiles is then counted and percentage occurrence values derived. The reduction in the number of profile shapes is accomplished by selecting a relatively small number of depth levels.

Self-organizing maps (SOM) are useful to better categorize current profiles. The SOM process begins with a two-component EOF analysis. Then, a nonlinear cluster analysis groups the thousands of current profiles into a smaller number of clusters [3.117]. The EOF amplitudes are varied to produce a two-dimensional array of current profiles. Each original profile is assigned to the EOF profile that it best matches. The EOF profiles are modified by taking weighted averages of the neighboring profiles in the grid. Then, the original profiles are re-assigned to the modified profiles that they best match. This process is iterated until the sum of differences between the SOM profiles and the original profiles is minimized. If the array of profiles is small, there can be a lot of variability around some of the weaker SOM profiles. The variability around the SOM profiles decreases when more profiles are used.

Prevosto et al. [3.114] found that using a few hundred profiles calculated by one of these methods gave good accuracy in fatigue damage calculations.

3.7 Extreme Criteria

3.7.1 Risk and Reliability

Metocean design specifications should be set considering the risk and cost of failure. The risk tolerance is different for structures that are not normally manned and structures that are evacuated before severe storm conditions than it is for structures that are manned and not evacuated before severe storms. Gulf of Mexico structures are evacuated upon the approach of a hurricane. North Sea structures remain manned during frequent severe winter storms. For structures that are unmanned or evacuated, the risk calculation is complicated but straightforward. The cost of strengthening the structure is balanced against the monetary cost of structural damage or failure. The cost includes not only repairing or replacing the structure, but sometimes also lost production, pollution-related costs, and damage to corporate image. These costs can be an order of magnitude greater than the cost of replacement.

The failure rate is found by calculating the ultimate strength of the structure and comparing it to the metocean loading at different probability levels. The cost of strengthening the structure is then added to the cost of failure after strengthening. If the total cost is lower, designing to a lower probability of failure is economically justified. For standard steel jacket structures, an annual failure rate near 10^{-3} is generally appropriate. This is consistent with the normal practice of designing for a 100-y storm because steel jackets have considerable reserve strength beyond the first yielding of a member.

Establishing an appropriate failure rate for a manned structure is conceptually more difficult because no

one wants to put a price tag on human life. Rational risk levels can still be set by considering risk levels in other industries and risk on offshore structures due to causes other than structural failure. Those risks include travel, explosions, collisions, and falls. These considerations indicate that the individual risk per annum (IRPA) should be reduced to a level below 10^{-3}. An IRPA lower than 10^{-6} is considered negligible. However, the risk should be reduced below 10^{-3} to a level that is as low as reasonably practical (ALARP). Measures to reduce IRPA should be examined and implemented until the cost of the upgrade becomes grossly disproportionate to the benefit obtained. *Efthymiou* et al. [3.118] discuss the ALARP principle in detail. The cost of stuctural strengthening should be weighed against the cost of lowering other risks. Manned structures in the North Sea are now usually designed for a 10^{-4} annual risk of failure. Providing criteria with such a low probability is a special challenge to the metocean specialist, who must extrapolate conditions far beyond experience levels.

3.7.2 The Historical Method

The traditional way of estimating metocean extreme values is extrapolation from historical data. The data generally come from hindcasts rather than measurements so that more years of data are available. However, even hindcast records are short compared to 1000 or 10 000 years, so extrapolation using extreme value distributions is required.

Extreme value theory assumes a time series of independent events, so the first step is to choose those events. Generally, this is done by finding the peak values over a threshold (POT). The peaks are sorted in ascending order, and their probability is plotted against their magnitude. There are then many choices for choosing an extreme value functional form and fitting it to the data [3.119]. In the limit as the number of points tends to infinity, it can be shown that the extremes follow the generalized Pareto distribution

$$F(y) = 1 - (1 + \xi y/\sigma)^{-1/\xi} \,. \tag{3.39}$$

The parameter ξ controls the shape of the distribution, giving a heavy tail if $\xi > 0$ and a finite upper limit if $\xi < 0$. In practice, we do not know whether the data extends far enough into the tail of the distribution for the limit to hold, and small changes in the data can influence whether an upper limit is predicted. For these reasons, engineers often choose to fit peaks to the Weibull distribution

$$F(y) = 1 - \exp\left[-\left(\frac{y-\gamma}{\alpha}\right)^{\beta}\right] \,. \tag{3.40}$$

The commonly used Weibull plotting position is

$$P_i = \frac{i}{N+1} \,, \tag{3.41}$$

but *Goda* [3.120] showed that the unbiased plotting position is actually

$$P_i = \frac{i + \frac{0.5}{\sqrt{\beta}} - 0.6}{N + 0.2 + \frac{0.23}{\sqrt{\beta}}} \,. \tag{3.42}$$

Gibson et al. [3.121] tested various methods of fitting (3.40) to data simulated from a known Weibull distribution. They found that both least squares and maximum likelihood fits gave good results when

1. The unbiased plotting position in (3.42) was used.
2. The position parameter γ was set to the threshold value.
3. All of the data were used instead of binning the data into ranges of y.
4. The fit was made of y to $\alpha\,[\ln(1-P)]^{\beta} + \gamma$.

There are numerous weaknesses with the historical approach. First and foremost, historical datasets are often short relative to the probability level needed for design criteria. This is especially a problem for tropical storms, which are spatially small and infrequent. *Toro* et al. [3.122] show the 100-y criteria for a particular site in regions like the Gulf of Mexico, is most heavily influenced by how close a few strong storms passed to the west of the site. As a consequence, large differences in the 100-y design condition are often observed at sites separated by only 50 km in deep water far from the coast where there is no physical basis to believe the n-y condition would be any worse at one site than the other. These unrealistic spatial gradients are more apparent at even shorter return periods (e.g., 10 and 25-y) in basins like north Australia and the Gulf of Thailand, where the reliable historical database is shorter or the storm frequency is lower than in the Gulf of Mexico. The spatial gradients in n-y criteria are largely a result of under sampling. There are simply not enough larger storms in the database. Furthermore, it is reasonable to expect that if the database could be extended over a longer period of time, a strong storm would eventually cross near all the sites.

To counter this under sampling, metocean experts often *pool* nearby sites, as described in *Cooper* et al. [3.123]. Pooling basically combines all storm peaks from several nearby sites into a single probability distribution. In essence, pooling adds *synthesized* storms by shifting the tracks of the historical storms. When pooling, the probability distributions from each site are assumed to be statistically independent, even though they are not. However, *Toro* et al. [3.122] show

that this assumed independence does not lead to substantial errors for return intervals of up to roughly 100 years for the Gulf of Mexico hurricane population. That is because the 100-y condition is strongly dependent on the track crossing distance and much less dependent on the other particulars of the storm. Unfortunately, for rarer return periods beyond a few hundred years, pooling starts to yield increasingly biased results because the longer return intervals become more sensitive to the intensity of the stronger storms, and pooling does nothing to increase that population of storms. When pooling it is important not to extend the averaging grid too widely else one can suppress real spatial gradients like those suspected to exist in the Gulf of Mexico hurricane patterns, e.g., *Cooper* [3.124].

Another limitation with the historical method is that it cannot easily be used to develop criteria involving the rare combination of two relatively independent events. A case in point is the superposition of the Loop Current (or one of its detached eddies) and a hurricane. Recent simulations by *Cooper* and *Stear* [3.125] suggest these events happen roughly every 4 years. When they do, a number of potential nonlinear interactions can occur such as wave focusing [3.126], amplification of mid-water currents [3.13], and intensification of the hurricane [3.124]. The first two phenomena depend strongly on the distance between the hurricane and Loop, and there are virtually no comprehensive measurements of the wave and current field in joint events. Hence, historical events are missing.

3.7.3 Synthetic Storm Modeling

The previous section pointed out two major weaknesses of the historical approach. To address these weaknesses, researchers have looked at various means of generating so-called *synthetic* storms; that is, storms that did not actually occur but could have occurred. *Georgiou* et al. [3.127] describe one of the first efforts. They first fit standard storm parameters like intensity and radius to standard distribution functions (e.g., lognormal). They then drew randomly from these distributions to construct synthetic storms whose probability was calculated from the underlying distributions of the storm parameters. Once the combination of storm parameters was selected, these were input into a standard parametric wind model that could calculate the detailed wind field along the historical tracks. Because the probability distributions of each hurricane parameter is at most weakly dependent on the other parameters (e.g., radius to maximum wind is only weakly correlated to intensity), the overall probability of a given synthetic storm scales roughly as the product of the probability of the individual parameters. Hence the method can generate rare (low probability) synthetic storms using a combination of storm parameters that are well away from the tail of their respective probability distributions and hence have relatively low uncertainty.

While the early models went a long way in reducing statistical uncertainty of the longer return period estimates, they continued to utilize historical tracks to estimate the frequency of storm passage and they assumed that the change in storm parameters was independent of that track. This latter assumption is clearly problematic in places like the Gulf of Mexico, where the warm waters of the Loop Current likely affect storm intensity as do nearby land masses. To partially address these limitations, *Vickery* et al. [3.128] used statistical properties of track heading, track speed, and intensity, combined with a regression model to generate synthetic storms. This approach allows for the generation of thousands of years of storms with low statistical uncertainty. *Emanuel* et al. [3.129] investigated stochastic techniques to generate many synthetic storm tracks and a deterministic model to calculate storm intensity along each of those tracks. They investigated two track models. Their first model was conceptually similar to that of *Vickery* et al. [3.128], while their second track generation method accounted for large-scale weather, including vertical shear and steering flow. Once *Emanuel* et al. [3.129] had constructed the tracks, they used a deterministic model to calculate the parameters, including intensity and radius. *Vickery* et al. [3.130] used a track model that accounts for large-scale weather but in a more deterministic fashion than *Emanuel* et al. [3.129], by using NCEP reanalysis. To calculate the storm parameters they used a statistical intensity model that incorporated atmospheric inputs, much as Emanuel et al. [3.129] did, but *Vickery* et al. [3.130] also included ocean temperature feedback.

Perhaps the biggest challenge in using these models is determining whether some of the more extreme synthetic storms are realistic. The next section addresses this point.

3.7.4 Modeling Versus Measurements

In an ideal world, the ocean would be covered with measurement sites that have operated for centuries. In the real world, the metocean specialist is often faced with developing criteria where there are no measurements at the site, or if there are, they may only be a year or less in duration. Extrapolating such a short record to return intervals of a few decades or more will usually result in large statistical uncertainty at best, and at worst, large biases. On the other hand, numerical model hindcasts spanning many decades now cover most of the world, as discussed in Sect. 3.4. Depending on the hor-

izontal resolution of the model grid, the nearest model element to the site of interest is often only a few kilometers away. Thus the best strategy for developing extreme design criteria at site is often to use available measurements to calibrate a hindcast model that has been run for several decades, rather than to do an extreme analysis on the measurements themselves.

3.7.5 Accounting for Physical Limits

Whether one uses the historical method or synthetic modeling to estimate extremes, extrapolation of some form is almost always being used to estimate criteria well beyond any observed storms. This raises the concern that the method can be generating values that cannot be physically attained in the real world. Perhaps the clearest example of this danger is the case where a metocean specialist tries to fit a Weibull distribution (historical method) to waves measured during a 2-y long measurement program in a water depth where wave breaking can occur for the stronger storms. Fitting this kind of data with a classic historical method can yield 100-y estimates that are unrealistically high because those waves would have broken in the real world. The problem, of course, is that the extreme distributions are purely statistical functions with no physical basis.

One solution to this potential problem is to use numerical models that include the necessary physics to account for the limits. This can be a practical and straight forward solution for the example of breaking waves cited above. In that case, hindcasting storms over many decades using a wave model that accounts for breaking is usually a quick and effective solution.

Regrettably, incorporating physical limits into numerical models is not straightforward when the physics are not well understood. A case in point is calculating extremely rare hurricane conditions, say the 10 000 year significant wave height. *Cardone* and *Cox* [3.131] applied a third-generation wave model to strong storms and found that the wave heights trended toward an asymptotic limit. However, it is debatable whether the asymptotic limit is generated by real physical limits or artificial ones imposed by the model equations. There is no way to be sure, as wave and wind measurements during the events considered by Cardone and Cox have not been recorded. Another approach used by *Vickery* et al. [3.130] applied the concept of the maximum probable storm intensity. *Emanuel* [3.132] and others provide evidence that such limits appear to exist.

3.7.6 Seasonality

Fixed offshore facilities are designed for year-round conditions but there are some instances where metocean conditions are needed for seasonal construction or drilling. If the operation is, say, planned for only the three months of summer, then only the metocean conditions for those months need to be considered. More specifically, if a 1%/y risk of failure is desired (expected failure of once every 100-y), then the extreme values of metocean conditions in 100 years of summers should be calculated.

However, caution must be exercised when considering seasonality for a drilling rig or operations which will continue year-around. To illustrate this point, consider the question of how one might combine seasonal criteria to calculate the annual survival rate. Assume that the target reliability is an average 99% survival rate (1% failure rate) each year. One might be tempted to use the 99% probability value for each season, but more careful consideration reveals this will badly overestimate the survivability. That is because the annual survival rate is given by the probability that the rig will survive the summer *and* the fall *and* the winter *and* the spring. It follows that if the extremes in each season are statistically independent, then the annual survival probability is given by the product of the seasonal probabilities, or $0.99^4 = 0.96$; 4% less than the annual target survival rate of 99%. An obvious solution to this shortfall is to use the 0.9975 probability for each of the four seasons, which yields an annual survival rate $99\% = 99.75^4$.

3.7.7 Directionality

Directional metocean specifications are sometimes desired when a structure is considerably stronger or less prone to motion in some directions than others. The considerations in this case are similar to those for seasonal specifications, especially the concept that the total survival probability from all individual directions should not be significantly different from the omnidirectional survival probability. Using the same arguments given in the previous discussion on seasonality, it is clear that using the n-y metocean criteria in each direction bin will give a much lower survival probability than using the n-y omni-directional criteria [3.133].

The simplest way to insure a reasonable result is to make the probabilities in all of the direction bins equal. So, for example, if the target annual survivability is 99% and four direction bins are used, then the target survival probability in each of these four bins should be 99.75%.

3.7.8 Combining Long and Short-Term Distributions

Estimating extreme values of individual wave and crest heights requires combining a long-term extreme value

distribution with the short-term distributions discussed in Sect. 3.2.2. *Borgman* [3.134] showed how the maximum wave and crest height during a storm can be estimated by integrating the short-term wave and crest height distributions over the storm's sea state history. *Tucker* and *Pitt* [3.135] give a thorough description of how the Borgman integral has been applied to the calculation of extreme wave heights. *Forristall* [3.136] validated these methods using long-time series of individual waves.

If the probability that the wave or crest height exceeds η is given by $P(\eta)$, then the probability that the height will not exceed η in N waves is given by

$$P(\eta_{\max} < \eta) = [1 - P(\eta)]^N \ . \tag{3.43}$$

For a sequence of records $i = 1 \ldots k$ during a storm, the probability of non-exceedance becomes

$$P(\eta_{\max} < \eta) = \prod_{i=1}^{k} [1 - P_i(\eta)]^{N_i} \ . \tag{3.44}$$

The calculations can be performed more accurately by taking the logarithm of (3.44) to give

$$\log [P(\eta_{\max} < \eta)] = \sum_{i=1}^{k} N_i \log [1 - P(\eta)] \ . \tag{3.45}$$

Equation (3.45) is applied to calculate the expected maximum wave and crest height in each storm. The sets of maximum heights are then fit to extreme value distributions to determine the return period individual wave and crest heights.

Fitting an extreme value distribution to the most probable maxima does not account for the fact that values higher than the most probable value can occur in any storm. *Tromans* and *Vanderschuren* [3.137] proposed a method for taking account of this short-term variability. If the probability distribution of the most probable maxima in a storm is $P(H_{\text{mp}})$ and the distribution of the maximum given H_{mp} is $P(H|H_{\text{mp}})$, then the distribution of the maximum in a single random storm is

$$P(H|srs) = \int P(H|H_{\text{mp}}) p(H_{\text{mp}}) \mathrm{d}H_{\text{mp}} \ . \tag{3.46}$$

Tromans and Vanderschuren found that $P(H|H_{\text{mp}})$ was very similar from one storm to another, and that its mean could be described by the function

$$P(H|H_{\text{mp}}) = \exp\left(-\exp\left\{-\log N\left[\left(\frac{H}{H_{\text{mp}}}\right)^2 - 1\right]\right\}\right) \ , \tag{3.47}$$

where N is an *equivalent number of waves* in a storm. The value of $\ln N$ can be estimated from the short-term distributions in the historical storms. Values between $\ln N = 8$ and $\ln N = 10$ are typical, and the results are not very sensitive to the exact value. The result is to increase the estimates of extreme maximum wave and crest heights to about 5% more than the most probable values.

3.7.9 Rogue Waves

It is generally agreed that a *rogue wave* is one with a height greater than 2.2 times the significant wave height or a crest greater than 1.25 times the significant wave height. There have been many reports of such waves in the literature in the last few years. The best known is the *Draupner wave*, recorded in the North Sea on January 1, 1995 [3.138]. The crest height of this wave was 1.55 times the significant wave height. Unfortunately, very little is known about the instrumentation used for this measurement. The *Andrea wave* [3.139] is a much better documented case. It was also recorded in the North Sea on November 9, 2007. Essentially, the same wave was recorded by four laser altimeters. Analysis of the intensity of the return signals indicated that there was no sea spray at the wave crest. The height of the Andrea wave was 2.49 times the significant wave height, and the crest was 1.63 times the significant wave height.

The central question in the study of rogue waves is whether they can be explained as a statistical anomaly or whether they require a physical explanation different than second-order theory [3.140]. The statistical explanation for something like the Andrea wave is certainly a stretch. According to second-order statistics, its crest had a probability of 6×10^{-8}. However, *Christou* and *Ewans* [3.141] did a careful study of over 10^8 measured waves and found that the sample crest distribution was only slightly higher than predicted by second-order statistics.

Some processes that produce very high waves are understood reasonably well. Waves traveling into an opposing current can steepen and become much higher. Many ships have been damaged when they encountered such waves in the Agulhas Current south of Africa. Bottom features can refract waves, making them much larger in localized areas. Surfers are well aware of this phenomenon. The more difficult cases to explain are unusually high waves in deep water far from shore.

Theoretical attempts to explain rogue waves involve the integration of nonlinear equations that approximate the development of steep random waves [3.142]. All of these show a modulation of the wave envelope similar to the Benjamin–Feir instability observed in regular

waves. The modulated waves alternate between series of higher and lower waves than predicted by Gaussian statistics. The kurtosis of the wave trace becomes greater than 3.0, and the extreme waves are higher than the Rayleigh distribution. Steep random unidirectional waves in laboratory basins often show this behavior. However, several numerical and laboratory studies, such as that by *Toffoli* et al. [3.143], have shown that modulational instabilities are much less effective in producing large wave groups when the waves are spread.

Rogue waves remain an active area of research and it is too early to draw definite conclusions. Fortunately, rogue waves may not have a big influence on extreme wave heights for design. Almost by definition, they have a low probability. The probability that a rogue wave occurs during one of the sea states far out in the distribution of significant wave height is even lower. *Haver* [3.138] estimated the effect of adding rare rogue waves to the short term distribution and found that it had little effect on the risk of failure.

3.7.10 Extremely Rare Events

Designers now frequently request metocean criteria with return periods of 1000–10 000 years. Deriving these values from a few years of measurements is difficult, if not impossible, to justify. Even deriving such rare events from historical hindcasts is problematic, since reliable historical databases rarely extend beyond 50 years. Synthetic modeling certainly holds the most promise for deriving rare events, but even with this technology it is difficult to overcome our ignorance of the physical limits which probably occur for many metocean phenomena. This issue is discussed in more detail in Sect. 3.7.5.

3.7.11 Quantifying Uncertainty

Uncertainty affecting the calculation of metocean extremes comes primarily from the noise and/or bias in the numerical models or measurements used to generate the peaks, and from the inability of the chosen extreme distribution to fit the peaks – what is often referred to as statistical uncertainty. The impacts of these two types of errors on extreme value uncertainty are discussed in more detail in Sect. 3.7.4.

Statisticians have extensively studied statistical uncertainty and developed numerous ways of quantifying it, as discussed in *Tucker* and *Pitt* [3.135]. If the input peaks come from a short time series and the extrapolation is lengthy (e.g., 2-y of measurements extrapolated to a 100-y return period), then the statistical error can be large.

One often sees fits to extreme distributions that show confidence limits that are based on the statistical uncertainty only. If the peaks are based on site-specific measurements, the statistical uncertainty is fairly representative, but if the peaks come from measurements some distance from the site or from models, then the statistical uncertainty is probably much smaller than the uncertainty from the input data source. Sections 3.4.1 to 3.4.3 can help quantify that error.

3.7.12 Stationarity

Nonstationarities can be thought of as low-frequency processes that have been sampled at far less than their Nyquist frequency. For example, if one has only a few months of data to analyze, then nonstationarities will arise from seasonal, annual, decadal, etc., time scales. Innumerable papers and books have been written on the topic, including a relatively recent one by *Rao* et al. [3.144].

Issues regarding nonstationarities have always plagued metocean analysis. The challenge is perhaps greatest when dealing with the calculation of extreme values (e.g., 100-y wind speed) where stationarity of the underlying time series is assumed in almost any analysis method and nonstationarities in the underlying dataset will tend to be amplified. For storm extremes, important sources of nonstationarities can come from natural oscillations in the atmosphere like the North Atlantic Oscillation or El Nino, which can cause substantial variations in storm severity over periods of several decades [3.145]. In theory, the obvious solution is to include many decades of historical storms in the extreme value analysis, but such long time series are available in only a few regions of the world and even there, data quality from the older decades my be problematic and introduce other forms of bias [3.146].

Global warming is introducing strong nonstationarities in many variables, the most obvious being atmospheric temperature. Projections from the IPCC (Intergovernmental Panel on Climate Change) [3.147] show that these nonstationarities or trends will increase rapidly over the coming decades and for long-lived facilities, the changes will need to be considered. A starting point for estimating nonstationarities is to use projections from numerical models such as those provided by the IPCC [3.147]. However, these projections do not consider all variables of interest to engineers (e.g., waves) and use models with fairly large grid sizes which can fail to capture important regional variability. Fortunately, computer power is continuing to increase, so the limits on grid size are starting to recede, allowing for the development of regional nested models with smaller grid sizes [3.148].

3.8 Conclusions

The metocean environment controls many aspects of facility design and operation so errors in quantifying metocean conditions can cascade though the design and operational decisions. Errors can result in damage and lost lives. Conversely, if the variables are overestimated, costs will be overestimated perhaps to the point that the project becomes uneconomic and is never built.

Metocean criteria are typically broken into two categories: operating and extreme. The former involves quantification of metocean conditions in which the facility or vessel should be capable of achieving the routine functions of its primary purpose. In contrast, extreme conditions occur rarely and are often generated by episodic events (e.g., storms). Both categories may start with the same databases but the analysis techniques and final design specifications will differ substantially.

There are a host of sophisticated methods and tools that can be used to quantify the most important metocean variables that impact offshore facilities. We have suggested methods drawn largely from the offshore oil and gas industry but they are also generally applicable to other engineering applications involving the design and operation of vessels, coastal structures, offshore wind farms, navigational aids, coastal geomorphology, and pollution studies.

When developing a metocean design basis for a major project, the metocean engineer should first identify the variables of primary importance. This is because the sea and atmosphere are filled with complicated processes, many of which are site specific and poorly understood. If aggressive filtering is not undertaken then too much time can be spent quantifying variables that make little difference to the design or operation of the facility. The first and best way to eliminate variables from investigation is to understand the basic responses of the *particular* facility. In other words to answer the question: which metocean variables impact this facility most and which have little or no impact?

Finally, it should be noted that the methods, tools, and databases cited in this chapter reflect a snapshot in time; they are continually being updated and improved. The reader should always consider these citations as a starting point and check the web and journals for updates before proceeding with the analysis.

4. Mechanics of Ocean Waves

James M. Kaihatu, Palaniswamy Ananthakrishnan

This chapter reviews mechanics of water waves and wave–body interactions pertaining to ocean and coastal engineering based on linear and weakly nonlinear wave theories. Numerical methods based on Green's theorem and mixed Eulerian–Lagrangian formulation for fully nonlinear wave and wave–body interaction problems are also discussed. The discussion also covers methods to determine the wave forces on fixed and floating structures, including the viscous drag force.

4.1 Ocean Surface Waves

The interface between the atmosphere and water, when disturbed, results in the generation of surface waves. In an open domain, the disturbance has to continue for the waves to persist as the propagating waves radiate energy. There is a limit to the energy contained by waves; once exceeded, wave breaking occurs, at which point energy is dissipated by turbulence during the breaking process. The limit depends on parameters such as wave height to wave length (or steepness) and wave height to water depth ratios. Wave instabilities or damping are also governed by air flow and separation, surface tension and surfactant effects, and instability of the free surface boundary layers. The physics of water waves is unique in many respects compared to other wave motions in fluids because of the dispersive nature of the water waves. Water wave problems are among the earliest topics attempted in applied mathematics, as illustrated, for example, by the classical Cauchy–Poisson problem on transient waves, tackled as early as in 1815 [4.1] and *Michell*'s theory of ship wave resistance developed in 1898 [4.2, 3]. A historical account of the development of classical water wave theory is given in [4.1]. Today, from an engineering viewpoint, understanding the properties of waves and wave–body

interactions is essential for efficient design and performance prediction of surface ships, offshore platforms, coastal structures, beach erosion mitigation measures, and beach fill configurations.

This chapter of the Handbook deals with the mechanics of surface waves, in particular:

1. Kinematic properties of surface waves
2. Weakly nonlinear deep water waves
3. Transformation of waves as they approach land from the deep ocean
4. Shallow water waves
5. Evolution of deep and shallow water waves
6. Breaking waves
7. Nearshore long wave generation, and
8. Wave forces on floating and fixed ocean structure.

Linear, weakly nonlinear, and fully nonlinear theories, and results on above topics are reviewed. The formulation of nonlinear wave theories in deep and shallow water are outlined, including the spectral evolution of these waves. Methods to solve wave–body interaction problems and to determine wave forces are discussed. The subject is presented in a manner so that it can serve as a reference for practicing engineers and researchers in ocean engineering. In each section of the chapter, an overview of the mathematical theory and formulations is given along with references for details.

4.2 Wave Theories

With exact equations governing water waves, wave transformations and wave–body interactions being nonlinear and involving arbitrary boundaries which make analysis difficult, numerous approximate theories have been developed over the years. These include linear Airy wave theory, Stokes weakly nonlinear theory, Boussinesq weakly nonlinear long wave theory and Korteweg–de Vries (KdV) theory for shallow water waves. Recent developments include computational methods to solve the fully nonlinear wave problem with the notable one by *Longuet-Higgins* and *Cokelet* based on mixed Eulerian–Lagrangian formulation [4.4].

Table 4.1 Key wave and flow variables

A	wave amplitude
C_g	wave group speed
C_p	wave phase speed
g	acceleration of gravity
h	water depth
H	wave height
k	wave number
L	wave length
p	pressure field
s	surface tension
t	time variable
T	wave period
$\boldsymbol{u}$	velocity field
(x, y, z)	Inertial earth-fixed coordinates against g with $z = 0$ on the calm surface
γ	specific weight of water
η	wave elevation
$\boldsymbol{\phi}$	velocity potential
ρ	water density
ω	wave radian frequency
$\boldsymbol{\Omega}$	vorticity

The above theories are based on the potential flow formulation, which assumes water to be inviscid and flow irrotational. The wave boundary conditions are, however, still nonlinear; they may be linearized for the case of small amplitude waves as in Airy's water wave theory. Despite the idealization and assumptions involved, linear theory captures many properties of wave phenomena and measures wave effects quite reasonably in most cases. Of course, for practical engineering applications, knowledge of large amplitude waves, including transformation over rapidly changing bathymetry, is essential; here linear theory has limited application and one has to consider weakly and fully nonlinear wave models. This chapter reviews these theories and the corresponding wave properties.

4.2.1 Potential Flow Formulation

We begin with a brief overview of the mathematical formulation of the water wave problem. The notations used in this chapter for key wave and flow variables are shown in Table 4.1. Additional notations used locally in the text are explained in the context.

A typical wave–body interaction and wave transformation problem encountered in ocean engineering and considered in this chapter is illustrated in Fig. 4.1. The body S_B may either be stationary or moving with velocity $\boldsymbol{U}$ (translation) and $\boldsymbol{\Omega}$ (rotational), resulting in a normal velocity $V_n = \boldsymbol{U} \cdot \hat{n} + \boldsymbol{\Omega} \cdot (\boldsymbol{r} \times \hat{n})$ with $\boldsymbol{r}$ denoting the position vector from the axis of rotation.

Neglecting effect of viscosity and consequently assuming the flow to be irrotational (i. e., $\boldsymbol{\omega} \equiv (\nabla \times \boldsymbol{u} = 0)$), one can define the flow in terms of velocity potential so that

$$\boldsymbol{u} = \nabla \boldsymbol{\phi} \, . \tag{4.1}$$

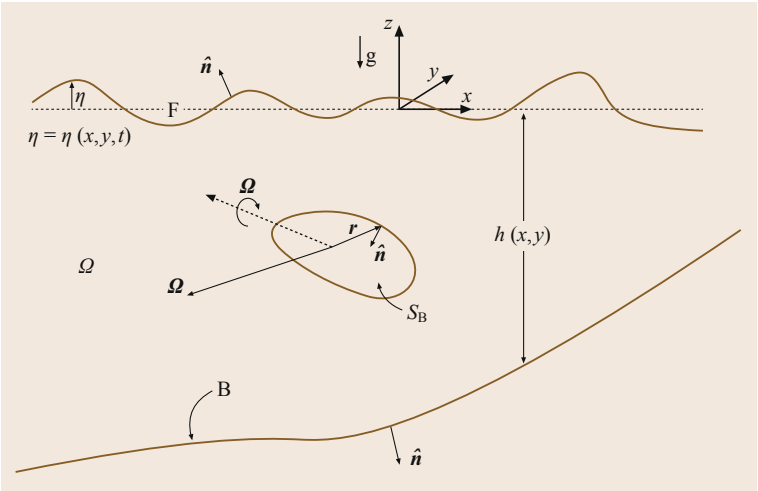

Fig. 4.1 Illustration of wave–body interaction and wave transformation over changing bathymetry

For incompressible fluid, per equation of continuity,

$$\nabla \cdot \boldsymbol{u} = 0\,, \tag{4.2}$$

which in terms of $\boldsymbol{\phi}$ is the Laplace equation

$$\nabla^2 \boldsymbol{\phi} = 0\,. \tag{4.3}$$

With $\boldsymbol{u} = \nabla\boldsymbol{\phi}$ in the Euler equation motion and through spatial integration one obtains the following Euler's integral for the pressure

$$p = -\rho g z - \rho \frac{\partial \boldsymbol{\phi}}{\partial t} - \frac{\rho}{2}|\nabla \boldsymbol{\phi}|^2, \tag{4.4}$$

with the first term on the right-hand side representing the static pressure and the last two terms denoting the dynamic pressure.

The bottom and body boundary conditions are the no-flux conditions given by

$$\frac{\partial \boldsymbol{\phi}}{\partial n} = 0, \quad \text{on the bottom B}\,, \tag{4.5}$$

and

$$\frac{\partial \boldsymbol{\phi}}{\partial n} = V_n, \quad \text{on the body surface } S_B\,. \tag{4.6}$$

On the free surface, we have the following two conditions, one based on the kinematics of free surface motion and the other on the continuity of pressure across the free surface

$$\frac{\partial \eta}{\partial t} + \frac{\partial \eta}{\partial x}\frac{\partial \boldsymbol{\phi}}{\partial x} + \frac{\partial \eta}{\partial y}\frac{\partial \boldsymbol{\phi}}{\partial y} = \frac{\partial \boldsymbol{\phi}}{\partial z} \quad \text{on } z = \eta\,, \tag{4.7}$$

$$\frac{\partial \boldsymbol{\phi}}{\partial t} + \frac{1}{2}|\nabla \boldsymbol{\phi}|^2 + g\eta = 0, \quad \text{on } z = \eta\,. \tag{4.8}$$

The former is called the free surface kinematic condition and the latter the free surface dynamic condition. Both are specified on $z = \eta$, which in itself is also an unknown and to be solved as a part of the problem. These conditions make the problem nonlinear and, therefore, difficult to solve.

For small amplitude waves (i. e., one in which the wave amplitude is much smaller than the wave length), the free surface boundary conditions can be linearized as

$$\frac{\partial \eta}{\partial t} + \frac{\partial \boldsymbol{\phi}}{\partial z} \quad \text{on } z = 0\,, \tag{4.9}$$

$$\frac{\partial \boldsymbol{\phi}}{\partial t} + g\eta = 0 \quad \text{on } z = 0\,. \tag{4.10}$$

Eliminating η from the above two conditions, one obtains the following linearized combined free surface condition

$$\frac{\partial^2 \boldsymbol{\phi}}{\partial t^2} + g\frac{\partial \boldsymbol{\phi}}{\partial z} = 0 \quad \text{on } z = 0\,. \tag{4.11}$$

In the case of spatially periodic waves with wave length L in, say, x direction, $\boldsymbol{\phi}(x,y,z,t) = \boldsymbol{\phi}(x \pm nL, y, z, t)$ and $\eta(x,y,t) = \eta(x \pm nL, y, t)$ and for time harmonic case with period T, $\boldsymbol{\phi}(x,y,z,t) = \boldsymbol{\phi}(x,y,z,t \pm nT)$ and $\eta(x,y,t) = \eta(x,y,t \pm nT)$ where n denotes positive integer. The wave length L and wave period T are related by the dispersion relation as discussed later in the chapter.

4.3 Properties of Small Amplitude Gravity Waves

In the absence of a body in the fluid, a periodic two-dimensional (long crested) progressive small amplitude (linear) wave solution to the linearized problem (as formulated above) can be written as

$$\phi = \frac{H}{2}\frac{\mathrm{g}}{\omega}\frac{\cosh k(z+h)}{\cosh kh}\sin(kx-\omega t)\,,$$
$$\eta = \frac{H}{2}\cos(kx-\omega t)\,, \tag{4.12}$$

where $k \equiv 2\pi/L$ denotes the wave number, H the wave height (which the vertical distance between the crest and trough), and h the mean water depth (taken here to be constant). In the case of a deep water wave, i. e., in the limit $kh \to \infty$ with $z \in [0, -h]$ the above solution becomes

$$\phi = \frac{H}{2}\frac{\mathrm{g}}{\omega}\mathrm{e}^{kz}\sin(kx-\omega t)\,,$$
$$\eta = \frac{H}{2}\cos(kx-\omega t)\,. \tag{4.13}$$

For the above velocity potential, the velocity field ($\boldsymbol{u} = \nabla\phi$) is given by

$$u = \frac{H}{2}\mathrm{g}k\omega\frac{\cosh k(z+h)}{\cosh kh}\cos(kx-\omega t)\,,$$
$$v = 0\,,$$
$$w = \frac{H}{2}\mathrm{g}k\omega\frac{\sinh k(z+h)}{\cosh kh}\sin(kx-\omega t)\,.$$

From above expressions one finds that the horizontal velocity field is in phase with the wave elevation. Its slip on the bottom is to be interpreted as the velocity at the outer edge of a bottom boundary layer. Using the Euler integral one can obtain the following expression for the pressure

$$p = -\rho\mathrm{g}z + \rho\mathrm{g}\frac{H}{2}\frac{\cosh k(z+h)}{\cosh kh}\cos(kx-\omega t)$$
$$= -\rho\mathrm{g}z + \rho\mathrm{g}\eta\frac{\cosh k(z+h)}{\cosh kh}\,.$$

In the case of shallow water waves – i. e., for $kh \to 0$ with $z \in [0, -h]$ (or approximately, $kh \le \pi/10$) –, the expression for pressure reduces to

$$p = -\rho\mathrm{g}(z-\eta).$$

The above expression looks very similar to the familiar hydrostatic pressure equation for homogeneous water. The static pressure corresponds to the depth measured from the calm surface while total pressure to the depth measured from the actual free surface with the difference contributes to the dynamic pressure.

4.3.1 Linear Dispersion Relation

As per the linear solution obtained above, the wave number $k \equiv 2\pi/L$ and wave frequency $\omega \equiv 2\pi/T$ are related by the dispersion relation

$$\omega^2 = \mathrm{g}k\,\tanh kh\,, \tag{4.14}$$

which approximates to

$$\omega^2 = \mathrm{g}k,\ \text{for}\ kh \ge \pi\,, \tag{4.15}$$

and to

$$\omega^2 = \mathrm{g}k^2h,\ \text{for}\ kh \le \pi/10\,. \tag{4.16}$$

The dispersion relation thus provides a basis for defining deep water, shallow water, and intermediate waves. Waves satisfying $kh \ge \pi$, which is the same as $h \ge L/2$, are referred to as deep water (or short) waves; that satisfying $kh \le \pi/10$, which is same as $L \ge 20h$, are referred to as shallow water (or long) waves and that in between (i. e., $\pi/10 < kh < \pi$) as the intermediate waves.

4.3.2 Phase Speed

The phase speed (also known as the wave speed or wave celerity) for linear waves becomes

$$C_\mathrm{p} \equiv \frac{L}{T} = \frac{\omega}{k} = \sqrt{\frac{\mathrm{g}}{k}\tanh kh}\,, \tag{4.17}$$

which reduces to

$$C_\mathrm{p} = \sqrt{\frac{\mathrm{g}}{k}\tanh kh}, \text{for}\ \pi/10 < kh < \pi$$
(intermediate waves)
$$= \sqrt{\frac{\mathrm{g}}{k}}, \text{for}\ kh \ge \pi$$
(deep water or short waves)
$$= \sqrt{\mathrm{g}h}, \text{for}\ kh \le \pi/10$$
(shallow water or long waves)\,. \tag{4.18}

As can be observed in the above expressions, longer deep water waves travel faster. In the case of shallow water waves the wave speed depends only on the local depth; the phase speed decreases with decreasing depth.

4.3.3 Group Speed

Often it is the group speed that govern many important wave properties, including the speed of energy propa-

gation, among others. The group speed is defined as

$$C_g \equiv \frac{d\omega}{dk}\,, \tag{4.19}$$

which in view of the dispersion relation for linear gravity waves become

$$\begin{aligned} C_g &= \frac{\omega}{2k}\left(1+\frac{2kh}{\sinh 2kh}\right), \text{ for } \pi/10 < kh < \pi \\ &= \frac{\omega}{2k} = \frac{C_p}{2} = \frac{1}{2}\sqrt{\frac{g}{k}}, \text{ for } kh \geq \pi \\ &\quad \text{(deep water waves)} \\ &= \frac{\omega}{k} = C_p = \sqrt{gh}, \text{ for } kh \leq \pi/10 \\ &\quad \text{(shallow water waves)}\,. \end{aligned} \tag{4.20}$$

So, for linear gravity waves, except in the limit of shallow water (long) waves, the group speed is different from the phase speed, and this fact has a bearing on some unique properties of shallow water waves to be discussed in later sections.

4.3.4 Amplitude Modulation of Water Waves

A wave consisting of two periodic progressive waves of equal amplitude and nearly equal wave number, and because of the continuous dispersion relation nearly equal frequency, will undergo an amplitude modulation with the modulation itself propagating as a wave but at the group speed rather than the phase speed. In other words,

$$\begin{aligned} \eta &= \eta_1 + \eta_2 \\ &= \frac{H}{2}\cos(k_1 x - \omega_1 t) + \frac{H}{2}\cos(k_2 x - \omega_2 t)\,, \\ &\quad \text{where } k_1 = k + \frac{\delta k}{2},\ k_2 = k - \frac{\delta k}{2}, \\ &= H\ \cos(\delta k\, x - \delta\omega\, t)\ \cos(kx - \omega t), \\ &\quad \omega_1 = \omega + \frac{\delta\omega}{2},\ \omega_2 = \omega - \frac{\delta\omega}{2}, \\ &= A\ \cos(kx - \omega t), \\ &\quad \text{where the amplitude } A \equiv H\ \cos(\delta k\, x - \delta\omega\, t)\,. \end{aligned} \tag{4.21}$$

The amplitude envelope propagates at speed $\delta\omega/\delta k$ and in the limit of $\delta\omega, \delta k \to 0$, at the group speed C_g! To an observer moving in the direction of wave propagation, the amplitude will appear stationary (constant); however, the observer will not be in phase with the wave, unless if it is a shallow water wave in which case $C_g = C_p$. Thus we observe that in the case of amplitude-modulated waves, the wave amplitude is conserved at the group speed.

4.3.5 Average Wave Energy Density

Through straightforward integration and averaging over a wave period, it can be shown that the average wave potential energy in a water column of unit cross area is given by

$$\overline{PE} = \frac{1}{16}\rho g H^2\,.$$

The word *density* in the present context corresponds to the unit area of the cross-section of the water column. Similarly, using the expressions for velocity and the definition of kinetic energy one can show that the average wave kinetic energy density is given by

$$\overline{KE} = \frac{1}{16}\rho g H^2\,,$$

and, therefore, the average wave mechanical energy density

$$\bar{E} \equiv \overline{PE} + \overline{KE} = \frac{1}{8}\rho g H^2\,.$$

To particularly note in the above expression is the fact that the wave energy is proportional to the square of the wave height.

4.3.6 Propagation of Wave Energy

Using the work-energy theorem, it can be shown that the average amount of energy propagating across a surface of unit crest length is given by

$$\bar{\mathcal{F}} = \bar{E} C_g\,,$$

meaning that the wave energy propagates at the group speed! For example, in the case of a wave front advancing in deep water the waves will appear to disappear at the wave front because $C_p = 2C_g$; in other words, propagation of energy cannot keep up with phase to sustain the wave. The above expression is quite useful to estimate the power required to generate waves and the wave resistance of vehicles moving over a free surface and wave energy conversion. In the case of confluence or divergence of waves, as due to bottom bathymetry or power take off, one has to multiply the above expression by the respective crest widths. The reader may refer to the topic of the *antenna effect* in the chapter on wave energy conversion of this Handbook for more on this aspect.

4.3.7 Water Particle Trajectory

For a propagating wave with velocity known (from above) one can determine the trajectory of water particles through time integration. For small amplitude waves, the trajectory is elliptical and closed

$$\frac{(X-X_o)^2}{A^2}+\frac{(Z-Z_o)^2}{B^2}=1\,,$$

where (X_o, Z_o) denote the coordinates of the center of the ellipse, A the major semi-axis

$$A\equiv\frac{H}{2}\frac{gk}{\omega^2}\frac{\cosh k(Z_o+h)}{\cosh kh}\,,$$

and B the minor semi-axis

$$B\equiv\frac{H}{2}\frac{gk}{\omega^2}\frac{\sinh k(Z_o+h)}{\cosh kh}\,.$$

As to be expected, near the bottom the particle will oscillate back and forth parallel to the bottom. In the case of deep water waves ($kh\to\infty$, or for practical calculations $kh\geq\pi$), above expressions for semi-axes reduce to

$$A=B=\frac{H}{2}\frac{gk}{\omega^2}e^{kZ_o}=\frac{H}{2}e^{kZ_o}\,.$$

In other words, the trajectory is a circle for small amplitude deep water waves. As the particle paths are closed, the average mass transport is zero. However, in the case of finite amplitude waves, this is not the case. In the case of finite amplitude waves, the trajectory is not quite closed, meaning that a particle will not return to the original position after one wave period but to a point slightly ahead of the original point. This is referred to as the Stokes drift. More on finite amplitude wave properties are given in later sections of this chapter.

4.3.8 Spatio-Temporal Evolution of Waves

Consider the generation of waves by (for example) a mudslide into water or by a seismic activity and the resulting waves propagating over water of varying depth. Here both wave numbers and frequency will vary with space and time. Let the direction of the wave propagation be along the x direction. Here the wave number and frequency may vary both in x and in time. In other words, the phase function will be

$$\Theta=(k(x,t)x-\omega(x,t)t)\,.$$

With the so-called slowly varying wave assumption, the wave number and wave frequency can be written as

$$k\approx\frac{\partial\Theta}{\partial x};\ \omega\approx-\frac{\partial\Theta}{\partial t}\,.$$

Cross-differentiating the above expressions we obtain

$$\frac{\partial k}{\partial t}+\frac{\partial\omega}{\partial x}=\frac{\partial^2\Theta}{\partial x\partial t}-\frac{\partial^2\Theta}{\partial t\partial x}=0\,. \tag{4.22}$$

In the special case of the steady-state limit, i. e., $k=k(x)$ and $\omega=\omega(x)$, from above we find ω to be constant. Thus, in the case of steady-state evolution of waves, the wave number (hence wave length) may change spatially in x, but the frequency will be the same everywhere.

The above equation for k and ω can be re-written as

$$\frac{\partial k}{\partial t}+C_g\frac{\partial k}{\partial x}=0,\ \text{where } C_g=\text{Group Speed}=\frac{d\omega}{dk}\,. \tag{4.23}$$

The above equation is called the wave number conservation equation; its solution implies that k will appear constant to an observer moving at the group speed. One could draw several other important conclusions using this equation. For example, assume waves are propagating in deep water (i. e., so that $kh\geq\pi$). At a fixed field point away from the wave source, as per the wave number conservation equation, the wave frequency and wave number will increase with respect to time, meaning that as time progresses shorter and shorter waves will reach the field point. To deduce this fact from the wave number conservation equation, consider the time that will be taken by a wave of wave number k generated at the source to reach the field point

$$t=\frac{d}{C_g}\ \to\ C_g=\frac{d}{t}\,,$$

where d denotes the distance between the source and the field point. Since $C_g=0.5\,g/\omega$ for deep water gravity waves, the above becomes

$$\frac{1}{2}\frac{g}{\omega}=\frac{d}{t}\to\omega=\frac{1}{2}\frac{gt}{d}\,.$$

In other words, the frequency of waves reaching the field point increases as the time increases. With $\omega^2=gk$ for deep water waves, the above equation can be written as

$$k=\frac{1}{4}\frac{gt^2}{d^2}\,,$$

meaning that the number of waves reaching the field point will also increase with time.

4.3.9 Shoaling and Refraction of Waves

One can generalize the derivations and findings of the previous section to allowing the waves to propagate along any arbitrary direction. In the case of slowly varying, small amplitude steady-state waves approaching an ideal coast (straight and long shore line with all bottom bathymetry contours parallel to the shore line) the direction of wave propagation is governed by Snell's law

$$\frac{\sin\theta}{C_\mathrm{p}} = \text{constant}\,, \tag{4.24}$$

where θ denotes the local angle of wave incidence measured from the shore normal, with $\theta = 0$ corresponding to crests parallel to the shore and $\theta = 90°$ to crests normal to the shore. The change of direction of wave propagation is called wave refraction. As one may recall from classical physics, the path of waves as predicted by the above Snell's law corresponds to the shortest time of travel between two points in a variable velocity field. If the velocity is constant, then θ will also be constant, meaning that the path of wave propagation will be a straight line.

As the waves approach the shore with depth $h \to 0$, $C_\mathrm{p} \to \sqrt{gh} \to 0$, then θ should also $\to 0$ for the ratio $\frac{\sin\theta}{C_\mathrm{p}}$ to remain constant; in other words, the wave rays will be normal to the shoreline irrespective of the angle of incidence of the wave while offshore.

Note that in the case of slowly varying steady-state waves, the wave frequency will remain constant and the wave number evolve satisfying the dispersion relation

$$gk\tanh kh = \text{constant}\,.$$

Assuming no wave breaking (which would enhance dissipation through turbulence) and with conservation of mechanical energy, one can show that in the case of a slowly varying, steady-state, nonbreaking wave approaching an ideal shore, the wave height will vary, satisfying

$$H\sqrt{\cos\theta}\,\sqrt{C_\mathrm{g}} = \text{constant} \;\to\; H = \frac{\text{constant}}{\sqrt{C_\mathrm{g}\,\cos\theta}}\,. \tag{4.25}$$

4.3.10 Closing Remarks to the Section

The linear (Airy) wave theory enables us to understand the basic and unique properties of surface waves. There are several books that deal with the linear theory of water waves, which the reader may refer to for details. These include [4.5–9]. The linear potential flow theory will hold good only for small amplitude waves. For finite and large amplitude waves, one has to use weakly and fully nonlinear wave theories, as reviewed in the following sections.

4.4 Weakly Nonlinear Deep Water Wave Theories

While linear theory has proved to be quite useful, it is often insufficient to investigate many of the details of wave propagation. Bulk properties of waves (some measure of wave height) are generally well predicted by linear theory in many instances. However, the small amplitude assumption inherent in linear wave theory is often invalidated (when waves approach their breaking condition), so nonlinear wave theory becomes essential.

The nonlinearity in water wave theory arises from the treatment of the surface boundary conditions. The kinematic and dynamic free surface boundary conditions are both nonlinear (they involve the products of the dependent variables $\boldsymbol{\phi}$ and η) and apply at a surface whose position is unknown a priori, as mentioned above. To move beyond simple linearization of the free surface condition (which involves neglecting the nonlinear terms and applying the boundary conditions on the surface $z = 0$), successive approximations to the nonlinear boundary conditions are required. This requires the establishment of physical scales, which become the basis of these approximations.

We first discuss deep water nonlinear wave theory, or Stokes wave theory (Stokes [4.10]). In deep water, the relative depth kh (where k is the wave number and h the water depth) is large. This can be used to adjust the velocity potential toward its deep water asymptote

$$\boldsymbol{\phi} = \frac{H}{2}\frac{\mathrm{g}}{\omega}\frac{\cosh k(z+h)}{\cosh kh}\sin(kx-\omega t) \approx \frac{\mathrm{g}H}{2\omega}\times O(1)\,, \tag{4.26}$$

which reflects the observation that the hyperbolic cosine term approaches 1 as kh becomes large. The particle velocities u and w similarly become

$$u = \frac{\partial\boldsymbol{\phi}}{\partial x} = \frac{\mathrm{g}kH}{2\omega}\frac{\cosh k(z+h)}{\cosh kh}\cos(kx-\omega t) \approx \frac{\mathrm{g}ka}{\omega}\times O(1) = \frac{\mathrm{g}\epsilon}{\omega}\times O(1)\,, \tag{4.27}$$

$$w = \frac{\partial \phi}{\partial z} = \frac{gkH}{2\omega}\frac{\sinh k(z+h)}{\cosh kh}\sin(kx-\omega t) \approx \frac{gka}{\omega}\times O(1) = \frac{g\epsilon}{\omega}\times O(1)\,, \tag{4.28}$$

where $\epsilon = ka$ and where the amplitude $a = H/2$. It is evident that both u and w are of the same scale of variation, and as such there is no separation between the horizontal and vertical length scales. This allows both the horizontal and vertical scales to be the same. The time variable is scaled using the deep water approximation to the linear dispersion relation. These scales are then applied to the water wave boundary value problem. While the governing equation and bottom boundary conditions remain unchanged, the free surface boundary conditions are transformed to reflect this new scaling. The dynamic free surface boundary condition is now

$$g\eta + \frac{\partial \phi}{\partial t} + \frac{\epsilon}{2}\left[\left(\frac{\partial \phi}{\partial x}\right)^2 + \left(\frac{\partial \phi}{\partial z}\right)^2\right] = 0 \quad \text{on } z = \epsilon\eta\,, \tag{4.29}$$

and the kinematic free surface boundary condition is

$$\frac{\partial \eta}{\partial t} - \frac{\partial \phi}{\partial z} + \epsilon\frac{\partial \eta}{\partial x}\frac{\partial \phi}{\partial x} = 0 \quad \text{on } z = \epsilon\eta\,, \tag{4.30}$$

(It is noted that these boundary conditions are expressed in dimensional form, with the small parameter ϵ modifying the free surface elevation variable η). We further use Taylor series expansion about $z = 0$, which generates additional powers of ϵ. The dynamic free surface boundary condition would then become

$$g\eta + \frac{\partial \phi}{\partial t} + \frac{\epsilon}{2}\left[\left(\frac{\partial \phi}{\partial x}\right)^2 + \left(\frac{\partial \phi}{\partial z}\right)^2\right] + \epsilon\eta\frac{\partial}{\partial z}\left\{g\eta + \frac{\partial \phi}{\partial t} + \frac{\epsilon}{2}\left[\left(\frac{\partial \phi}{\partial x}\right)^2 + \left(\frac{\partial \phi}{\partial z}\right)^2\right]\right\} + \ldots \text{ on } z = 0\,, \tag{4.31}$$

and the kinematic free surface boundary condition

$$\frac{\partial \eta}{\partial t} - \frac{\partial \phi}{\partial z} + \epsilon\frac{\partial \phi}{\partial x}\frac{\partial \eta}{\partial x} + \epsilon\eta\frac{\partial}{\partial z}\left(\frac{\partial \eta}{\partial t} - \frac{\partial \phi}{\partial z} + \epsilon\frac{\partial \phi}{\partial x}\frac{\partial \eta}{\partial x}\right) + \ldots \text{ on } z = 0\,. \tag{4.32}$$

Finally the dependent variables ϕ and η are expanded in a power series in terms of the parameter ϵ

$$\phi = \sum_{n=1}^{\infty}\epsilon^{n-1}\phi_n = \phi_1 + \epsilon\phi_2 + \ldots\,, \tag{4.33}$$

$$\eta = \sum_{n=1}^{\infty}\epsilon^{n-1}\eta_n = \eta_1 + \epsilon\eta_2 + \ldots\,, \tag{4.34}$$

and substituted into the boundary value problem. The problem can then be separated into orders and solved sequentially. The order of the theory is denoted by the parameter ϵ; second-order Stokes theory retains terms up to $O(\epsilon)$, third-order Stokes theory up to $O(\epsilon^2)$, etc. The solutions at each higher order are dependent on lower-order solutions.

4.4.1 Properties of Weakly Nonlinear Deep Water Waves

The solution for ϕ at second order in ϵ can be found to be

$$\phi = Kx + \frac{gH}{2\omega}\frac{\cosh k(h+z)}{\cosh kh}\sin(kx-\omega t) + \frac{3\omega H^2}{32\sinh^4 kh}\cosh 2k(h+z)\sin 2(kx-\omega t)\,, \tag{4.35}$$

where $Kx = U$ is a mean current that accounts for any nonperiodic components of the solution (this is quantified below), and

$$\eta = \frac{H}{2}\cos(kx-\omega t) + \frac{kH^2\cosh kh(2\cosh^2 kh+1)}{16\sinh^3 kh}\cos 2(kx-\omega t) - \frac{kH^2}{8\sinh 2kh}\,. \tag{4.36}$$

It can be seen that the free surface elevation is comprised of a fundamental (or first harmonic) oscillating at a frequency ω, a second harmonic component oscillating at a frequency 2ω, and a mean set down. The two oscillating components are in phase at the crests and 180° out of phase at the troughs; this has the effect of sharpening the crests and flattening the troughs of the combined Stokes wave. The mean set down arises due to the choice of the Bernoulli constant to equal zero, and in this instance is relevant to the case of waves propagating up a slope in an otherwise infinite ocean.

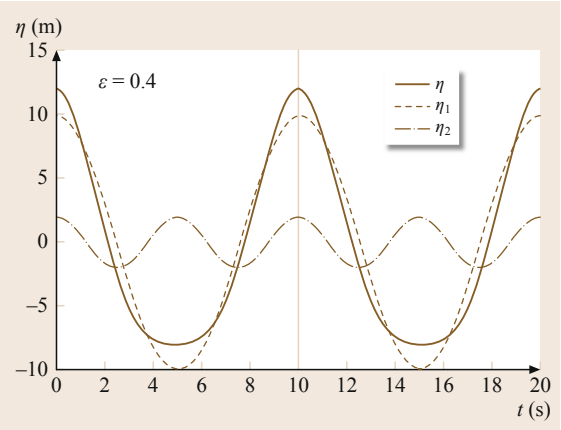

Fig. 4.2 Free surface of a second-order Stokes wave with $T = 10\ s$, along with the two component waves

However, for situations in which the motion is restricted to a finite domain (e.g., standing waves in a basin) the mean sea surface is necessarily zero, which would lead to a nonzero Bernoulli constant. Figure 4.2 shows the individual components and the total free surface profile for a second-order Stokes wave.

The particle velocities under a second-order Stokes wave can be derived from the velocity potential

$$u = \frac{\partial \phi}{\partial x} = K + \frac{gHk}{2\omega}\frac{\cosh k(h+z)}{\cosh kh}\cos(kx-\omega t) + \frac{3\omega H^2 k}{16\sinh^4 kh}\cosh 2k(h+z)\cos 2(kx-\omega t)\ , \tag{4.37}$$

$$w = \frac{\partial \phi}{\partial z} = \frac{gHk}{2\omega}\frac{\sinh k(h+z)}{\sinh kh}\sin(kx-\omega t) + \frac{3\omega H^2 k}{16\sinh^4 kh}\sinh 2k(h+z)\sin 2(kx-\omega t)\ . \tag{4.38}$$

The dispersion relation remains that of linear theory; the effects of nonlinearity on the wavelength appear at third order. Integrating the horizontal velocity u over depth and averaging over a wave period will allow an evaluation of the net mass flux (or Stokes drift). The value of the constant K is dictated by whether zero mass flux is indicative of the scenario at hand. For a large domain, the constant $K = 0$ and the mass flux is the value of the Stokes drift, while in confined situations the mass flux is necessarily zero and the mass flux would be carried by K. This also has implications for the definition of the phase speed C:

- The phase speed C can be defined as the speed of the wave relative to a stationary water column. In this case, $K = 0$, there is no net motion below the trough, and the phase speed

$$C = \sqrt{\frac{g}{k}\tanh kh}\ .$$

  The Stokes drift defines the net mass flux in the direction of wave propagation.
- The phase speed C can alternatively be defined as the speed of the wave relative to a stationary observer seeing waves with no mass flux. The phase speed would then be reduced by an amount proportional to the Stokes drift.

The pressure in the water column can be derived from the Bernoulli equation, and is

$$p = -\rho g z + \frac{\rho g H}{2}\frac{\cosh k(h+z)}{\cosh kh}\cos(kx-\omega t) - \frac{\rho g k H^2}{16\sinh kh\cosh kh}\cosh 2k(h+z) + \left[\frac{3\rho g k H^2}{16\cosh kh\sinh^3 kh}\cosh 2k(h+z) - \frac{\rho g h H^2}{16\sinh kh\cosh kh}\right]\cos 2(kx-\omega t)\ . \tag{4.39}$$

It is evident that the pressure contains a term that does not oscillate and another that is constant with depth. Evaluation of the pressure at the bottom ($z = -h$) reveals a term that reduces the static pressure due to the mean set down.

The basis of Stokes wave theory is that each harmonic of the fundamental frequency represents an additional order in the theory, and as such each harmonic amplitude becomes correspondingly smaller. It is difficult to establish a shallow water limit on the validity of Stokes theory based on the mathematical development, though a limit can be established on physical grounds. For example, one criterion could be that the second-order amplitude remain sufficiently small so that a bump does not appear in the trough of the wave; this implies that

$$kh > \sqrt{\frac{3a}{h}}\ , \tag{4.40}$$

for a bump to not appear in the trough.

4.4.2 Evolution of Weakly Nonlinear Deep Water Waves

Weakly nonlinear, deep water waves do not generally travel as permanent form waves, but evolve as a result of interactions with other waves of different frequencies and directions. These interactions can consist of

so-called *bound* waves (forced waves that do not satisfy the linear dispersion relation and, thus, can grow only a limited amount) and *resonant* waves (forced waves that do satisfy the linear dispersion relation and are thus able to grow without bound as the forcing is secular).

The expansion of the surface boundary conditions in powers of ϵ leads to products of unknowns that increase as the order of the expansion increases. Thus, given

$$\eta \approx e^{i\psi}, e^{-i\psi} , \tag{4.41}$$

(where $\psi = \mathbf{k}\cdot\mathbf{x} - \omega t$), higher-order terms lead to

$$\eta^2 \approx e^{2i\psi}, 1, e^{-2i\psi} , \tag{4.42}$$

$$\eta^3 \approx e^{3i\psi}, e^{i\psi}, e^{-i\psi}, e^{-3i\psi} , \tag{4.43}$$

and so on, until the desired truncation. Terms that result from this operation will remain bound to the primary harmonic and not experience unbounded growth. However, the η^2 will also generate terms proportional to $e^{i\psi}$ and $e^{-i\psi}$, and η^3 will generate terms proportional to $e^{2i\psi}$, 1, and $e^{-2i\psi}$, or (in both cases) terms proportional to the next lower-order solution. Solution of the resulting boundary value problem will generate terms that will grow linearly in either space or time without bounds (secular behavior). To ameliorate this, the method of multiple scales is often used to treat these problems. The application of this method allows the potentially secular behavior to be split into motions with different degrees of variation. In many cases, the fast degree of variation is associated with the waveform itself (the periodic motion) and the slow degree of variation with another property of the wave (for example, the amplitude of the wave form), which can then be linked to variations in some external field (e.g., the bathymetry).

The formalism in the previous section is most relevant to the case where a single wave component gives rise to harmonics, all of which can evolve during propagation to comprise a changing wave form. A coordinate system moving with the group velocity of the wave is defined; the resulting coordinates are defined as τ (time coordinate defining the slow temporal variation) and ξ (space coordinate defining the slow spatial variation). Carrying this analysis to third order will lead to the cubic nonlinear Schrödinger equations [4.11]

$$-i\frac{\partial A}{\partial \tau} - \frac{1}{2}\frac{\partial^2 \omega}{\partial k^2}\frac{\partial^2 A}{\partial \xi^2} + \beta|A|^2 A + \gamma A = 0 , \tag{4.44}$$

where

$$\beta = \frac{\omega k^2}{2} D + \frac{g^2 k^2}{2\omega(C_g^2 - gh)}\left(1 + \frac{kC_g}{2\omega\cosh^2 kh}\right)^2 , \tag{4.45}$$

and

$$\gamma = kS(\tau)\left(1 + \frac{kC_g}{2\omega\cosh^2 kh}\right) , \tag{4.46}$$

where $S(\tau)$ is an integration constant, and

$$D = \frac{\cosh 4kh + 8 - 2\tanh^2 kh}{8\sinh^4 kh} . \tag{4.47}$$

However, in most cases in the ocean, a description of wave propagation via the harmonics of a single wave is inapplicable, and we must turn toward a description comprised of a summation of waves of different frequencies and directions with random phases

$$\boldsymbol{\phi} = \sum_{n=1}^{\infty} -\frac{i}{2} B_n \frac{\cosh k_n(h+z)}{\cosh k_n h} e^{i(\mathbf{k_n}\cdot\mathbf{x} - \omega_n t + \epsilon_n)} + c.c. , \tag{4.48}$$

where B_n is the (complex) amplitude of the n-th component of $\boldsymbol{\phi}$ and ϵ_n is a random phase associated with this component. The corresponding expressions for the free surface elevation is

$$\eta = \sum_{n=1}^{\infty} \frac{A_n}{2} e^{i(\mathbf{k_n}\cdot\mathbf{x} - \omega_n t + \epsilon_n)} + c.c. , \tag{4.49}$$

where $c.c.$ refers to complex conjugate.

Substituting these expressions into the second-order boundary value problem will lead to expressions for the second-order contributions to the random sea, as shown by *Sharma* and *Dean* [4.12]

$$\begin{aligned}\boldsymbol{\phi} = &\sum_{n=1}^{\infty} -\frac{ig}{2\omega_n} A_n \frac{\cosh k_n(h+z)}{\cosh k_n h} e^{i(\mathbf{k_n}\cdot\mathbf{x} - \omega_n t + \epsilon_n)} \\ &+ \sum_{i=1}^{\infty}\sum_{j=1}^{\infty} -\frac{ig^2 A_i A_j D_{ij}^{+}}{8\omega_i\omega_j(\omega_i + \omega_j)} \frac{|\mathbf{k}_i + \mathbf{k}_j|(h+z)}{\cosh|\mathbf{k}_i + \mathbf{k}_j|h} \\ &\times e^{i(\psi_i + \psi_j)} \\ &+ \sum_{i=1}^{\infty}\sum_{j=1}^{\infty} -\frac{ig^2 A_i A_j D_{ij}^{-}}{8\omega_i\omega_j(\omega_i - \omega_j)} \frac{|\mathbf{k}_i - \mathbf{k}_j|(h+z)}{\cosh|\mathbf{k}_i - \mathbf{k}_j|h} \\ &\times e^{i(\psi_i - \psi_j)} + c.c. ,\end{aligned} \tag{4.50}$$

where i and j are two arbitrary frequency components in the spectrum. The coefficients D_{ij}^{+} and D_{ij}^{-} are

$$D_{ij}^{+} = \frac{\left\{\begin{array}{c}(\sqrt{R_i} + \sqrt{R_j})\left[\sqrt{R_j}(k_i^2 - R_i^2) + \sqrt{R_i}(k_j^2 - R_j^2)\right] \\ +2(\sqrt{R_i} + \sqrt{R_j})^2(\mathbf{k}_i\cdot\mathbf{k}_j - R_i R_j)\end{array}\right\}}{(\sqrt{R_i} + \sqrt{R_j})^2 - k_{ij}^{+}\tanh k_{ij}^{+} h} , \tag{4.51}$$

$$D_{ij}^{-} = \frac{\left\{(\sqrt{R_i}-\sqrt{R_j})\left[\sqrt{R_j}(k_i^2-R_i^2)-\sqrt{R_i}(k_j^2-R_j^2)\right]\right\} \\ \left\{+2(\sqrt{R_i}-\sqrt{R_j})^2(\mathbf{k}_i\cdot\mathbf{k}_j+R_iR_j)\right\}}{(\sqrt{R_i}-\sqrt{R_j})^2-k_{ij}^{-}\tanh k_{ij}^{-}h} , \tag{4.52}$$

where

$$k_{ij}^{\pm} = |\mathbf{k}_i \pm \mathbf{k}_j| \tag{4.53}$$

$$R_n = \frac{\omega_n^2}{g} . \tag{4.54}$$

The associated expression for the free surface elevation is

$$\begin{aligned}\eta = &\sum_{n=1}^{\infty}\frac{A_n}{2}e^{i(\mathbf{k_n}\cdot\mathbf{x}-\omega_n t+\epsilon_n)} \\ &+\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}\frac{1}{8}A_iA_j\left[\frac{D_{ij}^{+}-\mathbf{k}_i\cdot\mathbf{k}_j+R_iR_j}{\sqrt{R_iR_j}}+R_i+R_j\right] \\ &\times e^{i(\psi_i+\psi_j)} \\ &+\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}\frac{1}{8}A_iA_j\left[\frac{D_{ij}^{-}-\mathbf{k}_i\cdot\mathbf{k}_j-R_iR_j}{\sqrt{R_iR_j}}+R_i+R_j\right] \\ &\times e^{i(\psi_i-\psi_j)} .\end{aligned} \tag{4.55}$$

The terms $\psi_i+\psi_j$ and $\psi_i-\psi_j$ denote the sum and difference interactions, respectively. Of particular importance is the difference interaction $\psi_i-\psi_j$, a much longer wave than those wave components responsible for its generation and which is considered to have a role in harbor oscillation and seiching.

The waves generated by this second-order mechanism, as mentioned above, will not grow without limit, as they do not satisfy the linear dispersion relation and, thus, are not free waves. Resonant interactions, which generate waves that do satisfy the linear dispersion relation, are a particular subset of interactions. It can be shown [4.13] that no resonant interactions appear at second order (save for one trivial set), and one must go to third order to determine these interactions. The application of multiple scale techniques to address these resonances was first performed by *Benney* [4.14], and the resulting evolution equations are quite complicated; however, the resonance conditions can be written generically as follows

$$\psi_l + \psi_m - \psi_p = \psi_n , \tag{4.56}$$

where l, m, and p are indices that represent wave components which interact with ψ_n. These quartet interaction terms have been approximated for wind wave generation models [4.15] and are a primary engine for energy transfer within the spectrum in wind wave generation.

4.5 Shallow Water Wave Theories

In contrast to deep water, there is a distinct difference in the scale of variability between horizontal and vertical motions in shallow water (small kh). The horizontal motions are scaled similarly to deep water, but the vertical motions for small kh are

$$\begin{aligned}w = \frac{\partial\boldsymbol{\phi}}{\partial z} &= \frac{gkH}{2\omega}\frac{\sinh k(z+h)}{\cosh kh}\sin(kx-\omega t) \\ &\approx \frac{gHk^2(z+h)}{\omega}\times O(1) ,\end{aligned} \tag{4.57}$$

since $\sinh k(z+h) \approx k(z+h)$ for small kh. Using the shallow water asymptote of the linear dispersion relation and rearranging the shallow water asymptote of the vertical velocity w

$$\begin{aligned}w &\approx \frac{gHk^2(z+h)}{\omega} = \frac{gak^2h}{\omega}\left(1+\frac{z}{h}\right) \\ &= \frac{a}{h}\frac{\omega}{k}kh\left(1+\frac{z}{h}\right) = \delta\mu\left(\frac{\omega}{k}\right)\left(1+\frac{z}{h}\right) .\end{aligned} \tag{4.58}$$

As is the case with ϵ in deep water, two small parameters ($\delta = a/h$ and $\mu = kh$) are evident and are used for scaling. However, in this case, the vertical motions are much smaller than the horizontal motions. The shallow water asymptote of the linear dispersion relation, in addition to the scale difference between horizontal and vertical motions, is now applied to the boundary value problem. Unlike the deep water case, the governing equation here is altered

$$\frac{\partial^2\boldsymbol{\phi}}{\partial z^2}+\mu^2\frac{\partial^2\boldsymbol{\phi}}{\partial x^2} = 0 \quad -h \le z \le \eta , \tag{4.59}$$

and the disparity between horizontal and vertical motions is clear. The bottom boundary condition remains unchanged. The dynamic free surface boundary condition becomes

$$\mu^2\left(g\eta+\frac{\partial\boldsymbol{\phi}}{\partial t}\right)+\frac{\delta}{2}\left(\mu^2\left(\frac{\partial\boldsymbol{\phi}}{\partial x}\right)^2+\left(\frac{\partial\boldsymbol{\phi}}{\partial z}\right)^2\right) = 0$$

$$\text{on } z = \eta , \tag{4.60}$$

and the kinematic free surface boundary condition becomes

$$\mu^2\left(\frac{\partial\eta}{\partial t}+\delta\frac{\partial\eta}{\partial x}\frac{\partial\boldsymbol{\phi}}{\partial x}\right)=\frac{\partial\boldsymbol{\phi}}{\partial z}\quad\text{on } z=\eta\,. \tag{4.61}$$

Rather than using Taylor series about $z=0$ to address the unknown position of the free surface (as was done for Stokes theory), a power series for the depth dependence is used. This takes advantage of the fact that vertical variation of dynamical variables is weak in shallow water

$$\boldsymbol{\phi}(x,z,t)=\sum_{n=0}^{\infty}\left(\frac{z}{h}+1\right)^n\boldsymbol{\phi}_n(x,t)\,. \tag{4.62}$$

This expression for the velocity potential $\boldsymbol{\phi}$ can further be altered to satisfy the governing equation and the bottom boundary condition. The power series can then be expressed in terms of $\boldsymbol{\phi}_0$, the velocity potential at $z=-h$

$$\boldsymbol{\phi}=\boldsymbol{\phi}_0-\frac{\mu^2}{2}\left(\frac{z}{h}+1\right)^2\frac{\partial^2\boldsymbol{\phi}_0}{\partial x^2}+\frac{\mu^4}{24}\left(\frac{z}{h}+1\right)^4\frac{\partial^4\boldsymbol{\phi}_0}{\partial x^4}+O(\mu^6)\,. \tag{4.63}$$

This is then substituted into the kinematic and dynamic free surface boundary conditions and then integrated over depth. The result is a set of mass and momentum conservation equations, which are expressed in terms of powers of μ and δ, consistent with a weakly dispersive, weakly nonlinear assumption. Retaining terms up to $O(\delta,\mu^2)$ leads to the Boussinesq equations [4.16]

$$\frac{\partial\eta}{\partial t}+\frac{\partial}{\partial x}\left([h+\eta]\,\overline{u}\right)=0 \tag{4.64}$$

$$\frac{\partial\overline{u}}{\partial t}+\overline{u}\frac{\partial\overline{u}}{\partial x}+g\frac{\partial\eta}{\partial x}-\frac{h^2}{3}\frac{\partial^3\overline{u}}{\partial^2 x\partial t}=0\,, \tag{4.65}$$

where $\overline{u}$ is a depth-averaged velocity.

4.5.1 Properties of Weakly Nonlinear Shallow Water Waves

The Boussinesq equations can be modeled numerically for general wave propagation conditions. However, they can be further transformed into a single wave equation for η. This equation is known as the Korteweg–deVries (KdV) equation

$$\frac{\partial\eta}{\partial t}+c\frac{\partial\eta}{\partial x}+\frac{3c}{2h}\eta\frac{\partial\eta}{\partial x}+\frac{ch^2}{6}\frac{\partial^3\eta}{\partial x^3}=0\,, \tag{4.66}$$

where $c=\sqrt{gh}$. Due to an ambiguity in the derivation of the KdV equation, there are actually eight formally identical forms, but the form above is generally the version used.

The KdV equation is, in fact, exactly integrable. Two general analytic solution forms are possible with the KdV equation, each representing a wave of permanent form. The first is known as a solitary wave and is a wave consisting of an isolated hump of water with no trough. This wave is often used as a proxy for a tsunami propagating away from its origin. The free surface of a solitary wave is

$$\eta(x,t)=\eta_{\max}\operatorname{sech}^2\left[\frac{\sqrt{3}}{2}\left(\frac{\eta_{\max}}{h^3}\right)^{1/2}(x-ct-x_0)\right], \tag{4.67}$$

where $\eta_{\max}$ is the (specified) maximum free surface elevation and x_0 is the location of $\eta_{\max}$. One property of the solitary wave is that the wave form becomes narrower and more peaked as $\eta_{\max}$ increases. The phase speed c of the solitary wave is

$$c=\sqrt{gh}\left(1+\frac{\eta_{\max}}{h}\right)\,. \tag{4.68}$$

Figure 4.3 shows the free surface profile of a solitary wave for different values of η_{max}. The second form is a periodic wave known as a *cnoidal* wave, so named due to its dependence on the Jacobian *cn* function. Some of the calculable properties of cnoidal waves are listed below

$$c^2=gh\left(1+\frac{H}{h}\left[-1+\frac{2}{m}-\frac{3E(m)}{mK(m)}\right]\right)\,, \tag{4.69}$$

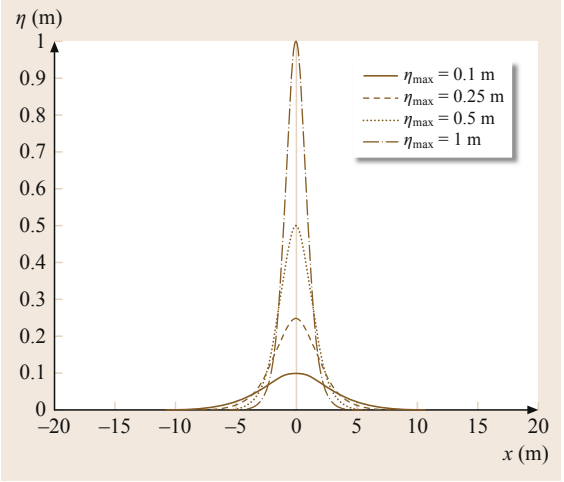

Fig. 4.3 Free surface profiles of a solitary wave with different values of $\eta_{\max}$

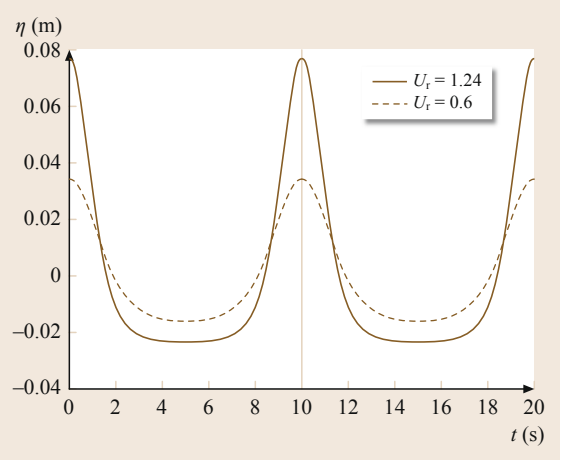

Fig. 4.4 Free surface profile of a cnoidal wave for two different values of the Ursell number U_r

$$\lambda = 4kh\left(\frac{m}{3\frac{H}{h}}\right)^2 , \tag{4.70}$$

$$T = \left(\frac{h}{g}\right)^2 \frac{4K(m)\left[\frac{h}{3H}\right]^2}{1+\frac{H}{h}\left(\frac{1}{2m}\right)\left(-m+2-3\frac{E(m)}{K(m)}\right)} , \tag{4.71}$$

$$\eta = \eta_2 + Hcn^2\left(\frac{2K(m)}{\lambda}(x-ct)\right) , \tag{4.72}$$

In these equations, $K(m)$ and $E(m)$ are the complete elliptic integrals of the first and second kind, respectively; m is a parameter, λ is the wave length, T is the wave period, and η_2 is the distance from the wave trough to the bottom at $z = -h$. The parameter m can be related to wave characteristics and determines the shape of the cnoidal wave; $m = 0$ recovers a sinusoidal wave, while $m = 1$ leads to a solitary wave. *Wiegel* [4.17] developed a straightforward procedure for calculating cnoidal wave profiles based on specified wave characteristics. Figure 4.4 shows cnoidal wave profiles for a wave with $t = 10$ *s* for two different values of the Ursell number $U_r = \delta/\mu^2$.

4.5.2 Evolution of Weakly Nonlinear Shallow Water Waves

In the context of irregular waves, this description of nearshore wave evolution can be described in terms of *wave–wave interaction*, a mechanism whereby waves of different frequencies in the spectrum can trade energy to alter the shape of the spectrum. This was mentioned earlier as a means by which wind sea transforms to long-period swell in the deep ocean. In the nearshore, the net effect of wave–wave interaction is to transfer energy from low frequencies to high ones; this accounts for changes in the spectral shape as waves evolve over sloping bathymetry; this was first described in detail by *Freilich* and *Guza* [4.18].

As with deep water waves, wave–wave interaction in shallow water is controlled by resonance between components of the wave spectrum. Unlike deep water, shallow water nonlinearity is dictated by *near*-resonant interaction among triads of waves. Given any arbitrary triad of wave components in a spectrum, the interaction triad is defined as

$$f_3 = f_2 + f_1 , \tag{4.73}$$

$$k_3 = k_2 + k_1 + O(\delta) , \tag{4.74}$$

where δ is a (small) parameter that describes the detuning away from perfect resonance. At the shallow water limit ($kh \to 0$) the parameter $\delta \to 0$, but even with finite δ significant energy transfer can take place. While the quartet interactions drive nonlinear energy transfer that occurs over spatial scales on the order of tens of kilometers, triad interactions force energy exchange, which can occur over tens of meters, drastically changing the shape and characteristics of the waves. These nonlinear interactions have been embedded into wave shoaling models, starting with *Freilich* and *Guza* [4.18], who derived a nonlinear shoaling model from the Korteweg–deVries equation, resulting in

$$\frac{\partial A_n}{\partial x} + \frac{1}{4h}\frac{\partial h}{\partial x}A_n - \frac{in^3k^3h^2}{6}A_n = \left[\sum_{l=1}^{N-1} A_l A_{n-l} + 2\sum_{l=1}^{N-n} A_l^* A_{n+l}\right] , \tag{4.75}$$

where A_n is the complex amplitude of the n-th Fourier component

$$\eta(x,y,t) = \sum_{n=1}^{N} \frac{A_n}{2} e^{i\int k_n \mathrm{d}x - \omega_n t} + c.c. , \tag{4.76}$$

and

$$nk = \frac{n\omega}{\sqrt{gh}} . \tag{4.77}$$

One limitation of this shoaling equation is the weakly dispersive assumption, which can be problematic for high frequency waves even in shallow water. This has been addressed via finite depth wave theory [4.19–22], among others.

4.6 Transformation of Waves Approaching Land

As waves approach the shoreline they undergo significant transformation in response to the arbitrarily varying bathymetry. Refraction and shoaling (as discussed above) will occur, but cannot be described by the Snell's law formulation. In addition, wave diffraction (the flow of energy along a wave crest due to high local gradients of wave height, and most often associated with waves encountering breakwaters) is also possible over bathymetric shoals.

The mild slope equation, developed by *Berkhoff* [4.23], has been used to simulate wave propagation over arbitrarily varying bathymetry

$$\nabla \cdot \left(CC_g \nabla \boldsymbol{\phi}\right) + k^2 CC_g \boldsymbol{\phi} = 0 \,, \tag{4.78}$$

where ∇ refers to differential operations in the horizontal (x, y) directions. It can be shown that the equation reduces to the Helmholtz equation for a flat bottom, and that it can also be transformed into a set of coupled equations for wave refraction by neglecting curvature terms. The equation is elliptic, which requires prespecification of the boundaries in advance. This is straightforward for enclosed harbors but challenging for open coasts, in which the location of wave breaking is unknown in advance. This has been addressed in the model's elliptic form [4.24]. However, the model has been transformed into a parabolic form [4.25], which affords a more straightforward numerical solution. *Kirby* [4.26] outlines several limitations of the parabolic form and offers some measures for ameliorating these limitations. The mild slope equation has been augmented with nonlinear interaction terms [4.20, 22, 27].

In the nearshore area, wave breaking is primarily controlled by the proximity of the bottom. The wave transformation process will force the wave to reach a limiting wave height, beyond which it cannot sustain its form. At this point the wave breaks. The breaking process and resultant generation of white water in the nearshore (the *surf zone*) is a major engine of nearshore processes (current generation, rip currents, infragravity waves, sediment transport, etc.)

The location of the initial breaking (or *incipient breaking*) of the wave demarcates the outer edge of the surf zone. It is important to identify conditions leading to incipient breaking for several reasons. For example, it is important in numerical modeling of wave propagation in the nearshore, since the wave breaking and dissipation terms are only activated within the surf zones, so it is essential to know when they need to be active.

One of the first incipient breaking criteria was developed by *McCowan* [4.28], who adapted the deep water solution of *Stokes* [4.10] to shallow water. Both studies assumed that a wave broke when the particle acceleration at the crest exceeds gravitational acceleration g, and showed that this condition resulted in an included crest angle of 120°. *McCowan* [4.28], however, also showed that, at this breaking condition

$$\frac{H_b}{h_b} = 0.78 \,, \tag{4.79}$$

or that the wave height reaches approximately 80% of the water depth at breaking. This criterion was developed using the properties of a solitary wave over a flat bottom, which would not generally fit the model of oscillatory motions in the surf zone. In an alternative treatment, *Miche* [4.29] developed a breaking criterion connected with wave steepness

$$\left(\frac{H_b}{L_b}\right) = \frac{1}{7} \tanh kh_b \,. \tag{4.80}$$

Note that this criterion approaches the maximum steepness criterion of *Stokes* [4.10] in deep water (large kh) and $H_b/h_b = 0.9$ in shallow water. A more complete development of the breaking criterion was developed by *Weggel* [4.30], who examined results from a number of laboratory experiments and determined that the bottom slope played an important role in the initiation of breaking. The resulting criterion is

$$\frac{H_b}{h_b} = b(m) - a(m)\frac{H_b}{gT^2} \,, \tag{4.81}$$

where

$$a(m) = 43.8\left(1 - e{-}19m\right) \,, \tag{4.82}$$

$$b(m) = \frac{1.56}{\left(1 + e^{-19.5m}\right)} \,. \tag{4.83}$$

This criterion reduces to (4.79) when the slope $m = 0$. Equation (4.81) is implicit for the breaking wave height H_b, so iteration is required.

Once the wave has broken, a description of the decay of the wave energy in the surf zone is needed. In this section, we discuss wave height decay mechanisms for both monochromatic and random waves. In general, the assumption of a spilling breaker is used; random wave formulations are typically determined by marrying this assumption to a probability distribution of some kind.

The equivalence between the energy decay in a spilling breaking wave and that of a hydraulic jump has been well established [4.31]. *Horikawa* and *Kuo* [4.32] conducted laboratory tests on breaking waves and determined the existence of a *stable* energy flux, which defines a state at which waves no longer break. This concept was further developed into a general description of wave evolution in the surf zone [4.33], with the hypothesis that the change in energy flux in the surf

zone would follow

$$\frac{\partial EC_g}{\partial x} = -\frac{K}{h}\left[EC_g - EC_{gs}\right] , \tag{4.84}$$

where K is a dimensionless decay coefficient, h is the still water depth, EC_g is the energy flux and the subscript s refers to the stable energy flux sought by the wave. Using shallow water wave theory and assuming that the stable wave height H_{stable} is a linear function of the water depth

$$H_{stable} = \Gamma h , \tag{4.85}$$

where Γ is a dimensionless coefficient, (4.84) can be transformed,

$$\frac{\partial\left[H^2\sqrt{h}\right]}{\partial x} = -\frac{K}{h}\left[H^2\sqrt{h} - \Gamma^2 h^{5/2}\right] . \tag{4.86}$$

Dally et al. [4.33] determined that $K = 0.15$ and $\Gamma = 0.4$ for minimum error to the data of *Horikawa* and *Kuo* [4.32]. *Dally* et al. [4.33] went on to develop analytical solutions for various bathymetric profiles, but (4.86) was the primary result.

Breaking of irregular waves in the surf zone requires a different approach than that for monochromatic waves, accommodating the random nature of waves by marrying the physics of wave breaking with probability theory. Early work by *Battjes* [4.34] and *Goda* [4.35] addressed the irregular nature of waves but did not allow for their evolution in the surf zone, constraining the statistical wave height measure to be some ratio between the wave height and the water depth.

Battjes and *Janssen* [4.36] developed a random wave breaking model based on energy flux conservation principles

$$\frac{\partial\overline{EC_g}}{\partial x} = -D , \tag{4.87}$$

where the overbar refers to averaged quantities and D is a dissipation rate. *Battjes* and *Janssen* [4.36] developed this dissipation rate from that of a dissipating bore, and introduced random wave heights by using the assumption that the heights of unbroken nearshore waves follow a Rayleigh distribution [4.37] for a range of heights that vary between zero and the maximum realizable wave height H_{max} at a particular water depth. The resulting dissipation rate D is

$$D = \frac{\alpha}{4} Q_b \overline{f} \rho g H_{max}^2 , \tag{4.88}$$

where H_{max} is the maximum wave height, Q_b is the percentage of breaking waves in a population of waves, $\overline{f}$ is an average frequency, and the coefficient α is of order 1. The maximum wave height is based on the *Miche* [4.29] criterion for maximum wave height, with some modification for the random nature of waves. This was then combined with the Rayleigh distribution for nearshore wave heights and further manipulated to lead to an expression for the fraction of breaking or broken waves Q_b

$$\frac{1 - Q_b}{\ln Q_b} = -\left(\frac{H_{rms}}{H_{max}}\right)^2 , \tag{4.89}$$

which is transcendental in Q_b. The model thus uses the offshore estimate of H_{rms} (from a measurement or a model) to calculate H_{max}, then Q_b from (4.89), and finally D from (4.88). With this estimate of the dissipation rate, (4.87) is then used to calculate the energy (and H_{rms}) at the new position.

Thornton and *Guza* [4.38] commented that the formulation of *Battjes* and *Janssen* [4.36] was, in effect, the implementation of a sharp cutoff value of the probability distribution of wave heights at H_{max}. They argue that waves in a group can momentarily exceed H_{max}, so a more gradual cutoff of the probability distribution near the maximum wave height is required. They then developed two weightings for this region of the probability distribution, either of which would allow wave heights above the theoretical maximum to occur. Using the same dissipative bore paradigm as *Battjes* and *Janssen* [4.36] but with different parameters, using the weightings, and integrating over the Rayleigh probability distribution, they determined two different dissipation rates for random waves. The first,

$$D = \frac{3\sqrt{\pi}}{16}\rho g \frac{B^3\overline{f}}{\gamma^4 h^5} H_{rms}^7 , \tag{4.90}$$

was less accurate when compared to data but leads to an analytical solution, while the second,

$$D = \frac{3\sqrt{\pi}}{16}\rho g B^3 \overline{f} \frac{H_{rms}^5}{\gamma^2 h^3}\left[1 - \frac{1}{\left(1 + \left(\frac{H_{rms}}{\gamma h}\right)^2\right)^{5/2}}\right] , \tag{4.91}$$

compared relatively well to data. The parameter B is nominally defined as the proportion of the front face of a breaking wave covered in foam, while γ is the ratio of the wave height to water depth in the surf zone; both are generally calibrated to data. *Thornton* and *Guza* [4.38] have shown that $\gamma = 0.42$ and $1.3 \le B \le 1.7$ work well for field data.

Both mechanisms have been used as a basis for the incorporation of random wave breaking into nonlinear phase-resolving models [4.20, 39]. The model of *Battjes* and *Janssen* [4.36] has been further extended for steep slopes [4.40], following work by *Baldock* et al. [4.41].

There is ample evidence for the existence of very long period of motion in the nearshore. These motions are generally thought to be largely the result of time variation of wave heights and breaking locations [4.42], though contributions from nonlinear wave–wave interactions [4.43] (see also *Bowen* and *Guza* [4.44]) may also be responsible. These long waves (often termed *infragravity* waves) have periods on the order of minutes and play a significant role in the evolution of the beach face.

The basic equations governing these long wave motions can be derived from the uniform depth equations of motion; the details can be found in [4.45]. The result can be expressed as an inhomogeneous wave equation

$$\frac{\partial^2\overline{\eta}}{\partial t^2} - \frac{\partial}{\partial x}\left(gh_O\frac{\partial\overline{\eta}}{\partial x}\right) - \frac{\partial}{\partial y}\left(gh_O\frac{\partial\overline{\eta}}{\partial y}\right) = F\,, \quad (4.92)$$

where h_O is a representative water depth and $\overline{\eta}$ is a mean (wave-averaged) free surface elevation. The term F represents forcing of the long wave motion.

In many cases [4.46], the long wave motion in the nearshore results from the transformation of long wave energy from offshore; the long wave propagates as a free wave. In this case, $F = 0$ in (4.92). The resulting motion in the nearshore is called an *edge wave*. The mean free surface elevation is assumed to have a longshore periodicity

$$\overline{\eta} = A(x)e^{i(k_y y \pm \omega t)}\,, \quad (4.93)$$

where $k_y = k\sin\theta$, or the longshore component of the wave number; the wave approach direction θ is assumed to be from shore normal. Substituting (4.93) into (4.92), and further assuming a plane beach, leads to a solution for $A(x)$ [4.47]

$$A(x) = a_n e^{-k_y x}L_n(2k_y x)\,, \quad (4.94)$$

where the subscript n denotes a mode of the solution (matching the number of zero crossings of the cross-shore structure of the edge wave) with amplitude a_n. The cross-shore structure is given by $L_n(2k_y x)$, which is the Laguerre polynomial of order n. The associated dispersion relation for this motion is

$$\omega^2 = gk_y\sin\left[(2n+1)\beta\right]\,, \quad (4.95)$$

where β is the angle of the beach from horizontal. Since there is no dissipation, the edge wave will fully reflect from the shoreline. For $n = 0$, all edge waves will propagate in the longshore direction, with crests perpendicular to the shoreline. For $n > 0$, however, the edge wave is affected by refraction; the wave reflects seaward from the shoreline, refracts to the point where the crests are perpendicular to the shoreline, then continues refracting back toward the shoreline. Such an edge wave is said to be *trapped*. On the other hand, a long wave which is *not* refracted back toward shore is said to be *leaky*. The phenomenon of *surf beat* [4.48, 49] is considered a leaky mode.

The discussion of edge waves in the previous section is useful as an introduction to nearshore long waves. However, because the motion is free, these long wave frequencies must be present at reasonable energy levels in the incident wave spectrum. The more significant source of long wave energy in the nearshore and surf zones comes from forced motion [4.46]. In this case, the forcing term F in (4.92) would be nonzero. If we dictate that the forcing is (as for nearshore circulation) dependent on the gradients of radiation stress [4.50], then the term F becomes

$$F = \frac{1}{\rho}\frac{\partial^2 S_{xx}}{\partial x^2}\,, \quad (4.96)$$

where the analysis is limited to processes in the cross-shore direction only (longshore derivatives are zero in (4.92)). In a wave group, the changes in radiation stress are assumed to be due to the spatial variations of the wave heights within the group. Using this assumption and limiting the domain to a constant water depth h_O gives the following solution for the mean sea surface

$$\overline{\eta} = -\frac{S_{xx}(x,t)}{\rho(gh_O - c_g)}\,, \quad (4.97)$$

where it can be seen that the mean sea surface is in antiphase with the gradient of radiation stress. Besides the limitation to constant depth, this solution is problematic in that $\overline{\eta}$ becomes quite large as the group velocity of the short waves in the group begins to approach the shallow water asymptote.

Later approaches sought to remedy these issues and move the area of interest closer to the surf zone. *Symonds* et al. [4.42] represented the wave group as a prescribed wave height variation about a mean amplitude and propagating over a sloping bottom, then used a constant breaking height-to-depth ratio *breaking index* inside the surf zone. The varying wave height led to a moving breakpoint, which served as a varying boundary condition for the generation of the long wave. The assumption of a constant breaking index was used to constrain the wave height in the surf zone, but destroyed any remaining group structure therein, which was later shown to be at least partially incorrect [4.51]. *Foda* and *Mei* [4.52] and *Schäffer* and *Svendsen* [4.53] perused an alternative formulation, in which the breakpoint was fixed but allowed for the group structure to remain in the surf zone.

The growth of the infragravity waves after this initial generation must now be considered. *Elgar*

et al. [4.54] showed that the infragravity wave energy tends to be a function of $h^{1.1}$, an almost linear dependence. However, coupling (4.97) with Green's Law shoaling yielded a growth rate closer to h^{-5}. The discrepancy is due to how the wave environment in the surf zone is treated. *Van Dongeren* and *Svendsen* [4.55], using a quasi-3-D (three-dimensional) nearshore circulation model, showed that the growth rate of infragravity waves can be dictated by manipulating the phase difference between the bound wave (locked with the wave group) and a free wave in the surf zone. Later, *Janssen* et al. [4.56] developed an analytical solution for the phase shift, leading to growth rates more consistent with measurements [4.57].

Oltman-Shay et al. [4.58], examining wave-like structures in nearshore current data taken at Duck, NC (USA), found that these structures did not correspond to any known wave theory. *Bowen* and *Holman* [4.59] applied stability theory to the equations governing nearshore circulation (with several simplifying assumptions) and determined that the most unstable modes had frequencies that were in the range of those observed in [4.58]. These instabilities were termed *shear waves* since they seemed to be caused by the shear instabilities of the longshore current. These motions only appeared when the longshore current was present and sufficiently energetic. The speed of these waves was independent of their frequency (a nondispersive phenomenon) and their signature in frequency longshore wave number space is both distinct and distinctly different from gravity wave phenomena.

Since the original papers there have been numerous studies on these shear waves. *Reniers* et al. [4.60] recreated these waves in the laboratory. Analytical means of studying the growth of these phenomena were advanced by *Dodd* and *Falques* [4.61], *Shrira* et al. [4.62], and *Feddersen* [4.63], among others. Additionally, the modeling of shear waves became a motivating factor for the development and application of numerical models of nearshore circulation ([4.64, 65], among others).

4.7 Computational Method for Fully Nonlinear Waves

With the development of powerful computers, numerical methods have been developed to tackle nonlinear wave problems and problems involving arbitrary body boundaries. Boundary integral methods are found to be more efficient for solving wave problems formulated using the potential flow theory, in particular to handle steep and overturning waves and complex body boundary shapes. For linear problems, boundary integral methods based on the free surface Green's function have been developed for analysis in both the frequency and time domains. Frequency domain analysis using a simple Rankine source has also been used to studying linear wave–body interaction problems in the frequency domain. An excellent review on numerical methods for free surface flows is given in [4.66].

Longuet-Higgins and *Cokelet* [4.4] developed a boundary integral method to solve the fully nonlinear inviscid wave motion problem. The method involves solution of Green's theorem, which is based on the Eulerian description of flow and the nonlinear free surface boundary conditions in the Lagrangian form; the method is, therefore, considered to be based on the mixed Eulerian–Lagrangian (MEL) formulation. To illustrate the method, let us consider a wave–body interaction problem such as that depicted in Fig. 4.1. Let the lateral extent of the domain be truncated by an open boundary Σ. Let us say that the flow has been started from rest with the initial condition being $\phi = 0$ and $\eta = 0$ at time $t = 0$. Since Σ is not a physical boundary, it has to be modeled so that waves incident on it may pass through without any reflection. There are several ways to achieve that approximately, as through use of nonlinear wave equations, free surface damping etc. Here let us consider a simple model by which it is assumed that $\phi = 0$ on Σ during the duration of flow simulation; in other words, simulation will be carried out only until the radiating waves reach the vicinity of the open boundary Σ.

Per Green's theorem,

$$2\pi\phi(P) + \int_{\partial\Omega} \phi \frac{\partial}{\partial n}\frac{1}{r_{PQ}} \mathrm{d}\partial\Omega - \int_{\partial\Omega} \frac{1}{r_{PQ}}\frac{\partial\phi}{\partial n}\mathrm{d}\partial\Omega = 0\,, \tag{4.98}$$

where $\partial\Omega$ is the union of all boundaries; i. e., $\partial\Omega = B + S_\mathrm{B} + \mathcal{F} + \Sigma$. Here Green's function $1/r_{PQ}$ corresponds to the potential at P due to the point source at Q. On B and S_B the normal velocity $\partial\phi/\partial n$ is known based on the no-flux condition, while ϕ is not known. On the open boundary, ϕ is known, here set to be zero, while $\partial\phi/\partial n$ is not known. On the free surface, one can time integrate the fully nonlinear free surface conditions at each time step to determine the free surface deformation and the velocity potential on the free surface; in other words, time integrate the dynamic condition

$$\frac{D\phi}{Dt} = \frac{1}{2}|\nabla\phi|^2 - \mathrm{g}Y\,,$$

to advance ϕ from discrete time n to $n+1$ and time integrate the free surface (material surface) kinematic

condition

$$\frac{D\boldsymbol{X}}{Dt} = \nabla\boldsymbol{\phi}\ ,$$

to advance position of free surface nodes $\boldsymbol{X} = (X, Y, Z)$ from discrete time n to $n+1$. Algorithms such as the fourth-order Runge–Kutta and Adams–Bashforth schemes [4.67, 68] may be used for the time integration. Thus, knowing $\boldsymbol{\phi}$ on the free surface, one may rewrite the above Green's theorem with known terms on the right-hand side and unknown terms on the left-hand side

$$\begin{aligned}
&2\pi\boldsymbol{\phi}(P \in B + S_B) \\
&+ \int\limits_{B+S_B} \boldsymbol{\phi}\frac{\partial}{\partial n}\frac{1}{r_{PQ}}\mathrm{d}\partial\Omega - \int\limits_{\Sigma+\mathcal{F}} \frac{1}{r_{PQ}}\frac{\partial\boldsymbol{\phi}}{\partial n}\mathrm{d}\partial\Omega \\
&= -2\pi\boldsymbol{\phi}(P \in \mathcal{F} + \Sigma) \\
&\quad - \int\limits_{\mathcal{F}+\Sigma} \boldsymbol{\phi}\frac{\partial}{\partial n}\frac{1}{r_{PQ}}\mathrm{d}\partial\Omega + \int\limits_{B+S_B} \frac{1}{r_{PQ}}\frac{\partial\boldsymbol{\phi}}{\partial n}\mathrm{d}\partial\Omega\ . \qquad (4.99)
\end{aligned}$$

The above integral equation is discretized and the resulting algebraic (matrix) equation solved either directly or iteratively for $\boldsymbol{\phi}$ on solid boundaries B and S_B, and for $\partial\boldsymbol{\phi}/\partial n$ on the free surface $\mathcal{F}$ and open boundary Σ. Upon determining $\boldsymbol{\phi}$ on the body, one can use the Euler integral (unsteady Bernoulli's equation) to determine pressure and through integration of pressure the hydrodynamic force on the body. The solution is thus advanced in time.

The mixed Eulerian–Lagrangian formulation has become a standard approach for solving fully nonlinear inviscid wave and wave–body interaction problems and it has been adopted in field discretization methods such as the finite difference method. Works on nonlinear wave and wave–body interaction problems based on the MEL formulation include those by *Vinje* and *Brevig* [4.69], *Grosenbaugh* and *Yeung* [4.67], *Dommermuth* et al. [4.68], *Saout* and *Ananthakrishnan* [4.70], *Ananthakrishnan* [4.71] and Xue et al. [4.72].

4.8 Wave Forces on Fixed and Floating Structures

In this section, the methods to determine the wave exciting force (which consists of incident and body-diffracted wave forces) on a body, and in the case of a freely floating body the additional wave radiation force due to the body motion generated waves are presented. Both theoretical and numerical methods to determine the wave forces will be discussed. We shall take the mean forward of the bodies to be zero here. One can find the nonzero forward speed cases in the literature on ship hydrodynamics and naval architecture. Empirical and exact methods to determine the viscous drag force is also discussed. Particular emphasis is given to parameters that govern ratios of various wave component and viscous drag forces.

4.8.1 Incident Wave Force: Froude–Krylov Force

Let us consider a body (submerged or floating) in a wave field as illustrated in Fig. 4.1. Let the incident wave be of small amplitude and be propagating in the positive x direction with elevation and potential given by

$$\eta^{\mathrm{i}} = \frac{H^{\mathrm{i}}}{2}\cos(kx - \omega t)\ ,$$

$$\boldsymbol{\phi}^{\mathrm{i}} = \frac{H^{\mathrm{i}}}{2}\frac{\cosh k(z+h)}{\cosh kh}\sin(kx - \omega t)\ ,$$

where the superscript i denotes incident wave. Using the Euler integral, one can find the dynamic pressure of the incident wave as

$$p^{\mathrm{i}} = -\rho\frac{\partial\boldsymbol{\phi}^{\mathrm{i}}}{\partial t} = \rho g\frac{H^{\mathrm{i}}}{2}\frac{\cosh k(z+h)}{\cosh kh}\cos(kx - \omega t)\ .$$

By integrating the incident wave pressure about the body surface (mean surface if the body is undergoing oscillation) one can determine the incident wave force, which is also known as the Froude–Krylov force, $\boldsymbol{F}^{\mathrm{i}}$

$$\begin{aligned}
\boldsymbol{F}^{\mathrm{i}} &= \int\limits_{S_o} p^{\mathrm{i}}\mathrm{d}S_o \\
&= \int\limits_{S_o} \rho g\frac{H^{\mathrm{i}}}{2}\frac{\cosh k(z+h)}{\cosh kh}\hat{n}\cos(kx - \omega t)\,\mathrm{d}S_o\ ,
\end{aligned}$$

where S_o denotes the body surface and $\hat{n}$ the unit normal vector into the body. Using the Gauss theorem one may write the above as a volume integral

$$\boldsymbol{F}^{\mathrm{i}} = \int\limits_{S_o} p^{\mathrm{i}}\hat{n}\mathrm{d}S_o = -\int\limits_{\forall_o} \nabla p^{\mathrm{i}}\mathrm{d}\forall_o\ ,$$

where $\forall_o$ denotes the volume occupied by the body. In the component form, the incident wave forces are then

$$\begin{aligned}
F_x^{\mathrm{i}} &= \rho g k\frac{H^{\mathrm{i}}}{2}\frac{1}{\cosh kh} \\
&\quad \times \int\limits_{\forall_o} \cosh k(z+h)\sin(kx - \omega t)\mathrm{d}\forall_o\ ,
\end{aligned}$$

and

$$F_z^{\mathrm{i}} = -\rho g k \frac{H^{\mathrm{i}}}{2} \frac{1}{\cosh kh} \times \int_{\forall_{\mathrm{o}}} \sinh k(z+h) \cos(kx - \omega t) \mathrm{d}\forall_{\mathrm{o}} .$$

If the body is really small, or more precisely spans small distances along x and z compared to the incident wave length, then the above integral may be further approximated by replacing x and z in the integrals by the x and z coordinates of the centroid. The Froude–Krylov force will then simply be

$$F_x^{\mathrm{i}} = \rho g k \frac{H^{\mathrm{i}}}{2} \frac{\cosh k(\bar{z}+h)}{\cosh kh} \sin(k\bar{x} - \omega t) \ \forall_{\mathrm{o}} ,$$

and

$$F_z^{\mathrm{i}} = -\rho g k \frac{H^{\mathrm{i}}}{2} \frac{\sinh k(\bar{z}+h)}{\cosh kh} \cos(k\bar{x} - \omega t) \ \forall_{\mathrm{o}} ,$$

where $(\bar{x}, \bar{z})$ denote the coordinates of the centroid of the body (submerged part of the body if the body were floating). It is thus a straightforward calculation to determine the small amplitude incident wave force, in particular if the body size is small compared to the incident wave length.

From the above integrals, one can also estimate the order of magnitude of the incident wave force. For a near surface body, the incident wave force is of the order of magnitude

$$|\boldsymbol{F}^{\mathrm{i}}| \equiv F^{\mathrm{i}} = O(\rho g \forall_{\mathrm{o}} k \frac{H^{\mathrm{i}}}{2}) = \Delta O(k \frac{H^{\mathrm{i}}}{2}) ,$$

where Δ denotes the weight (displacement) of the body.

Note that $kH^{\mathrm{i}}/2$ denotes the slope of the incident wave. In other words, the Froude–Krylov force of the order of body weight times the wave slope.

4.8.2 Morison Force on a Stationary Body

The incident wave force given by the Froude–Krylov force does not account for the viscous drag force, which could be significant even if the body size is small compared to the incident wave length. Computing the viscous drag force exactly would require solving the incompressible Navier–Stokes equation with free surface conditions, which is a formidable task. *Morison* et al. [4.73] proposed an empirical method to determine the wave force on a body including the drag force. Decomposing the hydrodynamic force into inertia and drag components, which is exact for force on a submerged body without a free surface, Morison proposed to determine the wave force as

$$F = F_{\mathrm{inertia}} + F_{\mathrm{drag}} .$$

In terms of inertia and drag coefficients,

$$F = C_{\mathrm{I}} \rho \dot{u} \forall + C_{\mathrm{d}} \frac{\rho}{2} u|u| A_{\mathrm{p}} ,$$

where F denotes the x component of the force, u the x component of fluid velocity, $\dot{u}$ the x component of fluid acceleration, $\forall$ the displaced volume of the body, and A_{p} the projected area of the body normal to the x-axis. The inertia and drag coefficients C_{i} and C_{d} are empirically obtained; scaled with respect to volume and projected area, they are both $O(1)$. The above is referred to as the Morison equation for the wave force on a body [4.8]. In the Morison equation method the fluid velocity and acceleration are determined using wave theories. As per linear Airy wave theory, as seen in an earlier section, the amplitudes of u and $\bar{u}$ are given by

$$|u| = \frac{H^{\mathrm{i}}}{2} \frac{gk}{\omega} \frac{\cosh k(z+h}{\cosh kh} ,$$
$$|\dot{u}| = \frac{H^{\mathrm{i}}}{2} gk \frac{\cosh k(z+h}{\cosh kh} .$$

The above Morison equation method thus provides a practical method to determine the viscous incident wave force on a body. The decomposition also allows one to determine the relative significance of the inertia and drag components of the incident wave force. For a body in a wave under wave influence (i. e., $kz \approx 0$)

$$\frac{\text{Drag}}{\text{Inertia}} = \frac{C_{\mathrm{d}} \rho u|u| A_{\mathrm{p}}/2}{C_{\mathrm{I}} \rho \dot{u} \forall} = O\left(\frac{H^{i2} g^2 k^2 D^2}{\omega^2 H^{\mathrm{i}} g k D^3}\right)$$
(here D denotes body length)
$$= O\left(\frac{H^{\mathrm{i}} g k}{\omega^2 D}\right) = O\left(\frac{H^{\mathrm{i}}}{D} \frac{1}{\tanh kh}\right)$$
(using the dispersion relation) .

From the above, it is clear that the drag force is more significant for a large wave height to body length ratio and/or in shallow water (i. e., small kh) [4.8]. Using wave kinematics, one can easily establish that in the case of deep water waves, the above ratio is related to the Keulegan–Carpenter number KC of oscillating flows [4.74]

$$KC \equiv \frac{UT}{D} = \frac{\left(\frac{H^{\mathrm{i}}}{2\,\omega}\right)\left(\frac{2\pi}{\omega}\right)}{D} = \frac{H^{\mathrm{i}}}{D} .$$

From the above discussion, the following points are worth recapitulating:

- The ratio of drag force to inertia force depends on (i) the wave height to body diameter ratio and (ii) wave length to water depth ratio.
- In the case of small wave height to body diameter ratio H^{i}/D in deep water waves (i. e., tanh kh = 1), the Morison force will be equal to the Froude–Krylov force for appropriate value of C_i.
- When using the Morison equation method for wave force on a moving body, the velocity and accelerations are taken to be relative to the body motion.

If the body dimension is large compared to wave height and not small compared to the incident wave length, then the drag force will not be important, but the Morison equation cannot be used to determine the inertial force because the scattering (diffraction) of waves by the body will become significant. One can use the potential flow theory to solve the diffraction problem (as done in [4.75] for a vertical cylinder) and also determine the wave diffraction force. The wave exciting force will then be the sum of the Froude–Krylov and the diffraction wave forces. The diffraction wave problem pertaining to linear wave–body interaction is discussed in the next section.

4.8.3 Wave Diffraction over a Body

Let the body shown in Fig. 4.1 be stationary. The mere presence of the body will cause the incident waves to scatter. For small amplitude waves, governed by linearized free surface conditions, one may solve the diffraction problem separately and determine the total potential as

$$\boldsymbol{\phi} = \boldsymbol{\phi}^{\mathrm{i}} + \boldsymbol{\phi}^{\mathrm{d}} ,$$

where the superscripts i and d denote incidence and diffraction, respectively. The solution of the incident wave potential is simply that of a free periodic wave as presented in Sect. 3.2. The diffraction potential is governed by the following set of equations

$$\begin{aligned}
\nabla^2\boldsymbol{\phi}^{\mathrm{d}} &= 0 , \\
\frac{\partial\boldsymbol{\phi}^{\mathrm{d}}}{\partial z} &= 0, \text{ on the sea bottom } z = -h , \\
\frac{\partial\boldsymbol{\phi}^{\mathrm{d}}}{\partial n} &= -\frac{\partial\boldsymbol{\phi}^{\mathrm{i}}}{\partial n} \text{ on the body surface } S_B , \\
\frac{\partial^2\boldsymbol{\phi}^{\mathrm{d}}}{\partial t^2} + \mathrm{g}\frac{\partial\boldsymbol{\phi}^{\mathrm{d}}}{\partial z} &= 0, \text{ on the mean free surface } z = 0 .
\end{aligned}$$

Moreover, in the far field, the diffraction potential must satisfy the Sommerfeld radiation condition [4.9]

$$\sqrt{R}\left(-i\omega\boldsymbol{\phi}^{\mathrm{d}} + C\frac{\partial\boldsymbol{\phi}^{\mathrm{d}}}{\partial R}\right) = 0, \text{ as } R \to \infty ,$$

where $R = \sqrt{x^2 + y^2}$, which denotes the radial distance from the body and C the wave phase speed. The above diffraction problem was solved by *McCamy* and *Fuchs* for the case of a vertical circular cylinder [4.75]. The x component wave exciting force with diffraction is given by

$$F_{\mathrm{x}} = \frac{\rho \mathrm{g}\frac{H}{2}D^2\tanh(kh)}{k^2R^2H_1^{(2)'}(kR)} ,$$

where $H_1^{(2)}$ denotes the Hankel function of the second kind and order 1 and $R = D/2$ the radius of the cylinder.

In the case of small H/D and not so small L/D, as in the case of waves incident on a supertanker or a large gravity platform, the diffraction force will be more significant than the drag force. On the other hand, drag force will be the predominant part of the wave exciting force for a mooring cable (small diameter) in a similar sea.

4.8.4 Wave Radiation Force on an Oscillating Body

In the case of a compliant or freely floating body, the body will undergo oscillatory motion when subject to the wave exciting force. The force due to waves caused by body motion is referred to as the wave radiation force [4.9]. Now let the body considered in Fig. 4.1 undergo rigid body motion such that the normal velocity of the body may be written as

$$\begin{aligned}
V_{\mathrm{n}} &= \boldsymbol{U}\cdot\hat{n} + (\boldsymbol{\Omega}\times\boldsymbol{r})\cdot\hat{n} \\
&= \boldsymbol{U}\cdot\hat{n} + \boldsymbol{\Omega}\cdot(\boldsymbol{r}\times\hat{n}) \\
&= \sum_{i=1}^{i=6} U_i n_i ,
\end{aligned}$$

where $\hat{n}$ denotes the unit normal vector on the body surface and r the position vector from the axis of rotation through the center of gravity. Moreover, $U_i = U_1, U_2, U_3, \Omega_1, \Omega_2, \Omega_3$ and $n_i = n_1, n_2, n_3, (\boldsymbol{r}\times\hat{n})_1, (\boldsymbol{r}\times\hat{n})_2, (\boldsymbol{r}\times\hat{n})_3$ for $i = 1, 2, 3, 4, 5, 6$, respectively, corresponding to the sixth degree of freedom rigid body motion. For the linear small amplitude body and wave motion problem, the radiation wave potential can be decomposed as per Kirchoff modal decomposition [4.9]

and written as

$$\Phi^{\mathrm{r}} = \sum_{j=1}^{j=6} A_j \boldsymbol{\phi}_j^{\mathrm{r}}\, e^{-i\omega t}\,,$$

where Φ^{r} denotes the total wave radiation potential and $\boldsymbol{\phi}_i^{\mathrm{r}}$ the i-th mode of radiation potential per unit amplitude of body motion. The equations governing the unit radiation potentials are given by [4.9]

$$\begin{aligned}
\nabla^2 \boldsymbol{\phi}_j^{\mathrm{r}} &= 0\,,\\
\frac{\partial \boldsymbol{\phi}_j^{\mathrm{r}}}{\partial z} &= 0, \text{ on the sea bottom } z = -h\,,\\
\frac{\partial \boldsymbol{\phi}_j^{\mathrm{r}}}{\partial n} &= -i\omega n_j \\
&\quad \text{on the equilibrium body surface } S_{\mathrm{Bo}}\,,\\
-\omega^2 \boldsymbol{\phi}_j^{\mathrm{r}} + \mathrm{g}\frac{\partial \boldsymbol{\phi}_j^{\mathrm{r}}}{\partial z} &= 0, \,, \\
&\quad \text{on the mean free surface } z = 0\,.
\end{aligned}$$

At infinity, the radiation potential must satisfy the Sommerfeld radiation condition

$$\sqrt{R}\left(-i\omega \boldsymbol{\phi}_j^{\mathrm{r}} + C\frac{\partial \boldsymbol{\phi}_j^{\mathrm{r}}}{\partial R}\right) = 0, \text{ as } R \to \infty\,,$$

where $R = \sqrt{x^2 = y^2}$, which denotes the radial distance from the body and C the phase speed of the radiating waves (which, for example, for the deep water wave case is g/ω). Upon solving the above radiation problem, for example by using the simple source distribution method originated by *Yeung* [4.66], one can determine the complex hydrodynamic coefficient

$$f_{ij} = \rho \int_{S_{\mathrm{Bo}}} \boldsymbol{\phi}_i^{\mathrm{r}} n_j \mathrm{d}S_{\mathrm{Bo}}\,,$$

which can be decomposed into components that are proportional to body acceleration (known as the added mass force) and to velocity (known as the wave damping force)

$$f_{ij} = -\omega^2 \mu_{ij} - i\omega\lambda_{ij}\,,$$

where μ_{ij} denotes the added mass force coefficient and λ_{ij} the wave damping force coefficient, both for force/moment along direction i for the j-th mode of motion. Using Green's identity one can establish that the coefficients are symmetric: $f_{ij} = f_{ji}$. For bodies with symmetry one can show that wave damping and wave excitation forces can be related using the Haskind relation [4.9]. The linear wave–body interaction theory is thus quite useful from a practical viewpoint to determine the wave forces. The theory is also rich in classical mathematics. Thus both theoreticians and practical engineers are attracted to the subject. The reader may refer to classical texts such as those by *Wehausen* and *Laitone* [4.7], *Newman* [4.9], and *Mei* [4.76] for detailed accounts of formulation and analysis of wave–body interactions.

In the case of a linear wave body interaction problem involving freely floating bodies, one then has to solve rigid body dynamics problem to determine the body response to wave forces consisting of incident, diffraction, and radiation wave force. In the case of the fully nonlinear wave–body interaction problem, both the hydrodynamic and body dynamic problems have to solved simultaneously, as each affect the other through the boundary conditions of hydrodynamic problems and through hydrodynamic force and moment of the body dynamics problem. The hydrodynamic problem may be solved using the mixed Eulerian–Lagrangian method of *Longuet-Higgins* and *Cokelet* [4.4] discussed earlier. Between the linear and fully nonlinear wave–body interaction theories, there are also weakly nonlinear theories developed for wave forces, as for example in [4.77], which are not discussed here. As the fully nonlinear wave theories are computationally intensive, linear and weakly nonlinear theories remain useful for engineering solutions to problems involving wave and body motions.

4.9 Concluding Remarks

The fundamentals of the mechanics of ocean wave theory and wave–body interactions were presented in this chapter. It began with an overview of linear wave theory, including the assumptions and limitations inherent in its use. Weakly nonlinear deep and shallow water wave theories were then outlined, including both permanent form waves (classical *Stokes* and cnoidal wave theories), followed by a discussion of wave spectral evolution and nonlinear wave–wave interactions. The transformation of waves over arbitrarily varying bathymetry was then detailed, touching on the mild slope equation for water wave propagation, nearshore wave breaking, infragravity waves, and waves caused by instabilities of nearshore circulation. Computational

methods for calculating fully nonlinear waves and the resultant forces on bodies were discussed. The interaction of waves with a submerged or floating body was also considered, including discussions of the Froude–Krylov force of the incident wave and the Morison equation method for determining the inertia and drag-components of the wave exciting force.

Related topics such as wind wave generation, sea spectra, and wave energy conversion are discussed in other chapters of the Handbook.

5. Physical Properties of Seawater

Wendell S. Brown

This chapter presents the definitions of the principal physical properties of the seawater, including pressure, temperature, salinity, density, density anomaly, specific heat, and thermal expansion. The typical global ocean profiles and distribution maps of surface temperature, salinity, and density anomaly are presented. Other oceanic properties, including the stability of oceanic water columns, use of temperature–salinity diagrams in identifying water masses, sea water freezing, as well as oceanic sound transmission and light are treated.

Sea water can be characterized by its temperature, salinity (the dissolved solids), and pressure. From these three quantities and the equation of the state of sea water, the ocean scientist or engineer can calculate other desired quantities, such as the density, sound velocity, heat capacity, or electrical conductivity. The oceanographic tables of yesteryear have been replaced by the microcomputer for the calculation of these derived quantities.

5.1 Hydrostatic Pressure

Assuming a static ocean (zero velocity), the vertical equation of motion reduces to a static force balance between the pressure gradient and water parcel weight according to

$$\frac{\partial p}{\partial z} = -\rho g \,, \tag{5.1}$$

where z is elevation positive upward, ρ is local water density, and g is the acceleration due to gravity. Upon integration of (5.1) from the surface (where gauge pressure is zero by definition) to depth $-z$, we obtain the hydrostatic pressure p_h relation

$$p_h(-z) = -\rho g z \,, \tag{5.2}$$

in which ρ is the average surface to depth $-z$ density. Hydrostatic pressure dominates the total oceanic pressure field. The hydrostatic relation (5.2) enables us to convert measured pressure to depth, if one assumes the density of an average ocean profile. For example, a pressure of 4062 decibars (5891 psi) converts to a depth of 4000 m (*Sanders* and *Fofonoff* [5.1], for further details and limitations).

5.2 Temperature

The temperature T of a water parcel is expressed in degrees Celsius (°C) and gives an indication of the energy or work that has been done on or associated with that water parcel. Temperature is now being easily and accurately measured by electronic thermometers employing thermistors or platinum resistance probes as the sens-

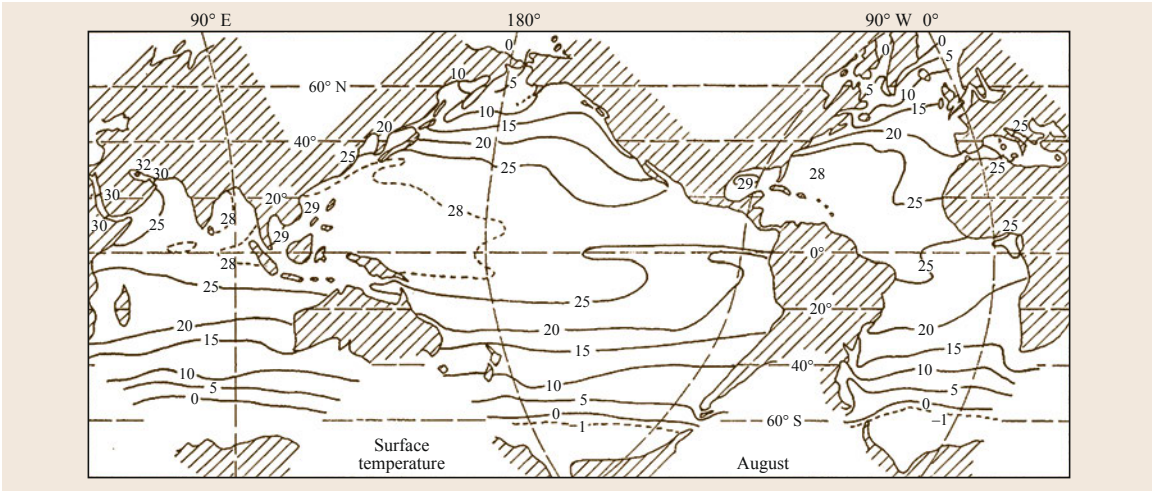

Fig. 5.1 Global ocean surface temperatures in August (after [5.2])

ing elements. These sensors are capable of resolving micro-degree temperature fluctuations, and are stable within millidegrees over a period of months. Oceanographic temperatures are referenced to the international practical temperature scale of 1968 (IPTS-68). (See *Mackenzie* [5.3] for a discussion of the IPTS-68 and the older IPTS-48 standards and the conversion between the two.)

Oceanographic temperature tends to vary systematically with depth and latitude. In the tropics, where there is an excess of the primarily short wave incoming solar radiation over outgoing long-wave radiation, the surface waters are warmer (with maxima of 25–30 °C) than those at adjacent latitudes. By contrast, surface waters at higher latitudes are cooler (minimums of ≈ −2 °C; the freezing point of saltwater), because energy is lost to the atmosphere and outer space by way of the outgoing long-wave radiation heat flux, which exceeds the incoming solar radiation heat flux at those latitudes. The typical global ocean sea surface temperature maps (Fig. 5.1) reflect that tropical warming and polar cooling. However, the distribution of temperature with latitude varies zonally, due to the general oceanographic circulation patterns, which vary with seasons. (See *Talley* et al. [5.4] for more detailed global ocean surface temperature distributions.)

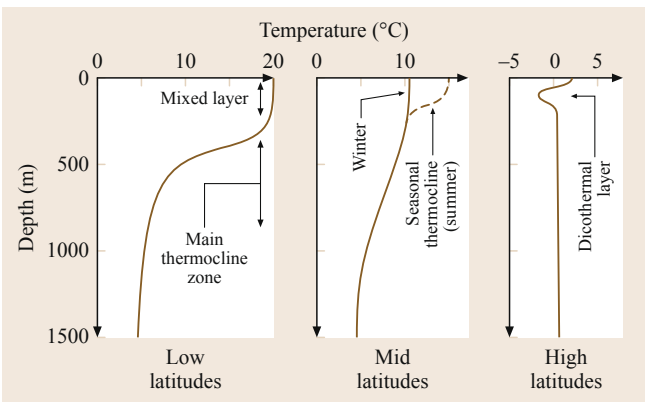

Fig. 5.2 Typical mean temperature profiles in the open ocean (after *Pickard* [5.2])

Typical vertical distributions of oceanic temperature at the low-, mid- and high-latitudes are presented in Fig. 5.2. Low- and mid-latitude oceans often feature a turbulence-induced mixed layer of relatively uniform temperatures that extend downward to a few 10 s of meters in depth. Below the mid-latitude mixed layer, temperature decreases rapidly through the *seasonal thermocline* – typically to a depth of about 100 m. While typical seasonal thermocline gradients are about 0.05 °C/m, they can vary in intensity and vertical extent depending on regional weather and seasonal climate. A permanent feature called the *main* thermocline, with typical vertical gradients of (order 0.02 °C/m), is found in the 100–1000 m depth range. The main thermocline is maintained by global ocean-scale surface heating/mixing and overturning processes. The deep water below the main thermocline is almost isothermal, featuring typically very small temperature gradients of order 0.001 °C/m.

Water is slightly compressible, so that the volume of a parcel of water moved from the surface to the ocean floor (5000 m depth), where the pressure is over 7000 psi (almost 500 times atmospheric pressure), will decrease by about 2%. If a sinking water parcel is compressed adiabatically (i. e., without loss or gain of heat), then the work done by the increasing pressure in forcing molecules closer together will raise its

measured or in-situ temperature T at a rate of about 1.4×10^{-4} °C/m – the *adiabatic temperature gradient*. For example, if a parcel with a temperature of 5.000 °C at the surface were lowered to a 4000 m depth, the temperature would increase to 5.438 °C. Conversely, if a parcel of sea water with an in-situ temperature of 5.000 °C at a 4000 m depth were raised adiabatically to the surface, then its in-situ temperature would decrease to 4.574 °C. (The difference in these two thought experiments is related to the compression process nonlinearity; something that is reflected in the equation of state of the water.) This pressure-induced temperature gradient is imposed on all water parcels uniformly and thus does not contribute to the buoyancy of a particular water parcel relative to the other surrounding water parcels.

So as to focus on the buoyancy-related temperature differences of water parcels, oceanographers define a *potential temperature* θ, which is the in-situ temperature that has been corrected mathematically for the compressibility effects described above. Generally, oceanographers correct in-situ temperatures to the ocean surface pressure which is zero gauge pressure. However, when comparing the temperatures of two water parcels at great depths, it is sometimes more accurate (because of the process nonlinearities) to correct to a common or a standard nonzero pressure or *zeroperfect*.

5.3 Salinity

Historically, ocean salinity was determined by the chemical titration of a sample collected in a bottle lowered on a wire from the ship. This titration-determined the chlorinity Cl of sea water (in units of parts per thousand – ‰) was directly related to salinity by the empirical Knudsen relation

$$S\,[\text{psu}] = 0.03 + 1.805\,\text{Cl}\,[‰]\,.$$

In the 1970s, considerable research was conducted on both the definition/measurement of conductivity and equation of state of sea water from which to calculate salinity. This work led to the adoption of the practical salinity scale of 1978 (PSS-78). (For details [5.5]) While modern computers enable the computation of salinity from these well-known complicated set of relationships, we find for practical purposes that they can be approximated by

$$S\,[\text{psu}] = 3.55 + 1.02\,C\,[\text{S/m}] - 0.73\,T\,[^\circ\text{C}]\,,$$

where *psu* is the practical salinity unit, T is the in-situ temperature measurements T (in units of degree Centigrade) and C is the in-situ conductivity measurement of (in units of Siemens/meter; a Siemen being an inverse ohm or the SI (international system of units) unit of conductivity). We find that seawater electrical conductivity varies around a value of 4. This technological advance has greatly expanded the measurement of ocean salinity.

The distribution of oceanic salinity (Fig. 5.3) is largely controlled by evaporation and precipitation pro-

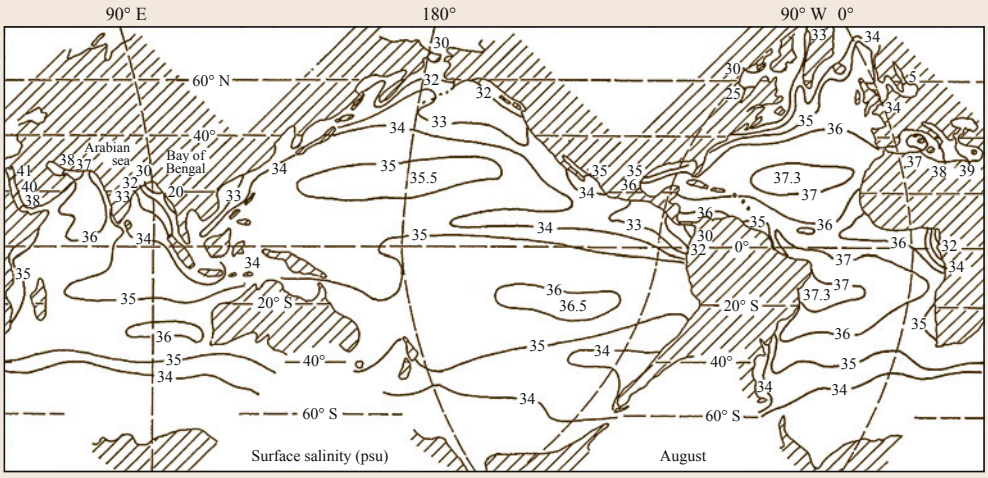

Fig. 5.3 Surface salinities of the oceans in August (after [5.2])

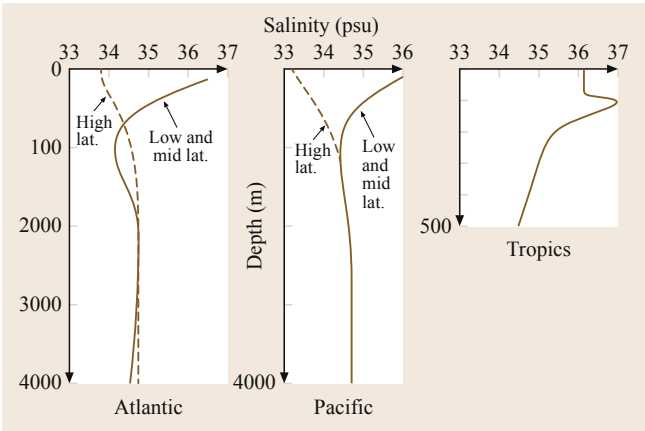

Fig. 5.4 Typical mean salinity profiles in the open ocean (after [5.2])

cesses in open ocean regions, fresh river runoff in coastal zones, and ice formation and melting in polar regions (both sea ice and glaciers). The lowest salinities (0–30 psu) are found in estuaries and polar regions. Coastal salinities are typically higher (30–34 psu), but less than open ocean salinities (33–37 psu). The average oceanic salinity is 34.7 psu. Semiclosed evaporation basins, such as the Mediterranean and the Red Sea, exhibit high salinities of 39 and 41 psu, respectively. The outflow of the very salty Mediterranean waters makes the Atlantic slightly saltier than the Pacific. The highest open ocean salinities are found in the center of the oceanic gyres (Chap. 2), while the lowest open ocean salinities are found along the equator due to excess rainfall. (See *Talley* et al. [5.4] for more detailed global ocean surface salinity distributions).

Typical vertical distributions of salinity are shown in Fig. 5.4. As with temperature, there is a surface mixed layer with relatively low salinity gradients. Below the mixed layer, there is a strong halocline where the salinities decrease; with a destabilizing influence. The depth of the halocline roughly agrees with the depth of the thermocline. There tends to be a salinity minimum around 800–1000 m at mid-latitudes. At low latitudes there tends to be a high surface salinity, while low surface salinities are found at high latitudes.

5.4 Density

The most important dynamic property of sea water is its *density* ρ, which is sometimes expressed as inverse of density or *specific volume* α_{STP}. Density is generally computed from the sea water equation of state, which is expressed as a function of in-situ temperature T, salinity S, and pressure P. (Oceanographers generally express pressure in units of decibars, since 1 decibar is nearly equal to the pressure due to 1 m of sea water. Note that 1 decibar $= 10^{-4}$ pascals, the SI unit of pressure.) Typical values of surface oceanic density vary from 1020 to 1030 $\mathrm{kg/m^3}$. Because oceanic density variations are relatively small, oceanographers have defined a quantity called density anomaly σ

$$\sigma(T,S,p) = \rho(T,S,p) - 1000\,, \tag{5.3}$$

which depends on in-situ temperature T, salinity S, and pressure P. The corresponding quantity for specific volume anomaly is

$$\delta = \alpha_STp - \alpha_{35,0,p}\,, \tag{5.4}$$

where $\alpha_{35,0,p}$ is the specific volume of the *standard ocean* with properties $T = 0°\mathrm{C}C$; $S = 35psu$, and p. The 1980 equation of state of sea water (EOS-80) (as given by *UNESCO* [5.5]) is the currently accepted standard for computing sea water properties.

Differing oceanic pressures induce small but significant volume differences in a water parcel, and hence in-situ density differences throughout the water column. For example, a parcel with a density anomaly of 28.106 $\mathrm{kg/m^3}$ at the surface will have a density anomaly of 46.644 $\mathrm{kg/m^3}$ at 4000 m. The significant pressure effect on the density anomaly in the deep ocean can obscure the effects of temperature and salinity variability.

Therefore, to compare the densities of two water parcels more conveniently, oceanographers have defined two related density anomaly quantities called σ_t and σ_θ. σ_t, which is evaluated according to

$$\sigma_t = \rho(T,S,p=0) - 1000\,, \tag{5.5}$$

is the density anomaly for a water parcel that has been raised to the ocean's surface adiabatically, essentially removing the largest effect of the pressure on the water parcel volume. Potential density anomaly (or sigma-theta σ_θ) is the density anomaly of a parcel of water for which the pressure effects on the volume and in-situ temperature removed. σ_θ is evaluated according to

$$\sigma_\theta = \rho(T=\theta,S,p=0) - 1000\,, \tag{5.6}$$

by using the potential temperature θ and zero pressure. Thus, value of potential density of a water parcel, which

is computed according to

$$\rho_{\text{pot}} = \sigma_\theta + 1000\,, \tag{5.7}$$

is based solely in terms of its surface temperature and salinity.

One of the most important features of the ocean is its vertical density gradient or stratification. In general, oceanic density increases with depth (i. e., $-z$) because there is the tendency for more dense parcels to sink below less dense parcels. This density environment supports a restoring force (due to the density difference and gravity) on a water parcel that has been displaced from its equilibrium position, such that it tends to its equilibrium position. The restoring force, whose strength is related to the vertical potential density gradient, gives rise to a class of oscillations called internal waves (discussed elsewhere). Oceanographers express the strength of this restoring force in terms of the buoyancy frequency, N or natural frequency of oscillation, given by

$$N(z) = \sqrt{-\frac{\mathrm{g}}{\rho}\frac{\partial \rho_{\text{pot}}}{\partial z}} \quad \text{(in units of rad/s)}\,. \tag{5.8}$$

The vertical density gradient – corrected for the effects of compressibility – is the relevant quantity here. If the more dense water is deeper, then the potential density gradient is negative, the water column is stable, N is positive, and internal waves are possible. If the water column density is uniform, then the potential density gradient and N are zero, the water column is neutrally stable, and oscillations are not possible. If more dense water sits atop less dense water, then the potential density gradient is positive, N is imaginary, the water column is unstable, and short-term water column overturning is inevitable.

Open ocean density is largely controlled by temperature, except in polar regions where salinity variations become significant. These relationships can be seen in the latitudinal variations of surface temperature, salinity, and density anomaly (σ_t), as shown in Fig. 5.5. The sampling of representative vertical profiles of density anomaly in Fig. 5.6 features the high-density gradient (high N and stability) zone called a pycnocline in the tropical/equatorial ocean. These upper ocean zones strongly resist vertical displacement, but support internal wave variability.

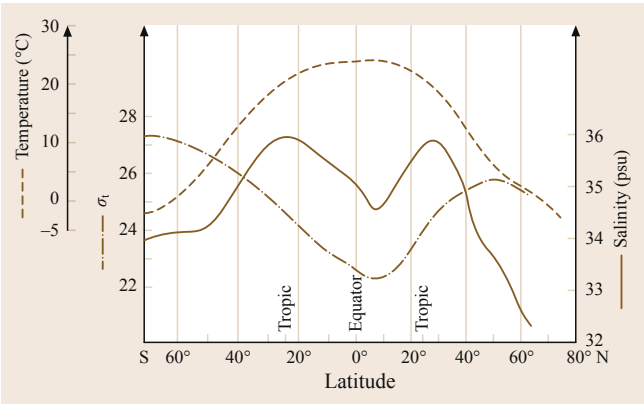

Fig. 5.5 Latitudinal variations of average ocean surface temperature, salinity and density anomaly σ_t (after [5.2])

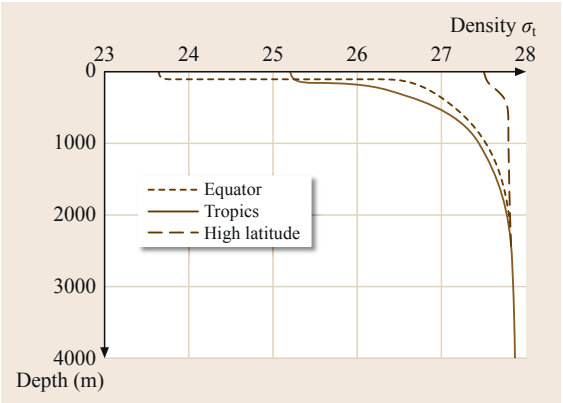

Fig. 5.6 Typical density/depth profiles at low and high latitudes (after [5.2])

5.5 Temperature–Salinity Relationships

Waters from different parts of the ocean can be identified by their distinctively different potential temperature and salinity characteristics as defined by their θ–S *relationships*, as revealed on a θ–S diagram like that in Fig. 5.7. The different curves in Fig. 5.7 are the distinctive θ–S *relationships* of water masses that have different mixing histories. Oceanographers use their knowledge of θ–S relationships to interpret the origin of waters that make up the local water column. Superimposed on the θ–S diagram are lines of equal σ_t. Oceanographers use such relationships to study water motion and mixing, while engineering designers can use water mass distributions to define design criteria.

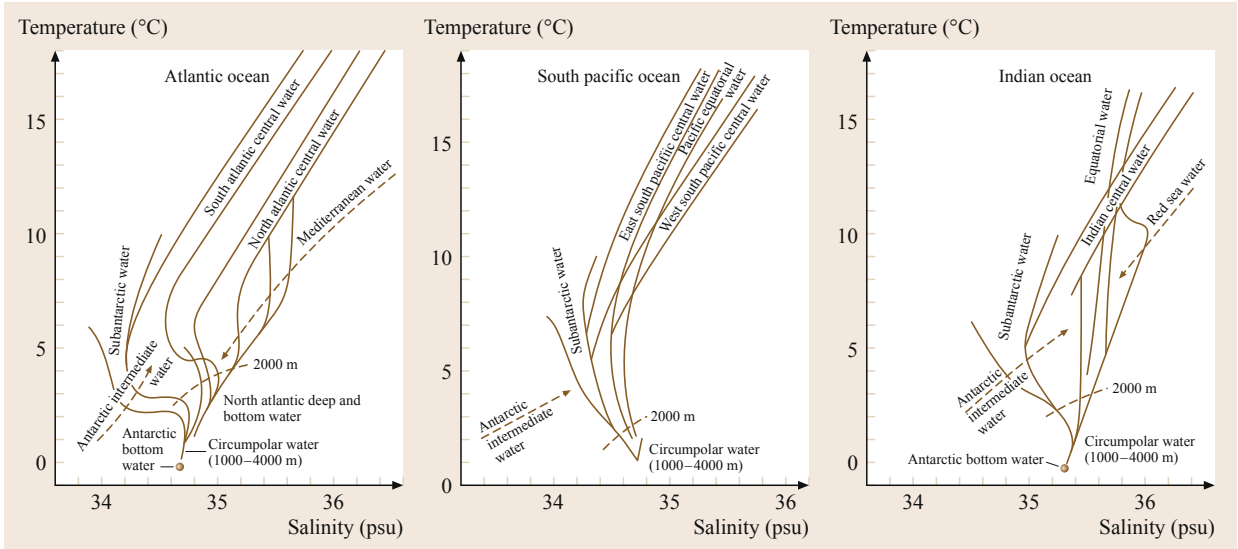

Fig. 5.7 Each of these schematic θ–S relationships that were derived from measurements in different ocean basins are characterized by their distinctly different water mass structures (after [5.6])

5.6 Specific Heat

The specific heat of sea water C_p is defined by the amount of heat in J that is required to raise the temperature of 1 kg of sea water 1 °C at a constant pressure; and thus has units of J/(kg°C). For sea water, the specific heat increases with temperature and decreases with salinity and pressure; with typical values $\approx 4000\,\mathrm{J/(kg°C)}$. The best empirical fit at zero pressure is given by *Millero* et al. [5.7] which extends to low temperatures. The pressure effect has not been directly measured, but has been estimated in UNESCO [5.8, p. 32–35]

5.7 Freezing of Sea Water and Sea Ice

The freezing temperature of sea water depends on the salinity and pressure of water. *Millero* and *Leung* [5.9] (or *UNESCO* [5.8, p. 29]) give an empirical form to laboratory measurements at low pressure. For example, sea water of 35 psu at the surface freezes at a temperature of −2.54 °C. As sea water freezes, the salt settles out of the forming ice and becomes part of a cold, salty water mass below the ice. Conversely, low salinity or freshwater layers are found at the surface in regions of melting ice.

5.8 Coefficient of Thermal Expansion

One of the unique properties of fresh water is the reversal in the sign of the coefficient of thermal expansion at 4 °C. Thus, water starting to freeze at 0 °C is less dense than water at 4 °C. As the salinity increases, this temperature of maximum density decreases. At a salinity of 24.7 psu, the freezing point and temperature of maximum density are equal at −1.33 °C. For salinities greater than 24.7 psu, the water continues to decrease in density with decreasing temperature until the freezing point is reached. A typical value of the coefficient of the thermal expansion is 2×10^{-4} °C. This value increases with temperature and pressure.

5.9 Sound Velocity

Communication in the ocean is done primarily with sound, because the ocean is opaque to all forms of electromagnetic radiation (from long-radio waves through short ultraviolet). Relative to electromagnetic radiation the ocean is relatively transparent to sound transmission. This is because sea water is compressible and so can support waves of compression and expansion, or small fluctuations in pressure about the mean – or *sound*. In the ocean, sound travels with a velocity of about 1500 m/s or about five times faster than in air.

Acoustics are a valuable tool for communication and getting a *view* through the ocean. The velocity of sound is a function of the temperature, salinity, and pressure, increasing with all three factors. (The work by *Chen* and *Millers* [5.10] used standard sea water and so it is both consistent with the Practical Salinity Scale of 1978 and in good agreement with values computed from the 1980 equation of state of sea water.) Temperature effects dominate the sound velocity profile in the upper ocean causing a decrease in sound velocity with depth. Pressure effects dominate in the deep ocean; increasing sound velocity with depth. Therefore, the resulting sound speed profile has a minimum at about 1200 m depth. The variations in sound velocity with depth have little effect on vertical or near-vertical transmissions of sound. However, the sound velocity profile and the minimum or *sound channel* have important implications for horizontal or near-horizontal transmission of sound.

Sound traveling from a point source will spread out spherically, so that the sound energy will decrease as the square of the distance from the source. The limit to the distance for effective sound transmission is reached when the energy density equals that of the ambient noise level (see below). If the sound energy can be confined between two vertical surfaces, then the reduction in energy is dictated by cylindrical spreading to be proportional to the distance. Under those circumstances, sound will travel further than in the point source case.

Sound travels along paths or *rays* whose orientation θ (angle from vertical) is dictated by sound speed C differences in two oceanic layers according to Snell's law

$$C - 1 \sin\theta_2 = C_2 \sin\theta_1 \,, \tag{5.9}$$

where the indices refer the 2 different oceanic layers.

From this relationship, it is obvious that the rays are bent or refracted toward lower velocity. Thus, a ray path from a source at the depth of the sound channel will be refracted toward the sound channel. The energy contained within a solid angle marked by four rays being emitted from the source is constant. Thus when the energy is concentrated in the sound channel, the energy density loses are dictated more by cylindrical spreading than spherical spreading. Hence, it is not surprising that large distances can be obtained by transmitting near the depth of the sound velocity minimum.

Sound transmission in the upper ocean is more difficult. Consider the case of a mixed layer where the sound velocity is controlled by pressure and increases with depth. Any sound transmitted into this region will be bent toward the surface. If this layer is above a layer with decreasing temperature which dominates over pressure, then rays penetrating into this layer will be refracted toward the bottom. This results in a shadow zone where acoustic communication or detection is impossible (Fig. 5.8).

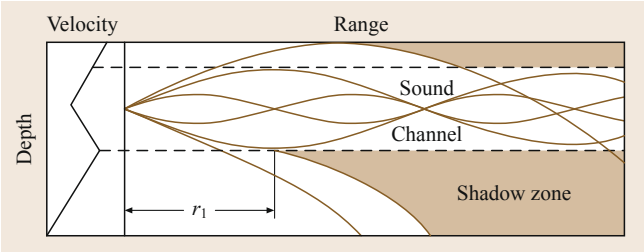

Fig. 5.8 Given the shape of the sound speed profile on the left, this is an acoustic ray trace showing sound channel and shadow zones (which is displaced from the sound source by r_1)

5.10 Acoustic Ambient Noise

The ambient noise level limits acoustic transmission and detection in the ocean. The background noise spectrum (Fig. 5.9) shows that oceanic noise levels decrease with increasing frequency. The main sources of low frequency noise (between 1 and 100 Hz) are seismic activity and explosions. At mid-frequencies (10–1000 Hz), ship noise dominates except when the noise of the rain hitting the surface becomes significant. At high frequencies (100–10 000 Hz), wind-generated noise, which depends on wind speed, dominates.

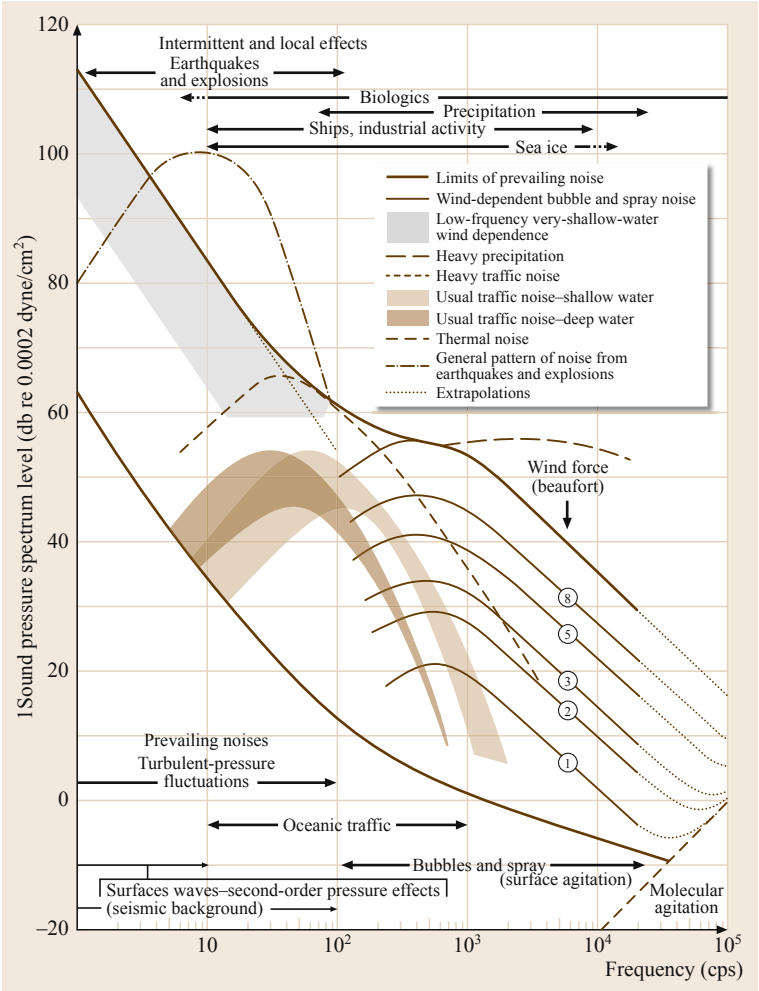

Fig. 5.9 Oceanic acoustic noise spectra

5.11 Light Transmission

Sunlight striking the ocean surface occupies a very narrow part of the spectrum of electromagnetic radiation; namely from 390 to 760 nm (or $390–760 \times 10^{-7}$ cm). The visible light part of this spectrum is defined by the familiar colors: violet, blue, green yellow, orange, and red. As light passes downward through the ocean waters, it is attenuated through absorption and scattering by water molecules, ions, and other living, dead, and inorganic suspended particles. The intensity of light at any depth $-z$ can be estimated from computations using Beer's law in the following form,

$$I_z = I_0 e^{+kz} ,$$

where I_0 is the intensity of light at the ocean's surface and k is the attenuation coefficient, which depends on the clarity of the water. For example in the open ocean, about 50% of the entering light is extinguished by a depth of 10 m and nearly 100% by a depth of 100 m (Fig. 5.10a). In typical coastal waters, nearly 100% of the light is extinguished by a depth of 10 m. However, the rate that light is attenuated differs with its color (i. e., wavelength). For example, in Fig. 5.10b, the longer wavelength red light is clearly attenuated more rapidly than the blue-violets.

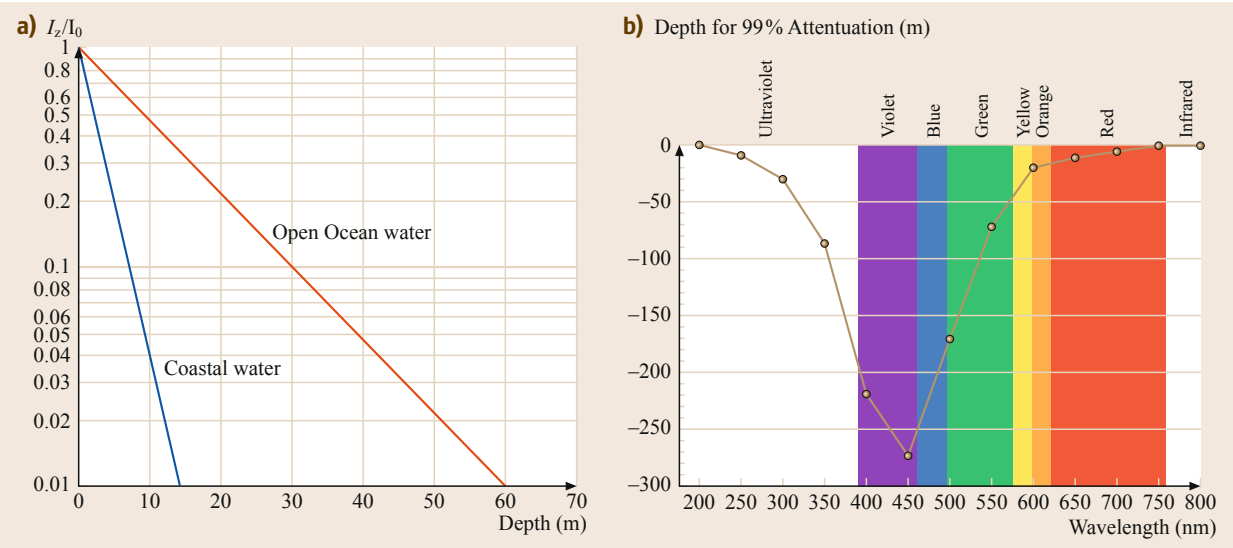

Fig. 5.10 **(a)** Depth versus light attenuation ratio I_z/I_0 for typical open ocean and coastal waters. **(b)** The open ocean 99% attenuation depths of various electromagnetic radiation wavelengths in which visible light color is indicated

6. Principles of Marine Corrosion

Robert E. Melchers

Seawater is an aggressive environment for materials particularly in warmer and polluted waters. In this environment, steel infrastructure, such as offshore platforms, pipelines, and tanks may corrode quickly, and for engineering and management purposes, the rate at which this occurs is of interest. Here, recently developed understanding of the corrosion processes over extended exposure periods is reviewed and recently developed science-based mathematical models for the prediction of corrosion and pitting of structural steels are described. The effect of various influencing factors is reviewed, including that of seawater quality and the effect of microorganisms on corrosion. Also, short discussions of the corrosion of stainless steels, aluminum, and copper-nickels, all materials that are used under marine exposure conditions, are given. This is followed by a description of recent observations of the corrosion of steel reinforcing bars in reinforced concrete, another widely used construction material in marine environments. It shows that reinforced concrete can be a highly successful construction material, even in long term and under marine conditions, but that severe loss of reinforcement may occur without obvious external signs detectable by visual inspection.

References 123

Seawater is a hostile environment – not only for people. Often it is considered to be the most severe environment to which materials can be exposed. Warmer waters accelerate the rate of corrosion, and warmer climate seawater is particularly aggressive. This was found to be a major problem during the later part of the Pacific campaigns in the Second World War when military equipment was found to corrode unexpectedly quickly in the Tropics [6.1]. However, even in colder waters, corrosion can be severe, as described in the following.

6.1 Chemical and Physical Composition of Seawater

On average, both the chemical and physical compositions of seawater are surprisingly uniform in the oceans around the world (Table 6.1). There are also similar small variations with depth, even for very deep waters [6.3]. The annual variation in water temperature (which typically lags about 3 months behind the seasons) is largely responsible for cyclic changes in many parameters, such as dissolved oxygen (DO) in seawater. It is also responsible in the variation in biological components, including the microbiological components, such as algae, archaea, and bacteria [6.4].

In enclosed seas and estuaries, and generally closer to shore, there are usually deviations in average water quality from those in open sea conditions. This applies particularly to nutrients, such as organic carbon, nitrogenous materials, phosphates, and sulfates. Typically, these variations are caused, in the natural environment, by natural, usually cyclic, annual processes

Table 6.1 Typical major components and physical properties of seawater in selected oceans

Salinity (predominantly Na^+ and Cl^-) [ppt]	34.4 (range mainly 31–38%)
Density [mg/l]	1.025 (average, at surface) 1.05 or more at depth
pH	8.1 typical (range 7.5–8.4)
Ions	**Weight [ppt]**
Chlorine (Cl^-)	18.98
Sulfate (SO_4^-)	2.65
Magnesium (Mg^+)	1.272
Bicarbonate (HCO_3^-)	0.14
Calcium (Ca^{2+})	0.40
Potassium (K^+)	0.38
Bromine	0.067
Carbon	0.028
Dissolved gasses	**Weight [ppm]**
Oxygen (O_2)	
At surface	7.5 (approx.)
−500 m	1.5
−2000 m	3.0
Carbon dioxide (CO_2)	
At surface	1.5
−500 m	4.0
−2000 m	6.0

Many of these are functions of water temperature and/or pressure (after [6.2])

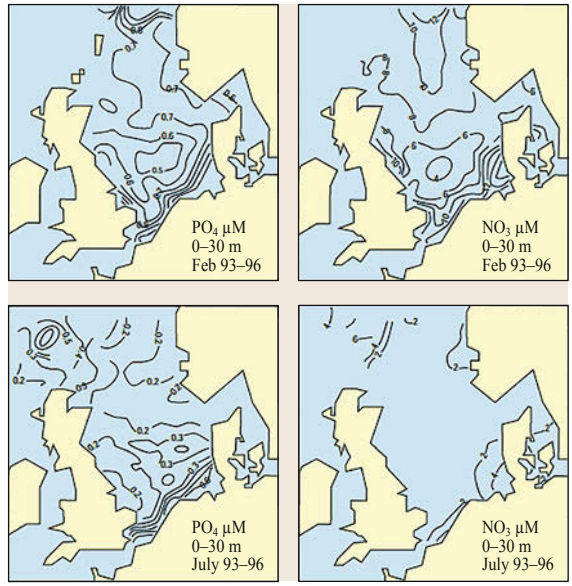

Fig. 6.1 Example of the summer–winter variations in phosphates (PO_4^-) and ammonia (NO_3^-) in the Greater North Sea (after [6.10])

involving marine growth and death [6.3]. However, in some locations, there may be a substantial discharge of nutrients or fertilizers or sewage effluents. Examples include highly populated areas or cities, where adjacent coastal water quality may be lower than that in open sea conditions. In particular, water quality can show elevated concentrations of nutrients. For example, the quality of seawater in the North Atlantic and that of the adjacent North Sea is considerably different from the usual open ocean conditions [6.5]. Figure 6.1 shows an example of the summer–winter variations in dissolved inorganic nitrogen (which in practice is mainly nitrate NO_3^-) and phosphates (PO_4^-). Largely these variations are caused by discharge, from the major rivers in that part of Europe, of sewage effluent and fertilizers (typically rich in N and P) and also some industrial wastes, although all such discharges increasingly have become subject to considerable restrictions [6.6]. Elevated nutrient levels have also been associated with areas usually considered to be almost pristine, such as Florida Keys [6.7] and the Great Barrier Reef [6.8]. Perhaps less surprising is that the elevated nutrient levels have been noted for offshore oil production facilities [6.9].

Elevated nutrient levels are seldom such that they are noticeable in a superficial examination of the water, such as, for example, at a bathing beach, although there may be some possible health effects for humans. Usually, the concentration levels of nutrients are quite low, and they change the overall chemical water properties only very slightly and, thus, have negligible effect on ordinary corrosion kinetics governed by electro chemical reactions. However, elevated nutrient levels can have major effects on living organisms and thus can have a major effect on marine growth and microbiological activity [6.11]. This applies for seawater in oceans, seas, and estuaries, and also in seawater harbors. Elevated nutrient levels relative to ambient can cause unpleasant effects, such as algal blooms in estuaries and unexpected fouling of ships and harbor facilities.

One example of the importance of nutrients in marine microbiology is the experiment in which iron filings were discharged from a vessel in the Pacific Ocean [6.12]. In a very short time, the seawater around the boat turned bright red, the result of the almost immediate proliferation of algae. This illustrates the critical importance even of a minor nutrient, in this case iron. Although iron is a requirement for biological activity, it usually lacks in seawater. The experiment also showed the fast response time of microbiology to changing conditions. For example, bacteria can double in numbers within a few hours [6.13]. From this follows the conclusion that simply counting bacteria at any point in time, as has been a traditional measure of microbiological activity, is largely irrelevant. The critical issues are: (i) the availability of sufficient energy for mi-

crobiological activity and (ii) the availability of essential nutrients to permit microbiological activity to occur. As will be discussed further, nutrients and thus microbiological activity can also have an important effect on the deterioration of metals in seawater and in freshwater.

The component of seawater most often associated with its (deleterious) effect on materials is salinity. Again, apart from the Baltic (where salinity tends to be lower than average) and the Dead Sea (where it is very high), salinity is remarkably similar in open ocean waters. Typically, salinity is reduced in estuaries and harbors, as a result of the inflow of river water. In chemistry, common salt (NaCl) is classed as one of the salts supplying chloride ions (Cl^-). It is one of the halides, a small group of chemicals that usually act as aggressive ions in chemical reactions. An often overlooked property of common salt is that it is hygroscopic, meaning that it attracts water, as is easily verified by attempting to dry out a seawater-soaked garment, such as a T-shirt without washing-out the salt. In other than dehumidified air, it will not dry. This means that once a metal object has been exposed to seawater, or has been sprayed with salt particles, and then not washed, it will attract moisture and thus tend to corrode at a much greater rate than otherwise would be the case, simply because the surface remains *wet* for longer. This is particularly important for the atmospheric corrosion of steel in coastal environments.

The other important component of seawater is its calcium carbonate content. It is supersaturated with it. For the usual pH of seawater (about 8.2), it occurs as calcium bicarbonate. Seashells (largely composed of calcium carbonate) exist because they are able to maintain their pH at just a sufficiently high level to avoid dissolution. The precise mechanisms involved are not of concern here, but it is known that an increase in carbon dioxide in the atmosphere will cause the pH of seawater to drop slightly, thereby upsetting the calcium carbonate balance in the sea, with, as is well known, potentially serious effects on seashells and molluscs. This is one of the well-recognized concerns associated with climate change. As will become clear in the following, it also can have a significant effect on marine corrosion of metals such as steels.

6.2 Materials Used in Marine Environments

Natural constructional materials are restricted largely to rocks, some pure metals (e.g., gold), many oxidized metals (e.g., iron ore), and various plant forms, including wood. However, there is an incredibly large (and growing) range of man-made materials available for commercial and industrial use. They include steels of various types including chromium steels, reinforced concrete, aluminum, glass and carbon fiber composites, nylon and other man-made organic materials. To a greater or lesser extent all of these are used in marine environments. Which material actually is used, or which combinations, depends largely on the economics involved and often this includes the first cost and, increasingly, also the anticipated maintenance and replacement costs. In some cases, it may include the consequential costs should failure occur. In practice, the materials most used in major marine infrastructure applications are steel and reinforced concrete. For mechanical equipment such as harbor facilities and shipping steel is predominant, although aluminum and fiber composites also are used for many applications. Herein attention is focused on steel structures.

Good quality information and prediction tools for likely long-term performance are scarce. Comprehensive compendia of the corrosion performance of many metals and alloys and for many nonmetals are available [6.14, 15] but the approach is largely anecdotal. Until recently this was also the case for steels, as described in more detail in the following. For reinforced concrete, the principles governing the corrosion of steel reinforcement and the performance of the concrete itself in marine environments are established and readily available [6.16, 17], but there are some aspects not yet fully explained, as also described in more detail in the following.

6.3 Marine Corrosion of Steel

Steel is used extensively in industrial, institutional, and commercial projects, and in structural systems, and has a long history of such uses. Applications include offshore structures (floating and fixed), commercial ships, defense force and commercial ships, mooring chain, submerged pipelines, coastal jetties, sheet and other piling, cranes and other loading and offloading facilities, storage tanks, bridges, multistory car-parks, electric-

Table 6.2 Typical steel properties

	Composition [%]									Mechanical Properties			
Steel type	Description	C	Mn	S max	P max	Si	Cu	Ni	Cr	Fsy [ksi]	Fsy [MPa]	Fult [ksi]	Fult [MPa]
Carbon steel A36	General purpose structural	0.26	< 1.65	< 0.05	< 0.04	< 0.6	< 0.6			36	250	58–80	400–550
HSLA A992	Ditto	0.23	0.5–1.5	0.045	0.035	0.4	0.6	0.45	< 0.35	50–65	340–450	65	450
HSLA A588	Structural weathering steel	0.15–0.2	0.75–1.35	0.05	0.04	0.15–0.4	0.2–0.5	< 0.5	0.3–7	42–50	290–350	63–70	435–480

Fsy = yield strength; Fult = ultimate strength; HSLA = high strength low alloy; Conversion: 1 MPa = 0.145 ksi (after [6.18])

ity transmission towers, and industrial and commercial buildings. Mostly these are constructed from mild or low alloy structural steels. Compared to more specialized steels, they are relatively cost-effective and readily available. Table 6.2 shows the typical chemical composition and physical properties of some steel types used in industrial infrastructure.

To ensure steel structures are sufficiently safe against collapse or loss of serviceability, much attention has been given to understanding and defining the capability of steel structures to resist various loading conditions. The results have been formulated into mathematical models and design requirements. Mostly these are set out in design codes and similar documents, increasingly at an international level. In the main the rules in the design codes are based on probabilistic concepts. This recognizes that perfect safety is unattainable in practice and that some element of risk always remains, no matter how well understood the materials and the loading conditions are [6.19].

Components of steel infrastructure may fail in a number of ways, including in tension or in compression, or by buckling, fatigue, corrosion or wear or some combination. Of these, tension, compression, buckling failure modes, and fatigue have received much research attention over a long period of time and comprehensive design rules now exist [6.21]. Fatigue typically displays a significant level of uncertainty and as a result the factors of safety against failure by fatigue tend to be higher than for most other failure modes. In addition, for critical structures, such as high-rise cranes and certain offshore structures, periodic in-situ inspection is warranted. Less well understood are stress corrosion cracking and wear. This is reflected in the wide variations in observed effects and the poor prediction capabilities of existing analytical models.

Corrosion, the subject of this chapter, often is considered well understood, at least from a scientific perspective. But design rules for practical implementation are not readily available, although, as described in the following, some progress has been made recently. In particular, models based on sound scientific principles are now available for the progression of corrosion loss and of corrosion pitting. These are described in Sect. 6.4. First, it is necessary to review some fundamental aspects of the marine corrosion of steel.

Many practical applications in marine environments ensure that steels are protected in some way. By far the most common methods are cathodic protection by impressed current or by sacrificial anodes and the use of protective coatings such as paints. When properly applied and if well maintained, these systems often perform very well, and under these conditions, the progression of corrosion of steel is not of a significant concern. However, in practice, protective coatings are not always applied correctly or with sufficient care or, more typically, are not maintained. Similarly, cathodic protection systems are sometimes neglected. In other cases, these protective measures are not technically feasible, or are deemed uneconomic. As a result, infrastructure located in or near seawater invariably shows some level of corrosion and perhaps structural damage resulting from corrosion.

For the design of new steel structures likely to be subject to corrosive conditions, the usual approach is to add a nominal sacrificial corrosion allowance on top of the minimum thickness required by structural design considerations. This is meant to allow for expected future loss of material. For example, shipping Classification Society rules for commercial vessels typically have a 10% plate thickness allowance for *wastage*. Once this is reached, the element with this degree of corrosion loss must be replaced, usually at considerable cost. In other cases, such as in holds of bulk carrier ships and for chains, surface coatings are ineffective or insufficiently robust and cathodic protection is problematic. Only a sacrificial corrosion allowance is used. Particularly in these cases, there is considerable interest in the progression of corrosion loss and of pitting with time and as a function of various influencing factors.

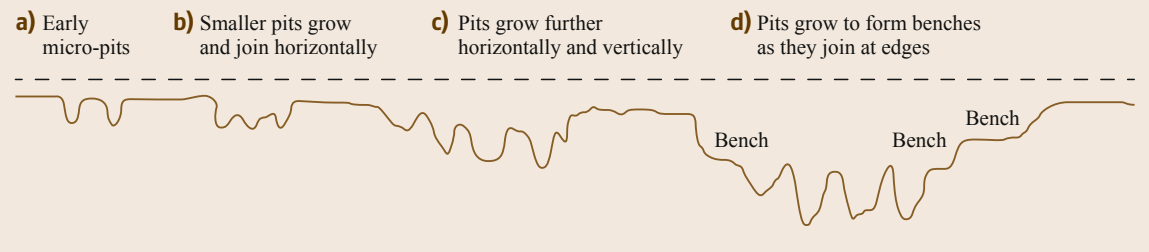

Fig. 6.2a–d Development of pitting as a function of time, showing initial pitting brooding out to form a rough plateau on which new pits then form, giving eventually a series of stepped pit plateaus (after [6.20])

Corrosion of steel invariably produces rusts. Usually, they are much more bulky than the steel lost. They also tend to hide the state of the remaining metal underneath and makes assessment of the state of the remaining steel more difficult. Commonly, ultrasonic measurements at randomly selected spot locations are used to estimate the thickness of the remaining steel. Other techniques based on electrochemistry may also be suitable in some circumstances. However, all techniques are expensive, invasive, and do not provide estimates of the rate of corrosion, or the likely corrosion loss in the future. As shown in below, simple linear extrapolation is usually very conservative.

Information about the corrosion likely to occur under given conditions in the future can be gleaned from corrosion handbooks [6.14, 15] and in some specific application cases estimated using models of the relationship between corrosion loss and time and the various factors that influence corrosion. In the main, such models are empirical and have a high degree of uncertainty, despite considerable efforts to obtain relevant data. Unfortunately, many corrosion texts describe corrosion loss or pit depth observations obtained under accelerated (electro-chemical) conditions in laboratory experiments using artificial seawater. Although this may add an insight into fundamental corrosion processes and conditions, the results do not relate well to field experience [6.22]. How then does steel actually corrode in seawater?

The corrosion of steel of interest under ocean conditions is corrosion in *wet* environments. It can occur only in the presence of water and requires oxygen or some other electron acceptor. It is distinguished from a purely chemical reaction in that it usually involves the physical transport of electrons from one site (anode) to another (cathode) with parts of the chemical reaction occurring at each site. Of course, the sites may be very close to each other (nanometers) or meters apart, provided there is electrical conductivity between the sites. Water provides such an electrolyte but steel itself has much greater conductivity. The initiation of corrosion invariably is by pitting at a micro-scale, set up by very small differences in the surface topography and grain structure of a steel surface. This permits very small (electrical) potential differences to develop and eventually lead to pit initiation [6.23, 24].

In real seawater, invariably there will be a colonization also by biofilms and very soon afterward also by bacteria and various other microorganisms present in seawater. Some microorganisms, such as the sulfate reducing bacteria, can produce hydrogen sulfide, known to be very corrosive for steels and typically also producing localized corrosion or pitting [6.4, 24]. The net result is that within hours of being exposed to seawater a steel surface begins to form very small pits. Many, if not most, of these very small early pits stop growing soon after formation and are essentially overtaken by the others. These continue to grow in depth for some time (days, weeks) but then slow down and grow mainly in width. It follows that microscopic examination of a corroded steel surface invariably reveals a complex mix of larger and smaller pits as well as unaffected regions (cathodes), at least for some time. Figure 6.2 shows a schematic view of the development of pitting with increased exposure time. In particular, it shows that the initial major pits stop growing in depth but amalgamate to form shallow depressions and that later new pitting develops on the depression surfaces. The net result is that a series of depressions are formed and that there is always a range of pit depths and sizes. Importantly, unlike the conventional wisdom about pit growth, it is not a continuous single function process. Figure 6.3 shows some microscopic photographs (at the same scale) of the progression of pitting [6.20].

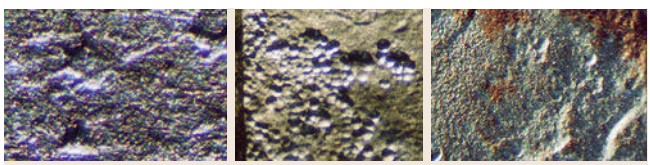

Fig. 6.3 Successive views of pitted surface of steel coupons (after [6.20])

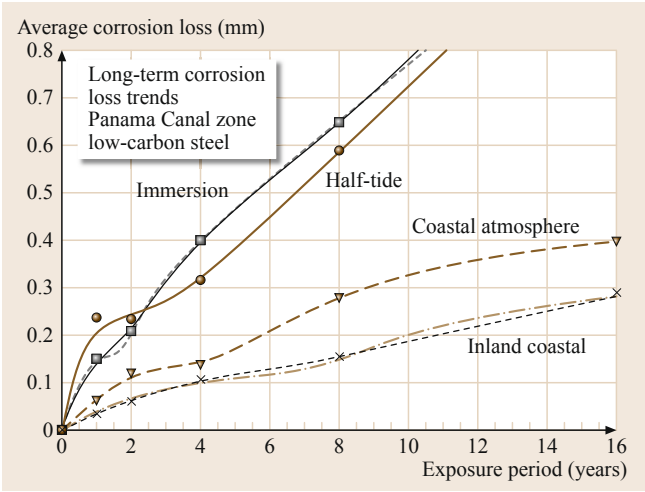

Fig. 6.4 Corrosion as measured by mass loss for different exposure zones in the Panama Canal zone, based on reported data with trends curves added (after [6.25, 26])

It is thus seen that the so-called *uniform* corrosion is an erroneous but still a convenient concept, particularly for engineering design. In practice, it is obtained usually from the differences in mass loss obtained from coupons exposed for different periods of time. Figure 6.4 shows some typical curves for the development of mass loss with time, for four different exposure environments.

Sometimes other types of corrosion are also defined, but mostly they are special cases of pitting. For example, crevice corrosion can be considered a special case of pitting corrosion that occurs in sharp, narrow deviations from the surface, but that involves the same fundamental mechanisms involved in pitting corrosion [6.23]. Another type of corrosion is *galvanic* corrosion, indicating that it is caused by a difference in the electrochemical potential of different materials (such as galvanizing zinc compared to steel). Again, this is a special, macro-level, case of the potential differences observed at the micro-level on metal surfaces and involving slight differences in composition or grain structure or both.

Table 6.3 Selection of factors known to influence corrosion

Factor E_i	Importance
Bacteria	Very high, long term
Biomass	Likely low
Oxygen supply	Very high, shorter term
Carbon dioxide	Low
Salinity	None by itself
pH	High
Carbonate solubility	Low
Pollutants	Varies
Temperature	Very high
Pressure	None
Suspended solids	None
Wave action	High
Water velocity	High

The factors that often are considered to influence the rate at which corrosion occurs in seawaters are summarized in Table 6.3, together with subjective estimates of their impact on corrosion and pitting.

6.4 Modeling Longer Term Corrosion of Steel

The many factors in Table 6.3 make science-based modeling complex, since the relationships between the factors and corrosion are not all known with a high degree of certainty. A more practical approach is to restrict data sources and factors to the main influences. Thus, model development might be restricted initially to a seemingly simple case – steel immersed relatively close to the surface of unpolluted, protected coastal seawater. Under these conditions, full aeration could be expected and all factors other than water temperature and bacteria can be eliminated from initial consideration. Using basic concepts drawn from accepted corrosion science theory, it was then hypothesized that when a steel plate (say) is immersed in seawater it will be subjected to immediate oxidation using oxygen drawn from the water in the immediate surroundings, thereby setting up an oxygen concentration gradient. As this develops, the rate of oxygen supply will reduce slowly but a more noticeable effect will begin once the rust products start to build up. Eventually, these will be such that the rate of diffusion of oxygen through them will become very slow. This gives rise to a gradually reducing rate of corrosion. These two processes may be idealized as sequential and can be represented as phases 1 and 2, respectively, in the model shown in Fig. 6.5. Phase 0 of the model refers mainly to the processes that occur immediately on immersion. This includes pit initiation and colonization of the metal surface by biofilm materials and bacteria.

Figure 6.5 shows that in phase 2, there is a gradually declining rate of corrosion and that after time, shown as t_a, further corrosion increases at a considerable rate (phase 3) which then slowly declines to a near steady state (phase 4). The rationalization for phase 3 lies in

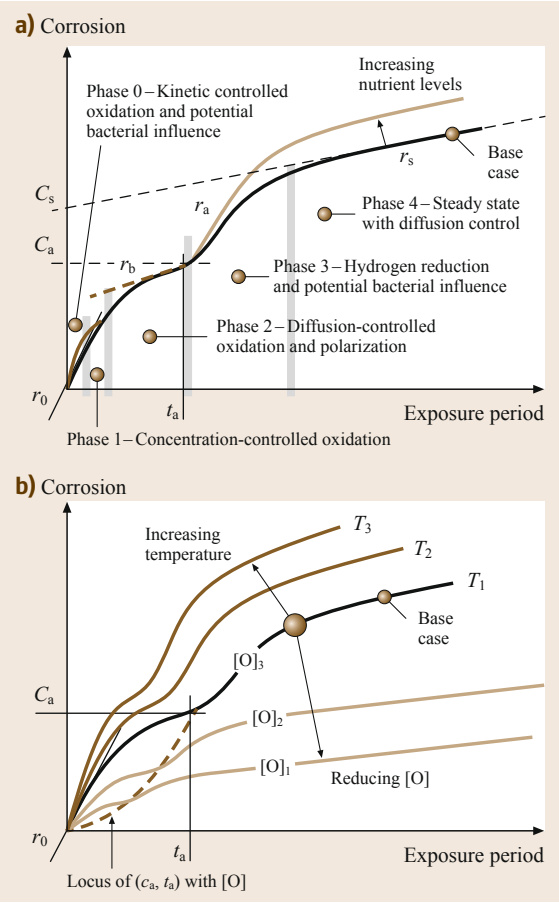

Fig. 6.5a,b Corrosion loss as a function of exposure time, showing also the effect of nutrients on microbiologically influenced corrosion **(a)**, of water temperature and of reduced oxygen concentration in seawater **(b)** (after [6.27])

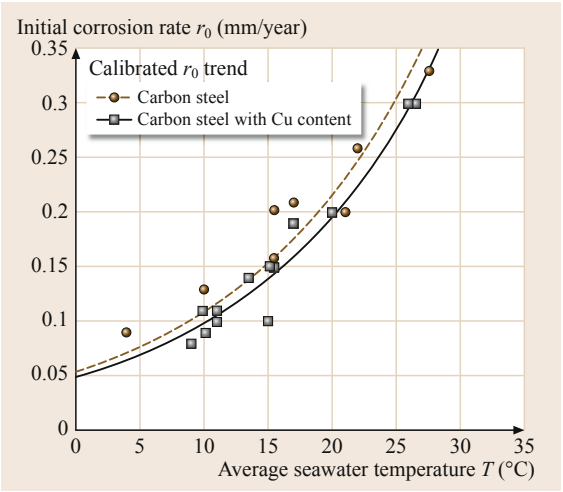

Fig. 6.6 Initial corrosion rate r_0 as a function of mean seawater temperature for carbon steel and for copper-bearing carbon steel

two components – the autocatalytic corrosion processes that form crevices and pits under substantial rust deposits and that occur within anoxic local regions, and the development of microbiological activity and microbiologically influenced corrosion in anoxic regions under anaerobic conditions. Both were hypothesized from the observed behavior of steel corrosion (Fig. 6.4) and verified by the observations of substantial pitting and the presence of bacteria, both under well-developed rusts [6.28]. The fact that pitting occurs also under sterile or clean water corrosion conditions supports the occurrence of two related but independent processes – abiotic and biotic corrosion.

The basic model of Fig. 6.5 must be adjusted to account for the effects summarized in Table 6.2. Figure 6.5 shows, schematically, some of these effects [6.27]. Generally, an increased availability of nutrients will increase the microbiological activity and hence corrosion losses and pitting severity. The effect of seawater temperature, is shown schematically in Fig. 6.5a based on average water temperatures in the range 4–28 °C. It is evident that as the water temperature increases, t_a decreases and that phases 0–2 become shorter and show less corrosion in the interval $0 - t_a$. At higher water temperatures the later phases, 3 and 4, are dominant. This shows the complexity of the effect of water temperature on corrosion. It is not simply a matter of considering the Arrhenius relationship – the latter applies strictly only to the initial corrosion rate r_0. Similarly, lower concentrations of oxygen in the seawater will reduce corrosion losses (Fig. 6.5). The effect of other influences is summarized in Table 6.4.

Mathematical formulations have been given for the most important phases in Fig. 6.5. Further details are available in the technical literature [6.29, 30]. More importantly, the conceptual model of Fig. 6.5 has been calibrated to a multitude of field observations reported by a considerable number of authors from quite separated (and essentially independent) field investigations. Table 6.5 summarizes the functional relationships that have been established for the model parameters. As an example, the calibration curves for the initial corrosion rate r_0 as a function of average seawater temperature are shown in Fig. 6.6 [6.31].

Figure 6.5 shows that it is misleading to use the initial corrosion rate r_0 for long-term corrosion. Unfortunately, short-term corrosion tests, often used for estimating longer term corrosion, typically estimate

Table 6.4 Some factors influencing seawater corrosion of steel

Factor E_i	Importance
Water velocity	Tends to increase corrosion in the first few weeks as rusts build up, pushing standard function upward and thereafter little additional effect
Composition (shows effect on model parameters)	Salinity	Important but effect also influenced by water hardness. Some soft fresh waters are highly corrosive
Timing	Steel exposed, say in autumn or winter has initially a slower rate of corrosion. This pushes model (to the right) in time by about 6 months
Pressure	No evidence that increased water pressure has any noticeable effect on corrosion. Any depth effects are due primarily to temperature, DO and nutrient levels
Depth	Any depth effects are due primarily to temperature, DO and nutrient levels
Size/area	Precise shape or area involved in corrosion not discernible as important variable, for moderate-sized objects, i. e., with distances insufficient for the water properties to change

Table 6.5 Values for model parameters based on calibration to field data (after [6.30, 31])

Model parameter	General corrosion
r_0 [mm/year]	$r_0 = 0.076\exp(0.054T)$
c_a [mm]	$c_a = 0.32\exp(-0.038T)$
t_a [year]	$t_a = 6.61\exp(-0.088T)$
r_a [mm/year]	$r_a = 0.066\exp(0.061T)$
c_s [mm]	$c_s = 0.141 - 0.00133\,T$
r_s [mm/year]	$r_s = 0.039\exp(0.0254\,T)$

only r_0, and this clearly is not indicative of the longer term behavior. From a practical perspective, the most important parts of the model of Fig. 6.5 are the short-term corrosion rate r_0 and the long-term rate r_s together with its intercept c_s on the vertical (corrosion loss) axis. Table 6.5 gives the relevant values as a function of average seawater temperature. Similar curves and parameters are available for pitting corrosion of steel in seawaters [6.32].

6.5 Other Influences on Steel Corrosion

The size and orientation of the steel being corroded can be important. Most information about the corrosion of steels has been obtained from coupons, that is, relatively small pieces of flat steel exposed in the marine environment. It is known that in immersion and tidal conditions, the size of the sample is not critical to measuring mass loss (general corrosion), but this is not necessarily the case for atmospheric corrosion. Also, long steel strips (or sheet piling or similar) extending upward from the immersion zone, through the tidal zone and into the splash zone or even the atmosphere zone, will show corrosion characteristics quite different to individual, electrically isolated, coupons extending over an identical vertical range. Figure 6.7 shows a typical plot for mass loss for strips and coupons, standardized to an equivalent coupon size. It is clear that while corrosion in the tidal zone is high for coupons, it is quite low for strips. This demonstrates the importance of the orientation of steel equipment relative to the tidal zone. It also shows that electrical connectivity can be very important.

Figure 6.7 also shows the effect of higher nutrient levels in the seawater where steel strips or piling is located. Typically, under higher levels of nutrients in natural seawater, microbiological activity is enhanced such that in the zone immediately below mean low tide there is increased corrosion. This is known as *accelerated low water corrosion*. It is a major problem in seawater harbors located in regions where high levels of seawater pollution occur [6.33], has been associated with microbially induced corrosion (MIC) [6.34, 35] and has been shown to be closely correlated with the level of dissolved inorganic nitrogen in the seawater. Typically, this is caused by fertilizers that reach the seawater through agricultural runoff or from sewage treatment plants [6.36]. Sim-

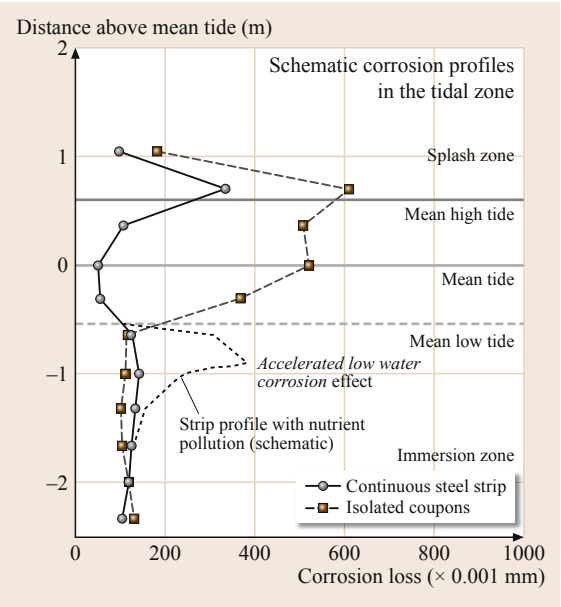

Fig. 6.7 Profile of corrosion intensity with elevation relative to mean tide, for coupons and for strips, showing for strips also the effect of elevated nutrient concentration in the seawater (based on classical data as interpreted in [6.36])

ilar problems have been noted for ships moored for extensive periods of time in polluted marine waterways [6.37].

Bacteria also have been held to be involved in corrosion of steel at considerable depths in the oceans. The most famous example is the corrosion that is occurring, albeit slowly, of the Titanic in the North Atlantic at a depth of nearly 4 km. At that depth, the dissolved oxygen concentration is very low, the water temperature is also low and there is only low water velocity. Under these conditions, conventional corrosion involving oxygen is unlikely. Instead, corrosion under localized anoxic conditions is highly likely and this then permits the possibility of microbiologically influenced corrosion with sulfate reducing bacteria (i. e., corrosion equivalent to that in phases 3 and 4 of Fig. 6.5). One possible restriction on the severity of the rate of corrosion is that MIC requires an adequate rate of nutrient supply and also an adequate rate of supply of energy. At these deep locations, it is not immediately obvious how these requirements can be met. The presence of bacteria at the corrosion sites and of rusts often associated (but not exclusively so) with MIC are not sufficient evidence to guarantee that MIC plays a major role, or even that MIC is involved at all [6.38, 39].

6.6 Pitting Corrosion of Steel

Although pitting usually is considered separately from the so-called general or uniform corrosion, the two are intimately linked. This may be seen from observations of the details of the corrosion of surfaces of mild steel coupons as a function of exposure time (Figs. 6.2 and 6.3). As noted earlier, when exposed to seawater, the steel very quickly develops localized corrosion and pitting and after only 1–2 days pits up to 100 µm deep have been observed [6.40]. Soon the deepest pits then almost stop growing in depth but tend to grow sideways and this continuous for some time. Eventually, however, when sufficient rust products have formed on the surface, localized anoxic conditions develop and the maximum pit depth increases sharply (Fig. 6.8).

Because of the close links between pitting and general corrosion, it is not surprising that Fig. 6.8 shows the same general characteristic functional form as seen for general corrosion loss as a function of time (Fig. 6.5). However, maximum pit depth in phases 3 and 4 are much greater relative to pit depths in phase 2 than the corresponding mass losses. This reflects the fact that the deepest pits occur over relatively small areas of a steel surface (Fig. 6.3). The apparent randomness of the location of the deepest pits in the early stages of corrosion is related to the apparently random na-

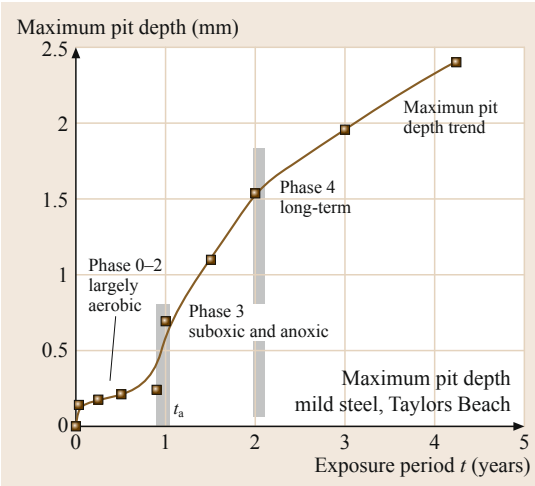

Fig. 6.8 Typical growth of pit depth with increased exposure time as inferred from observations of feel coupons exposed to coastal seawater (after [6.32])

ture of the defects in a metallic crystal structure but somewhat later it is influenced also by the cessation in the growth of some pits (meta stable pits) in favor of others [6.41]. This can be considered to influence subsequent pit growth and the development of pitting, and giving the appearance of randomness also for later pitting. However, studies of the correlation structure of larger corroded surfaces show a high degree of uniformity in pit depth with only a small proportion of greater depth than the remainder [6.42]. Although this finding tends to undermine statistical analyses (such as those based on extreme value theory) that are based on each pit depth being independent from all other pit depths, it is, from a practical perspective, not unexpected. A high degree of correlation can be expected since the corrosive environment is common to the whole steel surface and the surface itself is largely homogeneous except for the microscopic crystal structure and its associated defects. As noted, the latter become almost irrelevant as corrosion proceeds.

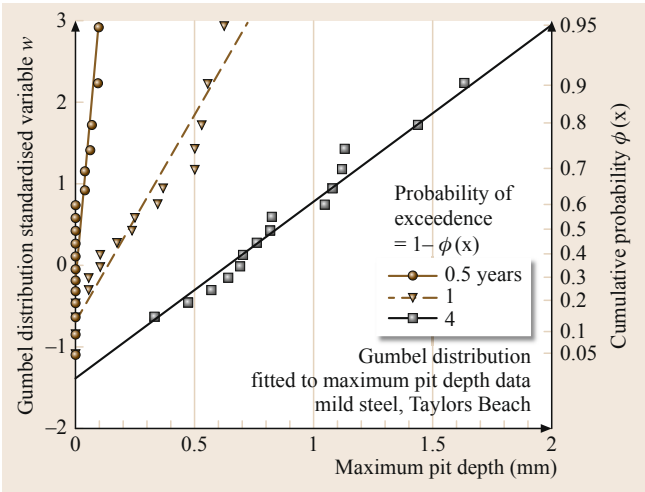

Fig. 6.9 Gumbel extreme value plot showing several sets of data for pit depth

Fig. 6.10 Localized corrosion on a stainless steel plate formed by sucker footprint of a marine mollusk (*centre*) and at one of the identification holes (2 mm diam.) (*top left*) for one quarter of a 100 × 200 mm coupon, after 9 months exposure in coastal seawater. Note that this is a stainless steel plate for which the rest of the surface has no significant corrosion (although fine pitting is widespread over the surface when examined under the microscope) and thus the effect of localized corrosion due to marine growth can be seen more clearly

Fortunately, for statistical analyses, a certain degree of dependence can be tolerated in extreme value analysis, provided it can be assumed that the maximum pit depths are asymptotically independent, that is, independence of the deepest pit depths can be assumed as the total number of pits increases [6.43]. Usually, it is assumed that the deepest pits follow the Gumbel extreme value distribution and also that the shallowest pits are of a different statistical distribution and follow an exponential distribution. The concept is shown, schematically, in Fig. 6.9. This is a Gumbel plot. Its vertical axis, representing (cumulative) probability, is deliberately distorted such that if the data were indeed truly Gumbel distributed, they would plot in a straight line (in the general direction south-west to north-east, with north at the top of the plot). Extrapolation of the upper end (right hand) of the distribution then allows the estimation of the probability of exceedence of a given depth of pit. This is important in estimating the probability of failure through perforation of the wall of a pipe or tank or other steel containment structure.

The approach represented by Fig. 6.9 and as described in many papers has a long history. It is adequate for relatively shallow pits or, similarly, for relatively short-term exposures, that is, within phases 0–2 of the model in Fig. 6.8. However, since the character of pit growth changes with the commencement of phase 3, the probabilistic properties will also change. As a result, it has been shown that for longer exposures, the extreme value probability distribution will deviate from Gumbel [6.44]. This observation is important for estimating the probability of failure due to pitting particularly for infrastructure that can pit severely. Thus, it is directly relevant, for example, for assessing the life of steel pipelines used in offshore oil installations.

As in general corrosion, microbiologically influenced corrosion can play a major role in the rate of pit growth. This can occur under biofilms and under marine growth but also, for example, under the footprint of marine organisms that settle on steel surfaces. Figure 6.10 shows an example of the localized corrosion that has occurred after 9 months exposure in seawater. The example given here is for stainless steel plate as this has negligible general or uniform corrosion in seawater (at least for shorter exposure periods) and thus shows the effect of marine organism footprints more clearly. Similar high rates of localized corrosion can oc-

cur also under corrosion products, under washers and fasteners, and under marine growth. While the general concepts are well understood, quantitative estimation of the depth and extent of pitting under these conditions awaits model development similar to that for general corrosion. This includes developing relationships between seawater nutrient content and the likely depth of the extreme pits.

6.7 Some Other Important Materials

6.7.1 Stainless Steel

Stainless steels often are considered the ideal solution to corrosion problems involving seawater conditions. This is correct for exposures in the atmosphere, particularly for marine grade stainless steel such as grade 316. In the atmosphere, the high chromium content of 316 ensures that the exterior of the steel is always covered with a highly resistant oxide film. Any steel that is exposed to the atmosphere as a result of scratches or damage to the oxide film quickly oxidizes to form more protective oxide film. Under aggressive conditions, such as near the coast, or inside swimming pool halls, a small amount of corrosion may occur, leaving the so-called *tea-staining* – small areas of brown rust stains. In the tidal zone, the oxide film is somewhat less effective and under immersion conditions, it can be quite ineffective, with long-term corrosion approaching that of mild steel. The reason is that marine biofilms and marine biological growth can inhibit the recovery of oxide film, even though the water may be highly oxygenated. Particularly, under fasteners such as bolt heads or nuts, or under marine growth (Fig. 6.10), localized or pitting corrosion can be severe [6.45]. Also, other grades of stainless steel, such as 304, contain lower amounts of chromium and usually are much less resistant to atmospheric marine corrosion than is 316. Conversely, a range of highly alloyed steels is available, ostensibly with very good corrosion resistance. In many cases, longer term experience and quantitative data are lacking, although behavior similar to Fig. 6.5 has been proposed [6.46]. At this time, the use of stainless steel under conditions where rapid oxidation may not be possible requires expert advice. Stainless steels are considerably more expensive than mild and low alloy steels.

6.7.2 Aluminum

A variety of aluminum alloys are available and these can have quite different corrosion characteristics [6.47]. In general, however, they can be summarized by noting that in air aluminum alloys form a protective oxide that, similar to that for stainless steel, is *self-healing* when damaged. As a result, aluminum tends to be very resistant to atmospheric corrosion. In seawater, it forms a noticeable gray oxide and is known to be subject to pitting. The latter is not always superficially obvious since the pits tend to undercut the metal surface [6.48]. The corrosion resistance of aluminum in freshwater environments is complicated by the fact that it is pH dependent, with lower and higher pH waters being very aggressive. Unlike steels, including stainless steel, the available evidence indicates that aluminum is not subject to microbiological attack under seawater conditions [6.49]. Again, the application of aluminum alloys requires expert advice.

6.7.3 Copper–Nickels

There is a long tradition of using copper-nickels and various brasses for fittings on naval vessels and for smaller bore pipework. The common grades are 90 : 10 and 70 : 30 copper-nickels, with the former being both less resistant to corrosion and cheaper than the latter, reflecting the cost of the nickel component. Both general corrosion and pitting tend to be relatively low, but copper-nickels are prone to microbiologically influenced corrosion, despite the fact that copper is used in antifouling treatments as a biocide. A considerable body of literature exist that deal with the practical aspects of corrosion of copper–nickel alloys for infrastructure applications [6.14, 15, 50] and with their resistance to microbiologically influenced corrosion.

6.7.4 Reinforced Concrete

Reinforced concrete structures are used in many marine locations. Local economics of material availability and the easy of construction compared to steel structures as well as maintenance issues usually are decisive in the choice. Reinforced concrete structures are generally considered to have good resistance to marine exposure conditions, largely because the steel reinforcing bars are protected to some degree by the concrete. Typically, the steel bars are located 30–50 mm or more inside the concrete. However, not all modern reinforced concrete structures exposed to marine conditions perform well, and there are many cases where the concrete has cracked along the steel bars, exposing them to sea-

Fig. 6.11 Typical cracking of concrete cover along a reinforcing bar as a result of rust build-up in a marine environment (after [6.52])

water or sea-spray and then causing severe corrosion (Fig. 6.11). Conventionally, this is considered to result from the ingress of chlorides (from seawater, or from brine where used for de-icing roads) reaching the steel bars and initiating corrosion [6.16, 17]. Much research has been carried out on this topic to estimate the rate of ingress of chlorides and to find means to eliminate or reduce the rate of chloride diffusion to the steel reinforcement bars. The conventional wisdom is that denser, less permeable concretes, greater concrete cover thickness to the bars, better quality control for both cover thickness and concrete quality and the use of various additives to reduce concrete permeability are all beneficial. Galvanizing the reinforcement bars, or coating them with a plastic (epoxy) material, or even substituting them with stainless steel also have been tried, with mixed success [6.51].

Despite the conventional wisdom, many examples are available where the rules have not been followed and yet the concrete structures have shown, over many decades, very good performance, with little or no evidence of reinforcement corrosion [6.52–54]. Importantly, this is despite evidence that in many older structures the concrete was made with seawater rather than freshwater as is mandatory under current design requirements. It should be clear that in these cases, the chloride concentration next to the steel reinforcement was at a very high level right from the beginning, as also verified by the high concentration of chlorides in many older reinforced concrete structures for which no corrosion is evident, even when the steel bars are exposed after many years [6.55, 56]. Thus, the rate of ingress of chlorides is irrelevant. If the conventional wisdom is correct, these structures should have shown serious reinforcement corrosion already quite early in their lives.

According to fundamental corrosion thermodynamics, corrosion of steel can initiate only when the pH of the solution environment immediately adjacent to the steel is sufficiently low. The pH of new concrete is around 13 as a result of the alkalis formed during the concrete setting reaction. Such pH is too high for corrosion initiation despite the high concentration of chlorides. In fact, the chloride/alkali ratio has been recognized as the important criterion for initiation [6.57]. It follows that in the cases where corrosion has not occurred, even with high chloride levels, the alkali content has remained high. It follows also that corrosion initiation in this case requires reduction in alkalis. Some leach out relatively easily but the main alkali, calcium hydroxide, formed by the cement reaction, is considered to be relatively insoluble. However, there is evidence that it leaches out much more quickly in the presence of chlorides [6.58, 59]. Taken to its logical conclusion, these observations imply that chlorides facilitate alkali leaching and thus alkali reduction at the reinforcing bars rather than directly causing corrosion initiation. It follows also that reinforcement corrosion can be delayed simply by ensuring a very high reserve of alkalis (i. e., increased *alkalinity* or *buffering* capacity) in the concrete. This correlates well with a study of older reinforced concrete structures that showed that those made with alkali-rich aggregates (including finer aggregates and sand) showed longer times before corrosion commenced and longer service lives [6.53]. Of course, any reduction in the rate of ingress of chlorides, if not already present, will also delay the rate of alkali leaching and, therefore, be beneficial for durability.

Fig. 6.12 Interior of a concrete element broken open after some 65 years exposure to the North Sea, showing the almost complete loss of the reinforcing bar inside the concrete (at *top*). All that remains to show where the bar had been is the thin black line. Note the watery rust stains and also the severe local corrosion (lower center) of the reinforcing bar that is almost uncorroded only a short distance away (at *right*)

Fig. 6.13 Severely corroded end of a 6 mm diameter reinforcing bar shown in Fig. 6.12

The marine environment is, nevertheless, severe for concrete structures. Under suitable conditions, the chlorides in seawater can combine with the ferrous ions released by the steel reinforcement in the corrosion process to produce highly soluble ferrous chlorides ($FeCl_2$), and with the sufficient availability of oxygen, very soluble ferric chloride ions ($FeCl_3$). These can leach out of concretes very readily and leave merely brown watery-looking rust stains rather than the usual build-up of solid rust products responsible for cracking, such as shown in Fig. 6.11. The corrosion associated with $FeCl_2$ production can be very severe. Figure 6.12 shows a case where apparently sound concrete, some 65 years old, without any visible external rust staining or cracking was broken open as part of a routine scientific investigation. It revealed almost complete loss of about 300 mm length of reinforcement bars inside the concrete. Only some magnetite (the black material) was left to show the location of the bar. Figure 6.13 shows the severely corroded end of the bar, that some small distance away, was left intact within the adjacent concrete [6.52]. Several other, similar cases have are now available, some in summary form [6.55, 56] and detailed investigations are proceeding. Finally, the marine environment can also be a problem for the concrete itself [6.16, 17], but modern practices largely have eliminated this as an issue.

These observations show that reinforced concrete can be a very successful construction material in marine environments, provided a high level of alkali material is embodied in the concrete mass, giving long-term buffering against alkali loss through leaching. However, it is possible for severe localized corrosion loss of reinforcement to occur without obvious external warning signs. This latter aspect is currently under urgent investigation as the implications for existing reinforced concrete infrastructure as significant.

6.8 Conclusion

Seawater is a complex mix of many different chemicals and microorganisms, even though it is remarkably uniform for most parts of the world. It is usually considered to be a hostile environment for materials and this is evident in the research efforts devoted to understanding the initiation of corrosion and its propagation once it starts. The present chapter has outlined some of the current research in this area, focusing mainly on engineering rather than purely scientific investigations. The research is driven largely by the needs of industry but anchored in fundamental science and the basic understanding of the processes involved. It is focused on developing tools and techniques that can be applied in the offshore, shipping, and coastal environment engineering industries. The present chapter gives an overview of this work and some of its principal findings and models.

7. Hydromechanics

Karl Dietrich von Ellenrieder, Manhar R. Dhanak

Ocean engineering is a systems engineering field and requires a relatively broad background in several aspects of engineering. The role of hydrodynamics is central to all ocean engineering activities and despite an ocean engineer's specialist designation, sooner or later some aspects of hydrodynamics will encroach upon the problem he or she is trying to solve. The intent of this chapter is not to provide an exhaustive treatment of marine hydrodynamics, but instead to act as a reference source to provide enough working knowledge to solve practical problems, or at least a good idea of where to start looking. A range of topics is covered including dimensional analysis, static and dynamic flows, potential and viscous flows, laminar and turbulent flows, boundary layers, wakes, jets and shear layers, and drag and lift forces.

7.1 Dimensional Analysis, Basic Estimation, and Model Testing

At a fundamental level, dimensional analysis and similitude allow the development of physical laws and equations, *from-scratch* or based on observation and measurement.

Dimensional analysis is the starting point for understanding many physical phenomena. It is most often used for:

- Estimating the effects of different parameters
- Interpreting experimental data
- Defining scaling laws that can be used to predict the performance of full-sized prototypes using the data from measurements conducted on engineering models.

In hydromechanics, the use of dimensional analysis and similitude is especially important as there are a small number of *exact* solutions to the equations governing fluid flow and numerical solutions are limited to flows with fairly simple geometries or to restricted ranges of conditions.

The use of dimensional analysis might be best explained through use of a simple example.

7.1.1 Drag Force on a Sphere

Here we wish to find an estimate for the drag force D acting on a spherical body completely immersed in a flowing fluid and far from any boundaries. We might start by asking ourselves what physical properties of the flow and spherical body the drag might depend upon. One could argue that the size of the sphere is likely important and pick the diameter A of the sphere as being a characteristic or representative length scale of the body. The speed of the flow will also likely play a role and so the freestream speed U of the flow can be used as a characteristic value. One could argue that part of the

force felt on the sphere comes from the change in momentum which occurs when the flowing fluid impacts the spherical body. As the momentum is related to both the specific mass and speed of the fluid, we can add the density of the fluid ρ as another important characteristic parameter that should be taken into account (we already have speed). The viscosity of the fluid might also be expected to set up shear stresses in the flow, which creates additional drag on the spherical body. Thus, the dynamic (molecular) viscosity of the flow might also be expected to be an important parameter that should be included in our analysis. Thus, we get some sort of functional relationship of the form

$$D = f(A, U, \rho, \mu) \,. \tag{7.1}$$

In order to determine this functional relationship, one could propose performing an experiment in which the drag is measured for 10 different values of A, 10 different values of U, 10 different values of ρ, and 10 different values of μ. This process would require 10^4 experiments and would be infeasible in terms of cost and time for most! How can this process be made more tractable?

If one thinks of the functional relation in (7.1) as being an equation, D is the dependent variable and A, U, ρ, and μ are the independent variables. If we could somehow reduce the number of independent variables, we can reduce the number of experiments that would need to be performed to characterize the functional dependence in (7.1). Dimensional analysis is the process by which we will do this. However, before we embark on a description of how to use dimensional analysis, we will need to consider two basic concepts: dimensional homogeneity and the Buckingham-Π theorem.

Dimensional Homogeneity

Any equation that describes a basic law of physics must have the same dimensions (units) on every term and on both the right hand side and the left-hand side of the equation. The units of all additive terms in an equation must be the same, and the dimensions will remain homogeneous after any mathematical operation on the equations, such as differentiation or integration. The basic dimensions are mass M, length L, and time T – all physical quantities can be quantified by combinations of these units. In practice, it may be convenient to use nonfundamental units in dimensional analysis. For example in engineering, the temperature Θ is sometimes taken as a basic unit and in physics the luminosity L is often used as a basic unit of measure, although strictly speaking, temperature is a measure of energy and luminosity is a measure of power flux, both of which are composed of the more fundamental M, L, and T units. Here, we will use square brackets to denote *dimensions of*, e.g.,

$$[U] = \frac{L}{T} \,.$$

Buckingham-Π Theorem

The Buckingham-Π theorem can be used to determine the number of dimensionless groups that can be found in a functional relation, such as (7.1). If we let n be the number of variables we believe it is involved in our functional dependence and m be the number of basic physical dimensions involved in those n variables, the Buckingham-Π theorem states that $(n-m)$ dimensionless groups can be found by combining variables. The combinations of variables are referred to as Π groups and are used to re-write the sought after functional dependence as a function of Π groups.

$$\Pi_1 = \phi(\Pi_2, \Pi_3 \ldots, \Pi_{n-m})$$

Getting back to the spherical body, we see that the number of variables involved in (7.1) is $n = 5$ and the number of basic dimensions can be found by looking at the units of the five variables.

$$[D] = \frac{ML}{T^2} \quad [U] = \frac{L}{T} \quad [\mu] = \frac{M}{LT} \,,$$
$$[A] = L \quad [\rho] = \frac{M}{L^3} \,, \tag{7.2}$$

where we see that $m = 3$. Thus, we expect to be able to reduce (7.1) to a functional dependence between $n - m = 2$ Π groups

$$\Pi_1 = \phi(\Pi_2) \,, \tag{7.3}$$

which, as one might expect, will vastly reduce the number of experiments required to characterize the functional relation. There are several different approaches that can be used to identify the Π groups in (7.3). Here two approaches will be discussed.

The Step-by-Step Elimination Method [7.1]

Each variable in a functional dependence such as (7.1) is combined with other variables by multiplying or dividing it into the other variables. One starts by *eliminating* the simplest or purest variables first, meaning those with the fewest number of basic units. In general, one should not eliminate the dependent variable. Each elimination can be thought of as being the same as removing one of the basic dimensions, length L, mass M, or time T. Going back to our example, from (7.2) we can see that the variable with the simplest dimensions is the diameter A, so we begin by using A to eliminate the length dimension from our problem:

i. Eliminate length

$$\left[\frac{D}{A}\right] = \frac{M}{T^2}\,, \quad \left[\frac{U}{A}\right] = \frac{1}{T}\,,$$
$$[\rho A^3] = M\,, \quad [\mu A] = \frac{M}{T}\,.$$

We can see that the dimension of length has been removed from the combined variables thus far and that each step of the process will reduce the total number of variables by 1, until $n-m$ of them remain. We will next repeat the process for the dimensions of M and T. Looking at the dimensions of the combined variables we see that both U/A and ρA^3 have simple dimensions of only one type of unit each. Thus, we have a choice of using either set of combined variables to remove one of the remaining dimensions. Here we proceed next by eliminating time.

ii. Eliminate time

$$\left[\frac{DA}{U^2}\right] = M\,, \quad \left[\frac{\mu A^2}{U}\right] = M\,, \quad [\rho A^3] = M\,.$$

The only dimension remaining in the combined variables is now mass. Remembering that we never want to use the set of variables that contains the dependent variable, we must next choose which set of combined variables we will use to eliminate mass. This example illustrates one of the advantages of using the step-by-step elimination method over other nondimensionalization approaches – it is possible to examine the resulting combined variables at each step of the process and if it becomes clear that any of them could be reduced to one of the well-known dimensionless numbers, such as Reynolds number or Froude number, we can elect to steer the elimination process in that direction. Here it can be seen that if the set ρA^3 is used to eliminate mass, the resulting sets will be the inverse of the well-known Reynolds number and a set similar to what is known as a drag coefficient.

iii. Eliminate mass

$$\Pi_1 = \frac{D}{\rho U^2 A^2}\,, \quad \Pi_2 = \frac{\mu}{\rho U A}\,.$$

Thus, we have identified the dimensionless Π groups (combined variables) which give a simpler functional dependence (7.3) than the original (7.1). This analysis only specifies that there is a functional dependence and which groups are likely to be involved, not the actual function or form of the dependence, which must typically be determined from physical observation or experimental data. Therefore, we can equally say that perhaps $\Pi_1 = \phi(1/\Pi_2)$, or that

$$C_\mathrm{D} = \frac{D}{\frac{1}{2}\rho U^2 A^2} = \phi\left(\frac{\rho U A}{\mu}\right) = \phi(\mathrm{Re})\,, \tag{7.4}$$

where C_D is the common form of the coefficient of drag and Re is defined as the Reynolds number. A plot of the relationship between C_D and Re for a sphere can be seen in Fig. 7.1.

The Exponent Method

If we can combine the variables involved in our expected functional dependence (7.1) as a product of exponentials, the resulting equation must be dimensionally homogeneous

$$[D] = [U^a \rho^b \mu^c A^d]\,. \tag{7.5}$$

Thus, solving for the exponential terms a, b, c, d which make the relation (7.5) dimensionally homogeneous should provide the nondimensional Π groups we seek. Writing out the units in the terms of (7.5) gives

$$\frac{ML}{T^2} = \left(\frac{L}{T}\right)^a \left(\frac{M}{L^3}\right)^b \left(\frac{M}{LT}\right)^c L^d\,,$$

which results in having to solve the following system of equations so that (7.5) is dimensionally homogeneous

$$\begin{aligned} L:&\quad 1 = a - 3b - c + d \\ M:&\quad 1 = b + c \\ T:&\quad -2 = a - c\,. \end{aligned} \tag{7.6}$$

This is an underdetermined system of equations. We can solve for three of the variables in terms of a fourth. It is convenient to choose that variable which appears most often, which is c in this case. Solving the system of equations (7.6), we find that $a = 2-c$, $b = 1-c$, and $d = 2-c$. Re-writing (7.5) using these exponential values gives

$$D = \rho U^2 A^2 \left(\frac{\mu}{\rho U A}\right)^c\,. \tag{7.7}$$

Thus, we can see that (7.7) is of the functional form (7.4).

7.1.2 Physical Significance of the Dimensionless Π Groups

Π Groups can be interpreted as the ratio of typical values of two different, competing, physical effects. In

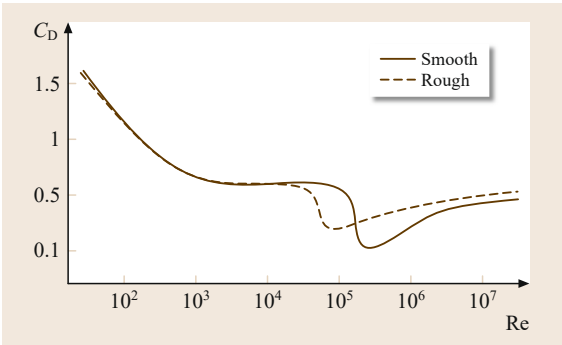

Fig. 7.1 Drag coefficient C_D vs. Reynolds number Re

order to determine which of the two physical effects might be the dominant effect in a particular situation, we use an order of magnitude analysis approach. Here, the following common rule of thumb will be used to determine the order of magnitude $\mathcal{O}$ of a Π group.

$$\begin{aligned} &\vdots \\ 0.3 \le \Pi \le 3 \quad &\mathcal{O}(1) \\ 3 \le \Pi \le 30 \quad &\mathcal{O}(10) \\ 30 \le \Pi \le 300 \quad &\mathcal{O}(100) \\ &\vdots \end{aligned}$$

In order to conduct an order of magnitude analysis one must think abstractly, for example, think of an object as having a single characteristic length scale, say L, which may be moving through a fluid moving with a characteristic velocity scale U. Generally, the velocity will vary throughout a flow, especially near objects in the flow or at the flow's boundaries. Thus, the most appropriate velocity scale is often taken to be the freestream velocity, far upstream or downstream of an object in the flow where the flow is relatively unaffected by the presence of a body.

If we approximate the forces acting on our object in an abstract way we can find the following:

Inertial force – from Newton's second law – this will vary as the product of object mass and acceleration

$$F_i = ma \approx \rho L^3 \frac{U}{T} ,$$

where T is the time it will take a particle of fluid to traverse the object $T \approx L/U$ – using this expression for T in the above gives

$$F_i \approx \rho U^2 L^2 .$$

The shear stress τ acting on an object varies as the product of dynamic viscosity of the fluid μ and the gradient of the velocity $\partial u/\partial y$ at the object's surface

$$\tau = \mu \frac{\partial u}{\partial y} .$$

When the boundary layer region around an object is relatively large, we can approximate the gradient term as

$$\frac{\partial u}{\partial y} \approx \frac{U}{L} .$$

If the surface area of the object varies as L^2, the viscous force F_v acting on the object will vary as

$$F_v \approx \mu \left(\frac{U}{L}\right) L^2 = \mu U L .$$

If an object has a pressure differential Δp acting across it, the force from this pressure F_p will vary as

$$F_p \approx \Delta p L^2 .$$

Lastly, when an object is neutrally buoyant, its weight will be equal to the weight of water that it displaces. We can approximate the force related to gravity F_g as

$$F_g \approx \rho g L^3 .$$

As mentioned above, each of the Π groups can be interpreted as the ratio of competing physical effects:

a) Reynolds number.
The Reynolds number is very important in determining when viscous effects can be neglected in a flow and for predicting (in an approximate way) when a boundary layer flow may be turbulent or laminar. The Reynolds number is the ratio of inertial to viscous forces

$$\mathrm{Re} = \frac{F_i}{F_v} \approx \frac{\rho U^2 L^2}{\mu U L} = \frac{\rho U L}{\mu} = \frac{U L}{\nu} , \qquad (7.8)$$

where $\nu \equiv \mu/\rho$ is the kinematic viscosity of the fluid.

b) Pressure coefficient.
The ratio of the pressure force to the inertial force is known as the pressure coefficient and plays a major role in the characterization of the flow over hydrofoils

$$C_p = \frac{F_p}{F_i} \approx \frac{\Delta p L^2}{\rho U^2 L^2} = \frac{\Delta p}{\rho U^2} . \qquad (7.9)$$

c) Froude number.(FR)
The ratio of the inertial to gravity forces is the square of the Froude number

$$\mathrm{Fr}^2 = \frac{F_\mathrm{i}}{F_\mathrm{g}} \approx \frac{\rho U^2 L^2}{\rho \mathrm{g} L^3} = \frac{U^2}{\mathrm{g}L} \rightarrow \mathrm{Fr} = \frac{U}{\sqrt{\mathrm{g}L}} \,. \tag{7.10}$$

The Froude number is most often used to characterize the flow at a free surface and is related to the celerity (phase speed) of a gravity wave. It can also be used to predict when wave drag is important for ships and other vessels. As the equilibrium position of subsurface buoys represents a balance between buoyancy, weight, and drag, which varies as the square of the freestream flow speed, Froude scaling can also be used to model their dynamic responses, even when they are deeply submerged [7.2].

d) Weber number.
The Weber number is the ratio of inertial forces to surface tension forces

$$\mathrm{We} = \frac{\rho U^2 L^2}{T_\mathrm{s} L} = \frac{\rho U^2 \mathrm{L}}{T_\mathrm{s}} \,, \tag{7.11}$$

where T_s is the surface tension ($T_\mathrm{s} = 0.073\,\mathrm{N\,m^{-1}}$ for water). The Weber number can be used to estimate the size of droplets in a spray, the thickness of a spray sheet (such as at the chine of a planing hulled vessel), and is also important in formation of ventilated cavities behind surface piercing propellers [7.3, 4]. Note that it is not generally possible to match both the Weber number and the Froude number in a flow.

e) Cavitation number.
This is the ratio of the difference between the local pressure in a flow and the vapor pressure and the dynamic pressure of the flow $\frac{1}{2}\rho U^2$

$$\sigma \equiv \frac{p_0 - p_\mathrm{v}}{\frac{1}{2}\rho U^2} \,, \tag{7.12}$$

where the vapor pressure of water at 20 °C is $p_\mathrm{v} = 2.336\,\mathrm{kPa}$. Cavitation may generally occur when $\sigma < 0.1$ and the inception will tend to depend on a number of factors including water purity, water depth, and background pressure – which can necessitate the use of pressured model test facilities in practice. As the local pressure over a submerged surface approaches the local vapor pressure of the water, the water essentially starts to boil and small pockets of water vapor will form over the surface. The process is unsteady and when the air pockets begin to collapse they can damage the surface. Cavitation differs from ventilation, in which there is a connection or small tunnel of air between the submerged surface and the free surface of the water. Both cavitation and ventilation can lead to a loss of lift on submerged hydrofoils or propeller blades.

f) Force coefficients.
The two-dimensional (2-D) drag coefficient is typically defined using the drag per unit span of a wing, d, whereas the three-dimensional (3-D) drag coefficient is defined using the total drag on a wing, D

$$\text{2-D} \qquad C_\mathrm{d} \equiv \frac{d}{\rho U^2 L} \,, \tag{7.13}$$

$$\text{3-D} \qquad C_\mathrm{D} \equiv \frac{D}{\rho U^2 L^2} \,. \tag{7.14}$$

The lift coefficients are defined similarly, where l is the drag per unit span and L is the total lift

$$\text{2-D} \qquad C_\mathrm{l} \equiv \frac{l}{\rho U^2 L} \,, \tag{7.15}$$

$$\text{3-D} \qquad C_\mathrm{L} \equiv \frac{L}{\rho U^2 L^2} \,. \tag{7.16}$$

g) Strouhal number.
The Strouhal number represents the ratio of a characteristic flow time to a characteristic oscillation time. For example, if the frequency of vortex shedding in the wake of a cylinder of diameter L in a flow with a speed U is f, then the Strouhal number will be

$$\mathrm{Sr} \equiv \frac{\text{char. flow time}}{\text{char. oscillation time}} \approx \frac{L/U}{1/f} = \frac{fL}{U} \,, \tag{7.17}$$

the Strouhal number relates the frequency of vortex shedding in a flow and is important for ocean engineering problems, such as the strumming of underwater cables and structures in a current and the swimming of marine animals [7.5–7]. Incidentally, the Strouhal number is proportional to the tip speed ratio (TSR) of underwater ocean energy extraction turbines [7.2, 8] and varies as the inverse of the advance ratio J (often used to characterize propellers) [7.5].
In the motion of a bluff body such as a cylinder of diameter d, accelerating from rest to moving at a constant speed U normal to its axis, the body experiences an adverse pressure gradient on its

downstream side, leading to a backward flow and flow separation from the aft surface of the body. The detached boundary layer rolls up aft of the body into two coherent counter-rotating vortices that are shed from the body once they reach a certain size for a given local convective flow. The vortices are typically shed asymmetrically from the two sides of the body and continue to form and get shed alternately at a frequency f, leading to a staggered array of counter-rotating vortices, known as a von Karman vortex street, in the wake of the body. The vortex shedding induces an alternating lift force normal to the direction of the flow and the body axis. The lift force per unit span of the bluff body may be estimated as

$$l(t) = \rho U \Gamma(t) \,,$$

where ρ is the density of the fluid and $\Gamma(t)$ is the instantaneous circulation around the body. Γ is related to the net vorticity shed from body at any instance. $l(t)$ therefore fluctuates at a frequency f and amplitude $l_{\max}$ as $\Gamma(t)$ varies between $\pm\Gamma_{\max}$, where $\Gamma_{\max}$ is the amplitude of the fluctuating circulation. The lift coefficient and the nondimensional frequency of the fluctuation

$$C_{l\max}(\mathrm{Re}) = \frac{l_{\max}}{0.5\rho U^2 d} = \frac{\Gamma_{\max}}{0.5 U d} \,,$$
$$S(\mathrm{Re}) = \frac{fd}{U} \,,$$

are functions of the Reynolds number (and the shape of the body). For a cylinder S has been shown to be approximately $S \approx 0.22{-}0.27$ for Reynolds numbers between 10^4 and 10^7 [7.9]. The lift coefficient is approximately given by $C_{l\max} \approx 0.5$ [7.10]. If the natural frequency of vibration of the body is close to f, then the body undergoes transverse resonant vibrations [7.10]. Such vibrations are called vortex-induced vibrations (VIV). Strumming oscillations of cables in crosswinds and transverse vibrations of pilings are examples of the phenomena. Use of a splitter plate at the back of the cylinder or of helical ribbon fairings on the cylinder can be made to minimize VIV.

Example 7.1

Dispersion of surface waves on water: assume that the wave speed c depends on the other five parameters listed in Table 7.1. Find the Π groups, note that the wavenumber is defined as $k \equiv 2\Pi/\lambda$, where λ is the wavelength of a wave.

Table 7.1 Potential dispersion parameters of interest

Parameter	Dimension
c Wave speed	$[c] = \frac{L}{T}$
g Gravity	$[\mathrm{g}] = \frac{L}{T^2}$
γ Surface tension	$[\gamma] = \frac{M}{T^2}$
k Wave number	$[k] = \frac{1}{L}$
h Water depth	$[h] = L$
ρ Density	$[\rho] = \frac{M}{L^3}$

Solution 7.1

6 variables, 3 dimensions $\rightarrow 3\Pi$-groups.

- Eliminate length:

$$[ck] = \frac{1}{T} \,, \quad [\mathrm{g}k] = \frac{1}{T^2} \,,$$
$$[\gamma] = \frac{M}{T^2} \,, \quad [hk] = 1 \,, \quad [\rho k^3] = M \,.$$

- Eliminate time:

$$\left[\frac{ck}{\sqrt{\mathrm{g}k}}\right] = \left[c\sqrt{\frac{k}{\mathrm{g}}}\right] = 1 \,,$$
$$\left[\frac{\gamma}{\mathrm{g}k}\right] = M \,, \quad \left[\rho k^3\right] = M \,.$$

- Eliminate mass:

$$\left[\frac{\gamma k^2}{\rho \mathrm{g}}\right] = 1$$
$$\therefore \quad c\sqrt{\frac{k}{\mathrm{g}}} = \varphi\left(kh, \frac{\gamma k^2}{p\mathrm{g}}\right) .$$

This can be rewritten as

$$c^2 = \frac{\mathrm{g}}{k}\varphi^2\left(kh, \frac{\gamma k^2}{\rho \mathrm{g}}\right) .$$

As shown in [7.11], the phase speed of deep water waves (gravity is the restoring force) is

$$c^2 = \frac{\mathrm{g}}{k}\tanh(kh) \,,$$

and the phase speed of capillary waves (surface tension is the restoring force) is

$$c^2 = \frac{\mathrm{g}}{k}\left(1 + \frac{\gamma k^2}{\rho \mathrm{g}}\right)\tanh(kh) \,.$$

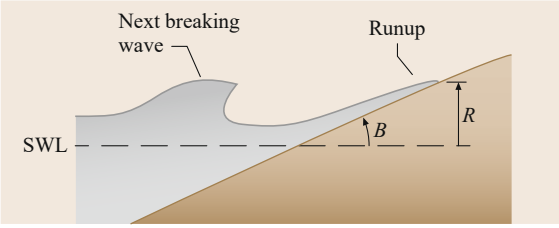

Fig. 7.2 Definition of the main parameters of beach runup

Example 7.2

Wave *runup* R is the height above the still water line (SWL) that an ocean wave will wash up onto a beach (Fig. 7.2). R has been found to depend on waveheight H, deep water wavelength λ, and beach angle β. Use dimensional analysis to find the associated Π groups and explicitly write the resulting functional dependence of R on the other terms.

Solution 7.2

$$R = f(H, \lambda, \beta)\,, \quad [R] = L\,, \quad [H] = L\,,$$
$$[\lambda] = L\,, \quad [\beta] = 1\,.$$

4 variables, 1 dimension $\rightarrow$ 3 Π-groups.

- Eliminate length:

$$\left[\frac{R}{H}\right] = 1\,, \quad \left[\frac{\lambda}{H}\right] = 1\,.$$
$$\therefore \quad \frac{R}{H} = \varphi\left(\frac{\lambda}{H}, \beta\right).$$

Empirical solutions for wave runup have been found by [7.12]

$$\frac{R}{H} = \sqrt{\frac{2\pi}{\beta}}\,,$$

and [7.13]

$$\frac{R}{H} = \sqrt{\frac{\lambda}{H}}\tan\beta\,.$$

Example 7.3

Longshore currents flow parallel to the shoreline and are typically confined to the area between the shore and the zone of breaking waves (Fig. 7.3). The current forms due to the oblique approach of waves to the shore at angle α_b, with the volume rate of flow depending primarily on the height of the incoming waves H_b (which break under the influence of gravity) and the slope of the beach m. Use dimensional analysis to find an expression for the functional dependence of the longshore current speed u.

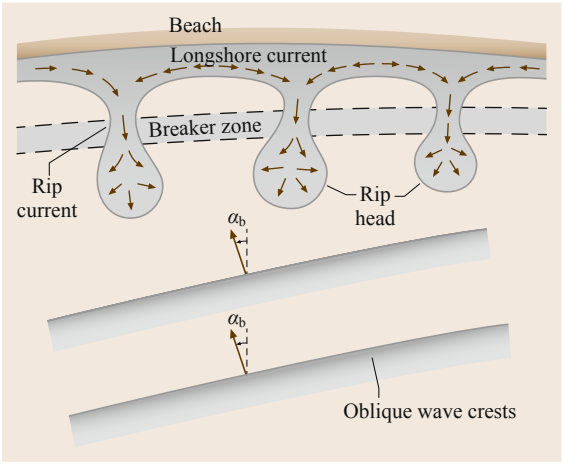

Fig. 7.3 Longshore current and wave approach (after [7.14])

Solution 7.3

$$u = f(\alpha_b, H_b, g, m)\,, \quad [u] = \frac{L}{T}\,, \quad [\alpha_b] = 1\,,$$
$$[H_b] = L\,, \quad [g] = \frac{L}{T^2}\,, \quad [m] = 1$$

5 variables, 2 dimensions $\rightarrow 3\Pi$-groups. There are already two dimensionless terms $\Pi_2 = \alpha_b$, $\Pi_3 = m$.

- Eliminate length:

$$\left[\frac{u}{H_b}\right] = \frac{1}{T}\,, \quad \left[\frac{g}{H_b}\right] = \frac{1}{T^2}\,,$$

- Eliminate time:

$$\Pi_1 = \frac{u}{H_b}\sqrt{\frac{H_b}{g}} = \frac{u}{\sqrt{gH_b}}\,.$$
$$\therefore \quad \boxed{u = \sqrt{gH_b}\,\varphi(\alpha_b, m)\,.}$$

From theory and experiment [7.15]

$$u = 20.7m\sqrt{gH_b}\,\sin(\alpha_b)\,.$$

Example 7.4

The waterplane area is the horizontal cross section formed by the intersection of the free surface of the water and the hull of a vessel. A catamaran (two hulls) has

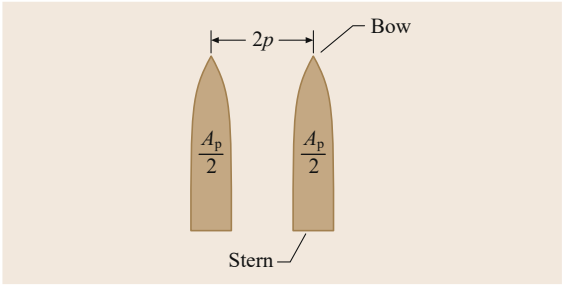

Fig. 7.4 Waterplane area of catamaran hulls

a waterplane area A_P and a displacement (weight) Δ (Fig. 7.4). The two hulls are separated by a transverse distance $2p$. If the density of seawater is ρ, use dimensional analysis to estimate:

a) The natural heave (vertical – z direction) period of the vessel for gravity-induced motion.
b) The natural roll (about the x-axis) period of the vessel for gravity-induced motion.

In each case you must explain the physical rationale behind your selection of the relevant parameters.

Solution 7.4

a) As the motion is gravity induced, gravity must be included in the dimensional analysis. The catamaran will oscillate like a mass–spring system with buoyancy acting as the restoring (spring) force. The dimensions of each of the physical variables are

$$[A_P] = L^2\,, \quad [\Delta] = \frac{\mathrm{ML}}{T^2}\,,$$
$$[\rho] = \frac{M}{L^3}\,, \quad [\mathrm{g}] = \frac{L}{T^2}\,,$$

the natural heave (vertical – z direction) period T_h, where $[T_h] = T$. Assume that the ship's motion is completely vertical, in which case the variables of interest are $A_P, \Delta, \rho, \mathrm{g}, T_h \rightarrow n = 5; m = 3; n-m = 2\Pi$ groups:

- Eliminate mass:

$$[A_P] = L^2, \left[\frac{\Delta}{\rho}\right] = \frac{L^4}{T^2}, [g] = \frac{L}{T^2}, [T_h] = T\,.$$

- Eliminate length:

$$\left[\frac{\Delta}{\rho A_P^2}\right] = \frac{1}{T^2}, \left[\frac{\mathrm{g}}{\sqrt{A_P}}\right] = \frac{1}{T^2}, [T_h] = T\,.$$

- Eliminate time:

$$T_h\sqrt{\frac{\Delta}{\rho A_P^2}} = \Pi_1, \frac{\rho \mathrm{g} A_P^{3/2}}{\Delta} = \Pi_2\,.$$

Thus, it should be possible to express the heave period as

$$\therefore \boxed{T_h = \sqrt{\frac{\rho A_P^2}{\Delta}} f\left(\frac{\rho \mathrm{g} A_P^{3/2}}{\Delta}\right),}$$

where f is a function to be identified through experimental analysis or numerical simulation. In practice, it can be shown that the natural period varies like

$$T_h = \sqrt{\frac{M + A_{33}}{2\Pi\rho \mathrm{g} A_p}}\,,$$

where M is the mass of the vessel and A_{33} is the added mass of the vessel. If we let

$$f\left(\frac{\rho \mathrm{g} A_P^{3/2}}{\Delta}\right) = \frac{\Delta}{\rho \mathrm{g} A_P^{3/2}}\,,$$

then

$$T_h = \sqrt{\frac{\rho A_P^2}{\Delta}} f\left(\frac{\rho \mathrm{g} A_P^{3/2}}{\Delta}\right) = \frac{1}{\mathrm{g}}\sqrt{\frac{\Delta}{\rho A_P}}\,.$$

As you can see the period will vary as the square root of the vessel mass and the inverse of the square root of the waterplane area.

b) The natural roll (about the x-axis) period T_r of the vessel for gravity-induced motion: Here the variables of interest will be the same, but with the addition of the side hull separation distance p. Now $[p] = L$ and $n = 6, m = 3, n-m = 3\Pi$-groups. The dimensional analysis proceeds as above, except with the addition of eliminating the length p. This gives a third group $\Pi_3 = p/\sqrt{A_p}$. So the functional dependence for roll period is

$$\boxed{T_r = \sqrt{\frac{\rho A_P^2}{\Delta}} f\left(\frac{\rho \mathrm{g} A_P^{3/2}}{\Delta}, \frac{p}{\sqrt{A_p}}\right).}$$

7.1.3 Similitude

Similitude is the art and practice of predicting prototype performance from model tests. Basically, dimensionless Π groups are used to scale test results:

a) Geometric similitude.
The model is an exact, but scaled replica of the prototype. Usually, all linear dimensions are scaled by the same factor.

b) Dynamic similitude.
Forces acting on model masses must have the same ratio everywhere in the flow field. To achieve this, *relevant* dimensionless numbers are equated so that each type of force (e.g., viscous, momentum, gravitational, etc.) that is considered to be dominant in determining the flow will act in a proportion determined by the Π-groups.

The *relevant* Π-groups are those which are most likely to play a role in governing a particular flow phenomenon. For example, when examining the flow in a completely enclosed space with no free surface, one would not generally need to consider the possible effects of either gravity or capillary waves. Hence the Froude number and Weber number are unlikely to play a role. The interplay between viscous and momentum forces is likely to dominate the flow. Hence, the Reynolds number would be likely to play a role.

When determining which Π groups might play a role in governing a flow, it is often helpful to examine the magnitude of the Π groups. When a Π group is much larger than unity $\Pi \gg 1$ or much smaller than unity $\Pi \ll 1$, the effects of the Π group can sometimes be neglected.

Solving similitude problems:

i. Think about the dominant Π groups that are likely to apply. When a free surface is present, the Froude number, Weber number, and Reynolds number are likely to play a role. When there is no free surface, the Reynolds number is likely to be an important parameter. When vortex shedding is present, the Strouhal number will play role.
ii. Equate the Π groups that are felt to be important and use geometric similitude to solve for the related length and velocity scales.
iii. Equate force and pressure coefficients to find the corresponding forces on the prototype, when model forces are known.

Example 7.5

An offshore wind turbine is supported with a cylindrical monopile. The system is deployed in currents of $U_\mathrm{p} = 2.5\ [\mathrm{m\,s^{-1}}]$ and waves with a $T_\mathrm{p} = 8.8$ [s] period and $H_\mathrm{p} = 1.9$ [m] height. If a 1 : 40 scale model is tested in a wave flume, what are the model current speed U_m, model wave period T_m and model wave height H_m?

Solution 7.5

The geometry of the model wave can be scaled by $L_\mathrm{m}/L_\mathrm{p} = 1/40$, where L_m and L_p are characteristic length scales for the model and prototype flows, respectively

$$H_\mathrm{m} = \frac{H_\mathrm{p}}{60} = 4.75\,\mathrm{cm}\,.$$

As the flow past the monopile will create surface gravity waves, the Froude number scaling can be used to determine the model current speed and wave period. Using the definition of the Froude number,

$$\mathrm{Fr} \equiv \frac{U}{\sqrt{gL}}\,,$$

we can develop relations for the model current U_m

$$\frac{U_\mathrm{m}}{\sqrt{gL_\mathrm{m}}} = \frac{U_\mathrm{p}}{\sqrt{gL_\mathrm{p}}}$$

$$\rightarrow \boxed{U_\mathrm{m} = U_\mathrm{p}\sqrt{\frac{L_\mathrm{m}}{L_\mathrm{p}}} = 0.40\,\mathrm{m\,s^{-1}}\,.}$$

The celerity (phase speed) of a wave is its wavelength λ divided by its period T. Froude scaling can also be used to relate the celerity of the prototype and model waves

$$\frac{\lambda_\mathrm{m}/T_\mathrm{m}}{\sqrt{gL_\mathrm{m}}} = \frac{\lambda_\mathrm{p}/T_\mathrm{p}}{\sqrt{gL_\mathrm{P}}} \rightarrow \boxed{T_\mathrm{m} = T_\mathrm{p}\sqrt{\frac{L_\mathrm{m}}{L_\mathrm{p}}} = 1.39\,\mathrm{s}\,,}$$

where we have taken $\lambda_\mathrm{m}/\lambda_\mathrm{p} = L_\mathrm{m}/L_\mathrm{p}$.

7.1.4 Skin-Friction Drag

Breakdown of a Laminar Boundary Layer

The transition to turbulence over a flat plate is mainly governed by the Reynolds number, but can be affected by the amount of freestream turbulence present in the flow and the surface roughness of the plate. Above a critical Reynolds number of about $\mathrm{Re}_x \equiv Ux/\nu \approx 5\times10^5$ the flow becomes turbulent. Here the length scale for the Reynolds number is based on the distance from the leading edge of the plate x so that the Reynolds number increases with an increase in the downstream distance from the leading edge. The sequence of events that happen in the transition to turbulence in a flat plate boundary layer is shown in Fig. 7.5.

Near the leading edge of the flat plate, the flow is laminar and the full Navier–Stokes relations hold and $\mathrm{Re}_x \approx 1$. Downstream when $\mathrm{Re}_x \gg 1$, the flow is still laminar, but the approximate boundary layer equations hold [7.16]. A similarity solution for the Blasius boundary layer can be found (Fig. 7.6).

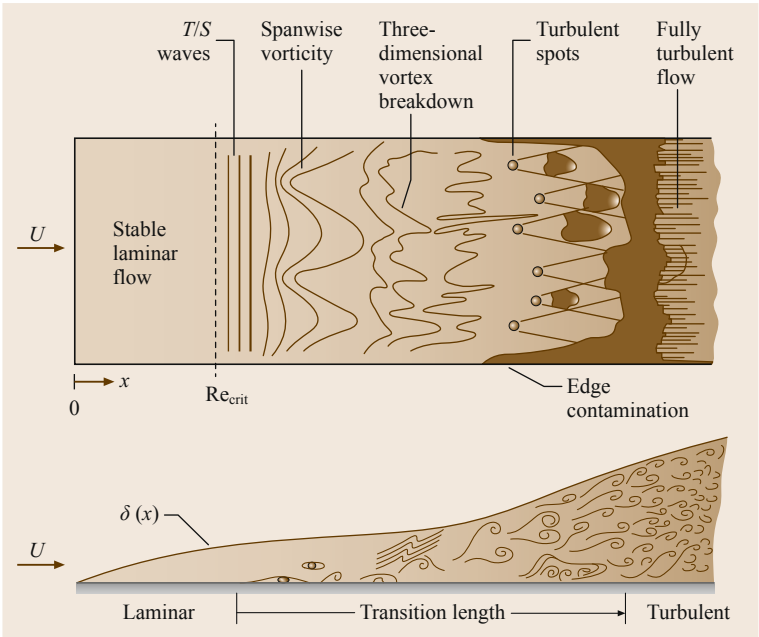

Fig. 7.5 Sequence of events occurring in transition to turbulence (after [7.16])

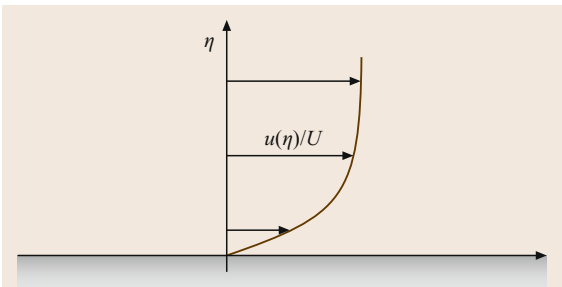

Fig. 7.6 Velocity distribution in a boundary layer over a flat plate. Here, η is the normalized height above the boundary layer, U is the freestream velocity and u is the local velocity. Both u and U are parallel to the plate

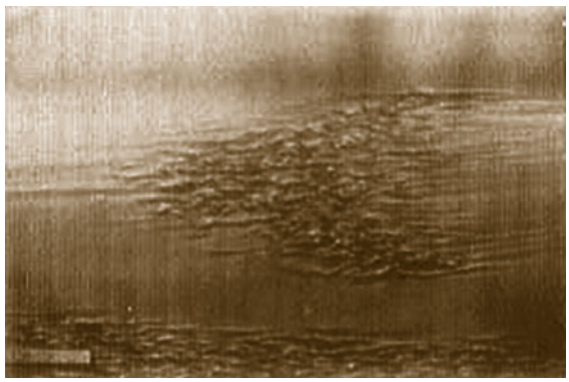

Fig. 7.7 A turbulent spot (after [7.17], courtesy of Cambridge University Press)

When $\mathrm{Re}_x \approx 5 \times 10^5$, instability starts to set in and the flow exhibits the development of two-dimensional Tollmein–Schlichting waves. As the Reynolds number continues to increase, the flow transitions to three-dimensional turbulent spots (Fig. 7.7), which are intermittent in nature. Lastly, the flow will transit to a fully three-dimensional turbulent flow (Fig. 7.8).

7.1.5 Estimating the Drag on a Ship from Model Testing

The results of model testing can be extended to approximate the drag on full-scale surface vessels. Here the prototype system is the full-scale system and the model system is typically geometrically similar, but smaller, and tested under controlled conditions in a towing tank or model basin. To avoid multiple scaling issues, test models do not usually include any appendages, such as fins or rudders; propulsion systems are also generally not included in model testing. The total resistance (drag) of surface vessels has been found to be a function of both the Reynolds number and the Froude number $C_\mathrm{T} = C_\mathrm{T}(\mathrm{Re}, \mathrm{Fr})$. However, it is not possible to simultaneously match both the model and prototype Reynolds and Froude numbers.

To circumvent this issue, Froude's hypothesis is used in practice. It is assumed that the total drag force can be split into two components, a frictional part F_v which is a function of the Reynolds number

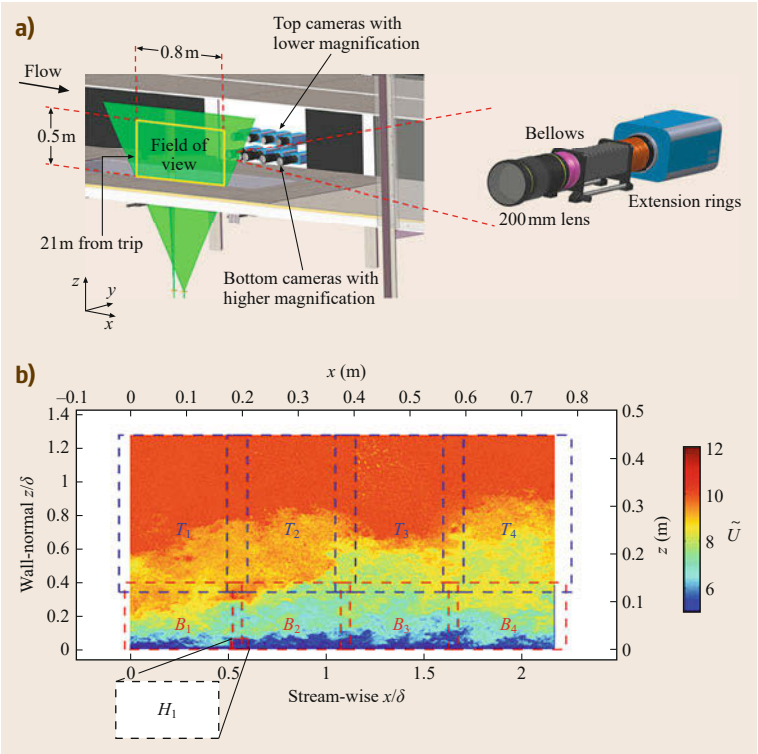

Fig. 7.8a,b Experimental measurement of a flat plat turbulent boundary layer. **(a)** Experimental setup; **(b)** spatial distribution of $\widetilde{U}$, the instantaneous velocity component in the streamwise direction (in meters per second). Here δ is the boundary layer thickness and the dashed rectangles represent the areas imaged by each of the cameras in **(a)**. The rectangle H_1 indicates an area where high resolution was used to image the near-wall region of the boundary layer (after [7.18], courtesy of AIP publishing)

only

$$C_F(\mathrm{Re}) \equiv \frac{F_v}{\frac{1}{2}\rho U^2 S}\,, \tag{7.18}$$

where S is the wetted surface area of the hull, and a residuary drag component F_R, which is a function of the Froude number only

$$C_R(\mathrm{Fr}) \equiv \frac{F_R}{\frac{1}{2}\rho U^2 S}\,. \tag{7.19}$$

The residuary part of the drag is assumed to arise from normal pressure forces acting perpendicularly to the hull (wave drag, viscous pressure resistance, and flow separation) and the frictional component is assumed to arise from shear stresses acting tangentially along the hull (skin friction). The total drag is simply the sum of the frictional and residuary components

$$C_T(\mathrm{Re},\mathrm{Fr}) = C_F(\mathrm{Re}) + C_R(\mathrm{Fr})\,. \tag{7.20}$$

Let a subscript m refer to the model hull and the subscript p refer to the corresponding prototype hull. The procedure for using Froude's hypothesis is as follows:

1. Use Froude scaling (7.10) to determine the model test speed from the anticipated operational speed of the prototype. Using the known model and prototype lengths, match the model and prototype Froude numbers and solve for the required test speed

$$\mathrm{Fr}_m = \frac{U_m}{\sqrt{gL_m}} = \frac{U_p}{\sqrt{gL_p}} = \mathrm{Fr}_p \rightarrow U_m = U_p\sqrt{\frac{L_m}{L_p}}\,.$$

Generally, the length on the waterline of the model and prototype are used as the reference lengths L_m and L_p, respectively.
2. The total drag on the model is experimentally measured and used to determine the total drag coefficient C_{Tm}.
3. The coefficient of residuary resistance of the model C_{Rm} is assumed to be equal to the coefficient of residuary resistance of the prototype C_{Rp} when the model and prototype Froude numbers are equal. The residuary resistance of the model is determined from Froude's hypothesis as $C_{Rm} = C_{Tm} - C_{Fm} = C_{Rp}$.
4. The coefficient of friction of both the model and prototype are determined using Reynolds number dependent empirical relations for the drag on a flat plate. In practice, the 1957 ITTC (International Towing Tank Conference) line [7.19] is often used

$$C_F = \frac{0.075}{[\log_{10}(\mathrm{Re}) - 2.0]^2}\,. \tag{7.21}$$

5. Then the total resistance of the prototype is

$$C_{Tp} = C_{Fp} + C_{Rp} = C_{Fp}(Re_p) + C_{Tm} - C_{Fm}(Re_m) .$$

Note that the ITTC line assumes that the flow is turbulent. For most models, even those of the modest length (about 1 m), towed at slow speeds (2 kn), the flow will be turbulent over at least part of the model. However, the geometrically scaled thickness of the boundary layer about the model will tend to be much thicker than that about the prototype and the difference can lead to some discrepancy in the drag predicted using Froude's hypothesis. To mitigate this, turbulence stimulators (tripwires, sandpaper, thick tape, etc.) are often utilized in model testing to ensure that the boundary layer transitions from laminar to turbulent flow as quickly as possible at the bow of the model. The required thickness of a trip t can be estimated using the following relation for the critical Reynolds number for transition [7.20]

$$Re_{crit} = \frac{Ut}{\nu} \approx 826 . \qquad (7.22)$$

Note that the selection of trip thickness is a balancing act between forcing the flow to transition to turbulence and affecting the pressure distribution about the hull and thereby affecting the global flow distribution.

7.1.6 Hydrofoil Lift and Drag

Strictly speaking, a hydrofoil is the cross-sectional shape of a larger rudder, fin or underwater wing. Any two-dimensional streamlined body that generates lift can be thought of as a hydrofoil. Here, the lift force per unit span l is perpendicular to the direction of the freestream flow (flow undisturbed by the presence of the hydrofoil) and the drag force d is always parallel to the direction of the freestream (Fig. 7.9). The hydrofoil chord c is defined as the straight line segment that connects the leading edge of the hydrofoil to its trailing edge. The angle of attack is the angle between the freestream flow direction and the chord line of the foil.

As mentioned above, the extension of a hydrofoil into three dimensions gives a fin or rudder. The dimension perpendicular to the hydrofoil cross section is called the span s and the projected area perpendicular to the fin or rudders lift force is known as the planform area A (Fig. 7.10).

The aspect ratio of the wing is defined as $\Lambda \equiv s^2/A$. When there is little twist about the span-wise axis of a rudder or fin, the flow can be approximated as two-dimensional when $\Lambda \gg 1$. In practice, when the aspect ratio Λ is larger than about 5–7, the flow around a hydrofoil can be approximated as two-dimensional flow for modeling, design, or experimental purposes. When performing experiments, endplates are often added to the ends of a fin or rudder to help ensure two-dimensionality of the flow at measurement locations near the center span.

The basic geometry of a hydrofoil is shown in Fig. 7.11. The thickness of a hydrofoil is its maximum dimension in a direction perpendicular to the chord line. The mean camberline is defined as the mean of the upper and lower positions of the hydrofoil in a direction perpendicular to the chord line. The *camber* of the hydrofoil is the maximum distance between the camberline and the chord line. Both the thickness and camber of a hydrofoil are typically specified as a fraction of the chord length. For example, a common convention for defining hydrofoil shape is use of the 4-digit NACA (National Advisory Committee for Aeronautics) desig-

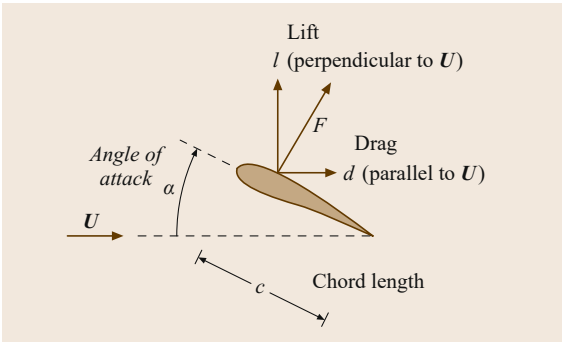

Fig. 7.9 Lift and drag on a foil

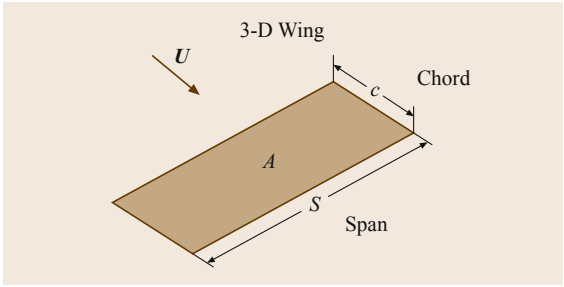

Fig. 7.10 Fin or rudder

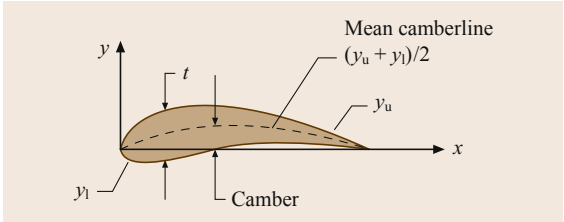

Fig. 7.11 Hydrofoil geometry

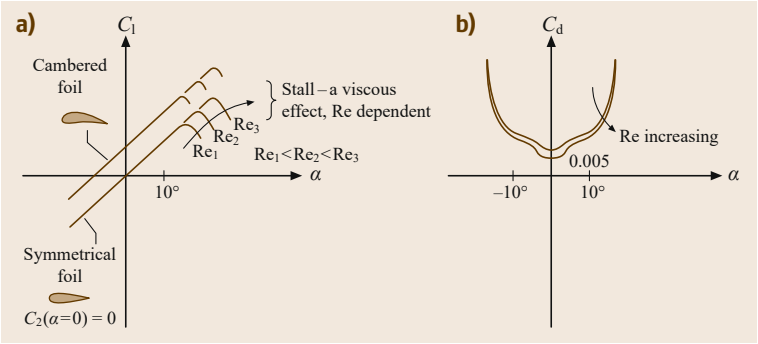

Fig. 7.12a,b Example hydrofoil lift coefficient **(a)** and drag coefficient**(b)** versus angle of attack

nation [7.21, 22]. The geometry of simple hydrofoils can be specified using the NACA convention, as follows [7.21]:

1. The first digit represents the camber of the foil as a percentage of the chord length.
2. The second digit represents the location of maximum camber with respect to the leading edge, as a percentage of the chord length divided by 10.
3. The last 2 digits represent the thickness of the foil as a percentage of the chord length.

For example, a NACA2412 hydrofoil has 2% camber, the location of maximum camber is 40% of the chord length from the leading edge, and the thickness of the foil is 12% of the chord length.

As shown in Fig. 7.12, the lift and drag coefficients of the hydrofoil have been found to be functions of the Reynolds number Re and angle of attack α of the foil. The Reynolds number dependence of the lift curve is a result of flow separation, which is a viscous effect. When the flow separates from the surface of the hydrofoil, the pressure difference across the foil is drastically reduced and there is a rapid loss of lift with increasing angle of attack. As can be seen in Fig. 7.12a, so long as there is no separation, the Reynolds number dependence of the two-dimensional lift coefficient can be ignored

$$C_l \equiv \frac{l}{\rho U^2 c} = C_l(\mathrm{Re}, \alpha) \approx C_l(\alpha) \,, \tag{7.23}$$

$$C_d \equiv \frac{d}{\rho U^2 c} = C_d(\mathrm{Re}, \alpha) = C_F(\mathrm{Re}) + C_P(\alpha) \,. \tag{7.24}$$

For thin hydrofoils, approximately when $t/c < 0.14$, the two-dimensional lift coefficient can be approximated as $C_l = 2\pi\alpha$, where α is in radians, using the *flat plate approximation*. In practice, this approximation works fairly well for estimating the lift produced by a hydrofoil in initial design estimates or simple simulations. Note that, cambered foils will produce lift when $\alpha = 0$.

The corresponding drag coefficient curves are shown in Fig. 7.12b. It is a common practice to separate the effects of Reynolds number and angle of attack into two, additive components. The first component C_F is a function of Reynolds number only and is related to the viscous friction of the hydrofoil. The second component C_P is a function of the angle of attack and is related to the pressure coefficient of the foil. The large increase in drag coefficient that occurs when magnitude of the angle of attack is large is due to stall effects.

A convenient approximation for the two-dimensional drag coefficient on a hydrofoil or submerged streamlined strut at zero angle of attack is given by *Hoerner*'s formula [7.23]

$$C_d = 2C_F[1 + 2\left(\frac{t}{c}\right) + 60\left(\frac{t}{c}\right)^4] \,, \tag{7.25}$$

where C_F is the skin friction coefficient, as given by the 1957 ITTC line (7.21).

Three-Dimensional Effects

Owing to the pressure difference across the top and bottom of a low aspect ratio, lift-generating fin (or rudder or sail), the streamlines at the tip of the fin will roll up to create wingtip vortices, as shown in Fig. 7.13.

These wingtip vortices induce a small velocity behind the fin in a direction normal to its planform. The induced velocity changes the local angle of attack of the flow at the hydrofoil and effectively causes the local lift vector rotate toward the downstream direction, effectively increasing the drag on the fin – this is known as *induced drag* or can sometimes be called *drag due to lift*. For thin fins with an elliptical planform shape, the aspect ratio effects of the wingtip vortices can be accounted for in the lift coefficient C_L and the induced drag coefficient C_{Di} as follows

$$C_L = \frac{2\pi\alpha}{1 + 2/\Lambda} \,, \tag{7.26}$$

$$C_{Di} = \frac{4\pi\alpha^2\Lambda}{(\Lambda+2)^2} = \frac{C_L^2\Lambda}{\pi(\Lambda+2)^2} \,, \tag{7.27}$$

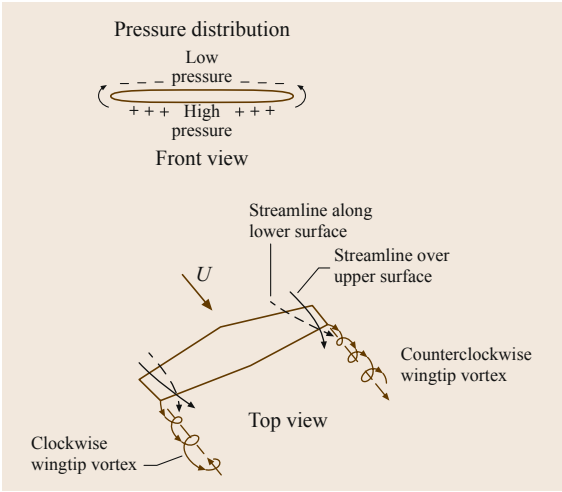

Fig. 7.13 Formation of wingtip vortices at the tips of a fin or rudder

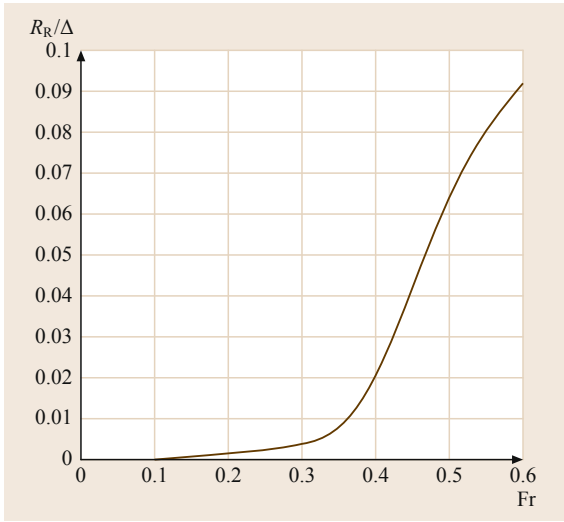

Fig. 7.14 Upright (no heel) residuary resistance R_R as a fraction of displacement Δ versus Fr on the model hull from experimental measurements

where the total drag coefficient is the sum of the two-dimensional drag coefficient C_d and the induced drag coefficient $C_{Dtot} = C_d + C_{Di}$.

Example 7.6

The following questions pertain to a prototype sailboat designed for oceanographic measurement [7.24–28]. Some of the model and prototype dimensions are shown in Table 7.2; properties of air and seawater at design conditions are given in Table 7.3.

The following questions may be posed:

1. The hullform:
   a) The model and prototype sailboats are geometrically similar:
      i. Fill-in the missing prototype values in Table 7.2.
      ii. The prototype will be operated at Fr = 0.375, where the relevant length scale is taken as the length on the waterline, LWL (Table 7.2). What is the design speed V_S of the prototype?
   b) Use Fig. 7.14 to estimate the C_D for the prototype sailboat (heel angle is not included) – calculate the weight of the prototype Δ from the volume of water displaced by the hull $\nabla = 8.0\,m^3$. Approximate the frictional drag coefficient of the vessel using the 1957 ITTC Line based on LWL (Table 7.2).
   c) What is the estimated hydrodynamic drag F_H on the prototype sailboat hull? We are ignoring the drag on the keel and rudder, any heel angle, the leeway angle, etc.
2. The sail:
   As shown in Fig. 7.12, the sailboat must be able to sail in a wind of $V_t = 20.0\,kn$ ($10.29\,m\,s^{-1}$) at an angle of $\psi = 40°$. A wing having a symmetrical airfoil cross section, a span of $s_s = 10\,m$ and a chord of $l_s = 2\,m$ will be used as the sail. Refer to Fig. 7.15 and treat the sail as a 2-D wing by ignoring the three-dimensional effects at the wingtip:
   a) Determine the angle β and speed V_A of the *apparent wind*.
   b) Determine the equation of motion (for constant V_S) along the boat's course.
   c) Assume F_H lies along the sailboat's course. If $\alpha = 15°$, compare the component of the sail drag F_D along the boat's trajectory with F_H – can this component of F_D be ignored?
   d) Estimate the slope of the lift curve ($\partial C_L/\partial\alpha$) from the airfoil data provided (Fig. 7.16).
   e) Using the slope of the lift curve in your equation of motion, determine the angle of attack α required for the sail. Will it stall?

Table 7.2 Model and prototype dimensions

Quantity	Model	Prototype
Length overall (LOA) [m]	2.47	11
Length on waterline (LWL) [m]	2.00	
Wetted surface area [m^2]	0.965	

Table 7.3 Properties of water and air at 15 °C

Medium	Sea water	Air
Density [$kg\,m^{-3}$]	1025.9	1.226
Kinematic viscosity [$m^2\,s^{-1}$]	1.19×10^{-6}	1.45×10^{-5}

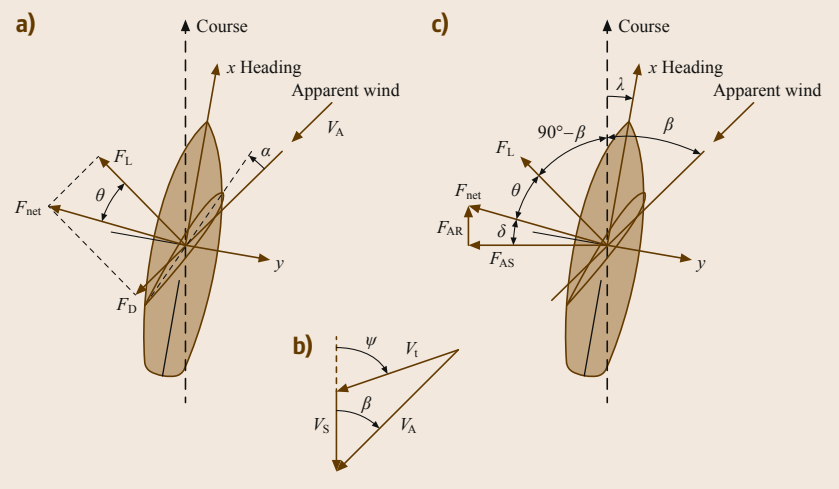

Fig. 7.15a–c Sailboat aerodynamic free body diagrams in the boat fixed frame. **(a)** The airfoil profile represents the wing and α is the angle of attack of the sail with respect to the apparent wind angle. **(b)** ψ is the true wind direction, β is the apparent wind angle. **(c)** The x- and y-axes are the boat-fixed maneuvering coordinate system, the x-axis gives the heading while the angle between course and heading is the leeway angle λ, $\delta = (\beta - \theta)$ is the angle between the net aerodynamic force F_{net} and the side force F_{AS} (after [7.25], courtesy of the Institute of Electrical and Electronics Engineers (IEEE))

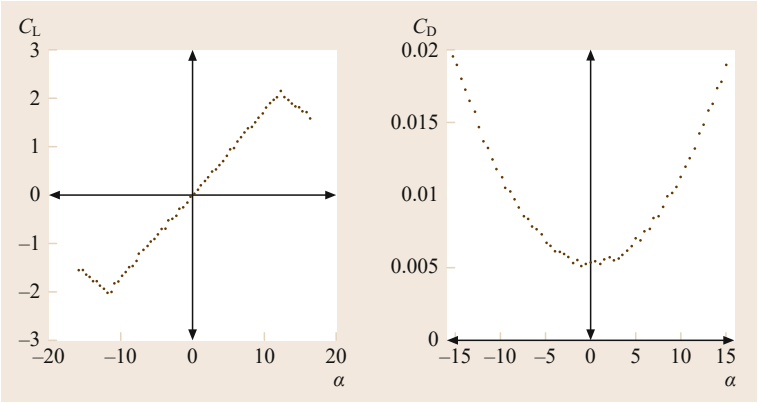

Fig. 7.16 Sailboat wing aerodynamic characteristics

3. The keel:
   Here, the keel will be a thin flat plate with a span of $S_k = 1.2\,\text{m}$ and a chord of $l_k = 1.5\,\text{m}$. In order to keep the lateral (transverse) component of the aerodynamic forces F_{AS} from pushing the yacht off course, the keel must have a small leeway angle λ (angle of attack) with respect to the boat's course (Fig. 7.17). Assuming F_{AS} is balanced entirely by the lift on the keel F_{HS} – calculate λ.

Solution 7.6

1. The hullform:
   a) The model and prototype sailboats are geometrically similar:
      i. The missing prototype values have been included in Table 7.4.
      ii. The prototype will be operated at $\text{Fr} = 0.375$, where the relevant length scale is taken as the length on the waterline, LWL (Table 7.2). What is the design speed V_S of the prototype?

$$V_S = F\sqrt{\text{gLWL}_p} = 3.51\,\text{m}\,\text{s}^{-1}$$

Table 7.4 Model and prototype dimensions

Quantity	Model	Prototype
Length overall (LOA) [m]	2.47	11
Length on waterline (LWL) [m]	2.00	$\text{LWL}_p = 8.91$
Wetted surface area [m^2]	0.965	$\text{Sw}_p = 19.1$

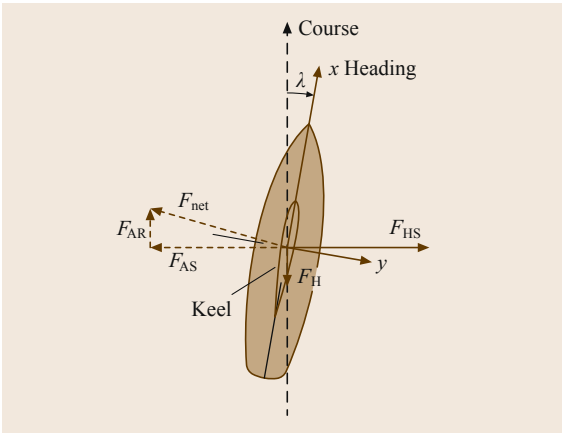

Fig. 7.17 Sailboat hydrodynamic free body diagram in the boat fixed frame. The hydrofoil profile represents the keel. At equilibrium,the hydrodynamic side force F_{HS} balances the aerodynamic side force F_{AS} and the force of hydrodynamic resistance F_{HR} balances the aerodynamic driving force F_{AR}, where F_{HS} and F_{HR} are perpendicular and parallel, respectively, to the course direction. Note that F_{HS} is generated by the keel and hull acting as an underwater wing with the leeway angle λ being the angle of attack (after [7.25]). Reproduced with permission from IEEE

b) Use Fig. 7.14 to estimate the C_D for the prototype sailboat (heel angle is not included) – calculate the weight of the prototype Δ from the volume of water displaced by the hull $\nabla = 8.0\,m^3$. Approximate the frictional drag coefficient of the vessel using the 1957 ITTC Line based on LWL (Table 7.2).

$$\Delta = \rho_{sw} g \nabla = 80.5\,kN$$

From Fig. 7.14,

$$R_R(F) = 1.18 \times 10^{-2} \Delta = 950\,N\,.$$

Using Froude's hypothesis,

$$C_D(R,F) = C_F(Re) + C_R(Fr)\,,$$

where $C_F(Re)$ is determined using the hull Reynolds number

$$Re_H = \frac{V_S LWL_p}{\upsilon_{sw}} = 2.62 \times 10^7$$

and the 1957 ITTC Line

$$C_F(Re_H) = \frac{0.075}{[\log_{10}(Re_H) - 2.0]^2} = 2.55 \times 10^{-3}$$

and

$$C_R(Fr) = \frac{R_R}{\frac{1}{2}\rho_{sw} V^2 S w_p} = 7.88 \times 10^{-3}\,,$$

so that $C_D = 10.4 \times 10^{-3}$.

c) What is the estimated hydrodynamic drag F_H on the prototype sailboat hull? We're ignoring the drag on the keel and rudder, any heel angle, the leeway angle, etc.

$$F_H = \frac{1}{2}\rho_{sw} V_s^2 S w_p C_D = 1.26\,kN\,.$$

2. The sail:
As shown in Fig. 7.12, the sailboat must be able to sail in a wind of $V_t = 20.0\,kn$ ($10.29\,m\,s^{-1}$) at an angle of $\psi = 40°$. A wing having a symmetrical airfoil cross section, a span of $s_S = 10\,m$, and a chord of $l_S = 2\,m$ will be used as the sail. Refer to Fig. 7.15 and treat the sail as a 2-D wing by ignoring the three-dimensional effects at the wingtip:

a) Determine the angle β and speed V_A of the *apparent wind*.

$$\beta = \tan^{-1}\left(\frac{V_t \sin\psi}{V_t \cos\psi + V_S}\right) = 30.1°$$

$$V_A = \frac{V_t \sin\psi}{\sin\beta} = 13.2\,m\,s^{-1}$$

b) Determine the equation of motion (for constant V_S) along the boat's course.

$$F_L \sin\beta - F_D \cos\beta - F_H = 0$$

c) Assume F_H lies along the sailboat's course. If $\alpha = 15°$, compare the component of the sail drag F_D along the boat's trajectory with F_H – can this component of F_D be ignored?
For $\alpha = 15°$, the drag coefficient of the sail $C_{DS} \approx 0.019$. The component of F_D along the boat's course is

$$F_D \cos\beta = \frac{1}{2}\rho_{air} V_A^2 C_{Ds} l_s s_s \cos\beta = 34.8\,N\,.$$

This is about 2.8% of the drag on the hull. As the sail will stall at angles of attack larger than this, we can ignore the drag on the sail, as the sail is likely to be operated at smaller angles, where the drag is lower.

d) Estimate the slope of the lift curve ($\partial C_L/\partial\alpha$) from the airfoil data provided (Fig. 7.16).

$$\frac{\partial C_L}{\partial\alpha} = \frac{2.2 - 0}{12° - 0} = 0.18\,[deg^{-1}] \rightarrow C_L = \frac{\partial C_L}{\partial\alpha}\alpha$$

e) Using the slope of the lift curve in your equation of motion, determine the angle of attack α required for the sail. Will it stall?

$$F_{\mathrm{L}} = \frac{\partial C_{\mathrm{L}}}{\partial \alpha}\alpha\frac{1}{2}\rho_{\mathrm{air}}V_{\mathrm{A}}^2 l_{\mathrm{s}}s_{\mathrm{s}}$$
$$\longrightarrow \frac{\partial C_{\mathrm{L}}}{\partial \alpha}\alpha\frac{1}{2}\rho_{\mathrm{air}}V_{\mathrm{A}}^2 l_{\mathrm{s}}s_{\mathrm{s}}\sin\beta = F_{\mathrm{H}}$$

Solving for α gives

$$\alpha = \frac{F_{\mathrm{H}}}{\frac{1}{2}\rho_{\mathrm{air}}V_{\mathrm{A}}^2 l_{\mathrm{s}}s_{\mathrm{s}}\frac{\partial C_{\mathrm{L}}}{\partial \alpha}\sin\beta} = 6.43^\circ\,.$$

From Fig. 7.16, we can see that this is smaller than the stall angle, so the sail will not stall.

3. The keel: Here, the keel will be a thin flat plate with a span of $s_{\mathrm{k}} = 1.2\,\mathrm{m}$ and a chord of $l_{\mathrm{k}} = 1.5\,\mathrm{m}$. In order to keep the lateral (transverse) component of the aerodynamic forces F_{AS} from pushing the yacht off course, the keel must have a small leeway angle λ (angle of attack) with respect to the boat's course (Fig. 7.17). Assuming F_{AS} is balanced entirely by the lift on the keel F_{HS}, calculate λ.

From thin airfoil theory for a flat plate, the lift coefficient of the keel can be calculated as $C_{\mathrm{Lk}} = 2\pi\lambda$ (where λ is in radians). Thus,

$$F_{\mathrm{HS}} = F_{\mathrm{AS}} = \frac{1}{2}\rho_{\mathrm{sw}}V_{\mathrm{S}}^2(2\pi\lambda)s_{\mathrm{k}}l_{\mathrm{k}}\,.$$

Solving for λ and converting to degrees gives $\lambda = 1.75^\circ$.

7.1.7 Screw Propellers

A typical screw propeller can be considered to be a combination of several hydrofoils arranged in a helicoidal fashion around a hub. Definitions of the basic terms are given in Fig. 7.18. The diameter of the circle traced by the tip of each blade is d and the radius is r. The tangential velocity of the blade tips is $2\pi nr$, where n is the rotational speed of the propeller in Hz. The shaft torque required to rotate the propeller is Q and the thrust generated is T. The velocity perpendicular to the plane of the rotor disk generated by the propeller is known as the advance speed and is given here by U. Thus, as shown in Fig. 7.19, the velocity of the flow approaching each blade has both a component normal to the plane of the rotor disk and parallel to the rotor disk, the resultant velocity is known as the relative velocity U_{rel}.

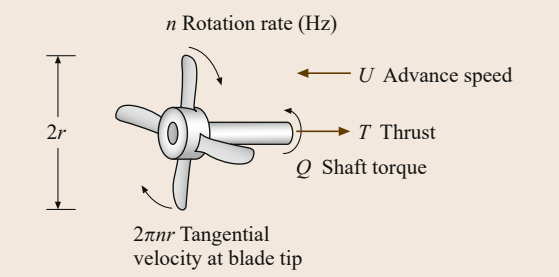

Fig. 7.18 Definition of the basic terms, here T and Q are drawn as the resultant thrust and shaft torque, respectively, of the fluid acting on the propeller

The term *pitch* can be used to refer to either an angle ϕ or a distance P (Fig. 7.20). When used in reference to angle, the pitch is the angle between the chord line of a propeller blade and the plane of the rotor disk. Alternatively, when used to reference a distance the pitch is the forward distance traveled by the rotor in one revolution when there is no slip with respect between the propeller and surrounding water.

The angle of attack of the blade α can be determined from the components of U_{rel} and the pitch angle of the blade ϕ

$$\alpha = \phi - \tan^{-1}\left(\frac{U}{2\pi nr}\right) = \phi - \tan^{-1}\left(\frac{J}{\pi}\right)\,, \quad (7.28)$$

where J is the advance ratio defined as

$$J \equiv \frac{U}{nd}\,. \quad (7.29)$$

As long as the propeller is not operated at an excessive angle of attack, flow separation on the blades can be

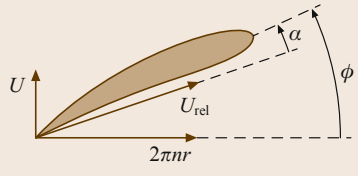

Fig. 7.19 Velocity components of the flow approaching each propeller blade

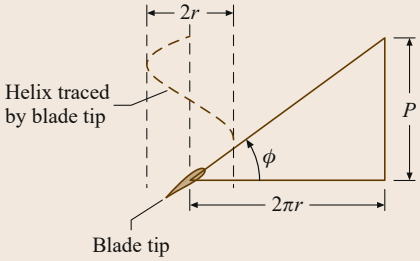

Fig. 7.20 The definition of propeller pitch

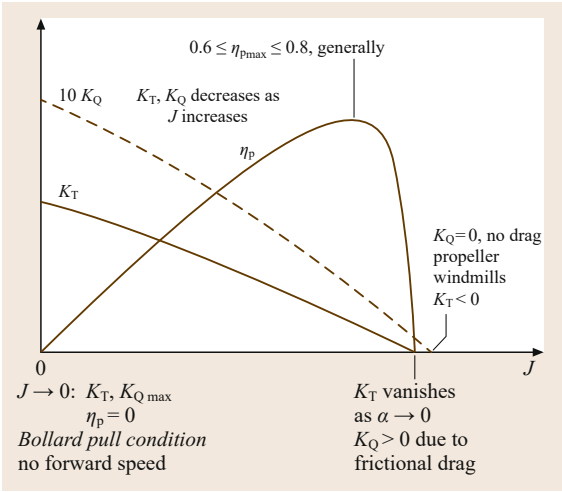

Fig. 7.21 Example of open-water propeller performance curves

avoided such that the thrust and torque on the propeller are independent of the Reynolds number. We define the thrust coefficient as

$$K_T(J) \equiv \frac{T}{\rho n^2 d^4} , \tag{7.30}$$

and the torque coefficient as

$$K_Q(J) \equiv \frac{Q}{\rho n^2 d^5} . \tag{7.31}$$

At a constant velocity, the power delivered by the propeller is UT and the power required to overcome shaft torque is $2\pi nQ$. Thus, the propeller's efficiency is the output power divided by the input power and can be written as

$$\eta_p = \frac{UT}{2\pi nQ} = \frac{U\rho n^2 d^4 K_T}{2\pi n \rho n^2 d^5 K_Q} = \frac{U}{2\pi n d}\frac{K_T}{K_Q} = \frac{J}{2\pi}\frac{K_T}{K_Q} . \tag{7.32}$$

A sketch of a typical open-water propeller performance curve is shown in Fig. 7.21. Here, the term open water indicates that the propeller was tested in the absence of any hull or other underwater surface, such that the advance velocity is not representative of any wake.

Blade Element Theory

Blade element theory can be used to estimate the output thrust and input torque on a propeller. A propeller blade is segmented into short, two-dimensional, differential elements and the lift and drag on each element are determined from the two-dimensional lift and drag coefficients, and then integrated across the span of the propeller blade. Typically, the analysis is conducted on one blade and multiplied by the number of blades N to determine the total thrust and torque on the propeller. The effects of camber and finite blade length are often omitted from the analysis for simplicity.

Let the two-dimensional drag and lift coefficients be defined as in (7.13) and (7.14), where l and d are the lift and drag per unit span of the blade, respectively, c is the blade chord length and U_{rel} (the relative velocity shown in Fig. 7.19) is used as the characteristic velocity scale. Then, the thrust and torque on a differential element are

$$\mathrm{d}T = l\cos(\phi-\alpha) - d\sin(\phi-\alpha) ,$$

and

$$\mathrm{d}Q = [l\sin(\phi-\alpha) + d\cos(\phi-\alpha)]r ,$$

respectively (r is the radial location of the blade element measured from the center of the propeller hub). Substituting the coefficients of lift and drag into these expressions gives

$$\mathrm{d}T = \frac{1}{2}\rho U_{rel}^2 c[C_l\cos(\phi-\alpha) - C_d\sin(\phi-\alpha)]\mathrm{d}r ,$$
$$\mathrm{d}Q = \frac{1}{2}\rho U_{rel}^2 c[C_l\sin(\phi-\alpha) + C_d\cos(\phi-\alpha)]r\mathrm{d}r .$$

Integrating these expressions over the span of the blade (between the radial location of the hub r_h and the tip of the blade r_0) and multiplying by the number of blades, gives the total thrust and drag on the propeller

$$T = \frac{1}{2}\rho U_{rel}^2 Nc \times \int_{r_h}^{r_0} [C_l\cos(\phi-\alpha) - C_d\sin(\phi-\alpha)]\mathrm{d}r , \tag{7.33}$$

$$Q = \frac{1}{2}\rho U_{rel}^2 Nc \times \int_{r_h}^{r_0} [C_l\sin(\phi-\alpha) + C_d\cos(\phi-\alpha)]r\mathrm{d}r . \tag{7.34}$$

Increasing the number of blades can increase the thrust output, but will also increase the torque. In theory, as the input power is the product of the torque and angular velocity and the output power is the product of the thrust and forward speed, the efficiency, which is the ratio of these products, will be independent of the number of propeller blades.

Actuator Disk Model

Here a propeller is modeled by the disk that the propeller blades trace out when spinning. The velocity upstream of the propeller is taken as U_0 and the velocity downstream is U_1. The streamlines passing through the propeller actuator disk form a continuous streamtube that contracts from the upstream side to the downstream side (Fig. 7.22). The upstream area of the streamtube is taken as A_0, the downstream area is A_1 and the area at the actuator disk itself is A_d. The velocity at the actuator disk itself is taken as the average of the upstream velocity and the downstream velocity

$$U_d = \frac{U_0 + U_1}{2} .$$

The total pressure across the actuator disk changes and energy is input into the flow at the actuator disk itself. Thus, Bernoulli's equation cannot be used across the actuator disk. However, it holds upstream and downstream of the actuator disk. The pressure on the upstream suction side of the disk p_b and on the downstream, pressure side of the disk p_f can be calculated as

$$p_b = p_\infty + \frac{1}{2}\rho U_0^2 - \frac{1}{2}\rho\left(\frac{U_1 + U_2}{2}\right)^2 ,$$

$$p_f = p_\infty + \frac{1}{2}\rho U_1^2 - \frac{1}{2}\rho\left(\frac{U_1 + U_2}{2}\right)^2 .$$

Thus, the pressure difference across the disk is

$$p_f - p_b = \frac{1}{2}\rho\left(U_1^2 - U_0^2\right) .$$

The thrust generated is

$$T = (p_f - p_b)A_d = \frac{1}{2}\rho\left(U_1^2 - U_0^2\right)A_d . \qquad (7.35)$$

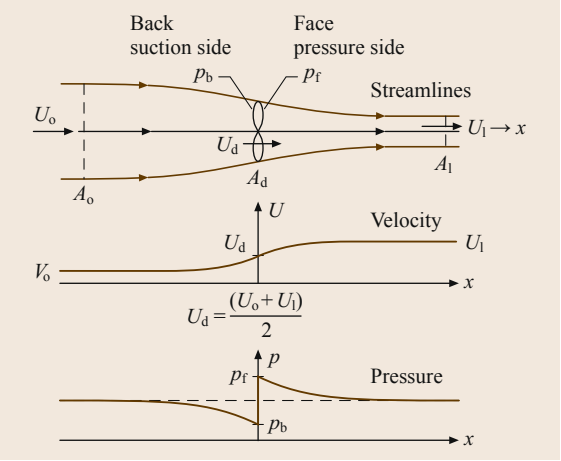

Fig. 7.22 The streamtube, velocity, and pressure across an actuator disk

Since the corresponding input power at the disk is

$$\mathbb{P}_{in} = TU_d = \frac{1}{2}\rho U_d\left(U_1^2 - U_0^2\right)A_d ,$$

and output power is

$$\mathbb{P}_{out} = TU_0 = \frac{1}{2}\rho U_0\left(U_1^2 - U_0^2\right)A_d ,$$

the efficiency is

$$\eta = \frac{\mathbb{P}_{out}}{\mathbb{P}_{in}} = \frac{2U_0}{U_0 + U_1} . \qquad (7.36)$$

Wake Effects and Propeller Slip

As explained above, the pitch is defined as the forward distance the propeller moves in one complete revolution when there is no slip (relative motion) between the propeller and surrounding water. In practice, however, slip must be present in order for a propeller to generate thrust. When no slip is present, the forward speed of the propeller would be the product of the pitch and propeller frequency, nP. Owing to hull drag, the forward speed U_S of a vessel driven by a propeller will be slightly lower. Apparent slip is the difference between nP and U_S (Fig. 7.23) and the related apparent slip ratio S_A is

$$S_A \equiv \frac{nP - U_S}{nP} . \qquad (7.37)$$

As a vessel moves through the water, it drags some water behind it, creating a wake, such that the advance velocity U at the propeller is reduced from the ship speed U_S by the wake speed. The difference between nP and U is the true slip speed and the related true slip ratio is defined as

$$S_R \equiv \frac{nP - U}{nP} . \qquad (7.38)$$

The overall propulsive efficiency is affected by the interaction of the vessel's wake and the flow into the

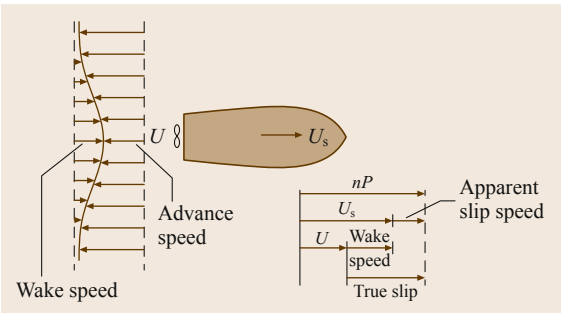

Fig. 7.23 Definition of slip

propeller. One can quantify the magnitude of the wake speed generated by a hull using the Taylor wake fraction, which is defined as

$$w \equiv \frac{U_S - U}{U_S} \,. \tag{7.39}$$

For most ships, the wake fraction lies in the range $0 < w < 0.4$, where a value of $w \approx 0.4$ would correspond to a very full (rounded) hull and is smaller for fine (slender) hulls.

The propulsion system and hull-form of a propeller-driven ship are typically designed separately. The bare-hull resistance R_T (hull drag without propulsion system, actuators, or rudders present) of the vessel is usually estimated from model test data. The performance of the propulsion system is also usually estimated from open water (no hull present) test data. However, the presence of a propeller at the stern of a ship reduces the pressure at the stern, in comparison to what it would be during bare hull resistance tests. This reduced pressure will typically result in an increase in drag. Thus, the thrust T required from the propeller is usually slightly higher than the bare hull resistance. The thrust deduction coefficient t is a measure of the difference between required thrust and bare hull resistance

$$t = \frac{T - R_T}{T} \,. \tag{7.40}$$

Generally, the thrust deduction coefficient is in the range $t < 0.2$. From (7.32), the propulsive efficiency can be expressed as the ratio of thrust power to propulsive power

$$\eta_p = \frac{UR_T}{2\pi nQ(1-t)} \,. \tag{7.41}$$

7.1.8 Air and Wind Resistance

When examining air drag on a surface-going vessel, one must account for both the velocities of the vessel through the air and the velocities of any surface winds (Fig. 7.24). The total velocity of the vessel through the air will be the vector sum of these two velocities. Of particular importance is how to model the velocity profile of each of these two components. The velocity distribution for the vessels motion will be uniform in height; the vertical profile of the wind will vary with height above the free surface owing to boundary layer effects.

For calculation of the wind resistance, the 10 min average of the wind speed at a height of 10 m (approximately 33 ft) above the water surface u_{10} is used as a reference. Generally, turbulence models are used to approximate the velocity profile of the wind. One such approximation is a modification of the *log law* for fully rough flow. If z is the height in meters above the waterline, the log law gives

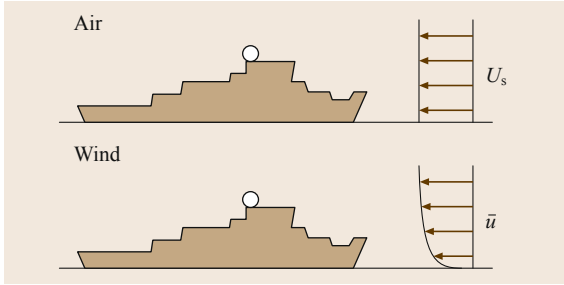

Fig. 7.24 Velocity profile of wind and air speed about a surface vessel

$$\frac{\bar{u}}{u_{10}} = \frac{\ln(z/k_s)}{\ln(10/k_s)} \,, \tag{7.42}$$

where $k_s = 6.0 \times 10^{-3}$ m. Another useful expression for modeling the wind profile [7.3] is

$$\frac{\bar{u}}{u_{10}} = \left(\frac{z}{10}\right)^{1/7} \,, \tag{7.43}$$

where z is in meters and u_{10} can be estimated from a known sea state.

Using these estimates for the speed of the wind acting on the vessel, the wind resistance can be approximated as

$$D_w = \frac{1}{2}\rho_{air} C_D A U^2 \,. \tag{7.44}$$

Here ρ_{air} is the air density and A is the frontal area of the area normal to the wind. The frontal area is used, rather than the wetted surface area (as in calculating the drag on the underwater hull) as pressure effects tend to dominate wind drag, whereas skin friction effects tend to dominate the overall drag on the underwater hull. Also, note that airflow can affect the trim and sinkage of a surface vessel, and thus the drag on the underwater hull.

7.1.9 Hydrodynamic Characterization of Marine Surface Vessels

The forces that support the weight (W) of a marine vehicle are found by integrating the pressure over the surface of the vehicle. The way in which this pressure is developed can be categorized into four broad operational regimes:

(1) Hydrostatic: The vehicle is principally supported by buoyancy forces, which are proportional to the volume of water displaced by the submerged volume

of the vessel (∇), that is, $W = \rho g \nabla$ (Archimedes' principle).

(2) Hydrodynamic: A vehicle pushes water downward as it moves across the water surface, imparting a downward momentum on fluid near the free surface. The resulting reaction force on the hull supports the vessel.

(3) Aerostatic: The pressure generated by a *lifting fan* at the top of a plenum chamber supports the vehicle's weight, even when it has no forward velocity.

(4) Aerodynamic: Some marine vehicles rely on the aerodynamic lift created by their forward velocity to support themselves near the free surface.

Hydrostatic and Hydrodynamic Regimes

The majority of marine vessels operate in either the hydrostatic or the hydrodynamic-pressure regime above. Since the hull is that part of a ship that generally supports its weight, hull design is strongly driven by the operational regime. Good hull design is critical for efficient powering, stability, controllability, and maneuverability [7.29]. The Froude number can be used to determine whether a vehicle operates in pressure regime (1), (2) or in an intermediate zone between regimes (1) and (2). Here, the waterline-length-based Froude number is defined as

$$\mathrm{Fr} \equiv \frac{U}{\sqrt{g L_{\mathrm{WL}}}} , \tag{7.45}$$

where U is vehicle speed, g is the acceleration of gravity and L_{WL} is a length-scale characteristic of the dimension of the ship parallel to the direction of the freestream flow (often taken as the design waterline LWL).

Calm Water Wave Drag and the Froude Number Limit of Displacement Hulls. As a ship or other marine vessel moves across the water's surface, it generates a distinctive pattern of waves, which create one component of the overall drag by radiating energy from the vessel to the far field (wave-making resistance). When viewed from far above the surface, the divergent and transverse waves created at the hull can be seen to interact to produce a Kelvin wave pattern (Fig. 7.19). Very close to the hull, the shape and pattern of the waves strongly depends on the form of the hull. At distances of a few hull lengths, the waves generated at all points on the hull's surface will contribute to the Kelvin wave system. However, the high-pressure regions at the bow and stern of a ship contribute most to the generation of the wave field. As the waves generated at the bow and stern move with the ship, their speed is equivalent to the speed of the ship U.

The celerity (c), or phase speed, of an attached deepwater wave, its wavelength λ, and the ship speed U are related by

$$c = \sqrt{\frac{g}{k}} = \sqrt{\frac{g\lambda}{2\pi}} = U , \tag{7.46}$$

where g is the acceleration of gravity and $k \equiv 2\pi/\lambda$ is the wavenumber. Here, we are considering the *transverse waves* (the wave fronts are perpendicular to the path of the ship), rather than divergent waves (the wave fronts lie at angles of about 19°28′ to the ship's trajectory) (Fig. 7.25).

Interference of the transverse waves generated at the bow and stern affects hull resistance. When the wave crests from the bow and the wave crests from the stern coincide, they constructively interfere to generate large waves which radiate away more energy and increase drag. If the bow wave crests coincide with the troughs in the stern waves, they destructively interfere creating attenuated waves and the drag is decreased. See (7.3), which gives 2-D wave energy/length across crest.

$$E = \frac{\rho g \lambda H^2}{8} \tag{7.47}$$

As can be seen in Fig. 7.26, when there are an integer number of wave crests spanning the hull $L_{\mathrm{WL}}/\lambda =$

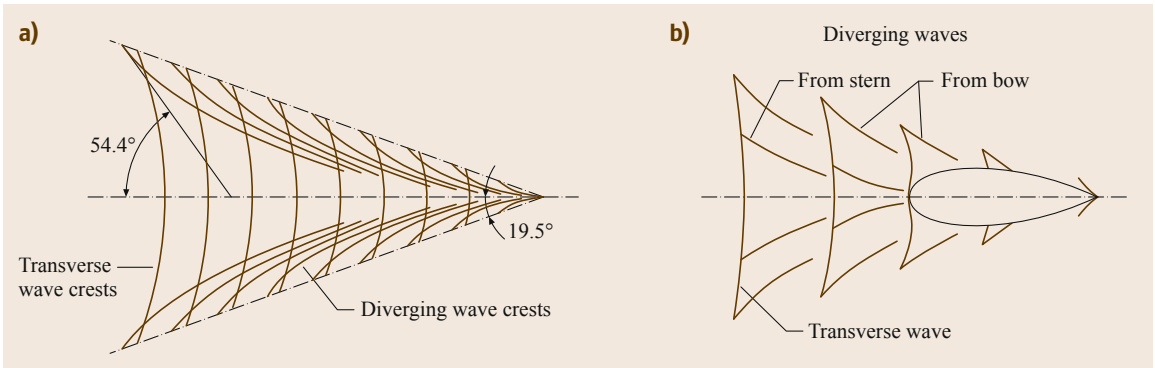

Fig. 7.25 **(a)** Far-field Kevin wave pattern; **(b)** Local bow and stern wave systems (after [7.30])

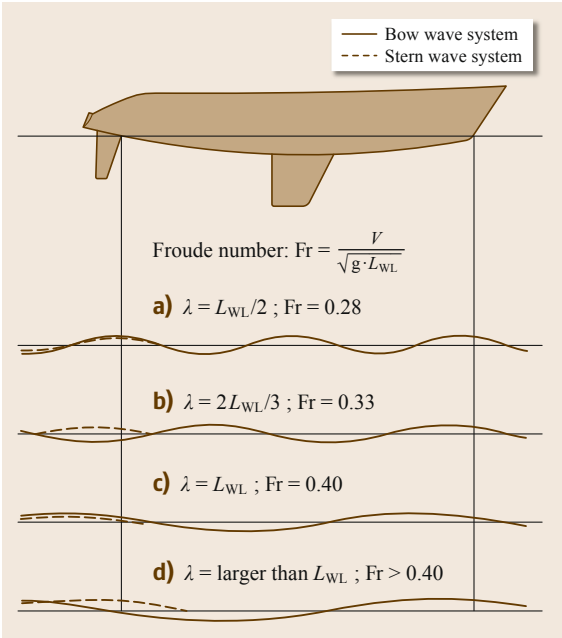

Fig. 7.26 Interference between bow and stern waves (after [7.11])

$\{1, 2, 3, \ldots\}$, constructive interference occurs; when there are an odd number of $\frac{1}{2}$ wavelengths $L_{WL}/\lambda = \{0.5, 1.5, 2.5, 3.5, \ldots\}$, the wave system behind the ship is attenuated. From (7.45)

$$U = \sqrt{\frac{g\lambda}{2\pi}} = \sqrt{\frac{gL_{WL}}{2\pi}}\sqrt{\frac{\lambda}{L_{WL}}},$$

solving for the Froude number gives

$$\mathrm{Fr} = \frac{U}{\sqrt{gL_{WL}}} = \sqrt{\frac{\lambda}{2\pi L_{WL}}}.$$

Thus, we can see that when $\mathrm{Fr} = 0.28$ and 0.4, the waves behind the ship are amplified and for $\mathrm{Fr} = 0.33$, the waves are attenuated. The corresponding effects on hull resistance are manifested as humps and hollows in the wave-resistance curve (Fig. 7.27).

When $\lambda = L_{WL}$, $\mathrm{Fr} = 0.4 \approx 1/\sqrt{2\pi}$ there are wave crests (high pressure) at both the bow and stern of the ship and a trough (low pressure) amidships. This condition corresponds to the *hull speed* of the vessel and, as explained in more detail below, gives $U_{\mathrm{hull}} = 0.4\sqrt{gL_{WL}}$ as the speed limit above which it is usually impractical to run a displacement hull vessel. When the Froude number is much higher than this, there is only a wave crest at the bow (with high pressure) and the ship is constantly *climbing a hill of water*. Ships that travel at $\mathrm{Fr} > 0.4$ are generally considered *high speed*.

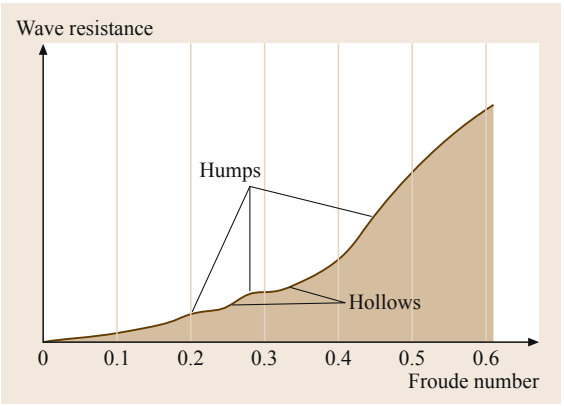

Fig. 7.27 Humps and hollows on the wave-resistance curve (after [7.11])

Fig. 7.28 RORO ferry (courtesy of J.H. Kantor)

It may be noted that:

- Another important hydrodynamic effect associated with high Fr is the generation of negative pressures along convex surfaces of the hull – these pressures have a tendency to draw a ship down into the water (squatting).
- In the design of high-speed ships, special consideration must be given to the structural weight of the ship, propeller cavitation/ventilation, seakeep-

Fig. 7.29 An ultra large crude carrier (ULCC)

ing at speed, and the effects of the wave wash created [7.3].

Basic Hull Forms. The Froude number determines the hull type (adapted from [7.29]):

1. Displacement hulls:
   $Fr \leq 0.4$ Hydrostatic buoyancy completely dominates. Examples of this type of ship include cruise ships, common carriers (bulk transports, cargo ships, reefers), roll on roll off (RORO) ships, fishing trawlers, tankers, and submarines (Figs. 7.28 and 7.29).
   The main geometric characteristics of displacement vessels (Fig. 7.30) are sharp, fine bows, midsections that are convex in both the longitudinal and transverse directions, and narrow stern sections.
   Displacement vessels are designed to operate in the narrow range of $0.3 \leq Fr < 0.4$ and are almost entirely supported by hydrostatic buoyancy forces. At their design speeds, the convex shape of their midsections prevent flow separation. When operated at higher Froude numbers ($Fr > 0.4$), their sterns tend to get drawn down into the water so that the aft part of the deck starts to become submerged, the bow starts to pitch upward, and the transverse flow along the sides clings to the hull so that it generates a sheet of spray.
2. Semidisplacement (also called semiplaning):
   $0.4 - 0.5 \leq Fr \leq 1.0 - 1.2$ both hydrostatic and hydrodynamic forces are important.
   A typical line drawing for a semidisplacement hull is shown in Fig. 7.31. These hullforms are characterized by water entry lines that are fine, a sharp wide transom that is partially submerged and straight, vee-formed transverse cross-sections near the bow. Small waterplane area (SWA) vessels, catamarans (two hulls) and trimarans (three hulls) are examples of typical semidisplacement hullforms (Figs. 7.32 and 7.33)
   Semidisplacement hulls are designed to avoid the squatting and trim angles observed in displacement hulls when $Fr \geq 0.4$. In contrast to displacement hulls, the aft part of a semidisplacement hull is almost flat and horizontal so that it terminates a sharp, submerged transom at the stern. At operational speeds, the flow separates from the transom so that

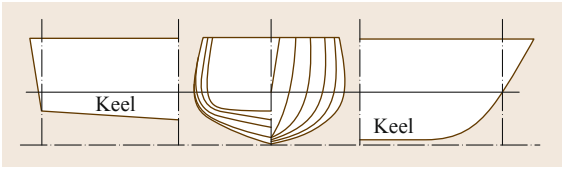

Fig. 7.31 Typical lines drawing for a semidisplacement catamarcan hull (after [7.29])

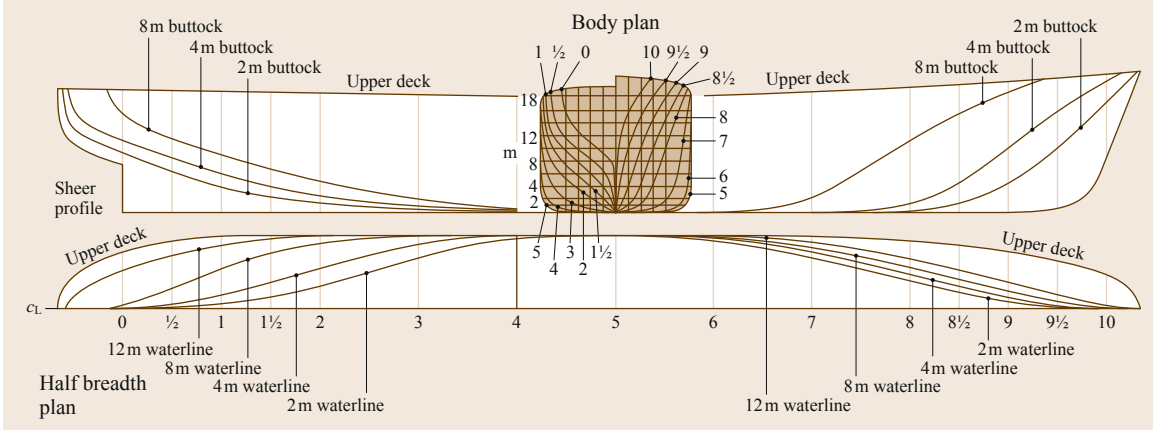

Fig. 7.30 Typical displacement hull lines drawing (after [7.31])

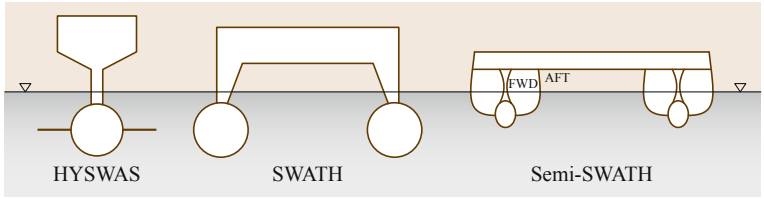

Fig. 7.32 SWATH concept – HYSWAS (hydrofoil SWA ship); SWATH (SWA twin hull) (after [7.32])

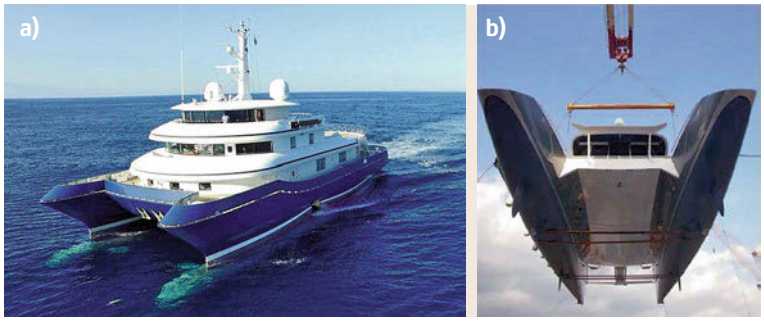

Fig. 7.33 **(a)** SWATH hull form (courtesy of Yacht Silver Cloud); **(b)** Catamaran hull form (viewed from stern)

it is ventilated and exposed to the atmosphere. With this geometry, positive dynamic pressure forces are generated in the flow at the stern, which reduce the squatting and large pitch angles seen in displacement vessels at higher Froude numbers.

3. Planing hulls:
   $1.0 - 1.2 \leq \mathrm{Fr}$ mainly hydrodynamically generated forces carry the weight of the vessel. At speed, the boat starts to ride up and over the crest of its own bow wave. A lower fraction of the hull is submerged decreasing its wetted surface area and frictional resistance. Examples of planing hull vessels include: rigid hull inflatable boats (RHIBs), sometimes simply called rigid inflatable boats (RIBs), recreational power and fishing boats, and police patrol boats (Fig. 7.34).

A lines drawing for a planing hull is shown in Fig. 7.35. The principal geometric features of planing hulls are:

- The avoidance of convex surfaces (except for the bow which is out of the water at planing speeds) to limit the development of bottom suction pressures
- Sharp-edged chines at the intersection of the bottom and sides to promote the separation of flow from the hull
- A deeply submerged wide transom that is ventilated to the atmosphere
- To reduce wave impacts, V-bottomed transverse sections with a sharp bow.

At low Froude numbers (below Fr of about 1.0–1.2 pre-planing speeds), the planing hull has more resistance than displacement or semidisplacement hulls because of the sharp chines and wide, submerged transom, which promote flow separation and increase the form drag component of the hull. The performance of a planing hull is very dependent upon the longitudinal location of the center-of-gravity, which affects the trim angle of the craft when planning and in turn influences the resistance/weight ratio. Typically, the resistance of planing hulls is reduced for trim angles of about 3–4°.

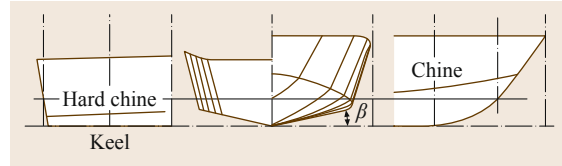

Fig. 7.35 Typical lines drawing for a hard chine planning hull (after [7.29])

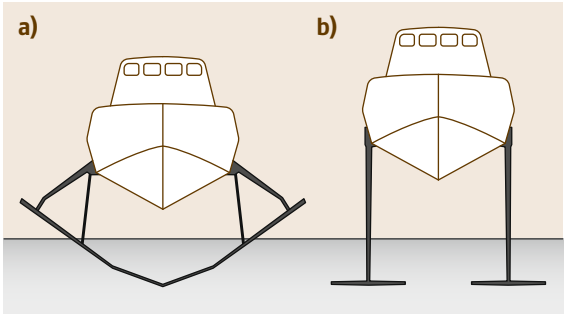

Fig. 7.36 **(a)** Surface piercing hydrofoil; **(b)** fully submerged hydrofoils (after [7.33])

Fig. 7.37 Vessel with fully submerged foils (courtesy of Sottome Jacaranda Lilan)

Transom interceptors can be used to adjust the trim angle and reduce resistance when a planing vessel is operating at design speeds [7.3].

Hydrofoil Vessels. Hydrofoil-supported vessels are a special class of vehicles that operate in the hydrodynamic pressure regime. However, they differ from conventional ships in that when they are at operating speed, the lifting function is taken away from the hull by a set of *underwater wings*. At speed, the main advantages of this approach are that the vehicle experiences lower wave drag, lower frictional drag, and the shocks caused by wave impacts are reduced. Disadvantages include a more complex propulsion drive train, a more complex attitude (trim and roll) control system, and a deeper low speed (off foil) draft. These vessels are typically operated at speeds where careful foil cross section design is required to handle cavitation and ventilation effects on the foils.

Hydrofoil vessels are typically characterized by the configuration of the foils as either surface piercing or fully submerged (Figs. 7.36 –7.38).

Fig. 7.38 A vessel with surface-piercing hydrofoils (courtesy of Martin Gimm)

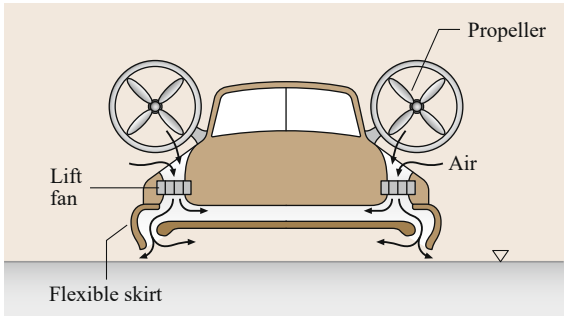

Fig. 7.39 ACV design

Fig. 7.40 ACV (photo public domain)

Aerostatic Support

Vehicles operating in the aerostatic regime use a lift fan to pressurize the air in a plenum chamber that lies below deck. Generally, the lower surface of the plenum is the free surface of the water and either the underside of the deck itself or a horizontal plate is the upper surface. When flexible skirts surround the front, back, and sides of the ship, it is known as an air cushion vehicle (ACV) or hovercraft (Figs. 7.39 and 7.40).

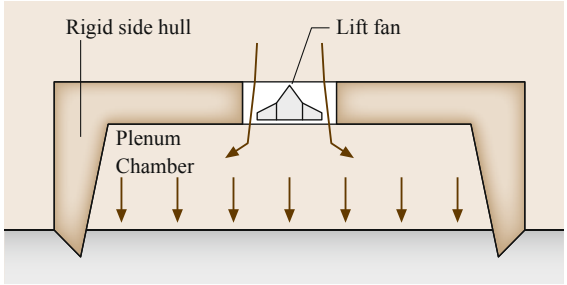

Fig. 7.41 CAB vehicle design (after [7.32])

Fig. 7.42 CAB (photo by Mark Harkin)

ACVs can rise completely above the water surface on a cushion of air and can operate amphibiously. When the front and back of a catamaran are enclosed using flexible skirts to create a plenum chamber, the vehicle is known as a captured air bubble (CAB) vehicle (Figs. 7.41 and 7.42). Since part of the weight of a CAB is supported by the cat hulls, this type of vehicle is not amphibious. Advantages of using ACV and CAB vessels are reduced wave and frictional drag (air resistance is lower than water resistance); disadvantages include poor tracking (primarily ACVs) and maintenance issues related to the use of flexible skirts and seals. Turbofans are often used to propel ACVs, while CABs are usually propelled by waterjets or surface-piercing propellers.

Aerodynamic Support

When a wing is operated near the ground (or alternatively the free surface of a lake/sea), less than about $\frac{1}{2}$

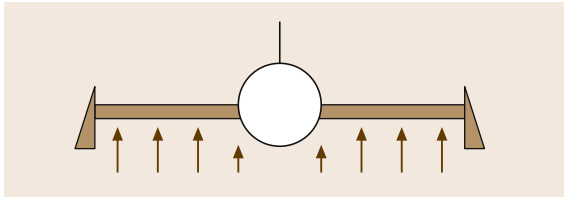

Fig. 7.43 Wing in ground-effect (WIG) concept (after [7.32])

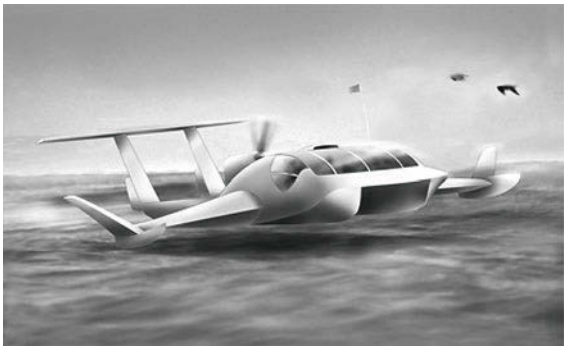

Fig. 7.44 Artist's impression of a WIG. An air-cushion effect is generated between the floats during takeoff (artist: Bjarne Stenberg; after [7.3], reproduced with permission)

a wingspan away, the lift coefficient of the wing increases and the drag due to lift is substantially reduced. A *cushion of air* is essentially trapped under the wing, which increases lift and reduces the downwash angle of the flow behind the wing (Fig. 7.43). Flying vehicles that utilize this *ground effect* can be designed with smaller wings and higher power-to-weight ratios than conventional aircraft. Vehicles of this sort are generally referred to as wing-in-ground effect (WIG) vehicles or ground effect vehicles (GEVs). The concept works best for very large vehicles since the height required to clear waves is a smaller percentage of the wingspan – most fly about 1/20-th of a wingspan above the water's surface (Fig. 7.44). Many early WIGs utilized flying boat hulls, which are quite heavy and have a substantial amount of drag. Some vehicles use extra turbofans or turbojets, which are mounted fore of the wings with their exhausts pointed downward, to provide added lift by increasing the pressure beneath the wings (power augmented ram – PAR).

7.2 Fluid Statics

In a solid, shear stress is directly proportional to shear strain. In a fluid flow viscous shear (tangential) stresses are directly proportional to the rate of change of shear strain with time. When a fluid is at rest, there are no tangential stresses and the only force between adjacent fluid surfaces is normal to the surface. In static equilibrium, the surface force per unit area (pressure) at a point is equal in all directions. However, owing to the density of a fluid, a pressure gradient exists. If we assume that gravity is acting in the $-z$ direction, the magnitude of the pressure gradient is

$$\frac{\mathrm{d}p}{\mathrm{d}z} = -\rho \mathrm{g} \,.$$

Here, ρ is the fluid density. A typical value of ρ for seawater is $\rho = 1025.9\,\mathrm{kg\,m^{-3}}$. The pressure gradient can be integrated to give

$$p = p_0 - \rho \mathrm{g} z \,,$$

where p_0 is the pressure at $z = 0$. Thus, when density and gravity can be taken as constant, we see that the pressure varies linearly with depth. When $z = 0$ is taken as the vertical location of a free surface of a body of water, such as the sea, the local pressure can be taken as atmospheric p_{atm}. A typical value of atmospheric pressure is $p_{\mathrm{atm}} = 101\,325\,\mathrm{Pa} = 1.013\,\mathrm{bar}$. Sometimes pressure is reported as *gauge pressure* p_{gauge}, which is the absolute pressure p, measured with respect to atmospheric pressure

$$p_{\mathrm{gauge}} = p - p_{\mathrm{atm}} \,.$$

7.2.1 Pressure Forces on Surfaces

Forces on a Horizontal Planar Surface

Examine the forces on a floating ship (Fig. 7.45). Take the ship to be wall-sided, such that its sides are vertical and perpendicular to the water surface.

The waterplane area A_{w} is the cross-sectional area representing the intersection of the still waterline (water surface with no waves present) and the vessels hull.

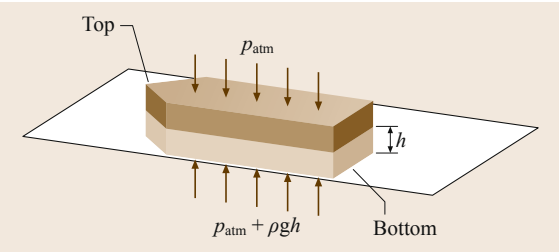

Fig. 7.45 Hydrostatic pressure on a wall-sided ship

As the pressure on the sides of the vessel is normal to the vertical axis, the buoyancy force F_{z} can be determined by integration of the pressure forces across the top and bottom surfaces. The bottom of the hull is taken to rest at a depth (draft) h below the surface (the small hydrostatic variation of air pressure is neglected).

$$\begin{aligned} F_{\mathrm{z}} = \int p \mathrm{d}A &= -\int_{\mathrm{top}} p_{\mathrm{atm}} \mathrm{d}A \\ &\quad + \int_{\mathrm{bottom}} (p_{\mathrm{atm}} + \rho g h) \mathrm{d}A \\ &= \rho g h A_{\mathrm{w}} \end{aligned}$$

We see that F_{z} is equivalent to the weight of the water displaced by the submerged volume of the hull, $\rho g h A_{\mathrm{w}}$. Note that here we used an example with a wall-sided ship that allowed us to forgo integration of the pressure forces on the sides of the hull. However, the result that the buoyancy force is equivalent to the weight of the water displaced by the submerged volume of a floating object generally holds because lateral forces will cancel due to symmetry (Archimedes' principle) [7.34].

Note that a floating object, such as a ship or boat, will trim (pivot) about its center of flotation (which is the centroid of the waterplane area) when weight is redistributed [7.35]. The center of flotation should not be confused with the center of buoyancy, which is the centroid of the submerged hull volume. The resultant buoyancy force acts vertically through the center of buoyancy and is in force and moment equilibrium with the total weight, which acts through the center of gravity.

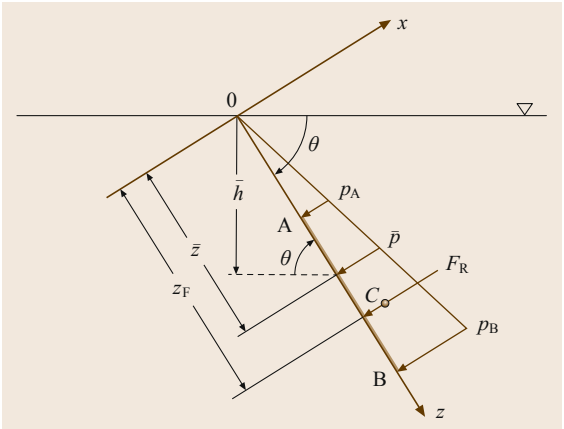

Fig. 7.46 Force on an inclined surface

Forces on an Inclined Planar Surface

Force Magnitude. Examine a submerged object with a planar surface oriented at an angle to the horizontal (Fig. 7.46).

Determine the force acting normal to a portion of the submerged surface spanning two points A and B, as shown

$$F_R = \int_A^B p\,dA = \rho g \int_A^B h\,dA\,,$$

where $h = z\sin\theta$. Then

$$F_R = \rho g \sin\theta \int_A^B z\,dA$$
$$= \rho g \sin\theta \frac{\int_A^B z\,dA}{\int_A^B dA} A = \rho g \bar{z} \sin\theta A\,.$$

Here $\bar{z}$ is the position of the area centroid, which is related to the depth of the area centroid as $\bar{h} = \bar{z}\sin\theta$ so that

$$F_R = \rho g \bar{h} A = \bar{p} A\,,$$

where $\bar{p}$ is the pressure at the area centroid. The point of the resultant force application is

$$z_F F_R = \int_A^B pz\,dA = \int_A^B \rho g h z\,dA = \int_A^B \rho g h z^2 \sin\theta\,dA$$
$$= \rho g \sin\theta \int_A^B z^2\,dA = \rho g \sin\theta I_0\,,$$

where I_0 is the area moment of inertia about the intersection between the submerged body and the water surface. Using the parallel axis theorem, I_0 can be rewritten in terms of the area moment of inertia of the submerged area about its own centroid $I_0 = I_C + \bar{z}^2 A$. Then

$$z_F F_R = \rho g \sin\theta (I_C + \bar{z}^2 A)\,,$$

and using the solution for the resultant force above, we get

$$z_F = \frac{I_C + \bar{z}^2 A}{\bar{z} A} = \bar{z} + \frac{I_C}{\bar{z} A}\,.$$

Thus, the resultant force acts below the centroid for an inclined plate.

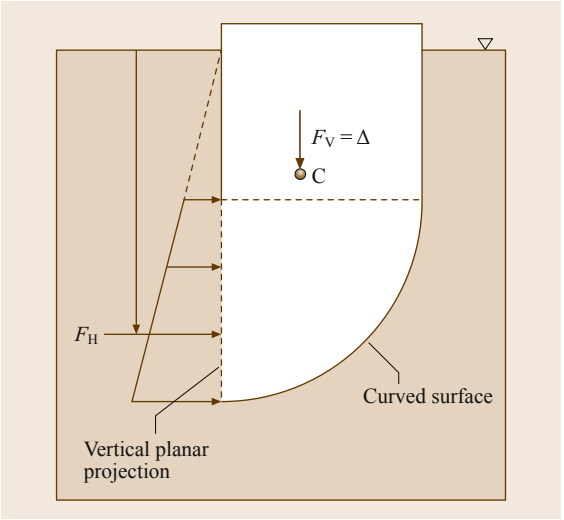

Fig. 7.47 Forces on a curved surface

Forces on Curved Surfaces

Examine the hydrostatic forces on the curved surface in Fig. 7.47. The pressure always acts normal to the surface – to find the resultant force, we can split it into a horizontal and a vertical component. The horizontal component F_H will have the same magnitude and point of application h_F as a force on the projected horizontal vertical surface. The vertical component F_V acts through the volume centroid C and corresponds to the weight of the water above the curved surface.

7.2.2 Static Stability

A floating object is considered to be hydrostatically stable when it returns to its initial state of static equilibrium when disturbed by an unbalanced force or moment. Generally, the attitude of a floating body is determined by the relative location of its center of gravity with respect to its center of buoyancy. At static equilibrium, the center of buoyancy and gravity are collinear and aligned with the vertical. Some floating objects, such as spar buoys [7.34], are designed so that their center of gravity lies below their center of buoyancy and are stable for small angular displacements. Other floating systems, such as ships are designed such that their center of gravity lies above their center of buoyancy – they are stable for small angular displacements as their hullforms are typically designed so that the center of buoyancy shifts laterally providing a restoring moment.

Consider the hull of a ship, as shown in Fig. 7.48. When an external torque is applied about its longitudinal axis it will heel to an angle ϕ as shown in Fig. 7.48a. If the ship is hydrodynamically stable the center of buoyancy will shift laterally from the point B to the

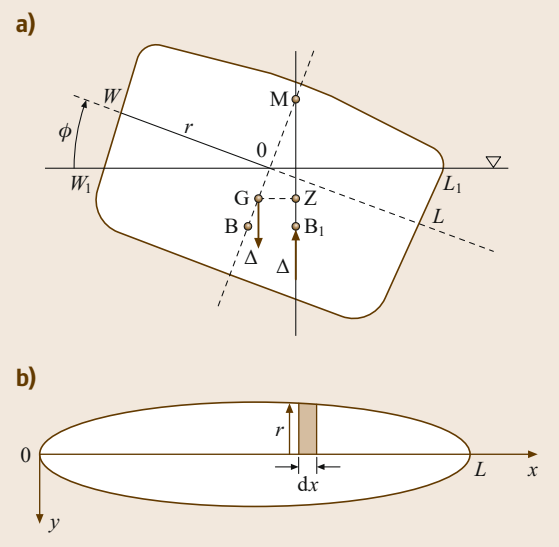

Fig. 7.48a,b Geometry for the inclined stability of a ship; **(a)** view from bow; **(b)** top view

point B_1 to provide a righting moment given by

$$RM = \Delta\overline{GZ} = \Delta\overline{GM}\sin\phi\,. \tag{7.48}$$

Here Δ is the weight (displacement) of the vessel, $\overline{GZ}$ is the righting arm and the line segment $\overline{GM}$ is the metacentric height. $\overline{GM}$ is the distance between the location of the center of gravity of the vessel G and the instantaneous metacenter M, which is the point of intersection between the vertical axis of the ship (when upright) and the line of action of gravity (when heeled).

If the ship is loaded such that M is above G, the moment will tend to right the body (positive righting moment). If M is below G, $\overline{GM} < 0$ and the body will capsize.

When an external torque is applied, perhaps through the action of wind across a deck or the placement of a weight on board, the vessel will heel. When heeled, the vessel will gain buoyancy from the newly immersed portion of the hull LOL_1, but it will also lose buoyancy owing to part of the hull which emerges from the water WOW_1. The emerged and immersed volumes will be identical for a laterally symmetric hullform. Let r be the half breadth (width) of the ship and dx be a differential element of length along the longitudinal axis of the vessel (Fig. 7.48b). The volume moment of the immersed wedge LOL_1 is given by the integral

$$\int_0^L \frac{1}{2}r(r\phi)\frac{2}{3}r\mathrm{d}x\,,$$

where L is the length of the ship. As volume moment of the emerged wedge is the same, the total volume moment of the ship when heeled is given by

$$\frac{2}{3}\int_0^L r^3\phi\mathrm{d}x\,,$$

which is $I\phi$, the product of the area moment of inertia of the waterplane about the longitudinal axis of the ship I and the heel angle ϕ. This is equivalent to the volume moment arising from the shift in the center of buoyancy, which is given by $\Delta\overline{BB_1}$, where from geometry we see that $\nabla\overline{BM}\sin\phi$, where ∇ is the volumetric displacement of the submerged hull. For small angles, $\sin\phi \approx \phi$ such that

$$\nabla\overline{BM}\phi \approx I\phi\,.$$

Often the stability of a ship or vessel is examined in terms of its initial stability, when disturbances cause small changes in ϕ. In practice, ϕ is typically taken to be less than $7{-}10^\circ$ [7.35]. Solving for $\overline{BM}$ gives

$$\overline{BM} = \frac{I}{\nabla}\,. \tag{7.49}$$

The metacentric height can then be determined from the relation

$$\overline{GM} = \overline{BM} - \overline{BG}\,, \tag{7.50}$$

where $\overline{BG}$ is determined from the geometry of the underwater hull and the known location of the center of gravity of the vessel.

7.3 Hydrodynamics

7.3.1 Flow Kinematics

Any vector field can be decomposed into a purely solenoidal (expanding/contracting) part and a rotational part. Thus, we can generally write the velocity vector as the sum of two fields. For example, in two-dimensional x–y Cartesian components we have

$$\boldsymbol{u} = \nabla\times(\psi\hat{k}) + \nabla\phi\,, \tag{7.51}$$

where ψ is the stream function, $\hat{k}$ is the unit vector perpendicular to the x–y plane, and ϕ is a scalar ve-

locity potential. It can be shown that $\nabla\cdot[\nabla\times(\psi\hat{k})]=0$ and so $\nabla\times(\psi\hat{k})$ gives the part of $\boldsymbol{u}$ with no contraction/expansion. Since $\nabla\times(\nabla\phi)=0$, $\nabla\phi$ is the part of $\boldsymbol{u}$ with no rotation. For an incompressible flow, $\nabla\cdot\boldsymbol{u}=\nabla^2\phi=0$ and for an irrotational flow $\nabla\times\boldsymbol{u}=\nabla\times[\nabla\times(\psi\hat{k})]=\nabla^2\psi=0$. Thus, for a two-dimensional incompressible, irrotational flow, both the velocity potential and stream function satisfy Laplace's equation.

7.3.2 The Navier–Stokes Equations

Material Derivative

The material derivative, sometimes also referred to as the either *total derivative* or the *substantial derivative*, is a differential operator that gives the total time rate of change of a quantity as that quantity moves through a flow field. There are essentially two contributions to the time rate of change. The first is the unsteady, time-dependent change in the quantity over time, which would happen even if the quantity were not moving with the flow. The second contribution is the change in the quantity as it moves through the flow. This second part is sometimes referred to as either the convective rate of change or the advective rate of change. For three-dimensional Cartesian coordinates, the total derivative can effectively be written as

$$\mathrm{d}f=\frac{\partial f}{\partial t}\mathrm{d}t+\frac{\partial f}{\partial x}\mathrm{d}x+\frac{\partial f}{\partial y}\mathrm{d}y+\frac{\partial f}{\partial z}\mathrm{d}z\,.$$

Taking the total derivative with respect to time gives

$$\frac{\mathrm{d}f}{\mathrm{d}t}=\frac{\partial f}{\partial t}+\frac{\partial f}{\partial x}\frac{\mathrm{d}x}{\mathrm{d}t}+\frac{\partial f}{\partial y}\frac{\mathrm{d}y}{\mathrm{d}t}+\frac{\partial f}{\partial z}\frac{\mathrm{d}z}{\mathrm{d}t}\,,$$

which can be written compactly as

$$\frac{\mathrm{d}f}{\mathrm{d}t}=\underbrace{\frac{\partial f}{\partial t}}_{\substack{\text{unsteady, local}\\ \text{rate of change}}}+\underbrace{\boldsymbol{u}\cdot\nabla f}_{\substack{\text{rate of change}\\ \text{due to convection}}}\,, \tag{7.52}$$

where the gradient operator in three-dimensional Cartesian coordinates is

$$\nabla(\,)=\frac{\partial(\,)}{\partial x}\hat{i}+\frac{\partial(\,)}{\partial y}\hat{j}+\frac{\partial(\,)}{\partial z}\hat{k}\,,$$

and the velocity is

$$\boldsymbol{u}=\frac{\mathrm{d}x}{\mathrm{d}t}\hat{i}+\frac{\mathrm{d}y}{\mathrm{d}t}\hat{j}+\frac{\mathrm{d}z}{\mathrm{d}t}\hat{k}\,.$$

Example 7.7

In a river with a velocity field $\boldsymbol{v}(\boldsymbol{x},t)$ with respect to the ground, the temperature is given by the function $f(\boldsymbol{x},t)$. A small boat is in the river and has a velocity $\boldsymbol{U}(t)$ with respect to the ground:

1. Give the time rate of change of f experienced by the boat when forced to move at the velocity $\boldsymbol{U}$

$$\frac{\mathrm{d}f}{\mathrm{d}t}=\frac{\partial f}{\partial t}+\boldsymbol{U}\cdot\nabla f\,.$$

2. If the engine is turned off and the vessel freely drifts with the surrounding current, give the time rate of change of f experienced by the boat

$$\frac{\mathrm{d}f}{\mathrm{d}t}=\frac{\partial f}{\partial t}+\boldsymbol{v}\cdot\nabla f\,.$$

3. The boat is anchored. Give the time rate of change of f experienced by the vessel

$$\frac{\mathrm{d}f}{\mathrm{d}t}=\frac{\partial f}{\partial t}\,.$$

Conservation of Mass

The integral form of conservation of mass for a fluid volume V enclosed by surface S is

$$\underbrace{\frac{\partial}{\partial t}\int_V\rho\mathrm{d}V}_{\substack{\text{rate of change}\\ \text{of mass in } V}}=\underbrace{-\int_S\rho\boldsymbol{u}\cdot\mathrm{d}\boldsymbol{S}}_{\substack{\text{flux of mass}\\ \text{across surface of } V}}\,. \tag{7.53}$$

This is a mathematical statement that the time rate of change of mass within V is equal to the net flux of mass into or out of V, which is enclosed by the surface S (Fig. 7.49). The differential form obtained through the application of Gauss' theorem (divergence theorem) to the integral above is

$$\frac{\partial\rho}{\partial t}+\nabla\cdot(\rho\boldsymbol{u})=\frac{\mathrm{d}\rho}{\mathrm{d}t}+\rho\nabla\cdot\boldsymbol{u}=0\,. \tag{7.54}$$

For a flow of constant density, this reduces to

$$\nabla\cdot\boldsymbol{u}=0\,. \tag{7.55}$$

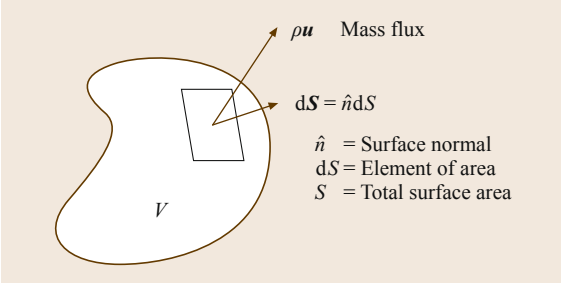

Fig. 7.49 Fluid volume V for formulation of mass conservation

Conservation of Momentum

This is basically a statement of Newton's second law in a fluid flow. Mass per unit volume multiplied by fluid acceleration (the material derivative of the velocity) is the sum of applied forces. In an incompressible fluid, the applied forces can consist of viscous shear and pressure acting at the surface of a fluid element, or body forces acting on the volume of the fluid element, giving

$$\underbrace{\rho\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t}}_{\text{mass}\times\text{acceleration}} = \underbrace{\underbrace{-\nabla p+\mu\nabla^2\boldsymbol{u}}_{\text{pressure and viscous forces}}+\underbrace{\rho\boldsymbol{g}}_{\text{body forces}}}_{\text{applied external forces}} . \tag{7.56}$$

The integral form of conservation of momentum in the volume V (Fig. 7.50) can be written as

$$\underbrace{\frac{\partial}{\partial t}\int\limits_V \rho\boldsymbol{u}\mathrm{d}V}_{\text{time rate of change of momentum in V}} + \underbrace{\int\limits_S \rho\boldsymbol{u}(\boldsymbol{u}\cdot\mathrm{d}\boldsymbol{S})}_{\text{flux of momentum into or out of V}}$$
$$= \underbrace{\underbrace{\int\limits_V \rho\boldsymbol{g}\mathrm{d}V}_{\text{body forces}} + \underbrace{\int\limits_S \boldsymbol{\tau}\cdot\mathrm{d}\boldsymbol{S}}_{\text{pressure and viscous stress terms}}}_{\text{applied external forces}} , \tag{7.57}$$

where $\boldsymbol{\tau}$ is the second-order stress tensor

$$\boldsymbol{\tau} \equiv p\mathbf{I}+\mu[\nabla\boldsymbol{u}+(\nabla\boldsymbol{u})^{\mathrm{T}}] , \tag{7.58}$$

$\mathbf{I}$ is the identity matrix, T denotes the transpose, and $\nabla\boldsymbol{u}$ is the gradient of the velocity vector (also a second-order tensor).

The integral form of the conservation laws is generally used when one is trying to determine the effect of a volume of flow. The differential forms are used when trying to determine the distribution of quantities, such as velocity or pressure within a flow.

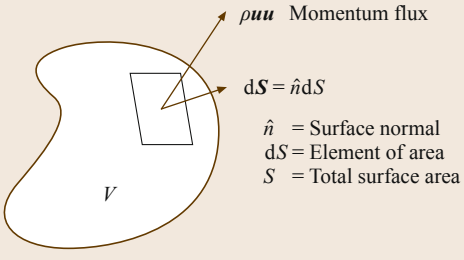

Fig. 7.50 Fluid volume V for formulation of momentum conservation

Example 7.8

An experimental underwater magnetohydrodynamic drive unit is being developed (Fig. 7.51). The drive consists of a long, deep, and narrow channel with magnets mounted in the channel walls. Actuation of the magnets drives seawater through the channel with a body force per unit mass of $\boldsymbol{f}$. Assume that $\boldsymbol{f}$ is constant throughout the channel. Find the velocity profile of the flow in the channel.

Solution 7.7

Let $\boldsymbol{f} = f\hat{i}$. For constant f (in time) the flow is steady. As the channel is long and deep, we can assume that $w = 0$ and $\partial u/\partial x = 0$. Since both ends of the channel are open to the surrounding seawater, we can also assume that there is no pressure gradient in the x direction. Apply the no slip condition on the top and bottom walls (Fig. 7.52).

- Continuity:

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0\rightarrow\frac{\partial v}{\partial y}=0\rightarrow v = \text{constant} = 0 .$$

- X-momentum:

$$\rho\left(\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}\right) = -\frac{\partial p}{\partial x}+\rho f+\mu\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right)$$
$$\rightarrow \frac{\partial^2 u}{\partial y^2} = -\frac{f}{\nu} .$$

Integrating twice with respect to y gives

$$u = -\frac{f}{2\nu}y^2+c_0 y+c_1 .$$

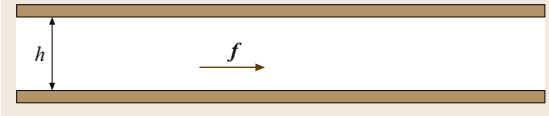

Fig. 7.51 Channel of the magnetohydrodynamic drive unit

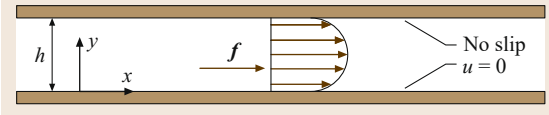

Fig. 7.52 Velocity profile in the magnetohydrodynamic drive unit

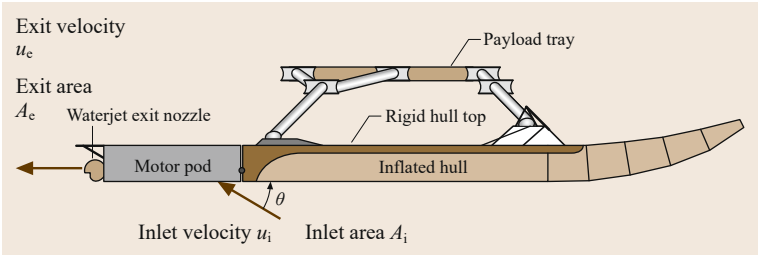

Fig. 7.53 A water-jet propelled catamaran (courtesy of Marine Advanced Research of Berkeley, USA)

Applying the boundary condition for u at $y = 0$ we get $c_1 = 0$ and using the boundary condition at $y = h$ gives $c_0 = fh/(2\nu)$. Thus, we find

$$\boxed{u = \frac{fy}{2\nu}(h - y)\,.}$$

Example 7.9

The thrust developed to propel the catamaran (twin hull boat) shown below is a result of the water pumped through the vehicle and exiting as a high-speed water jet. For the conditions shown in Fig. 7.53, find an expression for the exit velocity required to produce a total thrust T if the catamaran is moving at a constant velocity? Assume the outlet jets of water are free jets, and that the inlet jet is at an angle θ, with respect to the horizontal.

Solution 7.8

From the momentum equation (steady inviscid flow) we have

$$\int_S (\rho \boldsymbol{u})\boldsymbol{u} \cdot \mathrm{d}\boldsymbol{S} = \boldsymbol{F}_{\mathrm{ext}}\,,$$

where $\boldsymbol{F}_{\mathrm{ext}}$ represents the external forces acting on the control volume (Fig. 7.54) including the reaction force of the thrust, the weight, buoyancy, and a vertical component of the incoming momentum. The balance of forces across the control volume in the x-direction gives

$$\frac{T}{2} = \rho u_e^2 A_e - \rho u_i^2 A_i \cos\theta\,.$$

The mass flow rate is $\dot{m} = \rho u_e A_e = \rho u_i A_i$. From the continuity equation we have $\int_S \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{S} = 0$ over the control surface, giving $u_e A_e = u_i A_i$. Substituting this into the equation for T, we can solve for the exit velocity

$$u_e = \sqrt{\frac{T}{2\rho A_e\left(1 - \frac{A_e}{A_i}\cos\theta\right)}}\,.$$

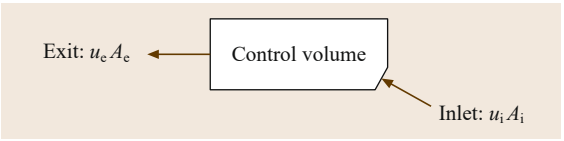

Fig. 7.54 Control volume for the waterjet

Special Forms of the N–S Equations

Rotating coordinate system [7.36]: In geophysical fluid applications positions and velocities are measured with respect to a reference frame (coordinate system) rotating with the Earth. The true acceleration, in an inertial reference frame, must account for the centripetal and Coriolis acceleration in the rotating reference frame

$$\rho\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t} = -\nabla p + \mu\nabla^2\boldsymbol{u} + \rho\left[\boldsymbol{g} + \underbrace{\boldsymbol{\Omega}\times\boldsymbol{\Omega}\times\boldsymbol{r}}_{\text{centripetal acceleration}} - \underbrace{2\boldsymbol{\Omega}\times\boldsymbol{u}}_{\text{Coriolis acceleration}}\right], \tag{7.59}$$

where $\boldsymbol{\Omega}$ is the angular velocity vector corresponding to the Earth's rotation, $\boldsymbol{r}$ is a position vector from the center of the Earth to a point on the surface where the acceleration is being calculated. The centripetal acceleration is largest at the equator and diminishes toward the North and South Poles. The Coriolis force tends to deflect the trajectory of a fluid particle to the right of its direction of travel in the northern hemisphere and to the left of its direction of travel in the south of the equator.

The Vortex Twisting and Tilting Equation (Vorticity Transport Equation). Under the Boussinesq approximations, which assumes that the fluid density is not a strong function of pressure (so that small changes in density are caused by small changes in temperature) and that the dynamic viscosity and thermal conductivity of the fluid are constant [7.36], the vorticity transport

equation can be written as

$$\underbrace{\frac{\mathrm{d}\boldsymbol{\omega}}{\mathrm{d}t}}_{\substack{\text{rate of change}\\ \text{of vorticity}}} = \underbrace{\boldsymbol{\omega}\cdot\nabla\boldsymbol{u}}_{1} + \underbrace{2\boldsymbol{\Omega}\cdot\nabla\boldsymbol{u}}_{2} + \underbrace{\frac{1}{\rho^2}\nabla\rho\times\nabla p}_{3} + \underbrace{\nu\nabla^2\boldsymbol{\omega}}_{4}. \tag{7.60}$$

Here:

1. This term is sometimes called the *twisting and tilting term* and gives the generation of vorticity from the stretching/compression of vortex lines, as well as, vorticity that is increased or decreased as vortex lines are tilted in a shear flow.
2. This term gives the change in vorticity that occurs as vortex lines are tilted into or away from the axis of rotation in a rotating coordinate system (as in a geostrophic flow).
3. This term gives the changes in vorticity arising from baroclinic torque (when $\nabla\rho$ and ∇p are not collinear). This term can arise, for example, when there is a disturbance along a therm in an ocean. The density gradient of the associated pycnocline can become misaligned with the pressure gradient caused by the hydrostatic pressure, causing an internal wave to propagate along the thermocline.
4. The last term is the rate of change of vorticity caused by viscous diffusion.

Euler's Equation.

$$\rho\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t} = -\nabla p + \rho\boldsymbol{g} \tag{7.61}$$

Bernoulli's Equation

Under certain assumptions, Bernoulli's equation relates quantities at different points in a flow. Representing the gravitational force as a conservative force in a Cartesian coordinate system such that its potential is $\Pi = gz$ and $\boldsymbol{g} = -\nabla\Pi$, the general form for a fluid of constant density is

$$\frac{\partial\boldsymbol{u}}{\partial t} + \nabla\left(\frac{\boldsymbol{u}^2}{2} + gz + \frac{p}{\rho}\right) = \boldsymbol{u}\times\boldsymbol{\omega}\,, \tag{7.62}$$

where $\boldsymbol{u}$ is the fluid velocity and $\boldsymbol{\omega}$ is the vorticity. Let

$$B = \left(\frac{\boldsymbol{u}^2}{2} + gz + \frac{p}{\rho}\right),$$

be the Bernoulli constant. Bernoulli's equation can be simplified for several different conditions:

1. For steady flow

$$\nabla\left(\frac{\boldsymbol{u}^2}{2} + gz + \frac{p}{\rho}\right) = \boldsymbol{u}\times\boldsymbol{\omega}\,.$$

The streamlines and vortex lines form surfaces. Changes in B are perpendicular to these surfaces.
2. For irrotational flows, $\boldsymbol{\omega} = 0$ and B is constant everywhere.

$$\left(\frac{\boldsymbol{u}^2}{2} + gz + \frac{p}{\rho}\right) = B = \text{constant}$$

3. If the flow is unsteady, but irrotational, such that the velocity can be represented as the gradient of a scalar potential $\boldsymbol{u} = \nabla\phi$, Bernoulli's equation reduces to

$$\frac{\partial\boldsymbol{u}}{\partial t} + \nabla B = \frac{\partial(\nabla\phi)}{\partial t} + \nabla B = \nabla\left(\frac{\partial\phi}{\partial t}\right) + \nabla B = \nabla\left(\frac{\partial\phi}{\partial t} + B\right) = 0\,.$$

As the gradient of the term in brackets above is zero, the term in brackets must either be a function of time or a constant. In general, we have

$$\frac{\partial\phi}{\partial t} + B = F(t)\,,$$

which is a form of the Bernoulli equation often used to solve problems in offshore wave mechanics [7.11].

7.3.3 Flow of an Ideal Fluid

As shown above, the vorticity transport equation (7.60) can be used to show that in a high Reynolds number flow (where viscosity becomes negligible) an initially irrotational flow will remain irrotational ($\mathrm{d}\boldsymbol{\omega}/\mathrm{d}t = 0$).

Assuming that there is no separation, any rotational flow around solid surfaces will be confined to thin boundary layers and wakes. For two-dimensional (or axisymmetric), inviscid, incompressible flow, potential flow theory is a good approximation to a real flow. Models of the flow around complex bodies can be built from adding (superposing) simple solutions for the stream function ψ and velocity potential ϕ.

As shown in Sect. 7.3.1, the stream function ensures conservation of mass

$$\nabla\cdot\boldsymbol{u} = \nabla\cdot[\nabla\times(\psi\hat{k})] = 0\,.$$

In two-dimensional Cartesian components, the velocity can be written as the curl of the stream function $\psi\hat{k}$

$$\boldsymbol{u} = u\hat{i} + v\hat{j} = \frac{\partial\psi}{\partial y}\hat{i} - \frac{\partial\psi}{\partial x}\hat{j} .$$

In two-dimensional polar coordinates, this is

$$\boldsymbol{u} = u_r\hat{r} + u_\theta\hat{\theta} = \frac{1}{r}\frac{\partial\psi}{\partial\theta}\hat{r} - \frac{\partial\psi}{\partial r}\hat{\theta} .$$

Likewise, the velocity potential ensures the irrotationality of the flow

$$\nabla\times\boldsymbol{u} = \nabla\times(\nabla\phi) = 0 .$$

In two-dimensional Cartesian components, the velocity can be written as the gradient of a scalar potential ϕ

$$\boldsymbol{u} = u\hat{i} + v\hat{j} = \frac{\partial\phi}{\partial x}\hat{i} + \frac{\partial\phi}{\partial y}\hat{j} .$$

In two-dimensional polar coordinates, this is

$$\boldsymbol{u} = u_r\hat{r} + u_\theta\hat{\theta} = \frac{\partial\phi}{\partial r}\hat{r} + \frac{1}{r}\frac{\partial\phi}{\partial\theta}\hat{\theta} .$$

For irrotational, incompressible flow, both the velocity potential and stream function satisfy Laplace's equation

$$\nabla^2\phi = 0$$

and

$$\nabla^2\psi = 0 ,$$

which is linear, such that solutions can be superposed

$$\nabla^2(\psi_1 + \psi_2) = \nabla^2\psi_1 + \nabla^2\psi_2$$

and

$$\nabla^2(\phi_1 + \phi_2) = \nabla^2\phi_1 + \nabla^2\phi_2 .$$

Solutions for ϕ and ψ can be superposed in the complex plane to find a complex velocity potential w, such that $w = \phi + \mathrm{i}\psi$, where $\mathrm{i} = \sqrt{-1}$ is the imaginary number and

$$\frac{\mathrm{d}w}{\mathrm{d}z} = u - \mathrm{i}v ,$$

gives the velocity component in two-dimensional Cartesian coordinates. Here, the complex coordinate $z = x + \mathrm{i}y = re^{\mathrm{i}\theta}$.

As Laplace's equation is second order, solutions generally require two boundary conditions in each of the independent variables (either x and y in Cartesian coordinates or r and θ in polar coordinates):

1. The velocity of the fluid at solid surfaces must match the velocity of the solid surface. Without loss of generality the problem can be formulated such that the coordinate system is in the reference frame of the surface, such that the velocity is zero. With $\hat{n}$ as a unit vector perpendicular to the surface and $\hat{s}$ as a unit vector tangent to the surface, we have

$$\frac{\partial\phi}{\partial n} = 0 \text{ and } \frac{\partial\psi}{\partial s} = 0 .$$

2. Far from the surface of the body, the velocity must approach its freestream value U, such that

$$\frac{\partial\phi}{\partial x} = U \text{ and } \frac{\partial\psi}{\partial y} = U .$$

The flow velocity can be found from solutions to Laplace's equation for the velocity potential and stream function. However, these solutions are based purely on the geometry of the flow (kinematic) and cannot be directly used to determine the forces acting on objects embedded in the flow. In order to solve for these fluidic forces, Bernoulli's equation must be used to determine the pressure around an object in the flow – by integrating the pressure around an object, one can then determine the fluidic forces acting on it.

The steady, irrotational, and incompressible form of Bernoulli's equation is often used to solve potential flow problems

$$\frac{\boldsymbol{u}^2}{2} + \mathrm{g}z + \frac{p}{\rho} = \frac{(\nabla\phi)^2}{2} + \mathrm{g}z + \frac{p}{\rho} = B , \qquad (7.63)$$

where B is constant everywhere in the flow field.

Catalog of Flow Fields

Complex flows around objects can be built from the superposition of very simple flows. Here, a reference list of some of the most basic flows is provided as a guide:

1. Simple flows:
   a) Uniform flow (Fig. 7.55)
      The velocity potential ϕ and stream function can be determined by quadrature $\partial\phi/\partial x = u = U$. We can integrate this with respect to x to find $\phi = Ux + f_1(y)$. Then, $v = \partial\phi/\partial y = \mathrm{d}f_1/\mathrm{d}y = 0$. Integrating with respect to y, we find that $f_1(y) = C$, where C is a constant. Without loss of generality we can let $C = 0$. Therefore, $\phi = Ux$ is the velocity potential for a uniform flow. Similarly, we can solve for the stream function by integrating the relation $\partial\psi/\partial y = u = U$ to

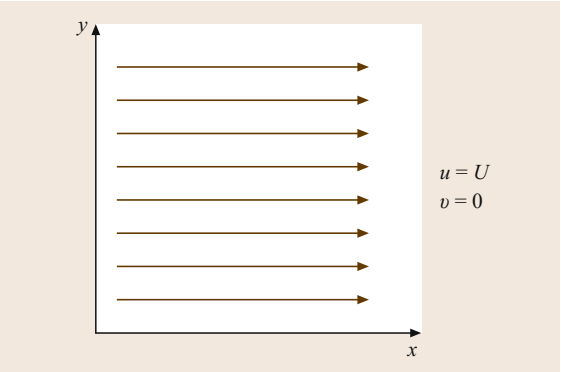

Fig. 7.55 Velocity in a uniform flow field

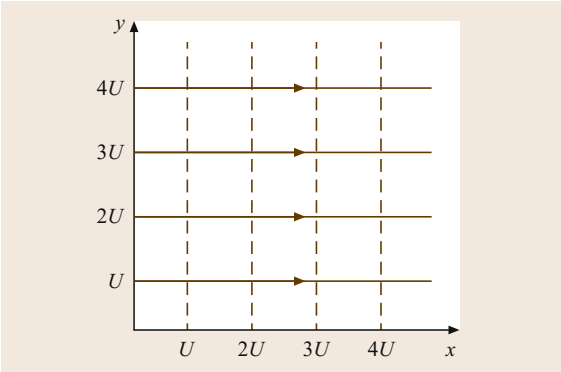

Fig. 7.56 Potential flow lines (*dashed lines*, ϕ) and streamlines (*continuous lines*, ψ) for uniform flow. The directions of the *arrows* on the streamlines are reversed when $U < 0$

get $\psi = Uy + f_2(x)$. Differentiating this expression with respect to x gives the y-component of the velocity $v = -\partial\psi/\partial x = -\mathrm{d}f_2/\mathrm{d}x = 0$. Again, upon integration we find that $f_2(y) = \mathrm{C}$ and without loss of generality we can let $C = 0$ so that $\psi = Uy$.

The complex velocity potential is then given by $w = \phi + \mathrm{i}\psi = Ux + \mathrm{i}Uy = Uz$. If we plot the velocity potential and stream function in the complex plane, we can see that they form straight lines (Fig. 7.56).

b) Source/sink flow (line source)

In this type of flow, fluid moves either radially outward (source) or inward (sink) only (Fig. 7.57). The radial velocity can be related to the strength of the source/sink through the volumetric flow rate per unit length in the out of plane direction $m = 2\pi r u_\mathrm{r}$, so that the radial velocity is given by

$$u_\mathrm{r} = \frac{m}{2\pi r} = \frac{\partial\phi}{\partial r} \,.$$

The tangential velocity is taken to be zero everywhere $u_\theta = 0$. As above, we can integrate to find the velocity potential. This operation will result in a constant of integration that can be determined by looking at the tangential velocity and again without loss of generality the constant of integration can be taken to be zero. The resulting velocity potential is found to be

$$\phi = \frac{m}{2\pi} \ln r \,.$$

The corresponding stream function and complex velocity potential can be shown to be

$$\psi = \frac{m\theta}{2\pi}$$

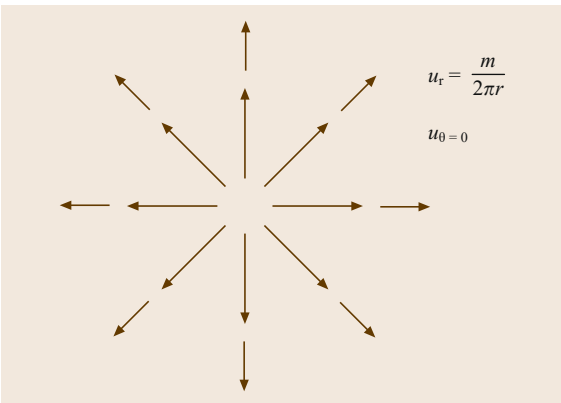

Fig. 7.57 Velocity profile in a source flow

and

$$\begin{aligned} w(z) &= \frac{m}{2\pi}(\ln r + i\theta) \\ &= \frac{m}{2\pi} \ln(r\mathrm{e}^{i\theta}) \\ &= \frac{m}{2\pi} \ln(z) \,. \end{aligned}$$

When $m > 0$, $u_\mathrm{r} > 0$ and the flow is a source flow. When $m < 0$, $u_\mathrm{r} < 0$ the flow is a sink flow. An examination of the velocity potential and stream function reveals that level curves of constant ψ (streamlines) are rays and level curves of constant ϕ are circles (Fig. 7.58).

c) Irrotational line vortex flow

The velocity field produced by a counterclockwise irrotational line vortex of circulation strength Γ (Fig. 7.59) is given by

$$u_\mathrm{r} = 0 \,, \quad u_\theta = \frac{\Gamma}{2\pi r} \,.$$

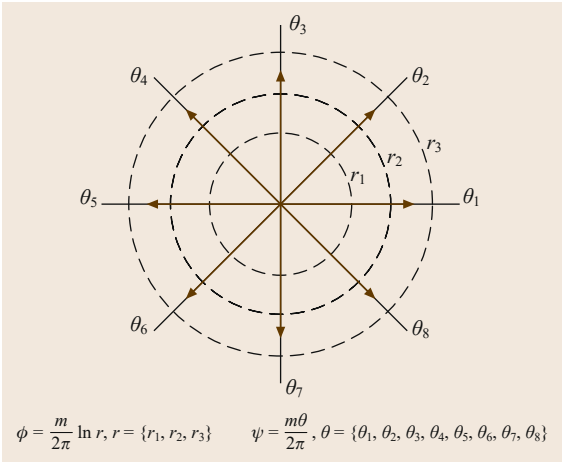

Fig. 7.58 Potential flow lines (*dashed lines*, ϕ) and streamlines (*continuous lines*, ψ) for a source flow. The directions of the *arrows* on the streamlines are reversed for a sink flow, when $m < 0$

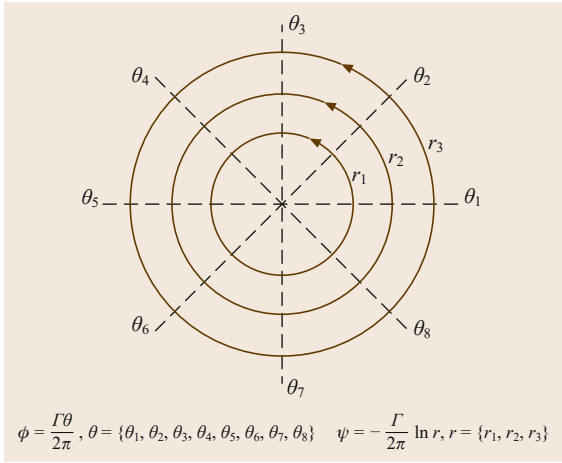

Fig. 7.60 Potential flow lines (*dashed lines*, ϕ) and streamline (*continuous lines*, ψ) for an irrotational line vortex flow. The directions of the *arrows* on the streamlines is reversed when the circulation is negative $\Gamma < 0$

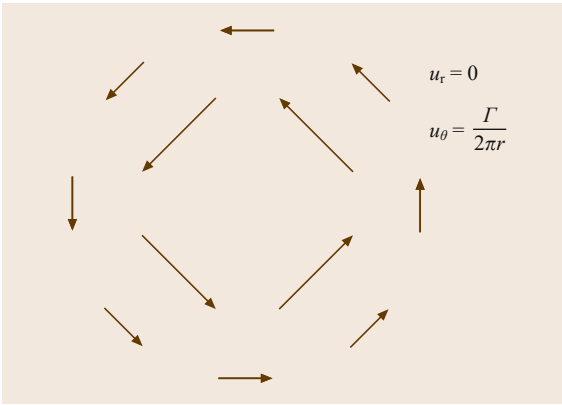

Fig. 7.59 Velocity vectors in an irrotational line vortex flow. The directions of the arrows on the streamlines is reversed when the circulation is negative $\Gamma < 0$

Integrating the velocity as above to solve for ϕ, ψ and w gives

$$\phi = \frac{\Gamma\theta}{2\pi}\,, \quad \psi = -\frac{\Gamma}{2\pi}\ln r\,, \quad w = -\frac{i\Gamma}{2\pi}\ln(z)\,.$$

An examination of the velocity potential and stream function reveals that level curves of constant ψ (streamlines) are circles and level curves of constant ϕ are rays (Fig. 7.60).

2. Superposed flows:
   a) Rankine half-body
   Add a source flow to a uniform freestream flow – for the velocity potential we get

$$\phi = Ux + \frac{m}{2\pi}\ln r = Ur\cos\theta + \frac{m}{2\pi}\ln r$$

and for the stream function we have

$$\psi = Uy + \frac{m\theta}{2\pi} = Ur\sin\theta + \frac{m\theta}{2\pi}\,. \qquad (7.64)$$

Superposed flows, such as this one, often form the outline of bodies in a flow. As stagnation points (where both components of the 2-D velocity vanish) typically lie on the surface of a body, one can determine the equation for the streamlines that pass through the body's surface by first identifying the stagnation points. The stagnation points occur at locations where $u_r = 0$ and $u_\theta = 0$. Using the expression for the stream function above, we have

$$u_r = \frac{1}{r}\frac{\partial\psi}{\partial\theta} = U\cos\theta + \frac{m}{2\pi r}$$

and

$$u_\theta = -\frac{\partial\psi}{\partial r} = -U\sin\theta\,.$$

We see that $u_\theta = 0$ when $\theta = 0$ or π. If we take $\theta = 0$, the corresponding solution for u_r would give that $r < 0$, which is nonphysical. Thus, we take the other solution giving the location of the stagnation point as

$$\theta = \pi\,, \quad r = \frac{m}{2\pi U}\,.$$

The streamline that passes through the stagnation point forms the outline of the half-body. We

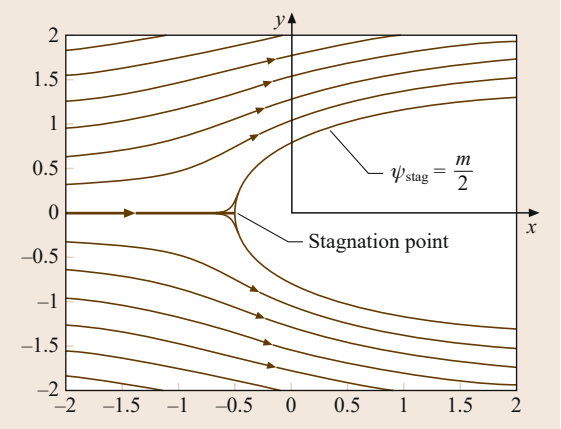

Fig. 7.61 Rankine half-body flow

can find the value of the stream function ψ_{stag} by evaluating (7.64) at the stagnation point.

$$\psi_{stag} = U\frac{m}{2\pi U}\sin\pi + \frac{m\pi}{2\pi} = \frac{m}{2}$$

The values of r and θ lying along the streamline are given by

$$Ur\sin\theta + \frac{m\theta}{2\pi} = \frac{m}{2}\,,$$

for $0 \le \theta \le \pi$. The $\frac{1}{2}$ width of the body h can be determined by examining the value of ψ_{stag} for $\theta \to 0$; using (7.64) it can be seen that $m/2 = Uh$ so that

$$h = \frac{m}{2U}\,.$$

The streamlines of the Rankine half-body flow are shown in Fig. 7.61.

b) Source and sink of equal strength
As in Fig. 7.62, let a source be placed at the location $(x, y) = (-a, 0)$ and a sink be placed at the location $(x, y) = (+a, 0)$. The combined velocity potential is

$$\phi = \frac{m}{2\pi}\ln r_1 - \frac{m}{2\pi}\ln r_2 = \frac{m}{2\pi}\ln\left(\frac{r_1}{r_2}\right)$$
$$= \frac{m}{2\pi}\ln\left(\frac{(x+a)^2+y^2}{(x-a)^2+y^2}\right)^{1/2},$$

because $r_1^2 = (x+a)^2 + y^2$ and $r_2^2 = (x-a)^2 + y^2$.
Similarly,

$$\psi = \frac{m\theta_1}{2\pi} - \frac{m\theta_2}{2\pi} = -\frac{m}{2\pi}(\theta_2 - \theta_1)\,.$$

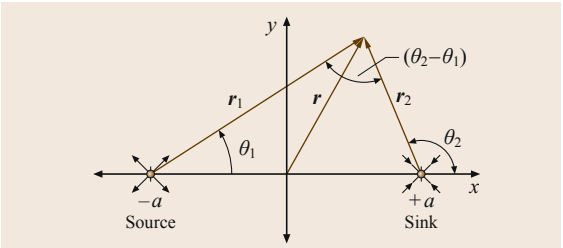

Fig. 7.62 Geometry of the source/sink flow

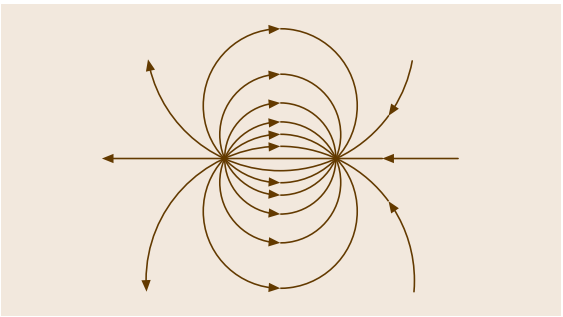

Fig. 7.63 Sketch of the flow generated by a superposed source and sink

ψ can be recast in Cartesian coordinates as

$$\psi = -\frac{m}{2\pi}\tan^{-1}\left(\frac{2ay}{x^2+y^2-a^2}\right).$$

The streamlines for the source–sink flow are shown in Fig. 7.63.

c) Rankine body
A Rankine body can be constructed by combining a source and sink of equal strength with a uniform freestream flow. The velocity potential ϕ and stream function ψ are

$$\phi = Ux + \frac{m}{2\pi}\ln\left(\frac{(x+a)^2+y^2}{(x-a)^2+y^2}\right)^{1/2},$$
$$\psi = Uy - \frac{m}{2\pi}\tan^{-1}\left(\frac{2ay}{x^2+y^2-a^2}\right).$$

As above the equation of the streamline forming the Rankine body can be determined by finding the stagnation points and then solving for the value of the stream function that passes through them. The resulting equation for the streamline is

$$\tan\left(\frac{2\pi Uy}{m}\right) = \frac{2ay}{x^2+y^2-a^2}\,.$$

The streamlines for a Rankine body flow are shown in Fig. 7.64.

d) Doublet
Let $a \to 0$ in the source/sink flow above, we have

$$\phi = \frac{m}{2\pi} \ln\left(\frac{r_1}{r_2}\right).$$

From geometry, $r_1 = 2a\cos\theta_1 + r_2\cos(\theta_2 - \theta_1)$. Therefore,

$$\phi = \frac{m}{2\pi} \ln\left(\frac{2a\cos\theta_1}{r_2} + \cos(\theta_2 - \theta_1)\right).$$

When $a \to 0$ but m is increased such that ma/π remains finite and constant, $r_2 \to r$, $\theta_2 \to \theta$, and $\cos(\theta_2 - \theta_1) \to 1$ so that

$$\lim_{a\to 0} \phi = \frac{m}{2\pi} \ln\left(\frac{2a\cos\theta}{r} + 1\right).$$

A Taylor's series expansion of the argument about 1 gives

$$\phi = \frac{ma\cos\theta}{\pi r} = \frac{\mu x}{x^2 + y^2}.$$

Similarly, for small angles $\tan\theta \approx \theta$ and

$$\psi = -\frac{m}{2\pi}\left(\frac{2ay}{x^2 + y^2}\right) = -\frac{ma}{\pi}\left(\frac{y}{x^2 + y^2}\right),$$
$$= -\frac{\mu y}{x^2 + y^2}.$$

With $r^2 = x^2 + y^2$ so that $\cos\theta = x/r$ and $\sin\theta = y/r$,

$$\phi = \frac{\mu\cos\theta}{r} \text{ and } \psi = -\frac{\mu\sin\theta}{r}.$$

The complex velocity potential is then

$$w(z) = \phi + \mathrm{i}\psi = \frac{\mu}{r}(\cos\theta - \mathrm{i}\sin\theta)$$
$$= \frac{\mu \mathrm{e}^{\mathrm{i}\theta}}{r} = \frac{\mu}{z}.$$

The streamlines for this flow are shown in Fig. 7.65.
Note that a doublet can also be produced from the superposition of a line vortex of circulation strength $-\Gamma$ and infinitesimal distance above the origin with a line vortex of circulation strength $+\Gamma$ and infinitesimal distance below the origin.

e) Uniform flow + doublet
Adding the stream functions for a uniform flow and doublet gives

$$\psi = Ur\sin\theta - \frac{\mu\sin\theta}{r},$$

where $\mu = ma/\pi$, as above. Solving for the tangential and radial velocities in the flow gives

$$u_\mathrm{r} = \frac{1}{r}\frac{\partial\psi}{\partial\theta} = \frac{1}{r}\left(Ur - \frac{\mu}{r}\right)\cos\theta,$$

and

$$u_\theta = -\frac{\partial\psi}{\partial r} = -\left(U + \frac{\mu}{r^2}\right)\sin\theta,$$

respectively. The stagnation points are located where $\theta = 0$ and $\theta = \pi$ so that $u_\theta = 0$ and

$$Ur - \frac{\mu}{r} = 0 \to r = \sqrt{\frac{\mu}{U}} \equiv R,$$

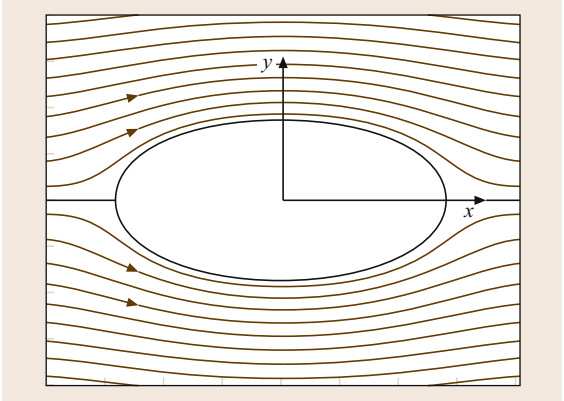

Fig. 7.64 Rankine body flow

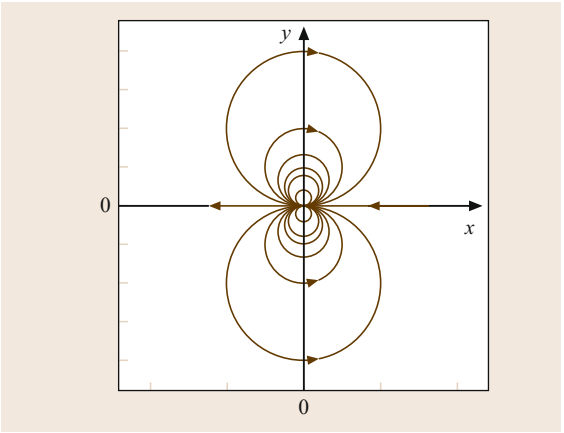

Fig. 7.65 A doublet flow

so that $u_r = 0$. We can define the stagnation streamline such that $\psi = \psi_{stag} = 0$, which gives

$$\psi_{stag}\big|_{r=R} = \frac{1}{R}(UR^2 - \mu)\sin\theta = 0\,,$$

for all θ. Thus, the body defined by ψ_{stag} is a circle of radius R. We can re-write ψ as

$$\psi = Ur\sin\theta\left(1 - \frac{R^2}{r^2}\right), \quad \text{for } r \geq R\,.$$

This gives the flow over a circular cylinder (Fig. 7.66).

Note that the forces acting on the cylinder can be determined by first using the incompressible, irrotational form of Bernoulli's equation (7.63) to determine the pressure everywhere on the surface of the cylinder and then integrating the pressure across the cylinder's surface.

The Magnus Effect

A rotating body in a freestream flow will produce a force transverse to the direction of the freestream. This can be seen by superposing a uniform flow past a circular cylinder with circulation, that is, a cylinder spinning about its axis of symmetry (Fig. 7.67).

Normally, the thin boundary layer about a spinning body would be responsible for creating the circulation; in this inviscid flow we have introduced the circulation using a line vortex.

$$\psi = Ur\sin\theta\left(1 - \frac{R^2}{r^2}\right) - \frac{\Gamma}{2\pi}\ln r + C\,,$$

where we set the constant C to $C = \Gamma/(2\pi)\ln R$ to make $\psi = \psi_s = 0$ on the cylinder surface $(r = R)$.

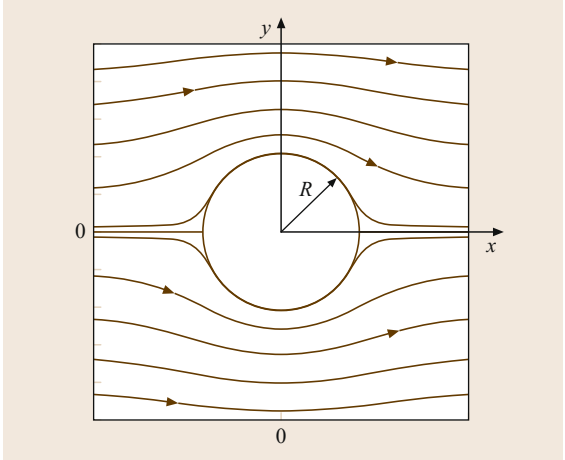

Fig. 7.66 Flow about a circular cylinder

Then

$$\psi = Ur\sin\theta\left(1 - \frac{R^2}{r^2}\right) - \frac{\Gamma}{2\pi}\ln\left(\frac{r}{R}\right).$$

The associated radial and tangential velocities are

$$u_r = \frac{1}{r}\frac{\partial\psi}{\partial\theta} = U\cos\theta\left(1 - \frac{R^2}{r^2}\right)$$

and $$u_\theta = -\frac{\partial\psi}{\partial r} = -U\sin\theta\left(1 + \frac{R^2}{r^2}\right) + \frac{\Gamma}{2\pi r}\,,$$

respectively. On $r = R$, $u_r = 0$ and $u_\theta = -2U\sin\theta + \Gamma/(2\pi R)$ (Fig. 7.68).

The pressure on the surface of the cylinder can be determined using Bernoulli's equation (7.63)

$$p_\infty + \rho\frac{U^2}{2} = p_0 = p(\theta) + \rho\frac{u_\theta^2}{2}\,,$$

where p_0 is the pressure at the stagnation point and p_∞ is the freestream pressure.

Using the value of u_θ determined above, the pressure on the cylinder is

$$\begin{aligned} p(\theta) &= p_0 - \rho\frac{u_\theta^2}{2} \\ &= p_0 - 2\rho U^2\sin^2\theta + \frac{\rho U\sin\theta\,\Gamma}{\pi R} - \frac{\rho\Gamma^2}{8\pi^2R^2}\,. \end{aligned} \tag{7.65}$$

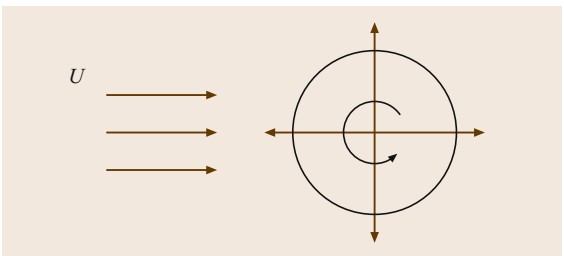

Fig. 7.67 Sketch of superposed uniform flow, cylinder, and circulation

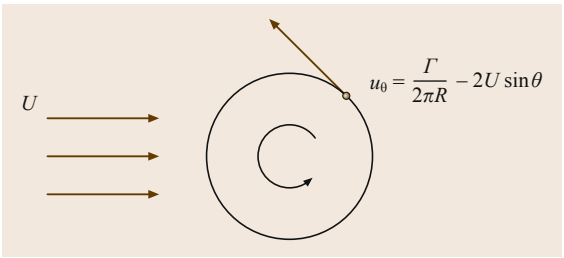

Fig. 7.68 Tangential velocity on the surface of the cylinder

The drag acting on the cylinder can be determined by integrating the streamwise component of the pressure force acting on the cylinder (Figs. 7.69 and 7.70).

$$F_x = -\int_0^{2\pi} p(\theta)\cos\theta R b \mathrm{d}\theta \ ,$$

where the element of surface area is $Rb\mathrm{d}\theta$ with b being the dimension in the z direction. Substituting the pressure around the cylinder surface into this integral, we find that the drag force per unit span is $F_x/b = 0$. This result is known as D'Alembert's paradox – according to two-dimensional, incompressible, irrotational flow theory, the drag on any body, of any shape in a uniform freestream flow is zero.

Turning now to the force component in the cross-stream direction we have

$$F_y = -\int_0^{2\pi} p(\theta)\sin\theta R b \mathrm{d}\theta \ .$$

Substituting the pressure around the cylinder surface into this integral, we find that the lift force per unit span is $F_y/b = -\rho U\Gamma$.

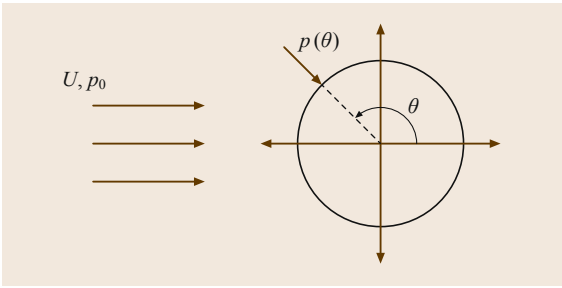

Fig. 7.69 Pressure on the cylinder surface

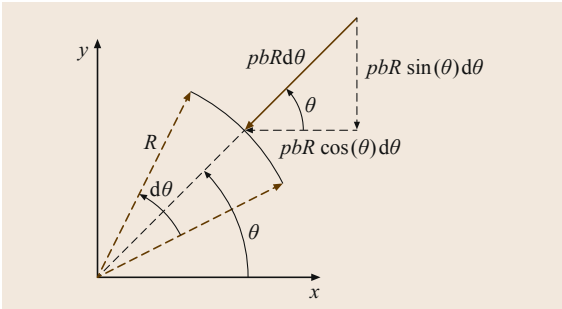

Fig. 7.70 Force components of the pressure acting on the cylinder surface. Here b is the dimension of the cylinder along the z-axis

This result is generally true and is known as the Kutta–Jukowski lift theorem. According to two-dimensional, incompressible, irrotational flow theory, the magnitude of the lift force per unit span of a cylinder of any shape, which possess circulation Γ, immersed in a freestream flow is $\rho U\Gamma$ – the direction of lift is 90° from the freestream direction.

So what does the flow look like? At the cylinder surface $r = R$, $u_r = 0$ and $u_\theta = -2U\sin\theta + \Gamma/(2\pi R)$. The stagnation points occur where $u_\theta = 0$

$$\sin\theta = \frac{\Gamma}{4\pi UR} \ .$$

For $\sin\theta \le 1$, $\Gamma < 4\pi UR$ and there are two values of θ that satisfy the equation, that is, two stagnation points (Fig. 7.71) the corresponding streamlines are shown in Fig. 7.72.

It is interesting to compare the corresponding velocity and pressure distributions about the cylinder with and without circulation. The pressure

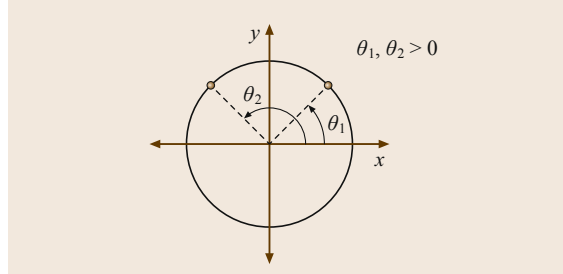

Fig. 7.71 Stagnation point locations

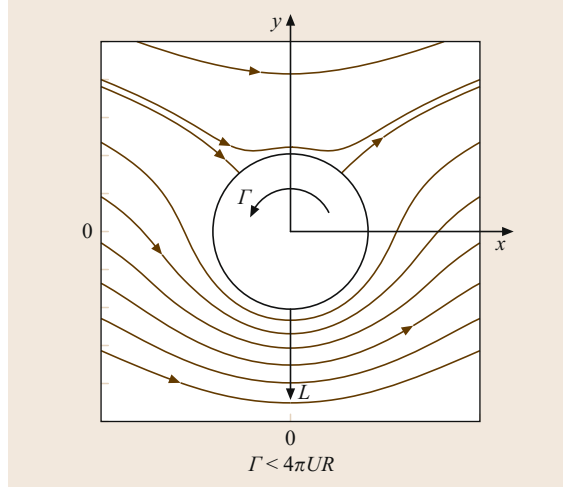

Fig. 7.72 Flow about the circular cylinder with circulation and the corresponding lift force

coefficient

$$C_p \equiv \frac{p-p_\infty}{\frac{1}{2}\rho U^2} = \left(1-\frac{u_\theta^2}{U^2}\right),$$

about the cylinder without circulation is shown in Fig. 7.73a. As can be seen from Figs. 7.66 and 7.73a the symmetrical velocity distribution produces a correspondingly symmetrical pressure coefficient distribution about both the vertical and horizontal axes of the flow. Because of this, both the lift and drag, as determined by integrating the pressure about the cylinder with no circulation, are zero. As one can imagine, the asymmetrical velocity distribution about the cylinder with circulation in a uniform flow (Fig. 7.72) will produce an asymmetrical pressure distribution about the horizontal axis. The integration of the pressure about the cylinder then gives rise to the lift force, which is acting in the cross-stream (vertical) direction.

The Blasius Integral

The Blasius integral is a convenient means of determining the lift and drag per unit span on an object in a flow when the complex velocity potential is known.

Combining the lift and drag in complex form (Fig. 7.74), we have

$$\begin{aligned} \mathrm{d}D - \mathrm{i}\mathrm{d}L &= -p\mathrm{d}y - \mathrm{i}p\mathrm{d}x \\ &= -\mathrm{i}p(\mathrm{d}x - \mathrm{i}\mathrm{d}y) = -\mathrm{i}p\mathrm{d}\bar{z}\,. \end{aligned}$$

Integrating the pressure over the surface of the body, we get the total force on the body in complex form

$$D - \mathrm{i}L = -\oint_C \mathrm{i}p\mathrm{d}\bar{z}\,, \qquad (7.66)$$

where the integral is taken in the counterclockwise direction about the closed curve C that encloses the body. Using the Bernoulli equation (7.63) to find the local

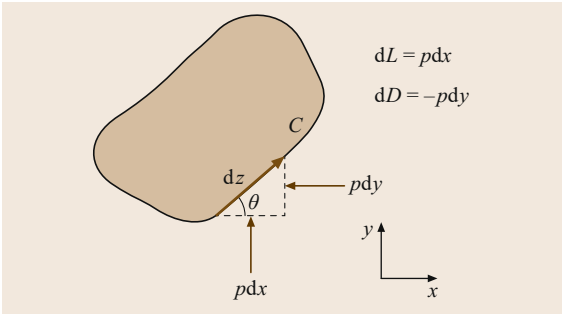

Fig. 7.74 Determination of lift dL and drag dD components from pressure on surface for Blasius integral

pressure on the body surface, we have

$$p = \left(p_\infty + \frac{1}{2}\rho U^2\right) - \frac{1}{2}\rho(u^2+v^2)\,.$$

Incorporating this expression for the pressure into the integral gives

$$D - \mathrm{i}L = -\oint_C \mathrm{i}\left[\left(p_\infty + \frac{1}{2}\rho U^2\right) - \frac{1}{2}\rho(u^2+v^2)\right]\mathrm{d}\bar{z}\,.$$

Since the integral over the closed loop of the constant term

$$\left(p_\infty + \frac{1}{2}\rho U^2\right)$$

is zero, the integral reduces to

$$D - \mathrm{i}L = \oint_C \frac{\mathrm{i}}{2}\rho(u+\mathrm{i}v)(u-\mathrm{i}v)\mathrm{d}\bar{z}\,.$$

Writing the expressions $(u+\mathrm{i}v)$ and $\mathrm{d}\bar{z}$ in polar form gives $(u+\mathrm{i}v) = \sqrt{u^2+v^2}\,\mathrm{e}^{\mathrm{i}\theta}$ and $\mathrm{d}\bar{z} = \mathrm{d}x - \mathrm{i}\mathrm{d}y =$

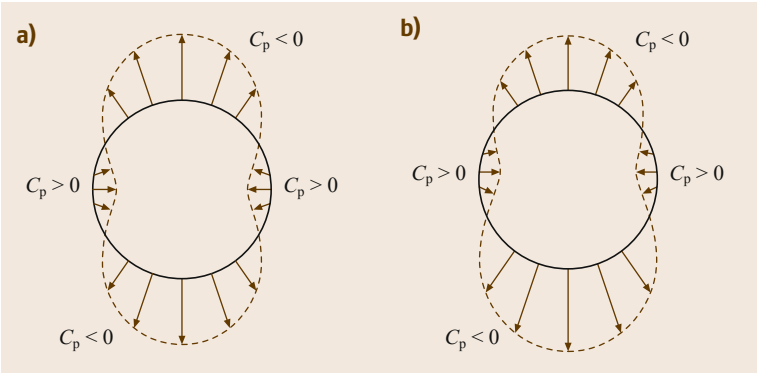

Fig. 7.73 **(a)** Symmetrical pressure distribution about the cylinder with no circulation. **(b)** Asymmetrical pressure distribution about the cylinder with circulation. The lift generated results from asymmetry of the pressure distribution

$\sqrt{dx^2+dy^2}e^{-i\theta}$, respectively (Fig. 7.75). Therefore, the product of these two terms can be rewritten as

$$\begin{aligned}(u+iv)d\bar{z} &= \sqrt{u^2+v^2}e^{i\theta}\sqrt{dx^2+dy^2}e^{-i\theta}\\ &= \sqrt{u^2+v^2}e^{-i\theta}\sqrt{dx^2+dy^2}e^{i\theta}\\ &= (u-iv)dz\,.\end{aligned}$$

Then the integral becomes

$$D-iL=\frac{i\rho}{2}\oint_C(u-iv)^2dz=\frac{i\rho}{2}\oint_C\left(\frac{dw}{dz}\right)^2dz\,. \tag{7.67}$$

Use of this integral is known as the Blasius theorem for calculating the lift and drag on a body of any cross-sectional shape in a steady, two-dimensional, incompressible, irrotational flow. The contour integral does not need to be taken at the surface of the body – so long as there are no singularities (e.g., sources/sinks, irrotational vortices, etc.) between the body and C (Fig. 7.76).

At a very large distance from the body all singularities appear to be located at $z=0$. We can use series expansions to simplify the Blasius integral in this case using the Residue Theorem.

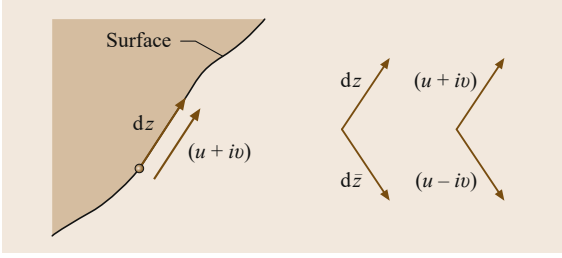

Fig. 7.75 As the flow is everywhere tangent to the surface, $(u+iv)$ and dz are in the same direction. The reflection of these complex vectors about the horizontal axis gives $(u-iv)$ and $d\bar{z}$

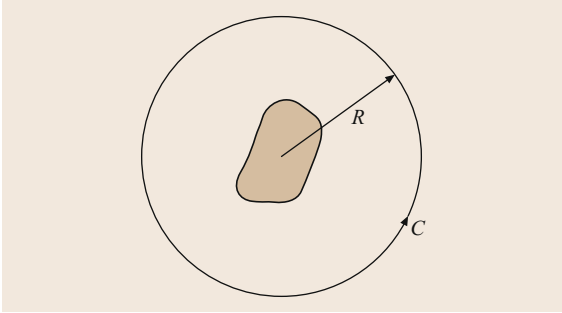

Fig. 7.76 Contour integral about a body in a flow to evaluate the Blasius integral

Example 7.10

If the stream function ψ can be expressed as the sum of two functions in the form $\psi=\psi_1+\psi_2$, the streamlines can be drawn when the curves $\psi_1=$ constant, $\psi_2=$ constant are known. Take a small constant ω and draw the curves $\psi_1=\omega,2\omega,3\omega,\ldots$ and $\psi_2=\omega,2\omega,3\omega,\ldots$ as shown in Fig. 7.77.

At the points marked 3, $\psi=\psi_1+\psi_2=3\omega$, at points marked 4, $\psi=\psi_1+\psi_2=4\omega$, etc. By joining the points with the same numeral (dashed lines in Fig. 7.77) the streamlines, along which $\psi=\psi_1+\psi_2=$ constant, can be plotted out.

Try this. By hand (using a ruler and protractor), plot the streamlines for the flow given by the complex potential

$$w(z)=(-m+ik)\ln z\,.$$

Let $m=1$, and $k=7\pi/[4\ln(10)]$, and $\omega=\pi/4$. Plot the streamlines for $\psi=n\omega$, where $n=\{0,1,2,\ldots,7\}$.

Note

It will be easier to represent z with polar coordinates r,θ.

Solution 7.9

Expanding the expression for $w(z)$ gives

$$\begin{aligned}w(z) &= (-m+ik)\ln z\\ &= -(m\ln r+k\theta)+i(k\ln r-m\theta)=\phi+i\psi\,.\end{aligned}$$

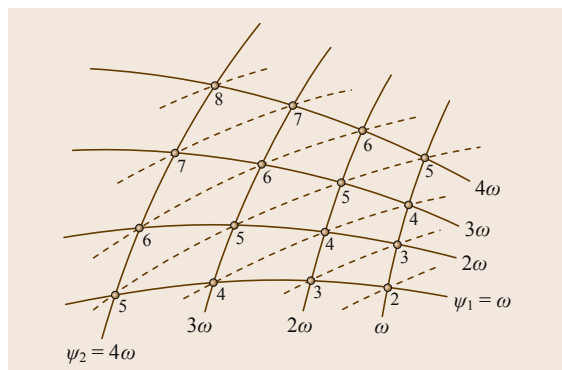

Fig. 7.77 Constructing streamlines by hand. The *solid curves* correspond to constant values of ψ_1 and ψ_2. The *dashed curves* correspond to the streamlines created by joining points with the same values of $\psi=\psi_1+\psi_2$

Therefore,

$$\psi = k \ln r - m\theta = \psi_1 + \psi_2 = \frac{7\pi}{4\ln(10)} \ln r - \theta \,.$$

Then, we have the system

$$\psi_1 = k \ln r = n\omega \,,$$
$$\psi_2 = -\theta = n\omega \,.$$

Solving the system for r gives

$$r = \mathrm{e}^{-\theta/k} = \mathrm{e}^{-n\omega/k} = \exp[\ln 10^{n/7}] = 10^{n/7} \,.$$

Values for the required n are given in Table 7.5. The resulting streamlines are plotted in Fig. 7.78.

7.3.4 Flow of a Viscous Fluid

The viscosity of a fluid, which is a measure of its resistance to deformation by shear stresses imposed on the fluid, plays a critical role in flow of the fluid, being significantly responsible for frictional resistance, flow instability, flow separation, lubrication, heat transfer, dissipation of fluid motion, and other related flow features. As discussed in Sect. 7.2.1, for Newtonian fluids, such as air and water, dynamic viscosity (units: $\mu\mathrm{N\,s\,m^{-2}}$ or $\mathrm{kg\,m^{-1}s^{-1}}$) is the coefficient of proportionality between the imposed stresses and rate of strain or deformation of the fluid. In Couette flow [7.5] between two parallel plates (Fig. 7.52), this is represented in terms of the shear stress and the velocity gradient as $\tau = \mu \partial u/\partial y$. μ is a thermodynamic quantity that varies with temperature and pressure. As shown in Sect. 7.1.2, *Reynolds number* and (7.8), the effect of the viscous forces is typically compared with the inertia forces in the fluid and expressed in terms of the Reynolds number as $\mathrm{Re} = \rho U l/\mu = U l/\nu$, where U and l are, respectively, the characteristic speed and length scales of the flow. Typically, a low Reynolds number indicates that the flow may be laminar while a large Reynolds number indicates that the flow is likely to be turbulent.

Table 7.5 Values to be plotted for the spiral flow

n	θ	r	ψ_1/ψ_2
0	0	1	0
1	$-\pi/4$	1.39	$\pi/4$
2	$-\pi/2$	1.93	$\pi/2$
3	$-3\pi/4$	2.68	$3\pi/4$
4	$-\pi$	3.73	π
5	$-5\pi/4$	5.18	$5\pi/4$
6	$-3\pi/2$	7.20	$3\pi/2$
7	$-7\pi/4$	10	$7\pi/4$

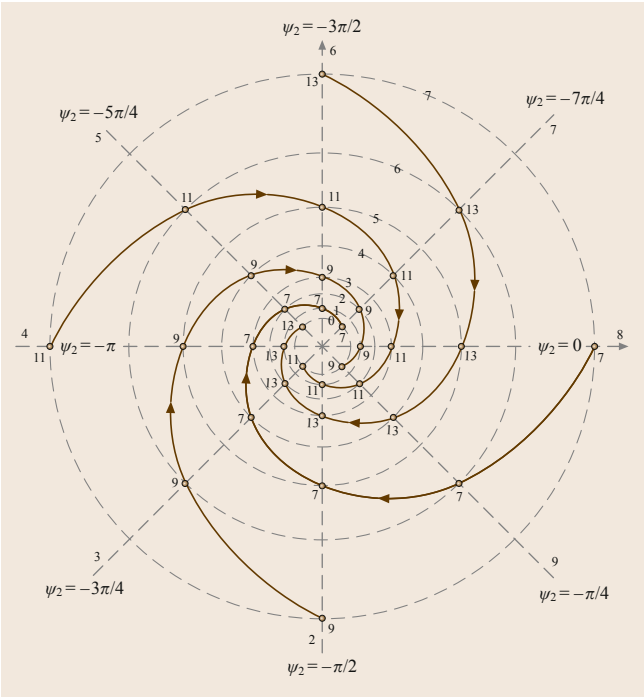

Fig. 7.78 Streamlines for a spiral flow

Laminar Flows

A laminar flow is orderly and is a solution of the Navier–Stokes equations and the associated boundary and initial conditions, so that viscous forces and pressure gradient acting on the fluid balance the inertial forces. Representing the gravitational force as a conservative force in a Cartesian coordinate system such that its potential is $\Pi = gz$ and $\boldsymbol{g} = -\nabla\Pi$, we can express the incompressible isothermal form of Navier–Stokes equations as

$$\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}t} = -\frac{1}{\rho}\nabla p + \boldsymbol{g} + \nu\nabla^2\boldsymbol{u} \,, \tag{7.68}$$

$$\nabla \cdot \boldsymbol{u} = 0 \,. \tag{7.69}$$

If the flow is stable, small perturbations to the flow decay. If it is unstable, small perturbations grow and lead to breakdown of the orderly flow and onset of turbulence.

Exact analytical solutions of the Navier–Stokes equations include:

Hagen–Poiseuille Flow in a Circular Pipe. This is a well-known steady flow driven by a constant pressure gradient along the length of a circular pipe that is balanced by viscous forces. The flow speed at a radial distance r from the axis of symmetry in a pipe of

diameter $D = 2r_0$ is given by

$$u(r) = -\frac{1}{4\mu}\frac{\mathrm{d}(p+\rho g z)}{\mathrm{d}s}\left(r_0^2 - r^2\right) = u_{\max}\left(1 - \frac{r^2}{r_0^2}\right), \tag{7.70}$$

where s is the distance along the pipe. The mean speed is $\bar{u} = u_{\max}/2$ and the volume flow rate is $Q = \pi r_0^2 \bar{u}$. The shear stress at the pipe wall is

$$\tau_w = -\mu \frac{\mathrm{d}u}{\mathrm{d}r}|_{r=r_0} = \frac{4\mu\bar{u}}{r_0} .$$

This implies a skin-friction coefficient of

$$C_F = \frac{2\tau_w}{\rho\bar{u}^2} = \frac{16}{\mathrm{Re}_D} ,$$

where the diameter-based Reynolds number is $\mathrm{Re}_D = \rho\bar{u}D/\mu$. The friction represents a head loss of $h_f = 32\mu\bar{u}/(\rho g D^2)$ in the pipe. The laminar flow undergoes transition to turbulence when $\mathrm{Re}_D \approx 2000$ and is fully turbulent when $\mathrm{Re}_D > 3000$. See [7.32] for other internal flow solutions.

Similarity Solutions. A class of solutions of the Navier–Stokes equations obtained through introduction of a similarity variable and reduction of the set of partial differential equations to ordinary differential equations that can be solved analytically or numerically is referred to as a self-similar solution. Such solutions include:

Flow at an Axisymmetric Stagnation Point. At an axisymmetric stagnation point, with free stream flow given by $u = ar$ and $v = -2az$, in cylindrical coordinates (r, θ, z) centered on the axisymmetric stagnation point. Upon introduction of a similarity variable $\eta \equiv z\sqrt{a/\nu}$, the radial and normal components of velocity are, respectively, given by $u = arF'(\eta)$ and $v = -2F(\eta)\sqrt{a\nu}$, where $F(\eta)$ satisfies

$$F''' + 2FF'' + 1 - F'^2 = 0 ,$$
$$F(0) = F'(0) = 0 , \; F'(\infty) = 1 . \tag{7.71}$$

$F(\eta)$ and its derivatives are plotted in Fig. 7.79.

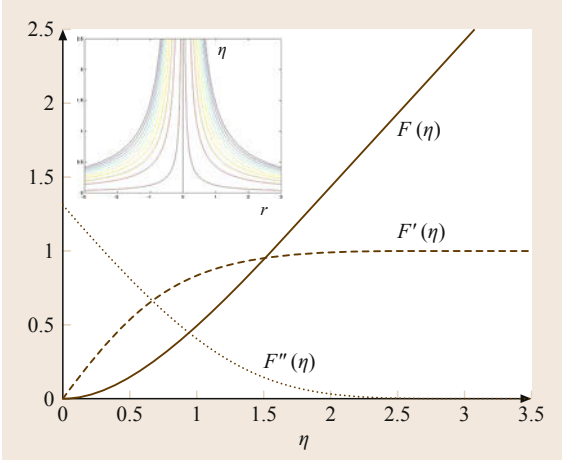

Fig. 7.79 $F(\eta)$ and $F'(\eta)$ for stagnation point flow; $F''(0) = 1.31194$

Stokes Flow Over Steadily Oscillating Wall. Over a plane wall oscillating with speed $u(0,t) = U_0 \cos\omega t$ (Fig. 7.80), upon introduction of similarity variable $\eta = y\sqrt{\omega/2\nu}$, the solution for the flow speed along the plane is given by

$$u(\eta) = U_0 \mathrm{e}^{-\eta}\cos(\omega t - \eta) . \tag{7.72}$$

This is the well-known Stokes solution; a detailed development of the solution is given in [7.5].

Flow Over a Suddenly Accelerated Plane Wall. Over a plane wall suddenly accelerated to speed U_0, using the similarity variable $\eta = y/\sqrt{4\nu t}$, the solution for the flow speed along the plane is given by

$$u(\eta) = U_0(1 - \mathrm{erf}\eta) , \tag{7.73}$$

where $\mathrm{erf}\eta$ is the error function $\mathrm{erf}(x) \equiv 2/\sqrt{\pi}\int_0^x \mathrm{e}^{-t^2}\mathrm{d}t$.

Laminar Boundary Layers. In flow past a rigid surface in air or water, the rate of convection along the surface is much greater than the rate of diffusion normal to the surface. Thus the diffusion of momentum over the surface occurs in a thin layer, which is referred to as the boundary layer. The larger the Reynolds number, the thinner the boundary layer. On this basis, the velocity $\boldsymbol{u}(\boldsymbol{x}, t) = (u, v, w)$ within the boundary layer due to an external freestream flow $\boldsymbol{U}(x, z, t) = (U_e, 0, W_e)$ can be shown to be governed by the simpler equations

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z} = \frac{\partial U_e}{\partial t} + U_e\frac{\partial U_e}{\partial x} + W_e\frac{\partial U_e}{\partial z} + \nu\frac{\partial^2 u}{\partial y^2} , \tag{7.74}$$

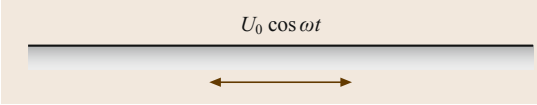

Fig. 7.80 Geometry of the oscillating wall

$$\frac{\partial w}{\partial t} + u\frac{\partial w}{\partial x} + v\frac{\partial w}{\partial y} + w\frac{\partial w}{\partial z}$$
$$= \frac{\partial W_e}{\partial t} + U_e\frac{\partial W_e}{\partial x} + W_e\frac{\partial W_e}{\partial z} + \nu\frac{\partial^2 w}{\partial y^2}\,, \qquad (7.75)$$
$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0\,. \qquad (7.76)$$

For steady two-dimensional flow over a flat plate with its upstream edge at $x = 0$ and $\boldsymbol{U}_e = (U_e, 0, 0)$, where U_e is a constant, a well-known Blasius similarity solution [7.16] for the flow in the boundary layer is obtained upon introducing the similarity variable $\eta = y\sqrt{U/(2\nu x)}$ as $u = U_e F'(\eta)$, and $v = \sqrt{\nu U/(2x)}(\eta F' - F)$, where $F(\eta)$ satisfies

$$F''' + FF'' = 0,\ F(0) = F'(0) = 0\,,$$
$$F'(\infty) = 1\,. \qquad (7.77)$$

$F(\eta)$ and its derivatives are plotted in Fig. 7.81.

The thickness of the Blasius boundary layer $\delta_{0.99} = 4.9x/\sqrt{\mathrm{Re}_x}$, where $\mathrm{Re}_x \equiv U_e x/\nu$. The momentum thickness is given by $\delta^* = 1.7208x/\sqrt{\mathrm{Re}_x}$. The friction coefficient is given by

$$c_f = \frac{2\tau_w}{\rho U^2} = \frac{0.664}{\sqrt{\mathrm{Re}_x}}\,.$$

The integrated drag coefficient on a plate of length $C_D = 2C_F(L) = 1.328/\sqrt{\mathrm{Re}_L}$. The Blasius solution is valid for $\mathrm{Re}_x > 1000$. At $\mathrm{Re}_x = O(10^6)$, the laminar boundary layer becomes unstable, leading to transition to turbulence. See [7.16] for comparison of these results with experiments as well as for other similarity solutions of boundary layer equations, including flows in a wedge and flow into a convergent channel.

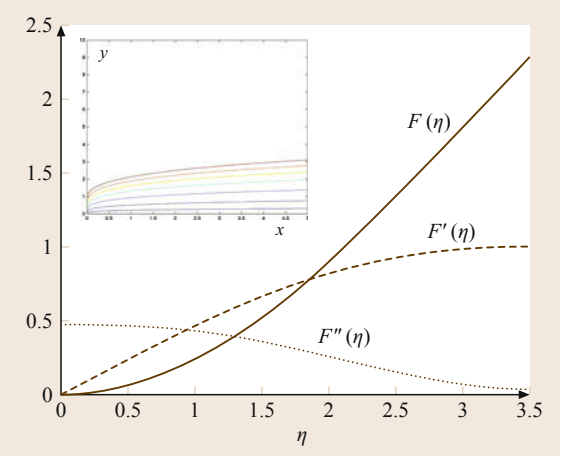

Fig. 7.81 $F(\eta)$ and its derivatives for Blasius boundary layer flow; $F''(0) = 0.469600$

Flow Separation. Flow separation occurs at the location where the surface stress at the bounding wall vanishes such that

$$\tau_w = \mu\left(\frac{\partial u}{\partial y}\right)_{y=0}\,. \qquad (7.78)$$

Close to the freestream, the curvature of the velocity profile, characterized by

$$\frac{\partial^2 u}{\partial y^2}\,, \qquad (7.79)$$

is negative since the velocity shear reduces to zero upon approach to the freestream. At the wall, however, $u = v = 0$ in (7.74) and the streamwise pressure gradient in the boundary layer, assumed constant across the boundary layer and given by

$$\frac{\mathrm{d}p}{\mathrm{d}x} = -r\left(\frac{\partial U_e}{\partial t} + U_e\frac{\partial U_e}{\partial x} + W_e\frac{\partial U_e}{\partial z}\right)\,, \qquad (7.80)$$

is balanced by the viscous force,

$$\mu\frac{\partial^2 u}{\partial y^2}|_{y=0} = \frac{\mathrm{d}p}{\mathrm{d}x}\,. \qquad (7.81)$$

Therefore, the curvature of the velocity profile has the same sign as the pressure gradient. When the pressure gradient is favorable ($\mathrm{d}p/\mathrm{d}x < 0$) or zero (as for the flat plate Blasius boundary layer) the profile curvature is less than or equal to zero throughout the boundary layer. When the pressure gradient is adverse ($\mathrm{d}p/\mathrm{d}x > 0$), such as on the aft side of a curved surface of a body, the sign of the profile curvature changes across the boundary layer and is an indication that flow separation may occur.

Laminar Wakes, Jets, and Shear Layers. Far-field behavior of laminar wakes of bodies, jets, and free shear layers can be determined as similarity solutions of the steady Navier–Stokes equations.

For an axisymmetric wake associated with a uniform flow of speed U_e past a body with related drag force D, introducing a transverse similarity variable, $\eta = r\sqrt{U/(x\nu)}$, the far-field velocity defect in the wake at a distance x (at least three times body length) downstream of the body can be shown to have a Gaussian profile [7.16] given by

$$U_e - u = \frac{D}{4\pi\mu x}\exp\left(-\frac{\eta^2}{4}\right)\,. \qquad (7.82)$$

For an axisymmetric round jet of momentum $J = \rho\int_0^a 2\pi u^2 r\mathrm{d}r$ from a circular hole of radius a, introducing a transverse similarity variable, $\eta = r/x$, the

far-field axial velocity in the jet at a distance x downstream of the hole can be shown to be given by

$$u = \frac{3J}{8\pi\mu x}\left(1 + \frac{3J\eta^2}{64\pi\rho\nu^2}\right)^{-2} . \tag{7.83}$$

Thus the speed decreases approximately linearly with downstream distance.

Finally, velocity associated with a two-dimensional laminar shear layer where the streamwise speed u transitions from U_2 to U across the layer may be represented by Blasius type profiles [7.37] upon introducing the similarity variable $\eta = y\sqrt{U/(2\nu x)}$ as $u = UF'(\eta)$, and $v = \sqrt{\nu U/(2x)}(\eta F' - F)$, where $F(\eta)$ satisfies

$$F''' + FF'' = 0 , \quad F(0) = 0 ,$$
$$F'(-\infty) = \frac{U}{U_2} , \quad F'(\infty) = 1 . \tag{7.84}$$

The case of $U/U_2 = 0.5$ is shown in Fig. 7.82.

Laminar wakes, jets, and shear layers are relatively unstable and break down into turbulent flows.

Turbulent Flows

A turbulent flow is chaotic and involves self-sustaining, random irregular fluctuations in velocity, pressure, and other dependent variables. Turbulent flows are characterized by the presence of eddies (vortices) that induce significant mixing of mass and momentum. The eddies in a turbulent flow exist over a range of spatial and temporal scales. Typically, the largest scales are respectively determined by the size of the flow domain and the time period under consideration. The smallest (Kolmogorov) length and time scales are given by $(\nu^3/\epsilon)^{1/4}$ and $(\nu/\epsilon)^{1/2}$, where ϵ is the rate of energy dissipation per unit mass. A statistical description of the turbulent flow is based on defining deviation of the instantaneous velocity, pressure, and other variables at a location from the mean, as

$$\boldsymbol{u}(\boldsymbol{x}, t) = \boldsymbol{U}(\boldsymbol{x}, t) + \boldsymbol{u}'(\boldsymbol{x}, t) , \tag{7.85}$$
$$p(\boldsymbol{x}, t) = P(\boldsymbol{x}, t) + p'(\boldsymbol{x}, t) , \tag{7.86}$$

etc., where the mean is typically considered to be a temporal average. Here, the mean terms are indicated using capitalized variables and the deviations, or fluctuations are indicated with the superscripted symbol $'$. The mean flow satisfies

$$\rho\left(\frac{\partial \boldsymbol{U}}{\partial t} + \boldsymbol{U}\cdot\nabla\boldsymbol{U}\right) = -\nabla P + \mu\nabla^2\boldsymbol{U} - \overline{\rho\boldsymbol{u}'\cdot\nabla\boldsymbol{u}'} , \tag{7.87}$$

$$\nabla\cdot\boldsymbol{U} = 0 , \tag{7.88}$$

or in tensor notation,

$$\rho\left(\frac{\partial U_i}{\partial t} + U_j\frac{\partial U_i}{\partial x_j}\right) = -\frac{\partial P}{\partial x_i} + \mu\frac{\partial^2 U_i}{\partial x_j^2} - \frac{\partial\overline{\rho u_i' u_j'}}{\partial x_j} , \tag{7.89}$$

$$\frac{\partial U_i}{\partial x_i} = 0 , \tag{7.90}$$

so that the mean flow depends on the product of fluctuations about the mean. These equations are referred to as the Reynolds averaged Navier–Stokes (RANS) equations. $\tau_{ij} = -\overline{\rho u_i' u_j'}$ is the Reynolds stress and may be computed directly, or more typically modeled using constitutive equations in terms of the mean quantities, in order to provide a closed system of equations. A simple form is given by the Boussinesq model [7.38], which for incompressible flow is given by

$$\tau_{ij} = \frac{\mu_t}{\rho_0 U}\left(\frac{\partial U_i}{\partial x_j} + \frac{\partial U_j}{\partial x_i}\right) , \tag{7.91}$$

where μ_t is known as the eddy viscosity. See [7.38] for detailed description of various models that are commonly used as well as a review of several attempts to verify the models and their implementation in numerical schemes.

Turbulence in flow over boundaries is often characterized in terms of a three-layer model: The *inner layer* close to the boundary where viscous dissipative processes dominate, the *outer layer* close to the freestream where larger scale turbulent eddies dominate the shear flow, and the *overlap layer* where both processes are equally important. Recognizing these characteristics, the flow in the inner layer is described in terms of

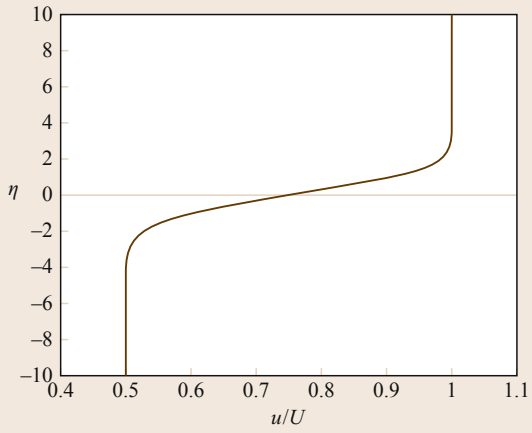

Fig. 7.82 Viscous shear layer profile

nondimensional viscous *wall units*, using the *friction velocity* $u_\tau = (\tau_w/\rho)^{1/2}$, where τ_w is the shear stress at the boundary and ρ is the fluid density, to scale the velocity and u_τ/ν to scale length. The distance normal to the boundary is then expressed as $y^+ = yu_\tau/\nu$ and the velocity in the boundary layer as $u^+ = u/u_\tau$. The velocity and length scales in the outer region are, respectively, the freestream speed U_e, and the boundary layer thickness δ. Dimensional analysis and use of the overlap region suggest that the mean speeds in the inner and outer layers, respectively, are approximately given by

$$U^+ = \begin{cases} y^+ & \text{for } y^+ \lesssim 5 \\ \frac{1}{\kappa}\ln y^+ + B - \frac{1}{\kappa}\ln(1+0.3k^+) & \text{for } y^+ \gtrsim 30 \end{cases}, \tag{7.92}$$

and

$$U_e^+ - U^+ = -\frac{1}{\kappa}\ln\frac{y}{\delta} + A\left(\frac{\delta}{\tau_w}\frac{dp_e}{dx}\right), \tag{7.93}$$

where dp_e/dx is the pressure gradient in the flow and k is average height of surface roughness [7.16]. Experimental results suggest $\kappa \approx 0.41$ and $B \approx 5$. The logarithmic dependence of the velocity in the inner layer is known as *the law of the wall*, while the outer flow dependence on U_e^+ and δ is known as the *law of the wake*.

Unlike boundary layer flows, free-stream turbulence generated through the breakdown of shear layers, wakes or jets is characterized by the maximum velocity U_{max} and the width of the shear layer, $b(x)$, where x is the downstream distance.

Turbulent Flow in a Circular Pipe. The flow in a pipe is fully turbulent when the Reynolds number based on the pipe diameter is $Re_D > 3000$. The distribution of the mean velocity in the pipe can be represented by the law of the wall across the entire pipe cross-section, the wake layer in Fig. 7.83 shows the case where $a^+ = 1000$. The mean velocity of turbulent flow is fuller than that of laminar flow as turbulent eddies mix the momentum across the pipe cross-section. The drag in the pipe is represented in terms of a friction factor $\Lambda = 4C_F$. If k is the average height of the sand-grain roughness of the pipe surface, then Λ is given by

$$\frac{1}{\Lambda^{\frac{1}{2}}} = 2\log_{10}\left(\frac{Re_D\Lambda^{\frac{1}{2}}}{1+0.1(\frac{k}{D})Re_D\Lambda^{\frac{1}{2}}}\right) - 0.8\,. \tag{7.94}$$

The equation is typically represented in terms of the Moody diagram [7.16].

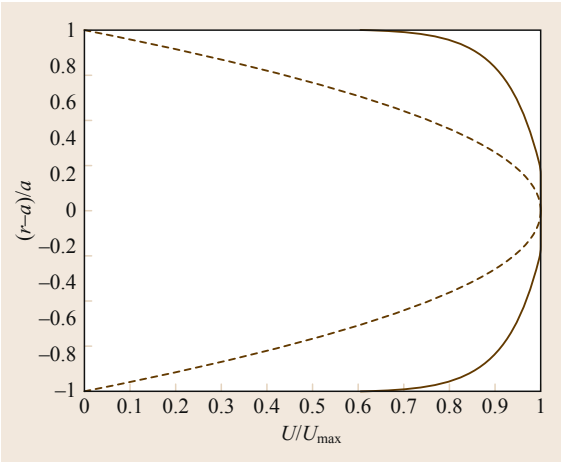

Fig. 7.83 Mean velocity profile of turbulent flow (*solid line*) in a pipe compared with corresponding laminar flow profile (*dotted line*)

Turbulent Boundary Layer Over a Flat Plate. The mean velocity in a turbulent boundary layer over a smooth flat plate is approximately given by the 1/7-th power law

$$\frac{U}{U_e} = \left(\frac{y}{\delta}\right)^{1/7}, \tag{7.95}$$

and the associated skin-friction coefficient is given by $C_F \approx 0.027/Re_x^{1/7}$.

The boundary layer thickness grows as $\delta \approx 0.16x/Re_x^{1/7}$. For fully rough surface, with sand-grain roughness $k > xRe_x/1000$, the skin-friction coefficient is given by

$$C_F \approx \left[2.87 + 1.58\log_{10}\left(\frac{x}{k}\right)\right]^{-2.5}. \tag{7.96}$$

Turbulent Mixing. Turbulent eddies tend to accelerate the mixing of mass and momentum. Mixing occurs over a range of scales and involves fluid *entrainment, dispersion*, and *diffusion* over a range of spatial and temporal time scales of the flow [7.39]. Thus, turbulent flows effectively mix fluid through entrainment and dispersion via a cascade of large to small eddies to diffusion to molecular scales that has a wide range of consequences for oceanic and engineering flows. The largest scale δ is associated with the outer eddies spanning the local region of the turbulent flow, while the smallest scale (Taylor microscale) is associated with the smallest eddies and is given by $\lambda_T = (15\nu/\epsilon)^{\frac{1}{2}}$, where $\epsilon = O(U^3/\delta)$ is the rate of dissipation per unit mass. For a jet, the range of scales varies with the flow

Reynolds number $\mathrm{Re}_\delta = U\delta/\nu$ as

$$\frac{\lambda_\mathrm{T}}{\delta} \approx 2.3\mathrm{Re}_\delta^{-1/2} \,. \tag{7.97}$$

so that the larger the Reynolds number, the greater the range of eddies and length scales involved.

Turbulent Jets and Wakes. The maximum speed in a turbulent circular jet of momentum $J = \iint_\mathrm{S} u^2 \mathrm{d}s$, where S is the cross-sectional area of the nozzle exit, decays linearly with downstream distance x, where x is measured from a virtual origin as

$$U_\mathrm{max} \approx \frac{7.4}{x}\left(\frac{J}{\rho}\right)^{1/2} . \tag{7.98}$$

The cross-sectional extent of the jet varies as $b \approx 0.4x$ and self-similar mean flow profile in the jet may be approximated [7.16, 39] as

$$U \approx U_\mathrm{max}\mathrm{sech}^2\left(\frac{10.4r}{x}\right) . \tag{7.99}$$

For an axisymmetric wake, the maximum defect in the mean velocity in the wake is given by

$$U_\mathrm{e} - U_\mathrm{min} \approx C_0 x^{-2/3} \,, \tag{7.100}$$

and the width of the wake varies as

$$b(x) \approx C_1 x^{-2/3} \,, \tag{7.101}$$

where C_0 and C_1 are constants. These results may be compared with the corresponding cases of laminar flow. The various parameters characterizing the behavior of the turbulent jets or wakes are fairly independent of flow Reynolds number.

8. Ocean Electromagnetics

John J. Holmes

Even though acoustic waves can travel long distances in the sea with little attenuation, ocean electromagnetics has important applications in the areas of geophysical surveys and searches of the seafloor and sub-bottom, communications across the sea–air boundary, and high data transfer rate at short ranges. Unlike in-air propagation of electromagnetic fields, the finite conductivity of seawater results in a frequency-dependent phase velocity, attenuation, intrinsic impedance, and reflection and transmission coefficients at the ocean's surface. After giving a short summary of the electric and magnetic properties of the ocean, this chapter begins with Maxwell's equations and develops the mathematical descriptions of electromagnetic fields and dipole sources within a conducting media. The differences between plane wave reflection and transmission at the surface of fresh water and seawater are used to highlight how electromagnetic propagation within the electrically conducting ocean is so very different than the more familiar radio frequency transmissions in air. In addition, equations are presented that describe the fields from submerged electric and magnetic dipoles that are located both far and near the sea surface. These formulations are valid over the frequency range from 0 Hz to a few MHz. Finally, a brief discussion of ocean electromagnetics at optical wavelengths is given at the end of this chapter.

Even though acoustic waves can travel long distances in the sea with little attenuation, ocean electromagnetics has several important applications. For example; electromagnetic surveys, searches, and communication systems can operate effectively in acoustically noisy environments, they can cross the sea–air boundary and be received by high speed airborne sensors, and they have much higher data transfer rates at short ranges. In addition, electromagnetic surveys of seafloor gas hydrate pockets can determine their methane content, a shortfall of seismic techniques. Moreover, the short range limitations of underwater electromagnetic field propagation are actually beneficial when pinpointing submerged targets during naval operations.

8.1 Electromagnetism in an Ocean Environment

The oldest known application of electromagnetism in an ocean environment is the magnetic compass used for navigation. Today, electromagnetic sources and sensors are useful tools found in many diverse areas of oceanographic study such as physical oceanography, seafloor geophysics, marine chemistry, and biology. Advances in the understanding of electromagnetism within the boundaries of these scientific disciplines have found application to engineering systems for energy generation, oil and gas exploitation and recovery, commercial fishing, weather prediction, Tsunami warning, archeology, and the military. This chapter will

present a brief description of the science behind electromagnetic fields and their interaction with an ocean environment.

Pure water is a very good dielectric. Its *permittivity* is given by $\varepsilon = \varepsilon_0 \varepsilon_w$, where ε_0 is the free-space permittivity ($\approx 8.8541878176 \times 10^{-12}$ F/m), and ε_w is the water's dielectric constant equal to approximately 80.1 at 20 °C. Due to the strong covalent bonds of the hydrogen and oxygen atoms in the water molecule, there are no electrons in the conduction band until they are pumped up to that energy level by applying high amplitude electric fields. If the field reaches a few megavolts/cm, pure water will undergo a dielectric *breakdown* forming an electric arc in the process. Although pure water is a very good insulator, seawater is a good electric conductor.

The disassociated salt ions in seawater cause it to be a good electric conductor at all field levels. Although electrons are the primary charge carriers in metallic conductors, the positively charged salt ions, called *cations* and negatively charged *anions*, are both charge carriers in seawater. If a source of electric potential gradient is introduced into the seawater, the cations will migrate toward the source's *cathode* (negative pole), while the anions travel toward the *anode* (positive pole). Electrochemical reactions occur at the anode, releasing electrons in the process that then flow in the source's metallic conductor to the cathode where they recombine with the cations.

The mobility of seawater ions is hampered by their interaction with water molecules as they migrate, resulting in loss of energy in the form of heat. At the engineering level, seawater can be treated as a simple conductor with an *electric conductivity* σ ranging from about 2.5 S/m in cold deep waters, and approaches 6 S/m in very warm waters. (A value of 4 S/m is typically used for open ocean seawater.) This finite conductivity attenuates electromagnetic energy as it propagates through seawater, which is categorized as a lossy medium.

Fortunately, seawater is nonmagnetic. Its *magnetic permeability* is the same as free-space given by $\mu_0 = 4\pi 10^{-7}$ H/m. This means the only way that seawater can be a source of a static magnetic field is by electric current flowing through it.

This chapter will focus on the science of electromagnetic field propagation and attenuation in seawater, and the reflection and transmission of the fields at the sea's surface. Emphasis will be placed on electromagnetic field theory in the ultralow frequency (ULF) band of ≈0 to 3 Hz, and the extremely low frequency (ELF) band from 3 Hz to 3 kHz. Since the attenuation of electromagnetic waves increases rapidly with frequency, radio frequency bands will not be covered here. Although remote observations of the sea surface from airborne and satellite-based microwave radiometers and radars are important tools for oceanographic research, they are beyond the scope of this discussion. (The interested reader should consult [8.1, pp. 405–510] on this topic.) A brief cursory discussion of ocean electromagnetics at optical wavelengths will be given at the end of this chapter.

8.2 Electromagnetic Field Theory

It is not possible to give an in-depth description of general electromagnetic field theory here. A comprehensive treatment of engineering electromagnetics is presented in [8.2]. In order to introduce some basic principles for electromagnetic fields in a lossy media such as seawater, the formulations for magnetic and electric fields in an unbounded ocean will be presented first.

All electromagnetic field theories are based on *Maxwell's equations*. In differential form, they are

$$\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t}\,, \tag{8.1}$$

$$\nabla \times \boldsymbol{H} = \boldsymbol{J} + \frac{\partial \boldsymbol{D}}{\partial t}\,, \tag{8.2}$$

$$\nabla \cdot \boldsymbol{D} = q_e\,, \tag{8.3}$$

$$\nabla \cdot \boldsymbol{B} = 0\,, \tag{8.4}$$

where $\boldsymbol{E}$ (v/m) and $\boldsymbol{H}$ (A/m) are the electric and magnetic field *intensity vectors*, $\boldsymbol{D}$ (c/m^2) and $\boldsymbol{B}$ (wb/m^2 or T) are the electric and magnetic *flux density vectors*, $\boldsymbol{J}$ (A/m^2) is the electric *current density*, q_e (c/m^3) represents the *electric charge density*, and t stands for time (seconds). Maxwell's equations by themselves are sufficient to solve any problem in electromagnetics.

Although magnetic charge and magnetic current densities are not realizable, they can be included in Maxwell's equations through the *generalized* current concept to aid mathematically in the solutions of certain problems. For example, a magnet can be represented mathematically as two opposite polarity magnetic charges at its ends. Adding the virtual magnetic sources to Maxwell's equations, and separating the current density into its impressed and conduction components, allows (8.1) through (8.4) to be written in a more symmetrical form as

$$\nabla \times \boldsymbol{E} = -\boldsymbol{M}_i - \frac{\partial \boldsymbol{B}}{\partial t}\,, \tag{8.5}$$

$$\nabla \times \boldsymbol{H} = \boldsymbol{J}_\mathrm{i} + \boldsymbol{J}_\mathrm{c} + \frac{\partial \boldsymbol{D}}{\partial t} , \tag{8.6}$$

$$\nabla \cdot \boldsymbol{D} = q_\mathrm{e} , \tag{8.7}$$

$$\nabla \cdot \boldsymbol{B} = q_\mathrm{m} , \tag{8.8}$$

where $\boldsymbol{M}_\mathrm{i}$ $(\mathrm{v/m^2})$ is the *impressed magnetic current density*, $\boldsymbol{J}_\mathrm{i}$ $(\mathrm{A/m^2})$ is the *impressed electric current density* produced by an active source, $\boldsymbol{J}_\mathrm{c}$ is the *conduction current* density flowing in the media, and the equivalent *magnetic charge density* is represented as q_m $(\mathrm{wb/m^3})$. The symmetric form of Maxwell's equations, (8.5) through (8.8), will be used here.

The electromagnetic properties of seawater are very different than air or free space. As a result, the interaction of electromagnetic fields with the ocean is unlike that in air. The relationships between the field intensities and flux densities are related by the *constitutive parameters* of the media as given by

$$\boldsymbol{B} = \mu \boldsymbol{H} , \tag{8.9}$$

$$\boldsymbol{D} = \varepsilon \boldsymbol{E} , \tag{8.10}$$

$$\boldsymbol{J} = \sigma \boldsymbol{E} , \tag{8.11}$$

where μ, ε, and σ for seawater have been defined previously. In air, $\mu = \mu_0$, $\varepsilon = \epsilon_0$, and $\sigma = 0$.

Continuity of electric charge is an important relationship that can be derived from Maxwell's equations. The *continuity equation* is given by

$$\nabla \cdot \boldsymbol{J} = -\frac{\partial \rho}{\partial t} . \tag{8.12}$$

This expression relates how the charge in a volume changes with the current density entering or leaving it.

The first two Maxwell's equations, (8.5) and (8.6), are a set of first-order differential equations that are coupled. The first step in their solution is to uncouple them. Using (8.9)–(8.11) to rewrite (8.5)–(8.8) gives

$$\nabla \times \boldsymbol{E} = -\boldsymbol{M}_\mathrm{i} - \mu \frac{\partial \boldsymbol{H}}{\partial t} , \tag{8.13}$$

$$\nabla \times \boldsymbol{H} = \boldsymbol{J}_\mathrm{i} + \sigma \boldsymbol{E} + \varepsilon \frac{\partial \boldsymbol{E}}{\partial t} , \tag{8.14}$$

$$\nabla \cdot \boldsymbol{E} = \frac{q_\mathrm{e}}{\varepsilon} , \tag{8.15}$$

$$\nabla \cdot \boldsymbol{H} = \frac{q_\mathrm{m}}{\mu} . \tag{8.16}$$

Taking the curl of both sides of (8.13) and (8.14) produces

$$\nabla \times \nabla \times \boldsymbol{E} = -\nabla \times \boldsymbol{M}_\mathrm{i} - \mu \frac{\partial}{\partial t} (\nabla \times \boldsymbol{H}) , \tag{8.17}$$

$$\nabla \times \nabla \times \boldsymbol{H} = \nabla \times \boldsymbol{J}_\mathrm{i} + \sigma \nabla \times \boldsymbol{E} + \varepsilon \frac{\partial}{\partial t} (\nabla \times \boldsymbol{E}) . \tag{8.18}$$

Substituting (8.14) into the right-hand side of (8.17), and using the vector identity $\nabla \times \nabla \times \boldsymbol{A} = \nabla \cdot (\nabla \cdot \boldsymbol{A}) - \nabla^2 \boldsymbol{A}$ on the left-hand side, gives

$$\nabla (\nabla \cdot \boldsymbol{E}) - \nabla^2 \boldsymbol{E} = -\nabla \times \boldsymbol{M}_\mathrm{i} - \mu \frac{\partial \boldsymbol{J}_\mathrm{i}}{\partial t} - \mu\sigma \frac{\partial \boldsymbol{E}}{\partial t} - \mu\varepsilon \frac{\partial^2 \boldsymbol{E}}{\partial t^2} . \tag{8.19}$$

Using (8.15), (8.19) can be rewritten as

$$\nabla^2 \boldsymbol{E} = \nabla \times \boldsymbol{M}_\mathrm{i} + \frac{1}{\varepsilon} \nabla q_\mathrm{e} + \mu \frac{\partial \boldsymbol{J}_\mathrm{i}}{\partial t} + \mu\sigma \frac{\partial \boldsymbol{E}}{\partial t} + \mu\varepsilon \frac{\partial^2 \boldsymbol{E}}{\partial t^2} . \tag{8.20}$$

This is an uncoupled second-order differential equation for $\boldsymbol{E}$.

The same process can be applied to obtain an uncoupled second-order differential equation for $\boldsymbol{H}$. Substituting (8.13) into the right-hand side of (8.18) and using the vector identity from the above on the left-hand side results in

$$\nabla (\nabla \cdot \boldsymbol{H}) - \nabla^2 \boldsymbol{H} = \nabla \times \boldsymbol{J}_\mathrm{i} - \sigma \boldsymbol{M}_\mathrm{i} - \varepsilon \frac{\partial \boldsymbol{M}_\mathrm{i}}{\partial t} - \mu\sigma \frac{\partial \boldsymbol{H}}{\partial t} - \mu\varepsilon \frac{\partial^2 H}{\partial t^2} . \tag{8.21}$$

Substituting (8.16) into (8.21) and reducing gives

$$\nabla^2 \boldsymbol{H} = -\nabla \times \boldsymbol{J}_\mathrm{i} + \sigma \boldsymbol{M}_\mathrm{i} + \frac{1}{\mu} \nabla q_\mathrm{m} + \varepsilon \frac{\partial \boldsymbol{M}_\mathrm{i}}{\partial t} + \mu\sigma \frac{\partial \boldsymbol{H}}{\partial t} + \mu\varepsilon \frac{\partial^2 \boldsymbol{H}}{\partial t^2} . \tag{8.22}$$

Equations (8.20) and (8.22) are vector wave equations for $\boldsymbol{E}$ and $\boldsymbol{H}$.

Only time-harmonic electromagnetic fields will be considered here. Time-harmonic fields can be represented by the real part of $\mathrm{e}^{\mathrm{i}\omega t}$, where ω is the angular frequency given by $2\pi f$, f is the linear frequency of the electromagnetic wave in hertz (Hz), and $i = \sqrt{-1}$. Since it is understood that $\mathrm{e}^{\mathrm{i}\omega t}$ appears in each term of Maxwell's equations, in can be dropped from the notation, allowing (8.5) through (8.8) to be rewritten as

$$\nabla \times \boldsymbol{E} = -\boldsymbol{M}_\mathrm{i} - \mathrm{i}\omega\mu \boldsymbol{H} , \tag{8.23}$$

$$\nabla \times \boldsymbol{H} = \boldsymbol{J}_\mathrm{i} + \boldsymbol{J}_\mathrm{c} + \mathrm{i}\omega\varepsilon \boldsymbol{E} , \tag{8.24}$$

$$\nabla \cdot \boldsymbol{E} = \frac{q_\mathrm{e}}{\varepsilon} , \tag{8.25}$$

$$\nabla \cdot \boldsymbol{H} = \frac{q_\mathrm{m}}{\mu} , \tag{8.26}$$

while the time-harmonic vector wave equations become

$$\nabla^2 \boldsymbol{E} = \nabla \times \boldsymbol{M}_\mathrm{i} + \frac{1}{\varepsilon}\nabla q_\mathrm{e} + \mathrm{i}\omega\mu \boldsymbol{J}_\mathrm{i} + \mathrm{i}\omega\mu\sigma \boldsymbol{E} - \omega^2 \mu\varepsilon \boldsymbol{E} \,, \tag{8.27}$$

$$\nabla^2 \boldsymbol{H} = -\nabla \times \boldsymbol{J}_\mathrm{i} + \sigma \boldsymbol{M}_\mathrm{i} + \frac{1}{\mu}\nabla q_\mathrm{m} + \mathrm{i}\omega\varepsilon \boldsymbol{M}_\mathrm{i} + \mathrm{i}\omega\mu\sigma \boldsymbol{H} - \omega^2 \mu\varepsilon \boldsymbol{H} \,. \tag{8.28}$$

Although $\boldsymbol{J}_\mathrm{i}$ and q_e can represent either real or virtual sources, $\boldsymbol{M}_\mathrm{i}$ and q_m are only virtual. In a source free region, $\boldsymbol{J}_\mathrm{i} = q_\mathrm{e} = 0$ and $\boldsymbol{M}_\mathrm{i} = q_\mathrm{m} = 0$, so that (8.27) and (8.28) reduce to the homogenous form of the wave equation

$$\nabla^2 \boldsymbol{E} - \gamma^2 \boldsymbol{E} = 0 \,, \tag{8.29}$$

$$\nabla^2 \boldsymbol{H} - \gamma^2 \boldsymbol{H} = 0 \,, \tag{8.30}$$

where

$$\gamma^2 = \mathrm{i}\omega\mu\sigma - \omega^2\mu\varepsilon \,. \tag{8.31}$$

Equations (8.29) and (8.30) describe electromagnetic waves traveling in a lossy medium with a propagation constant given by γ.

The last equations needed to completely define electromagnetic fields in the ocean are boundary conditions. Boundary conditions describe how the fields respond at an interface formed between two media of different constitutive properties, such as at the sea surface and seafloor. In this case, air is nonconducting with a permittivity and permeability the same as free space, while seawater is conductive with a high permittivity. Although the seafloor is conductive, its effective conductivity is one to four orders of magnitude less than the ocean's; depending on the depth the fields propagate below the bottom.

The generalized boundary conditions are well known. Their detailed derivation from Maxwell's equations can be found in [8.2]. Let the unit normal at the interface between two different media be given by $\hat{n}$ and pointing into the second region. Let the fields in media 1 and 2 be given by $\boldsymbol{E}_1$, $\boldsymbol{H}_1$, $\boldsymbol{D}_1$, $\boldsymbol{B}_1$ and $\boldsymbol{E}_2$, $\boldsymbol{H}_2$, $\boldsymbol{D}_2$, $\boldsymbol{B}_2$, respectively. Then the boundary conditions at the interface between them are

$$-\hat{n} \times (\boldsymbol{E}_2 - \boldsymbol{E}_1) = \boldsymbol{M}_\mathrm{s} \,, \tag{8.32}$$

$$\hat{n} \times (\boldsymbol{H}_2 - \boldsymbol{H}_1) = \boldsymbol{J}_\mathrm{s} \,, \tag{8.33}$$

$$\hat{n} \cdot (\boldsymbol{D}_2 - \boldsymbol{D}_1) = q_\mathrm{es} \,, \tag{8.34}$$

$$\hat{n} \cdot (\boldsymbol{B}_2 - \boldsymbol{B}_1) = q_\mathrm{ms} \,, \tag{8.35}$$

where $\boldsymbol{M}_\mathrm{s}$ and $\boldsymbol{J}_\mathrm{s}$ are the linear magnetic and electric surface currents along the boundary, and q_es and q_ms are the linear surface charge densities on the boundary. Although $\boldsymbol{M}_\mathrm{s}$ and q_ms are virtual boundary sources, they do arise in equivalent source representations of the fields within a closed region.

8.3 Plane Wave Propagation

The homogenous wave (8.29) and (8.30) can be solved in any of the separable coordinate systems. Their solution in rectangular coordinates will result in the expressions for plane waves. Using the method of separation of variables, the solution to (8.29) and (8.30) for a wave traveling along the positive z-axis is

$$\boldsymbol{E} = \boldsymbol{E}_0 \mathrm{e}^{-\gamma z} \,, \tag{8.36}$$

$$\boldsymbol{H} = \boldsymbol{H}_0 \mathrm{e}^{-\gamma z} \,, \tag{8.37}$$

where $\boldsymbol{E}_0$ and $\boldsymbol{H}_0$ are the amplitudes of the electric and magnetic fields. The propagation constant γ, defined by (8.31), can be written as

$$\gamma = \sqrt{\mathrm{i}\omega\mu(\sigma + \mathrm{i}\omega\varepsilon)} \,, \tag{8.38a}$$

$$\gamma = \alpha + \mathrm{i}\beta \,, \tag{8.38b}$$

and α is the attenuation constant in Np/m, and β is the phase constant in rad/m. If the waves were traveling in the negative z direction, then z in (8.36) and (8.37) would be replaced by $-z$. Solutions to the homogenous wave equation in cylindrical and spherical coordinates are derived in [8.2, pp. 12–18].

The electric and magnetic fields in (8.36) and (8.37) are linked through Maxwell's equations. For a source-free region, (8.24) can be written as

$$\boldsymbol{E} = \frac{1}{\sigma + \mathrm{i}\omega\varepsilon} \nabla \times \boldsymbol{H} \,. \tag{8.39}$$

If the magnetic field vector $\boldsymbol{H}$ in (8.39) has only an x component, given by H_x, taking its curl and substituting it in (8.36) gives

$$E_\mathrm{y} = \frac{-\gamma}{\sigma + \mathrm{i}\omega\varepsilon} H_\mathrm{x} \,. \tag{8.40}$$

Substituting (8.38a) into (8.40) and reducing gives

$$E_\mathrm{y} = -\eta H_\mathrm{x} \,, \tag{8.41}$$

where

$$\eta = \sqrt{\frac{\mathrm{i}\omega\mu}{\sigma + \mathrm{i}\omega\varepsilon}} \,. \tag{8.42}$$

The term η is called the *intrinsic impedance* of the medium and has the units of Ω. For a plane wave, the orthogonal electric and magnetic field components perpendicular to the propagation direction are related by the media's impedance.

In this section, only the ULF and ELF bands will be considered. Using the seawater dielectric permittivity constant from above, $\omega\varepsilon$ at the high end of the ELF band (3 kHz) is equal to $\approx 1.337\times10^{-5}$, which is much less than the water conductivity of 2.5 to 6. Therefore, the $\mathrm{i}\omega\varepsilon$ term will be dropped for electromagnetic frequencies up through the ELF band. In fact, displacement currents in seawater do not become appreciable until frequencies approach the high megahertz region.

At ELF frequencies and below, the seawater's attenuation constant is equal to its phase constant. Eliminating the $\mathrm{i}\omega\varepsilon$ in (8.38) gives

$$\gamma = \sqrt{\mathrm{i}\omega\mu\sigma}\,, \tag{8.43a}$$

$$\gamma = \sqrt{\frac{\omega\mu\sigma}{2}}(1+\mathrm{i})\,, \tag{8.43b}$$

$$\alpha = \beta = \sqrt{\frac{\omega\mu\sigma}{2}}\,. \tag{8.43c}$$

The distance at which the wave attenuates to e^{-1} is called the skin depth, and is denoted by the term δ. The skin depth is the reciprocal of the attenuation constant, $\delta = \frac{1}{\alpha}$, which for seawater is

$$\delta = \sqrt{\frac{2}{\omega\mu\sigma}}\,. \tag{8.44}$$

The field's wavelength λ is related to the propagation by $\lambda = \frac{2\pi}{\beta}$, and in this case can be written as

$$\lambda = 2\pi\sqrt{\frac{2}{\omega\mu\sigma}}\,, \tag{8.45}$$

while the speed of an electromagnetic wave v, is equal to $f\lambda$, and in seawater is given by

$$v = \sqrt{\frac{2\omega}{\mu\sigma}}\,. \tag{8.46}$$

Finally, the intrinsic impedance of seawater at ELF frequencies and below is expressed as

$$\eta = \sqrt{\frac{\mathrm{i}\omega\mu}{\sigma}}\,. \tag{8.47}$$

In the ocean, an electromagnetic wave's skin depth and wavelength is inversely proportional to the square root of its frequency, while its speed and intrinsic impedance is directly proportional to it.

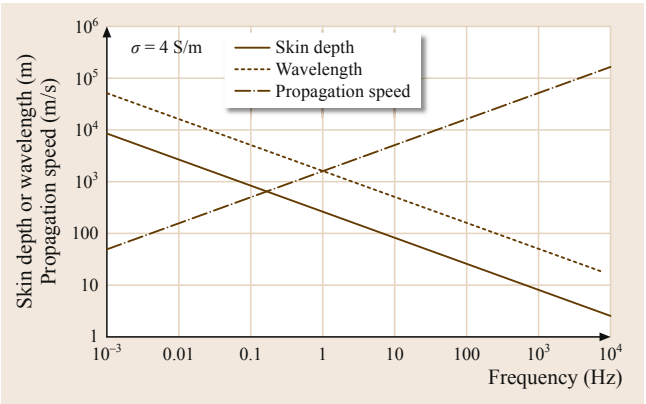

Fig. 8.1 Propagation characteristics of an electromagnetic wave in seawater

The characteristics of a propagating electromagnetic wave in the ocean are quite different than in air. In free space, the propagation speed of an electromagnetic field is always the same as that of light c (3×10^8 m/s), regardless of its frequency. This is not the case in the ocean. The skin depth, wavelength, and propagation speed given by (8.44) through (8.46) are plotted in Fig. 8.1 over the frequency range from 1 mHz to 10 kHz, using a seawater conductivity of 4 S/m. At 1 Hz, the skin depth is 252 m, while the wavelength and propagation speed are 1581 m and 1581 m/s. The propagation speed of electromagnetic fields in seawater at 1 Hz is more than 5 orders of magnitude slower than in air, and is approximately equal to the speed of sound in the ocean!

The intrinsic impedance of seawater is much smaller than free space. In air, η can be computed from (8.42) by setting $\sigma = 0$. This results in a free space impedance of 377 Ω, and is independent of frequency. Conversely, the intrinsic impedance of seawater

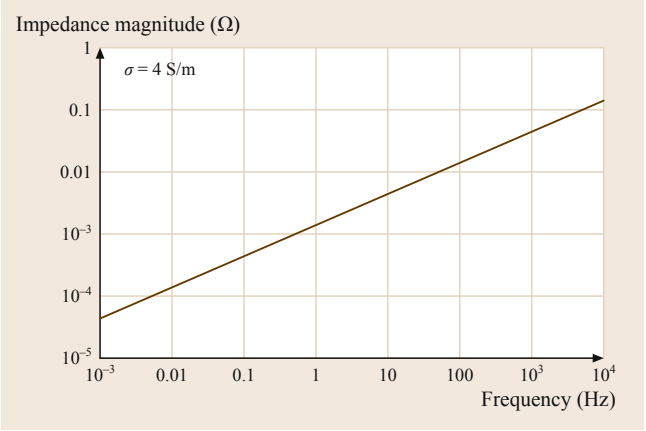

Fig. 8.2 Magnitude of the intrinsic impedance of seawater as a function of frequency

is $1.405\times10^{-3}(1+\mathrm{i})\,\Omega$ at 1 Hz. The magnitude of (8.47) has been plotted in Fig. 8.2 for the same parameters as above. As will be shown later, the difference in impedances between air and the ocean will significantly affect the reflection and transmission of electromagnetic fields at the sea surface.

As the frequency of the electromagnetic wave increases, so does its velocity. At the top end of the ELF band, an electromagnetic field propagates more than 100 times faster than sound, but the skin depth decreases to less than 3 m. For this reason, underwater electromagnetic communication systems for short distance wireless data transfers are preferred over acoustic modems. In addition, the rapid attenuation of electromagnetic fields in the ocean can be exploited to reduce interference from nearby transmitters, and for covert underwater communications systems that must avoid long range detection.

Another advantage of ULF and ELF electromagnetic fields is their ability to cross the air–ocean boundary. The description of plane wave transmission from air into conducting seawater is more complex than for fresh water. Therefore, the formulation of the *reflection and transmission coefficients* at the sea surface will begin with that of a plane wave incident on fresh water, such as a lake.

8.4 Reflection and Transmission of a Plane Wave at the Surface of Fresh Water

The reflection and transmission coefficients of a plane wave at the surface of fresh water depend on the polarization of the incident field. If the electric field vector of the incident uniform plane wave is perpendicular to the plane of incidence as shown in Fig. 8.3, then the wave is said to have a *perpendicular polarization* or *horizontal polarization*. Using the coordinate system and geometry of Fig. 8.3, the incident perpendicular polarized electric $\boldsymbol{E}^{\mathrm{i}}_{\perp}$ and magnetic $\boldsymbol{H}^{\mathrm{i}}_{\perp}$ field of a uniform plane wave can be written as

$$\boldsymbol{E}^{\mathrm{i}}_{\perp} = \hat{a}_{\mathrm{y}} E_0 \mathrm{e}^{-\mathrm{i}\beta_{\mathrm{a}}(x\sin\theta_{\mathrm{i}}+z\cos\theta_{\mathrm{i}})}\,, \tag{8.48}$$

$$\boldsymbol{H}^{\mathrm{i}}_{\perp} = (-\hat{a}_{\mathrm{x}}\cos\theta_{\mathrm{i}} + \hat{a}_{\mathrm{z}}\sin\theta_{\mathrm{i}}) \frac{E_0}{\eta_{\mathrm{a}}}\mathrm{e}^{-\mathrm{i}\beta_{\mathrm{a}}(x\sin\theta_{\mathrm{i}}+z\cos\theta_{\mathrm{i}})}\,, \tag{8.49}$$

where E_0 is the amplitude of the incident electric field, β_{a} is the propagation constant for the incident wave in air, η_{a} is the intrinsic impedance of air (377 Ω), θ_{i} is the incidence angle with respect to the vertical, and $\hat{a}_{\mathrm{x}}$, $\hat{a}_{\mathrm{y}}$, $\hat{a}_{\mathrm{z}}$ are the unit vectors in their respective directions. The relationship between the electric and magnetic field components for a uniform plane wave given by (8.41) was used to arrive at (8.49). Similarly, the reflected electric $\boldsymbol{E}^{\mathrm{r}}_{\perp}$ and magnetic $\boldsymbol{H}^{\mathrm{r}}_{\perp}$ plane waves are given by

$$\boldsymbol{E}^{\mathrm{r}}_{\perp} = \hat{a}_{\mathrm{y}}\Gamma_{\perp}E_0\mathrm{e}^{-\mathrm{i}\beta_{\mathrm{a}}(x\sin\theta_{\mathrm{r}}-z\cos\theta_{\mathrm{r}})}\,, \tag{8.50}$$

$$\boldsymbol{H}^{\mathrm{r}}_{\perp} = (\hat{a}_{\mathrm{x}}\cos\theta_{\mathrm{r}} + \hat{a}_{\mathrm{z}}\sin\theta_{\mathrm{r}}) \times \frac{\Gamma_{\perp}E_0}{\eta_{\mathrm{a}}}\mathrm{e}^{-\mathrm{i}\beta_{\mathrm{a}}(x\sin\theta_{\mathrm{r}}-z\cos\theta_{\mathrm{r}})}\,, \tag{8.51}$$

where $\Gamma_{\perp}$ is the reflection coefficient for a perpendicular polarized wave, and θ_{r} is the angle of the reflected wave with respect to the vertical. Finally, the transmitted electric $\boldsymbol{E}^{\mathrm{t}}_{\perp}$ and magnetic $\boldsymbol{H}^{\mathrm{t}}_{\perp}$ field can be expressed as

$$\boldsymbol{E}^{\mathrm{t}}_{\perp} = \hat{a}_{\mathrm{y}}T_{\perp}E_0\mathrm{e}^{-\mathrm{i}\beta_{\mathrm{f}}(x\sin\theta_{\mathrm{t}}+z\cos\theta_{\mathrm{t}})}\,, \tag{8.52}$$

$$\boldsymbol{H}^{\mathrm{t}}_{\perp} = (-\hat{a}_{\mathrm{x}}\cos\theta_{\mathrm{t}} + \hat{a}_{\mathrm{z}}\sin\theta_{\mathrm{t}}) \times \frac{T_{\perp}E_0}{\eta_{\mathrm{f}}}\mathrm{e}^{-\mathrm{i}\beta_{\mathrm{f}}(x\sin\theta_{\mathrm{t}}+z\cos\theta_{\mathrm{t}})}\,, \tag{8.53}$$

where $T_{\perp}$ is the transmission coefficient for a perpendicular polarized wave, and θ_{t} is the angle of the transmitted wave or *refraction angle* with respect to the vertical, and β_{f} and η_{f} are the propagation constant and intrinsic impedance of freshwater, respectively.

Equations (8.48)–(8.53) can be related through the boundary conditions of the continuity of the horizontal components of the electric and magnetic fields at the surface of the water. Since there are no sources at the air–water interface, $\boldsymbol{M}_{\mathrm{s}}$ and $\boldsymbol{J}_{\mathrm{s}}$ in (8.32) and (8.33)

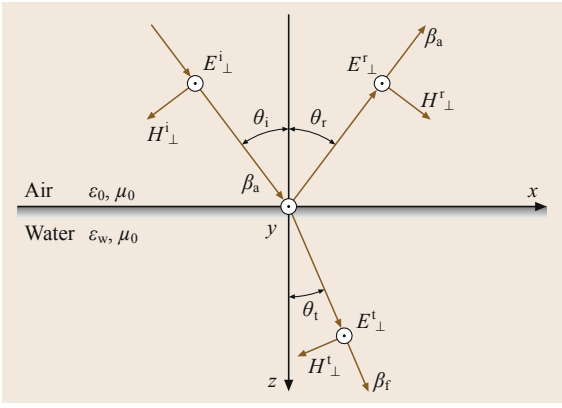

Fig. 8.3 Plane wave incident on the surface of fresh water, perpendicular polarization

are set to zero. Applying these boundary conditions to (8.48)–(8.53) at z = 0 gives

$$e^{-i\beta_a x \sin\theta_i} + \Gamma_\perp e^{-i\beta_a x \sin\theta_r} = T_\perp e^{-i\beta_f x \sin\theta_t} , \quad (8.54)$$

$$\frac{1}{\eta_a}\left(-\cos\theta_i e^{-i\beta_a x \sin\theta_i} + \cos\theta_r \Gamma_\perp e^{-i\beta_a x \sin\theta_r}\right) = -\frac{T_\perp}{\eta_f}\cos\theta_t e^{-i\beta_f x \sin\theta_t} . \quad (8.55)$$

Equations (8.54) and (8.55) are sufficient to solve for θ_r, θ_t, $\Gamma_\perp$, and $T_\perp$.

Breaking (8.54) and (8.55) into their real and imaginary parts will produce four equations with which to solve for the four unknowns. Following this procedure results in the relationships between the incident, reflected, and transmission angles given by

$$\theta_r = \theta_i , \quad (8.56a)$$

$$\beta_a \sin\theta_i = \beta_f \sin\theta_t . \quad (8.56b)$$

Equations (8.56a) and (8.56b) are called *Snell's laws* of reflection and refraction, respectively. Placing (8.56a) and (8.56b) into (8.54) and (8.55) and solving for the reflection and transmission coefficients produces the expressions

$$\Gamma_\perp = \frac{\boldsymbol{E}^r_\perp}{\boldsymbol{E}^i_\perp} = \frac{\eta_f \cos\theta_i - \eta_a \cos\theta_t}{\eta_f \cos\theta_i + \eta_a \cos\theta_t} , \quad (8.57)$$

$$T_\perp = \frac{\boldsymbol{E}^t_\perp}{\boldsymbol{E}^i_\perp} = \frac{2\eta_f \cos\theta_i}{\eta_f \cos\theta_i + \eta_a \cos\theta_t} . \quad (8.58)$$

Because air and water are both nonmagnetic (8.57) and (8.58) can be reduced to

$$\Gamma_\perp = \frac{\cos\theta_i - \sqrt{\varepsilon_w} cos\theta_t}{\cos\theta_i + \sqrt{\varepsilon_w}\cos\theta_t} , \quad (8.59)$$

$$T_\perp = \frac{2\cos\theta_i}{\cos\theta_i + \sqrt{\varepsilon_w}\cos\theta_t} , \quad (8.60)$$

where ε_w is the dielectric constant of water defined previously as 80.1.

A similar procedure is used to obtain the reflection and transmission coefficients for a uniform plane wave that has a *parallel polarization* incident on the surface of fresh water. A wave of this type also referred to as having a *vertical polarization* has an electric field that is parallel to the plane of incidence as shown in Fig. 8.4. Using the coordinate system and geometry of Fig. 8.4, the incident parallel polarized electric $\boldsymbol{E}^i_\parallel$ and magnetic $\boldsymbol{H}^i_\parallel$ field of a uniform plane wave can be written as

$$\boldsymbol{E}^i_\parallel = (\hat{a}_x \cos\theta_i - \hat{a}_z \sin\theta_i) E_0 e^{-i\beta_a(x\sin\theta_i + z\cos\theta_i)} , \quad (8.61)$$

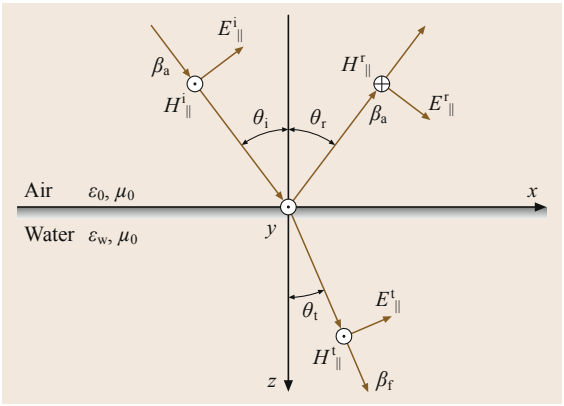

Fig. 8.4 Plane wave incident on the surface of fresh water, parallel polarization

$$\boldsymbol{H}^i_\parallel = \hat{a}_y \frac{E_0}{\eta_a} e^{-i\beta_a(x\sin\theta_i + z\cos\theta_i)} . \quad (8.62)$$

Similarly, the reflected electric $\boldsymbol{E}^r_\parallel$ and magnetic $\boldsymbol{H}^r_\parallel$ plane waves are given by

$$\boldsymbol{E}^r_\parallel = (\hat{a}_x \cos\theta_r + \hat{a}_z \sin\theta_r)\Gamma_\parallel E_0 e^{-i\beta_a(x\sin\theta_r - z\cos\theta_r)} , \quad (8.63)$$

$$\boldsymbol{H}^r_\parallel = -\hat{a}_y \frac{\Gamma_\parallel E_0}{\eta_a} e^{-i\beta_a(x\sin\theta_r - z\cos\theta_r)} , \quad (8.64)$$

and the transmitted electric $\boldsymbol{E}^t_\parallel$ and magnetic $\boldsymbol{H}^t_\parallel$ plane waves are

$$\boldsymbol{E}^t_\parallel = (\hat{a}_x \cos\theta_t - \hat{a}_z \sin\theta_t) T_\parallel E_0 e^{-i\beta_f(x\sin\theta_t + z\cos\theta_t)} , \quad (8.65)$$

$$\boldsymbol{H}^t_\parallel = \hat{a}_y \frac{T_\parallel E_0}{\eta_f} e^{-i\beta_f(x\sin\theta_t + z\cos\theta_t)} , \quad (8.66)$$

where $\Gamma_\parallel$ and $T_\parallel$ represent the reflection and transmission coefficients for a parallel polarized incident wave, respectively. All other parameters have been defined previously.

The analysis proceeds in the same manner as used for the perpendicular polarized waves. Applying the continuity boundary conditions for the tangential components of the electric and magnetic fields at the air–water interface ($z = 0$) give the equations

$$\cos\theta_i e^{-i\beta_a x \sin\theta_i} + \cos\theta_r \Gamma_\parallel e^{-i\beta_a x \sin\theta_r} = \cos\theta_t T_\parallel e^{-i\beta_f x \sin\theta_t} , \quad (8.67)$$

$$\frac{1}{\eta_a}\left(e^{-i\beta_a x \sin\theta_i} - \Gamma_\parallel e^{-i\beta_a x \sin\theta_r}\right) = \frac{T_\parallel}{\eta_f} e^{-i\beta_f x \sin\theta_t} . \quad (8.68)$$

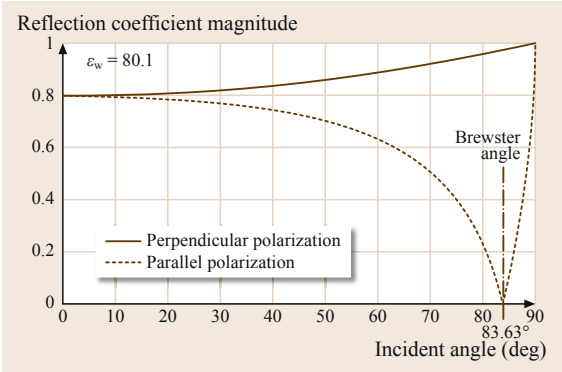

Fig. 8.5 Reflection coefficients for a perpendicular and parallel polarized uniform plane wave incident on the surface of fresh water

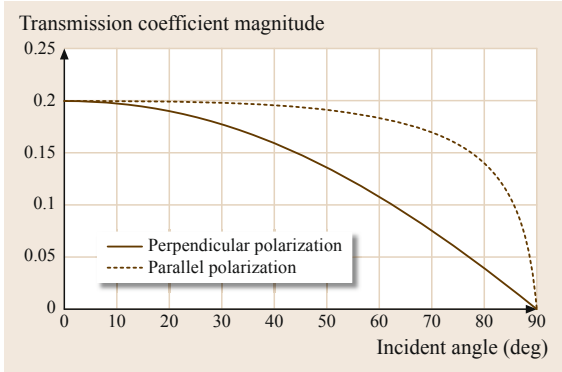

Fig. 8.6 Transmission coefficients for a perpendicular and parallel polarized uniform plane wave incident on the surface of fresh water

Once again, equating the real and imaginary parts of (8.67) and (8.68) will yield Snell's laws of reflection and refraction (8.56a) and (8.56b), along with the reflection and transmission coefficients for parallel polarization written as

$$\Gamma_{\parallel} = \frac{\boldsymbol{E}^{\mathrm{r}}_{\parallel}}{\boldsymbol{E}^{\mathrm{i}}_{\parallel}} = \frac{-\eta_{\mathrm{a}} \cos\theta_{\mathrm{i}} + \eta_{\mathrm{f}} \cos\theta_{\mathrm{t}}}{\eta_{\mathrm{a}} \cos\theta_{\mathrm{i}} + \eta_{\mathrm{f}} \cos\theta_{\mathrm{t}}} , \tag{8.69}$$

$$T_{\parallel} = \frac{\boldsymbol{E}^{\mathrm{t}}_{\parallel}}{\boldsymbol{E}^{\mathrm{i}}_{\parallel}} = \frac{2\eta_{\mathrm{f}} \cos\theta_{\mathrm{i}}}{\eta_{\mathrm{a}} \cos\theta_{\mathrm{i}} + \eta_{\mathrm{f}} \cos\theta_{\mathrm{t}}} . \tag{8.70}$$

For the interface between air and fresh water, (8.69) and (8.70) reduce to

$$\Gamma_{\parallel} = \frac{-\sqrt{\epsilon}_{\mathrm{w}} \cos\theta_{\mathrm{i}} + \cos\theta_{\mathrm{t}}}{\sqrt{\epsilon}_{\mathrm{w}} \cos\theta_{\mathrm{i}} + \cos\theta_{\mathrm{t}}} , \tag{8.71}$$

$$T_{\parallel} = \frac{2\cos\theta_{\mathrm{i}}}{\sqrt{\epsilon}_{\mathrm{w}} \cos\theta_{\mathrm{i}} + \cos\theta_{\mathrm{t}}} . \tag{8.72}$$

Although (8.59) and (8.60) are similar in form to (8.71) and (8.72), a simple example will highlight the differences.

The reflection and transmission coefficients for perpendicular and parallel polarizations were evaluated for a plane wave incident on the surface of fresh water with a dielectric constant of 80.1. Using Snell's law of refraction (8.56) at the air–water interface, the $\cos\theta_{\mathrm{t}}$ term in (8.59), (8.60), (8.71), and (8.72) can be computed from

$$\cos\theta_{\mathrm{t}} = \sqrt{1 - \frac{1}{\varepsilon_{\mathrm{w}}} \sin^2\theta_{\mathrm{i}}} . \tag{8.73}$$

The magnitudes of $\Gamma_{\perp}$ and $\Gamma_{\parallel}$ are plotted in Fig. 8.5 for all incidence angles from 0 to 90°, while $T_{\perp}$, and $T_{\parallel}$ are similarly plotted in Fig. 8.6. Interestingly, $\Gamma_{\parallel}$ goes through zero at an angle of 83.63°. This angle is called the *Brewster angle* for which there is no reflection from the water's surface. The Brewster angle only exists for incident plane waves that have parallel polarization.

8.5 Plane Wave Incident on Seawater

The general forms of the reflection and transmission coefficients computed for fresh water are also valid when the wave is incident on the surface of the electrically conducting ocean. In this case, the intrinsic impedance of fresh water η_{f} used in (8.57), (8.58), (8.69), and (8.70) is replaced with that of seawater η_{s} given by (8.47). Since η_{s} is a complex impedance with both real and imaginary parts, $\Gamma_{\perp}$, $T_{\perp}$, $\Gamma_{\parallel}$, and $T_{\parallel}$ will all be complex. This means that both the amplitude and phase of the reflected and transmitted fields will be modified by the ocean's surface.

The most dramatic effect of the sea surface on a uniform plane wave is its impact on the transmitted field's propagation characteristics. Rewriting Snell's law of refraction (8.56b) for seawater gives

$$\mathrm{i}\beta_{\mathrm{a}} \sin\theta_{\mathrm{i}} = \gamma \sin\theta_{\mathrm{t}} , \tag{8.74}$$

where γ has both a real and imaginary part given by (8.43c). In this case, the $\sin\theta_{\mathrm{t}}$ term in (8.74) can be expressed as

$$\sin\theta_{\mathrm{t}} = \frac{\mathrm{i}\beta_{\mathrm{a}}}{\alpha + \mathrm{i}\beta} \sin\theta_{\mathrm{i}} . \tag{8.75}$$

Using (8.75) and the identity $\cos\theta_t = \sqrt{1-\sin^2\theta_t}$, the term $\cos\theta_t$ becomes

$$\cos\theta_t = \sqrt{1-\left(\frac{i\beta_a}{\alpha+i\beta}\right)^2 \sin^2\theta_i}\,, \tag{8.76}$$

which can be reduced to a general form of

$$\cos\theta_t = s e^{i\xi}\,. \tag{8.77}$$

It is clear that the wave transmitted into the sea will be at an angle that is complex. The idea of a real and imaginary transmission angle needs further explanation.

The electric field for a perpendicular or parallel polarized field transmitted into seawater, (8.52) or (8.65), can be written in a general form given by

$$\boldsymbol{E}^t = \boldsymbol{E}_0^t e^{-\gamma(x\sin\theta_t + z\cos\theta_t)}\,, \tag{8.78}$$

that can be expanded to

$$\boldsymbol{E}^t = \boldsymbol{E}_0^t \exp[-(\alpha+i\beta)(x\sin\theta_t + z\cos\theta_t)]\,. \tag{8.79}$$

All the terms in front of the exponential in either (8.52) or (8.65) have been lumped into $\boldsymbol{E}_0^t$. Placing (8.75) and (8.77) into (8.79) gives

$$\boldsymbol{E}^t = \boldsymbol{E}_0^t \exp\left[-(\alpha+i\beta)\left(x\frac{i\beta_a}{\alpha+i\beta}\sin\theta_i + zs(\cos\xi + i\sin\xi)\right)\right], \tag{8.80}$$

and can be reduced to

$$\boldsymbol{E}^t = \boldsymbol{E}_0^t e^{-zp}\exp[-i(x\beta_a\sin\theta_i + zq)]\,, \tag{8.81}$$

where

$$p = s(\alpha\cos\xi - \beta\sin\xi)\,, \tag{8.82}$$

$$q = s(\alpha\sin\xi + \beta\cos\xi)\,. \tag{8.83}$$

The expression given by (8.81) describes a nonuniform wave.

A plane wave refracted into conducting seawater has planes of constant amplitude and phase that are not coincident. Equation (8.81) shows that the planes of constant amplitude (z = constant) are parallel to the ocean's surface as drawn in Fig. 8.7. The attenuation vector of the refracted wave is $\hat{\alpha}_s = \hat{a}_z p$, where p is the attenuation constant. To find the direction of propagation of the refracted wave, the phase term given in (8.81) is rewritten as

$$x\beta_a\sin\theta_i + zq = \beta_s(x\sin\Psi + z\cos\Psi)\,, \tag{8.84}$$

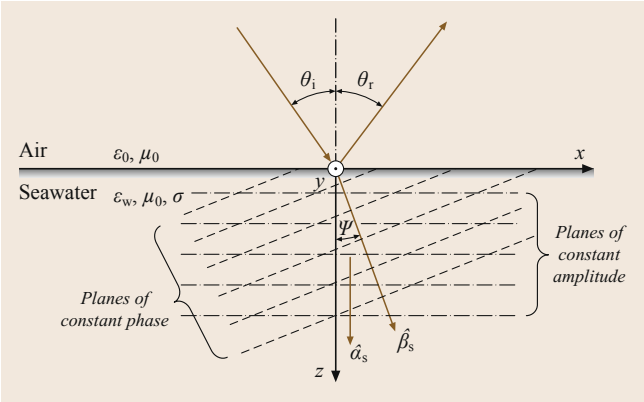

Fig. 8.7 Plane wave refracted into seawater

where

$$\beta_s = \sqrt{u^2+q^2}\,, \tag{8.85}$$

$$\sin\Psi = \frac{u}{\sqrt{u^2+q^2}}\,, \tag{8.86}$$

$$\cos\Psi = \frac{q}{\sqrt{u^2+q^2}}\,, \tag{8.87}$$

$$u = \beta_a\sin\theta_i\,. \tag{8.88}$$

The phase propagation direction for the refracted wave is $\hat{\beta}_s = \hat{a}_x\sin\Psi + \hat{a}_z\cos\Psi$, and produces planes of constant phase perpendicular to $\hat{\beta}_s$ as drawn in Fig. 8.7. The angle of refraction for the direction of propagation is determined from

$$\Psi = \tan^{-1}\left(\frac{u}{q}\right). \tag{8.89}$$

The phase velocity of the refracted wave is given by

$$v_r = \frac{\omega}{\beta_s}\,. \tag{8.90}$$

The refracted wave's attenuation, direction of propagation and velocity are all dependent on the incident angle; but to what extent? Another example is in order.

In this example, a 1 Hz plane wave is incident on the surface of the open ocean at an oblique angle θ_i. Using the intrinsic parameters for air $\sigma = 0$, μ_0, and ε_0 in (8.38) and (8.42), the free space propagation constant β_a is equal to $\frac{\omega}{c}$ (c is the speed of light in a vacuum is 3×10^8 m/s), and the intrinsic impedance of air is 377 Ω that is independent of frequency. For a seawater conductivity of 4 S/m, (8.76) can be written as

$$\cos\theta_t \approx \sqrt{1-(-i2.2\times10^{-11})\sin^2\theta_i} \approx 1$$

for all angles of incidence. This produces the values $s = 1$, $\xi = 0$, and $q = \beta$ from (8.77) and (8.83). The electromagnetic wave's angle of refraction in the ocean, given by (8.89), reduces to

$$\Psi = \tan^{-1}\left(\frac{\omega}{c\beta}\sin\theta_\mathrm{i}\right). \tag{8.91}$$

At 1 Hz, $\frac{\omega}{c\beta} = 5.27\times10^{-6}$, and the maximum angle of refraction is $\Psi_{\max} \le \tan^{-1}(5.27\times10^{-6})$ or $\Psi_{\max} \le 3\times10^{-4\circ}$ (≈ 1 s of an arc). Even at 3 kHz the refracted angle is computed to be less than 0.02°. Therefore, for frequencies up through the ELF band, a plane wave incident on the surface of the ocean at any angle will refract, propagate, and attenuate toward the bottom along a path that is nearly vertical.

The analysis presented above for a single interface can be extended to include any number of layers with different intrinsic parameters. The derivation of the iterative equation can be found in [8.2, pp. 110–120]. Plane wave reflection and transmission for multilayered ocean environments would arise when modeling depth variations of uniformly stratified seawater or seafloor conductivities.

8.6 Magnetic and Electric Dipoles in an Unbounded Ocean

Strictly speaking, plane waves do not exist in nature. They can be used to approximate an electromagnetic field that is far from its source (transmitter), or in the case where a uniform distribution of sources extend to very large distances in comparison to the receiver's range to it. An example of the latter case would be the geomagnetic fields present at the ocean's surface generated by solar-wind-induced electric currents in the ionosphere.

The two elemental sources of electromagnetic fields are the electric and magnetic point dipoles. An electric dipole source p is created by an electric current I flowing in a conductor over a linear distance l ($p = Il$), and has units of A m. A magnetic dipole m is produced if the current flows around a closed circular path that encloses an area a ($m = Ia$), and has units of A m^2. If the observation point is at a distance that is large compared to the source's dimensions, then it can be represented mathematically as an infinitesimally small or point dipole. With sources present, the time-harmonic vector wave equations, (8.27) and (8.28), are now inhomogeneous.

Although it is possible to solve for the electric and magnetic fields directly from the inhomogeneous vector wave equations, it is generally mathematically advantageous to replace them with equivalent representations in terms of the *magnetic vector potential* $\boldsymbol{A}$ and *electric vector potential* $\boldsymbol{F}$. The solutions to the inhomogeneous vector wave equations in terms of vector potentials are derived in [8.3], and can be written as

$$\boldsymbol{E} = -\mathrm{i}\omega\boldsymbol{A} + \frac{1}{\mu\sigma}\nabla(\nabla\cdot\boldsymbol{A}) - \frac{1}{\varepsilon}\nabla\times\boldsymbol{F}\,, \tag{8.92}$$

$$\boldsymbol{H} = -\mathrm{i}\omega\boldsymbol{F} + \frac{1}{\mu\sigma}\nabla(\nabla\cdot\boldsymbol{F}) + \frac{1}{\mu}\nabla\times\boldsymbol{A}\,, \tag{8.93}$$

where

$$\boldsymbol{A} = \frac{\mu}{4\pi}\iiint_V \boldsymbol{J}_\mathrm{i}\frac{\mathrm{e}^{-\gamma R}}{R}\,\mathrm{d}v'\,, \tag{8.94}$$

$$\boldsymbol{F} = \frac{\varepsilon}{4\pi}\iiint_V \boldsymbol{M}_\mathrm{i}\frac{\mathrm{e}^{-\gamma R}}{R}\,\mathrm{d}v'\,, \tag{8.95}$$

$$R = \sqrt{(x-x')^2 + (y-y')^2 + (z-z')^2}\,, \tag{8.96}$$

and the elements of the impressed electric $\boldsymbol{J}_\mathrm{i}$ and magnetic $\boldsymbol{M}_\mathrm{i}$ current densities are located at (x', y', z') with the observation point at (x, y, z). The integration is taken over the entire volume of the source.

Equations (8.92)–(8.96) are sufficient to compute the electric and magnetic fields from dipole sources. Consider first an electric point dipole of strength p located at the origin of the coordinate system shown in Fig. 8.8, and aligned along the z-axis. The impressed source's electric current density for this dipole can be represented mathematically as

$$\boldsymbol{J}_\mathrm{i} = \hat{a}_z p\delta(x')\delta(y')\delta(z')\,, \tag{8.97}$$

where the δ used here represents the Dirac delta function. Placing (8.97) into (8.94) yields the magnetic vector potential

$$A_\mathrm{z} = \frac{\mu p\mathrm{e}^{-\gamma r}}{4\pi r}\,, \tag{8.98}$$

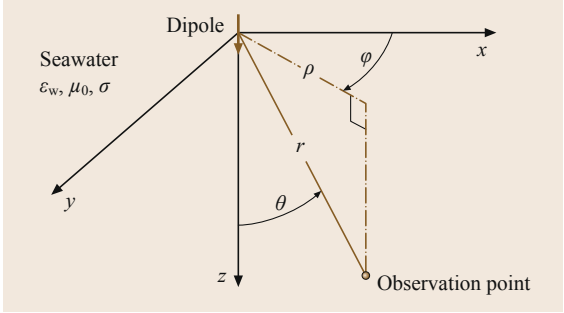

Fig. 8.8 Coordinate system for a dipole in an unbounded ocean

where r is the radial distance from the origin as shown in Fig. 8.8. Converting (8.98) to spherical coordinates and placing it into (8.92) and (8.93), the electric and magnetic fields of a point electric dipole in an unbounded ocean are written as

$$E_r = \frac{p\cos\theta}{2\pi\sigma r^3}(1+\gamma r)e^{-\gamma r}\,, \tag{8.99}$$

$$E_\theta = \frac{p\sin\theta}{4\pi\sigma r^3}(1+\gamma r+\gamma^2 r^2)e^{-\gamma r}\,, \tag{8.100}$$

$$H_\varphi = \frac{p\sin\theta}{4\pi r^2}(1+\gamma r)e^{-\gamma r}\,. \tag{8.101}$$

If the point dipole was located at coordinates (x_0, y_0, z_0) instead of the origin, then r becomes

$$\sqrt{(x-x_0)^2+(y-y_0)^2+(z-z_0)^2}\,.$$

The derivation of a magnetic point dipole follows that shown above for the electric. In this case, the magnetic point dipole has a source strength m that is also located at the origin, and is aligned along the z-axis. A dipole of this type could be produced by an electric current flowing in the φ direction of the coordinate system in Fig. 8.8. This is mathematically equivalent to a virtual magnetic current source aligned along the z-axis. Therefore, the equivalent impressed magnetic current density for this dipole can be written as

$$\boldsymbol{M}_i = \hat{a}_z m\delta(x')\delta(y')\delta(z')\,. \tag{8.102}$$

Using (8.102) in (8.95) yields the electric vector potential

$$F_z = \frac{\varepsilon m e^{-\gamma r}}{4\pi r}\,. \tag{8.103}$$

Converting (8.103) to spherical coordinates and placing it into (8.92) and (8.93), the electric and magnetic fields of a point magnetic dipole in an unbounded ocean can be written as

$$H_r = \frac{m\cos\theta}{2\pi r^3}(1+\gamma r)e^{-\gamma r}\,, \tag{8.104}$$

$$H_\theta = \frac{m\sin\theta}{4\pi r^3}(1+\gamma r+\gamma^2 r^2)e^{-\gamma r}\,, \tag{8.105}$$

$$E_\varphi = \frac{-i\omega\mu m\sin\theta}{4\pi r^2}(1+\gamma r)e^{-\gamma r}\,. \tag{8.106}$$

It should be noted that the electromagnetic fields for both the electric and magnetic dipole sources are circularly symmetric and are not a function of the φ coordinate.

The equations for the electromagnetic fields of electric and magnetic point dipoles in an unbounded ocean reduce to the standard static magnetic and electric expressions by setting the frequency in (8.99) to (8.101) and (8.104) to (8.106) to zero. Carrying this out gives the electric and magnetic fields of a static electric dipole in an unbounded ocean as

$$E_r = \frac{p\cos\theta}{2\pi\sigma r^3}\,, \tag{8.107}$$

$$E_\theta = \frac{p\sin\theta}{4\pi\sigma r^3}\,, \tag{8.108}$$

$$H_\varphi = \frac{p\sin\theta}{4\pi r^2}\,, \tag{8.109}$$

and for the static magnetic dipole (8.104) to (8.106) reduce to

$$H_r = \frac{m\cos\theta}{2\pi r^3}\,, \tag{8.110}$$

$$H_\theta = \frac{m\sin\theta}{4\pi r^3}\,, \tag{8.111}$$

$$E_\varphi = 0\,. \tag{8.112}$$

It should be noted that all electric and magnetic field components for static dipoles fall off in the radial direction as r^{-3} except for the φ component of the magnetic field of the static electric dipole, which fall off as r^{-2}, and the φ component of the electric field of the static magnetic dipole, which is zero.

Except for the zero E_φ component of the static magnetic dipole, the static and time-harmonic dipole equations differ by a factor of either $(1+\gamma r)e^{-\gamma r}$ or $(1+\gamma r+\gamma^2 r^2)e^{-\gamma r}$. The magnitude of these two multiplication factors are plotted in Fig. 8.9 as a function of the radial distance in skin depths. This data shows the range over which the electric and magnetic field equations for static sources can be used to estimate the time-harmonic fields. Depending on accuracy requirements, the static equations could be used out to distances approaching a skin depth. It is interesting that $|(1+\gamma r+\gamma^2 r^2)e^{-\gamma r}|$ is 1 at a distance equal to a half-

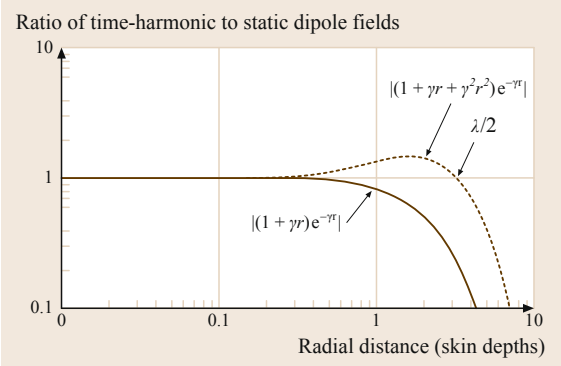

Fig. 8.9 Correction factors to convert electric and magnetic fields computed for static dipoles to those of time-harmonic sources

wavelength, as indicated in Fig. 8.9. The region in close vicinity to a time-harmonic dipole for which the static equations are sufficiently accurate is sometimes called the *quasi-DC* (direct current) range.

The equations for electric and magnetic dipoles in an unbounded ocean are sufficient if the range between the source and observation point is small in comparison to their distances from the sea surface or seafloor. If this is not the case, then reflections from one or both of the interfaces must be accounted for in the magnetic and electric field formulations. Since the dipole sources are close to an interface, simple plane wave reflection coefficients cannot be used. A more complete and, unfortunately, more complex treatment are required.

8.7 Magnetic and Electric Dipoles in a Bounded Ocean

In this section, magnetic and electric dipoles submerged in a bounded ocean will be considered. What is meant by *a bounded ocean* is that the separation between the source and observation point are comparable to their distance from either the sea surface or bottom. The change in conductivity between the seawater and air or the seafloor produces an interface that modifies the spreading and propagation of fields generated by submerged magnetic and electric sources. The effects of the interfaces are accounted for in the descriptive equations by satisfying the boundary conditions along them. Therefore, mathematical solutions to the inhomogeneous wave equations must be in a form that will easily accommodate solving for the boundary conditions when a source is near an interface.

Because of their close proximity to one of the ocean's interface, the solution to the problem of a submerged magnetic or electric dipole will also depend on their orientation with respect to the sea surface or seafloor. As a result, there are four types of dipoles that must be addressed separately when computing their electric and magnetic fields in a bounded ocean. They are; the vertical electric dipole (VED), vertical magnetic dipole (VMD), horizontal magnetic dipole (HMD), and the horizontal electric dipole (HED). The equations for the in-water fields from a subsurface time-harmonic VED in a deep ocean (only the surface interface) will be derived to demonstrate the analysis method. References will then be cited where solutions to the other source types can be found.

The geometry for a submerged vertical dipole and observation point is drawn in Fig. 8.10. As before, the air is nonconducting with free-space permittivity and permeability, while the ocean has its standard intrinsic parameters. The dipole is located on the z-axis at a depth h, with the observation point also located in the seawater at (ρ, φ, z). Although this problem can be solved in rectangular coordinates, cylindrical coordinates are employed due to the electromagnetic fields' circular symmetry about the source.

A slightly different form of the vector potential is typically used when solving the problem of dipoles in a layered medium. The alternate form is called the *Hertz* vector potential. For a VED, the electric Hertz vector potential, denoted by $\boldsymbol{\Pi}$, has only a z component and is given by

$$\Pi_z = \frac{p}{4\pi(\sigma + i\omega\epsilon)} \frac{e^{-\gamma r}}{r} , \tag{8.113}$$

where

$$r = \sqrt{\rho^2 + (z-h)^2} .$$

The general relationships between the magnetic vector potential, the electric *Hertz* vector potential, and the electric and magnetic fields are

$$\boldsymbol{A} = \mu(\sigma + i\omega\epsilon)\boldsymbol{\Pi} , \tag{8.114}$$

$$\boldsymbol{E} = -\gamma^2 \boldsymbol{\Pi} + \nabla(\nabla \cdot \boldsymbol{\Pi}) , \tag{8.115}$$

$$\boldsymbol{H} = -(\sigma + i\omega\epsilon)\nabla \times \boldsymbol{\Pi} . \tag{8.116}$$

Placing (8.113) in (8.115) and (8.116), and reducing them in cylindrical coordinates, gives

$$E_\rho = \frac{\partial^2 \Pi_z}{\partial \rho \partial z} , \tag{8.117}$$

$$E_z = -\gamma^2 \Pi_z + \frac{\partial^2 \Pi_z}{\partial z^2} , \tag{8.118}$$

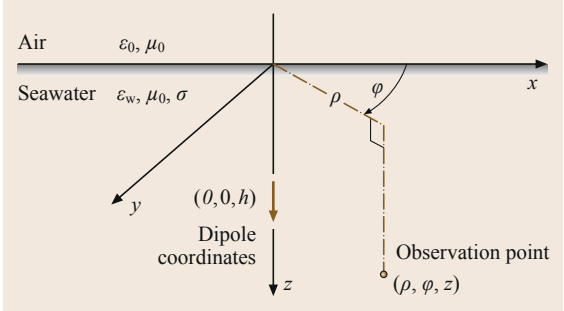

Fig. 8.10 Coordinate system for a submerged vertical dipole and submerged observation point in an electrically deep ocean

$$H_\varphi = -(\sigma + \mathrm{i}\omega\epsilon)\frac{\partial \Pi_z}{\partial \rho}\,, \tag{8.119}$$

and all other electric and magnetic field components are zero. Equations (8.113) through (8.119) apply to both the seawater and air using the appropriate constitutive parameters for each media.

The Hertz electric vector must be put in a form suitable for matching the boundary conditions at the surface interface. Using the identity

$$\frac{\mathrm{e}^{-\gamma r}}{4\pi r} = \frac{1}{4\pi}\int_0^\infty \frac{\lambda}{u}\mathrm{e}^{-u|z|}J_0(\lambda\rho)\,\mathrm{d}\lambda\,, \tag{8.120}$$

where J_0 is the Bessel function of order 0, and

$$u = (\lambda^2 + \gamma^2)^{\frac{1}{2}}\,, \tag{8.121}$$

the electric Hertz vector for a VED located at a depth h on the z-axis, (8.113), can be written as

$$\Pi_z^{(\mathrm{w})} = \frac{p}{4\pi(\sigma + \mathrm{i}\omega\varepsilon_\mathrm{w})}\int_0^\infty \frac{\lambda}{u_\mathrm{w}}\mathrm{e}^{-u_\mathrm{w}|z-h|}J_0(\lambda\rho)\,\mathrm{d}\lambda\,, \tag{8.122}$$

and the subscript and superscript, w, indicates that the constitutive parameters for seawater are to be applied. The integral representation in (8.122) can be replaced with

$$\int_0^\infty \frac{\lambda}{u_\mathrm{w}}\mathrm{e}^{-u_\mathrm{w}(z-h)}J_0(\lambda\rho)\,\mathrm{d}\lambda \quad \text{when } (z-h)\geq 0\,, \tag{8.123}$$

$$\int_0^\infty \frac{\lambda}{u_\mathrm{w}}\mathrm{e}^{u_\mathrm{w}(z-h)}J_0(\lambda\rho)\,\mathrm{d}\lambda \quad \text{when } (z-h)\leq 0\,. \tag{8.124}$$

Equations (8.120) and (8.122) are called *Hankel transforms* or *Sommerfeld integrals*.

Equation (8.122) must be modified to account for reflections from the surface interface, and an additional equation is needed to describe the transmitted fields in the air. The system of Hertz equations sufficient to solve for the electromagnetic fields in both the air $\Pi_z^{(\mathrm{a})}$ and seawater $\Pi_z^{(\mathrm{w})}$ layers are

$$\Pi_z^{(\mathrm{a})} = P_\mathrm{w}\int_0^\infty f_1(\lambda)\mathrm{e}^{u_0 z}J_0(\lambda\rho)\,\mathrm{d}\lambda \quad \text{for } z\leq 0\,, \tag{8.125}$$

$$\Pi_z^{(\mathrm{w})} = P_\mathrm{w}\int_0^\infty \frac{\lambda}{u_\mathrm{w}}\mathrm{e}^{-u_\mathrm{w}|z-h|}J_0(\lambda\rho)\,\mathrm{d}\lambda + P_\mathrm{w}\int_0^\infty f_2(\lambda)\mathrm{e}^{-u_\mathrm{w}z}J_0(\lambda\rho)\,\mathrm{d}\lambda \quad \text{for } z\geq 0\,, \tag{8.126}$$

where

$$P_\mathrm{w} = \frac{p}{4\pi\sigma}\,, \tag{8.127}$$

$$u_\mathrm{w} = (\lambda^2 + \gamma^2)^{\frac{1}{2}}\,, \tag{8.128}$$

$$u_0 = (\lambda^2 + \gamma_0^2)^{\frac{1}{2}}\,, \tag{8.129}$$

and $\gamma_0^2 = -\omega^2\mu_0\varepsilon_0$, while $\gamma^2 = \mathrm{i}\omega\mu_0\sigma$. The terms f_1 and f_2 are determined by the boundary conditions at the ocean surface.

The boundary conditions require that the tangential components of the electric and magnetic fields must be continuous across the sea surface. For this problem, E_ρ (8.117) and H_φ (8.119) are the components tangential to the interface. The continuation of these tangential field components can be expressed in terms of their electric Hertz vectors as

$$\left.\begin{aligned}\frac{\partial \Pi_z^{(\mathrm{a})}}{\partial z} &= \frac{\partial \Pi_z^{(\mathrm{w})}}{\partial z}\\ \gamma_0^2\Pi_z^{(\mathrm{a})} &= \gamma_\mathrm{w}^2\Pi_z^{(\mathrm{w})}\end{aligned}\right] \quad \text{at } z = 0\,. \tag{8.130}$$

Applying these boundary conditions results in a system of equations for f_1 and f_2 given by

$$\frac{u_0}{u_\mathrm{w}}f_1 + f_2 = \frac{\lambda}{u_\mathrm{w}}\mathrm{e}^{-u_\mathrm{w}h}\,, \tag{8.131}$$

$$\frac{\gamma_0^2}{\gamma_\mathrm{w}^2}f_1 - f_2 = \frac{\lambda}{u_\mathrm{w}}\mathrm{e}^{-u_\mathrm{w}h}\,. \tag{8.132}$$

Solving for f_1 and f_2 produces

$$f_1(\lambda) = \frac{\frac{2\lambda}{u_\mathrm{w}}\mathrm{e}^{-u_\mathrm{w}h}}{\frac{u_0}{u_\mathrm{w}} + \frac{\gamma_0^2}{\gamma_\mathrm{w}^2}}\,, \tag{8.133}$$

$$f_2(\lambda) = \frac{\lambda}{u_\mathrm{w}}\mathrm{e}^{-u_\mathrm{w}h}\left(-\frac{\frac{2u_0}{u_\mathrm{w}}}{\frac{u_0}{u_\mathrm{w}} + \frac{\gamma_0^2}{\gamma_\mathrm{w}^2}}\right). \tag{8.134}$$

Since $\gamma_0^2 \ll \gamma_\mathrm{w}^2$ for all frequencies up through the ELF band, γ_0 can be set to zero in (8.125), (8.133), and (8.134). Under these conditions, f_1 and f_2 reduce to

$$f_1(\lambda) = 2\mathrm{e}^{-u_\mathrm{w}h}\,, \tag{8.135}$$

$$f_2(\lambda) = -\frac{\lambda}{u_\mathrm{w}}\mathrm{e}^{-u_\mathrm{w}h}\,. \tag{8.136}$$

This *no-propagation* approximation for air is sometimes called the *quasi-static condition*, and should not be confused with the quasi-DC case discussed previously.

With the solutions to f_1 and f_2 in hand, (8.125) and (8.126) can be placed in (8.120) through (8.122) to compute the electric and magnetic fields above and below the sea surface. For some special cases, the field equations can be solved in the analytical form; but in general, the Sommerfeld integrals must be evaluated numerically. Unfortunately, the integrands are oscillatory and slowly damped, increasing the difficulty in their numerical integration. Special techniques have been developed to efficiently evaluate Sommerfeld-type integrals, most of which have been reviewed in [8.4].

Derivation of the more complicated equations for a VED in a shallow ocean, which includes the interface at the seafloor, follows the same procedure as shown above for the deep water analysis. In the shallow water case, a third Hertz vector is needed to describe propagation within the sea bottom, and another term must be included in (8.126) to account for reflections off the seafloor. Satisfying the boundary conditions at both the seafloor and sea surface produce four equations with four unknowns, this time f_1 through f_4. The Sommerfeld integral formulations for a VED in a three layer media can be found in [8.5], and applied to the shallow-ocean problem using the appropriate constitutive parameters.

The complementarity problem of a VMD in a deep or shallow ocean is solved in an analogous manner using a magnetic Hertz vector in place of the electric vector. The in-air fields from a time-harmonic VMD submerged in shallow water have been reported in [8.6], while the in-water fields from an airborne VMD are found in [8.7]. Because of the presence of the ocean surface and/or bottom interface, the field solutions for an HED require both horizontal and vertical electric Hertz vectors to satisfy the boundary conditions [8.8]. Although this complicates the algebra by doubling the number of boundary equations and unknowns, the Sommerfeld formulation for the in-water electric and magnetic fields from a submerged HED in shallow water have been derived, with the solution given in [8.9]. Similarly, computing the fields for an HMD in the ocean requires both the horizontal and vertical magnetic Hertz vectors. The equations for the in-air electric and magnetic fields from submerged VED, HED, and HMD sources have been complied in [8.10], while the in-water fields from these three sources located above the ocean are summarized in [8.11]. The referenced shallow water equations can be reduced to the deep-ocean case by setting the bottom conductivity equal to that of the water.

Although the electromagnetic fields from dipole sources submerged in a deep ocean have been formulated in the generalized form of Sommerfeld integrals, it is very convenient to have algebraic equations readily accessible for obtaining quick estimates; even if they are only valid for special cases. The algebraic in-water and in-air electric and magnetic field equations for VED, HED, VMD, and HMD sources submerged in a deep ocean will be presented in tabular form for a few special cases. These tabularized equations have been found to be useful as a fast and easy reference.

The coordinate system and geometry for the tabulated equations are again shown in Fig. 8.10. All sources will be located at a depth h, with the VED and VMD aligned in the positive z direction, while the HED and HMD are oriented along the positive x-axis. The planner sea surface interface is at $z = 0$. The magnetic and electric dipole source strengths will be designated as m and p, respectively.

The magnetic and electric fields for static magnetic and electric dipoles in an unbounded ocean were given previously in spherical coordinates. At times, it is more convenient to apply the formulas in the Cartesian system. For easy reference, the Cartesian field equations for a static VMD and HMD source in an unbounded ocean (no sea surface) are listed in Table 8.1. Although static magnetic sources produce no electric fields, static VED and HED dipoles create both magnetic and electric fields as given in Table 8.2 for an unbounded ocean.

If the sea surface interface is now reintroduced at $z = 0$ (Fig. 8.10), the magnetic field equations for the static VMD and HMD sources in Table 8.1 remain unchanged. These equations are valid whether the observation point is in water, air, or sea bottom. The reason is that all three media are nonmagnetic with a permeability equal to that of free-space.

The jump in conductivity at the ocean's surface does, however, affect both the electric and magnetic fields from submerged electric dipoles. Because the air is nonconducting, the electric current in the conducting seawater will stay confined within it and will not flow across the surface interface. The sea surface is equivalent to an ideal reflector of static electric current. In addition, the discontinuity in the electric current across the surface interface produces additional components of magnetic fields.

Mathematically, the effects of the sea surface on the in-water static electric fields is equivalent to placing images of the VED and HED directly above the water at a distance equal to the depth of the sources. The electric fields produced by these images are listed in Table 8.3 [8.12]. To get the total in-water static electric fields for the deep ocean case, the VED and

components in Table 8.2 yields the total in-water magnetic field for VED and HED sources submerged in a deep ocean.

For completeness, the equations for the total in-air electric fields from static VED and HED sources submerged in a deep ocean are listed in Table 8.5. The total in-air magnetic fields for the same case are found in Table 8.6. Tables 8.5 and 8.6 are the total in-air equations and are not added to any others. It should be noted that a negative value for z is to be used when computing the fields above the ocean surface. The deep ocean equations in Tables 8.3–8.6 were reduced from those found in [8.12] for a shallow sea.

The equations in Tables 8.1 through 8.6 apply for the special case where the sources are static or quasi-DC. They are valid for frequencies that correspond to seawater skin-depths that are large compared to the distance between the source and observation point, and their depths below the surface. At the other extreme, analytic equations have been formulated for the special case where the separation between the source and observation point is much greater than a seawater skin-depth and their depths. These equations were derived by taking the asymptotic limits for the Sommerfeld formulations.

The condition that the submerged source is many seawater skin-depths from the in-water observation point is equivalent to $1 \ll |\gamma\rho|$. In addition, if $\rho \gg h$ and z and the quasi-static range applies, $|\gamma_0\rho| \ll 1$, the subsurface-to-subsurface electric field equations in

Table 8.7 can be used for the four dipole types. The corresponding subsurface-to-subsurface magnetic field equations are listed in Table 8.8. These Cartesian formulations are re-arrangements of the cylindrical forms found in Table 3–16 of [8.13].

The propagation path described by the formulations in Tables 8.7 and 8.8 is quite unique. Since $1 \ll |\gamma\rho|$, the fields that travel directly from the source to the observation point or reflected off the sea-surface are significantly attenuated. Instead, the dominated propagation path is vertical to the surface, along the water–air interface, and then directly down to the observation point. The fields are attenuated in this *up-over-and-down* path only over the vertical distances between the source and surface, and from the surface to the observation point.

There are many other special cases in which analytic propagation equations can be used instead of numerically evaluating the Sommerfeld formulations. Many of the asymptotic conditions has been tabulated in [8.13]. In addition, the region between the quasi-DC and asymptotic conditions have been subdivided into ranges for which analytic formulations are been produced using *modified image theory* [8.14].

8.8 Electromagnetic Propagation in the Ocean at Optical Wavelengths

The electromagnetic constitutive parameters of seawater are not constant at microwave frequencies and higher. Indeed, if the nominal seawater ELF constitutive parameters are used to determine the electromagnetic attenuation at an optical frequency of visible blue–green light (6×10^{14} Hz), a value of 731 dB/m is computed. And yet, experimental measurements of blue–green light attenuation in clear seawater shows only 0.15 dB/m [8.15]. Obviously, the interaction of electromagnetic waves with the ocean at optical wavelengths is quite different than at low frequencies.

Although the physics of light transmission through seawater is quite involved, the discussion here will be at the engineering level, and confined to the *apparent optical properties* (AOP) of the ocean. The AOP for seawater is applicable to many problems in ocean engineering and, with the appropriate equipment, they can be measured in situ. Here, the in air optical wavelengths of interest cover the visible range from about 400 nm for violet colors to 700 nm for red.

The primary electromagnetic parameter of interest at optical wavelengths is the *specular irradiance*. The specular irradiance, designated by the term $E_{\lambda 0}$, is the band-limited power per unit area, with units of $\mathrm{W\,m^{-2}\,nm^{-1}}$. This is a measure of the scalar power density of an electromagnetic wave. The scalar power density or specular irradiance is proportional to the square of the electric or magnetic field presented in the previous sections of this chapter.

An important ocean engineering AOP is the attenuation coefficient for the specular irradiance as the light propagates through the sea. The equation describing the attenuation of optical irradiance from point r_1 to r is given by

$$E_{\lambda 0}(r) = E_{\lambda 0}(r_1)\mathrm{e}^{-\mathrm{K}_\lambda(\mathrm{r}-\mathrm{r}_1)}\,, \qquad (8.137)$$

where K_λ is the diffuse attenuation coefficient, which is a function of wavelength. Equation (8.137) is similar to that of a plane wave given in Sect. 8.3, and in fact, does not account for any spatial spreading of the light energy. The major difference is that (8.134) describes the attenuation of power instead of field amplitude, and the attenuation coefficient K_λ is quite different from the ELF values given previously for the field attenuation constant α.

The optical diffuse attenuation coefficient is a function of wavelength, and is comprised of two major components that contribute to its overall value: absorption and scattering. Although there is absorption of light due to the intrinsic or inherent properties of clear seawater, other optical absorption mechanisms found in the ocean include organic materials such as chlorophylls in phytoplankton and dissolved organic compounds called *yellow substance* or *Gelbstoffe*. In addition, the small wavelength of visible light will cause it to scatter off organic and inorganic particulates suspended in the water, adding to its attenuation. As would be expected, the optical attenuation coefficient varies with

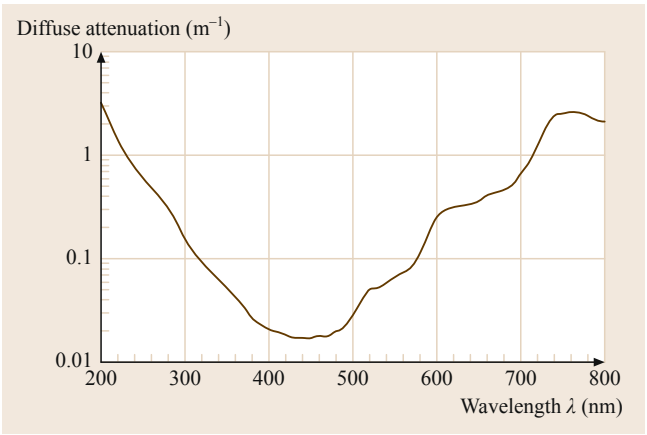

Fig. 8.11 Diffuse attenuation coefficient for clear seawater (after [8.16])

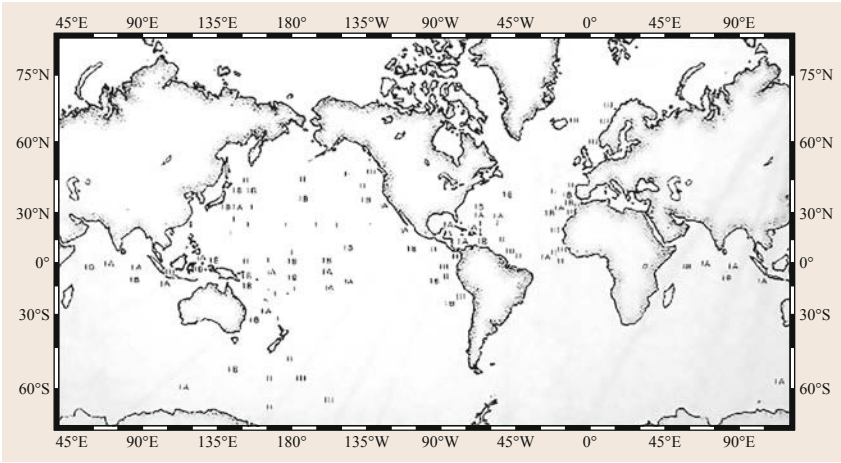

Fig. 8.12 The global distribution of Jerlov water types (after [8.1])

depth and between different regions of the world's oceans.

Laboratory measurements of the attenuation, absorption, and scattering coefficients of pure or clear seawater have been reviewed and tabulated [8.16]. The diffuse attenuation coefficients in pure seawater are plotted in Fig. 8.11, and includes water absorption and a small amount of scattering from sea salts. The estimated accuracy of this data is reported to be within +25 and −5% for wavelengths between 300 and 480 nm, and 10 and 5% from 480 to 800 nm. Below 300 nm the data is considered to be no better than an *educated estimate* [8.16]. The region of minimum attenuation between 400 and 500 nm is called the blue–green window, and has been the subject of many investigations to engineer underwater communication and detection systems [8.15, 18].

The seminal work of Jerlov produced a classification method for characterizing the optical properties of the world's oceans. Based on the measured irradiance transmissivity in the upper 10 m of the water, the oceans are categorized as Type I to III, with a subsequent subdivision of Type I into IA and IB. Coastal waters are divided into types ranging from 1 to 9. These water clarity classifications account not only for the absorption and scattering of pure seawater, but also included the effects of the suspended organic and inorganic particles as described above. A map of the global distribution of Jerlov water types is shown in Fig. 8.12 [8.1, p. 584].

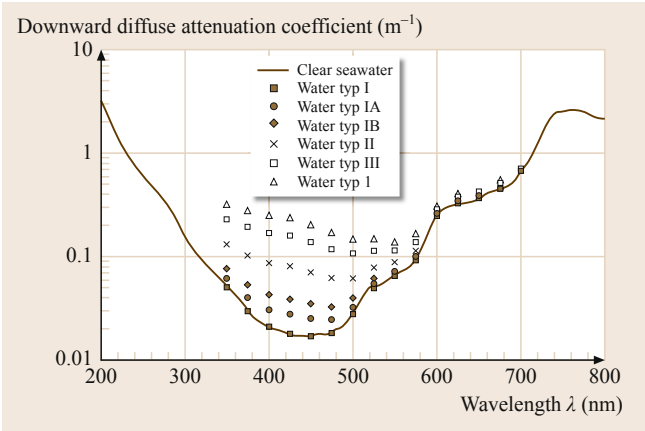

Fig. 8.13 Diffuse attenuation coefficient for Jerlov water types (after [8.17])

The downward looking diffuse attenuation coefficients for some of the Jerlov water types have been measured and tabulated [8.17]. The attenuation coefficients for ocean water Types I though III and coastal Type 1 are plotted in Fig. 8.13. As expected, the attenuation coefficient increases as water clarity decrease, with the minimum in the optical window moving toward longer wavelengths. The higher attenuation of light in natural seawaters, especially for coastal regions, limits the useful ranges of communication and detection systems that are based on blue–green lasers.

Although the dielectric constant of seawater is approximately 80 up through the ELF band, its value at an optical wavelength of 700 nm is only 1.79 at 20 °C, and increases to only 1.83 for 400 nm at 4 °C at the other extreme [8.1, pp. 532–539]. A nominal value of 1.8 gives a propagation constant of $\beta \approx 1.4 \times 10^7$ rad/m at 450 nm (20 °C), while the equivalent field attenuation constant for pure seawater is estimated from K_λ to be $\alpha \approx 0.008$ Np/m at this wavelength. Therefore, seawater can be considered a dielectric at optical wavelengths, with an average index of refraction of $n \approx 4/3$ ($n = \sqrt{\varepsilon_w}$). The index of refraction is the ratio of the speed of light in air, 3×10^8 m/s, to that in seawater, 2.24×10^8 m/s.

Since seawater can be treated as a dielectric at optical wavelengths, the expressions for the field reflection and transmission coefficients given previously for fresh

water can also be used for the ocean. The only difference is that they must be squared before applying them to irradiance, which is power. The power reflection coefficients for perpendicular $R_\perp$ and parallel polarization $R_\parallel$ can be obtained from (8.59) and (8.71), giving

$$R_\perp = \Gamma_\perp^2 = \frac{\tan^2(\theta_\mathrm{i} - \theta_\mathrm{t})}{\tan^2(\theta_\mathrm{i} + \theta_\mathrm{t})} \,, \tag{8.138}$$

$$R_\parallel = \Gamma_\parallel^2 = \frac{\sin^2(\theta_\mathrm{i} - \theta_\mathrm{t})}{\sin^2(\theta_\mathrm{i} + \theta_\mathrm{t})} \,, \tag{8.139}$$

and

$$\theta_\mathrm{r} = \theta_\mathrm{i} \,, \tag{8.140a}$$

$$\sin\theta_\mathrm{i} = n \sin\theta_\mathrm{t} \,. \tag{8.140b}$$

where all terms have been defined previously. The Brewster angle can be computed directly from $\tan\theta_\mathrm{B} = n$. These equations are valid for a smooth surface. A discussion of optical scattering from a rough ocean surface produced by wind waves can be found in [8.1, p. 528].

The maximum refraction angle of light into the ocean is limited. If the incidence angle of light entering the flat surface of the sea approaches the grazing angle ($\theta_\mathrm{i} = 90°$), then from (8.140b) the transmission angle of the refracted light is computed to be approximately 48.6°. This means that all images from the entire hemisphere above water is funneled into an upward looking cone whose sides are 48.6° from the vertical. Any image that is seen at an angle greater than this could only be coming from a submerged object.

9. Digital Signal Processing

Nikolaos I. Xiros

In this chapter the concept of discrete-time signals and sampled-data systems implemented on digital hardware versus those of continuous-time signals driving analog systems and processes is introduced early on. The processes of signal sampling and analog signal reconstruction are then investigated, and the Nyquist sampling rate to avoid aliasing is explained by means of Fourier series analysis. Then the Z-transform is introduced as the tool of preference for analysis and synthesis of discrete-time linear, time-invariant systems defined by difference equations in the discrete time domain. A detailed account of the most important and practical continuous-time system mapping techniques to discrete-time ones is then presented. A brief account of digital filter structures and types is also given along with a presentation of the fast Fourier transform algorithm for the calculation of the discrete Fourier transform of discrete-time signals with finite duration admitting periodic expansion. The notions of waveform statistics as encountered in random signals and stochastic processes are then given in order to conclude with the effect on a random signal's statistics due to its propagation through a linear, time-invariant system. Finally, concepts of optimal signal estimation and the Wiener filter are presented, leading to matched filter and zero-forcing equalizer parametric designs in the discrete-time domain.

9.1 Discrete-Time Systems

The progress in integrated circuit manufacturing (Very Large Scale Integration (VLSI)) combined with the need for high complexity and accuracy signal analysis and processing algorithms without development cost or time increase are the basic factors that contributed to the continuously increasing use of digital systems in industry and technology [9.1, 2].

9.1.1 Discrete-Time Signals and Digital Systems

A digital processing system is a system where the basic mathematical operations and functions, including signal transformations and data series analysis, are implemented as an embedded program onboard real-

time, computer hardware [9.1, 2]. Since the computer hardware employed is digital, the signals that can be processed or generated cannot be continuous time, i. e., defined for any instant in time. Instead, the computer processes and generates tables (i. e., *vectors*) of values for the input and output signal, respectively. Such tables hold the values of the corresponding signals at discrete time instants and are referred to as discrete-time signals. The time instants for which a discrete-time signal is known or defined are in most practical cases equally spaced; this scheme is known as uniform sampling and the spacing interval between two successive samples of the signal is mentioned as sampling interval or period.

The systems, e.g., real-time digital hardware, processing discrete-time signals are known as discrete-time systems. The main advantages in using computers in marine vehicle or process instrumentation, telecommunications, acoustics etc., instead of analog (continuous-time) systems are [9.1, 3–5]:

1. (Re)use of general purpose hardware for implementing a wide variety of algorithms instead of custom-built, proprietary designs that may become obsolete causing higher acquisition and development cost.
2. Changes in the algorithm can be easily implemented as changes in the software through reprogramming without need to modify the hardware.
3. Easy implementation of adaptive or time-varying algorithms due to programming.
4. Very small to zero sensitivity to environmental conditions, e.g., ambient temperature, in contrast to, e.g., analog electric circuitry.
5. Given, well-defined accuracy in computation determined by the computer's word length.
6. User-friendly human–machine interface (HMI).
7. Network connectivity.

However, there are some disadvantages in using discrete-time systems, the most important of which is the need for converter or adapter circuits or interface systems at their input and output in order to be able to interact with the vast majority of the real-world physical or engineering systems or processes, which are most often continuous-time. Such interfaces are the analog-to-digital (A/D) and digital-to-analog (D/A) converters.

9.1.2 Signal Sampling

Modeling of Ideal Sampler

Consider a continuous-time signal $x(t)$, which is driven through a sampling circuit (sampler) operating at a constant sampling rate (frequency), $f_s = 1/T_s$, as shown in Fig. 9.1.

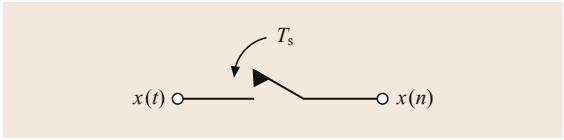

Fig. 9.1 Analog signal sampler

The sampler's output is a sequence of entries of the sampled signal, $x(nT_s)$, where n is an integer and T_s the sampling period. Sequence $x(n) = x(nT_s)$ is a discrete-time signal.

We will now represent the discrete-time signal as well as the sampling process in a continuous-time framework. Such a representation can be derived on the basis of Fig. 9.2.

A pulsed continuous-time signal $x_\Delta(t)$, which corresponds to sequence $x(nT_s)$, can be generated from the original continuous-time signal $x(t)$ (dashed line), if the latter is multiplied by the following *sampling pulse train* $P_\Delta(t)$

$$P_\Delta(t) = \sum_{n=-\infty}^{+\infty} p_\Delta(t - nT_s)\,, \tag{9.1}$$

where

$$p_\Delta(t) = \begin{cases} 1/\Delta, & t \in [0, \Delta] \\ 0 & t \notin [0, \Delta] \end{cases}, \quad 0 < \Delta \ll T_s\,. \tag{9.2}$$

In effect

$$x_\Delta(t) = x(t) \cdot P_\Delta(t)\,. \tag{9.3}$$

However, the following holds

$$\lim_{\Delta \to 0} p_\Delta(t) = \delta(t) \Rightarrow \lim_{\Delta \to 0} P_\Delta(t) = \sum_{n=-\infty}^{+\infty} \delta(t - nT_s)\,. \tag{9.4}$$

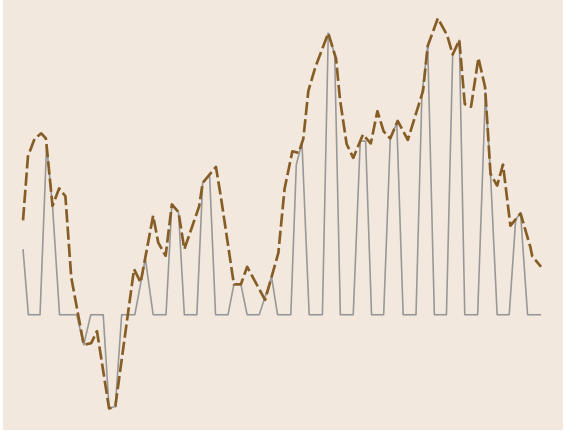

Fig. 9.2 Sampling of continuous-time waveform at uniform rate

In the above *ideal* case, the sampling pulse train is an impulse train or Dirac comb. In effect, (9.4) becomes

$$\begin{aligned} x_\delta(t) &= x(t)\cdot\sum_{n=-\infty}^{+\infty}\delta(t-nT_\mathrm{s}) \\ &= \sum_{n=-\infty}^{+\infty} x(nT_\mathrm{s})\delta(t-nT_\mathrm{s}) \\ &= \sum_{n=-\infty}^{+\infty} x(n)\delta(t-nT_\mathrm{s})\,. \end{aligned} \tag{9.5}$$

Above, the following fact for Dirac's impulse delta has been used: $\chi(t)\delta(t)=\chi(0)\delta(t)$, which implies the assumption that signal $\chi(t)$ assumes non-infinite values.

Hence, the ideal sampler operation consists of multiplicatively applying the input signal by a Dirac comb with T_s. Now we will determine the spectrum of signal $x_\delta(t)$ at the output of the sampler by employing the Fourier transform.

Fourier Series Expansion and Fourier Transform

Any periodic signal $x(t)$ with period T can be expanded to a complex Fourier series according to the following

$$x(t)=\sum_{n=0}^{+\infty} c_n \exp\left(in\frac{2\pi}{T}t\right). \tag{9.6}$$

Coefficients c_n of the series are calculated according to

$$c_n=\frac{1}{T}\int_0^T x(t)\exp\left(-in\frac{2\pi}{T}t\right)\mathrm{d}t\,. \tag{9.7}$$

The above can be extended to the case of aperiodic (non-periodic) signals assuming that period T is infinite. That is how the *Fourier transform* emerges

$$\begin{aligned} X(\omega) &= \mathcal{F}\{x(t)\} \\ &= \int_{-\infty}^{+\infty} x(t)\exp(-i\omega t)\,\mathrm{d}t, \quad \omega=\frac{2\pi}{T}\,. \end{aligned} \tag{9.8}$$

The inverse Fourier transform is defined by

$$x(t)=\frac{1}{2\pi}\int_{-\infty}^{+\infty} X(\omega)\exp(i\omega t)\,\mathrm{d}\omega\,. \tag{9.9}$$

To generalize formalism we refer to the Fourier transform of any signal, periodic or not. In the case of periodic signals, the Fourier transform is directly connected to coefficients c_n of its series expansion as follows

$$X(\omega)=2\pi\sum_{n=0}^{+\infty} c_n\delta\left(\omega-n\frac{2\pi}{T}\right). \tag{9.10}$$

The above can be derived directly by plugging it into (9.8) and generating (9.6). The Fourier transform, just like the Laplace transform, from which the former can be defined by setting $s=i\omega$, is a linear integral transform. Its properties are identical to those of the Laplace transform, and can be sought in the literature. An important property is that of multiplication-convolution duality

$$\begin{aligned} x(t) &= x_1(\xi)\otimes x_2(\xi) \\ &\triangleq \int_{-\infty}^{+\infty} x_1(\xi)\cdot x_2(t-\xi)\cdot\mathrm{d}\xi \\ &\Rightarrow X(\omega)=X_1(\omega)\cdot X_2(\omega) \\ x(t) &= x_1(t)\cdot x_2(t)\Rightarrow X(\omega) \\ &= X_1(\omega)\otimes X_2(\omega) \\ &\triangleq \int_{-\infty}^{+\infty} X_1(\xi)\cdot X_2(\omega-\xi)\cdot\mathrm{d}\xi\,. \end{aligned} \tag{9.11}$$

Here, $\otimes$ stands for the convolution operator. Note that the above can be directly applied to the Dirac comb describing the function of an ideal sampler as well as its periodicity.

Indeed, the Dirac comb in (9.4) is a periodic signal with period T_s. Its Fourier series is given below

$$\begin{aligned} c_n &= \frac{1}{T_\mathrm{s}}\int_0^{T_\mathrm{s}}\delta(t)\exp(-in\omega_\mathrm{s}t)\,\mathrm{d}t \\ &= \frac{\exp(-in\omega_\mathrm{s}0)}{T_\mathrm{s}}\int_0^{T_\mathrm{s}}\delta(t)\,\mathrm{d}t=\frac{1}{T_\mathrm{s}}, \quad \omega_\mathrm{s}=\frac{2\pi}{T_\mathrm{s}}\,. \end{aligned} \tag{9.12}$$

Hence, based on (9.10) the spectrum (Fourier transform) of the Dirac comb is given by

$$\begin{aligned} \mathcal{F}\left\{\sum_{n=-\infty}^{+\infty}\delta(t-nT_\mathrm{s})\right\} &= 2\pi\sum_{n=0}^{+\infty}\frac{1}{T_\mathrm{s}}\delta\left(\omega-n\frac{2\pi}{T_\mathrm{s}}\right) \\ &= \omega_\mathrm{s}\sum_{n=0}^{+\infty}\delta(\omega-n\omega_\mathrm{s})\,. \end{aligned} \tag{9.13}$$

Nyquist Sampling Rate – Aliasing

Combining the relationship above for the Dirac comb spectrum with (9.5), as well as the Fourier transform du-

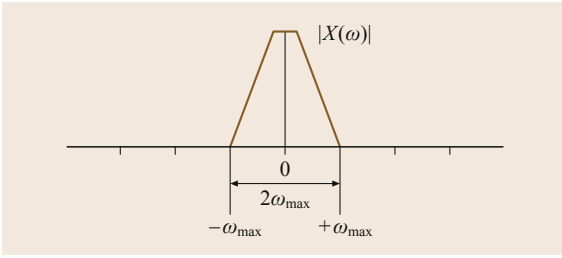

Fig. 9.3 Typical spectrum of real low-pass signal

ality between multiplication and convolution, one can determine the spectrum of signal $x_\delta(t)$ at the output of an ideal sampler

$$x_\delta(t) = x(t) \cdot \sum_{n=-\infty}^{+\infty} \delta(t - nT_s) \Rightarrow$$

$$\Rightarrow X_\delta(\omega) = X(\omega) \otimes \mathcal{F}\left\{\sum_{n=-\infty}^{+\infty} \delta(t - nT_s)\right\}$$

$$= \omega_s X(\omega) \otimes \sum_{n=0}^{+\infty} \delta(\omega - n\omega_s)$$

$$\Rightarrow X_\delta(\omega) = \omega_s \sum_{n=0}^{+\infty} X(\omega) \otimes \delta(\omega - n\omega_s)$$

$$= \omega_s \sum_{n=0}^{+\infty} \int_{-\infty}^{+\infty} X(\xi)\delta(\omega - n\omega_s - \xi)\,\mathrm{d}\xi\,.$$

The following property of the Dirac impulse delta can now be employed

$$\chi(r) \otimes \delta(r - r_0) = \int_{-\infty}^{+\infty} \chi(\xi)\delta(r - r_0 - \xi)\,\mathrm{d}\xi = \chi(r - r_0)\,. \tag{9.14}$$

Eventually one obtains

$$X_\delta(\omega) = \mathcal{F}\left\{\sum_{n=-\infty}^{+\infty} x(nT_s)\delta(t - nT_s)\right\} = \omega_s \cdot \sum_{n=0}^{+\infty} X(\omega - n\omega_s)\,. \tag{9.15}$$

Using (9.15) one can assess the effect of sampling on spectrum $X(\omega)$ of the analog, the continuous-time signal at the input. Sampling introduces, therefore, an infinite number of aliases of spectrum $X(\omega)$ of the analog signal, centered at integer multiples of the sampling circular frequency ω_s.

To visualize this, consider a real signal with all its spectral content lying within the low frequency range (low-pass or baseband signal); like, e.g., the signal with spectrum as in Fig. 9.3. Note that the amplitude spectrum $|X(\omega)|$ of the signal is an odd function of circular frequency ω due to the fact is assumed to be purely real in the time domain.

The amplitude spectrum of signal $x_\delta(t)$ is shown in the Fig. 9.4 as generated by sampling of low-pass signal $x(t)$ above at three (9.3) different sampling rates: $\omega_{s,0} = 2\omega_{max}$, $\omega_{s,1} = 4\omega_{max}$, $\omega_{s,2} = \omega_{max}$.

Using the plot, one can readily derive the following sampling rate criterion attributed to Nyquist (or the Shannon sampling theorem) for the low-pass signal like the one in Fig. 9.4

$$\omega_s \geq \omega_{s,0} = 2\omega_{max}\,. \tag{9.16}$$

If the condition above holds as seen in (9.15) (spectrum periodicity for the sampled signal), as well as Fig. 9.5, an ideal (*brick*) low-pass filter with transfer function as follows can be used to reconstruct the original continuous-time signal

$$H_{LPF}(\omega) = \begin{cases} 1, & |\omega| \leq \omega_s/2 \\ 0, & |\omega| > \omega_s/2 \end{cases}\,. \tag{9.17}$$

The original spectrum is ideally reproduced without any distortion since it holds that

$$H_{LPF}(\omega)X_\delta(\omega) = \omega_s X(\omega)\,. \tag{9.18}$$

This is made clearer next when reconstruction of a continuous-time signal based on the values of a discretized version is discussed.

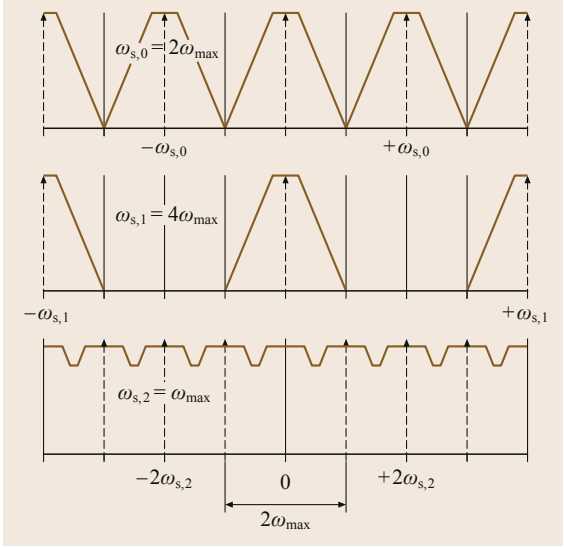

Fig. 9.4 Sampled signal spectrum at various sampling rates

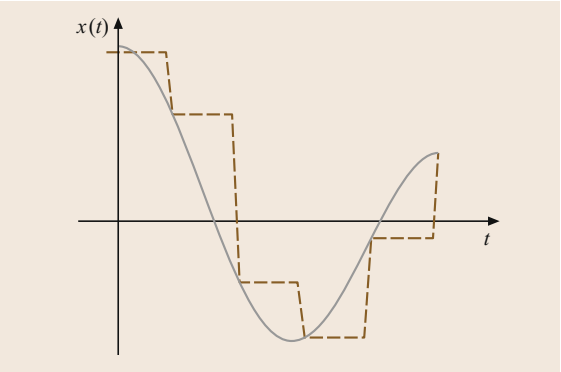

Fig. 9.5 Original continuous-time signal (*continuous line*) and reconstructed version using a non-brick filter (*dashed line*)

9.1.3 Analog Signal Reconstruction Using a Discrete-Time Signal

The simplest process to generate a continuous-time signal, $x(t)$, from a discretized sequence (discrete-time signal) $x(n)$ is to employ the zero-order hold (ZOH) network. This system *holds* the output constant and equal to the one applied to its input for an entire sampling period T_s. In effect, the output of ZOH when driven by a discretized signal is given in the Fig. 9.5.

The mathematical description of a ZOH system is achieved through the following impulse response and transfer function in the complex frequency domain of variable s

$$h_{\mathrm{ZOH}}(t) = u_{\mathrm{step}}(t) - u_{\mathrm{step}}(t - T_s)$$
$$\Leftrightarrow H_{\mathrm{ZOH}}(s) = \frac{1 - e^{-sT_s}}{s}. \tag{9.19}$$

To better understand the action of the ZOH system, its transfer function in the circular frequency domain ω (Fourier transform) is given below, as well

$$H_{\mathrm{ZOH}}(\omega) = \frac{1 - e^{-i\omega T_s}}{i\omega} = T_s e^{-i\omega T_s/2} \frac{\sin(\omega T_s/2)}{(\omega T_s/2)}$$
$$= \frac{e^{-i\pi^{f/f_s}}}{f_s} \mathrm{sinc}(f/f_s)\,. \tag{9.20}$$

In the above $\mathrm{sinc}(\chi) = \mathrm{sinc}(\pi\chi)/\pi\chi$. In Fig. 9.6 the amplitude spectra of the transfer functions of the ZOH system (normalized by setting $f_s = 1\,\mathrm{Hz}$) and the ideal reconstruction low-pass filter which was introduced with (9.17).

Indeed, in the circuit above if resistance R is small (theoretically zero), then time constant τ indicating the time needed for charging the capacitor in the hold circuit is small when compared to sampling period T_s. The

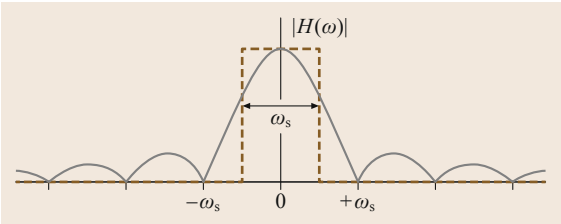

Fig. 9.6 Amplitude spectrum of transfer function $H_{\mathrm{ZOH}}(\omega)$ (*continuous line*) and $H_{\mathrm{LPF}}(\omega)$ (*dashed line*)

voltage across the terminals of the capacitor stays at the value set in the previous sampling instant, when the switch was momentarily switched on, until the next instant the switch is on, etc. The differences of the analog memory element, as the switched resistor and capacitor (RC) circuit is known, and the model ZOH system are:

a) The ohm resistance value of the circuit is non-zero and, therefore, the time to charge the capacitor is finite and not zero.
b) The duration of the conduction phase of the switch is finite and non-zero.
c) The ohm resistance applied to the terminals of the capacitor when the switch is off is not infinite (open circuit) but finite, eventually leading to discharge of the capacitor.

The use of the RC hold circuit is widespread due to its simplicity. However, if a more accurate reconstruction with less distortion, without increasing the sampling rate, then hold circuits of order higher than zero (e.g., first-order hold, FOH) so that its transfer function better approximates the ideal *brick* low-pass filter in (9.17), as shown in Fig. 9.6.

9.1.4 The Z-Transform

The single-sided (unilateral) Z-transform is a linear transform defined as follows for a discrete-time signal $x(n)$

$$X(z) = \mathcal{Z}\{x(n)\} = \sum_{n=0}^{+\infty} x(n) \cdot z^{-n}\,. \tag{9.21}$$

The Z-transform is derived from the Laplace transform of signal $x_\delta(t)$, which is generated by the ideal sampler shown in Fig. 9.7,

$$x_\delta(t) = \sum_{n=-\infty}^{+\infty} x(n)\delta(t - nT_s) \Rightarrow X_\delta(s)$$
$$= \mathcal{L}\left\{\sum_{n=-\infty}^{+\infty} x(n)\delta(t - nT_s)\right\} = \sum_{n=0}^{+\infty} x(n) e^{-n \cdot sT_s}\,. \tag{9.22}$$

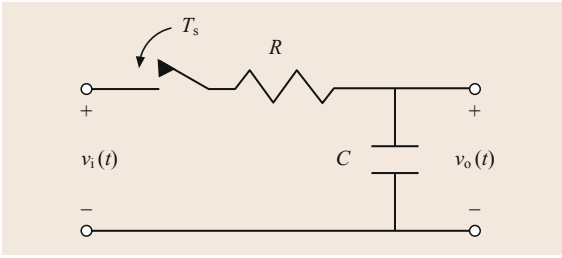

Fig. 9.7 Switched RC circuit modeled by the ZOH system

In effect,

$$X(z)|_{z^{-1}=\exp(-sT_s)} = X_\delta(s) \,. \tag{9.23}$$

Variable z^{-1} is used for describing a signal, or system as we will see later on. Its significance lies in the fact that multiplying by z^{-1} in the transform domain translates to a time shift by one sampling period, T_s, in the discrete-time domain n. Indeed,

$$y(n) = x(n-1) \Leftrightarrow Y(z) = z^{-1}X(z) \,. \tag{9.24}$$

Furthermore, here are some more of the most important properties of the Z-transform:

1. Linearity

$$\left.\begin{aligned} &X_1(z) = \mathcal{Z}\{x_1(n)\} \\ &X_2(z) = \mathcal{Z}\{x_2(n)\} \\ &k_1, k_2 \in \mathbb{R} \end{aligned}\right\} \Rightarrow k_1 \cdot X_1(z) + k_2 \cdot X_2(z) = \mathcal{Z}\{k_1 \cdot x_1(n) + k_2 \cdot x_2(n)\} \,. \tag{9.25}$$

2. Delay or advance by N discrete-time units

$$\mathcal{Z}\{x(n)\} = X(z) \Rightarrow \begin{cases} \mathcal{Z}\{x(n-N)\} = z^{-N}X(z) \\ \mathcal{Z}\{x(n+N)\} = z^{N}X(z) - \sum_{k=0}^{N-1} z^{N-k}x(k) \end{cases} . \tag{9.26}$$

3. Initial or final value theorems

$$\mathcal{Z}\{x(n)\} = X(z) \Rightarrow \begin{cases} x(n=0) = \lim_{z\to\infty}(X(z)) \\ \lim_{n\to\infty}(x(n)) = \lim_{z\to 1}((1-z^{-1})X(z)) \end{cases} . \tag{9.27}$$

Note: the final value theorem ($n \to \infty$) holds only if $X(z)$ is an analytic function of complex variable z.

4. Discrete convolution theorem

$$\left.\begin{aligned} &X_1(z) = \mathcal{Z}\{x_1(n)\} \\ &X_2(z) = \mathcal{Z}\{x_2(n)\} \\ &x(n) = x_1(k) \otimes x_2(k) \triangleq \sum_{k=-\infty}^{+\infty} x_1(k) \cdot x_2(n-k) \end{aligned}\right\} \Rightarrow X(z) = \mathcal{Z}\{x(n)\} = X_1(z) \cdot X_2(z) \,. \tag{9.28}$$

Note: because $x(n)$ needs to be *causal*, i. e., can only depend on values of signals x_1 and x_2 prior or up to instant n, the bounds of the convolutional summation are set as follows,

$$(x_1(k) \otimes x_2(k))(n) = \sum_{k=0}^{n} x_1(k) \cdot x_2(n-k) \,.$$

It is also pointed out here that the commutative and associative properties hold for the convolution operator applied on two discrete-time signals.

Finally, it is pointed out that the change of variable, $z = \exp(sT_s)$, on the basis of which the Z-transform is obtained from the Laplace transform of signal $x_\delta(t)$, defines a single-valued mapping of complex frequency s-plane to the plane of, also complex, delay operator z. Remember that the stability region on the complex plane $s = a + i\omega$, is the left-hand half-plane defined by inequality $\alpha \le 0$. In effect, the stability region on the delay operator z-plane is defined by inequality

$$|z| \le 1 \,. \tag{9.29}$$

Since

$$z = e^{sT_s} = e^{aT_s}e^{i\omega T_s} \Rightarrow \begin{cases} |z| = e^{aT_s} \\ \arg(z) = e^{i\omega T_s} \end{cases} . \tag{9.30}$$

That is, the stability region is the unit disc. Similarly, the origin of the s-plane is mapped to point $z = A + j0$ on the z-plane, while the imaginary axis of the s-plane is wrapped around the unit circle on the z-plane. Finally, the real s axis is mapped to the real z semi-axis. The Z-transform of several elementary discrete-time signals are shown in Table 9.1. In the interest of completeness and allowing for comparisons a Laplace transform table is provided in Table 9.2.

9.1.5 Discrete-Time LTI Systems

Difference Equations

A special class of dynamic systems, widely used in systems and signal theory, is linear time invariant sys-

tems (LTI) [9.1, 2, 4–6]. Such systems are described in continuous time by linear differential equations with constant coefficients. In discrete time, such a differential equation is converted to a difference equation corresponding to a discrete-time system described by a transfer function in variable z, or equivalently z^{-1}. The general form of a linear difference equation with input $u(n)$ and output $y(n)$ is the following,

$$y(n) = \sum_{k=0}^{M} b_k u(n-k) - \sum_{k=1}^{N} a_k y(n-k)\,. \qquad (9.31)$$

To obtain the iterative process started in order to obtain samples of discrete-time output signal $y(n)$ for $n \geq 0$, N initial conditions are needed: $y(-k)$, $k = 1, \ldots, N$. Using (9.31) we can conclude that the n-th sample of the output is determined as a weighed sum of the current plus M past input samples and N past output samples.

Table 9.1 Some Z-transform pairs

k-th term of the time sequence	z-transform
1 at k, 0 elsewhere (Kronecker delta sequence)	z^{-k}
1 (unit step sequence)	$\frac{z}{z-1}$
k (unit ramp sequence)	$\frac{z}{(z-1)^2}$
A^k (for complex numbers A)	$\frac{z}{z-A}$
kA^k	$\frac{Az}{(z-A)^2}$
$\frac{(k+1)(K+2)\cdots(K+n-1)}{(n-1)!}A^k$	$\frac{z^n}{(z-A)^n}$

Table 9.2 Laplace transform pairs

Time function	Laplace transform
Unit impulse $\delta(t)$	1
Unit step $\mathbb{1}(t)$	$\frac{1}{s}$
Unit ramp t	$\frac{1}{s^2}$
Polynomial t^n	$\frac{n!}{s^{n+1}}$
Exponential e^{-at}	$\frac{1}{s+a}$
Sine wave $\sin \omega t$	$\frac{\omega}{s^2+\omega^2}$
Cosine wave $\cos \omega t$	$\frac{s}{s^2+\omega^2}$
Damped sine wave $e^{-at} \sin \omega t$	$\frac{\omega}{(s+a)^2+\omega^2}$
Damped cosine wave $e^{-at} \cos \omega t$	$\frac{s+a}{(s+a)^2+\omega^2}$

Linear Time-Invariant Discrete-Time Systems

The generic difference (9.31) in the discrete-time domain defines an LTI discrete-time system. In the Z-transform domain the difference equation becomes the transfer function as follows

$$\begin{aligned} H(z^{-1}) &= \frac{Y(z)}{U(z)} \\ &= \frac{b_0 + b_1 z^{-1} + \ldots + b_M z^{-M}}{1 + a_1 z^{-1} + \ldots a_{N-1} z^{-N+1} + a_N z^{-N}} \\ &\Updownarrow \\ H(z) &= \frac{b_0 z^N + b_1 z^{N-1} + \ldots + b_M z^{N-M}}{z^N + a_1 z^{N-1} + \ldots + a_N}, \\ & M \leq N\,. \end{aligned} \qquad (9.32)$$

A special, yet very important case of discrete-time systems are finite impulse response (FIR) systems in contrast to the generic IIR (infinite impulse response) system defined in (9.31). For a FIR system it holds that $a_k = 0$, $\forall k > 0$ in (9.31), hence

$$\begin{aligned} y(n) &= \sum_{k=0}^{M} b_k u(n-k) \quad \text{and} \\ H(z^{-1}) &= b_0 + b_1 z^{-1} + \ldots + b_M z^{-M}\,. \end{aligned} \qquad (9.33)$$

In effect, the n-th output sample is *exclusively* determined as a weighed sum of the current plus M past input samples. In effect, the difference equations seizes to be recursive and that is why in the literature FIR systems are also mentioned as MA (moving average) ones.

In contrast, discrete-time LTI systems that have exclusively poles, i. e., $b_i = 0$, for every $i > 0$ in (9.32), are also known as AR (auto-regressive), while the generic IIR system is mentioned also as auto-regressive moving average (ARMA) in this framework.

9.1.6 Continuous-Time System Mapping

There are many ways (methods) to map a continuous-time system to a discrete-time equivalent [9.1, 2, 4–6]. All of these methods are based on preserving some characteristic of the continuous-time system during this procedure; this is why there is more than one way. However, *stability* (or instability) of a continuous-time system is preserved by employing any of the methods presented here.

The mapping methods considered here can be classified into the following categories:

1. Approximate differentiation or integration:
   - Backward difference
   - Forward difference
   - Trapezoidal integration (Tustin transformation).

2. Time-domain response matching at sampling instants:
   - Impulse response matching
   - Step response matching.
3. Dynamic matching, i. e., matching of all poles and zeroes appearing in the transfer function.

Approximate Differentiation or Integration

Consider a continuous-time signal $x(t)$ being sampled with sampling interval T_s and the discrete-time signal $x(n)$ is obtained. Then, the following approximations can be derived.

Approximate derivative with respect to time using backward difference

$$\dot{x}(t) \simeq \frac{x(n)-x(n-1)}{T_s} \Rightarrow s \equiv \frac{1-z^{-1}}{T_s} \,. \tag{9.34}$$

Approximate derivative with respect to time using forward difference

$$\dot{x}(t) \simeq \frac{x(n+1)-x(n)}{T_s} \Rightarrow s \equiv \frac{z-1}{T_s} = \frac{1-z^{-1}}{T_s z^{-1}} \,. \tag{9.35}$$

Approximate integral with respect to time using the trapezoidal rule

$$\begin{aligned} x_1(nT_s) &= \int_0^{nT_s} x(\xi)\,\mathrm{d}\xi = \int_0^{(n-1)T_s} x(\xi)\,\mathrm{d}\xi + \int_{(n-1)T_s}^{nT_s} x(\xi)\,\mathrm{d}\xi \\ &\triangleq x_1((n-1)T_s) + \Delta x_1(n) \,, \\ \Delta x_1(n) &\simeq T_s \cdot \frac{x(n)+x(n-1)}{2} \,. \end{aligned} \tag{9.36}$$

However,

$$\begin{aligned} X_1(s) &= \frac{1}{s}X(s) \quad \text{and} \\ X_1(z) &= z^{-1}X_1(z) + T_s\frac{1+z^{-1}}{2}X(z) \,. \end{aligned} \tag{9.37}$$

The above in effect yields

$$\frac{1}{s} \equiv \frac{T_s}{2}\cdot\frac{1+z^{-1}}{1-z^{-1}} \Leftrightarrow s \equiv \frac{2}{T_s}\cdot\frac{1-z^{-1}}{1+z^{-1}} \,. \tag{9.38}$$

Equations (9.34), (9.35), and (9.38) mean that when presented with a transfer function $H(s)$ in the complex frequency (s) domain, describing a continuous-time LTI system, it is possible to derive a discrete-time transfer function $H(z)$, or $H(z^{-1})$, defining a discrete-time LTI system by substituting variable s with the approximation desired.

Impulse Response Matching

The methods presented previously were based on approximating the integration or differentiation operator appearing in the differential (dynamic) equation of an LTI system. However, an LTI system can, also, be described in full by its response to an arbitrary input signal. Common choices include using either Dirac's delta (impulse) or the unit step signal (Heaviside signal).

In effect, if the impulse or step response of a continuous-time system is sampled, then a discrete-time description can be derived as follows.

Invariance of impulse response: the impulse delta is defined as follows in discrete time

$$\delta(n) = \begin{cases} 0, & n \neq 0 \\ 1, & n = 0 \end{cases} \Leftrightarrow \Delta(z) = 1 \,. \tag{9.39}$$

Given the transfer function, $H(z)$ of a discrete-time LTI system, it is easy to prove that, just like in the continuous time case, $H(z)$ is the Z-transform of the system's impulse response.

Indeed, the output $y(n)$ of a discrete-time LTI system is given by the following convolutional sum

$$\begin{aligned} y(n) = u(k) \otimes h(k) &\triangleq \sum_{k=-\infty}^{+\infty} u(k)\cdot h(n-k) \Rightarrow Y(z) \\ &= H(z)\cdot U(z) \,. \end{aligned} \tag{9.40}$$

In effect,

$$u(n) = \delta(n) \Rightarrow U(z) = 1 \Rightarrow Y(z) = H(z) \,.$$

Consider a continuous-time LTI system with impulse response $h(t) = \mathcal{L}^{-1}\{H(s)\}$, which is being sampled at rate f_s. This means that continuous-time signal $h_\delta(t) = \sum_{n=-\infty}^{+\infty} h(nT_s)\delta(t-nT_s)$ corresponds to discrete-time signal $h_\delta(n) \equiv h(nT_s)$, i. e., a sample set of $h(t)$.

The Z-transform of $h_\delta(n)$,

$$H_\delta(z^{-1}) = \sum_{n=0}^{+\infty} h_\delta(n) z^{-n} \,,$$

defines a discrete-time LTI system, the impulse response of which, by definition, coincides with that of continuous-time transfer function $H(s)$, at all sampling instants.

Assume, now, that for every positive M there is a positive integer ε such that

$$\sum_{n=M+1}^{+\infty} h_\delta^2(n) < \varepsilon \,. \tag{9.41}$$

Given the above, one can proceed to impulse response truncation with accuracy ε. This procedure consists of approximating the original IIR system with transfer function $H_\delta(z^{-1}) = \sum_{n=0}^{+\infty} h_\delta(n) z^{-n}$ by the following FIR one with memory M

$$\hat{H}_{\text{FIR}}(z^{-1}) = \sum_{n=0}^{M} h_\delta(n) z^{-n} = \sum_{n=0}^{M} b_n z^{-n} \,. \tag{9.42}$$

Approximating a continuous-time system with a discrete-time one, which on top might be FIR, comes with a number of advantages, especially for real-time applications.

Invariance of step response: the unit step signal in discrete time is defined as follows

$$u_{\text{step}}(n) = \begin{cases} 1, & n \geq 0 \\ 0, & n < 0 \end{cases} \quad \Leftrightarrow$$

$$U_{\text{step}}(z) = \sum_{n=0}^{+\infty} z^{-n} = \frac{1}{1 - z^{-1}} \,. \tag{9.43}$$

The Z-transform of the unit step signal is derived by applying the lemma for the infinite sum of a geometric progression with a ratio that in magnitude is less than 1.

Consider now an LTI system with impulse response as follows

$$y_{\text{step}}(t) = \mathcal{L}^{-1}\{H(s) U_{\text{step}}(s)\} = \mathcal{L}^{-1}\left\{\frac{H(s)}{s}\right\} \,. \tag{9.44}$$

We will now determine a discrete-time transfer function $H(z)$ such that the latter's unit step response coincides with that of the continuous-time system above. Mathematically, this is defined as follows

$$\mathcal{Z}^{-1}\{H(z) U_{\text{step}}(z)\} = y_{\text{step}}(n) = y_{\text{step}}(nT_{\text{s}}) \,. \tag{9.45}$$

Then, by employing (9.43), one obtains that

$$H(z) = (1 - z^{-1}) \mathcal{Z}\{y_{\text{step}}(nT_{\text{s}})\} \,. \tag{9.46}$$

Since

$$z^{-1} = \exp(-sT_{\text{s}}) \quad \text{and} \quad Y_{\text{step}}(s) = \frac{H(s)}{s} \,.$$

We can finally obtain that

$$H(z) = \mathcal{Z}\{y_{\text{ZOH}}(nT_{\text{s}})\} \,. \tag{9.47}$$

In the above, it holds that

$$y_{\text{ZOH}}(t) = h_{\text{ZOH}}(t) \otimes h(t) \Leftrightarrow$$

$$Y_{\text{ZOH}}(s) = H_{\text{ZOH}}(s) H(s) = \frac{1 - e^{-sT_{\text{s}}}}{s} H(s) \,. \tag{9.48}$$

Pole and Zero Matching of a Transfer Function

This method derives from equation

$$z^{-1} = \exp(-sT_{\text{s}})$$

connecting variable z with complex frequency s. Combining the above with the following factorized form of a continuous-time scalar transfer function

$$H(s) = K_{\text{s}} \frac{(s + z_1)(s + z_2) \ldots (s + z_m)}{(s + p_1)(s + p_2) \ldots (s + p_n)}, \quad m \leq n \,. \tag{9.49}$$

One can map every pole and every zero of the continuous-time transfer function to a corresponding pole and zero of an equivalent discrete-time transfer function

$$\begin{aligned} \zeta_{\text{i}} &= -\exp(-T_{\text{s}} z_{\text{i}}), \quad i = 1, \ldots, m \,, \\ \pi_{\text{i}} &= -\exp(-T_{\text{s}} p_{\text{i}}), \quad i = 1, \ldots, n \,. \end{aligned} \tag{9.50}$$

In effect, the following discrete-time transfer function is derived in its factorized from

$$H(z) = k_z \frac{(z+1)^{n-m}(z + \zeta_1)(z + \zeta_2) \ldots (z + \zeta_m)}{(z + \pi_1)(z + \pi_2) \ldots (z + \pi_n)} \,. \tag{9.51}$$

Factor $(z+1)^{n-m}$ is introduced in the discrete-time transfer function above in correspondence to factor $(\tau s + 1)^{n-m}$ with $\tau \to \pm j0$, which is *hidden* in the continuous-time transfer function (9.49). The intent is to equate the numerator degree to that of the denominator. This is achieved by introducing an extra zero at imaginary infinity ($\pm j\infty$) with multiplicity $(n - m)$ using factor $(\tau s + 1)^{n-m}$. In the discrete-time transfer function, factor $(\tau s + 1)^{n-m}$ is mapped to $(z + 1)^{n-m}$, since point $\pm j\infty$ on the s-plane is mapped to -1 on the z-plane.

Finally, gain k in the discrete-time transfer function is determined by equating its value at a certain z with that of the continuous-time transfer function at the equivalent point s. For example, for $z = 1$, the corresponding point is $s = 0$, and, therefore, k is calculated as follows

$$\begin{aligned} H(z)|_{z=1} &= H(s)|_{s=0} \\ &\Leftrightarrow k_z \frac{2^{n-m}(1 + \zeta_1)(1 + \zeta_2) \ldots (1 + \zeta_m)}{(1 + \pi_1)(1 + \pi_2) \ldots (1 + \pi_n)} \,, \\ &= K_{\text{s}} \frac{z_1 z_2 \ldots z_m}{p_1 p_2 \ldots p_n} \,. \end{aligned} \tag{9.52}$$

9.2 Digital Filters

In the previous section we studied different ways of describing discrete-time systems that are linear and time invariant. It was verified that the Z-transform greatly simplifies the analysis of discrete-time systems, especially those initially described by difference equations.

In this section, we study in finer detail several structures used to realize a given transfer function associated with a specific difference equation through the use of the Z-transform. The transfer functions considered here will be of the polynomial form (non-recursive filters, FIR) and of the rational-polynomial form (recursive filters, IIR). In the non-recursive case we emphasize the existence of the important subclass of linear-phase filters. Then we introduce some tools to calculate the digital network transfer function, as well as to analyze its internal behavior. We also discuss some properties of generic digital filter structures associated with practical discrete-time systems.

9.2.1 Important FIR Filter Structures

Non-recursive filters are characterized by a difference equation in the form

$$y(n) = \sum_{l=0}^{M} b_l x(n-l) \,, \tag{9.53}$$

where the b_l coefficients are directly related to the system impulse response; that is, $b_l = h(l)$. Owing to the finite length of their impulse responses, non-recursive filters are also referred to as finite-duration impulse response (FIR) filters. We can rewrite (9.53) as follows

$$y(n) = \sum_{l=0}^{M} h(l)x(n-l) \,. \tag{9.54}$$

Applying the Z-transform to the equation above, we end up with the following input–output relationship

$$H(z) = \frac{Y(z)}{X(z)} = \sum_{l=0}^{M} h(l)z^{-l} = \sum_{l=0}^{M} b_l z^{-l} \,. \tag{9.55}$$

In practical terms, (9.55) can be implemented in several distinct forms, using as basic elements the delay, the multiplier, and the adder blocks. These basic elements of digital filters and their corresponding standard symbols are depicted in Fig. 9.8. An alternative way of representing such elements is the so-called signal flow graph shown in Fig. 9.9.

These two sets of symbolisms representing the delay, multiplier, and adder elements are used throughout this text interchangeably.

Direct Form

The simplest realization of an FIR digital filter is derived from (9.55). The resulting structure, which can be seen in Fig. 9.10, is called the direct-form realization, as the multiplier coefficients are obtained directly from the filter transfer function. Such a structure is also referred to as the canonic direct form, where we understand canonic form to mean any structure that realizes a given transfer function with the minimum number of delays,

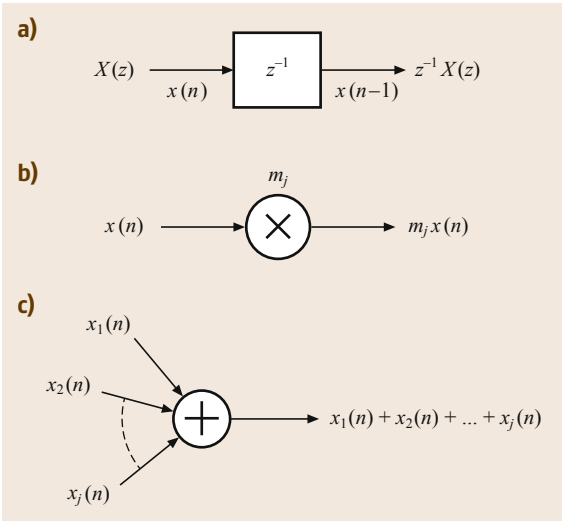

Fig. 9.8a–c Classic representation of basic elements of digital filters: **(a)** delay; **(b)** multiplier; **(c)** adder

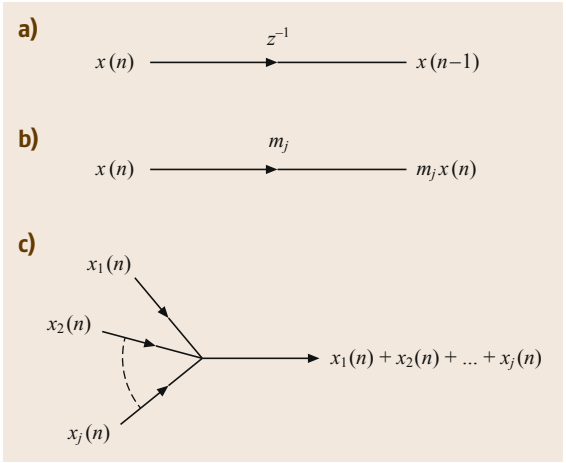

Fig. 9.9a–c Signal-flow graph representation of basic elements of digital filters: **(a)** delay; **(b)** multiplier; **(c)** adder

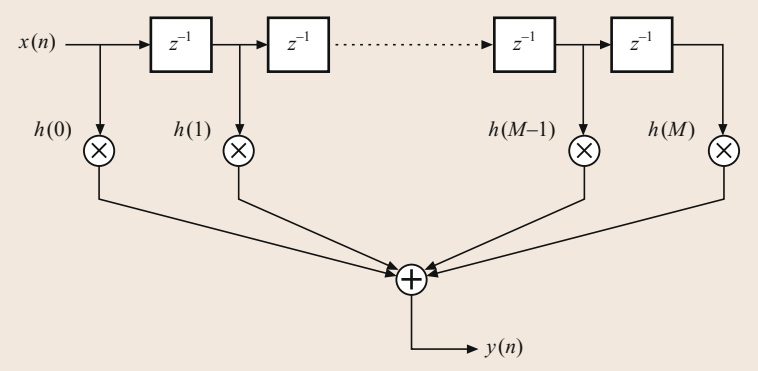

Fig. 9.10 Direct form for FIR digital filters

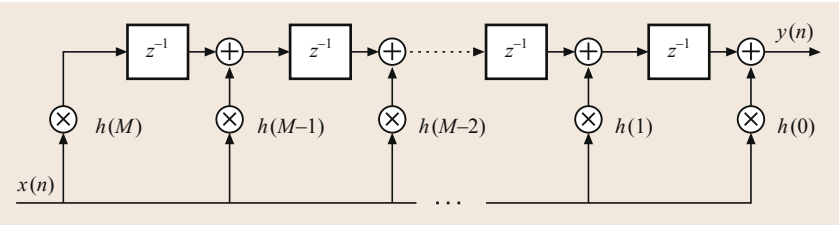

Fig. 9.11 Alternative direct form for FIR digital filters

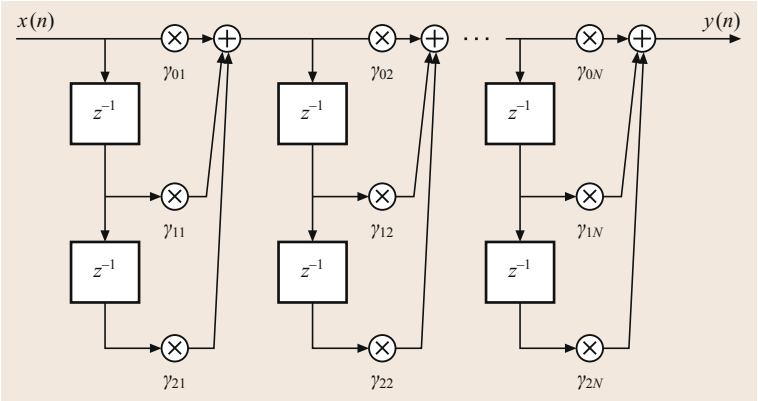

Fig. 9.12 Cascade form for FIR digital filters

multipliers, and adders. More specifically, a structure that utilizes the minimum number of delays is said to be canonical with respect to the delay element, and so on.

An alternative canonical direct form for (9.76) can be derived by expressing $H(z)$ as follows

$$(z) = \sum_{l=0}^{M} h(l)z^{-l} = h(0) + z^{-1}\left(\sum_{l=1}^{M} h(l)z^{-l}\right) . \quad (9.56)$$

The implementation of this form is shown in Fig. 9.11.

Cascade Form

Equation (9.55) can be realized through a series of equivalent structures. However, the coefficients of such distinct realizations may not be explicitly the filter impulse response or the corresponding transfer function. An important example of such a realization is the so-called cascade form, which consists of a series of second-order FIR filters connected in cascade, thus the name of the resulting structure, as seen in Fig. 9.12. The transfer function associated with such a realization is of the form

$$H(z) = \prod_{k=1}^{N} (\gamma_{0k} + \gamma_{1k}z^{-1} + \gamma_{2k}z^{-2}) . \quad (9.57)$$

In the above, if M is the filter order, then $N = M/2$ when M is even and $N = (M+1)/2$ when M is odd. In the latter case, one of the γ_{2k} vanishes.

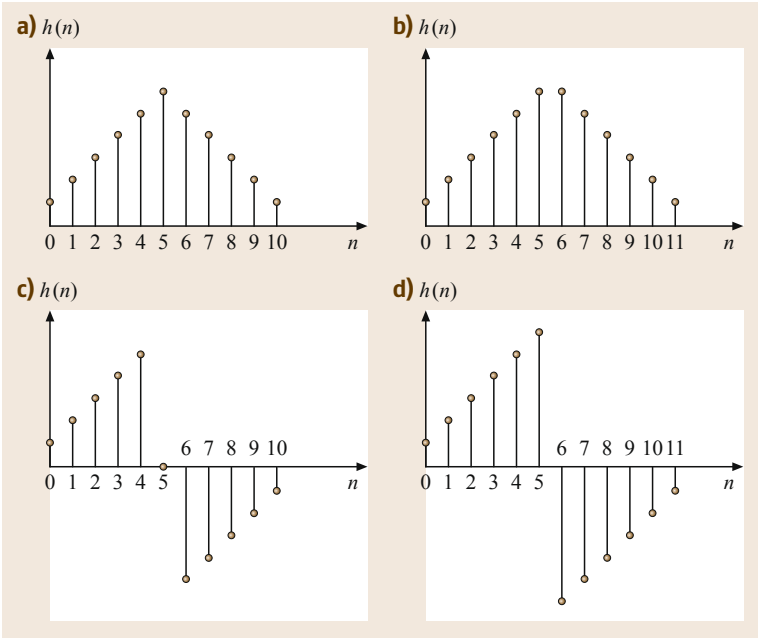

Fig. 9.13a–d Example of impulse responses of linear-phase FIR digital filters: **(a)** type I; **(b)** type II; **(c)** type III; **(d)** type IV

Linear-Phase Form

An important subclass of FIR digital filters is the one that includes linear-phase filters. Such filters are characterized by a constant group delay τ; therefore, they must present a frequency response of the following form

$$H(e^{i\omega}) = B(\omega)\exp(-i\omega\tau + i\varphi)\,. \tag{9.58}$$

In the above $B(\omega)$ is real and τ and φ are constant. We now proceed to show that linear-phase FIR filters present impulse responses of very particular forms. Specifically, if $h(n)$ is to be causal and of finite duration, for $0 \le n \le M$, we must necessarily have that

$$\tau = \frac{M}{2}\,. \tag{9.59}$$

Therefore, one obtains that

$$h(n) = e^{2i\varphi}h^*(M-n)\,. \tag{9.60}$$

This is the general equation that the coefficients of a linear-phase FIR filter must satisfy. In the common case, where all the filter coefficients are real, one finally obtains that the filter impulse response must be either *symmetric* or *antisymmetric*. In effect, the frequency response of linear-phase FIR filters with real coefficients becomes as follows

$$H(e^{i\omega}) = B(\omega)\exp\left(-i\omega\left(\frac{M}{2}\right) + i\left(\frac{k\pi}{2}\right)\right). \tag{9.61}$$

As a result, solely four distinct cases need be considered that are described by the equations above. Their types have been standardized and are referred to in literature as follows [9.2]:

- Type I: $k = 0$ and M even
- Type II: $k = 0$ and M odd
- Type III: $k = 1$ and M even
- Type IV: $k = 1$ and M odd.

Typical impulse responses of the four cases of linear-phase FIR digital filters are depicted in Fig. 9.13.

9.2.2 Important IIR Filter Structures

Direct Form

Recursive filters have transfer functions of the following form

$$H(z) = \frac{N(z)}{D(z)} = \frac{\sum_{i=0}^{M} b_i z^{-i}}{1 + \sum_{i=1}^{N} a_i z^{-i}}\,. \tag{9.62}$$

Since, in most cases, such transfer functions give rise to filters with impulse responses having infinite durations, recursive filters are also referred to as infinite-duration impulse response (IIR) filters.

We can consider that $H(z)$ as above results from the cascading of two separate filters of transfer functions $N(z)$ and $1/D(z)$. The $N(z)$ polynomial can be realized with the FIR direct form, as shown in the previous section. The realization of $1/D(z)$ can be performed as depicted in Fig. 9.14, where the FIR filter shown will

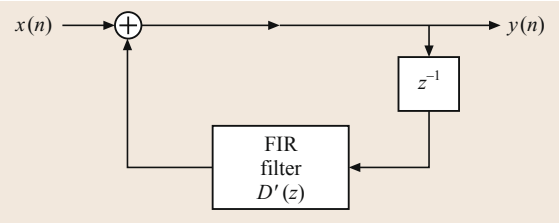

Fig. 9.14 Block diagram realization of $1/D(z)$

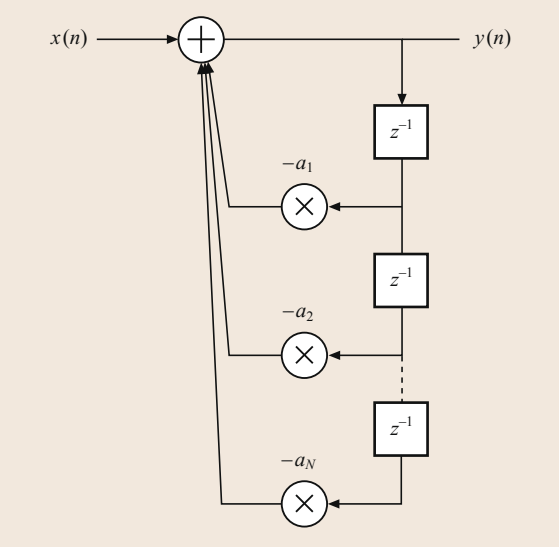

Fig. 9.15 Detailed realization of $1/D(z)$

be an $(N-1)$-th order filter with transfer function as follows

$$D'(z) = z(1-D(z)) = -z\sum_{i=1}^{N} a_i z^{-i} . \qquad (9.63)$$

The direct form of realizing $1/D(z)$ is shown in Fig. 9.15.

The complete realization of $H(z)$, as a cascade of $N(z)$ and $1/D(z)$, is shown in Fig. 9.16. Such a structure is not canonic with respect to the delays, since for an (M,N)-th order filter this realization requires $(N+M)$ delays.

Clearly, in the general case we can change the order in which we cascade the two separate filters; that is, $H(z)$ can be realized as

$$N(z) \times \frac{1}{D(z)} \quad \text{or} \quad \left(\frac{1}{D(z)}\right) \times N(z) .$$

In the second option, all delays employed start from the same node, which allows us to eliminate the consequent redundant delays. In that manner, the resulting structure, usually referred to as the Type 1 canonic direct

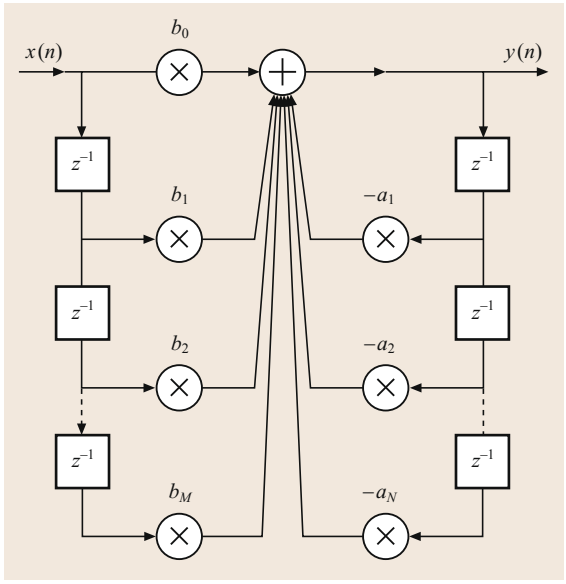

Fig. 9.16 Non-canonic IIR direct form realization

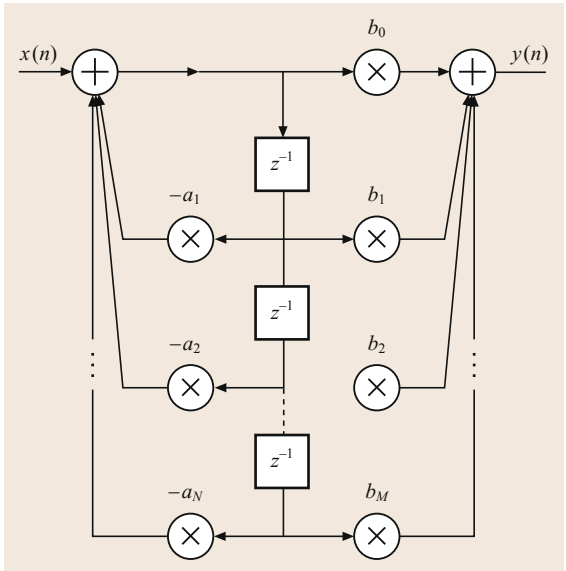

Fig. 9.17 Type 1 canonic direct form for IIR filters

form, is the one depicted in Fig. 9.17, for the special case $N = M$.

An alternative structure, the so-called Type 2 canonic direct form, is shown in Fig. 9.18. Such a realization is generated from the corresponding non-recursive form.

The majority of IIR filter transfer functions used in practice present a numerator degree M smaller than or equal to the denominator degree N. In general, one can consider, without much loss of generality, that $M = N$.

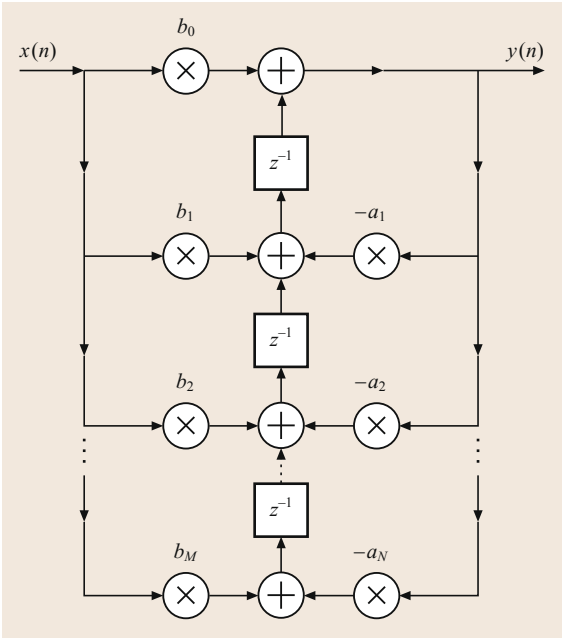

Fig. 9.18 Type 2 canonic direct form for IIR filters

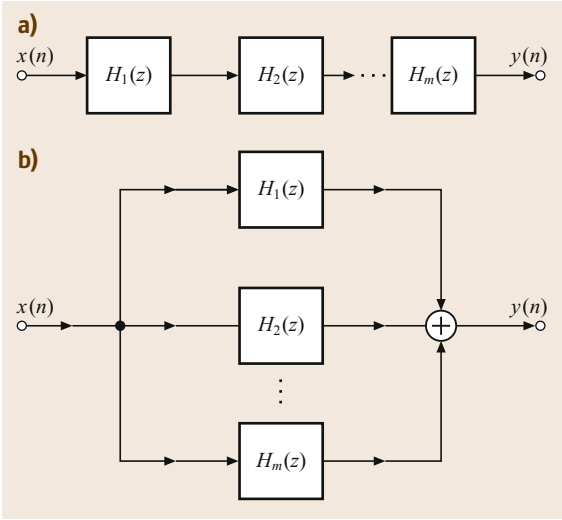

Fig. 9.19a,b Block diagrams of: **(a)** cascade form; **(b)** parallel form

In the case where $M < N$, we just make the coefficients $b_{M+1}, b_{M+2}, \ldots, b_N$ in Figs. 9.17 and 9.18 equal to zero.

Cascade Form

In the same way as their FIR counterparts, IIR digital filters present a large variety of possible alternative realizations. An important one, referred to as cascade

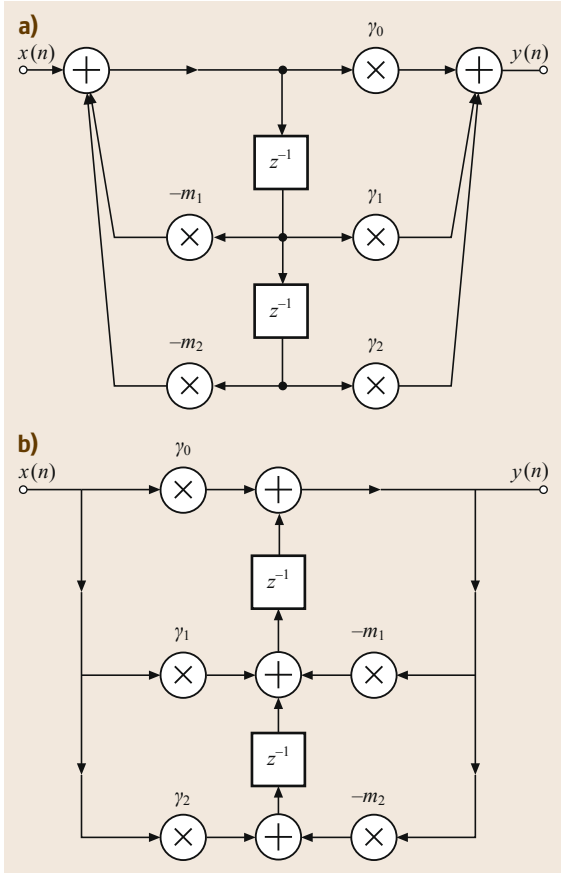

Fig. 9.20a,b Block diagrams of: **(a)** cascade form; **(b)** parallel form

realization, is depicted in Fig. 9.19a, where the basic blocks represent simple transfer functions of orders 2 or 1. In fact, the cascade form, based on second-order blocks, is associated with the following transfer function decomposition

$$H(z) = \prod_{k=1}^{m} \frac{\gamma_{0k} + \gamma_{1k} z^{-1} + \gamma_{2k} z^{-2}}{1 + m_{1k} z^{-1} + m_{2k} z^{-2}} ,$$

$$= \prod_{k=1}^{m} \frac{\gamma_{0k} z^2 + \gamma_{1k} z + \gamma_{2k}}{z^2 + m_{1k} z + m_{2k}} ,$$

$$= H_0 \prod_{k=1}^{m} \frac{z^2 + \gamma'_{1k} z + \gamma'_{2k}}{z^2 + m_{1k} z + m_{2k}} . \qquad (9.64)$$

Parallel Form

Another important realization for recursive digital filters is the parallel form represented in Fig. 9.19b. Using second-order blocks, which are the most commonly

used in practice, the parallel realization corresponds to the following transfer function decomposition

$$H(z) = \prod_{k=1}^{m} \frac{\gamma_{0k}^{\mathrm{p}} z^2 + \gamma_{1k}^{\mathrm{p}} z + \gamma_{2k}^{\mathrm{p}}}{z^2 + m_{1k} z + m_{2k}} ,$$
$$= h_0 + \prod_{k=1}^{m} \frac{\gamma_{1k}^{\mathrm{p}'} z + \gamma_{2k}^{\mathrm{p}'}}{z^2 + m_{1k} z + m_{2k}} ,$$
$$= h_0' + \prod_{k=1}^{m} \frac{\gamma_{0k}^{\mathrm{p}''} z^2 + \gamma_{1k}^{\mathrm{p}''} z}{z^2 + m_{1k} z + m_{2k}} . \qquad (9.65)$$

The above is also known as the partial-fraction decomposition. This equation indicates three alternative forms of the parallel realization, where the last two are canonic with respect to the number of multiplier elements.

It should be mentioned that each second-order block in the cascade and parallel forms can be realized by any of the existing distinct structures, as, for instance, one of the direct forms shown in Fig. 9.20.

All these digital filter realizations present different properties when one considers practical finite-precision implementations; that is, the quantization of the coefficients and the finite precision of the arithmetic operations, such as additions and multiplications. In fact, the analysis of the finite-precision effects in the distinct realizations is a fundamental step in the overall process of designing any digital filter [9.2].

9.3 The Fast Fourier Transform (FFT)

The FFT (fast Fourier transform) algorithm is a faster version of the discrete Fourier transform (DFT). FFT utilizes some clever algorithms to do the same thing as the DFT, but in much less time [9.2].

The DFT is extremely important in the area of frequency (spectral) analysis because it takes a discrete signal in the time domain and transforms that signal into its discrete frequency domain representation. Without a discrete-time to discrete-frequency transform we would not be able to compute the Fourier transform with a microprocessor or DSP-based (DSP: Digital Signal Processor) system [9.1, 2, 4–6].

It is the speed and discrete nature of the FFT that allows us to analyze a signal's spectrum, as will soon become evident.

9.3.1 Review of Integral Transforms

We first give a review of the integral transforms that have been used in the text, possibly in their unilateral (single-side) version.

The bilateral Laplace transform

$$X(s) = \mathcal{L}\{x(t)\} = \int_{-\infty}^{+\infty} x(t) e^{-st} \mathrm{d}t, x(t) \overset{\mathcal{L}}{\rightleftarrows} X(s) . \qquad (9.66)$$

The continuous-time Fourier transform

$$X(i\omega) = \mathcal{F}\{x(t)\} = \int_{-\infty}^{+\infty} x(t) e^{-i\omega t} \mathrm{d}t, x(t) \overset{\mathcal{F}}{\rightleftarrows} X(i\omega) . \qquad (9.67)$$

The bilateral Z-transform

$$X(z) = \mathcal{Z}\{x(n)\}$$
$$= \sum_{n=-\infty}^{+\infty} x(n) z^{-n}, x(n) \overset{\mathcal{Z}}{\rightleftarrows} X(z) . \qquad (9.68)$$

The Laplace transform is used to obtain a pole-zero representation of a continuous-time signal or system, $x(t)$, in the s-plane. Similarly, the Z-transform is used to find a pole-zero representation of a discrete-time signal or system, $x(n)$, in the z-plane.

The continuous-time Fourier transform can be found by evaluating the Laplace transform form at $s = i\omega$. The picture can be extended by introducing the discrete-time Fourier transform (DTFT). The DTFT can be found by evaluating the Z-transform at $z = \exp(i\Omega)$, as follows

$$X(e^{i\Omega}) = \sum_{n=-\infty}^{+\infty} x(n) e^{-i\Omega n}, x(n) \overset{\mathrm{DTFT}}{\rightleftarrows} X(e^{i\Omega}) . \qquad (9.69)$$

One needs to point out here that the frequency variable Ω is in normalized units of radians per sample rather than *absolute* units of rad/s, which apply to ω appearing in the standard Fourier transform. This can be justified by recollecting that sequences $x(n)$ are generated by sampling a continuous-time signal $x(t)$ at a certain sampling rate f_s. In this respect, the DTFT can be viewed as a discrete approximation of the Fourier

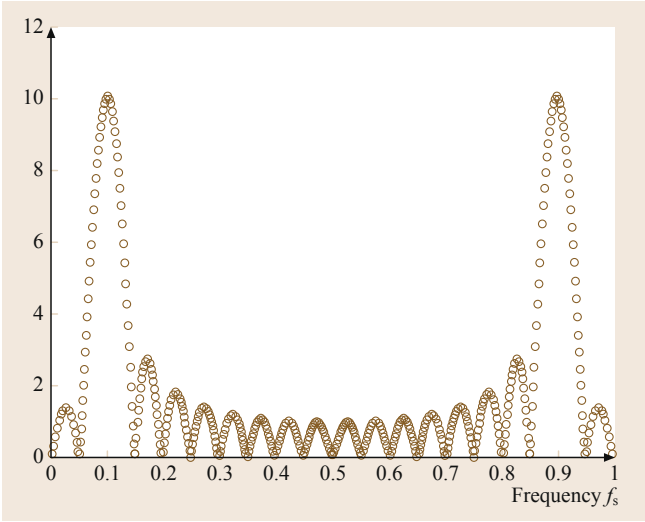

Fig. 9.21 Plot showing the symmetry of DFT

transform as explained below

$$\mathcal{F}\{x(t)\} = \int_{-\infty}^{+\infty} x(t)e^{-i\omega t}\,\mathrm{d}t$$
$$\simeq T_s \sum_{n=-\infty}^{+\infty} x(nT_s)\exp(-i\omega nT_s)$$
$$\Downarrow$$
$$\mathcal{F}\{x(t)\} \simeq T_s \cdot X(e^{i\Omega}), \Omega = \omega T_s = 2\pi\frac{f}{f_s}\,. \qquad (9.70)$$

9.3.2 The Discrete Fourier Transform (DFT)

First of all, the discrete Fourier transform (DFT) is *not* the same as the DTFT. Both start with a discrete-time signal, but DFT produces a discrete frequency domain representation while DTFT is continuous in the frequency domain. These two transforms have much in common, however. It is, therefore, helpful to have a basic understanding of the properties of the DTFT.

Periodicity

DTFT is periodic because of the fact that the signal is a discrete-time one. Indeed,

$$X(e^{i(\Omega+2\pi k)}) = \sum_{n=-\infty}^{+\infty} x(n)e^{-i(\Omega+2\pi k)n}$$
$$= \sum_{n=-\infty}^{+\infty} x(n)e^{-i\Omega n}e^{-i2\pi kn} = X(e^{i\Omega})\,. \qquad (9.71)$$

One fundamental period is, therefore, 2π, i. e., extends from $f = 0$ to f_s, where f_s is the sampling frequency. Taking advantage of this redundancy, the DFT is only defined in the region between 0 and f_s, in terms of f, or, 0 and 2π, in terms of Ω.

Symmetry

When the region between 0 and f_s is examined, it can be seen that there is even symmetry around the center point, i. e., point $f_s/2$ (half the sampling rate). Indeed,

$$\Omega_{1,2} = \pi \pm \varepsilon, 0 < \varepsilon < \pi :$$
$$X(e^{i\Omega_2})$$
$$= \sum_{n=-\infty}^{+\infty} x(n)e^{-i(\pi+\varepsilon)n} = \sum_{n=-\infty}^{+\infty} x(n)e^{-i\varepsilon n}e^{-i\pi n}$$
$$= \sum_{n=-\infty}^{+\infty} x(n)e^{-i\varepsilon n}e^{+i\pi n} = \sum_{n=-\infty}^{+\infty} x(n)e^{-i(\pi-\varepsilon)n}$$
$$= X(e^{i\Omega_1})\,. \qquad (9.72)$$

This symmetry adds redundant information. Figure 9.21 shows the DFT (implemented with Matlab's FFT function) of a cosine with a frequency one tenth of the sampling frequency. Note that the data between $0.5f_s$ and f_s is a mirror image of the data between 0 and $0.5f_s$.

Therefore, the discrete Fourier transform (DFT) can be introduced as follows

$$X_k = \sum_{n=0}^{N-1} x_n \exp\left(-\frac{i2\pi nk}{N}\right),$$
$$k = 0, 1, 2, \ldots, (N-1)\,. \qquad (9.73)$$

Note that the above is actually a transformation between a finite-length real or complex sequence x_n, corresponding to a sampled, at rate $f_s = 1/T_s$, segment of a real or complex signal with actual duration NT_s, to a generally complex sequence (discrete spectrum) of equal finite length N corresponding to frequency values in the range between 0 and $(N-1)f_s/N$ with a step equal to f_s/N; note that the corresponding range in terms of Ω is 0 to $(N-1)2\pi/N$ and the step $2\pi/N$.

Fast Fourier Transform (FFT)

FFT is simply an algorithm to speed up the DFT calculation by reducing the number of multiplications and additions required. It was popularized by J.W. Cooley and J.W. Tukey in the 1960s and, was actually a rediscovery of an idea of Runge (1903) and Danielson and Lanczos (1942), first occurring prior to the availability of computers and calculators – when numerical calculation could take many man hours. In ad-

Table 9.3 8-point DFT ($N = 8$)

Symmetry: $W_N^{r+N/2} = -W_N^r$, Periodicity: $W_N^{r+N} = W_N^r$	

dition, the German mathematician Carl Friedrich Gauss (1777–1855) had used the method more than a century earlier.

In order to understand the basic concepts of FFT and its derivation, note that the DFT expansion shown in Table 9.3 can be greatly simplified by taking advantage of the symmetry and periodicity of the twiddle factors as shown in Table 9.4. If the equations are rearranged and factored, the result is the fast Fourier transform (FFT), which requires only $(N/2)\log_2(N)$ complex multiplications. The computational efficiency of FFT versus DFT becomes highly significant when the FFT point size increases to several thousand, as shown in Table 9.5. However, notice that FFT computes *all* the output frequency components (either all or none!). If only a few spectral points need to be calculated, DFT may actually be more efficient. Calculation of a single spectral output using the DFT requires only N complex multiplications.

Table 9.5 FFT versus DFT. FFT is simply an algorithm for efficiently calculating DFT. Computational efficiency of an N-point FFT: 1) DFT: N^2 Complex multiplications; 2) FFT: $(N/2)\log_2(N)$ Complex multiplications

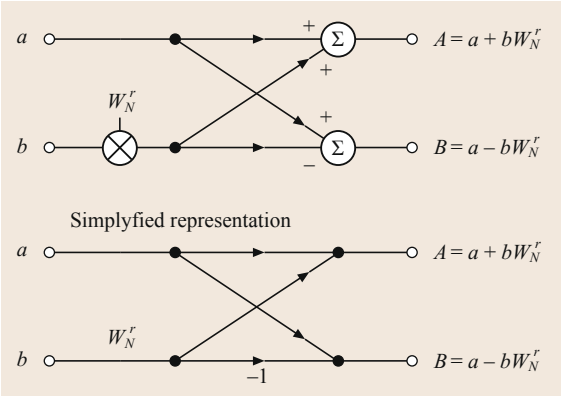

Fig. 9.22 The basic butterfly computation in the DIT-FFT algorithm

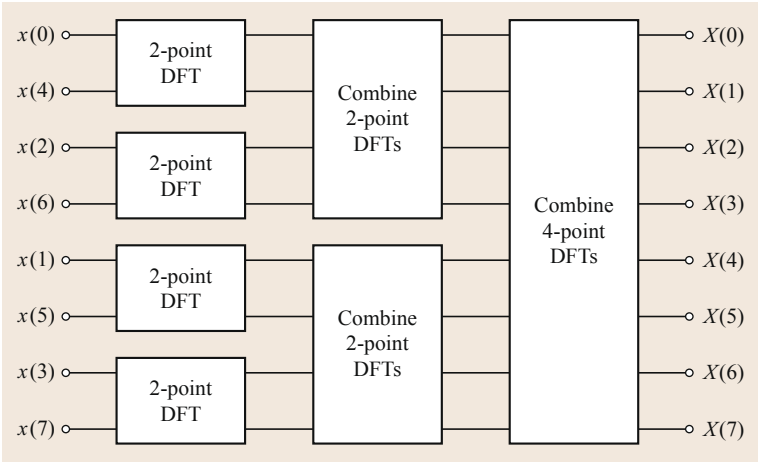

Fig. 9.23 Computation of eight-point FFT in three stages using DIT

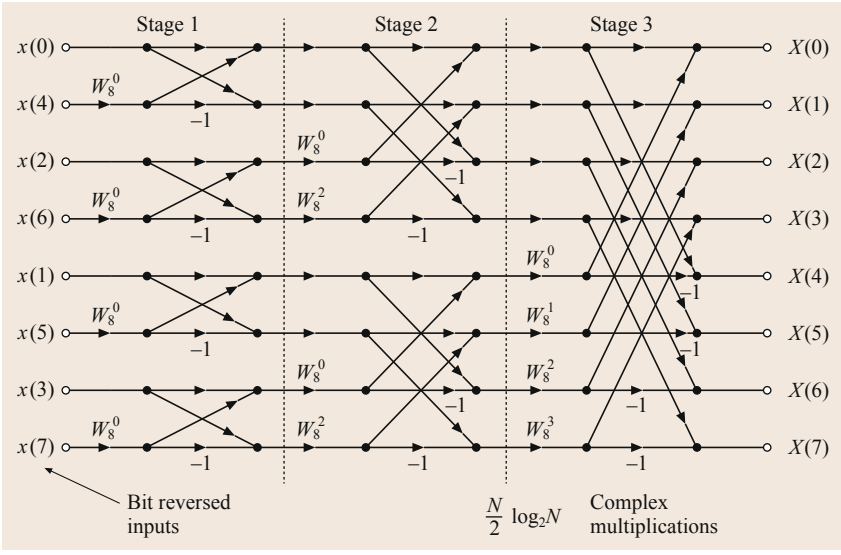

Fig. 9.24 Eight-point DIT-FFT algorithm

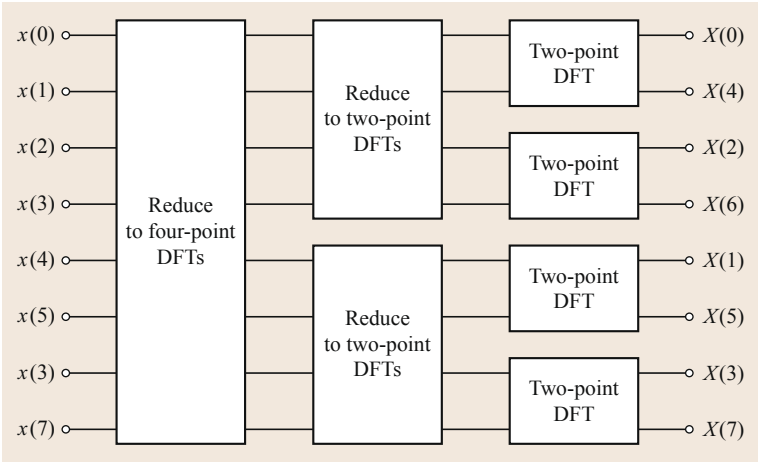

Fig. 9.25 Computation of eight-point FFT in three stages using DIF

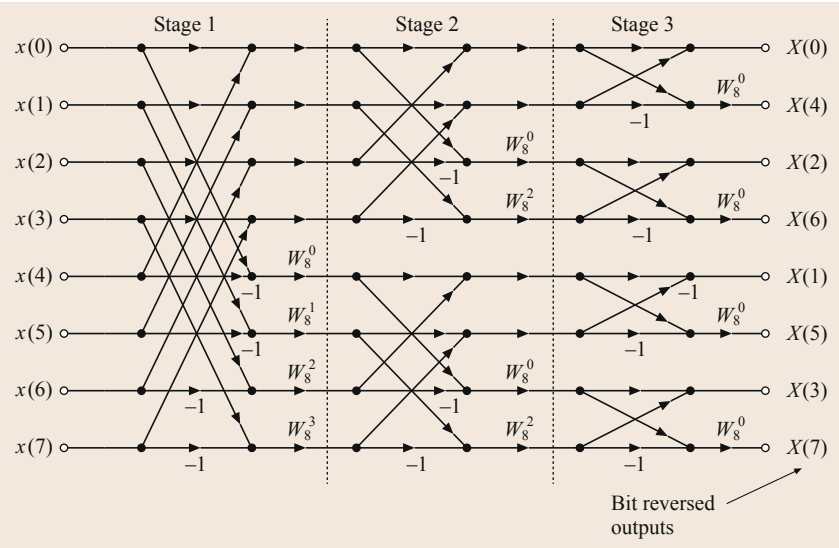

Fig. 9.26 Eight-point DIF-FFT algorithm

The radix-2 FFT algorithm breaks the entire DFT calculation down into a number of two-point DFTs. Each two-point DFT consists of a multiply-and-accumulate operation called a *butterfly*, as shown in Fig. 9.22. Two representations of the butterfly are shown in the diagram: the top diagram is the actual functional representation of the butterfly showing the digital multipliers and adders. In the simplified bottom diagram, the multiplications are indicated by placing the multiplier over an arrow, and addition is indicated whenever two arrows converge at a dot.

The eight-point decimation-in-time (DIT) FFT algorithm computes the final output in three stages as shown in Fig. 9.23. The eight input time samples are first divided (or *decimated*) into four groups of two-point DFTs. The four two-point DFTs are then combined into two four-point DFTs. The two four-point DFTs are then combined to produce the final output $X(k)$. The detailed process is shown in Fig. 9.24, where all the multiplications and additions are shown. Note that the basic two-point DFT butterfly operation forms the basis for all computations. The computation is done in three stages. After the first stage computation is complete, there is no need to store any previous results. The first stage outputs can be stored in the same registers that originally held the time samples $x(n)$. Similarly, when the second stage computation is completed, the results of the first stage computation can be deleted.

In this way, *in-place* computation proceeds to the final stage. Note that in order for the algorithm to work properly, the order of the input time samples, $x(n)$, must be properly re-ordered using a *bit reversal* algorithm.

The *bit reversal* algorithm used to perform this reordering is shown in Table 9.6. The decimal index, n, is converted to its binary equivalent. The binary bits are then placed in reverse order, and converted back to a decimal number. Bit reversing is often performed in DSP hardware in the data address generator (.*), thereby simplifying the software, reducing overhead, and speeding up the computations.

Decimal equivalent:	0	4	2	6	1	5	3	7

The computation of FFT using *decimation-in-frequency* (DIF) is shown in Figs. 9.25 and 9.26. This method requires that the bit reversal algorithm be applied to the output $X(k)$. Note that the butterfly for the DIF algorithm differs slightly from the decimation-in-time butterfly, as shown in Fig. 9.27.

The use of decimation-in-time versus decimation-in-frequency algorithms is largely a matter of preference, as either yields the same result. System constraints may make one of the two a more optimal solution. It should be noted that the algorithms required to compute the inverse FFT are nearly identical to those required to compute the FFT, assuming complex FFTs are used. In fact, a useful method for verifying a complex FFT algorithm consists of first taking the FFT of the $x(n)$ time samples and then taking the inverse FFT of the $X(k)$. At the end of this process, the original time samples, $Re(x(n))$, should be obtained and the imaginary part, $Im(x(n))$, should be zero (within the limits of the mathematical round off errors).

The FFTs discussed up to this point are radix-2 FFTs, i. e., the computations are based on two-point butterflies. This implies that the number of points in the FFT algorithms must be a power of 2. However, non-radix-2 FFT algorithms have been developed and are available in modern computational software packages like Matlab, Mathematica, Maple, etc., to be used in a variety of applications in ocean engineering as well as beyond [9.1, 2, 4–6].

9.4 Waveform Analysis

A waveform is one recording of a deterministic signal or that of an instance of a random signal (also referred to in the literature as a stochastic process). Actually, in practice we can make a recording of finite duration, which means that a waveform is the set of signal recordings over possibly non-contiguous time intervals. Typical examples of (lumped) waveforms in ocean engineering are significant wave height at a point or average, oceanic temperature or salinity, acoustic recordings of marine life, sonar or radar signals, etc. [9.3].

9.4.1 Definitions for Waveforms and Random Signals

The time mean (or average) of a waveform is defined as follows in the continuous time domain

$$\mu_x \triangleq \lim_{T\to\infty}\left\{\frac{1}{2T}\int_{-T}^{+T} x(t)\,\mathrm{d}t\right\} . \tag{9.74}$$

The time-wise cross-correlation of two waveforms is defined as follows

$$\begin{aligned} R_{y,x}(\tau) &\triangleq \lim_{T\to\infty}\left\{\frac{1}{2T}\int_{-T}^{+T} y(t)x(t+\tau)\,\mathrm{d}t\right\} , \\ &= [y \otimes x_{-(t)}](\tau) . \end{aligned} \tag{9.75}$$

In the above, $\otimes$ stands for the convolution operation applied in the square brackets between signal y and signal $x_{(-t)}$, which is the mirrored version of signal x about origin of time ($t = 0$), with time shift τ, i. e.,

$$x_{-(t)}(t) = x(-t) .$$

Also, note that cross-correlation as defined above can be used to introduce (time-wise) autocorrelation of a single waveform if we set $y \equiv x$.

The limiting process to infinity for time variable T introduced in the equations above is required in the case when the waveform has infinite duration so that the definitions make sense and do not give rise to indeterminate or infinite sums.

On the other hand, if the waveform (or at least one of them in the cross-correlation case) is finite in duration, then the time interval ($2T$) needs to be set equal to the full finite, and not infinite, duration of the signal. In this case, the definitions need to look like the following to avoid any issues

$$\mu_x \triangleq \frac{1}{2T}\int_{-\infty}^{+\infty} x(t)\,\mathrm{d}t , \tag{9.76}$$

$$R_{y,x}(\tau) \triangleq \frac{1}{2T}\int_{-\infty}^{+\infty} y(t)x(t+\tau)\,\mathrm{d}t . \tag{9.77}$$

The above equations are well defined in the case of deterministic signals and waveforms that occur as instances of random signals. Specifically, a random signal, denoted with a capital letter, e.g., $X(t)$, in contrast to lowercase latters used for deterministic signals, is associated with a probability density function (PDF), $f_X(x)$ quantifying the probability of the signal value at any

time instant t to lie within an arbitrary real interval $[a, b]$ as follows

$$\Pr[a \le X(t) \le b] = \int_a^b f_X(x)\,\mathrm{d}x\,. \tag{9.78}$$

As well established by probability theory, the probability density function is, in turn, associated with a cumulative distribution function (CDF) for random signal $X(t)$ as follows

$$F_X(x) = \Pr[X(t) \le x] = \int_{-\infty}^{x} f_X(x_\#)\,\mathrm{d}x_\#\,. \tag{9.79}$$

One can easily verify by combining (9.78) with (9.79) that

$$\Pr[a \le X(t) \le b] = F_X(b) - F_X(a) \tag{9.80}$$

holds. Finally and assuming certain smoothness conditions hold, the PDF can be calculated as the derivative of the CDF for the same random variable, i. e.,

$$f_X(x) = \frac{\mathrm{d}}{\mathrm{d}x} F_X(x)\,. \tag{9.81}$$

For a random signal one can, in effect, define a probabilistic mean value as follows

$$\langle X(t)\rangle = \mu_X(t) \triangleq \int_{-\infty}^{+\infty} x f_{X(t)}(x)\,\mathrm{d}x\,. \tag{9.82}$$

Along the same lines a probabilistic correlation (cross and/or autocorrelation) can be introduced

$$\begin{aligned}\langle X(t_1), Y(t_2)\rangle &= R_{X,Y}(t_1, t_2)\,,\\ &\triangleq \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} xy f_{X(t_1),Y(t_2)}(x, y)\,\mathrm{d}y\,\mathrm{d}x\,.\end{aligned} \tag{9.83}$$

To properly define it, though, the joint probability density function needs to be introduced; as can be seen below, it quantifies the probability of random signal X assuming a value in an infinitesimal vicinity of x at instant t_1 and, jointly, random signal Y assuming a value in an infinitesimal vicinity of y at instant t_2

$$\begin{aligned}&f_{X(t_1),Y(t_2)}(x, y)\,\mathrm{d}x\,\mathrm{d}y\\ &= \Pr[(x \le X(t_1) \le x + \mathrm{d}x) \text{ and}\\ &\qquad (y \le Y(t_2) \le y + \mathrm{d}y)]\,.\end{aligned} \tag{9.84}$$

In effect, the probability on the right-hand side in the above is that of the joint event to find the values of signals X and Y at certain time instants within an arbitrary infinitesimal rectangle on the XY plane. Applying Bayes' theorem on the joint probability of the right-hand side of (9.84) one can derive the following equations involving conditional probabilities

$$\begin{aligned}&\Pr[x \le X(t_1) \le x + \mathrm{d}x | y \le Y(t_2) \le y + \mathrm{d}y]\\ &\quad \cdot \Pr[y \le Y(t_2) \le y + \mathrm{d}y]\\ &= f_{X(t_1),Y(t_2)}(x, y)\,\mathrm{d}x\,\mathrm{d}y\\ &= \Pr[y \le Y(t_2) \le y + \mathrm{d}y | x \le X(t_1) \le x + \mathrm{d}x]\\ &\quad \cdot \Pr[x \le X(t_1) \le x + \mathrm{d}x]\,.\end{aligned} \tag{9.85}$$

In the case that random variables X and Y are independent (not to be confused with mutually exclusive variables or events), then using (9.85) for the conditional probabilities one can see that the following holds

$$f_{X(t_1),Y(t_2)}(x, y) = f_{X(t_1)}(x) \cdot f_{Y(t_2)}(y) \tag{9.86}$$

A very important category of random signals is that of wide sense stationary (WSS). A WSS signal is one that has: (a) constant, i. e., time invariant, probabilistic mean, and, (b) autocorrelation solely depending on the time shift (delay) $\tau = t_2 - t_1$ and not on the individual time instants. In effect, for a random signal to be WSS it must hold that

$$\langle X(t)\rangle = \langle X\rangle = \mu_X\,, \tag{9.87}$$

$$\langle X(t), X(t+\tau)\rangle = R_{X,X}(\tau)\,. \tag{9.88}$$

In part, WSS signals are important because both the probabilistic mean value and autocorrelation can be obtained as the time-wise mean and autocorrelation of anyone of its instances, $x(t)$, introduced for waveforms earlier. For this to be possible though, the random signal (stochastic process) X needs to be ergodic on top of WSS. Indeed, for an ergodic process statistical (probabilistic) properties (such as its mean, correlation, and variance) can be deduced from a single, sufficiently long instance (sample realization) of the process. Therefore, for an ergodic WSS process, the following hold

$$\langle X(t)\rangle = \mu_{\mathrm{x}}\,, \tag{9.89}$$

$$\langle X(t), X(t+\tau)\rangle = R_{x,x}(\tau)\,. \tag{9.90}$$

It should be noted, however, that for the above equations to hold exactly the integrals over time in (9.74)

and (9.75) need to span the entire real line from minus to plus infinity. If not, then (9.89) and (9.90) provide only an estimate of the mean and autocorrelation values of the random signal; the accuracy of the estimate (probabilistically) increases as time parameter T in the time-wise integrals of (9.74) and (9.75) grow larger.

A final note is made regarding strictly or strongly stationary processes versus WSS ones. A strictly stationary process is a stochastic process whose joint probability distribution does not change when shifted in time. This requirement is much stronger than just mean and autocorrelation and, therefore, much harder to meet or assume in practical situations; that is why in the remaining text we will only employ WSS as well as ergodicity.

9.4.2 Signal Power and Power Spectral Density

For a waveform $x(t)$, i. e., a deterministic signal or an instance of a random one, the following definitions are given:

1. The time mean is the direct current (DC) offset (component) of the waveform and $|\mu_x|^2$ is the DC power of it.
2. Consider

$$R_{x,x}(0) = \lim_{T\to\infty}\left\{\frac{1}{2T}\int_{-T}^{+T} x^2(t)\,\mathrm{d}t\right\} \geq 0\,. \quad (9.91)$$

   This is the (total averaged) power of the waveform.
3. Then consider

$$\mathrm{cov}(x) = R_{x,x}(0) - |\mu_x|^2 \geq 0\,. \quad (9.92)$$

   This is the covariance or alternating current (AC) power of the waveform. Also, $[\mathrm{cov}(x)]^{1/2}$ is the standard deviation or RMS (root-mean-square) value of the waveform.

The use of term *power* here stands for electric power, i. e., that the waveform is considered as voltage across or electric current through a reference resistance equal to 1 ohm.

Finally, the following notation for cross-correlation (for two waveforms) or autocorrelation (for a single waveform)

$$\langle y, x\rangle = R_{y,x}(0) \triangleq \lim_{T\to\infty}\left\{\frac{1}{2T}\int_{-T}^{+T} y(t)x(t)\,\mathrm{d}t\right\}\,. \quad (9.93)$$

In the case of two distinct waveforms $\langle y, x\rangle$ is also identified as their dot product. In the case of a single waveform $\langle x, x\rangle$ is its power.

In the frequency domain and using the two-sided Fourier transform as introduced in (9.8), the (cross) power spectral density (PSD) can be defined for a couple of waveforms as follows

$$S_{y,x}(\omega) \triangleq \mathcal{F}\{R_{y,x}(\tau)\} = Y(\omega)X^*(\omega)\,. \quad (9.94)$$

Note that for a real waveform it holds that

$$X(\omega) = \mathcal{F}\{x(t)\} = \int_{-\infty}^{+\infty} x(t)\exp(-i\omega t)\,\mathrm{d}t$$

$$\Updownarrow$$

$$X^*(\omega) = \left(\int_{-\infty}^{+\infty} x(t)\exp(-i\omega t)\,\mathrm{d}t\right)^* = \int_{-\infty}^{+\infty} x^*(t)\exp(+i\omega t)\,\mathrm{d}t = X(-\omega)\,.$$

Furthermore

$$\mathcal{F}\{x(-t)\} = \int_{-\infty}^{+\infty} x(-t)\exp(-i\omega(-t))\,\mathrm{d}(-t) = \int_{-\infty}^{+\infty} x(t)\exp(i\omega t)\,\mathrm{d}t = X(-\omega)\,.$$

Therefore, for a real waveform it holds that

$$X^*(\omega) = \mathcal{F}\{x(-t)\} = X(-\omega)\,. \quad (9.95)$$

Then, using (9.94) one can directly derive the following

$$S_{x,y}(\omega) = S_{y,x}(-\omega) = S^*_{y,x}(\omega) \Leftrightarrow R_{x,y}(\tau) = R_{y,x}(-\tau)\,. \quad (9.96)$$

Moreover, in the case of autocorrelation PSD obtains the following form

$$S_{x,x}(\omega) \triangleq \mathcal{F}\{R_{x,x}(\tau)\} = |X(\omega)|^2 \geq 0 \quad \text{and} \quad S_{x,x}(\omega) = S_{x,x}(-\omega)\,. \quad (9.97)$$

In effect, the PSD of a single signal is an even, non-negative complex function of frequency. Also, for the autocorrelation it holds that it is an even function of time τ, i. e., $R_{x,x}(\tau) = R_{x,x}(-\tau)$.

A final note has to do with the extension of the PSD concept to random signals (stochastic processes in mathematical terminology). Assuming ergodicity and WSS, the Wiener–Khinchin theorem can be employed to introduce a PSD for a random signal X or at least a power spectral distribution function $F_X(f)$ as follows

$$\begin{aligned}\langle X(t), X(t+\tau)\rangle &= R_{X,X}(\tau) \\ &= \int_{-\infty}^{+\infty} e^{i\omega\tau}\,\mathrm{d}F_X(f), \omega = 2\pi f\,.\end{aligned} \tag{9.98}$$

For the above to hold, the autocorrelation of X needs to exist and be finite for any value of time shift variable τ, but its Fourier transform may not be well defined. Indeed, the Fourier transform of a random signal may not exist in general, because stationary stochastic processes may not generally be square or absolutely integrable. Nor does their autocorrelation need to be absolutely integrable, so it need not have a Fourier transform, either. However, in most practical applications the autocorrelation is integrable and even satisfies the conditions to obtain a Fourier transform. In this case, the PSD can be introduced through the Fourier transform as follows

$$\begin{aligned}S_{X,X}(\omega) &= \int_{-\infty}^{+\infty} R_{X,X}(\tau)e^{-i\omega\tau}\,\mathrm{d}\tau \Leftrightarrow R_{X,X}(\tau) \\ &= \int_{-\infty}^{+\infty} S_{X,X}(f)e^{i\omega\tau}\,\mathrm{d}f, \omega = 2\pi f\,.\end{aligned} \tag{9.99}$$

Finally, in this case the PSD is the averaged derivative of the power spectral distribution function introduced previously. This is why the latter is also referred to as the integrated spectrum of the stochastic process.

9.4.3 Waveform Propagation Through a Linear, Time-Invariant System

Consider a linear, time-invariant (LTI) system with a single input and a single output (SISO), as shown in Fig. 9.28, driven by input waveform $x(t)$ and generating as response output waveform $y(t)$.

The system is assumed to be in continuous time, as well as the waveforms at its input and its output. Then, the output can be determined as the convolution ($\otimes$) of

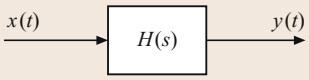

Fig. 9.28 LTI-SISO system with waveforms at its input and its output

the LTI system's scalar impulse response with the input waveform

$$\begin{aligned}y(t) = h(t)\otimes x(t) &= \int_{-\infty}^{+\infty} h(t_\#)x(t-t_\#)\,\mathrm{d}t_\# \\ &\Leftrightarrow Y(\omega) = H(\omega)\cdot X(\omega)\,.\end{aligned} \tag{9.100}$$

In the above, $h(t)$ stands for the system's impulse response that can be determined on the basis of the system's transfer function $H(s)$ in the complex frequency (Laplace transform) domain

$$h(t) = \mathcal{L}^{-1}\{H(s)\}\,. \tag{9.101}$$

It is noted here that for a causal system, the convolutional integral must be finitely bounded as follows

$$\begin{aligned}y(t) = h(t)\otimes x(t) &= \int_{0}^{t} h(t_\#)x(t-t_\#)\,\mathrm{d}t_\# \\ \text{and}\quad h(t) &= 0, \forall t < 0\,.\end{aligned} \tag{9.102}$$

For the means of the input and output waveforms the following can be derived

$$\begin{aligned}\mu_y &\triangleq \lim_{T\to\infty}\left\{\frac{1}{2T}\int_{-T}^{+T} y(t)\,\mathrm{d}t\right\} \\ &= \mu_x\cdot\int_{-\infty}^{+\infty} h(t)\,\mathrm{d}t = H(0)\cdot\mu_x\,.\end{aligned} \tag{9.103}$$

For the various correlations, as well as the PSD of the input and output, the following hold

$$\begin{aligned}R_{y,y}(t) &= R_{h,h}\otimes R_{x,x} \\ &\Leftrightarrow S_{y,y}(\omega) = |H(\omega)|^2\cdot S_{x,x}(\omega)\,,\end{aligned} \tag{9.104}$$

$$\begin{aligned}R_{y,x}(t) &= h\otimes R_{x,x} \\ &\Leftrightarrow S_{y,x}(\omega) = H(\omega)\cdot S_{x,x}(\omega)\,,\end{aligned} \tag{9.105}$$

$$R_{x,y}(t) = h_{-(t)} \otimes R_{x,x}$$
$$\Leftrightarrow S_{x,y}(\omega) = H^*(\omega) \cdot S_{x,x}(\omega) \,. \qquad (9.106)$$

All of the above can be derived on the basis of the definitions and properties given previously, as well as the commutativity and associativity of scalar convolution. For example, in the case of (9.104)

$$\begin{aligned} R_{y,y}(t) &= y \otimes y_{-(t)} \\ &= [h \otimes x] \otimes [h_{-(t)} \otimes x_{-(t)}] \\ &= R_{h,h} \otimes R_{x,x} \,. \end{aligned} \qquad (9.107)$$

It is noted here that:

1.

$$S_{h,h}(\omega) = H(\omega)H^*(\omega) = |H(\omega)|^2 \,,$$

2.

$$\begin{aligned} R_{h,h}(\tau) &= \int_{-\infty}^{+\infty} S_{h,h}(f) e^{i\omega\tau} \, \mathrm{d}f \\ &= \int_{-\infty}^{+\infty} |H(\omega)|^2 e^{i\omega\tau} \, \mathrm{d}f, \omega = 2\pi f \,, \end{aligned}$$

and

3.

$$\begin{pmatrix} x_{-(t)} \\ y_{-(t)} \\ h_{-(t)} \end{pmatrix} (t) = \begin{pmatrix} x \\ y \\ h \end{pmatrix} (-t), \forall t \in \mathbb{R} \Leftrightarrow \mathcal{F} \left\{ \begin{matrix} x_{-(t)} \\ y_{-(t)}(t) \\ h_{-(t)} \end{matrix} \right\}$$
$$= \begin{pmatrix} X^* \\ Y^* \\ H^* \end{pmatrix} (\omega \text{ or } f) \,.$$

9.5 Optimal Signal Estimation

9.5.1 System Identification

One of the most fundamental problems in science and engineering is the determination of a system's dynamics, preferably in the form of a mathematical model, when presented with the system response(s) to given deterministic or random driving inputs. This is the fundamental system identification problem [9.7, 8].

In the case of an LTI system, especially in the case of discrete-time or sampled-data systems, system identification is essentially equivalent to a problem of minimum square error approximation. Consider the problem statement as shown in Fig. 9.29.

A fundamental prerequisite for the system identification problem to have a solution in its basic form is that the additive measurement noise superimposed to the system output is of zero mean and uncorrelated to the driving forcing signal applied as input to the system. Therefore, the following two conditions must hold

$$\mu_v \triangleq \lim_{T\to\infty} \left\{ \frac{1}{2T} \int_{-T}^{+T} v(t) \, \mathrm{d}t \right\} = 0 \,, \qquad (9.108)$$

$$R_{vx}(\tau) = R_{xv}(\tau) = 0, \forall \tau$$
$$\Leftrightarrow S_{vx}(\omega) = S_{xv}(\omega) = 0, \forall \omega \,. \qquad (9.109)$$

At this point it is important to emphasize the importance of the definition of the appropriate time window T in (9.75). Indeed, it is possible that for some (commonly small) value of T condition (9.109) may not be satisfied with sufficient accuracy. However, assuming that condition (9.109) is satisfied for an infinite time window as well as appropriate stationarity and ergodicity assumptions, it is possible to determine a finite value for T such that condition (9.109) is met at arbitrarily small (*epsilon*) accuracy.

Given the property in (9.109) and by use of the linearity property of both cross-correlation and PSD, as well as (9.105), one can derive the following

$$S_{yx}(\omega) = S_{ux}(\omega) + S_{vx}(\omega) = H(\omega) \cdot S_{xx}(\omega) \,. \qquad (9.110)$$

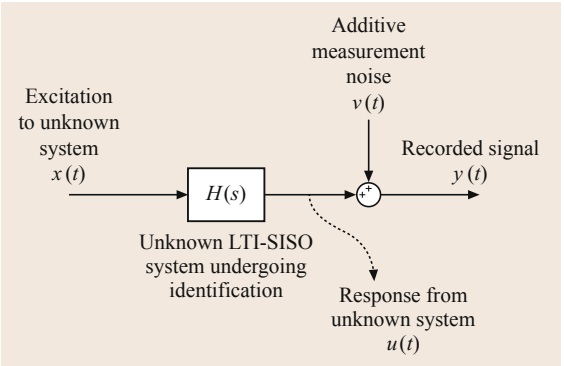

Fig. 9.29 LTI-SISO system identification problem

The above holds since $y(t) = u(t) + v(t)$ and $u(t) = h(t) \otimes x(t) \Leftrightarrow U(\omega) = H(\omega)X(\omega)$. In effect, the unknown transfer functions of the intermitted LTI system

$$H(\omega) = \frac{S_{yx}(\omega)}{S_{xx}(\omega)} \,. \tag{9.111}$$

In the time domain the equivalent equation to (9.111) is

$$R_{yx}(t) = h(t) \otimes R_{xx}(t) = \int_{-\infty}^{+\infty} h(t_\#) R_{xx}(t - t_\#)\, \mathrm{d}t_\# \,. \tag{9.112}$$

In the above equation, the unknown signal (function) is the impulse, $h(t)$. The integral equation is known as the Wiener–Hopf equation with infinite time horizon [9.1, 2, 4–6].

What is most important in both (9.111) and (9.112) is that system identification using them can be implemented with either deterministic or random signals. In effect, signals, $x(t)$, $v(t)$ and $y(t)$ may be known only probabilistically (statistically); this means that the individual instances (realizations) of the signals do not need to be known as long as their statistics are, e.g., means, correlations, or covariance coefficients.

Typically in practice, statistical characterization of signals can be effectively, yet approximately, performed by taking advantage of ergodicity and stationarity, if they apply. Assuming that these hold, then a sufficiently long, yet finite, recording of a single realization of a random signal allows for its statistical characterization in terms of its autocorrelation and cross-correlation with other signals. Such a recording, e.g., for $v(t)$ or $x(t)$ in the case of our system identification framework, can be performed once and be used along with measurements for $y(t)$ to identify the system; all due to ergodicity and stationarity.

9.5.2 Discrete-Time Wiener–Hopf Equation over a Finite-Duration Window

Integral (9.112), despite its immense theoretical value, does not really indicate how it can be applied in practice for system identification. In this passage, we will introduce a methodology allowing identification of an LTI-SISO system when presented only with sampled-data recordings of $x(t)$ and $y(t)$, with a sampling rate meeting the Nyquist requirement for both. Furthermore, it will be assumed that the observation window (time horizon) of the recordings of the forcing and the noisy response is finite in duration instead of infinite.

The outcome of the processing will be the determination of a given finite number of impulse response samples for the unknown system undergoing identification. In effect, it is possible to define a discrete-system FIR (finite impulse response) system in either the time domain, by its very impulse response, or as a transfer function in the Z-transform domain without any poles. In effect, the FIR system will approximate the behavior of the unknown LTI system undergoing identification in the sense of (truncated) impulse response matching.

We start from the integral equation for $y(t)$ given previously

$$\begin{aligned} y(t) &= h(t) \otimes x(t) + v(t) \\ &= \int_{-\infty}^{+\infty} h(t_\#) x(t - t_\#)\, \mathrm{d}t_\# + v(t) \,. \end{aligned} \tag{9.113}$$

However, to satisfy causality for the unknown system the following needs to be introduced

$$\begin{aligned} y(t) &= \int_0^t h(t_\#) x(t - t_\#)\, \mathrm{d}t_\# \\ +v(t) &= \int_0^t h(t - t_\#) x(t_\#)\, \mathrm{d}t_\# + v(t) \,. \end{aligned} \tag{9.114}$$

Converting the above to discrete time by sampling interval T_s, compliant to the Nyquist rate criterion, one can derive the following

$$y(nT_\mathrm{s}) = T_\mathrm{s} \sum_{k=0}^{n} h(kT_\mathrm{s}) x((n-k)T_\mathrm{s}) + v(nT_\mathrm{s}) \,. \tag{9.115}$$

Without loss of generality we can assume that $T_\mathrm{s} = 1$, since any other sampling interval value can be absorbed multiplicatively in the impulse response sample values.

$$y(n) = \sum_{k=0}^{n} h(k) x(n-k) + v(n) \,. \tag{9.116}$$

An important prerequisite for our identification method to be successful is that the unknown LTI system is stable. If this holds, then for an arbitrarily small ε one can find a positive integer M, such that

$$\sum_{n=M+1}^{+\infty} h^2(n) < \varepsilon \,. \tag{9.117}$$

In effect, with epsilon accuracy it is possible to truncate the impulse response of the unknown system. We note here that impulse response truncation is an approximation of the system undergoing identification by the

following FIR one with memory M

$$\hat{H}_{\mathrm{FIR}}(z^{-1}) = \sum_{n=0}^{M} h(n) z^{-n} \,. \tag{9.118}$$

Using the approximation above, (9.116) yields

$$y(n) = \sum_{k=0}^{M} h(k) x(n-k) + v(n) \,. \tag{9.119}$$

Furthermore, assuming that the recording for waveform $y(t)$ spans a finite interval $[0, T]$, the identification problem can be reduced to determining the $(M+1)$ samples of the impulse response, $h(n)$, $0 \le n \le M$, of the unknown system so that the following $(L+1)$ equations are satisfied

$$y(n) = \sum_{k=0}^{M} h(k) x(n-k) + v(n), 0 \le n \le L$$
$$\text{and} \quad L = \frac{T}{T_\mathrm{s}} \,. \tag{9.120}$$

It is noted here that containing the recording of signal $y(t)$ within interval $[0, T]$ allows limiting the need to record signal $x(t)$ also in the finite interval $[-MT_\mathrm{s}, +LT_\mathrm{s}]$.

In effect, the $((L+1)\times(M+1))$ set of algebraic (9.120) can be put in the following matrix form

$$\boldsymbol{y} = \ddot{X} \cdot \boldsymbol{h} + \boldsymbol{v} \,. \tag{9.121}$$

In the above, vectors y and v are defined as follows

$$\boldsymbol{y} = [y(0) \quad y(1) \quad \cdots \quad y(L)]^{\mathrm{T}}$$
$$\boldsymbol{v} = [v(0) \quad v(1) \quad \cdots \quad v(L)]^{\mathrm{T}} \,. \tag{9.122}$$

Vector h is defined as follows

$$\boldsymbol{h} = [h(0) \quad h(1) \quad \cdots \quad h(M)]^{\mathrm{T}} \,. \tag{9.123}$$

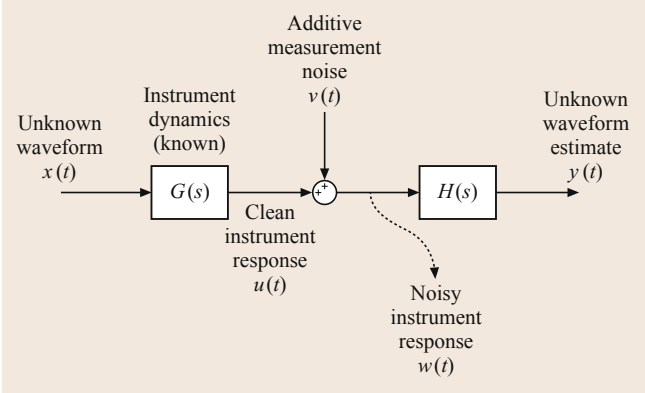

Fig. 9.30 Signal estimation framework

Matrix $\mathbf{X}$, known as observation matrix, is defined by the following

$$\mathbf{X} = \begin{bmatrix} x(0) & x(-1) & \cdots & x(-M) \\ x(1) & x(0) & \cdots & x(-M+1) \\ \vdots & \vdots & \ddots & \vdots \\ x(L) & x(L-1) & \cdots & x(-M+L) \end{bmatrix} \,. \tag{9.124}$$

The equation set in (9.121) is not square; therefore, an algebraically exact solution is not feasible. In effect, only a solution minimizing the following mean square error (MSE) vector spanning the observation window

$$\|e\|_2 = \|y - X \cdot h\|_2 \,. \tag{9.125}$$

If the above MSE vector is minimized, then the effect of the noise vector v, i. e., signal $v(t)$, is removed from the measurement vector y, i. e., signal $y(t)$. The Euclidean norm of vector e is defined as follows

$$\|e\|_2 = e^{\mathrm{T}} \cdot e = \sum_{i=0}^{L} e_i^2 \,. \tag{9.126}$$

The solution achieving minimization of $\|e\|_2$ can be proven to be that of the following square $((M+1)\times(M+1))$ set of algebraic *canonical equations*

$$(\mathbf{X}^T \cdot \mathbf{X}) \cdot h = \mathbf{X}^T \cdot y \Rightarrow h = (\mathbf{X}^T\mathbf{X})^{-1}\mathbf{X}^T y \,. \tag{9.127}$$

It is interesting to observe the equivalence between the time-domain (9.127) and (9.112); the equivalence can be straightforwardly derived if one observes that (9.112) needs to hold for any time instant t. This means that if it were converted to discrete time a (countable infinite in number) set of algebraic equations would be derived like in (9.121). Furthermore, the solution of canonical (9.127) is fully equivalent to (9.111), since there exists an one-to-one correspondence between: (a) square matrix $(\mathbf{X}^{\mathrm{T}}\mathbf{X})$ and autocorrelation $R_{xx}(t)$, and thereof PSD $S_{xx}(\omega)$; (b) vector $(\mathbf{X}^{\mathrm{T}}y)$ and cross-correlation $R_{yx}(t)$, and thereof PSD $S_{yx}(\omega)$.

On a technical note, it is pointed out that for (9.127) to hold, matrix $(\mathbf{X}^{\mathrm{T}}\mathbf{X})$ has to be invertible. In the case of zero initial conditions for x, i. e., $x(n) = 0, -M \le n < 0$, it must hold that $x(0) \neq 0$ so that $(\mathbf{X}^{\mathrm{T}}\mathbf{X})$ is, indeed, invertible.

9.5.3 Signal Estimation and the Wiener Filter

We will now look into a closely related problem: that of the estimation of a signal or waveform which is outlined in the block diagram of Fig. 9.30.

As can be seen a known, in this case, the LTI-SISO system is driven by an unknown (to be estimated) $x(t)$. or the known LTI system, the transfer function $G(s)$, in the complex frequency (Laplace) domain, or $G(\omega)$, in the Fourier (frequency) domain, or equivalently its impulse response $g(t)$ in the time domain is assumed known. Such an LTI system may model a measurement instrument, or sensor, or transducer, or telecommunications receiver.

Then, a linear filter with transfer function $H(s)$ is sought that will receive as input the noisy instrument response $w(t)$ and output waveform $y(t)$, which is expected to be the optimum, in the mean square sense, estimate of the unknown waveform $x(t)$.

The objective is to determine transfer function $H(s)$, or equivalently $H(\omega)$, of the estimation filter that minimizes the following *objective cost function*

$$\langle e, e\rangle \triangleq R_{ee}(0) = \int_{-\infty}^{+\infty} e^2(t)\,\mathrm{d}t\,. \tag{9.128}$$

In the above, the instantaneous error signal is defined as follows

$$e(t) = x(t) - y(t)\,. \tag{9.129}$$

For waveform $y(t)$ it holds that

$$\begin{aligned} y(t) = h(t) \otimes w(t) &= \int_{-\infty}^{+\infty} h(\xi)\, w(t-\xi)\,\mathrm{d}\xi \\ &\approx T_\mathrm{s} \sum_{k=-\infty}^{+\infty} h(kT_\mathrm{s})\, w(t-kT_\mathrm{s})\,. \end{aligned} \tag{9.130}$$

In the above, the convolutional integral has been approximated by the convolutional sum, assuming that sampling interval, T_s, satisfies the Nyquist criterion. Consequently, (9.128) becomes

$$\langle e, e\rangle = \int_{-\infty}^{+\infty} \left\{ x(t) - T_\mathrm{s} \sum_{k=-\infty}^{+\infty} h(kT_\mathrm{s})\, w(t-kT_\mathrm{s}) \right\}^2 \mathrm{d}t\,. \tag{9.131}$$

In effect, the impulse response of the least-squares estimator has to fulfill the following condition, so that cost $\langle e, e\rangle$ becomes minimum

$$\frac{\partial}{\partial[h(nT_\mathrm{s})]}\langle e, e\rangle = 0,\ \forall n \in Z\,. \tag{9.132}$$

However,

$$\begin{aligned} &\frac{\partial}{\partial[h(nT_\mathrm{s})]}\langle e, e\rangle \\ &= -2 \int_{-\infty}^{+\infty} \left\{ x(t) - T_\mathrm{s} \sum_{k=-\infty}^{+\infty} h(kT_\mathrm{s})\, w(t-kT_\mathrm{s}) \right\} \\ &\quad \times w(t-nT_\mathrm{s})\,\mathrm{d}t\,. \end{aligned} \tag{9.133}$$

Therefore, condition (9.132) finally yields

$$\int_{-\infty}^{+\infty} e(t)\, w(t-nT_\mathrm{s})\,\mathrm{d}t = 0,\ \forall n \in \mathbb{Z}\,. \tag{9.134}$$

Setting $\tau = nT_\mathrm{s}$ in the above and gradually diminishing T_s, we end up back in the continuous time domain, and (9.134) yields the following *orthogonality condition*

$$\begin{aligned} &\int_{-\infty}^{+\infty} e(t)\, w(t-\tau)\,\mathrm{d}t = 0,\ \forall \tau \in \mathbb{R} \\ &\qquad\qquad \Leftrightarrow R_{we}(\tau) = 0,\ \forall \tau \in \mathbb{R}\,. \end{aligned} \tag{9.135}$$

Using the above orthogonality condition

$$R_{we}(\tau) = 0 \Leftrightarrow S_{we}(\omega) = 0 \Leftrightarrow S_{xw}(\omega) = S_{yw}(\omega)\,. \tag{9.136}$$

Furthermore, since $S_{yw}(\omega) = H(\omega)S_{ww}(\omega)$, the following equation can be derived for the transfer function of the estimation filter

$$H(\omega) = \frac{S_{xw}(\omega)}{S_{ww}(\omega)}\,. \tag{9.137}$$

The above expression for the estimator is commonly known as the Wiener filter and of is of widespread use in many science and engineering application fields.

The signal power of the minimum square error, achieved by the Wiener filter in (9.137), can be determined as follows

$$\begin{aligned} S_{ee}(\omega) &= S_{xe}(\omega) - \underbrace{S_{ye}(\omega)}_{0} = S_{xx}(\omega) - S_{xy}(\omega) \\ &= S_{xx}(\omega) - \left(S_{yy}(\omega) + \underbrace{S_{ey}(\omega)}_{0} \right) \\ &\Downarrow \\ S_{ee}(\omega) &= S_{xx}(\omega) - S_{yy}(\omega)\,. \end{aligned} \tag{9.138}$$

For the derivation of the above it is reminded that

$$e = x - y \,.$$

Also, using the orthogonality condition (9.135), the following important result can be derived

$$S_{ye}(\omega) = H(\omega) S_{we}(\omega) \overset{S_{we}=0}{\Rightarrow} S_{ye}(\omega) = 0 = S_{ey}(\omega) \,.$$

It is noted here that

$$R_{ee}(\tau) = \mathcal{F}^{-1}\{S_{ee}(\omega)\} = \int_{-\infty}^{+\infty} S_{ee}(\omega) e^{\mathrm{i}\omega\tau}\, \mathrm{d}\omega \Rightarrow \langle e, e \rangle$$
$$= R_{ee}(0) = \int_{-\infty}^{+\infty} S_{ee}(\omega)\, \mathrm{d}\omega \,.$$

An alternative expression for the minimum error PSD can be derived on the basis of the following

$$S_{yy}(\omega) = |H(\omega)|^2 S_{ww}(\omega) = \frac{|S_{xw}(\omega)|^2}{S_{ww}^2(\omega)} S_{ww}(\omega)$$
$$= \frac{|S_{xw}(\omega)|^2}{S_{ww}(\omega)} \,.$$

Then

$$S_{ee}(\omega) = S_{xx}(\omega) - S_{yy}(\omega)$$
$$= \frac{S_{xx}(\omega) S_{ww}(\omega) - |S_{xw}(\omega)|^2}{S_{ww}(\omega)} \,. \qquad (9.139)$$

Further treatment of (9.137) is possible since the additive measurement noise is uncorrelated to the unknown signal $x(t)$ at the instrument input. In this case,

$$S_{xw}(\omega) = S_{xu}(\omega) + S_{xv}(\omega)$$
$$= G^*(\omega) S_{xx}(\omega) \quad \text{because} \quad S_{xv}(\omega) = 0 \,. \qquad (9.140)$$

Also

$$S_{ww}(\omega) = S_{uu}(\omega) + S_{vv}(\omega)$$
$$= |G(\omega)|^2 S_{xx}(\omega) + S_{vv}(\omega)$$
$$\text{since } u = v + w \,. \qquad (9.141)$$

Therefore, the Wiener filter in (9.137) becomes as follows

$$H(\omega) = \frac{G^*(\omega) S_{xx}(\omega)}{|G(\omega)|^2 S_{xx}(\omega) + S_{vv}(\omega)} \,. \qquad (9.142)$$

The above allows us to obtain an estimate of waveform $x(t)$ appearing at the instrument input port. As can be seen, to achieve this the signal's (waveform) statistics need to be known in advance, i. e., the signal PSD $S_{xx}(\omega)$ or autocorrelation $R_{xx}(\tau)$, as well as the dynamics of the measurement instrument, i. e., its transfer function $G(\omega)$ or its impulse response $g(t)$; last, but not least, prior information of the additive noise's statistics, ie, its PSD $S_{vv}(\omega)$ or autocorrelation $R_{vv}(\tau)$.

Two important specific subcases of (9.137) are given below:

1. *Zero-forcing equalization* [9.1, 5]:
   If $S_{vv}(\omega) \ll S_{xx}(\omega)$

$$H(\omega) = \frac{1}{G(\omega)} \,. \qquad (9.143)$$

   Evidently, in this subcase the statistics of either the unknown input signal or the additive noise need to be known in advance. Furthermore, one can easily verify that, if the inverse of the instrument's transfer function $G(\omega)$ does not introduce unstable poles, estimation error e vanishes.
2. *Matched filter* [9.1, 5]:
   If $|G(\omega)|^2 S_{xx}(\omega) \ll S_{vv}(\omega)$

$$H(\omega) = G^*(\omega) \frac{S_{xx}(\omega)}{S_{vv}(\omega)} \,. \qquad (9.144)$$

   In this subcase the major impairment toward obtaining an estimate of $x(t)$ is the additive noise rather than the instrument distortion, as was the case previously. Moreover note that if $S_{xx}(\omega) < S_{vv}(\omega)$, the instrument's output $w(t)$ will be noise-like, and yet by use of the Wiener filter it is possible to extract the unknown *information* signal $x(t)$.

Matched filter estimator design is widely used in communications engineering. At least as a first approximation, transfer function $G(\omega)$ models the telecommunication channel that introduces attenuation monotonically increasing with distance from the transmitter source. In a typical system, both the information signal $x(t)$, as well as disturbance noise $v(t)$ can be considered as *white noise*, i. e., signals with the following property

$$S_{nn}(\omega) = N_0, \forall\omega \Leftrightarrow R_{nn}(\tau) = N_0 \delta(\tau), \forall\tau \,. \qquad (9.145)$$

As can be seen, the case of a white noise signal demonstrates practically no predictability, since the value of the signal at any time instant is entirely uncorrelated

with its value at any other time instant in the past or in the future. Therefore, if both the information signal and the additive noise are modeled as white noise, (9.144) becomes

$$H(\omega) = \frac{X_0}{V_0} G^*(\omega) \,. \tag{9.146}$$

The ratio (X_0/V_0) with the PSD of the information signal $x(t)$ in the numerator and that of the additive noise in the denominator is known as signal-to-noise ratio (SNR) and is a very important parameter to characterize a system's sensitivity to external noise, as well as exogenous disturbance and crosstalk interference [9.1, 5].

9.6 Concluding Remarks

In this chapter, an account of digital signal processing concepts, methods and techniques employed in ocean engineering is given. After looking into the fundamental processes of continuous signal sampling and reconstruction, the Z-transform is introduced as the tool of convenience to analyze difference equations just like the Laplace transform is suited to analyze differential equations. Digital filters are presented then as well as the Fast Fourier Transform algorithm. Fundamentals of waveform analysis and stochastic processes are presented last as employed for system identification and signal estimation.

10. Control Theory and Applications

Nikolaos I. Xiros, Pak-Cheung Edgar An

In this chapter, a presentation of control theory and engineering as applied to ocean engineering is given. The chapter starts with the fundamentals of systems science and theory, i. e., descriptions of systems in state space and for linear, time-invariant ones in the frequency domain using the Laplace transform as well as with ordinary differential equations with respect to time. Then stability, controllability, and observability with an emphasis to linear, time-invariant systems are presented. Bode plots for sinusoidal steady-state analysis as well as the root locus technique for proportional gain feedback design are presented. For single-input, single-output systems, PID control is introduced as both a pole placement problem as well as in the framework of conventional Ziegler–Nichols methods. Pole placement design with the addition of Luenberger observers is presented for linear, time-invariant systems with any time of inputs and outputs. A brief presentation of digital controller implementations is given. Applications from ocean engineering include control of autonomous underwater vehicles and autopilots for surface vessels.

10.1 System Theory

10.1.1 Definitions and Fundamentals

Signal

A signal is any function that contains time t as an independent variable. Typical examples of signals are the position and velocity of a moving body, for example, a ship. The symbols used for signals are commonly lower case letters of the Greek or Latin alphabet. In classical control theory signals are only functions of time. However, there has been recently a growing interest for distributed signals, that is, signals that contain more than one independent variables. For example, a beam supported at one end is described by signals that depend on both time and the distance x from the support point.

System

A confined space that accepts input signals (or excitations) and generates output signals (or responses) is

a system. Typical examples of engineering systems include electric networks, internal combustion engines, turbines, etc. Commonly, a system can be subdivided to subsystems with respect to its complexity. A marine engine, for example, includes its turbocharger, which in turn includes the turbine and the air compressor, the cylinders, the crankshaft. etc. All these subsystems may be regarded as systems with their own inputs and outputs. However, the engine is also a subsystem of a higher complexity system, that is, the propulsion plant or the vessel.

Recently the concept of system has been generalized in order to include, except technological or physical systems, biological systems, economical systems, administrative systems, etc. In correspondence the concept of signals has been expanded in order to include inputs and outputs to such systems.

Automatic Control and Feedback

The concept of control is directly related to that of *feedback* [10.1–3]. Specifically, Wiener defines automatic control as the method of controlling a system by applying as inputs the system's past responses. A similar description is given by the IEEE (Institute of Electrical and Electronics Engineers): An automatic control system, such as the cruise control system in automobiles, implements in the controller a decision process, also called the control law, that dictates the appropriate control actions to be taken for the speed to be maintained within acceptable tolerances. These decisions are taken based on how different the actual speed is from the desired, called the error, and on the knowledge of the car's response to fuel increase and decrease. This knowledge is typically captured in a mathematical model. Information about the actual speed is fed back to the controller by sensors, and the control decisions are implemented via a device, the actuator, that increases or decreases the fuel flow to the engine. This idea is also depicted in the following block diagram.

The use of block diagrams is wide in the control community and is not limited to demonstration of functionality as in Fig. 10.1. On the contrary, it is connected with mathematical properties and operations. However, coming back to Fig. 10.1, it can be seen that an automatic feedback control system includes a plant (controlled system) and a control system. The control system is composed of a controller, sensor(s), and actuator(s). When the feedback path (the line supplying information on the plant status through the sensors) is broken intentionally or unintentionally the system is called open-loop; otherwise, it is a closed-loop system.

An example of a closed-loop system is the automatic course-keeping system of a surface ocean vessel. This system includes all the components shown in Fig. 10.1. The plant in this case is the vessel. The control system consists of the autopilot unit (controller), the steering gear (actuator), and the compass and GPS (global positioning system) receiver (sensors). The controlled variable is the vessel's course and the control action is the rudder deflection from the centerline. Exogenous disturbances are present in the form of wind, wave, and current-generated forces and torques. The effect of the disturbances is demonstrated as a deviation of the actual heading of the vessel from the desired one, entered by the human operator as a waypoint (setpoint). In the case that either the waypoint is modified or excessive deviation is introduced to the controlled variable, as an effect of disturbance presence, the autopilot unit (controller) issues in response rudder position command signals (control signals) that drive the steering gear to appropriately adjust the rudder. The feedback signals are the positioning information provided by the GPS receiver and the heading indication provided by the compass. Both have additive noise which leads to more or less inaccurate readings; also, especially in the case of the GPS receiver, significant and in general variable delay between the actual occurrence of a change and its indication is experienced.

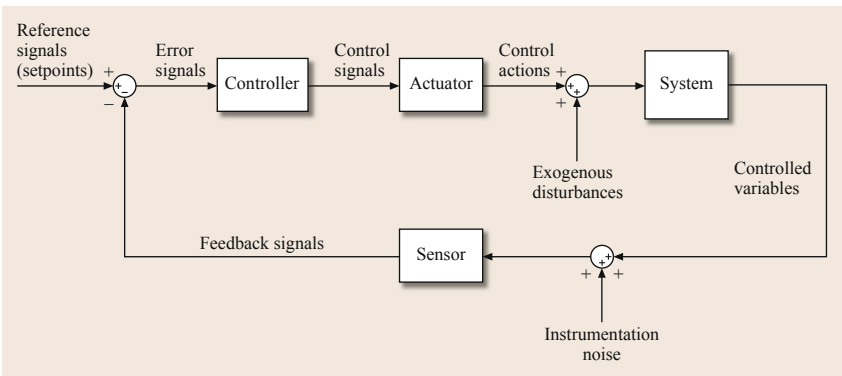

Fig. 10.1 Structure of system with automatic feedback control

Before embarking on the methods to develop a control system, a clear understanding of the behavior and analysis of the response of the plant is needed. This is commonly achieved by developing a mathematical model of the system. The type and the complexity of such a model, though, depend on various salient features of the plant in hand. One of the most important features is whether the plant is static or dynamic. A static system is one for which the output signal values at any given time instant can be determined by employing exclusively the input signal values at the exact same time instant. In effect, static systems are commonly described by algebraic equations of the following general form

$$\boldsymbol{y} = f(\boldsymbol{u}) \ . \tag{10.1}$$

In the above, $\boldsymbol{u}$ and $\boldsymbol{y}$ are the input and output signals, respectively, conveniently packed in vectors.

Another class of systems, though, which is usually the case in feedback control theory and engineering, are dynamic systems. A dynamic system is described by a number of *dynamic* equations, integro-differential equations including at least time as an independent variable. Specifically, the description of a dynamic system must encompass all the constraint equations as well as the full set of initial, or in some cases, final conditions required for the determination of a special solution of the integro-differential equations. A deeper insight in this definition as well as the fundamental description methods for linear and time-invariant dynamic systems is presented in the remainder of this chapter.

10.1.2 The Laplace Transform

The Laplace transform is a linear integral transform that is defined as follows for a signal $x(t)$

$$X(s) = \mathcal{L}\{x(t)\} = \int_0^\infty x(t)\mathrm{e}^{-st}\,\mathrm{d}t \ . \tag{10.2}$$

The (one-sided) Laplace transform is used extensively for analyses of either signals or systems in the complex frequency domain, $s = a + \mathrm{i}\omega$. The complex frequency comes as generalization of the (natural) frequency as defined especially for periodic signals, sinusoidal signals, or sums of such. This is manifested also by the fact that the Fourier transformation of any signal can be derived by substituting $s = \mathrm{i}\omega$ in its Laplace transformation or equivalently setting $a = 0$. These remarks are investigated in the following example.

Consider the signal

$$x(t) = \begin{cases} \exp(a_0 t)\sin(\omega_0 t) & t \geq 0 \ , \\ 0 & t < 0 \ . \end{cases}$$

The Laplace transform is calculated by the definition as follows

$$\begin{aligned} X(s) &= \int_0^\infty \exp(a_0 t)\sin(\omega_0 t)\mathrm{e}^{-st}\,\mathrm{d}t \\ &= \int_0^\infty \mathrm{e}^{a_0 t}\frac{\mathrm{e}^{\mathrm{i}\omega_0 t} - \mathrm{e}^{-\mathrm{i}\omega_0 t}}{2\mathrm{i}}\mathrm{e}^{-st}\,\mathrm{d}t \ . \end{aligned}$$

In the above, use of a well-known identity for the calculation of the sine signals has been made. By substituting $s_0 = a_0 + \mathrm{i}\omega_0$ and taking into account that $s_0^* = a_0 - \mathrm{i}\omega_0$, the following is obtained

$$\begin{aligned} X(s) &= \frac{1}{2\mathrm{i}}\int_0^\infty \mathrm{e}^{(s_0^* - s)t}\mathrm{d}t - \frac{1}{2\mathrm{i}}\int_0^\infty \mathrm{e}^{(s_0 - s)t}\,\mathrm{d}t \\ &= \frac{1}{2\mathrm{i}}\left(-\frac{1}{s_0 - s} + \frac{1}{s_0^* - s}\right) = \frac{\omega_0}{(s - a_0)^2 + \omega_0^2} \ . \end{aligned}$$

It is evident that signal $x(t)$ is a sine wave of angular frequency ω_0, which is either attenuating or growing, depending on the value of constant a_0. This fact is reflected to the Laplace transformation of $x(t)$, $X(s)$. Indeed, the denominator polynomial of $X(s)$, $p_c(s) = (s - a_0)^2 + \omega_0^2$ obtains the following roots

$$\begin{aligned} (s - a_0)^2 = -\omega_0^2 &\Rightarrow s - a_0 = \pm\mathrm{i}\omega_0 \\ &\Rightarrow s = s_0 \text{ or } s = s_0^* \ . \end{aligned}$$

In the case that the sine wave is shrinking it holds that $\mathrm{Re}(s_0) = \mathrm{Re}(s_0^*) = a_0 < 0$, while in the case that it is growing $a_0 > 0$. Finally, in the case that $a_0 = 0$, evidently it holds that $x(t) = \sin(\omega_0 t), t \geq 0$.

Some of the most important properties of the Laplace transform are given as follows:

1. Linearity

$$\left.\begin{aligned} &X_1(s) = \mathcal{L}\{x_1(t)\} \\ &X_2(s) = \mathcal{L}\{x_2(t)\} \\ &k_1, k_2 \in \mathbb{R} \end{aligned}\right\} \Rightarrow k_1 X_1(s) + k_2 X_2(s) = \mathcal{L}\{k_1 x_1(t) + k_2 x_2(t)\} \ . \tag{10.3}$$

2. Differentiation with respect to time

$$\mathcal{L}\{x(t)\} = X(s) \Rightarrow \mathcal{L}\{\dot{x}(t)\} = sX(s) - x(t=0)\,. \tag{10.4}$$

3. Integration with respect to time

$$\left.\begin{aligned}&\mathcal{L}\{x(t)\} = X(s)\\ &y(t) = \int x(\xi)\mathrm{d}\xi\end{aligned}\right\} \Rightarrow \mathcal{L}\left\{\int_0^t x(\xi)\mathrm{d}\xi\right\}$$
$$= \frac{X(s)}{s} \text{ and } \mathcal{L}\left\{\int_{-\infty}^t x(\xi)\mathrm{d}\xi\right\}$$
$$= \frac{X(s)}{s} + \frac{x(t=0)}{s}\,. \tag{10.5}$$

4. Initial and final value theorems

$$\mathcal{L}\{x(t)\} = X(s)$$
$$\Rightarrow \begin{cases}\lim\limits_{t\to 0}(x(t)) = \lim\limits_{s\to\infty}(sX(s))\\ \lim\limits_{t\to\infty}(x(t)) = \lim\limits_{s\to 0}(sX(s))\end{cases}\,. \tag{10.6}$$

5. Theorem of convolution

$$\left.\begin{aligned}&X_1(s) = \mathcal{L}\{x_1(t)\}\\ &X_2(s) = \mathcal{L}\{x_2(t)\}\\ &x(t) = x_1(t) * x_2(t)\\ &\quad \triangleq \int_{-\infty}^{+\infty} x_1(v)x_2(t-v)\mathrm{d}v\end{aligned}\right\} \Rightarrow$$
$$X(s) = \mathcal{L}\{x(t)\} = X_1(s)X_2(s)\,. \tag{10.7}$$

The signal $x(t)$ resulting from a convolution operation must be *causal*; it may not depend on the values of signals $x_1(t_1)$ and $x_2(t_2)$ that will occur at time instants t_1 and t_2, respectively, later than t. In effect, the limits of the convolutional integral in (10.7) must be bounded as follows

$$\left.\begin{aligned}&t_1 = v \le t\\ &t_2 = t - v \le t \Rightarrow v \ge 0\end{aligned}\right\} \Rightarrow$$
$$x_1(t) * x_2(t) = \int_0^t x_1(v)x_2(t-v)\,\mathrm{d}v\,.$$

Furthermore, the convolution operation, for which symbol $\otimes$ is also used in some texts, obtains the *commutative*, *associative*, and *distributive* with respect to addition properties. The *identity element* of convolution is the Dirac delta signal defined in the next section.

The proof of the above Laplace transform properties as well as various other lemmas of the transform can be sought after in either ordinary differential equations or introductory control systems literature [10.1, 2]. Some important Laplace transform pairs, used throughout this text, are given in Table 10.1.

10.1.3 Linear Time-Invariant Systems

Definition of LTI Systems

A category of dynamic systems of high importance in feedback control theory is *linear time-invariant* (LTI) *systems*. Such systems are described by linear differential equations with constant coefficients. The general form of such differential equations is given below for a single-input, single-output (SISO) system

$$\left(a_n\frac{\mathrm{d}^n}{\mathrm{d}t^n} + a_{n-1}\frac{\mathrm{d}^{n-1}}{\mathrm{d}t^{n-1}} + \cdots + a_1\frac{\mathrm{d}}{\mathrm{d}t} + a_0\right)y(t)$$
$$= \left(b_m\frac{\mathrm{d}^m}{\mathrm{d}t^m} + b_{m-1}\frac{\mathrm{d}^{m-1}}{\mathrm{d}t^{m-1}} + \cdots + b_1\frac{\mathrm{d}}{\mathrm{d}t} + b_0\right)u(t)\,. \tag{10.8}$$

In the above, $y(t)$ and $u(t)$ are the input and output signal, respectively, of the system. The initial conditions required are those for the up to the $(n-1)$-th derivative with respect to time of the output signal $y(t)$ at some initial time instant t_0 (commonly t_0 is set to zero by an appropriate translation of the time axis).

$$\left.\frac{\mathrm{d}^v}{\mathrm{d}t^v}y(t)\right|_{t=t_0} = y_0^{(v)}\,, \qquad v = 0, 1, \ldots, (n-1) \tag{10.9}$$

In practically realizable systems, that is, systems that can be implemented by interconnecting electrical (induction coils, capacitors, resistors, etc.), or mechanical (masses, springs, dampers, etc.), elements, it holds that $m \le n$; this assumption will be observed in the following of this text as well.

Order of an LTI System

The *order* of any LTI system is integer n, that is, the order of its differential equation.

Transfer Function of an LTI System

Considering a SISO–LTI system as in (10.8) with *zero initial conditions* in (10.9), by consecutively applying Laplace transform property (10.3) and then property (10.4), the following *algebraic* relationship between the Laplace transformations of the output and input signal

Table 10.1 Laplace and Z-transform tables

Continuous time	Laplace transform	Sampled time	Z-transform
$x(t)$	$X(s)$	$x(kT)$	$X(z)$

is obtained

$$H(s)=\frac{Y(s)}{U(s)}=\frac{b_m s^m+b_{m-1}s^{m-1}+\cdots+b_1 s+b_0}{a_n s^n+a_{n-1}s^{n-1}+\cdots+a_1 s+a_0},\quad s\in\mathbb{C}\,,\quad a_n\neq 0\,. \tag{10.10}$$

The complex polynomial ratio $H(s)$ is the system's transfer function. Transfer functions are used extensively in control theory. Commonly, the polynomial coefficients are normalized with respect to $a_n \neq 0$.

Characteristic Polynomial of an LTI System

The polynomial $p_c(s)=a_n s^n+a_{n-1}s^{n-1}+\cdots+a_1 s+a_0$ appearing at the denominator of the transfer function of a SISO–LTI system, $H(s)$, is the characteristic polynomial of the system. If the transfer function is normalized with respect to $a_n \neq 0$, it follows that $a_n = 1$. In the sequel, normalization will be assumed.

System Poles

The n distinct or multiple complex roots of the characteristic polynomial $p_c(s)$ of an LTI system are the system poles. In effect, an LTI system's poles are calculated as roots of the equation

$$p_c(s)=s^n+a_{n-1}s^{n-1}+\cdots+a_1 s+a_0=0\,. \tag{10.11}$$

In the above, the polynomial coefficients are assumed normalized in order that the highest order coefficient is equal to 1.

Otherwise it is noted that if all coefficients of a polynomial are *purely real* then the roots are either also purely *real* or form pairs of *complex conjugate* numbers.

System Zeros

The m distinct or multiple complex roots of the polynomial appearing at the numerator of the transfer function, $H(s)$, of an LTI system are the system zeros.

System Impulse Response

The response of an LTI system when the input is the Dirac delta signal and the initial conditions are set to zero is the impulse response. In effect, the impulse response, $h(t)$, can be calculated as the solution of the following differential equation

$$\left(a_n\frac{\mathrm{d}^n}{\mathrm{d}t^n}+a_{n-1}\frac{\mathrm{d}^{n-1}}{\mathrm{d}t^{n-1}}+\cdots+a_1\frac{\mathrm{d}}{\mathrm{d}t}+a_0\right)h(t)=\left(b_m\frac{\mathrm{d}^m}{\mathrm{d}t^m}+b_{m-1}\frac{\mathrm{d}^{m-1}}{\mathrm{d}t^{m-1}}+\cdots+b_1\frac{\mathrm{d}}{\mathrm{d}t}+b_0\right)\delta(t)\,.$$

In the above, $\delta(t)$ stands for the Dirac delta signal, referred to also as impulse function or signal. The Dirac

signal is defined on the basis of the following properties:

1.
$$\int_{-\infty}^{+\infty} \delta(t)\mathrm{d}t = 1 \tag{10.12}$$

2.
$$\delta(t) = \begin{cases} 0\,, & t \neq 0 \\ \text{undefined} & t = 0 \end{cases}\,. \tag{10.13}$$

By using the above definition properties the following properties can be derived,

3.
$$\int_{-\infty}^{+\infty} \delta(t) f(t)\,\mathrm{d}t = f(0) \tag{10.14}$$

4.
$$\Delta(s) = \mathrm{L}\left\{\delta(t)\right\} = \int_{0}^{+\infty} \delta(t)\mathrm{e}^{-st}\mathrm{d}t = 1\,. \tag{10.15}$$

By using (10.15) it can be shown that the transfer function and the impulse response are connected through the Laplace transform.

$$\mathrm{L}\left\{h(t)\right\} = H(s)\mathrm{L}\left\{\delta(t)\right\} = H(s)\Delta(s) = H(s) \tag{10.16}$$

In effect, by employing the theorem of convolution (10.7), the time-domain input–output relationship equivalent to the one given in (10.10) in the complex frequency domain is derived

$$\begin{aligned} &Y(s) = H(s)U(s) \Leftrightarrow \\ &y(t) = h(t) * u(t) = \int_{-\infty}^{+\infty} h(v)u(t-v)\mathrm{d}v \\ &\quad = \int_{0}^{t} h(v)u(t-v)\mathrm{d}v\,. \end{aligned} \tag{10.17}$$

The interval of the convolutional integral is also reduced from $(-\infty, +\infty)$ to $(0, t)$ on the basis of *causality*. Therefore, the output signal value $y(t)$ at time t depends on input signal values $u(v)$ occurring at time instants not later than t.

Conclusively, the determination of an LTI system's transfer function can be done on the basis of (10.6), by Laplace transformation of the system's impulse response. This is why it is interesting to determine the impulse response, $h(t)$, of the system. The direct method to determine $h(t)$ is to excite the system by the Dirac signal, $\delta(t)$, and record the response. However, in many practical cases this is not feasible, especially because implementation of the Dirac signal $\delta(t)$ is not without problems or approximations.

Alternatively, the impulse response $h(t)$ and, consequently, the transfer function of a system, $H(s)$, can be calculated using its *step response*, $y_{\mathrm{step}}(t)$. The step response is the output of the system when the input signal is the *unit step signal* (also referred to as Heaviside signal or function), $u_{\mathrm{step}}(t)$, defined as follows

$$\begin{aligned} &u_{\mathrm{step}}(t) = \begin{cases} 1 & t > 0 \\ 0 & t \leq 0 \end{cases} \Rightarrow u_{\mathrm{step}}(t) = \int_{-\infty}^{t} \delta(v)\mathrm{d}v \\ &\Leftrightarrow U_{\mathrm{step}}(s) = \mathrm{L}\left\{u_{\mathrm{step}}(t)\right\} = \frac{\Delta(s)}{s} = \frac{1}{s}\,. \end{aligned} \tag{10.18}$$

In effect, on the basis of property (10.4) it can be shown that

$$\begin{aligned} &h(t) = \frac{\mathrm{d}}{\mathrm{d}t} y_{\mathrm{step}}(t) \\ &\Leftrightarrow H(s) = sY_{\mathrm{step}}(s) = s\mathrm{L}\left\{y_{\mathrm{step}}(t)\right\}\,. \end{aligned} \tag{10.19}$$

Furthermore, in the case that the transfer function of an LTI system is known and the impulse response is sought after, the technique of *partial fraction expansion* is employed. In that end, the following fact is needed

$$\frac{1}{s-\lambda} = \mathrm{L}\left\{\mathrm{e}^{\lambda t}\right\}\,, \quad \lambda \in \mathbb{C}, t \geq 0\,. \tag{10.20}$$

At first, assume that we are presented with an nth order system obtaining n distinct, purely real poles; this means that the characteristic polynomial has no multiple roots and no complex roots. Then, the characteristic polynomial can be rewritten in the following *factorized* form

$$p_c(s) = \prod_{v=1}^{n} (s - \lambda_v)\,. \tag{10.21}$$

In the above λ_v, $v = 1, \ldots, n$ are the poles of the system and as explained previously it has been assumed that $a_n = 1$. On the basis of the factorization of $p_c(s)$ the transfer function $H(s)$ may be expanded to a sum of

fractions of the form shown in (10.20)

$$H(s) = \sum_{v=1}^{n} \frac{k_v}{s-\lambda_v} \,. \tag{10.22}$$

In the above constants (coefficients) $k_v, v = 1, \ldots, n$ can be calculated by using the following relationship

$$k_v = \lim_{s\to\lambda_v} [(s-\lambda_v)H(s)] \,, \quad v = 1, \ldots, n \,. \tag{10.23}$$

Based on the fact (10.20) and the expansion (10.22) the following expression is derived for the system's impulse response

$$h(t) = \sum_{v=1}^{n} k_v \exp(\lambda_v t) \,, \quad t \geq 0 \,. \tag{10.24}$$

The partial fraction expansion can also be employed in cases for which the characteristic polynomial obtains multiple real or complex roots. First, the case of a purely real pole, λ_0, with multiplicity $l > 1$, is examined. Then, the factorized form of the characteristic polynomial of the system includes factor $(s-\lambda_0)^l$. Consequently, in the system's transfer function this factor appears in the denominator. Therefore, the partial function expansion of the following general form is needed

$$\begin{aligned} & p_c(s) = (s-\lambda_0)^l \prod_{v=1}^{n} (s-\lambda_v) \\ & \Rightarrow H(s) = \sum_{v=1}^{n} \frac{k_v}{s-\lambda_v} + \sum_{\xi=1}^{l} \frac{k_{0\xi}}{(s-\lambda_0)^\xi} \,. \end{aligned} \tag{10.25}$$

In the above, additional terms augment the expansion of $\mathbf{H}(s)$ in (10.22) in order to encompass factor $(s-\lambda_0)^l$ of the characteristic polynomial. To obtain the values of constants $k_{0\xi}$ of the expansion, the following formula is used

$$\begin{aligned} & k_{0\xi} = \lim_{s\to\lambda_0} \left\{ \frac{1}{(l-\xi)!} \frac{\mathrm{d}^{(l-\xi)}}{\mathrm{d}s^{(l-\xi)}} \left[(s-\lambda_0)^l H(s) \right] \right\} , \\ & \xi = 1, \ldots, l \,. \end{aligned} \tag{10.26}$$

The inverse Laplace transform of each additional term in the expansion (10.25) is given by the following

$$\mathrm{L}^{-1} \left\{ \frac{1}{(s-\lambda_0)^\xi} \right\} = \frac{1}{(\xi-1)!} t^{(\xi-1)} \mathrm{e}^{\lambda_0 t} \,. \tag{10.27}$$

The above comes as a generalization of (10.20). In conclusion, each additional term (10.25) corresponds to a term of the form (10.27) in the impulse response expression (10.24).

In the case that the characteristic polynomial obtains a pair of complex conjugate roots, λ_C and λ_C^*, the factorized form includes the factor

$$(s-\lambda_\mathrm{C})(s-\lambda_\mathrm{C}^*) = s^2 - 2\mathrm{Re}(\lambda_\mathrm{C})s + |\lambda_\mathrm{C}|^2 \,.$$

In this case, (10.20), (10.22), and (10.23) are still valid for each one of the poles λ_C and λ_C^*, separately. Furthermore, the following fact for the combined partial fraction expansion of this factor can be shown

$$\begin{aligned} & \frac{1}{s^2 - 2\mathrm{Re}(\lambda_\mathrm{C})s + |\lambda_\mathrm{C}|^2} = \frac{k_\mathrm{C}}{s-\lambda_\mathrm{C}} + \frac{k_{\mathrm{C}*}}{s-\lambda_\mathrm{C}^*} \\ & \Rightarrow k_{\mathrm{C}*} = (k_\mathrm{C})^* \,. \end{aligned} \tag{10.28}$$

Therefore, for calculating the constant $k_{\mathrm{C}*}$ corresponding to factor $(s-\lambda_\mathrm{C}^*)$ it suffices to calculate constant k_C corresponding to factor $(s-\lambda_\mathrm{C})$.

10.1.4 Multivariable Systems and State Space

State Equations

State equations constitute a description in the time domain encompassing, besides LTI systems, other categories of systems such as time-varying or nonlinear systems [10.1–4]. A system described by state equations may in general accept more than one scalar input signals and produce more than one scalar output signals, also referred to as measurements. If the number of scalar input signals is m and that of scalar output signals is p, the following column vectors are introduced for convenience in notation

$$\begin{aligned} & \boldsymbol{u} = \boldsymbol{u}(t) = \begin{bmatrix} u_1 & u_2 & \ldots & u_m \end{bmatrix}^\mathrm{T} \\ & \text{and} \\ & \boldsymbol{y} = \boldsymbol{y}(t) = \begin{bmatrix} y_1 & y_2 & \ldots & y_p \end{bmatrix}^\mathrm{T} \,. \end{aligned} \tag{10.29}$$

In the disciplines of dynamic systems and control, the term *state* or *state vector* is used for a set of $n \geq 1$ variables *(state variables)* conveniently packed in a column vector as follow

$$\boldsymbol{x} = \boldsymbol{x}(t) = \begin{bmatrix} x_1 & x_2 & \ldots & x_n \end{bmatrix}^\mathrm{T} \tag{10.30}$$

If the value of $\boldsymbol{x}$ is known at some initial time instant t_0, then it must be possible to determine the values of both $\boldsymbol{x}$ and $\boldsymbol{y}$ for times $t \geq t_0$ provided that (a) the values of $\boldsymbol{u}$ are given and (b) the mathematical law connecting the input, output, and state vectors is known.

Commonly, the aforementioned mathematical law is expressed as a set of n first-order differential equations with respect to time, dynamic equations. The dynamic equations connect the input vector with the state vector

$$\dot{\boldsymbol{x}}(t) \triangleq \frac{\mathrm{d}}{\mathrm{d}t}\boldsymbol{x}(t) = f(\boldsymbol{x}(t), \boldsymbol{u}(t), t)\,. \tag{10.31}$$

The description of the system in state-space requires also a set of p *algebraic* output equations connecting the input and state vectors with the output one

$$\boldsymbol{y}(t) = g(\boldsymbol{x}(t), \boldsymbol{u}(t))\,. \tag{10.32}$$

By employing (10.31), it is directly concluded that if the initial state of a system is given at a time instant t_0 then the state at any future time instant can be calculated as follows

$$\boldsymbol{x}(t) = \boldsymbol{x}(t_0) + \int_{t_0}^{t} f(\boldsymbol{x}(\xi), \boldsymbol{u}(\xi), \xi)\mathrm{d}\xi\,. \tag{10.33}$$

Multivariable LTI Systems

In the case of LTI systems (10.31) and (10.32) assume the following form

$$\begin{aligned}\dot{\boldsymbol{x}} &= \mathbf{A}\boldsymbol{x} + \mathbf{B}\boldsymbol{u}\,,\\ \boldsymbol{y} &= \mathbf{C}\boldsymbol{x} + \mathbf{D}\boldsymbol{u}\,.\end{aligned} \tag{10.34}$$

In the above $\mathbf{A}$ is an $n \times n$ matrix, $\mathbf{B}$ an $n \times m$ matrix, $\mathbf{C}$ a $p \times n$ matrix, and $\mathbf{D}$ a $p \times m$ matrix.

An input–output relationship can be deduced for an LTI system described in state-space by the state and output equations of the form (10.34). This relationship comes as a natural extension of the transfer function concept already introduced for single-input, single-output (SISO) LTI systems to the case of MIMO (multi-input, multioutput) LTI systems. To obtain it the Laplace transform is applied to the time-domain expression (10.34) by employing property (10.4)

$$\begin{aligned}s\mathbf{X}(s) - \boldsymbol{x}(0) &= \mathbf{A}\mathbf{X}(s) + \mathbf{B}\mathbf{U}(s)\,,\\ \mathbf{Y}(s) &= \mathbf{C}\mathbf{X}(s) + \mathbf{D}\mathbf{U}(s)\,.\end{aligned} \tag{10.35}$$

In the above, it has been assumed that $t_0 = 0$ for convenience and without any loss of generality. The complex frequency domain algebraic (10.35) can be solved to yield the following

$$\begin{aligned}\mathbf{X}(s) &= (s\mathbf{I}_n - \mathbf{A})^{-1}\mathbf{B}\mathbf{U}(s) + (s\mathbf{I}_n - \mathbf{A})^{-1}\boldsymbol{x}(0)\,,\\ \mathbf{Y}(s) &= \left[\mathbf{C}\,(s\mathbf{I}_n - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D}\right]\mathbf{U}(s) + \mathbf{C}\,(s\mathbf{I}_n - \mathbf{A})^{-1}\boldsymbol{x}(0)\,.\end{aligned} \tag{10.36}$$

In the above, $\mathbf{I}_n$ stands for the $n \times n$ identity matrix. Formulas (10.36) allow the analytic calculation of any LTI system's response and are referred to as full-response equations in the literature [10.1–6]. The following special cases are investigated:

1. Zero initial state response, $x(0) = 0$

$$\mathbf{Y}(s) = \left[\mathbf{C}\,(s\mathbf{I}_n - \mathbf{A})^{-1}\mathbf{B} + \mathbf{D}\right]\mathbf{U}(s)\,. \tag{10.37}$$

2. Zero input response, $u = 0$

$$\mathbf{Y}(s) = \mathbf{C}\,(s\mathbf{I}_n - \mathbf{A})^{-1}\,x(0)\,. \tag{10.38}$$

In order to obtain the response in the time domain, the following formula of the Laplace transform theory is needed

$$(s\mathbf{I}_n - \mathbf{A})^{-1} = \mathrm{L}\left\{\mathrm{e}^{\mathbf{A}t}\right\}\,, \quad t > 0\,. \tag{10.39}$$

The above is the matrix generalization of (10.16). Expression $\mathrm{e}^{\mathbf{A}t}$, also referred to by the term system transient matrix, is defined as an $n \times n$ matrix with the following properties

$$\begin{aligned}\mathrm{e}^{\mathbf{A}t} &= \mathbf{I}_n + \mathbf{A}t + \frac{1}{2!}\mathbf{A}^2t^2 + \frac{1}{3!}\mathbf{A}^3t^3 + \cdots\\ &\Leftrightarrow \frac{\mathrm{d}}{\mathrm{d}t}\mathrm{e}^{\mathbf{A}t} = \mathbf{A}\cdot\mathrm{e}^{\mathbf{A}t}\,.\end{aligned} \tag{10.40}$$

By using (10.40), the full-response equation in the time domain is obtained

$$x(t) = \int_0^t \mathrm{e}^{\mathbf{A}v}\mathbf{B}u(t-v)\mathrm{d}v + \mathrm{e}^{\mathbf{A}t}x(0)\,, \quad t > 0\,. \tag{10.41}$$

The following matrix version of the theorem of convolution has been employed in the above

$$\begin{aligned}(s\mathbf{I}_n - \mathbf{A})^{-1}\mathbf{B}\mathbf{U}(s) &= \mathrm{L}\left\{\mathrm{e}^{\mathbf{A}t} * \mathbf{B}u(t)\right\}\\ &= \mathrm{L}\left\{\int_0^t \mathrm{e}^{\mathbf{A}v}\mathbf{B}u(t-v)\mathrm{d}v\right\}\,.\end{aligned} \tag{10.42}$$

Transfer Function Matrix

In the input–output relationship (10.37), the $p \times m$ matrix $\mathbf{H}(s) = \mathbf{C}\cdot(s\mathbf{I}_n - \mathbf{A})^{-1}\cdot\mathbf{B} + \mathbf{D}$ is the system's transfer matrix.

It is straightforward to show that

$$(s\mathbf{I}_n - \mathbf{A})^{-1} = |s\mathbf{I}_n - \mathbf{A}|^{-1}\,\mathrm{adj}(s\mathbf{I}_n - \mathbf{A})\,.$$

In the above, $|\bullet| = \det(\bullet)$ stands for the determinant of a matrix and adj$(\bullet)$ is the conjugate transpose of the matrix cofactors. In effect, the following conclusions are made:

- The characteristic polynomial of an LTI system with description in state-space as in (10.34) is the determinant of matrix $(s\mathbf{I}_n - \mathbf{A})$, $p_c(s) = |s\mathbf{I}_n - \mathbf{A}|$.
- The poles of a system with the general form (10.34), the roots of $p_c(s) = |s\mathbf{I}_n - \mathbf{A}|$, are the eigenvalues of matrix $\mathbf{A}$.

The above general remarks are now demonstrated in the special case of an LTI–SISO system, with a transfer function of the following format

$$\mathbf{H}(s) = \frac{\mathbf{Y}(s)}{\mathbf{U}(s)} = \frac{b_0}{s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0} \,. \quad (10.43)$$

It is noted here that although the system is SISO the state vector is of n dimension, that is, equal to the order of the system. However, there are more than one choices of the state vector's components. The problem of choosing the components of the state vector in order to formulate a state-space description of an LTI system, which is otherwise known only in the form of either a scalar transfer function or a transfer function matrix, is referred to as the *realization* problem [10.1, 2]. In general case of MIMO–LTI systems is not solvable. However, in the case of LTI–SISO systems with transfer function of the form (10.43), a *minimal* description, a description that includes no redundant components can be deduced as

$$\mathbf{H}(s) = \frac{\mathbf{Y}(s)}{\mathbf{U}(s)} = \frac{b_0}{s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0} = \frac{b_0}{s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0} \frac{\mathbf{X}_1(s)}{\mathbf{X}_1(s)} \,.$$

After introducing the auxiliary signal as above, the following differential equation is obtained in the time domain. Appropriate initial conditions of the form (10.9) for solving the differential equation must also be provided.

$$\left(\frac{\mathrm{d}^n}{\mathrm{d}t^n} + a_{n-1}\frac{\mathrm{d}^{n-1}}{\mathrm{d}t^{n-1}} + \cdots + a_1\frac{\mathrm{d}}{\mathrm{d}t} + a_0\right) x_1(t) = u(t) \Leftrightarrow x_1^{(n)}(t) = u(t) - \sum_{v=0}^{n-1} a_v x_1^{(v)}(t)$$

$$\text{and} \quad y(t) = b_0 x_1(t) \,. \quad (10.44)$$

In the above, $x_1^{(v)}(t)$ stands for the vth order time derivative of the auxiliary signal $x_1(t)$. An appropriate state vector x is

$$x = \left[x_1(t) \quad x_1^{(1)}(t) \quad \ldots \quad x_1^{(n-1)}(t)\right]^{\mathrm{T}} . \quad (10.45)$$

For the components of x the following differential equations hold,

$$\dot{x}_v = x_{v+1} \,, \quad v = 1, \ldots, n-1$$

$$\text{and} \quad \dot{x}_n = -\sum_{v=1}^{n} a_{(v-1)} x_v + u \,. \quad (10.46)$$

If the above are arranged in the matrix format the following equations are obtained

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \\ \dot{x}_3 \\ \vdots \\ \dot{x}_n \end{bmatrix} = \begin{bmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 1 & \ldots & 0 \\ 0 & 0 & 0 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -a_0 & -a_1 & -a_2 & \ldots & -a_{n-1} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ x_n \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix} u \,,$$

$$y = \begin{bmatrix} b_0 & 0 & 0 & \ldots & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ x_n \end{bmatrix} . \quad (10.47)$$

This form of the state equations and especially of matrix $\mathbf{A}$ is also known as the *companion canonical form*.

10.1.5 Nonlinear Systems and Linearization

Consider a nonlinear system with m inputs, p outputs, and n state variables with the following description in state space

$$\dot{x} = f(x, u) \,,$$
$$y = g(x, u) \,. \quad (10.48)$$

Significant progress has been achieved in recent years in the analysis and controller synthesis for a wide class of nonlinear systems, especially through the studies of *Isidori* [10.7, 8] and *Kokotovic* et al. [10.9]. However, the technique of linearization, the reduction to or approximation by a linear system is still extensively used.

The first step toward the linearization of a nonlinear system is to determine the equilibrium points. These points are defined by the following vector equation

$$\dot{x} = \mathbf{0} \Leftrightarrow f(x_0, u_0) = \mathbf{0} \,. \tag{10.49}$$

Linearization is then applied around some equilibrium point (x_0, u_0) by using the Taylor expansions for functions f and g

$$\begin{aligned} \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{u}) \approx & \boldsymbol{f}(\boldsymbol{x}_0, \boldsymbol{u}_0) + \mathbf{f}'_x(\boldsymbol{x}_0, \boldsymbol{u}_0)(\boldsymbol{x} - \boldsymbol{x}_0) \\ & + \mathbf{f}'_u(\boldsymbol{x}_0, \boldsymbol{u}_0)(\boldsymbol{u} - \boldsymbol{u}_0) \\ \boldsymbol{g}(\boldsymbol{x}, \boldsymbol{u}) \approx & \boldsymbol{g}(\boldsymbol{x}_0, \boldsymbol{u}_0) + \mathbf{g}'_x(\boldsymbol{x}_0, \boldsymbol{u}_0)(\boldsymbol{x} - \boldsymbol{x}_0) \\ & + \mathbf{g}'_u(\boldsymbol{x}_0, \boldsymbol{u}_0)(\boldsymbol{u} - \boldsymbol{u}_0) \,. \end{aligned} \tag{10.50}$$

In the above, matrices $\mathbf{f}'_x(x_0, u_0)$, $\mathbf{f}'_u(x_0, u_0)$, $\mathbf{g}'_x(x_0, u_0)$, $\mathbf{g}'_u(x_0, u_0)$ with dimensions $n \times n$, $n \times m$, $p \times n$ and $p \times m$, respectively, are defined as follows

$$\mathbf{f}'_x(x_0, u_0) = \left[\frac{\partial}{\partial x_j} f_i(x, u) \,\middle|\, \begin{matrix} x = x_0 \\ u = u_0 \end{matrix}, i, j = 1, \ldots, n \right] ,$$

$$\mathbf{f}'_u(x_0, u_0) = \left[\frac{\partial}{\partial u_j} f_i(x, u) \,\middle|\, \begin{matrix} x = x_0 \\ u = u_0 \end{matrix}, \begin{matrix} i = 1, \ldots, n \\ j = 1, \ldots, m \end{matrix} \right] , \tag{10.51}$$

$$\mathbf{g}'_x(x_0, u_0) = \left[\frac{\partial}{\partial x_j} g_i(x, u) \,\middle|\, \begin{matrix} x = x_0 \\ u = u_0 \end{matrix}, \begin{matrix} i = 1, \ldots, p \\ j = 1, \ldots, n \end{matrix} \right] ,$$

$$\mathbf{g}'_u(x_0, u_0) = \left[\frac{\partial}{\partial u_j} g_i(x, u) \,\middle|\, \begin{matrix} x = x_0 \\ u = u_0 \end{matrix}, \begin{matrix} i = 1, \ldots, p \\ j = 1, \ldots, m \end{matrix} \right] . \tag{10.52}$$

The following change of variables is then adopted

$$\begin{aligned} & \delta x = x - x_0 \,, \quad \delta u = u - u_0 \,, \\ & \delta y = y - y_0 = y - g(x_0, u_0) \,. \end{aligned} \tag{10.53}$$

In effect, the following linearized equations are deduced for the nonlinear system (10.48) which is valid exclusively in the vicinity of the equilibrium point (x_0, u_0)

$$\begin{aligned} \delta\dot{x} &= \mathbf{f}'_x(x_0, u_0)\,\delta x + \mathbf{f}'_u(x_0, u_0)\,\delta u \,, \\ \delta y &= \mathbf{g}'_x(x_0, u_0)\,\delta x + \mathbf{g}'_u(x_0, u_0)\,\delta u \,. \end{aligned} \tag{10.54}$$

Despite its virtues, the technique of linearization has also a major drawback. This drawback originates from the fact that the elements of matrices (10.51) and (10.52) depend on the equilibrium point in the vicinity of which they are calculated. Therefore, a *family* of linear systems is obtained in order to describe a single nonlinear system. In effect, the form of the results of the analysis and control scheme synthesis must be parameterized with respect to the equilibrium point. Furthermore, linearization cannot be used for nonlinear systems that do not demonstrate equilibrium points as well as systems whose behavior is of interest when operating away from any equilibrium points.

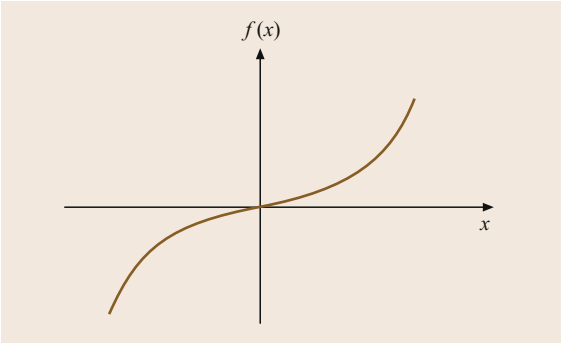

Fig. 10.2 A nonlinear function $x\,|x|$

Example 10.1 Nonlinear Function

Consider linearizing the term $x\,|x|$ shown in Fig.10.2.

One can see from the figure that the slope at any point of linearization is always non-negative and the nonlinear mapping is simply a quadratic relationship with x. Thus, the linearized term becomes

$$\begin{aligned} f(x) = x\,|x| &\approx x_0\,|x_0| + \left.\frac{\partial f}{\partial x}\right|_{x=x_0} (x - x_0) \\ &= x_0\,|x_0| + 2\,|x_0|\,(x - x_0) \,, \end{aligned} \tag{10.55}$$

where x_0 is the point of linearization. In this case, the slope and intercept are $2|x_0|$ and $x_0|x_0|$, respectively.

Example 10.2 Linearized AUV Forward Speed Model

Consider an autonomous underwater vehicle (AUV) travels at a constant heading. The dynamic modes in the longitudinal and lateral planes can be assumed uncoupled, and the forward speed model can be approximately described using only the vehicle and propeller speeds (u, Ω) as the system states, and the motor torque (τ) as the system input

$$\begin{aligned} & M\dot{u} + du\,|u| = c_T \Omega\,|\Omega| \,, \\ & \dot{\Omega} = \beta\tau - \alpha\Omega\,|\Omega| \,, \end{aligned} \tag{10.56}$$

where M is the mass of the vehicle, d, c_T, α, β are constant coefficients associated with the system. The absolute signs characterize the directional effect of the

vehicle and propeller speed. Despite the significant assumption used in the forward speed model, its mathematical equations remain highly nonlinear.

Based on the results obtained in the previous example, the forward speed model can be linearized to

$$\left.\begin{aligned} &M\dot{u} + d\{u_0|u_0| + 2|u_0|(u-u_0)\} \\ &= c_T\{\Omega_0|\Omega_0| + 2|\Omega_0|(\Omega-\Omega_0)\} \\ &\dot{\Omega} = \beta\tau - \alpha\{\Omega_0|\Omega_0| + 2|\Omega_0|(\Omega-\Omega_0)\} \end{aligned}\right\} \Rightarrow$$

$$\Rightarrow \begin{cases} M\dot{u} + 2d|u_0|u = 2c_T\Omega|\Omega_0| + du_0|u_0| \\ \quad -c_T\Omega_0|\Omega_0| \\ \dot{\Omega} + 2\alpha\Omega|\Omega_0| = \beta\tau + \alpha\Omega_0|\Omega_0| \end{cases} . \tag{10.57}$$

These linearized equations can be further simplified if the point of linearization is also the equilibrium point. That is, choose u_0, Ω_0, such that $\dot{u} = 0$, or

$$du_0|u_0| = c_T\Omega_0|\Omega_0| \ .$$

The simplified forward speed model can then be expressed as

$$\begin{aligned} &M\dot{u} + 2d|u_0|u = 2c_T\Omega|\Omega_0| \ , \\ &\dot{\Omega} + 2\alpha\Omega|\Omega_0| = \beta\tau + \alpha\Omega_0|\Omega_0| \ . \end{aligned} \tag{10.58}$$

It should be noted that the term $\alpha\Omega_0|\Omega_0|$ can be treated as a fictitious input that drives the propeller speed based on the point of linearization.

10.2 Analysis of LTI Systems

10.2.1 Block Diagrams

The block diagram of a system serves as a depiction of the interconnection structure of the various subsystems as well as the signals circulation and traffic. Each sub-block of the overall block diagram is defined by an input–output (I/O) relationship, which for LTI systems is commonly expressed in the complex frequency domain (Fig. 10.3. For example, consider the following transfer function

$$\mathbf{H}(s) = \frac{\mathbf{Y}(s)}{\mathbf{U}(s)} = \frac{1}{s+1} \ . \tag{10.59}$$

The corresponding block is shown below.

Using transfer functions for the representation of the I/O relationships of the various blocks allows to conveniently obtain the overall transfer function of a system that comprises of more than blocks interconnected in cascade (Fig. 10.4). For example, consider the system depicted in the following block diagram.

The overall transfer function of the full, interconnected system is as follows,

$$\begin{aligned} \mathbf{H}(s) &= \frac{\mathbf{Y}(s)}{\mathbf{U}(s)} = \mathbf{H}_1(s)\mathbf{H}_2(s)\mathbf{H}_3(s) \\ &= \frac{1}{s+1}\frac{s+2}{s^2+s+1}\frac{1}{s^2+5s+4} \end{aligned} \tag{10.60}$$

Except he individual transfer function blocks, another common element encountered frequently in block diagrams is the adder (or summing junction) (Fig. 10.5). An adder produces as output the algebraic sum of all the input signals.

Furthermore, a system may be defined as either open loop or closed loop on the basis of its block diagram. Indeed, if at least one output signal of a system is fed as input to at least one of its own blocks, the system is called closed-loop; otherwise, it is called open loop. A closed-loop system is shown in Fig. 10.6.

The system transfer function of the closed-loop system shown above, the I/O relationship connecting the reference signal r to the output signal y is given as

$$\mathbf{H}(s) = \frac{\mathbf{Y}(s)}{\mathbf{R}(s)} = \frac{\mathbf{G}(s)}{1+\mathbf{G}(s)\mathbf{F}(s)} \ . \tag{10.61}$$

By inspection of (10.61), it is evident that any closed loop can be reduced to a single-block system, that is, an equivalent open-loop system. The inverse is also possible; an open-loop system can also be converted to a closed loop one with unity feedback branch ($\mathbf{F}(s) \equiv 1$). Indeed, if $\mathbf{F}(s) = 1$, by solving (10.61) with respect to $\mathbf{G}(s)$, it is easily concluded that the direct (feedforward) branch must obtain the following transfer function

$$\mathbf{G}(s) = \frac{\mathbf{Y}(s)}{\mathbf{U}(s)} = \frac{\mathbf{H}(s)}{1-\mathbf{H}(s)} \tag{10.62}$$

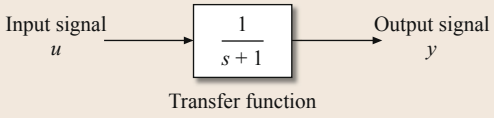

Fig. 10.3 Block representing a scalar (SISO) transfer function

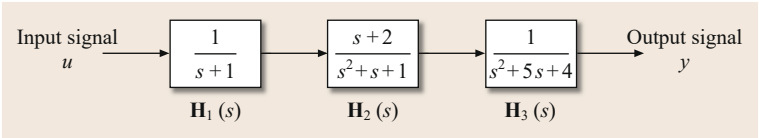

Fig. 10.4 Cascade interconnection of scalar transfer functions

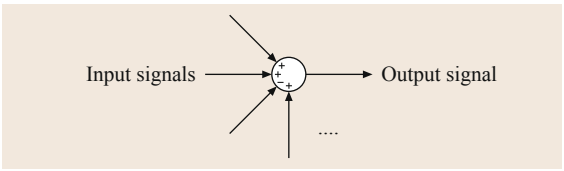

Fig. 10.5 Summing junction used in block diagrams

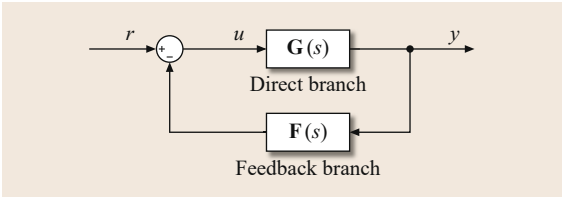

Fig. 10.6 Block diagram of a typical closed-loop system

The case that the closed-loop system in Fig. 10.6 is multivariable will also be now examined. The dimensions of the input and reference vectors, u and r, respectively, are assumed to be m and that for the output vector $\boldsymbol{y}$, p. Evidently, transfer function matrices $\mathbf{G}(s)$ and $\mathbf{F}(s)$ must be of dimensions $p \times m$ and $m \times p$, respectively. Following the same method used for deriving the scalar case (10.62), it can be shown that the $p \times m$ closed-loop, transfer function matrix $\mathbf{H}(s)$ is given by

$$\mathbf{Y}(s) = \mathbf{H}(s)\mathbf{U}(s) \,,$$
$$\text{where} \quad \mathbf{H}(s) = \left[I_p + \mathbf{G}(s)\mathbf{F}(s)\right]^{-1} \mathbf{G}(s) \,. \quad (10.63)$$

In the above, $\mathbf{I}_p$ stands for the identity $p \times p$ matrix. Equation (10.63) comes as a generalization of (10.61); it is reminded here though that commutativity in matrix multiplication does not hold.

10.2.2 Stability

Stability is a substantial structural characteristic of any dynamic system. Stability is not optional but compulsory and, therefore, must be guaranteed after the application of control to a system; otherwise, control must be employed to stabilize an unstable, open-loop system.

A working definition of stability is the following:

A system is stable if and only if it generates a bounded output when driven by any bounded input.

The above definition is generic and applicable to both linear as well as nonlinear systems [10.1]. In the case of linear, time-invariant systems (LTI), it is possible to determine stability without taking into account the class of the input signals applied; actually, the characterization can be done if either the transfer function or the state-space description is available.

Consider an LTI system with description in state space as follows

$$\dot{x} = \mathbf{A}x + \mathbf{B}u \,,$$
$$y = \mathbf{C}x + \mathbf{D}u \,. \quad (10.64)$$

The system is said to be *asymptotically* stable iff under zero input conditions (i. e., $u(t) \equiv 0$), the following criteria are met

$$\exists M(x(t=0)) \geq 0 : \forall t \geq 0 \,, \quad \|x(t)\| < M \,,$$
$$\lim_{t \to \infty} \|x(t)\| = 0 \,. \quad (10.65)$$

It is evident that the value of the bound M for the (Euclidean) norm of the state vector depends on the actual values for the initial condition. In the case that only the first of the criteria in (10.65) is met the system is said to be *critically stable*.

Some further insight is gained in these definitions of asymptotically and critically stable systems by applying them to two specific cases of LTI systems. Consider two LTI systems, (S1) and (S2), with one inputs and two outputs each. For their state-space representation, as in (10.64), assume that matrices $\mathbf{B}$ and $\mathbf{C}$ are the same for both (S1) and (S2).

$$\mathbf{B}^{\mathrm{T}} = \begin{pmatrix} 0 & 1 \end{pmatrix} \text{ and } \mathbf{C} = \mathbf{I}_2$$

Matrix $\mathbf{A}$ for both (S1) and (S2) is given below.

$$\text{(S1)}: \mathbf{A} = \begin{bmatrix} 0 & 1 \\ -1.04 & -0.4 \end{bmatrix} \,,$$
$$\text{(S2)}: \mathbf{A} = \begin{bmatrix} 0 & 1 \\ -0.09 & 0 \end{bmatrix} \quad (10.66)$$

In Fig. 10.7, the trajectories for both systems in state space are shown when the initial conditions are set to $x^{\mathrm{T}}(t=0) = \begin{bmatrix} 10.0 & 10.0 \end{bmatrix}$ for both. It can be seen that the trajectories will be similar for any other value of the

initial conditions. Both systems are stable as their trajectory remains in the interior of a disc as time elapses. For example, for the specific initial conditions value the radius of the disc can be set to $M = 40.0$. Furthermore, (S1) is asymptotically stable as the state vector's norm is converging to zero while (S2) is only critically stable as the state vector's norm, although remaining inside the disc with radius $M = 40.0$, it never decreases to zero (not even after infinite time).

Equation (10.65) is associated with the definition of stability in the time domain. The lemma given below, allows stability characterization of any LTI system (SISO or MIMO), with transfer function matrix given below, in the complex frequency domain

$$\begin{aligned}\mathbf{H}(s) &= \mathbf{C}\left(s\mathbf{I}_p - \mathbf{A}\right)^{-1}\mathbf{B} + \mathbf{D} \\ &= \mathbf{C}\frac{\operatorname{adj}\left(s\mathbf{I}_p - \mathbf{A}\right)}{\left|s\mathbf{I}_p - \mathbf{A}\right|}\mathbf{B} + \mathbf{D}\,. \end{aligned} \tag{10.67}$$

The system above is asymptotically stable iff *each and every one of its poles*, that is, the roots of the system's characteristic polynomial $p_c(s) = \left|s\mathbf{I}_p - \mathbf{A}\right|$, has *negative real parts*. In the case that at least one pair of conjugate complex poles have zero real parts (i. e., they are purely imaginary) the system is critically stable. It is noted here that the poles should be calculated as the *eigenvalues* of the system's matrix $\mathbf{A}$; this enables to avoid issues raised by a potential loss of *controllability* or *observability* (examined in the next sections) and are of concern if the poles are calculated as roots of the denominator polynomial of the transfer function.

Returning to (10.66), one may observe that matrix $\mathbf{A}$ for both systems (S1) and (S2) are in companion canonical form. In effect, their characteristic polynomial is calculated as follows

$$\begin{aligned}\text{(S1): } p_c(s) &= s^2 + 0.4s + 1.04 \\ &= (s + 0.2 + \mathrm{i})\,(s + 0.2 - \mathrm{i})\ , \\ \text{(S2): } p_c(s) &= s^2 + 0.0s + 0.09 \\ &= (s + 0.3\mathrm{i})\,(s - 0.3\mathrm{i})\ . \end{aligned}$$

In conclusion (S1) is asymptotically stable because both its poles obtain negative real part: $-0.2 < 0$. On the other hand, system (S2) is critically stable because it obtains poles with zero real part. Finally, consider the SISO system with the following transfer function

$$\begin{aligned}\mathbf{H}(s) &= \frac{1}{s^3 + 0.5s^2 - s + 3} \\ &= [(s + 1.8803)\,(s - 0.6902 + 1.0579\mathrm{i}) \\ &\quad \times (s - 0.6902 - 1.0579\mathrm{i})]^{-1}\ . \end{aligned} \tag{10.68}$$

This system is unstable because it obtains a pair of conjugate poles with positive real part: $0.6902 > 0$. The step response of the system is shown in Fig. 10.8. As can be seen, the response cannot be bounded.

There is a criterion allowing the characterization of an *unstable* system by simple inspection of its characteristic polynomial in reduced form, with no need to determine its roots. The criterion states that any polynomial, the coefficients of which are *real* and exhibit at least one *sign change*, is guaranteed to obtain at least one root in the *right-hand complex plane*. In effect, if the coefficients of the characteristic polynomial of an LTI system exhibit at least one sign change, the system is unstable. The converse, however, is not true in general; it is true in the case of first- and second- order polynomials and systems, only.

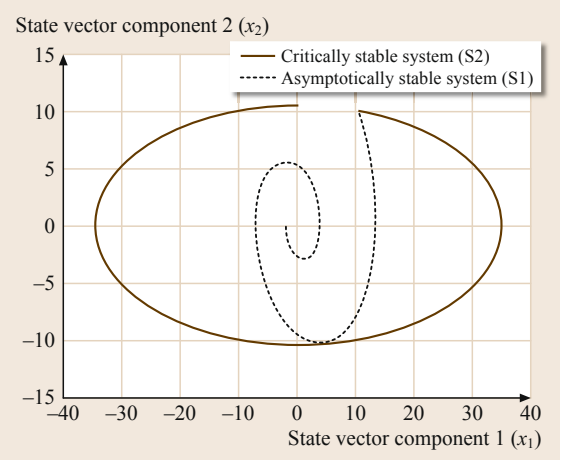

Fig. 10.7 State-space trajectories of critically and asymptotically stable systems

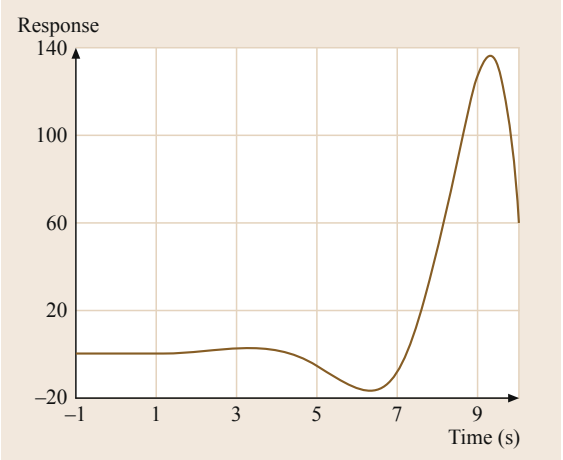

Fig. 10.8 Step response of an unstable system

Consider, for example, the characteristic polynomial of the transfer function in (10.68). This one exhibits two sign changes and therefore obtains roots in the right-hand complex plane. On the other hand, the following third-order polynomial also obtains roots in the right-hand complex plane, that is, with positive real part, although no coefficient sign changes occur

$$\begin{aligned} p(s) &= s^3 + 0.5s^2 + s + 3 \\ &= (s + 1.3694)\,(s - 0.4347 + 1.4148\mathrm{i}) \\ &\quad \times (s - 0.4347 - 1.4148\mathrm{i})\ . \end{aligned} \tag{10.69}$$

10.2.3 Controllability and Observability

The concepts of controllability and observability are fundamental in modern control system theory. For an LTI system with m inputs, p outputs and n states, controllability, and observability may be investigated by using its state-space description.

$$\begin{aligned} \dot{x} &= \mathbf{A}x + \mathbf{B}u\ , \\ y &= \mathbf{C}x + \mathbf{D}u \end{aligned} \tag{10.70}$$

The dimensions for matrix $\mathbf{A}$ are $n \times n$, for $\mathbf{B}$ $n \times m$, for $\mathbf{C}$ $p \times n$, and for $\mathbf{D}$ $p \times m$.

State Controllability

State vector controllability is the situation where there exists a control action vector that can drive the state vector to any finite value in a finite time interval. The formal definition is provided below.

The state vector $\boldsymbol{x}$ of an LTI system as in (10.70) is controllable if there exists a piecewise continuous control signal u that can drive the state vector from any initial condition x_0 to any final value x_f in a finite time interval $(t_\mathrm{f} - t_0)$.

In the case that system's matrix $\mathbf{A}$ in (10.70) is diagonal, one can easily see that, by the definition, matrix $\mathbf{B}$ must contain no rows that are identically zero in order for the LTI system to be controllable.

In the general case that $\mathbf{A}$ is not diagonal, the criterion to check controllability of the state vector for an LTI system, as in (10.70), is based on the rank of the *controllability matrix*, $\mathbf{C}^\dagger$, defined as

$$\mathbf{C}^\dagger = \begin{bmatrix} \mathbf{B} & \mathbf{AB} & \mathbf{A}^2\mathbf{B} & \cdots & \mathbf{A}^{(n-1)}\mathbf{B} \end{bmatrix}. \tag{10.71}$$

If the rank of $\mathbf{C}^\dagger$ is no less than n then the system is controllable, otherwise not. It is reminded here that the *rank* of a matrix is defined as the dimension of the vector subspace spanned by either its row or its column vectors [10.5, 6]. In effect, for an LTI system as in (10.70) to be controllable, its controllability matrix $\mathbf{C}^\dagger$ must contain n linearly independent row vectors or n linearly independent column vectors.

State Observability

State vector observability is the situation where the initial value, at any time instant, of the state vector may be determined solely on the basis of the recorded inputs (controls) and outputs (measurements). The formal definition is provided below.

The state vector $\boldsymbol{x}$ of an LTI system as in (10.70) is observable in the time interval $[t_0, t_\mathrm{f}]$ if it is possible to determine the initial value of the state vector, $x_0 = x(t_0)$, when presented with the values of the control signal u and output signal y in the finite time interval $[t_0, t_\mathrm{f}]$.

In the case that system's matrix $\mathbf{A}$ in (10.70) is diagonal, one can easily see that, by the definition, matrix $\mathbf{C}$ must contain no columns that are identically zero in order for the LTI system to be observable.

In the general case that A is not diagonal, the criterion to check observability of the state vector for an LTI system, as in (10.70), is based on the rank of the *observability matrix*, $\mathbf{O}^\dagger$, defined as

$$\mathbf{O}^\dagger = \begin{bmatrix} \mathbf{C} \\ \mathbf{CA} \\ \mathbf{CA}^2 \\ \vdots \\ \mathbf{CA}^{(n-1)} \end{bmatrix}. \tag{10.72}$$

If the rank of $\mathbf{O}^\dagger$ is no less than n then the system is observable, otherwise not. In effect, for an LTI system as in (10.70) to be observable, its observability matrix $\mathbf{O}^\dagger$ must contain n linearly independent row vectors or n linearly independent column vectors [10.5, 6].

Zero–Pole Cancellation

An important lemma connecting the transfer function (or the transfer function matrix) with the concepts of controllability and observability is given in this section [10.1, 2].

If the *same* system pole (at least one) is cancelled by a zero in *each and every one* of the transfer function matrix elements, then the system in hand is either uncontrollable or unobservable or both.

The lemma above is now investigated in depth for the case of SISO systems. Consider an nth order, SISO system with description in state space as follows

$$\begin{aligned} \dot{x} &= \mathbf{A}x + \boldsymbol{b}u\ , \\ y &= \boldsymbol{c}^\mathrm{T}x\ . \end{aligned} \tag{10.73}$$

In the above, $\boldsymbol{b}$ and $\boldsymbol{c}$ are n-dimensioned column vectors. For simplicity, assume that $\mathbf{A}$ in (10.73) is diagonal.

$$\mathbf{A} = \begin{bmatrix} \lambda_1 & 0 & \dots & 0 \\ 0 & \lambda_2 & \dots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \dots & \lambda_n \end{bmatrix} \tag{10.74}$$

The (scalar) transfer function of system is, then, given by the following

$$\mathbf{H}(s) = \frac{\mathbf{Y}(s)}{\mathbf{U}(s)} = \boldsymbol{c}^{\mathrm{T}} (s\mathbf{I}_n - \mathbf{A})^{-1} \boldsymbol{b} \,. \tag{10.75}$$

Based on the vector dynamic equation (10.73) and the diagonal form of matrix $\mathbf{A}$ it can be concluded that

$$\mathbf{X}_i(s) = \frac{b_i}{s - \lambda_i} \mathbf{U}(s) \,. \tag{10.76}$$

Furthermore, using the algebraic output equation in (10.73), the following is obtained

$$\begin{aligned} \mathbf{Y}(s) &= \sum_{i=1}^{n} c_i \mathbf{X}_i(s) = \sum_{i=1}^{n} \frac{c_i b_i}{s - \lambda_i} \mathbf{U}(s) \\ \Rightarrow \mathbf{H}(s) &= \sum_{i=1}^{n} \frac{c_i b_i}{s - \lambda_i} \,. \end{aligned} \tag{10.77}$$

If the expansion of the transfer function in (10.77) is compared against the one on in (10.22), that has been obtained through partial fraction expansion, it can be concluded that they are identical, provided that $k_i \equiv c_i b_i$. Therefore, if one of the poles, λ_i, of the system, which are determined as the eigenvalues of matrix $\mathbf{A}$, is absent from (10.22), this means that $k_i \equiv c_i b_i = 0$. In effect, this is due to either $b_i = 0$, or $c_i = 0$, or both. Taking into account that matrix $\mathbf{A}$ is diagonal, it is concluded that the system has to be either uncontrollable or unobservable or both.

In effect, the transfer function matrix of any LTI system encompasses information only for that part of the system which is both controllable and observable. As a result, it is a well-defined description of the system only if controllability and observability are guaranteed.

The importance of the above is demonstrated in the following example. Consider a 2-inputs, 2-outputs, and 3-states system with matrices $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, $\mathbf{D}$ as follows

$$\mathbf{A} = \begin{bmatrix} -2 & 0 & 0 \\ 0 & -0.4 & 0 \\ 0 & 0 & 1 \end{bmatrix},$$

$$\mathbf{B} = \mathbf{C}^{\mathrm{T}} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad \mathbf{D} = \mathbf{0}_{2\times 2} \,.$$

This system is evidently both uncontrollable and unobservable. Due to the diagonal form of matrix $\mathbf{A}$, poles are easily determined to be -2, -0.4, and $+1$. Therefore, the system is unstable, too. However, the 2×2 transfer function matrix is as follows

$$\mathbf{H}(s) = \frac{1}{s^2 + 2.4s + 0.8} \begin{bmatrix} s + 0.4 & 0 \\ 0 & s + 2 \end{bmatrix} .$$

Based solely on the transfer function, one might erroneously characterize the system to be a second order and stable one, as the apparent characteristic polynomial is determined to be the following,

$$p(s) = s^2 + 2.4s + 0.8 = (s + 0.4)\,(s + 2) \,.$$

However, the correct characteristic polynomial is the following,

$$\begin{aligned} p_c(s) &= |s\mathbf{I}_n - \mathbf{A}| = s^3 + 1.4s^2 - 1.6s - 0.8 \\ &= (s + 0.4)\,(s + 2)\,(s - 1) \,. \end{aligned}$$

Therefore, the system is actually third order and unstable. This simple example shows, in effect, that in order to arrive to safe conclusions for the system, especially concerning stability, by using solely the transfer function controllability and observability must be guaranteed in advance.

10.2.4 Sinusoidal Steady-State Response and Bode Plots

In Sect. 10.1.3, the impulse and the step response of any LTI system have been introduced. Equally important is the response of an LTI system when sinusoidals as applied as inputs.

When presented with the transfer function of an LTI–SISO system, the sinusoidal steady-state response, that is, its response when driven with a pure sine wave of arbitrary frequency ω and unity amplitude, can be calculated by replacing $s = \mathrm{i}\omega$ in the transfer function. Referring to the I/O relationship in (10.10), it holds that

$$\begin{aligned} u(t) = \sin(\omega t) \Rightarrow y(t) &= y_{\mathrm{SS}}(t) \\ &= |\mathbf{H}(\mathrm{i}\omega)| \sin(\omega t + \angle H(\mathrm{i}\omega)) \,. \end{aligned} \tag{10.78}$$

In the above, $|\bullet|$ stands for a complex number's magnitude (or modulus) and $\angle\bullet$ for a complex number's phase (or argument).

The graphs of the real functions

$$A(\omega) = 20 \log |\mathbf{H}(\mathrm{i}\omega)|$$

and

$$\varphi(\omega) = \angle \mathbf{H}(\mathrm{i}\omega)$$

for real and positive ω ($\omega \geq 0$) on plots with the x-axis, where the angular frequency ω is depicted, in logarithmic scale are called magnitude and phase Bode plots, respectively.

For example, in Fig. 10.9, the Bode plots of a third-order system are shown. The transfer function of the system is as follows

$$\mathbf{H}(s) = \frac{s-1}{s^3+2.2s^2+5.4s+1} = \frac{s-1}{(s+0.2)\,(s+1+2\mathrm{i})\,(s+1-2\mathrm{i})}\,.$$

Approximate (or Asymptotic or Corner) Bode Plots

The Bode plots are widely used for frequency response characterization mainly because they can be drawn approximately on the basis of a limited set of rules of thumb. Such approximate plots, also called asymptotic or corner plots, start with bringing the transfer function of the system to the following factorized form

$$\mathbf{H}(s) = K\frac{(1+\tau_1 s)\,(1+\tau_2 s)\cdots(1+\tau_m s)}{s^q\,(1+T_1 s)\,(1+T_2 s)\cdots(1+T_n s)}\,. \tag{10.79}$$

As a working example, consider the following third-order transfer function

$$\mathbf{H}(s) = K\omega_0^2\frac{(1+\tau s)}{s\,(1+Ts)\left(s^2+2\zeta\omega_0 s+\omega_0^2\right)}\,. \tag{10.80}$$

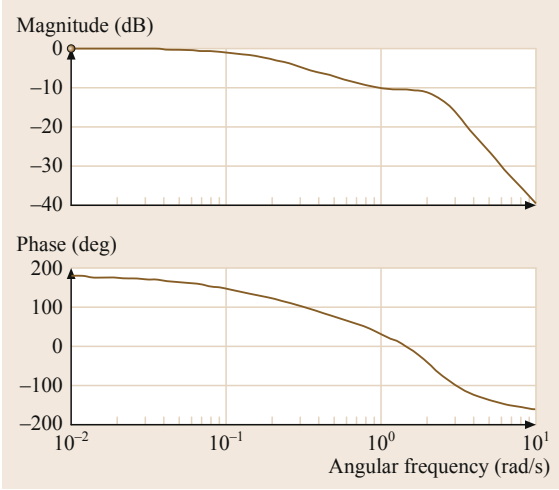

Fig. 10.9 Typical magnitude and phase Bode plots for an LTI system

The above is augmented, with respect to the transfer function in (10.79), by the quadratic factor $\left(s^2+2\zeta\omega_0 s+\omega_0^2\right)$ for which it is assumed that $\omega_0 > 0$ and $|\zeta| < 1$. This factor introduces two complex conjugate poles

$$p_{1,2} = \omega_0\left(-\zeta \pm \mathrm{i}\sqrt{1-\zeta^2}\right),$$

and therefore its investigation must be done with caution.

Substituting $s = \mathrm{i}\omega$ in (10.80) the following is obtained

$$\mathbf{H}(\mathrm{i}\omega) = K\frac{(1+\tau\omega\mathrm{i})}{(\omega\mathrm{i})\,(1+T\omega\mathrm{i})\left[1-\left(\frac{\omega}{\omega_0}\right)^2+\mathrm{i}2\zeta\left(\frac{\omega}{\omega_0}\right)\right]}\,. \tag{10.81}$$

To draw the magnitude and phase Bode plots the following manipulation is needed on the basis of (10.81),

$$\begin{aligned} A(\omega) &= 20\log|\mathbf{H}(\mathrm{i}\omega)| \\ &= 20\log|K| + 20\log|1+\tau\omega\mathrm{i}| - 20\log\omega \\ &\quad - 20\log|1+T\omega\mathbf{i}| \\ &\quad - 20\log\left|1-\left(\frac{\omega}{\omega_0}\right)^2+\mathrm{i}2\zeta\left(\frac{\omega}{\omega_0}\right)\right|\,. \end{aligned} \tag{10.82}$$

$$\begin{aligned} \varphi(\omega) &= \angle\mathbf{H}(\mathrm{i}\omega) \\ &= \angle K + \angle(1+\tau\omega\mathrm{i}) - \angle\omega \\ &\quad - \angle(1+T\omega\mathrm{i}) \\ &\quad - \angle\left[1-\left(\frac{\omega}{\omega_0}\right)^2+\mathrm{i}2\zeta\left(\frac{\omega}{\omega_0}\right)\right]\,. \end{aligned} \tag{10.83}$$

Therefore, it is concluded that in order to draw the Bode plots of a transfer function it suffices to graphically add up the various components appearing as terms in (10.82) and (10.83). The magnitude and phase contribution of each one of these components to the overall Bode plots is examined below.

Constant Gain K. The contribution of a constant to both Bode plots of a transfer function is a straight line with zero slope as follows

$$A(\omega) = 20\log|K| \text{ and } \varphi(\omega) = \begin{cases} 0^\circ\,, & K \geq 0 \\ 180^\circ\,, & K < 0\,. \end{cases} \tag{10.84}$$

Factor $(\mathrm{i}\omega)$. For the magnitude Bode plot of a transfer function that contains this factor as part of its denominator, the contribution consists of a straight line with slope $-20\,\mathrm{dB/dec}$ (decibels per decade). For the phase Bode plot of a transfer function that contains this factor as part of its denominator, the contribution consists of a horizontal straight line as follows

$$A(\omega) = -20\log\omega \quad \text{and} \quad \varphi(\omega) = -90^\circ\,. \tag{10.85}$$

In the case that the pole has multiplicity $q > 1$, as for example in (10.79), then (10.85) is modified accordingly.

$$\begin{aligned} A(\omega) &= -20q\log\omega \quad \text{and} \\ \varphi(\omega) &= -q90^\circ \end{aligned} \tag{10.86}$$

Finally, if factor $(\mathrm{i}\omega)$ appears on the numerator instead the denominator of the transfer function the above still hold but the sign has to be switched to positive.

Factor $(1+\mathrm{i}\omega T)$. Calculation of the contribution of this factor, when appearing as part of the denominator of the transfer function, is done on the basis of the following approximations

$$\begin{aligned} A(\omega) &= -20\log|1+\mathrm{i}\omega T| \\ &= -20\log\sqrt{1+\omega^2T^2} \\ &\approx \begin{cases} 0 & \omega T \ll 1 \\ -3 & \omega T \simeq 1 \\ -20\log(\omega T) & \omega T \gg 1 \end{cases}, \end{aligned} \tag{10.87}$$

$$\begin{aligned} \varphi(\omega) &= -\arctan(\omega T) \\ &\approx \begin{cases} 0^\circ & \omega T < 0.1 \\ -90^\circ & \omega T > 10.0 \end{cases}. \end{aligned} \tag{10.88}$$

As an example, consider the following first-order transfer function

$$\mathbf{H}(s) = \frac{1}{s+1} \Rightarrow \mathbf{H}(\mathrm{i}\omega) = \frac{1}{1+\mathrm{i}\omega}\,. \tag{10.89}$$

In the above, evidently $T = 1.0$.

The Bode plots of this transfer function are shown in Fig. 10.10. It is clear that these graphs can be approximated by straight lines. In this respect, the magnitude plot consists of a horizontal line until the breakpoint (or corner point) corresponding to $\omega T = 1.0$; beyond that point it can be approximated by a straight line with a slope of $-20\,\mathrm{dB/dec}$. The phase plot can be approximated by horizontal lines at the level of 0° for $\omega T < 0.1$ and -90° for $\omega T > 10.0$. These sections can then be connected with an appropriately negatively sloped straight line.

Finally, these remarks can be easily extended for the cases where factor $(1+\mathrm{i}\omega T)$ appears in the numerator of the transfer function or obtains multiplicity higher than 1.

Factor $\left[1-(\omega/\omega_0)^2+\mathrm{i}2\zeta(\omega/\omega_0)\right], |\zeta| < 1$. Calculation of the contribution of this factor, when appearing as part of the denominator of the transfer function, is done on the basis of the following approximations

$$\begin{aligned} A(\omega) &= -20\log\left|1-\left(\frac{\omega}{\omega_0}\right)^2+j2\zeta\left(\frac{\omega}{\omega_0}\right)\right| \\ &= -20\log\sqrt{\left[1-\left(\frac{\omega}{\omega_0}\right)^2\right]^2+4\zeta^2\left(\frac{\omega}{\omega_0}\right)^2} \\ \Rightarrow A(\omega) &= \begin{cases} 0\,, & \omega \ll \omega_0 \\ -20\log(2|\zeta|)\,, & \omega \simeq \omega_0 \\ -40\log\left(\frac{\omega}{\omega_0}\right), & \omega \gg \omega_0 \end{cases}, \end{aligned} \tag{10.90}$$

$$\begin{aligned} \varphi(\omega) &= -\arctan\left[\frac{2\zeta\left(\frac{\omega}{\omega_0}\right)}{1-\left(\frac{\omega}{\omega_0}\right)^2}\right] \\ \Rightarrow \varphi(\omega) &= \begin{cases} \approx 0^\circ\,, & \omega \ll \omega_0 \\ -90^\circ\,, & \omega = \omega_0 \\ \approx -180^\circ\,, & \omega \gg \omega_0 \end{cases}. \end{aligned} \tag{10.91}$$

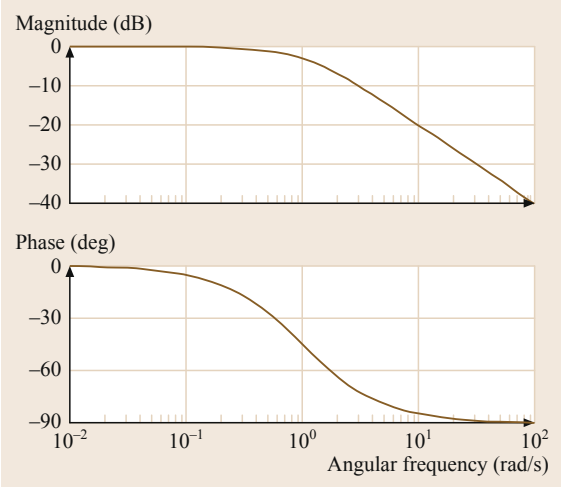

Fig. 10.10 Magnitude and phase Bode plots of a first-order factor in the denominator

The dependence of the corresponding plots on parameter ζ (known as the *damping factor* or *coefficient*) is shown in Fig. 10.11. Evidently, the smaller the damping coefficient is, the higher the intensity of resonance. By resonance, we mean the phenomenon according to which the system exhibits response of significantly amplified amplitude when driven by a sinusoidal of a specific frequency, known as the resonance frequency, $\omega = \omega_0$. In the extreme case that $\zeta = 0$, the output's amplitude is infinite. On the other hand, when $\zeta = 1$ the system obtains a double real pole located at $\omega = \omega_0$ and the analysis can be done as in the case of a first-order factor $(1 + i\omega T)$ with multiplicity equal to two.

The second-order factor Bode plots can be approximated by straight lines as in the case of factor $(1 + i\omega T)$, especially for frequencies far from the resonance point $\omega = \omega_0$. For $\omega \ll \omega_0$ a horizontal straight line is a good approximation while for $\omega \gg \omega_0$ a straight line with slope $-40\,\mathrm{dB/dec}$ represents the frequency dependence of the magnitude Bode plot. For the vicinity of the resonance point $\omega = \omega_0$, the intensity of the resonance, depending on the value of ζ, needs to be estimated. For the phase plot similar considerations with the first-order case hold; the final value, though, is now $-180°$ instead of $-90°$. Furthermore, the smaller the absolute value of the damping coefficient, the steeper the phase plot of the factor.

10.2.5 Analysis of Second-Order Systems

A large class of practical systems encountered in control engineering is either of first or second order.

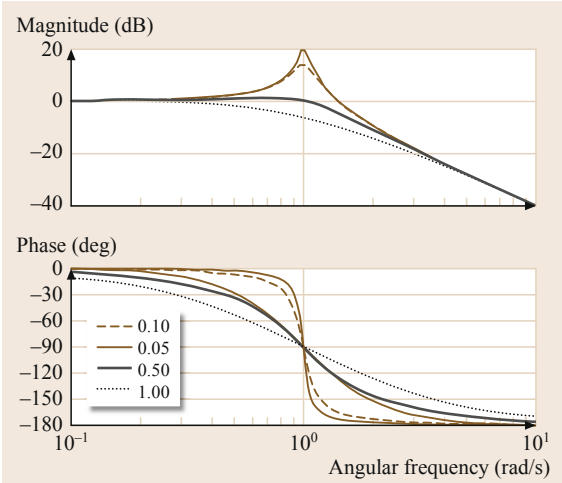

Fig. 10.11 Bode plots of a second-order factor in the denominator for various values of ζ

Furthermore, many other higher order systems can be approximated or *reduced* to first or second order ones, provided that certain conditions are valid. The importance of first- and second-order LTI systems is additionally emphasized by the fact that their poles can be conveniently calculated as functions of the coefficients of their characteristic polynomial.

In this section, the analysis of a generic second-order system without zeros, as in the transfer function below, is presented.

$$\mathbf{H}(s) = \frac{\omega_0^2}{s^2 + 2\zeta\omega_0 s + \omega_0^2} \tag{10.92}$$

The parameter $\omega_0 \geq 0$ is referred to as the eigenfrequency of the system and parameter ζ as the coefficient (or damping) coefficient.

The poles of the system are given by the expression

$$p_{1,2} = \omega_0 \left(-\zeta \pm \sqrt{\zeta^2 - 1}\right). \tag{10.93}$$

In the case that $|\zeta| < 1$, parameter $\omega_\mathrm{n} = \omega_0\sqrt{1-\zeta^2}$ is defined as the natural frequency of the system.

The step response of the generic second-order system is given by the following relationship in the complex frequency domain, if (10.19) is employed

$$\mathbf{Y}_\mathrm{step}(s) = \mathbf{H}(s)\mathbf{U}_\mathrm{step}(s) = \frac{\omega_0^2}{s\left(s^2 + 2\zeta\omega_0 s + \omega_0^2\right)}. \tag{10.94}$$

The analysis of the second-order system in hand will proceed on the basis of the following cases for the value of the damping coefficient. As shown, this coefficient plays a crucial role in determining the location of the system poles on the s-plane and effectively its stability and transient behavior:

a) $\zeta \leq -1$: Two positive purely real poles (or a single double one if $\zeta = -1$) – Unstable system
Step response (see Fig. 10.12).

b) $-1 < \zeta < 0$: Two complex conjugate poles on the right-hand s-plane – Unstable system
Step response (see Fig. 10.13).

c) $\zeta = 0$: Two conjugate purely imaginary poles – Critically stable system
Step response (Fig. 10.14)

$$y_\mathrm{step}(t) = 1 - \cos(\omega_0 t). \tag{10.95}$$

d) $0 < \zeta < 1$: Two complex conjugate poles on the left-hand s-plane – Stable system

Step response (Fig. 10.15)

$$y_{\text{step}}(t) = 1 - e^{-\sigma t}\cos(\omega_n t) - \frac{\sigma}{\omega_n} e^{-\sigma t}\sin(\omega_n t)$$
$$= 1 - \frac{e^{-\sigma t}}{\sqrt{1-\zeta^2}}\sin(\omega_n t + \theta) \ , \tag{10.96}$$

where

$$\sigma = \text{Re}\{p_{1,2}\} = -\zeta\omega_0 \quad \text{and}$$
$$\theta = \arctan\left(\frac{\sqrt{1-\zeta^2}}{\zeta}\right).$$

In Fig. 10.15, it is of interest to calculate the time (at which occurs) and the value of maximum overshoot.

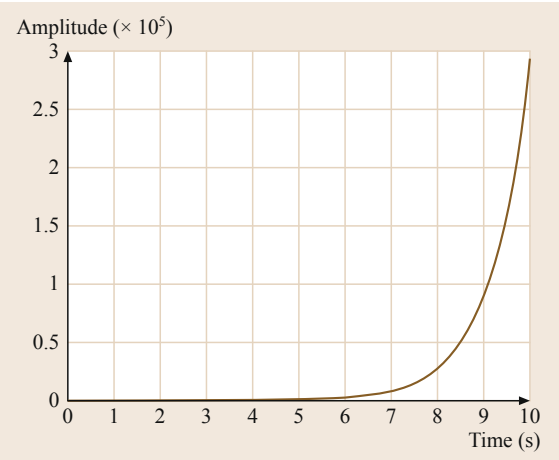

Fig. 10.12 Second-order system step response when $\zeta \leq -1$

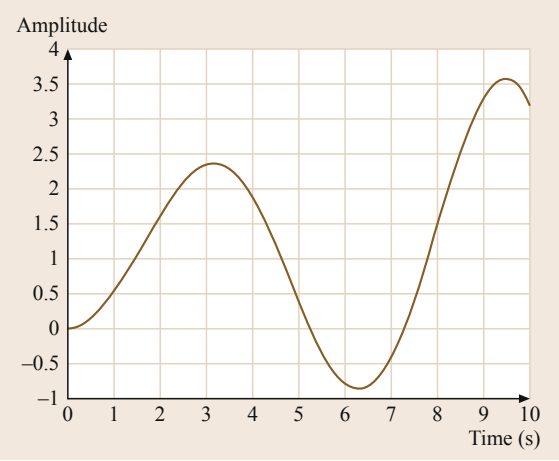

Fig. 10.13 Second-order system step response when $-1 < \zeta < 0$

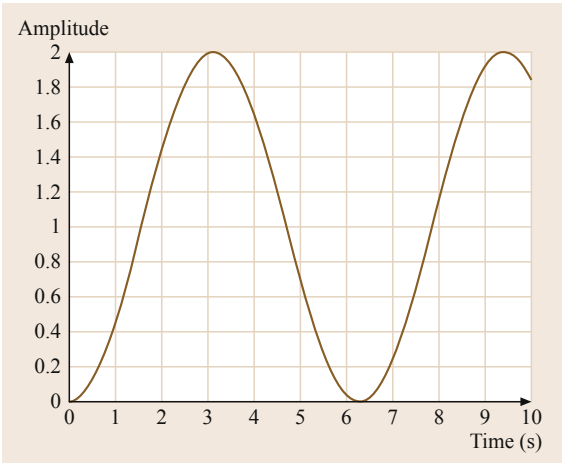

Fig. 10.14 Second-order system step response when $\zeta = 0$

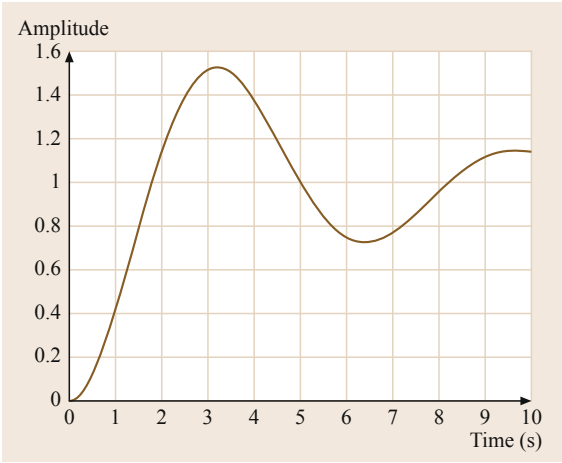

Fig. 10.15 Second-order system step response when $0 < \zeta < 1$

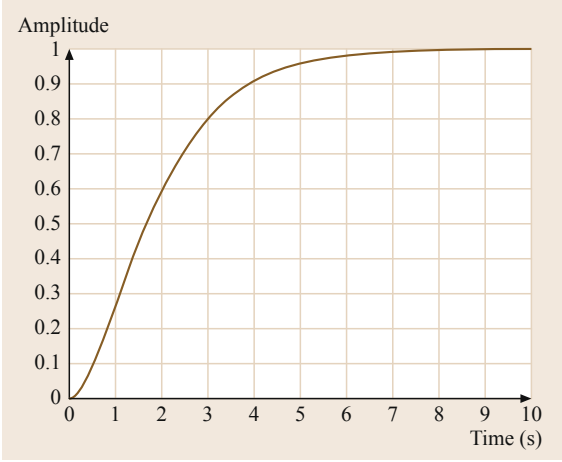

Fig. 10.16 Second-order system step response when $\zeta = 1$

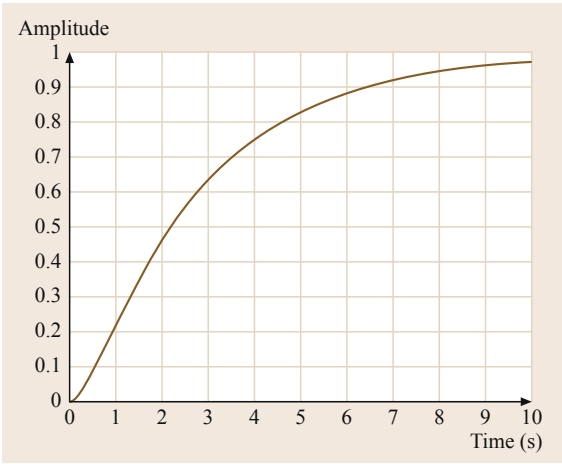

Fig. 10.17 Second-order system step response when $\zeta > 1$

This is achieved by differentiating the expression for the step response in (10.94). The derivative calculated is then equated to zero. The time of the first maximum's occurrence is the time instant of maximum overshoot t_{max} given as

$$t_{max} = \frac{\pi}{\omega_n} . \tag{10.97}$$

e) $\zeta = 1$: One double, purely real pole in the right-hand s-plane – Stable system
Step response (Fig. 10.16)

$$y_{step}(t) = 1 - e^{-\omega_0 t} - \omega_0 e^{-\omega_0 t} . \tag{10.98}$$

f) $\zeta > 1$: Two negative purely real poles – Stable system

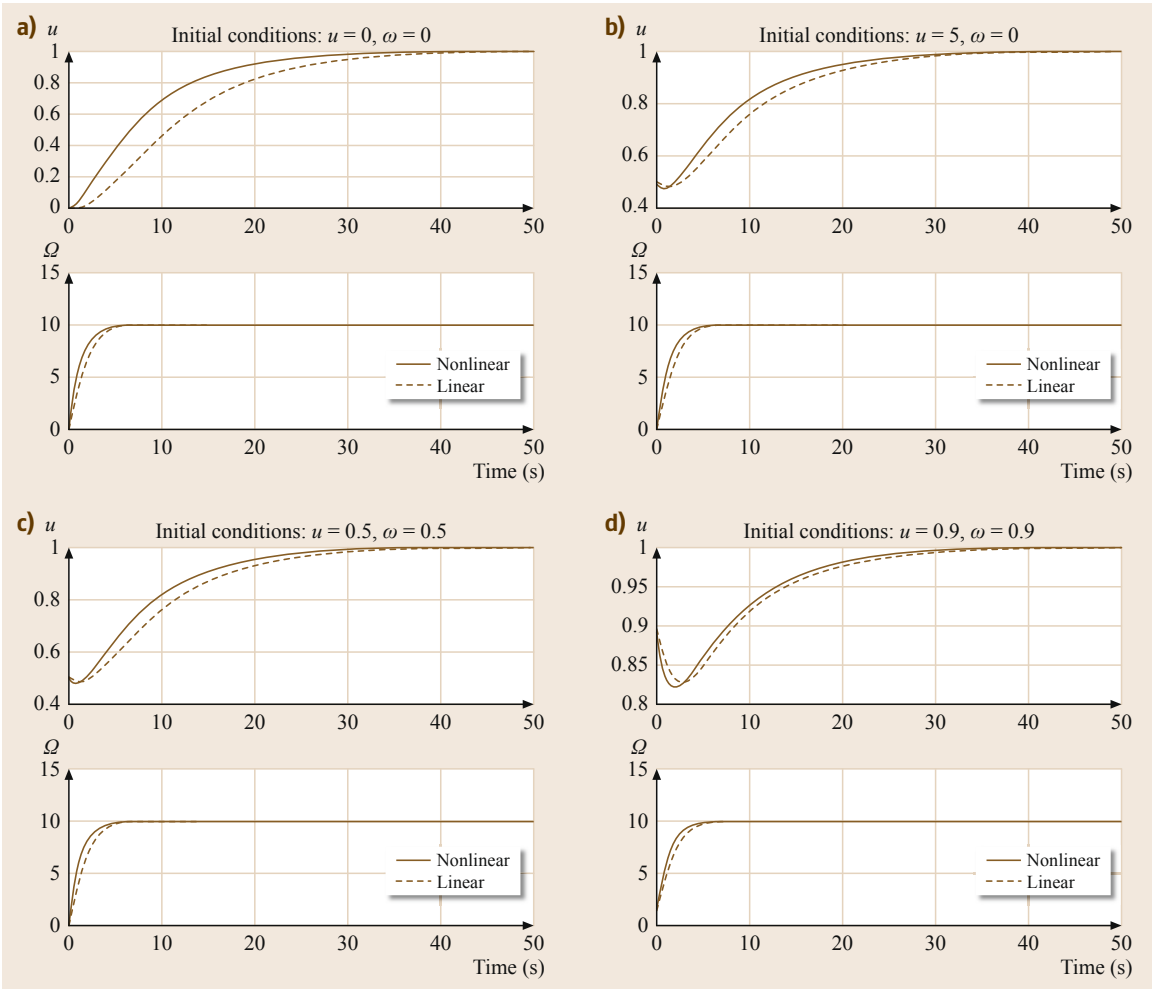

Fig. 10.18a–d Unit responses of the forward AUV speed model for four different initial conditions

Step response (Fig. 10.17)

$$y_{\text{step}}(t) = 1 - e^{-\sigma t}\cosh(at) - \frac{\sigma}{a}e^{-\sigma t}\sinh(at) \ , \tag{10.99}$$

where $\sigma = \text{Re}\{p_{1,2}\} = -\zeta\omega_0$ and $a = \omega_0\sqrt{\zeta^2 - 1}$. The Bode plots for various positive values of $\zeta > 0$ (therefore asymptotically stable cases) are given in Fig. 10.11.

Example 10.3 Linearized AUV Forward Speed Model

In this example, we will analyze the linearized AUV forward speed model introduced in Example 10.2.

Given $d = 20$, $M = 300$, $c_T = 0.2$, $\beta = 50$, $\alpha = 0.04$, $u_0 = 1$, $\Omega = 10$, the linearized model is

$$300\dot{u} + 40u = 4\Omega \ ,$$
$$\dot{\Omega} + 0.8\Omega = 50\tau + 4$$

and the transfer functions are expressed as follows using (10.67)

$$\mathbf{H}_U(s) = \frac{\mathbf{U}(s)}{\tau(s)} = \frac{200}{(300s + 40)(s + 0.8)} \ ,$$
$$\mathbf{H}_\Omega(s) = \frac{\Omega(s)}{\tau(s)} = \frac{50}{(s + 0.8)} \ ,$$

where $u(t) \leftrightarrow \mathbf{U}(s)$, $\Omega(t) \leftrightarrow \Omega(s)$, $\tau(t) \leftrightarrow \tau(s)$. These models are simulated in MATLAB/Simulink with a unit step of 0.08 Nm as the input torque. Figure 10.18 shows the simulated responses based on the nonlinear and linearized models at four different initial conditions.

One can clearly see that the linearized model becomes more accurate as the initial conditions move toward the point of linearization ($u_0 = 1$, $\Omega_0 = 10$). Also, the propeller response is visually more accurate with a shorter time constant as compared to the speed response.

10.3 SISO System Controls

This chapter presents some fundamental techniques for the control of LTI–SISO systems and basic performance criteria typically used in controller design. The techniques consist of (a) ON/OFF control; (b) PID (proportional-integral-derivative) control, and (c) controller design by use of the root locus.

The closed-loop control system given above is encountered in many practical, industrial plants and processes. The objective in introducing feedback control is to maintain the process response signal y as close as possible to the reference signal (setpoint) r. Deflection of the process output signal from the reference one is generated because either there is significant disturbance present, manifested by signal d, or the setpoint is modified or both. The first problem is referred to as the *regulation problem* while the second as the *tracking problem*.

In any of these cases, however, the controller (control system) is inserted in order to reduce the error signal, $e = r - y$, that is, the deviation of the output from the reference signal, to the lowest possible value; this can be achieved by appropriately processing the error signal in order to generate the driving control signal, that will compensate the effect of the disturbance. The block diagram in Fig. 10.19 is similar to the one shown in Fig. 10.2; for the sake of simplicity, however, the sensor and actuator blocks have been omitted, or equivalently included in the controller and process block, respectively, and the plant is assumed to be SISO.

In the complex frequency domain, the output signal is given by the relationship

$$\left.\begin{aligned}\mathbf{Y}(s) &= \mathbf{G}(s)\left[\mathbf{U}(s) + \mathbf{D}(s)\right] \\ \mathbf{U}(s) &= \mathbf{K}(s)\mathbf{E}(s) = \mathbf{K}(s)\left[\mathbf{R}(s) - \mathbf{Y}(s)\right]\end{aligned}\right\} \Rightarrow$$
$$\Rightarrow \mathbf{Y}(s) = \frac{\mathbf{G}(s)\mathbf{K}(s)}{1 + \mathbf{G}(s)\mathbf{K}(s)}\mathbf{R}(s) + \frac{\mathbf{G}(s)}{1 + \mathbf{G}(s)\mathbf{K}(s)}D(s) \ . \tag{10.100}$$

The above can be alternatively demonstrated by separately applying the general equation (10.61) for each one of the signals r and d and setting the other one identically equal to zero.

10.3.1 Performance Criteria

There are three primary criteria for which the performance of a system can be assessed. They are: transient response, steady-state response, and disturbance rejection response. These criteria are generally used for the setpoint control objective.

A *transient response* corresponds to how a system reacts to a new desired output. The associated criteria are usually defined in terms of:

- Delay time (t_d): the time it takes to reach 30% of the setpoint level

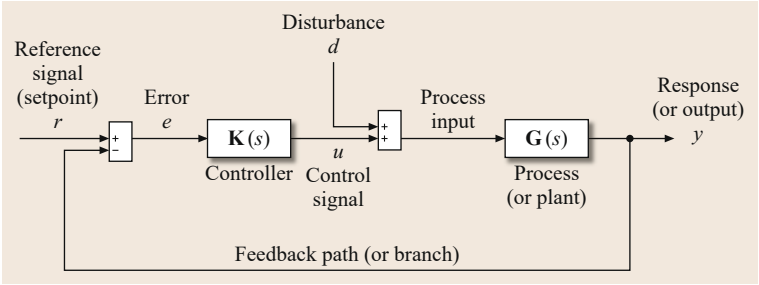

Fig. 10.19 Typical block diagram of a closed-loop system

- Rise time (t_r): the time it takes to reach 90% of the setpoint level
- Peak time (t_p): the time it takes to reach the peak value, that is, value ($A + B$)
- Maximum overshoot (M_p): a ratio of the amount of overshoot (A) to the setpoint (B)
- Settling time (t_s): the time it takes to reach within a predefined threshold around the setpoint (e.g., ± 3 or 5%).

Figure 10.20 shows a unit step response with the criteria depicted graphically. It is customary that the controller designs are based on the requirements associated with these criteria. For linear systems, their open-loop system responses can be decomposed into a combination of first-order (exponential) and second-order (oscillatory) responses, that is, factors in the transfer function as follows

$$\mathbf{H}_1(s) = \frac{1}{s+\alpha}\,,$$
$$\mathbf{H}_2(s) = \frac{1}{s^2 + 2\zeta\omega_n s + \omega_n^2}\,. \qquad (10.101)$$

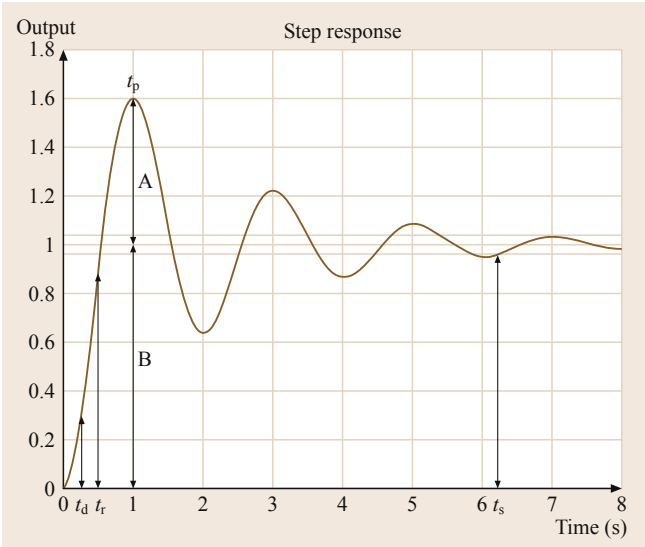

Fig. 10.20 A typical unit step response of an LTI system

In the above $\mathbf{H}_1(s)$ and $\mathbf{H}_2(s)$ correspond to the first- and second-order components. If the overall system response is dominated by its second-order component with an oscillatory response, the design requirements can be directly translated into desired natural frequency (ω_n) and damping ratio (ζ) requirements. For linear, pole-only systems, the translation can be performed using the formulas

$$t_r = \frac{\pi - \tan^{-1}\left(\frac{\sqrt{1-\zeta^2}}{\zeta}\right)}{w_d} \approx \frac{1.8}{\omega_n} \quad (\text{for } \zeta = 0.5)\,,$$
$$t_s \approx \frac{4.6}{\zeta\omega_n} \quad (\text{for } 1\% \text{ specification})\,,$$
$$M_p = \mathrm{e}^{-(\zeta/\sqrt{1-\zeta^2})\pi}\,. \qquad (10.102)$$

For an example, if the rise time must be < 1 s, maximum overshoot $< 16\%$, and the settling time less than 3 s, then the damping ratio must be > 0.5 (based on maximum overshoot) and the natural frequency > 1.8 rad/s (based on rise time) or 3.1 rad/s (based on settling time). Thus, the final design requirements are $\omega_n > 3.1$ rad/s, $\zeta > 0.5$.

A *steady-state response* corresponds to how well a system can maintain its desired output while incurring minimal offset. In many applications, the steady-state error, which is the difference between the desired output and the actual system output, is required to fall within a threshold. This can be related to the settling time requirement mentioned previously.

A *disturbance rejection response* corresponds to how well a system rejects any unexpected noise. The controller must be capable of rejecting the noise while achieving the transient and steady-state requirements.

10.3.2 ON/OFF Control

ON/OFF control is the simplest control technique and widely used in various practical systems. Typical applications include thermostats; two-positions pressure regulators; pneumatic and hydraulic actuator valves like the ones used, for example, in marine steering gears, etc.

The control law, that is, the relationship connecting the error to the control signal as implemented in the controller, is

$$u = \begin{cases} A\,\mathrm{sgn}(e)\,, & |e| \geq Z_d \\ 0\,, & |e| < Z_d \end{cases} = \begin{cases} +A\,, & e \geq +Z_d \\ 0\,, & |e| < Z_d \\ -A\,, & e \leq -Z_d \end{cases} . \tag{10.103}$$

In the above, A is a constant and $Z_d \geq 0$ a *threshold value* for the absolute error $|e|$ at which the control signal is activated. The region $|e| < Z_d$ for which the control signal is zero is called the *dead zone*; the dead zone need not be necessarily symmetrical around zero as shown in Fig. 10.21 for an ON/OFF controller with $A = 1$. Furthermore, this figure as well as (10.103) refer to controllers with *three switch positions*. Commonly, the controller switch may have only two positions, as indicated by the name ON/OFF, or four or more. However, the same features are shared by all controllers whose control law is based on switching as in (10.103); therefore, the analysis is general enough.

An important feature of all ON/OFF controllers is that the associated control law is nonlinear and, in effect, cannot be investigated with tools from linear control theory, like transfer functions (Fig. 10.22). In this end, an example is presented.

The step response of the closed-loop system for various values of parameter A and no dead zone, that is, $Z_d = 0$, is shown in Fig. 10.23. Starting with $A = 1$, one can easily see that the response is the same with the one obtained when the switch is not intermitted between the summing junction and the process. For $A = 0.1$, on the other hand, the response exhibits large steady-state error (≈ 0.9) from the setpoint value ($= 1$). For $A = 2$, one obtains a very good, from a practical viewpoint, step response as it approaches the setpoint in almost half the time needed in the case of $A = 1$. However, if one attempts to further reduce the *rise time*, by simply increasing A beyond 2, *limit cycle oscillations* of the control signal are induced. This is highly undesirable as it can cause various elements in the system (e.g., the actuator) to rapidly wear and fail.

In practical systems, dead zone cannot be exactly zero; this is mainly due to the fact that the control loop elements are not ideal and demonstrate finite sensitivity. Even a small dead zone may sever the limit cycle phenomenon. This is clearly seen in Fig. 10.24a, where $A = 2$ and the dead zone is just 3% of the absolute maximum error e observed (which is equal to 1.0 at start time). Furthermore, a relatively large dead zone is often deliberately introduced in order to reduce the frequency of the limit cycle oscillations. This is seen in Fig. 10.24b

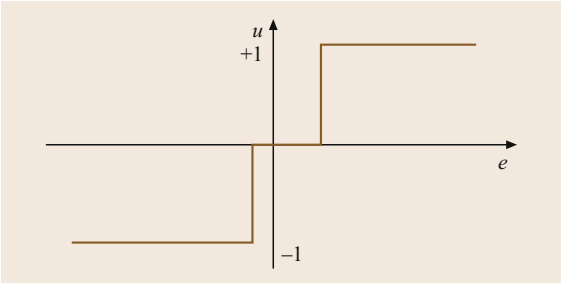

Fig. 10.21 General form of an ON/OFF controller with three positions switch

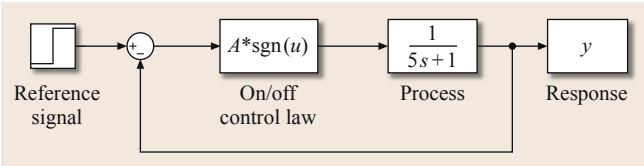

Fig. 10.22 Example for the analysis of ON/OFF controllers

where $Z_d = 0.3$ (30% of the absolute maximum error observed). However, this comes at the price of increasing the error in the response; indeed, the final value of the response as can be seen in Fig. 10.24 is ≈ 0.7, that is, 30% off the setpoint.

10.3.3 PID Control

The proportional-integral-differential (PID) control law was introduced as an alternative to ON/OFF control because it actually deals with practical control issues of SISO plants in a much improved manner.

The PID control law is commonly encountered in the following alternative forms (reference of symbols is Fig. 10.25):

(i) The analytic form which is also used in the rest of this text. The expressions for the control law in both the time and complex frequency domain are given below.

$$\begin{aligned} u(t) &= K_\mathrm{p} e(t) + K_\mathrm{i} \int_0^t e(\xi)\,\mathrm{d}\xi + K_\mathrm{d} \frac{\mathrm{d}}{\mathrm{d}t} e(t) \\ &\Updownarrow \\ \mathbf{U}(s) &= \mathbf{K}(s)\mathbf{E}(s) = \left(K_\mathrm{p} + \frac{K_\mathrm{i}}{s} + K_\mathrm{d} s \right) \mathbf{E}(s) \\ &= \frac{K_\mathrm{i} + K_\mathrm{p} s + K_\mathrm{d} s^2}{s} \mathbf{E}(s) \end{aligned} \tag{10.104}$$

In the analytic form, the control signal depends exclusively on the error signal. Furthermore, note that (a) the P-control law is a static system; (b) the PID

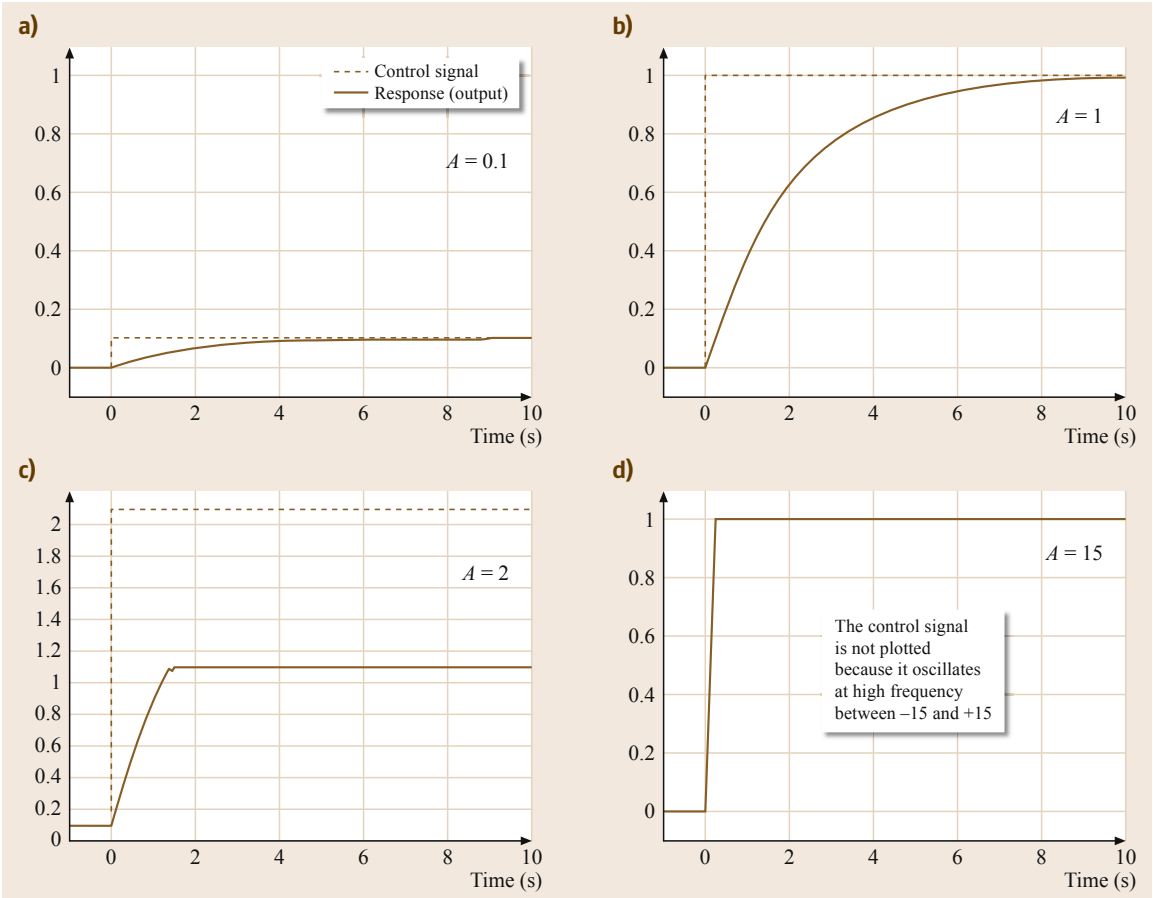

Fig. 10.23a–d Response with ON/OFF control various values of $A = 2$ and $Z_d = 0$

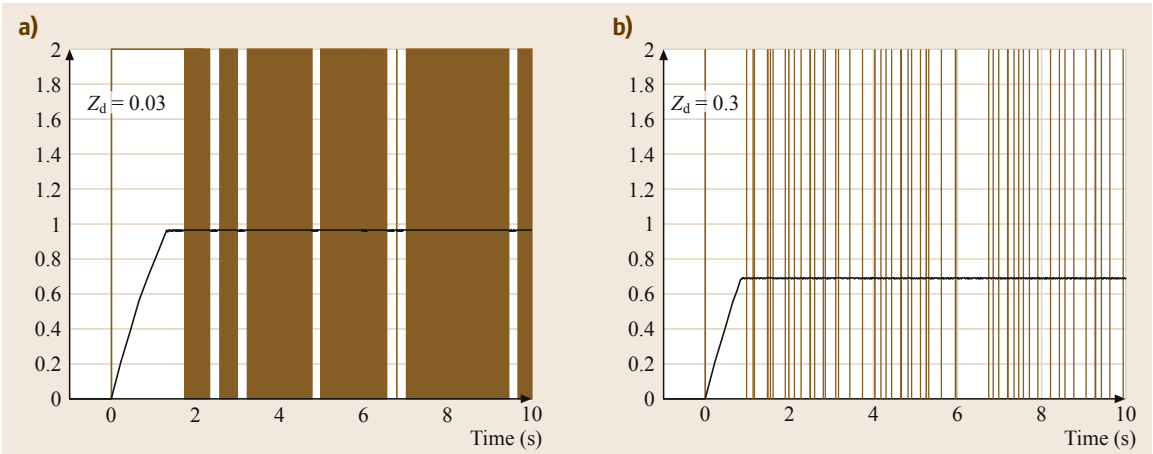

Fig. 10.24a,b Response with ON/OFF control for $A = 2$ and $Z_d = 0.03$ and 0.3

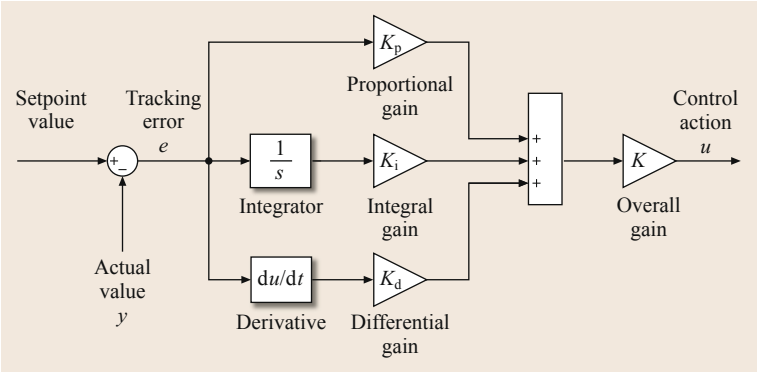

Fig. 10.25 General form of the PID controller

controller transfer function with nonzero I-term demonstrates a pole at $s = 0$; (c) the numerator polynomial of the PID controller transfer function with nonzero D-term is of higher order than its denominator one.

The block diagram of the generic PID controller is given in Fig. 10.25.

(ii) The practical form which is adopted commonly in industrial practice.

$$u(t) = K_\mathrm{p}\left(-y(t) + \frac{1}{T_\mathrm{i}}\int_0^t e(\xi)\,\mathrm{d}\xi - T_\mathrm{d}\frac{\mathrm{d}}{\mathrm{d}t}y(t)\right) \tag{10.105}$$

In this form, the error signal in both the P- and D-term is replaced by that of the process output signal (negated). In this way the closed-loop system response to abrupt changes of the setpoint, r, is significantly smoother

The problem of *tuning* a PID controller consists of determining the three P-I-D control law gains K_p, K_i and K_d so that certain transient and steady-state specifications for the closed-loop system are satisfied.

Proportional Control

For proportional control (P-control) it holds that: $K_\mathrm{i} = K_\mathrm{d} = 0$. Therefore, the tuning problem is limited to the determination of coefficient K_p in the control law. In this respect, P-control exhibits significant similarity to the ON/OFF controller presented previously. Below, a widespread version of P-control is given. In this version, the control signal is generated as the superposition of the output of a P controller plus an open-loop control action manifested as offset u_0.

$$u(t) = \begin{cases} u_0 + K_\mathrm{P}e_0\,, & e(t) > e_0 \\ u_0 + K_\mathrm{P}e(t)\,, & -e_0 \le e(t) \le e_0 \\ u_0 - K_\mathrm{P}e_0\,, & e(t) < -e_0 \end{cases} \tag{10.106}$$

In both the above relationship as well as in Fig. 10.26, one can easily assert the similarity of P-control to ON/OFF control (at least with a three-positions switch, as examined in the text).

As in the case of ON/OFF control, the control signal demonstrates saturation when the absolute value of the error signal exceeds a threshold in order to prevent excessive control signal values.

The ideal (i. e., without saturation) P controller eliminates the problem of limit cycle oscillations. On the other hand, it reduces, but does not fully eliminate, steady-state error. The effect of P-control is now investigated in two typical practical cases. At first, zero disturbance is assumed and the process block in Fig. 10.19 is assumed to be purely static as follows

$$y = K_\mathrm{SS}u = K_\mathrm{SS}(u_0 + K_\mathrm{p}e)\,. \tag{10.107}$$

In the above, K_SS stands for the steady-state gain of the process plant. After algebraic manipulation the output of the closed-loop system with P-control is obtained as follows

$$y = \frac{K_\mathrm{SS}u_0 + K_\mathrm{SS}K_\mathrm{p}r}{1 + K_\mathrm{SS}K_\mathrm{p}} \Rightarrow e = \frac{r - K_\mathrm{SS}u_0}{1 + K_\mathrm{SS}K_\mathrm{p}}\,. \tag{10.108}$$

In effect, for the steady-state error to be zero it is necessary for one of the following to hold:

- $u_0 = r/K_\mathrm{SS}$,
- $K_\mathrm{p} \to \infty$.

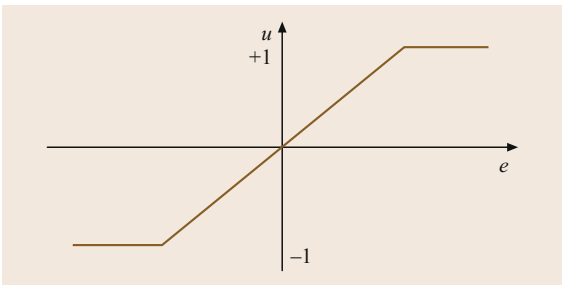

Fig. 10.26 P-control law with saturation and zero offset

The second case to be examined is when the process exhibits first-order linear dynamics and nonzero disturbance is present. Assume that $\mathbf{G}(s)$ in (10.100) is as follows

$$\mathbf{G}(s) = \frac{K_{SS}}{\tau s + 1} \,. \tag{10.109}$$

Then (10.100) with P-control ($K(s) = K_p$) yields

$$\mathbf{Y}(s) = \frac{K_{SS}K_p}{\tau s + 1 + K_{SS}K_p}\mathbf{R}(s) + \frac{K_{SS}}{\tau s + 1 + K_{SS}K_p}\mathbf{D}(s) \,. \tag{10.110}$$

By assuming that $R(s) = 0$, without any loss of generality, the final value theorem of the Laplace transform (10.6) may be employed in (10.100), to obtain the closed-loop response when there is a step change in disturbance ($d(t) = u_{step}(t) \Leftrightarrow D(s) = 1/s$).

$$\begin{aligned}
&\lim_{t\to\infty}(y(t)) = \lim_{s\to 0}(s\mathbf{Y}(s)) \\
&= \lim_{s\to 0}\left(s\frac{K_{SS}}{\tau s + 1 + K_{SS}K_p}D(s)\right) \\
&\Downarrow \\
&\lim_{t\to\infty}(y(t)) \\
&= \lim_{s\to 0}\left(s\frac{K_{SS}}{\tau s + 1 + K_{SS}K_p}\frac{1}{s}\right) = \frac{K_{SS}}{1 + K_{SS}K_p}
\end{aligned} \tag{10.111}$$

In conclusion in order to minimize the deviation of $y(t \to \infty)$ from $r = 0$ a large value for coefficient K_p is needed.

Proportional–Integral Control

For proportional-integral control (PI-control) it holds that $K_d = 0$. A control law including an integral term eliminates steady-state error which is the major drawback of P-control. It is for this reason that the PI controller finds widespread use in industry. A typical example is *speed governors* used for regulation of the rotational speed (rpm, revolutions per second) of engines, turbines, motors, etc.

PI control is defined by the transfer function

$$\begin{aligned}
&u(t) = K_p e(t) + K_i \int_0^t e(\xi)\,\mathrm{d}\xi \\
&\Updownarrow \\
&\mathbf{U}(s) = \left(K_p + \frac{K_i}{s}\right)\mathbf{E}(s) = \frac{K_p s + K_i}{s}\mathbf{E}(s) \,.
\end{aligned} \tag{10.112}$$

The effect of PI-control is now investigated in the case of an LTI–SISO process with a generic transfer function defined as a ratio of two polynomials $p_n(s)$ and $p_0(s)$ with degree m and n, respectively, and $m \le n$.

$$\mathbf{G}(s) = \frac{p_n(s)}{p_0(s)} \tag{10.113}$$

With PI control, (10.100) yields

$$\mathbf{Y}(s) = \frac{(K_i + K_p s)p_n(s)}{sp_0(s) + (K_i + K_p s)p_n(s)}\mathbf{R}(s) + \frac{sp_n(s)}{sp_0(s) + (K_i + K_p s)p_n(s)}\mathbf{D}(s) \,. \tag{10.114}$$

As an example, consider the transfer equation in (10.109). Then, (10.114) yields

$$\mathbf{Y}(s) = \frac{K_{SS}(K_i + K_p s)}{s(1 + \tau s) + K_{SS}(K_i + K_p s)}\mathbf{R}(s) + \frac{K_{SS}s}{s(1 + \tau s) + K_{SS}(K_i + K_p s)}\mathbf{D}(s) \,. \tag{10.115}$$

Assuming, as in the case of P-control, that $\mathbf{R}(s) = 0$ and applying the final value theorem for $d(t) = u_{step}(t) \Leftrightarrow \mathbf{D}(s) = 1/s$, the following is obtained

$$\begin{aligned}
y(t \to \infty) &= \lim_{s\to 0}(s\mathbf{Y}(s)) \\
&= \frac{K_{SS}\cdot 0}{0\cdot(1 + \tau\cdot 0) + K_{SS}\cdot(K_i + K_p\cdot 0)} \\
&= 0 \,.
\end{aligned} \tag{10.116}$$

As can be seen, PI control introduces a zero at $s = 0$ in the closed-loop transfer function connecting the disturbance to the output signal, resulting to elimination of the steady-state error.

A word of caution is needed here concerning closed-loop stability. The closed-loop characteristic polynomial as can be seen in (10.114) is as follows

$$p_c(s) = sp_0(s) + (K_i + K_p s)p_n(s) \,. \tag{10.117}$$

For the closed-loop system to be stable all the roots of the polynomial above must lie in the left-hand complex plane. However, the degree of this polynomial is $(n+1)$, that is, higher by 1 than the open-loop, process characteristic polynomial, $p_0(s)$. This is the price paid for the improvement in system's behavior after introducing PI-control.

In the specific case of the transfer function in (10.109), the closed-loop characteristic polynomials in

the cases when P and PI-control is employed are as follows

$$\text{P-control: } p_{c1}(s) = \tau s + K_{SS}K_p + 1\,, \tag{10.118}$$

$$\text{PI-control: } p_{c2}(s) = \tau s^2 + \left(K_{SS}K_p + 1\right) s + K_{SS}K_i\,. \tag{10.119}$$

In the case that $K_i = 0$ the polynomial in (10.119) in conjunction with the zero-pole cancellation taking place in (10.115) for $s = 0$, (10.119) coincides with the one in (10.118), that is, the one valid for P-control. Another interesting case is when $\left(K_{SS}K_p + 1\right) = 0 \Leftrightarrow K_p = -1/K_{SS}$, when polynomial $p_{c2}(s)$ has zero first-order term. In this case, the closed-loop system poles are as follows

$$p_{1,2} = \pm\sqrt{\frac{K_{SS}K_i}{\tau}}\,. \tag{10.120}$$

In conclusion, if $K_i > 0$ (and $K_{SS} > 0$) the closed-loop system becomes unstable with one pole in the right-hand complex plane, while if $K_i \le 0$ the closed-loop system is critically stable with two purely imaginary, conjugate poles. The analysis above demonstrates the importance of the proportional term in PI-control for guaranteeing closed-loop system stability.

The reason for which the PI-control law eliminates steady-state error is because the transient effect is not terminated before the output signal coincides with the setpoint. This is achieved due to the accumulation of error in the integrator, which, therefore, acts as a memory element in the closed-loop system. In effect, as long as the error integral is nonzero a persisting control action remains. The tradeoff for this advantage is that the output may be driven to damped on even sustained oscillations.

Proportional–Integral–Differential Control

This is the full form of the P-I-D control law. A differential term (D-term) is employed in order to allow us to deal with some of the problems attributed to the use of the I-term. One of the most important is the prohibitive overshoot observed in the closed-loop system response when PI-control is applied. For example, in Fig. 10.27 the response of a closed-loop system with PI control is shown exhibiting 70% overshoot above the setpoint value assumed by the output signal when steady-state is restored.

Employing the D-term in the control law incorporates prediction capabilities in the controller. Indeed, in a linear system if the error's rate of change $\mathrm{d}e/\mathrm{d}t$ is large, when a step disturbance signal is applied, it is safe to expect the output signal to demonstrate excessive overshoot. In this respect, the D-term incorporates the slope of the error signal $e(t)$ allowing to the controller to predict the imminent overshoot and to appropriately react in order to prevent it by generating a component in the control signal proportional to $\mathrm{d}e/\mathrm{d}t$.

The effect of the D-term to the response of the closed-loop system will be now investigated when the process transfer function is of the first-order as in (10.109). The controller transfer function to be used in this case is shown below.

$$\begin{aligned}\mathbf{U}(s) &= \left(K_p + \frac{K_i}{s} + K_d s\right)\mathbf{E}(s)\\ &= \frac{K_i + K_p s + K_d s^2}{s}\mathbf{E}(s)\end{aligned} \tag{10.121}$$

The general relation (10.100) for the closed-loop response yields

$$\mathbf{Y}(s) = \frac{K_{SS}(K_i + K_p s + K_d s^2)\mathbf{R}(s) + K_{SS}s\mathbf{D}(s)}{(\tau + K_{SS}K_d)\,s^2 + \left(1 + K_{SS}K_p\right)s + K_{SS}K_i}\,. \tag{10.122}$$

As can be readily seen in the above, all three coefficients of the closed-loop, second-order characteristic polynomial may be set as desired by simply adjusting the gain of each one of the terms present in the PID control law. It should be noted that the zeros and poles cannot be independently placed since they are both functions of K_p, K_i and K_d. When the stability of the closed loop takes priority, the location of zeros will be compromised, and this might result in an increased overshoot. Note that this method of determining the PID parameter values is only applicable when a system model exists.

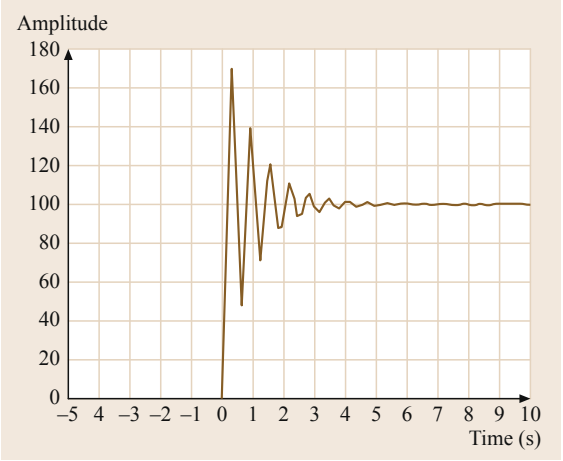

Fig. 10.27 Response of system with PI-control exhibiting prohibitive overshoot

A very interesting case of PID control, partially because of its widespread use in conventional ship course-keeping autopilots, is proportional differential control (PD-control), that is, when the I-term is absent from the control law ($K_i = 0$). Because of the missing I-term, steady-state error is exhibited in this case as well. Indeed, when $K_i = 0$ (10.122) yields

$$\mathbf{Y}(s) = \frac{K_{SS}(K_p + K_d s)}{(\tau + K_{SS}K_d)\, s + \left(1 + K_{SS}K_p\right)}\mathbf{R}(s) + \frac{K_{SS}}{(\tau + K_{SS}K_d)\, s + \left(1 + K_{SS}K_p\right)}\mathbf{D}(s)\,. \tag{10.123}$$

One can easily see that, by applying the final value theorem of the Laplace transform, for $\mathbf{R}(s) = 0$ and a step change in the disturbance signal, $d(t) = u_{step}(t)$, the steady-state response of the system, $y(t \to \infty)$, is the same with the one when simply P-control is employed

$$y(t \to \infty) = \frac{K_{SS}}{1 + K_{SS}K_p}\,.$$

It is finally noted that commonly in practice use of D-term is avoided. Although some issues in the realization of the full PID control law do exist, the main drawback is the amplification of noise due to the nonzero D-term. Indeed, consider the following relationship, demonstrating the effect of real-time signal differentiation, in the natural frequency (Fourier) domain.

$$\mathcal{L}\left\{\frac{\mathrm{d}}{\mathrm{d}t}y(t)\right\} = s\mathbf{Y}(s) \overset{s=\mathrm{i}\omega}{=} (\mathrm{i}\omega)\, Y(\mathrm{i}\omega) = \omega\,|Y(\mathrm{i}\omega)| \exp\left(\angle Y(\mathrm{i}\omega) + \frac{\pi}{2}\right)\,. \tag{10.124}$$

It is evident that high-frequency (HF, large ω), but otherwise weak in terms of power or amplitude, noise components inherent in the output signal $y(t)$ are amplified because of differentiation. This enhancement is manifested by the ω-factor in the frequency response. Therefore, the differential error signal $\mathrm{d}e/\mathrm{d}t$ is many times so noisy that cannot be practically used, at least for control applications.

10.3.4 Ziegler–Nichols' Methods for PID Controller Tuning

In many applications, open-loop system models do not exist or are highly nonlinear, and thus it is difficult to come up with accurate linear system models. To circumvent this difficulty, well-established tuning methods can be used to determine the PID parameters. The most commonly used tuning methods are those developed by Ziegler and Nichols. *Ziegler* and *Nichols* [10.10, 11] have developed an open-loop (first method) and a closed-loop tuning method (second method) for determining the PID parameters

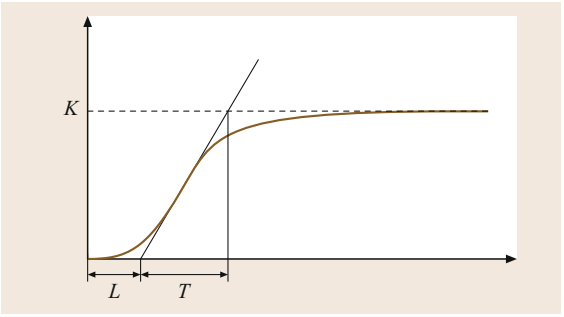

Fig. 10.28 An open-loop step response required for the first tuning method

Ziegler–Nichols' First Method

In this tuning method [10.12], the PID parameters for a system are obtained by observing its open-loop step response via experimentation. The step response must have an S-shape characterized by a time delay L, a time lag T and the static gain K as shown in Fig. 10.28.

Mathematically, this step response can be approximated by

$$\mathbf{H}(s) = \frac{K\mathrm{e}^{-Ls}}{Ts + 1}\,. \tag{10.125}$$

Mathematically, this step response can be approximated by: Once K, L, T are obtained, they can be used to design a P, PI, or PID controller using the expressions in Table 10.2. The parameters K_i, K_d can be related to T_i, T_d by the relationships

$$K_i = \frac{K_p}{T_i}\,, \quad K_d = K_p T_d\,. \tag{10.126}$$

Note that any system that has open-loop poles at the origin cannot be used with the first tuning method as its step response does not reach a steady level. In such cases, the second tuning method can be used.

Table 10.2 PID controller parameters based on the first tuning method

Type of controller	K_p	T_i	T_d
P	$\frac{T}{KL}$	∞	0
PI	$\frac{0.9T}{KL}$	$L/0.3$	0
PID	$\frac{1.2T}{KL}$	$2L$	$0.5L$

Ziegler–Nichols' Second Method

Similar to the first method, this method can be used to design a P, PI, or PID controller. Unlike the first method, the PID parameters for a system are obtained by observing its closed-loop response via experimentation. During the PID parameter identification phase, the system is driven with only a proportional controller, with its controller gain increased until the closed-loop response becomes marginally stable. The amplitude (K_{cr}) and period (P_{cr}) of oscillation are recorded and used to design a P, PI, or PID controller using the expressions in Table 10.3. As expected, this tuning method is not applicable to systems that cannot be driven to marginal stability.

Integrator Anti-Windup

In almost all physical systems, actuators saturate because they have finite range of operation, typically restricting the actuator output (control action) in terms of absolute value $u(t) = u_c(t)$, $|u_c(t)| \le u_{lim}$; $u_{lim} \times \text{sgn}(u_c(t))$, $|u_c(t)| > u_{lim}$.

If the integral control action is used, its error can be accumulated (or windup) excessively and drastically deteriorate the system performance. The integral control law thus needs to be modified

$$\dot{u}_I = \frac{k_P}{T_I} e(t) + \alpha(u(t) - u_c(t)) \,, \qquad (10.127)$$

where α is a user-defined coefficient for tracking the actuator saturation u, u_c are the control actions and control signals, respectively, (refer to Fig. 10.1). When there is actuator saturation, or $u \neq u_c$, the two terms will have opposite signs, and thus the effect of windup can be kept to a minimum. As expected, α must be chosen carefully so that it does not overcompensate the effect of windup; [10.10] suggests that $\alpha = 1/\sqrt{T_I T_D}$.

Example 10.4 AUV Forward Speed P-I-D Control

Consider the AUV forward speed model in Example 10.2 with the first tuning method. From the simulation results, we found $K = 1, L = 1.3, T = 18.7$. These are used to set up P, PI, and PID controllers for the system. Figure 10.29 shows the closed-loop responses using the P (blue), PI (red), and the PID (green) controllers. One can see that the PI controller has the worst transient performance whereas the PID controller has the best compromised performance in terms of overshoot and rise time. It should be noted that this tuning method only provides a starting point for the controller parameters, and manual fine tuning is almost always needed to further improve the system performance.

Table 10.3 PID controller parameters based on the second tuning method

Type of controller	K_p	T_i	T_d
P	$0.5K_{cr}$	∞	0
PI	$0.45K_{cr}$	$P_{cr}/1.2$	0
PID	$0.6K_{cr}$	$0.5P_{cr}$	$0.125P_{cr}$

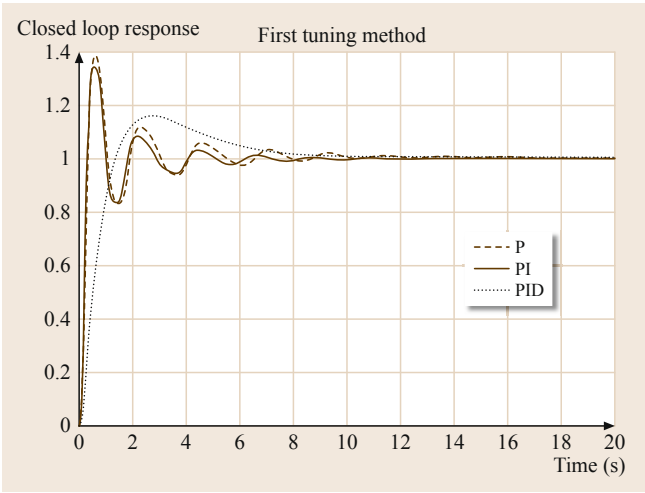

Fig. 10.29 Closed loop system responses using a P (in *blue*), PI (*red*), and a PID (in *green*) controller

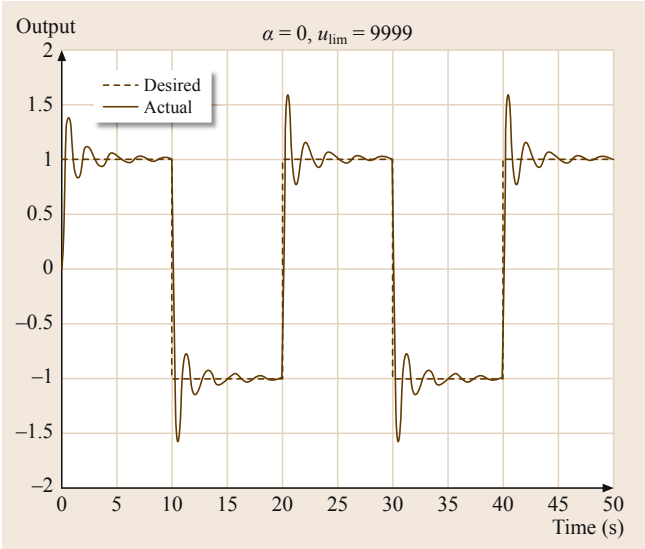

Fig. 10.30 A closed-loop AUV forward speed response using a PI controller with varying setpoints, no actuator saturation or anti-windup

To study the effect of anti-windup algorithm, the same forward speed model is controlled with a PI controller. Figure 10.30 shows the closed-loop response subject to varying setpoints over a period of 50 s. In this case, no actuator saturation is considered and $\alpha = 0$. Again, the sluggish transient response can be noticed.

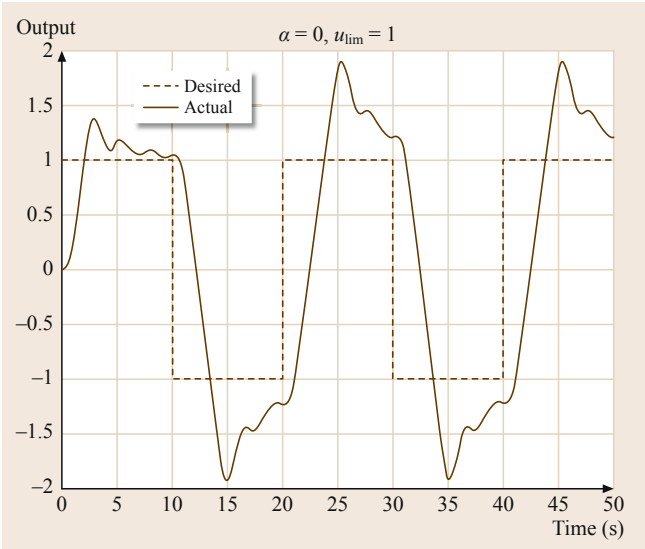

Fig. 10.31 A closed-loop AUV forward speed response using a PI controller with varying setpoints and actuator saturation but no anti-windup

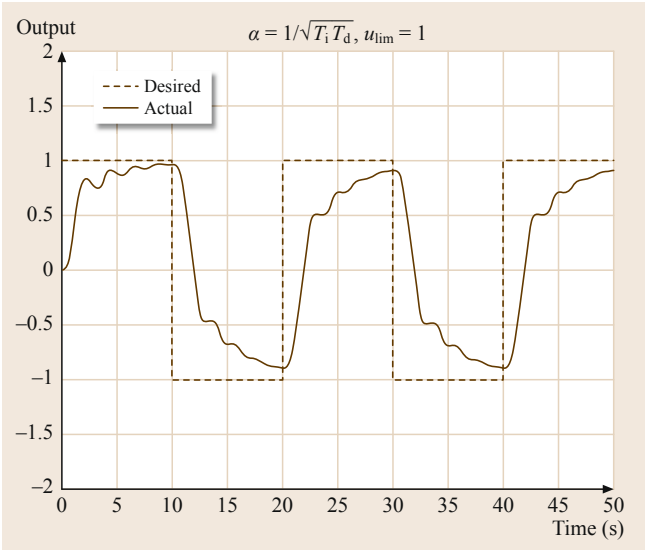

Fig. 10.32 A closed-loop AUV forward speed response using a PI controller with varying setpoints, actuator saturation and, also, anti-windup protection

In the presence of actuator saturation, $|\tau| \leq 1$, Fig. 10.31 shows the closed-loop system performance that is drastically deteriorated, especially after the first setpoint.

With the modified integral control law, Fig. 10.32 shows the much improved system performance.

10.3.5 Digital Controller Implementation

With rapid advance in computer technology, there are advantages for implementing controllers on computers because of increased flexibility, reduced cost, and more noise immunity. Controllers can be easily modified via software instead of reconfiguring or adding analog computers, thereby reducing the cost and time incurred. Since computers represent information at only low and high voltage levels, digital control systems are more immune to sensor noise and power fluctuations. In addition, many new system sensors have digital throughput, thus making the digital control choice more attractive. The only overhead in any digital control system involves two critical system components: analog-to-digital conversion (ADC) and digital-to-analog conversion (DAC).

Figure 10.33 shows a block diagram of a discrete-time closed-loop system of which the digital controller block consists of an ADC, a PC, and a DAC block. The system output is measured and digitized via the ADC and passed to the computer (PC). The digital controller implemented on the computer receives an error signal and computes a control signal, which in turn is converted back to an analog signal before it is fed to the system. Because of these additional blocks and that the signals are sampled, the closed-loop system performance and stability will have to be analyzed using different system tools from those for continuous-time systems [10.13].

Sample and Hold Function

Consider a continuous-time signal $f(t)$, shown in Fig. 10.34. If this signal is sampled at a regular time interval, the sampled values, $f^*(t)$, only exist at certain time instants.

$f^*(t)$ can be mathematically written as

$$\begin{aligned} f^*(t) &= f(0)\,[\delta(t)] + f(T)\,[\delta(t-T)] \\ &\quad + f(2T)\,[\delta(t-2T)]\cdots \\ &= \sum_{k=0}^{\infty} f(kT)\,[\delta(t-kT)]\,, \end{aligned} \tag{10.128}$$

where $\delta(t)$ is an impulse function. The Laplace transform of $f^*(t)$ can be written as [10.11]

$$F^*(s) = \sum_{k=0}^{\infty} f(kT)\mathrm{e}^{-kTs}\,. \tag{10.129}$$

In order to process the sampled signal (sampling function), its values must be kept constant between the time instants (zero-order hold function $f_\mathrm{h}(t)$), as shown

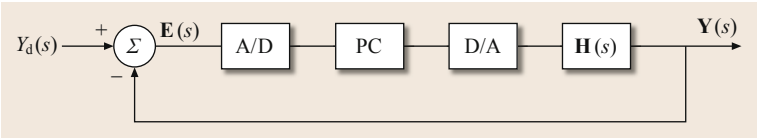

Fig. 10.33 A block diagram of a discrete-time closed-loop system

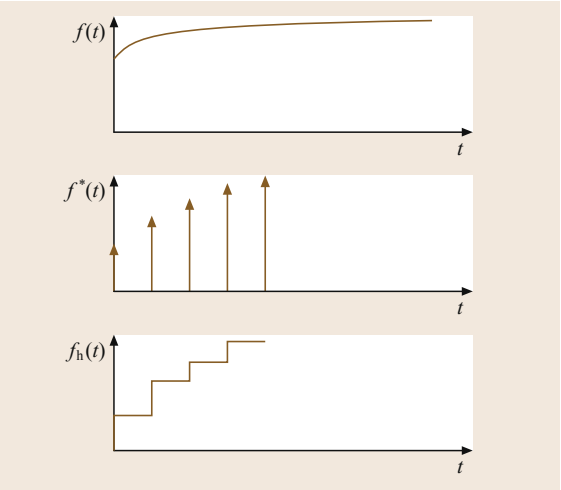

Fig. 10.34 A comparison between a continuous-time and discrete-time signal

in Fig. 10.34. An ADC process involves the sampling and holding characteristics of $f_h(t)$. Mathematically, $f_h(t)$ can be written as

$$\begin{aligned} f_h(t) &= f(0)\,[u(t)-u(t-T)] \\ &\quad + f(T)\,[u(t-T)-u(t-2T)] + \\ &\quad + f(2T)\,[u(t-2T)-u(t-3T)]\cdots \\ &= \sum_{k=0}^{\infty} f(kT)\,\{u(t-kT)-u[t-(k+1)T]\}\ , \end{aligned} \tag{10.130}$$

where $u(t)$ is an impulse function. The Laplace transform of $f_h(t)$ can be written as

$$\begin{aligned} F_h(s) &= \sum_{k=0}^{\infty} f(kT)\frac{\mathrm{e}^{-kTs}-\mathrm{e}^{-(k+1)Ts}}{s} \\ &= \frac{1-\mathrm{e}^{-Ts}}{s}\sum_{k=0}^{\infty} f(kT)\mathrm{e}^{-kTs} = \frac{1-\mathrm{e}^{-Ts}}{s}F^*(s)\ . \end{aligned} \tag{10.131}$$

It becomes apparent that the Laplace transform of a zero-order-hold function can be expressed as

$$F_{\mathrm{ZOH}}(s) = \frac{1-\mathrm{e}^{-Ts}}{s}\ , \quad F_h(s) = F_{\mathrm{ZOH}}(s)F^*(s)\ . \tag{10.132}$$

Discrete-Time System Stability

Unlike its continuous-time counterpart, the sampling time interval for a discrete-time control system needs to be chosen carefully in terms of stability and performance. The digital control system performance must be evaluated via Z-transformation instead of Laplace transformation. Some important Z-transform pairs are given in Tab. 10.1. Consider a closed-loop system in Fig. 10.37 with a sample-and-hold block.

The combined block in the feedforward path, $\mathbf{H}^*(s)$ can be written as

$$\begin{aligned} \mathbf{H}^*(s) &= \frac{1-\mathrm{e}^{-Ts}}{s}\mathbf{C}(s)\mathbf{H}(s) \\ &= \left(1-\mathrm{e}^{-Ts}\right)\frac{\mathbf{C}(s)\mathbf{H}(s)}{s}\ . \end{aligned} \tag{10.133}$$

Since $z \equiv \mathrm{e}^{sT}$ by definition, the discrete-time combined block in the feedforward path, $\mathbf{H}(z)$, can be expressed as

$$\begin{aligned} \mathbf{H}(z) &= Z\left\{\Im^{-1}\left(\mathbf{H}^*(s)\right)\right\} \\ &= Z\left\{\Im^{-1}\left(\left(1-\mathrm{e}^{-sT}\right)\frac{\mathbf{C}(s)\mathbf{H}(s)}{s}\right)\right\} \\ &= \left(1-z^{-1}\right)Z\left\{\Im^{-1}\left(\frac{\mathbf{C}(s)\mathbf{H}(s)}{s}\right)\right\}. \end{aligned} \tag{10.134}$$

Example 10.5 Discrete-Time Stability

Consider $\mathbf{C}(s) = k, \mathbf{H}(s) = a/(s(s+a))$ as shown in Fig. 10.35.

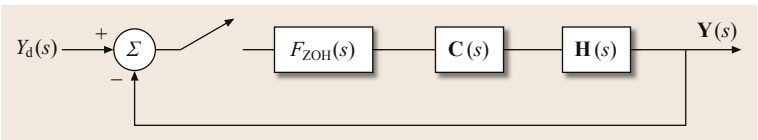

Fig. 10.35 A block diagram of a closed-loop discrete-time linear system

$$\mathbf{H}(z) = \left(1 - z^{-1}\right) Z\left\{\Im^{-1}\left[\frac{ka}{s^2(s+a)}\right]\right\} \tag{10.135}$$

is the inverse Laplace transform operator, and Z is the z-transform operator.

$Z\{\Im^{-1}[ka/(s^2(s+a))]\}$ can be computed by first evaluating the inverse Laplace transform via partial fraction techniques and then performing z-transform on the time functions via standard z-transform tables

$$\begin{aligned}
&\Im^{-1}\left\{\frac{a}{s^2(s+a)}\right\} = \Im^{-1}\left\{\frac{A}{s} + \frac{B}{s^2} + \frac{C}{s+a}\right\} \\
&= \Im^{-1}\left\{\frac{1}{s^2} - \frac{1/a}{s} + \frac{1/a}{s+a}\right\} = t - \frac{1}{a} + \frac{1}{a}\mathrm{e}^{-at} \\
&\Rightarrow \mathbf{H}(z) = k\frac{z-1}{z} \times \left\{\frac{Tz}{(z-1)^2} - \frac{z/a}{z-1} + \frac{z/a}{z-\mathrm{e}^{-aT}}\right\} \\
&= k\frac{T\left(z-\mathrm{e}^{-aT}\right) - (z-1)\,\frac{\left(1-\mathrm{e}^{-aT}\right)}{a}}{(z-1)\left(z-\mathrm{e}^{-aT}\right)} .
\end{aligned} \tag{10.136}$$

Consider $\alpha = 27$, $T = 0.1$, and we have

$$\mathbf{H}(z) = \frac{k(0.0655z + 0.027\,83)}{(z-1)(z-0.0672)} \tag{10.137}$$

Similar to the continuous-time analog, the closed-loop discrete-time transfer function, $\mathbf{H}_{\mathrm{cl}}(z)$, can be expressed as

$$\begin{aligned}
\mathbf{H}_{\mathrm{cl}}(z) &= \frac{\mathbf{H}(z)}{1 + \mathbf{H}(z)} \Rightarrow \mathbf{H}_{\mathrm{cl}}(z) \\
&= \left(k\left(0.0655z + 0.027\,83\right)\right) \\
&\quad \times \left(z^2 + \left(0.0655k - 1.0672\right)z \right. \\
&\quad \left. + 0.027\,83k + 0.0672\right)^{-1} .
\end{aligned} \tag{10.138}$$

Unlike the continuous-time stability consideration where its closed-loop poles must lie on the left-hand side of the complex s-plane, the closed-loop poles of a closed-loop discrete-time system must lie within the unit circle of the complex z-plane. At $k = 20$ the closed-loop discrete poles are located at $0.12 \pm 0.78\mathrm{i}$, and are within the unit circle. At $k = 200$ the closed-loop discrete poles are located at -0.58, -4.9, and are outside the unit circle. Thus, given a discrete-time controller, increasing its gain causes instability whereas the system stability is independent of the controller gain if a continuous-time controller is used. Similarly, when the sampling interval is increased to 0.5, the closed-loop poles become -8.17 and -0.09, and thus the closed-loop system becomes unstable.

Digital PID Controller

To implement a PID controller on a computer, its derivative and integral terms must be approximated with difference equations as signals only exist at a regular sampling time interval.

Proportional Control. The proportional term in a continuous-time system is $u(t) = k_{\mathrm{P}}(y_{\mathrm{d}}(t) - y(t))$. On a digital computer, this term is modified as

$$u(k) = k_{\mathrm{P}}(y_d(k) - y(k)) , \tag{10.139}$$

where k denotes the sampled time instants.

Integral Control. The integral term in a continuous-time system is given as

$$u(t) = \frac{k_{\mathrm{P}}}{T_{\mathrm{I}}}\int_0^t e(\tau)\mathrm{d}\tau . \tag{10.140}$$

The integral term is commonly approximated using the first-order backward difference method because of its numerical stability property

$$\begin{aligned}
&\dot{I}(t) = \frac{k_{\mathrm{P}}}{T_{\mathrm{I}}}e(t) \Rightarrow \frac{I(k) - I(k-1)}{T} = \frac{k_{\mathrm{P}}}{T_{\mathrm{I}}}e(k) \\
&\Rightarrow I(k) = I(k-1) + \frac{Tk_{\mathrm{P}}}{T_{\mathrm{I}}}e(k) .
\end{aligned} \tag{10.141}$$

Here $k = 0, 1, 2, \ldots$, and $I(-1) = 0$.

Derivative Control. The derivative (differential) term in a continuous-time system is given as

$$u(t) = k_{\mathrm{P}}T_{\mathrm{D}}\dot{e}(t) . \tag{10.142}$$

With consideration that $\dot{y}_d(t) = 0$, the derivative term is approximated using the backward difference method as follows

$$\begin{aligned}
u(t) &= k_{\mathrm{P}}T_{\mathrm{D}}\dot{e}(t) = -k_{\mathrm{P}}T_{\mathrm{D}}\dot{y}(t) \\
&\Rightarrow u(k) = -k_{\mathrm{P}}T_{\mathrm{D}}\left(\frac{y(k) - y(k-1)}{T}\right) .
\end{aligned} \tag{10.143}$$

Example 10.6 AUV Forward Speed Digital PID Control

Consider again controlling the forward speed of the AUV with a digital PID controller. Figure 10.36 shows the block diagram of the closed-loop discrete-time system generated using MATLAB/Simulink.

In the block, a continuous-time PID block is used, and its controller parameters are $K_{\mathrm{p}} = 17.26$, $T_{\mathrm{i}} = 2.6$

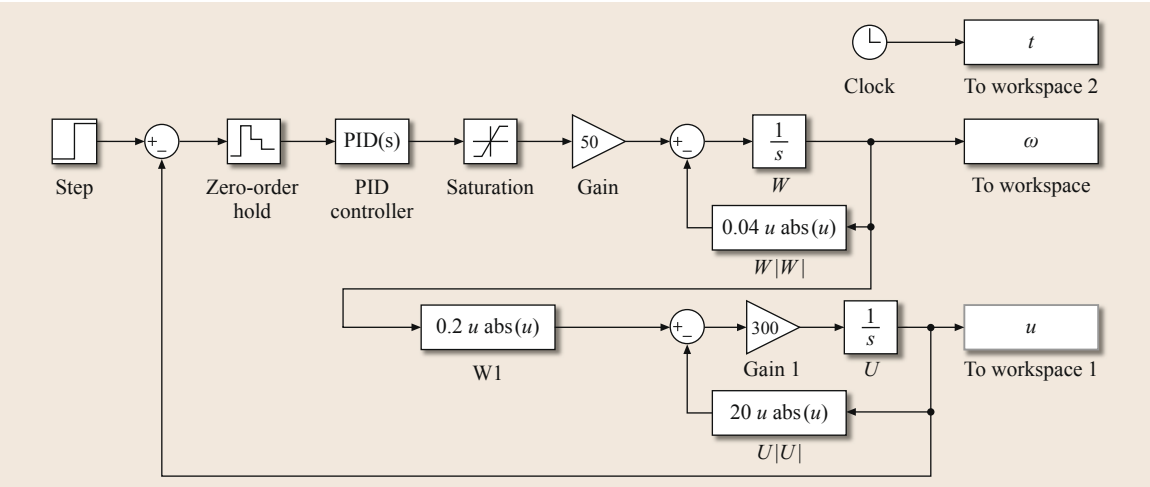

Fig. 10.36 A closed-loop discrete-time AUV speed control block diagram

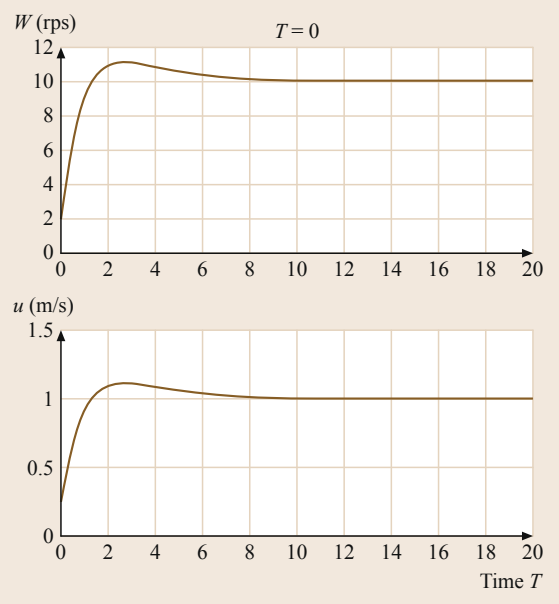

Fig. 10.37 The closed-loop vehicle and propeller speed responses without time discretization

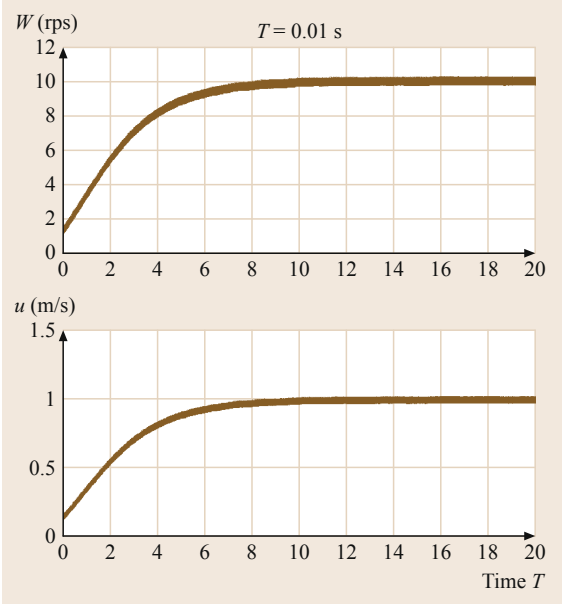

Fig. 10.38 The discrete-time closed-loop vehicle and propeller speed responses for $T = 0.01$ s

and $T_d = 0.65$. Figure 10.37 shows the closed-loop vehicle and propeller speed responses without the zero-order hold block, signifying a continuous-time control system.

In the presence of the zero-order-hold block (with $T = 0.01$ s), the closed-loop responses look significantly different, as shown in Fig. 10.38.

One can see that there is oscillation in the responses even for $T = 0.01$ s. The oscillation is worse as T is further increased to 0.1 s, as shown in Fig. 10.39. In Figs. 10.37–10.39, the x-axis represents the time in seconds.

10.3.6 The Root Locus Technique

The root locus technique was developed by W.R. Evans [10.1] for the design and comparative assessment of LTI–SISO systems. The methodology for the construction of the locus (i. e., the subset of the complex

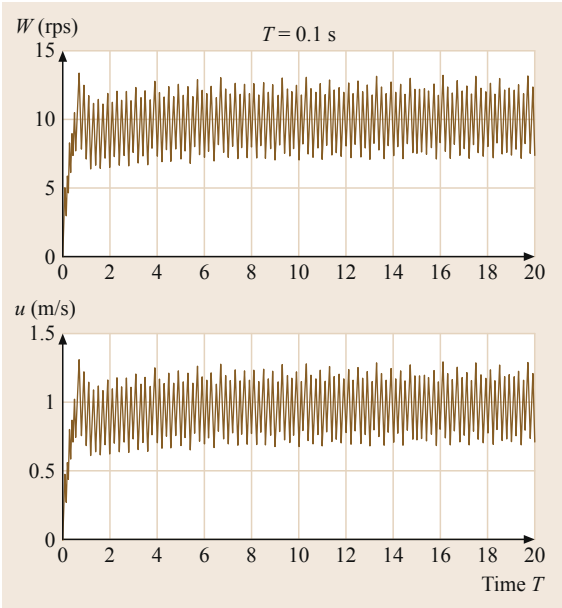

Fig. 10.39 The discrete-time closed-loop vehicle and propeller speed responses for $T = 0.1$ s

plane) of the closed-loop system poles, when a parameter (gain) of the controller varies, is shown in the present section. In specific, referring to Fig. 10.19 and forcing the disturbance d to be identically zero, a pure analog control law, that is, a gain K will be used, as shown in Fig. 10.40. The process transfer function will be presumed known in the factorized form as

$$\mathbf{G}(s) = \frac{(s+z_1)(s+z_2)\cdots(s+z_m)}{(s+p_1)(s+p_2)\cdots(s+p_n)} = \frac{s^m + b_1 s^{m-1} + \cdots + b_m}{s^n + a_1 s^{n-1} + \cdots + a_n} \qquad (10.144)$$

Note that for the root locus technique to be applied, all *poles* and *zeros* of the *open-loop*, process transfer function must be known or determined *in advance*.

In effect, the closed-loop transfer function assumes the form

$$\mathbf{H}(s) = \frac{K\mathbf{G}(s)}{1+K\mathbf{G}(s)} = [K(s+z_1)(s+z_2)\cdots(s+z_m)] \times [(s+p_1)(s+p_2)\cdots(s+p_n) + K(s+z_1)(s+z_2)\cdots(s+z_m)]^{-1} . \qquad (10.145)$$

The closed-loop characteristic polynomial, $p_c(s)$, is the denominator of the above and complying to our standard assumption that $n > m$ for the process transfer function, $\mathbf{G}(s)$, the order of $p_c(s)$ will be equal to n.

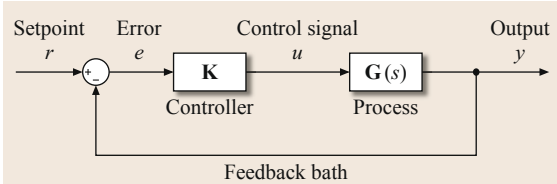

Fig. 10.40 Closed-loop block diagram for root locus analysis

The root locus (or simply the locus) of a closed-loop transfer function as in (10.145) is the location of all points on the complex plane satisfying the following for any $K \in (0, +\infty)$

$$p_c(s) = (s+p_1)(s+p_2)\cdots(s+p_n) + K(s+z_1)(s+z_2)\cdots(s+z_m) = 0 . \qquad (10.146)$$

The locus of complex plane points that satisfy (10.146) for $K \in (-\infty, 0)$ is referred to as the complementary root locus.

In the sequel, some fundamental properties of the root locus of polynomials with real coefficient are presented. These properties assist greatly in the graphical construction of the locus. Therefore, it is not necessary to determine mathematically the polynomial roots as functions of K. If this was not feasible, the locus determination would be an extremely tedious task or even impossible for polynomials of order higher than four. Proof of the lemmas are given below as it can be sought after in standard control systems literature:

1. The departure points of the locus, those for $K = 0$, are the poles of $\mathbf{G}(s)$.
2. The arrival points of the locus, those for $K \to \pm\infty$, are the zeros of $\mathbf{G}(s)$.
3. The number of discrete, component loci is n.
4. The root locus and the Complementary root locus are symmetrical with respect to the real axis.
5. For $|s| \to +\infty$ the root locus asymptotically converges toward straight lines with slopes as follows

$$\theta_i = \frac{2i+1}{n-m}\pi , \quad i = 0, 1, \ldots, (n-m)-1 . \qquad (10.147)$$

Similarly, the complementary root locus asymptotically converges toward straight lines with slopes as follows

$$\theta_i = \frac{2i}{n-m}\pi , \quad i = 0, 1, \ldots, (n-m)-1 . \qquad (10.148)$$

6. All $2(n-m)$ asymptotes in (10.147) and (10.148) for the root locus and the complementary root locus

pass through the same point on the real axis. This point is given as

$$\sigma_0 = -\frac{a_1 - b_1}{n-m} = -\frac{\sum_{i=1}^{n} p_i - \sum_{i=1}^{m} z_i}{n-m} \,. \tag{10.149}$$

7. a) A real-axis segment is part of the root locus provided that an *odd* cumulative number of poles and zeros of $\mathbf{G}(s)$ are located on its right-hand side.
   b) A real-axis segment is part of the root locus provided that an *even* cumulative number of poles and zeros of $\mathbf{G}(s)$ are located on its right-hand side.
8. The *breakpoints* (corner points) of the locus are the repeated (multiple) roots of the closed-loop characteristic polynomial $p_c(s)$; those can be determined as the roots of

$$\frac{\mathrm{d}}{\mathrm{d}s}\left[K\mathbf{G}(s)\right] = 0 \Rightarrow \frac{\mathrm{d}}{\mathrm{d}s}\mathbf{G}(s) = 0 \,. \tag{10.150}$$

9. a) The root locus angle of departure ϑ_j from the j-th pole of $\mathbf{G}(s)$, $(-p_j)$, is given by employing the following condition for $s \to (-p_j)$,

$$1 + K\mathbf{G}(s) = 0 \Rightarrow \begin{cases} |K\mathbf{G}(s)| = 1 \\ \angle K\mathbf{G}(s) = \pm(2v+1)\pi, \\ \quad v = 0, 1, 2, \ldots \end{cases} \tag{10.151}$$

The second (phase-related) of the above yields for $s \to (-p_j)$

$$\begin{aligned} &\lim_{s\to(-p_j)} \left[\angle K\mathbf{G}(s)\right] \\ &= \sum_{i=1}^{m} \angle(z_i - p_j) - \sum_{\substack{i=1 \\ i\neq j}}^{n} \angle(p_i - p_j) - \vartheta_j \\ &= \pm(2v+1)\pi \,. \end{aligned} \tag{10.152}$$

b) The root locus angle of arrival ϕ_j at the j-th zero of $\mathbf{G}(s)$, $(-z_j)$ is given by the same condition as the one used in 9(a) but applied for $s \to (-z_j)$.

$$\begin{aligned} &\lim_{s\to(-z_j)} \left[\angle K\mathbf{G}(s)\right] \\ &= \phi_j + \sum_{\substack{i=1 \\ i\neq j}}^{m} \angle(z_i - z_j) - \sum_{i=1}^{n} \angle(p_i - z_j) \\ &= \pm(2v+1)\pi \,, \quad v = 0, 1, 2, \ldots \end{aligned} \tag{10.153}$$

The properties presented previously are now applied to the construction of the root locus of various examples in Table 10.4 of process transfer function, $\mathbf{G}(s)$, as in (10.145).

10.4 Pole Placement of LTI Systems

Modern control design techniques rely heavily on the system's description in state space. The reason for this is the need to develop control systems for SISO as well as MIMO systems.

In the remaining of this chapter, LTI systems are considered. For the open-loop system (referred to as plant or process) a state-space description must be provided of the general form

$$\begin{aligned} \dot{x} &= \mathbf{A}x + \mathbf{B}u \,, \\ y &= \mathbf{C}x \,. \end{aligned} \tag{10.154}$$

In (10.154), u stands for the m-dimensional input vector (excitations), x for the n-dimensional state vector, and y for the p-dimensional output vector (measurements) of the LTI system at hand. By manipulating (10.154) the following open-loop transfer function is obtained

$$\mathbf{Y}(s) = \mathbf{H}(s)\mathbf{U}(s) = \mathbf{C}\left(s\mathbf{I}_n - \mathbf{A}\right)^{-1}\mathbf{B}\mathbf{U}(s) \tag{10.155}$$

10.4.1 Input–Output Decoupling

Consider the case below where the open-loop transfer function matrix $\mathbf{H}(s)$ is square and diagonal, that is, the process has the same number of inputs and outputs ($p = m$).

$$\mathbf{H}(s) = \begin{bmatrix} \mathbf{H}_{11}(s) & 0 & \ldots & 0 \\ 0 & \mathbf{H}_{22}(s) & \ldots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \ldots & \mathbf{H}_{mm}(s) \end{bmatrix} . \tag{10.156}$$

It is straightforward that the LTI–MIMO system is equivalent to m in number LTI–SISO systems with scalar transfer functions those appearing as the diagonal, nonzero elements of the transfer function matrix, $\mathbf{H}(s)$. This case is referred to by the term *input–output decoupling*.

Table 10.4 Examples of transfer functions with their root locus

G(s)	Root Locus	G(s)	Root Locus
$\frac{1}{s}$		$\frac{1}{s\,(s+0.1)\,(s+0.5)}$	$\frac{(s+1)}{s}$		$\frac{1}{(s+0.7)\,(s^2+s+1.69)}$	$\frac{1}{(s^2+s+1.69)}$		$\frac{(s+1)}{(s^2+0.8s+4.16)}$	
Table 10.4 (continued)

G(s)	Root Locus	G(s)	Root Locus
$\frac{(s+1)}{(s+0.8)(s^2+0.8s+4.16)}$		$\frac{1}{s(s+0.6)(s^2+0.8s+4.16)}$	$\frac{(s+2)}{(s+0.5)(s+1.2)(s-1)}$		$\frac{(s+2)(s^2+2s+2)}{(s+0.5)(s+1.2)(s^2-s+1.25)}$	

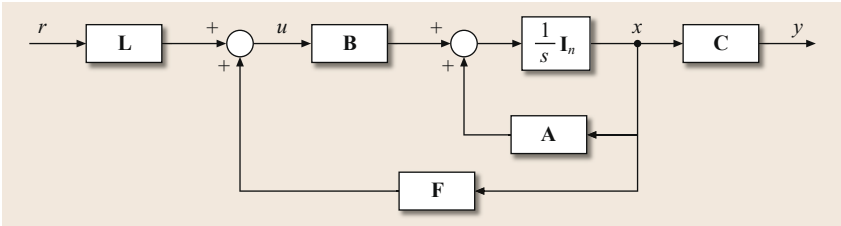

Fig. 10.41 Block diagram of a system with full-state feedback

It is evident that an input–output decoupled system as in (10.156) is only nominally MIMO because each and every one of the output signals is connected exclusively to a single input. In effect, for each and every of the m SISO systems a separate controller may be designed with techniques relevant to LTI–SISO systems.

10.4.2 Full-State Feedback

Given the description in (10.154) the control law is of the form

$$u = \mathbf{L}r + \mathbf{F}x\,. \tag{10.157}$$

In the above, r is a new input vector applied to the closed-loop system with dimension m_r. The controller design problem consists of determining the $m \times m_r$ matrix $\mathbf{L}$ and the $m \times n$ matrix $\mathbf{F}$ so that the closed-loop system demonstrates specified characteristics. The block diagram of this control scheme is shown in Fig. 10.41.

A typical example of closed-loop system specifications is input–output decoupling. In this case, the transfer function matrix, $\mathbf{H}(s)$, is square but not diagonal. Therefore, a control law of the general form in (10.157) is sought after that can render the closed-loop transfer function matrix diagonal. In effect, in the case of input–output decoupling it holds that $m = m_r = p$. By substitution of the control law in (10.157) in the state (10.154) and then application of the Laplace transform, the following is obtained

$$\left.\begin{aligned}\dot{x} &= (\mathbf{A}+\mathbf{BF})x + \mathbf{BL}r\\ y &= \mathbf{C}x\end{aligned}\right\} \Rightarrow$$
$$\Rightarrow \left\{\begin{aligned}s\mathbf{X}(s) &= (\mathbf{A}+\mathbf{BF})\mathbf{X}(s) + \mathbf{BLR}(s)\\ \mathbf{Y}(s) &= \mathbf{C}\mathbf{X}(s)\,.\end{aligned}\right\} \tag{10.158}$$

After manipulation the above yields

$$\mathbf{Y}(s) = \mathbf{G}(s)\mathbf{R}(s) = \mathbf{C}(s\mathbf{I}_n - \mathbf{A} - \mathbf{BF})^{-1}\mathbf{BLR}(s)\,. \tag{10.159}$$

Therefore, the control design problem is to determine matrices $\mathbf{F}$ and $\mathbf{L}$ in the control law so that the closed-loop transfer function matrix $\mathbf{G}(s)$ is diagonal. If this is achieved each and every component of the closed-loop system's input vector $\boldsymbol{r}$ is connected exclusively to one of the components of the output vector. Therefore, if further improvement of the system behavior is desired, m outer and decoupled SISO control loops may be employed.

10.4.3 Pole Placement Design

Generalities

As mentioned in Sect. 10.1.4, the poles of a multivariable LTI system are the eigenvalues of the system's matrix $\mathbf{A}$ and therefore can be computed as the roots of the characteristic polynomial

$$|s\mathbf{I}_n - \mathbf{A}| = 0\,. \tag{10.160}$$

The poles of a system determine its dynamics and mainly stability and transient behavior. This is the reason why in many situations full-state feedback is employed in order to relocate the poles of the open-loop system to new locations on the complex plane, specified for the closed-loop system. In effect, the related control problem is referred to as either *pole placement* or *eigenvalue assignment*. Solving the pole placement problem, allows for a closed-loop system with significantly improved characteristics. A great success story of pole placement with full-state feedback is to convert an unstable system, that is, an open-loop plant with one or more poles in the right-hand complex plane, to a stable closed-loop system.

A prerequisite for the applicability of linear, full-state feedback to a specific pole placement problem is that the open-loop plant is controllable according to the important theoretical result by *Wonham* [10.14]. In specific, if a system is state-controllable then all of its poles may be relocated arbitrarily on the complex plane. In the case that the system is uncontrollable, pole placement through state feedback is still applicable but only for a subset of the open-loop poles; the poles in this subset are the plant's controllable poles.

Given an LTI system as in (10.154) the closed-loop characteristic polynomial with full-state feedback can

be directly obtained as follows

$$p_c(s) = |s\mathbf{I}_n - \mathbf{A} - \mathbf{BF}| = s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0 \quad (10.161)$$

In (10.161), the coefficients of polynomial $p_c(s)$ are functions of the elements in the $m \times n$ feedback matrix $\mathbf{F}$. Furthermore, for the pole placement problem it can be assumed that $m = m_r$ and $L = I_m$.

The specifications in a pole placement problem consist of the desired locations of the closed-loop poles on the complex plane. As mentioned before, physically realizable systems, that is, with real parameters, have either purely real poles or pairs of complex conjugate poles. Therefore, in the factorized form of the characteristic polynomial of any physically realizable system, a purely real pole p corresponds to a factor of the form $(s-p)$ while a pair of complex conjugate poles p and p^* corresponds to the second-order factor $(s-p)(s-p^*) = s^2 - 2\mathrm{Re}(p)s + |p|^2$. By multiplicatively combining all such factors corresponding to the desired closed-loop poles and algebraically manipulating their product, a polynomial in reduced form like $\hat{p}_c(s) = s^n + \hat{a}_{n-1}s^{n-1} + \cdots + \hat{a}_1 s + \hat{a}_0$ is obtained.

Then, one has to equate the coefficients of the same powers of s of polynomials $p_c(s)$ and $\hat{p}_c(s)$. By doing that, a linear algebraic system of n equations is obtained, which if solved provides for the constants in the feedback matrix $\mathbf{F}$ of the controller

$$a_v(F_{ij}; i = 1, \ldots, m, j = 1, \ldots, n) = \hat{a}_v \,, \quad v = 1, \ldots, n \,. \quad (10.162)$$

In general, the number of equations of the algebraic system above is smaller than the number of unknowns. This means that after successfully solving the algebraic system (10.162), there remain $(m-1)n$ (if $m > 1$) free design parameters in the controller, to be used in order to meet objectives other than pole placement.

LTI–SISO Systems in Companion Canonical Form

Pole placement design is now investigated in the case of an LTI–SISO system with scalar transfer function of the form shown below.

$$\mathbf{H}(s) = \frac{\mathbf{Y}(s)}{\mathbf{U}(s)} = \frac{b_0}{s^n + a_{n-1}s^{n-1} + \cdots + a_1 s + a_0} \quad (10.163)$$

Further, the state-space realization in companion canonical form as in (10.47) is considered. The full-state feedback matrix $\mathbf{F}$ for this realization is, therefore, of dimensions $1 \times n$ and with the general form

$$\mathbf{F} = \begin{bmatrix} f_0 & f_1 & \ldots & f_{n-1} \end{bmatrix} . \quad (10.164)$$

The closed-loop transfer function matrix assumes the form as

$$\mathbf{A} + \mathbf{BF} = \begin{bmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 1 & \ldots & 0 \\ 0 & 0 & 0 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ -a_0 & -a_1 & -a_2 & \ldots & -a_{n-1} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ \vdots \\ 1 \end{bmatrix} \begin{bmatrix} f_0 & f_1 & f_2 & \ldots & f_{n-1} \end{bmatrix}$$

$$\Downarrow$$

$$\mathbf{A} + \mathbf{BF} = \begin{bmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 1 & \ldots & 0 \\ 0 & 0 & 0 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ f_0 - a_0 & f_1 - a_1 & f_2 - a_2 & \ldots & f_{n-1} - a_{n-1} \end{bmatrix} . \quad (10.165)$$

The characteristic polynomial can then be calculated as the determinant of matrix $(s\mathbf{I}_n - \mathbf{A} - \mathbf{BF}) = (s\mathbf{I}_n - (\mathbf{A} + \mathbf{BF}))$. A straightforward calculation is done if the determinant is deployed with respect to the last row, which yields the following closed-loop characteristic polynomial

$$p_c(s) = |s\mathbf{I}_n - \mathbf{A} - \mathbf{BF}| = s^n + (a_{n-1} - f_{n-1})\, s^{n-1} + \cdots + (a_1 - f_1)\, s + (a_0 - f_0) \,. \quad (10.166)$$

Then, by employing the procedure described earlier one obtains polynomial $\hat{p}_c(s)$ out of the specified pole locations of the closed-loop system. By equating the coefficients of the same powers of polynomials $p_c(s)$ and $\hat{p}_c(s)$, the following n in number design equations are obtained

$$f_i = a_i - \hat{a}_i \,, \quad i = 0, \ldots, n-1 \,. \quad (10.167)$$

Useful conclusions can be made if the pole placement controller design is compared to the root locus

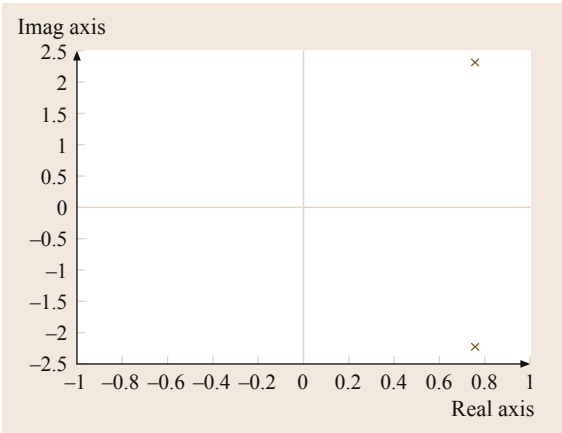

Fig. 10.42 Open-loop pole locations of plant (10.168)

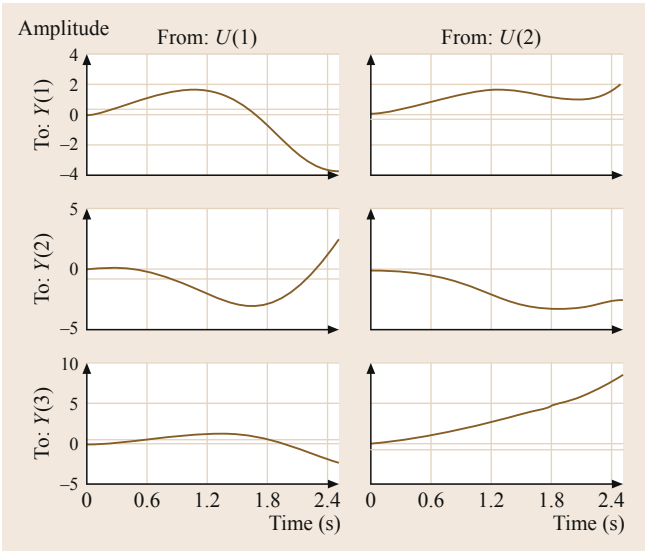

Fig. 10.43 Open-loop step response of plant (10.168)

technique where output, instead of state feedback, is employed.

LTI–MIMO Systems

It is better to investigate this case through an example. Consider the following multivariable system of the general form (10.154) with two inputs, three outputs, and three states

$$\mathbf{A} = \begin{bmatrix} 1 & 2.4 & 1 \\ -3 & 0.5 & 1 \\ 1 & 1 & 1 \end{bmatrix}, \quad \mathbf{B} = \begin{bmatrix} 1 & 1 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad \mathbf{C} = \mathbf{I}_3 \,. \tag{10.168}$$

It can be shown that this system is controllable.

The open-loop plant transfer function matrix of the LTI system at hand is as follows

$$\mathbf{H}(s) = \begin{bmatrix} \dfrac{s^2+0.9s-1.9}{s^3-2.5s^2+7.2s-5.6} & \dfrac{s^2-0.5s+1.4}{s^3-2.5s^2+7.2s-5.6} \\ \dfrac{s^2-5s+4}{s^3-2.5s^2+7.2s-5.6} & \dfrac{-2s}{s^3-2.5s^2+7.2s-5.6} \\ \dfrac{2s-2.1}{s^3-2.5s^2+7.2s-5.6} & \dfrac{s^2-0.5s+4.2}{s^3-2.5s^2+7.2s-5.6} \end{bmatrix}_3 . \tag{10.169}$$

The open-loop characteristic polynomial of this system is, therefore

$$p_0(s) = s^3 - 2.5s^2 + 7.2s - 5.6 \,. \tag{10.170}$$

The open-loop poles, that is, the roots of the polynomial above, are

$$s_0 = 0.9807 \,, \quad s_{1,2} = 0.7596 \pm \mathrm{i}2.2656 \,. \tag{10.171}$$

The locations on the complex plane of the open-loop poles are shown in Fig. 10.42 while the open-loop plant's step response is shown in Fig. 10.43. As can be seen, the system is unstable and its step response demonstrates oscillations.

In effect, a feedback control law of the form (10.157) is sought after so that the poles of the closed-loop system are stable (demonstrate negative real part). Furthermore, in order to mitigate oscillations, the closed-loop poles are specified to be purely real, demonstrate zero imaginary part. The desired closed-loop poles are specified to be the following ones

$$p_1 = -0.5 \,, \quad p_2 = -1.0 \,, \quad p_3 = -1.5 \,. \tag{10.172}$$

These poles yield the desired characteristic polynomial

$$\begin{aligned} \hat{p}_c(s) &= (s+p_1)\,(s+p_2)\,(s+p_3) \\ &= s^3 + 3s^2 + 2.75s + 0.75 \,. \end{aligned} \tag{10.173}$$

The closed-loop matrix $(\mathbf{A}+\mathbf{BF})$, parameterized by the elements of the 3×2 matrix $\mathbf{F}$ in the control law, is given by

$$\mathbf{A}+\mathbf{BF} = \begin{bmatrix} 1+F_{11}+F_{21} & 2.4+F_{12}+F_{22} & 1+F_{13}+F_{23} \\ -3+F_{11} & 0.5+F_{12} & 1+F_{13} \\ 1+F_{21} & 1+F_{22} & 1+F_{23} \end{bmatrix} . \tag{10.174}$$

Then, the determinant $|s\mathbf{I}_n - \mathbf{A} - \mathbf{BF}|$ is calculated. This determinant is the closed-loop characteristic polynomial $p_c(s)$ of order 3. The coefficients of $p_c(s)$ are parameterized by the elements of F, F_{ij}. By equating the coefficients of polynomials $p_c(s)$ and $\hat{p}_c(s)$ and solving the resulting linear algebraic system of equations, a matrix $\mathbf{F}$ is computed as follows

$$\mathbf{F} = \begin{bmatrix} 0.3021 & 1.4785 & -0.617 \\ 2.4378 & 0.9649 & 1.2816 \end{bmatrix}. \tag{10.175}$$

The closed-loop transfer function matrix of the system with feedback matrix $\mathbf{F}$ as in (10.175) is as follows

$$\mathbf{H}(s) = \begin{bmatrix} \dfrac{s^2+1.217s+0.2183}{s^3+3s^2+2.75s+0.75} & \dfrac{s^2+1.595s+0.4767}{s^3+3s^2+2.75s+0.75} \\ \dfrac{s^2-1.281s-2.282}{s^3+3s^2+2.75s+0.75} & \dfrac{-1.685s-1.549}{s^3+3s^2+2.75s+0.75} \\ \dfrac{-1.403s-1.399}{s^3+3s^2+2.75s+0.75} & \dfrac{s^2+1.281s+0.03623}{s^3+3s^2+2.75s+0.75} \end{bmatrix}_3 . \tag{10.176}$$

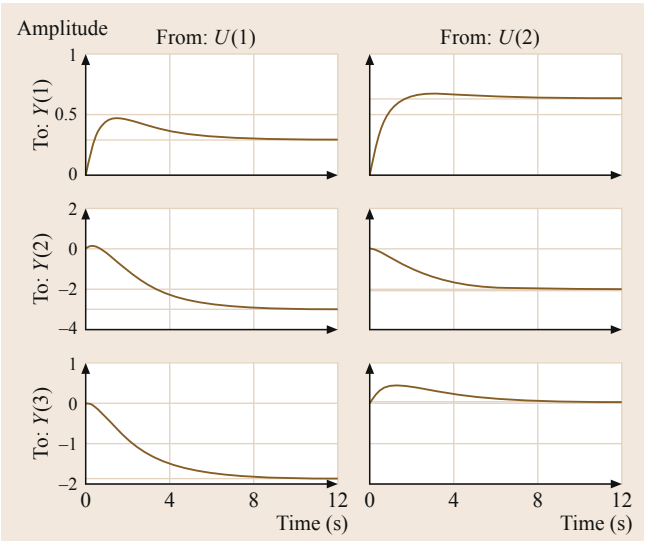

Fig. 10.44 Closed-loop step response of system with transfer function (10.176)

The step response of the closed-loop system is shown in Fig. 10.44. As can be seen, it complies with the requirements of stability and mitigated oscillations.

10.5 Course-Keeping Autopilots

10.5.1 The Vessel in the Control Loop

Surface Vessel Motions

A model describing the motions of a typical surface ship is needed. Such model should be simple, concise, as well as intuitive and fit for use in the control synthesis process.

The motions of a surface ship can be decomposed into six degrees of freedom when the vessel is considered as a rigid body (beam). In Fig. 10.45 the degrees of freedom of a ship's motion are shown and named.

The dynamic response of a vessel is modeled by a set of differential equations with respect to time. These equations concern the rate of change of linear and angular momentum of the vessel. With respect to a body-fixed (therefore noninertial in general) frame of reference, as used in ship dynamics, the equations of motion are given as

$$\frac{\mathrm{d}}{\mathrm{d}t}\left\{\int_{mS} (\boldsymbol{v}_S + \boldsymbol{\omega}_S \times \boldsymbol{r})\, \mathrm{d}m\right\} = \sum \boldsymbol{F}_{\text{ext}} ,$$

$$\frac{\mathrm{d}}{\mathrm{d}t}\left\{\int_{mS} \boldsymbol{r} \times (\boldsymbol{v}_S + \boldsymbol{\omega}_S \times \boldsymbol{r})\, \mathrm{d}m\right\} + m_S\,(\boldsymbol{v}_S \times \boldsymbol{v}_G) = \sum \boldsymbol{M}_{\text{ext}} , \tag{10.177}$$

where m_S is the vessel's mass, $\boldsymbol{v}_S$ the linear velocity of the origin O of the body-fixed reference frame (with respect to an inertial reference frame), $\boldsymbol{\omega}_S$ the angular velocity of the origin O of the body-fixed reference frame (with respect to an inertial reference frame), and $\boldsymbol{v}_G$ the translational motion of the ship's center of mass. Vector $\boldsymbol{r}$ stands for the position vector of an arbitrary mass infinitesimal element dm shipboard with respect to the body-fixed frame. The two vector sums on the right-hand side of the differential equations above are the total force and moment applied externally to the vessel. The spatial integrals on the left-hand side are the linear and angular moment of the vessel. Finally, note the inertial terms due to the fact that a noninertial reference frame is used moving at velocity $\boldsymbol{v}_S$ with respect to an inertial one. The body-fixed and inertial reference frames used are shown in Fig. 10.46. In the same figure, the symbols used to denote the translational and

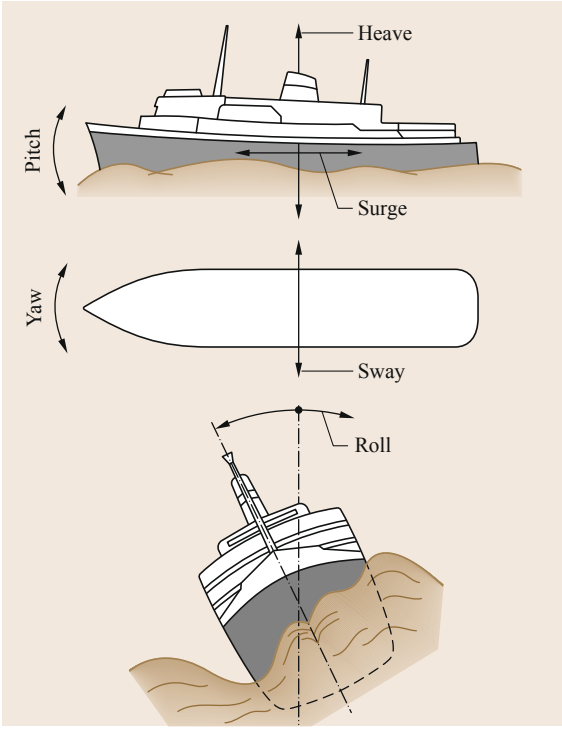

Fig. 10.45 Surface ship motions

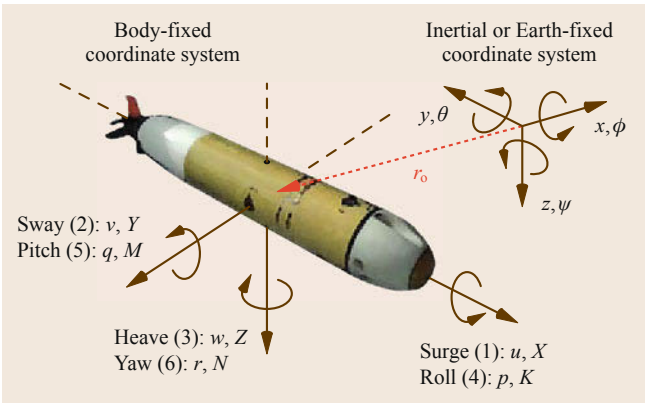

Fig. 10.46 Inertial and body-fixed reference frame used in the analysis

rotational velocities are shown as well as the ones used to denote the external forces and moments. On the axes of the inertial frame the symbols used for the infinitesimals of rotation and translation are given.

Choosing a body-fixed instead of an inertial reference frame, is based on the following reasoning: (a) acceleration measurements onboard provide with the absolute, inertial values but decomposed to the body-fixed reference frame instead of the inertial one; (b) the geometric and inertia characteristics of the vessel are time-invariant with respect to the body-fixed frame. This fact mathematically is expressed as $\dot{\boldsymbol{r}} = 0$. Also, it can be used to swap spatial integration with time differentiation in (10.177).

$$\int_{m_S} \frac{\mathrm{d}}{\mathrm{d}t} \{\boldsymbol{v}_S + \boldsymbol{\omega}_S \times \boldsymbol{r}\} \, \mathrm{d}m = \sum \boldsymbol{F}_{\text{ext}} \,,$$

$$\int_{m_S} \frac{\mathrm{d}}{\mathrm{d}t} \{\boldsymbol{r} \times (\boldsymbol{v}_S + \boldsymbol{\omega}_S \times \boldsymbol{r})\} \, \mathrm{d}m + m_S \, (\boldsymbol{v}_S \times \boldsymbol{v}_G)$$

$$= \Sigma \boldsymbol{M}_{\text{ext}} \qquad (10.178)$$

Formulation of the Linearized State Equations

Using the above, as well as the linearization procedure presented in Chap. 1, the generic surface vessel equations given previously are simplified in the sense of linearization. The linearized equations are derived by neglecting higher order, nonlinear terms in the original ship motion equations. Such terms are those including powers higher than one of $\boldsymbol{v}_S$ or $\boldsymbol{\omega}_S$ or cross-products thereof or their time derivatives. Furthermore, linearization is applied by considering perturbations around a stable equilibrium point. The derived set of linear ordinary differential equations is valid for small-amplitude variations of $\boldsymbol{v}_S$ and $\boldsymbol{\omega}_S$ around the equilibrium point. Therefore, the linearized differential equations hold for variations $\delta\boldsymbol{v}_S$ and $\delta\boldsymbol{\omega}_S$. However, in order to simplify the expressions the δ-notation is dropped, since the classical linear feedback control problem is formulated and solved on the basis of the linearized plant equations.

In the sequel the 3×3 following inertia tensor, $\overleftrightarrow{I}_S$, which is time invariant with respect to the body-fixed frame, is needed.

$$\overleftrightarrow{I}_S = \begin{bmatrix} I_{xx} & I_{xy} & I_{xz} \\ I_{xy} & I_{yy} & I_{yz} \\ I_{xz} & I_{yz} & I_{zz} \end{bmatrix} \qquad (10.179)$$

The scalar inertial entries in tensor $\overleftrightarrow{I}_S$ are given for I_{xx} and I_{xy}. For the other entries, definitions are analogous.

$$I_{xx} = \int_V \left(y^2 + z^2\right) \, \mathrm{d}m \,, \quad I_{xy} = -\int_V xy \, \mathrm{d}m \qquad (10.180)$$

For most practical autopilot designs, the following simplifying assumption that the body-fixed frame has been selected so as $\boldsymbol{r}_G = \begin{pmatrix} x_G & 0 & 0 \end{pmatrix}^{\mathrm{T}}$.

The small-signal analysis, for autopilot design in the case of ocean-going vessels moving in a time-averaged sense forward at constant speed U, can be applied if the following decomposition scheme is considered

$$\boldsymbol{v}_S = \begin{bmatrix} U+u \\ v \\ w \end{bmatrix} = \begin{bmatrix} U \\ 0 \\ 0 \end{bmatrix} + \begin{bmatrix} u \\ v \\ w \end{bmatrix},$$
$$\text{with } \frac{\mathrm{d}U}{\mathrm{d}t} = \boldsymbol{\omega}_S \times U, \text{ i. e., } \dot{U} = 0\,. \tag{10.181}$$

The equilibrium point around which the linearization is applied has to be evidently $\boldsymbol{U} = \begin{bmatrix} U & 0 & 0 \end{bmatrix}^{\mathrm{T}}$.

After analyzing and linearizing the equations, the following set of first order, linear differential equations are derived

$$\begin{aligned}
&\text{Surge:} && m_S\dot{u} = X \\
&\text{Sway:} && m_S\left[\dot{v} + Ur + x_G\dot{r}\right] = Y \\
&\text{Heave:} && m_S\left[\dot{w} - Uq - x_G\dot{q}\right] = Z + Z_{\mathrm{hs}} \\
&\text{Roll:} && I_{xx}\dot{p} = K + K_{\mathrm{hs}} \\
&\text{Pitch:} && I_{yy}\dot{q} + m_S x_G\left(-\dot{w} + Uq\right) = M + M_{\mathrm{hs}} \\
&\text{Yaw:} && I_{zz}\dot{r} + m_S x_G\left(\dot{v} + Ur\right) = N\,.
\end{aligned} \tag{10.182}$$

The above are derived on the assumption of a hull symmetric with respect to plane xz. Subscript "hs" indicates a hydrostatic component in a force or moment. Hydrostatic components are in general dependent upon displacement variables like translational ones x, y, z, as well as rotational ones φ, θ, ψ; however, hydrostatic components cannot depend on translational or rotational velocities. A force or moment component that depends on the vessel's translational (u, v, w) or rotational velocities (p, q, r) or higher order time derivatives (like accelerations) is called hydrodynamic.

As seen in (10.182), after linearization surge, sway and yaw become decoupled of roll, pitch, and heave. Furthermore, note that the forces and moments affecting the surge–sway–heave motions are purely hydrodynamic. At this point, expressions for X, Y, and N are needed. These excitation signals may originate:

a) From the ocean–hull interaction.
b) From control surface actuation. The most common control surface of surface vessels is the rudder. Other control surfaces include anti-roll stabilizing fins, etc.
c) From perturbation of random nature that is either difficult or impossible or even too complicated to be modeled.

$$\begin{aligned}
X(t) &= X_{\mathrm{R}}(t) + X_{\mathrm{H}}(t) + X_0(t) \\
Y(t) &= Y_{\mathrm{R}}(t) + Y_{\mathrm{H}}(t) + Y_0(t) \\
N(t) &= N_{\mathrm{R}}(t) + N_{\mathrm{H}}(t) + N_0(t)\,,
\end{aligned} \tag{10.183}$$

where subscript R indicates the component due to rudder action, H the one due to the ocean–hull interaction, and 0 a random signal due to modeling errors and simplifications.

The rudder components evidently depend exclusively on the deflection of the rudder from the vertical xz symmetry plane of the vessel's hull

$$\begin{aligned}
&X_{\mathrm{R}}(t) = X_{\mathrm{R}}\left(\delta_{\mathrm{R}}(t)\right)\,, \quad Y_{\mathrm{R}}(t) = Y_{\mathrm{R}}\left(\delta_{\mathrm{R}}(t)\right), \\
&N_{\mathrm{R}}(t) = N_{\mathrm{R}}\left(\delta_{\mathrm{R}}(t)\right)\,.
\end{aligned} \tag{10.184}$$

For small (in the absolute sense) deflection values of angle δ_{R} the following relationships can be employed

$$X_{\mathrm{R}} = X_\delta\delta_{\mathrm{R}}\,, \quad Y_{\mathrm{R}} = Y_\delta\delta_{\mathrm{R}}\,, \quad N_{\mathrm{R}} = N_\delta\delta_{\mathrm{R}}\,, \tag{10.185}$$

where hydrodynamic derivatives X_δ, Y_δ, and N_δ are defined as

$$X_\delta = \frac{\partial X_{\mathrm{R}}}{\partial\delta_{\mathrm{R}}}\,, \quad Y_\delta = \frac{\partial Y_{\mathrm{R}}}{\partial\delta_{\mathrm{R}}}\,, \quad N_\delta = \frac{\partial N_{\mathrm{R}}}{\partial\delta_{\mathrm{R}}}\,. \tag{10.186}$$

In a similar manner, the components originating from ocean–hull interaction are dependent solely on kinematical variables of the vessel

$$\begin{aligned}
&X_{\mathrm{H}} = X_{\mathrm{H}}\left(u, \dot{u}\right)\,, \quad Y_{\mathrm{H}} = Y_{\mathrm{H}}\left(v, \dot{v}, r, \dot{r}\right), \\
&N_{\mathrm{H}} = N_{\mathrm{H}}\left(v, \dot{v}, r, \dot{r}\right)\,.
\end{aligned} \tag{10.187}$$

By using the small-signal analysis concept, the following expressions can be obtained

$$\begin{aligned}
X_{\mathrm{H}} &= X_u u + X_{\dot{u}}\dot{u}\,, \\
Y_{\mathrm{H}} &= Y_v v + Y_{\dot{v}}\dot{v} + Y_r r + Y_{\dot{r}}\dot{r}\,, \\
N_{\mathrm{H}} &= N_v v + N_{\dot{v}}\dot{v} + N_r r + N_{\dot{r}}\dot{r}\,,
\end{aligned} \tag{10.188}$$

where the hydrodynamic derivatives X_u, $X_{\dot{u}}$, Y_v, $Y_{\dot{v}}$, Y_r, $Y_{\dot{r}}$, N_v, $N_{\dot{v}}$, N_r, $N_{\dot{r}}$ are defined similarly to the ones related to the rudder in (10.186).

10.5.2 Surface Vessel State-Space Model

On the basis of the decoupled model of surge, sway and yaw in (10.182) as well as (10.183), (10.185), and (10.188) for the exogenous forces and moments applied to a vessel, the following set of differential equations can be obtained

$$\begin{aligned}
&\left(m_S - X_{\dot{u}}\right)\dot{u} = X_u u + X_\delta\delta_{\mathrm{R}} + X_0(t)\,, \\
&\left(m_S - Y_{\dot{v}}\right)\dot{v} + \left(m_S x_G - Y_{\dot{r}}\right)\dot{r} \\
&\quad = Y_v v + \left(Y_r - m_S U\right) r + Y_\delta\delta_{\mathrm{R}} + Y_0(t)\,, \\
&\left(I_{zz} - N_{\dot{r}}\right)\dot{r} + \left(m_S x_G - N_{\dot{v}}\right)\dot{v} \\
&\quad = N_v v + \left(N_r - m_S x_G U\right) r + N_\delta\delta_{\mathrm{R}} + Z_0(t)\,.
\end{aligned} \tag{10.189}$$

In matrix form and after omitting the equation for surge (which is not coupled with the ones for yaw and sway), the following is obtained

$$\begin{aligned}
&\boldsymbol{\Theta}\dot{x}_{\emptyset} = \mathbf{A}_{\emptyset}x_{\emptyset} + b_{\emptyset}\delta_{\mathrm{R}} + d_{\emptyset} \quad , \\
&\qquad\qquad \Updownarrow \\
&\begin{bmatrix} m_S - Y_{\dot{v}} & m_S x_G - Y_{\dot{r}} \\ m_S x_G - N_{\dot{v}} & I_{zz} - N_{\dot{r}} \end{bmatrix} \begin{bmatrix} \dot{v} \\ \dot{r} \end{bmatrix} = \\
&\begin{bmatrix} Y_v & Y_r - m_S U \\ N_v & N_r - m_S x_G U \end{bmatrix} \begin{bmatrix} v \\ r \end{bmatrix} + \begin{bmatrix} Y_\delta \\ N_\delta \end{bmatrix} \delta_{\mathrm{R}} + \begin{bmatrix} Y_0 \\ N_0 \end{bmatrix} .
\end{aligned} \tag{10.190}$$

The correspondence between the brief and extended versions of (10.190) is obvious.

Assuming that matrix Θ in (10.190) is invertible the following are obtained

$$\begin{aligned}
\boldsymbol{\Theta}\dot{x}_{\emptyset} &= \mathbf{A}_{\emptyset}x_{\emptyset} + b_{\emptyset}\delta_{\mathrm{R}} + d_{\emptyset} \Leftrightarrow \dot{x}_{\emptyset} \\
&= \boldsymbol{\Theta}^{-1}\mathbf{A}_{\emptyset}x_{\emptyset} + \boldsymbol{\Theta}^{-1}b_{\emptyset}\delta_{\mathrm{R}} + \boldsymbol{\Theta}^{-1}d_{\emptyset} \ , \qquad (10.191) \\
\dot{x}_{\emptyset} &= \boldsymbol{\Theta}^{-1}\mathbf{A}_{\emptyset}x_{\emptyset} + \begin{bmatrix} b & \boldsymbol{\Theta}^{-1} \end{bmatrix} \begin{bmatrix} \delta_{\mathrm{R}} \\ d_{\emptyset} \end{bmatrix} , \\
b &= \boldsymbol{\Theta}^{-1}b_{\emptyset} \ . \qquad (10.192)
\end{aligned}$$

Equation (10.192) is the dynamic equation of a system with two states and three scalar input signals one of which is the control action (rudder deflection angle δ_{R}); the other two inputs are the random disturbances Y_0 and N_0. For reasons made clear later on, the state vector $x_{\emptyset}$ in (10.192) has to be enriched by the yaw angle ψ as follows

$$\begin{aligned}
\dot{x} &= \begin{bmatrix} 0 & 0 & 1 \\ 0 & & \\ & \Theta^{-1}A_{\emptyset} & \\ 0 & & \end{bmatrix} x + \left[\begin{array}{cc|c} 0 & 0 & 0 \\ b & & \boldsymbol{\Theta}^{-1} \end{array}\right] \begin{bmatrix} \delta_{\mathrm{R}} \\ d_{\emptyset} \end{bmatrix} \\
&\Leftrightarrow \dot{x} = \mathbf{A}x + \mathbf{B}u \quad \text{with} \quad x = \begin{bmatrix} \psi \\ v \\ r \end{bmatrix} .
\end{aligned} \tag{10.193}$$

By employing the Laplace transform, the following relation is obtained

$$\begin{aligned}
x(s) &= (s\mathbf{I}_3 - \mathbf{A})^{-1} \begin{bmatrix} 0 \\ b \end{bmatrix} \delta_{\mathrm{R}}(s) \\
&\quad + (s\mathbf{I}_3 - \mathbf{A})^{-1} d(s) \ , \\
\text{where} \quad d &= \begin{bmatrix} 0 \\ \boldsymbol{\Theta}^{-1}d_{\emptyset} \end{bmatrix} .
\end{aligned} \tag{10.194}$$

In many commonplace cases of autopilot design, the single feedback signal is the yaw angle $\psi(t)$ through means of either a magnetic compass or a gyrocompass. In these cases the input to the controller (autopilot) is the yaw error, that is, the difference obtained by subtracting ψ from the heading setpoint.

In effect, the dynamical equation (10.194) is complemented by the following output, algebraic one connecting the state vector $\boldsymbol{x}$ to the scalar output signal $\psi(t)$ (or $\psi(s)$ in the complex frequency domain).

$$y = cx = \begin{bmatrix} 1 & 0 & 0 \end{bmatrix} x = \psi \tag{10.195}$$

Since x is of order 3, the transfer function from the control action δ_{R} to the output signal ψ is of order 3 as well. Because of the special form of matrix $\mathbf{A}$ (exhibiting a full zero column) one of the eigenvalues and open-loop plant poles is 0. The full characteristic polynomial is given by the following

$$p_0(s) = s\left|sI_2 - \boldsymbol{\Theta}^{-1}A_{\emptyset}\right| . \tag{10.196}$$

Combining (10.196) in the generic matrix inversion formula the following transfer function from the control action δ_{R} to yaw angle ψ is obtained

$$\begin{aligned}
\mathbf{H}_N(s) &= \frac{\boldsymbol{\psi}(s)}{\delta_{\mathrm{R}}(s)} = \frac{\kappa_0 + (s + \kappa_1)}{p_0(s)} \\
&= \frac{k + k\tau_0 s}{s[\tau_1\tau_2 s^2 + (\tau_1 + \tau_2)s + 1]} .
\end{aligned} \tag{10.197}$$

The transfer function (10.197) connecting δ_{R} with ψ is known as the Nomoto equation. For most practical cases of displacement hulls, the factor

$$\left|s\mathbf{I}_2 - \boldsymbol{\Theta}^{-1}\mathbf{A}_{\emptyset}\right| = \tau_1\tau_2 s^2 + (\tau_1 + \tau_2)s + 1$$

exhibits two purely real roots denoted as $-1/\tau_1$ and $-1/\tau_2$.

The full expression for yaw angle ψ including the disturbance signals $\mathbf{Y}_0$ and $\mathbf{N}_0$, in the complex frequency domain, has the following form

$$\boldsymbol{\psi}(s) = \mathbf{H}_N(s)\delta_{\mathrm{R}}(s) + \mathbf{T}_N(s)N_0(s) + \mathbf{T}_Y(s)\mathbf{Y}_0(s) . \tag{10.198}$$

Similarly to the Nomoto equation transfer function, the expressions for transfer functions $\mathbf{T}_N(s)$ and $\mathrm{T}_Y(s)$ can be obtained as

$$\begin{aligned}
\mathbf{T}_N(s) &= \frac{k_N + k_N\tau_N s}{s[\tau_1\tau_2 s^2 + (\tau_1 + \tau_2)s + 1]} \\
&\text{and} \\
\mathbf{T}_Y(s) &= \frac{k_Y + k_Y\tau_Y s}{s[\tau_1\tau_2 s^2 + (\tau_1 + \tau_2)s + 1]} .
\end{aligned} \tag{10.199}$$

10.5.3 PID Autopilots

Many practical, specifically low-end autopilots employ the PID control law, given as

$$\begin{aligned}\delta_{\mathrm{R}}(t) &= -K_{\mathrm{p}}\psi(t) - K_{\mathrm{i}}\int_0^t \psi(\xi)\,\mathrm{d}\xi - K_{\mathrm{d}}\frac{\mathrm{d}}{\mathrm{d}t}\psi(t)\\ &\Updownarrow\\ \delta_{\mathrm{R}}(s) &= -K(s)\psi(s)\\ &= -\left(K_{\mathrm{p}} + \frac{K_{\mathrm{i}}}{s} + K_{\mathrm{d}}s\right)\psi(s)\\ &= -\frac{K_{\mathrm{i}} + K_{\mathrm{p}}s + K_{\mathrm{d}}s^2}{s}\psi\,.\end{aligned} \tag{10.200}$$

Substituting the above in (10.198) the following closed-loop expressions can be obtained

$$\begin{aligned}\psi(s) &= \mathbf{G}_N(s)\mathbf{N}_0(s) + \mathbf{G}_Y(s)\mathbf{Y}_0(s)\\ &= \frac{T_N(s)}{1+\mathbf{H}_N(s)\mathbf{K}(s)}\mathbf{N}_0(s)\\ &\quad + \frac{T_Y(s)}{1+\mathbf{H}_N(s)\mathbf{K}(s)}\mathbf{Y}_0(s)\,.\end{aligned} \tag{10.201}$$

In effect, transfer functions $\mathbf{G}_N(s)$ and $\mathbf{G}_Y(s)$ from the yaw moment and sway force disturbance have to be of the fourth order according to (10.197) and (10.199). However, for many practical applications the following first-order open-loop transfer functions consist a good approximation

$$\begin{aligned}\tilde{\mathbf{H}}_N(s) &= \frac{k}{s(\tau_1 s+1)}\,,\\ \tilde{\mathbf{T}}_N(s) &= \frac{k_N}{s(\tau_1 s+1)}\,,\\ \tilde{\mathbf{T}}_Y(s) &= \frac{k_Y}{s(\tau_1 s+1)}\,.\end{aligned} \tag{10.202}$$

For the above approximants to be valid, it must hold that $\tau_1 \gg \tau_2$ and in effect for $s \to 0$

$$\tau_1\tau_2 s^2 + (\tau_1+\tau_2)s + 1 \approx (\tau_1 s+1)\,.$$

Similar assumptions are needed for the time constants in the numerator of the full-order transfer functions. For most practical displacement hull forms, $\tau_1 \gg \tau_2$ and therefore the so-called dominant pole technique is applicable.

In effect

$$\begin{aligned}\tilde{\mathbf{G}}_N(s) &= \frac{\dfrac{k_N}{s(\tau_1 s+1)}}{1+\dfrac{K_{\mathrm{i}}+K_{\mathrm{p}}s+K_{\mathrm{d}}s^2}{s}\dfrac{k_N}{s(\tau_1 s+1)}}\\ &= \frac{k_N s}{\tau_1 s^3 + (k_N K_{\mathrm{d}}+1)s^2 + k_N K_{\mathrm{p}} s + k_N K_{\mathrm{i}}}\,.\end{aligned} \tag{10.203}$$

The expression for $\tilde{\mathbf{G}}_Y(s)$ is similar and as seen the reduced order transfer functions will be of the third order. Further reduction (simplification) can be achieved by intervening in the controller structure.

Such intervention is the design assumption that $K_{\mathrm{i}} \ll K_{\mathrm{p}}, K_{\mathrm{d}}$. This assumption is based on the fact that the integral term is included in the PID control law only for eliminating the long-term, near-steady-state effects of the **Y** and **N** disturbance signals. That is why the I-term constant can assume relatively small values. Furthermore as seen in (10.203) the I-term constant appears exclusively in the constant (zero-order) term of the closed-loop characteristic polynomial. Therefore, small I-term constant values will give a closed-loop pole in the vicinity of 0. Such a pole, however, will cancel out with the closed-loop zero at 0. In effect, the following simplified closed-loop transfer function can be obtained for small values of K_{i}

$$\tilde{\mathbf{G}}'_N(s) = \frac{k_N}{\tau_1 s^2 + (k_N K_{\mathrm{d}}+1)s + k_N K_{\mathrm{p}}}\,. \tag{10.204}$$

Finally, note that for small, purely positive values of K_{i} the pole $s=0$ moves inside the left-hand complex plane and the closed-loop system becomes asymptotically stable.

In conclusion, two of the poles of $\tilde{\mathbf{G}}_N(s)$ can be determined as ones of $\tilde{\mathbf{G}}'_N(s)$, while the third one, which happens to be the most dominant since it is closer to the imaginary axis at least for small values of K_{i}, is the one that coincides with the origin for $K_{\mathrm{i}}=0$.

In effect, the poles of $\tilde{\mathbf{G}}'_N(s)$ define whether the response of the vessel to yaw moment disturbance exhibits oscillations or not. Indeed if the value of the damping constant ζ of the second-order characteristic polynomial $\tilde{p}'_N(s) = \tau_1 s^2 + (k_N K_{\mathrm{d}}+1)s + k_N K_{\mathrm{p}}$ is below 0.7 then oscillations in the response are to be expected. In effect, proper selection of constants K_{p}, K_{d} can be made in order to eliminate excessive oscillatory behavior in closed-loop response. On the other hand, all controller constants, but predominantly K_{i}, contribute to obtain a closed-loop system that is adequately stable.

Similar conclusions hold for transfer function $\tilde{\mathbf{G}}_Y(s)$, too.

Example 10.7 Autopilot Steering System for Disturbance Rejection

A 6200 TEU container carrier will be examined as typical application of the analysis and methodology developed for autopilot pole placement design earlier. The principal particulars of the ship are given in Table 10.5.

Considering the linearized ship model introduced by (10.190), it is easily seen that the values of a number of parameters are required to be known. The geometric and physical data for a certain ship, for example, deadweight, length, breadth, etc., are usually given. On the other hand, the values of the involved hydrodynamic derivatives have to be estimated. A variety of estimation methods exists including direct measurement campaigns onboard ships and prediction of their values through similitude-based methods based on the experimental data of towing tank. In this work, strip theory results for the nondimensional hydrodynamic derivatives will be used, which will then be dimensionalized according to standard naval architecture practice.

For a symmetrical hull, the following equations proposed by Clarke and deduced through semianalytical methods, provide an estimate of the nondimensional hydrodynamic derivatives, involved in the ship motion dynamic equations [10.15]

$$Y'_{\dot{v}} = -\pi \left(\frac{T}{L}\right)^2 \left[1 + 0.16\mathbf{C}_b \frac{B}{T} - 5.1\left(\frac{B}{L}\right)^2\right], \tag{10.205}$$

$$Y'_{\dot{r}} = -\pi \left(\frac{T}{L}\right)^2 \left[0.67\frac{B}{L} - 0.0033\left(\frac{B}{T}\right)^2\right], \tag{10.206}$$

$$N'_{\dot{v}} = -\pi \left(\frac{T}{L}\right)^2 \left[1.1\frac{B}{L} - 0.041\frac{B}{T}\right], \tag{10.207}$$

$$N'_{\dot{r}} = -\pi \left(\frac{T}{L}\right)^2 \left[\frac{1}{12} + 0.017\mathbf{C}_b \frac{B}{T} - 0.33\frac{B}{L}\right], \tag{10.208}$$

Table 10.5 Ship principal particulars, deadweight, service speed and rudder area

$L = 292\,\text{m}$
$B = 40\,\text{m}$
$T = 12\,\text{m}$
Design load draft: 87 905 MT
$C_b = 0.6097$
$A_\delta = 66.314\,\text{m}^2$
$U = 24.4\,\text{kn}$

$$Y'_v = -\pi \left(\frac{T}{L}\right)^2 \left[1 + 0.40\mathbf{C}_b \frac{B}{T}\right], \tag{10.209}$$

$$Y'_r = -\pi \left(\frac{T}{L}\right)^2 \left[-\frac{1}{2} + 2.2\frac{B}{L} - 0.080\frac{B}{T}\right], \tag{10.210}$$

$$N'_v = -\pi \left(\frac{T}{L}\right)^2 \left[\frac{1}{2} + 2.4\frac{T}{L}\right], \tag{10.211}$$

$$N'_r = -\pi \left(\frac{T}{L}\right)^2 \left[\frac{1}{4} + 0.036\frac{B}{T} - 0.56\frac{B}{L}\right], \tag{10.212}$$

$$Y'_\delta = -\frac{3A_\delta}{L^2}, \tag{10.213}$$

$$N'_\delta = -\frac{Y'_\delta}{2}. \tag{10.214}$$

In the above it must hold that

$$\frac{A_\delta}{LT} \geq 0.01\left[1 + 25\left(\frac{B}{L}\right)^2\right], \tag{10.215}$$

where L (m) and B (m) are the hull length and breadth, respectively, T (m) is the ship's draft and A_δ is the rudder area (m^2). Moreover, the moment of inertia of the ship, I_Z (kg m^2), can be approximately calculated as the one of the circumscribed parallelepiped, where m (kg) is the mass of the ship.

$$I_Z = \frac{1}{12} m(L^2 + B^2) \tag{10.216}$$

The standard dimensionalization equations, used extensively in naval architecture practice, are [10.15]

$$Y'_v = \frac{Y_v}{\frac{1}{2}\rho L^2 U}, \tag{10.217}$$

$$Y'_r = \frac{Y_r}{\frac{1}{2}\rho L^3 U}, \tag{10.218}$$

$$N'_v = \frac{N_v}{\frac{1}{2}\rho L^3 U}, \tag{10.219}$$

$$N'_r = \frac{N_r}{\frac{1}{2}\rho L^4 U}, \tag{10.220}$$

$$Y'_\delta = \frac{Y_\delta}{\frac{1}{2}\rho L^2 U^2}, \tag{10.221}$$

$$N'_\delta = \frac{N_\delta}{\frac{1}{2}\rho L^3 U^2}. \tag{10.222}$$

In the above ρ (kg/m^3) is the seawater density and U (m/s) is the forward advance speed of the ship, for

Table 10.6 A model for the test case ship maneuvering dynamics

$$\begin{bmatrix}\dot\psi\\ \dot v\\ \dot r\end{bmatrix}=\begin{bmatrix}0 & 0 & 1\\ 0 & -0.0279 & -3.7140\\ 0 & -0.0005 & -0.0694\end{bmatrix}\begin{bmatrix}\psi\\ v\\ r\end{bmatrix}+\begin{bmatrix}0 & 0 & 0\\ -0.1077 & -0.5877\times10^{-8} & -0.0006\times10^{-8}\\ 0.0023 & -0.0002\times10^{-8} & +0.0001\times10^{-8}\end{bmatrix}\begin{bmatrix}\delta_R\\ Y_0\\ N_0\end{bmatrix}$$

$$\psi(s)=\frac{0.002305s+0.0001155}{s(s^2+0.09734s+0.0001754)}\delta_R(s)+\frac{-1.518\times10^{-12}s-2.832\times10^{-12}}{s(s^2+0.09734s+0.0001754)}Y_0(s)+\frac{9.43\times10^{-13}s+2.916\times10^{-14}}{s(s^2+0.09734s+0.0001754)}N_0(s)$$

$\tau_1=555.56s$, $\tau_2=10.47s$

$\tau_0=19.96s$, $\tau_Y=0.54s$, $\tau_N=32.34s$

example, service speed. The above formulas give for conventional hulls an a priori (before construction of the full-scale hull) estimation of the ship's maneuverability.

By using these values the major hydrodynamic derivatives have been calculated as in Table 10.6.

Finally, the state-space model of the ship for service speed of 24.4 kn is obtained and thereof the Nomoto transfer functions are calculated. The results are shown in Table 10.7. The values for the time constants in (10.197) and (10.199) are shown in the same table, as well.

From the values shown in Table 10.7, it is seen that the value of τ_1 is one order of magnitude larger than the values of all other time constants. This is typical for the hull forms used in the vast majority of merchant vessels. In specific, the hydrodynamic derivatives obtain such values that instead of the third order Nomoto transfer functions, the reduced (second) order ones in (10.202) may be used for control design. Then, as explained for practical automatic pilot applications, a PD control law can be, under general assumptions, considered, especially for disturbance rejection.

Eventually, a closed-loop transfer function, $\tilde{\mathbf{G}}'_N(s)$, connecting yaw disturbance to heading deflection is derived as in (10.204); a similar governs the effect of sway disturbance on heading.

The objective of disturbance rejection is to make sure that for the worst case scenario disturbance the induced heading fluctuation lies below specified levels. In this case, this can be assured, if transfer function $\tilde{G}'_N(s)$ is matched to the following form

$$\mathbf{G}(s)=\frac{k_0\omega_0^2}{s^2+2\zeta\omega_0 s+\omega_0^2} \tag{10.223}$$

with

$$k_0=0.0175\times10^{-9}\,\mathrm{rad/(N\,m)}\,,$$
$$\omega_0=0.1308\,\mathrm{rad}\,,\quad s,\zeta=1.0\,. \tag{10.224}$$

Then a sinusoidal turning torque N_0 at any frequency and with amplitude not exceeding 10^9 N m will result to a sinusoidal heading error of the same frequency and with amplitude not exceeding $1^\circ=0.0175$ rad. To

Table 10.7 Estimated values for the ship's hydrodynamic derivatives

$Y_{\dot v}$	$=-8.2534\times10^7$ kg

N_δ	$=2.4190\times10^9$ N m

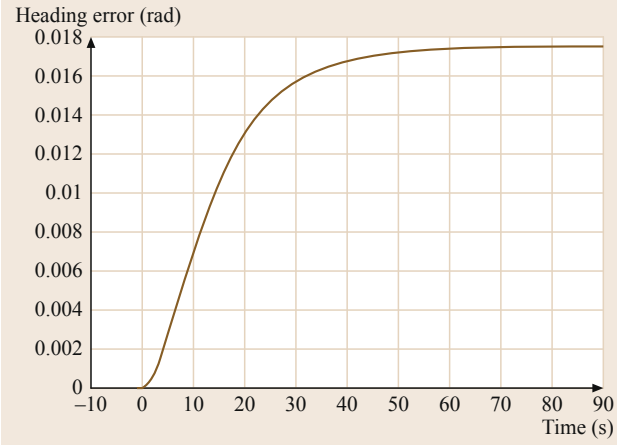

Fig. 10.47 Reduced-order model response to step yaw disturbance

match $\tilde{\mathbf{G}}'_N(s)$ with $\mathbf{G}(s)$ in (10.223) the PD controller gains need to be set as follows

$$k_\mathrm{p}=14.4311\,,\quad k_\mathrm{d}=219.1623s\,. \tag{10.225}$$

The response of the reduced order system (transfer functions of (10.202) in terms of heading error to a step disturbance with magnitude 10^9 N m is shown in Fig. 10.47. In Fig. 10.48, the step response of the full order system, with open-loop transfer functions as in (10.198) are given. As can be seen, in both cases, steady-state error of 1° is demonstrated, which is compliant to specification.

Note that the introduction of a small I-gain can remove the steady-state error, but will not significantly

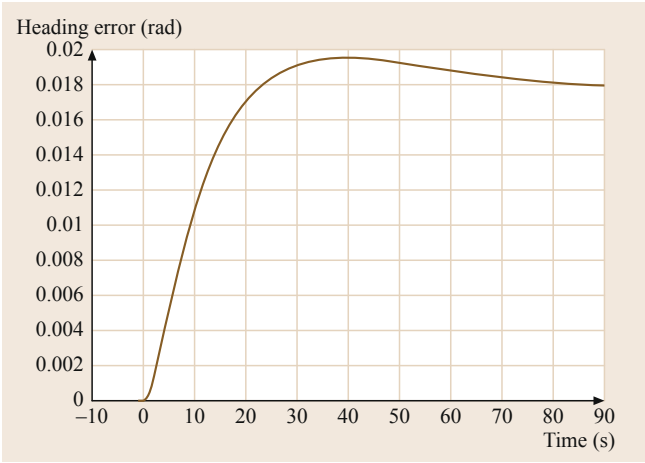

Fig. 10.48 Full-order model response to step yaw disturbance

affect the response of the ship in the first 1min, as during this interval the influence of the PD part of the controller is dominant. Furthermore, note the small overshoot demonstrated in the response of the full-order system is attributed to the presence of the zeros in the numerator of the transfer functions and not to the increase of the order of the characteristic polynomial.

In Fig. 10.49 top the full-order closed-loop system of the ship with the autopilot is shown, while in Fig. 10.49 bottom the reduced order system is shown. Note that the only feedback signal assumed to be available is heading error.

10.5.4 State Observers and Use in Autopilots

A rather important problem to apply the P(I)D control law arising in the common marine autopilot system, is the implementation of the D-term. In the marine autopilot, the D-term corresponds to the yaw rate.

Indeed, the only signal available for feedback is the heading $\psi(t)$ and its differentiation is not recommended in order to avoid amplifying the noise in the control loop. A solution to this problem in practice is to employ a system called a *state-vector observer* (or *estimator*).

In specific, a state observer allows reconstruction on the basis of the measurement (output) vector value. In the case of marine autopilots, the state vector is defined within the framework of the sway-yaw as introduced in the notes. The state observer then obtains the form as

$$\dot{\hat{x}} = \hat{\mathbf{A}}\hat{x} + \hat{B}\delta_{\mathrm{R}} + \mathbf{L}\psi \,, \tag{10.226}$$

where $\hat{x}$ is the state vector estimate (output of the state observer) and $\hat{\mathbf{A}}$, $\hat{\mathbf{B}}$, and $\mathbf{L}$ matrices of appropriate dimensions. Since they define the state observer equations, they need to be determined.

In the 1960s, Luenberger proposed a method to establish the observer matrices based on the pole placement principle introduced in the notes. Prerequisites for Luenberger's method are:

1. The system under investigation upon which state observation is to be applied has to be *observable*.
2. The measurement signals (in the case of the autopilot this is the heading error) need to be reasonably free of any noise or interference.

In the case that the second of the prerequisites is not met, it is possible to construct a state observer by employing optimal filtering techniques. The observer derived in this technique is known from signal theory as Kalman filter.

The Luenberger approach that will be developed here is based on obtaining a dynamic equation for the state prediction error $\hat{e}$, defined as follows

$$\hat{e} = x - \hat{x} \Rightarrow \dot{\hat{e}} = \dot{x} - \dot{\hat{x}} \,. \tag{10.227}$$

By substituting in the above $\dot{\hat{x}}$ as defined previously, $\dot{x}$ by the state equation and ψ from the output equation the following is readily obtained

$$\dot{\hat{e}} = \mathbf{A}x + \begin{bmatrix} 0 \\ \overline{b} \end{bmatrix} \delta_{\mathrm{R}} + d - \left[\hat{\mathbf{A}}\,(x - \hat{e}) + \hat{\mathbf{B}}\delta_{\mathrm{R}} + \mathbf{L}cx\right],$$

$$\Downarrow$$

$$\dot{\hat{e}} = \hat{\mathbf{A}}\hat{e} + \left(\mathbf{A} - \mathbf{L}c - \hat{\mathbf{A}}\right)x + \left(\begin{bmatrix} 0 \\ \overline{b} \end{bmatrix} - \hat{\mathbf{B}}\right)\delta_{\mathrm{R}} + d \,. \tag{10.228}$$

By setting

$$\hat{A} = \mathbf{A} - \mathbf{L}c \quad \text{and} \quad \hat{B} = \begin{bmatrix} 0 \\ \overline{b} \end{bmatrix} . \tag{10.229}$$

Then the differential equation for the state estimation error becomes

$$\dot{\hat{e}} = \hat{\mathbf{A}}\hat{\mathbf{e}} + d = (\mathbf{A} - \mathbf{L}c)\hat{e} + d \,. \tag{10.230}$$

Using the Laplace transform

$$\hat{e}(s) = (s\mathbf{I}_3 - \mathbf{A} + \mathbf{L}c)^{-1} d(s) \,, \tag{10.231}$$

where the above equation is essentially a dynamic equation whose poles can be placed ad hoc by appropriately selecting the values of matrix $\mathbf{L}$. Therefore, the state estimate $\hat{x}$ is finally given by

$$\dot{\hat{x}} = \mathbf{A}\hat{x} + \begin{bmatrix} 0 \\ \overline{b} \end{bmatrix} \delta_{\mathrm{R}} + \mathbf{L}\,(\psi - c\hat{x}) \,. \tag{10.232}$$

Moreover, a good choice for the entries $\mathbf{L}$ the estimation error $\hat{e}$ tends to coincide with random vector $\boldsymbol{d}$. It is noted here that the size of d decides the accuracy of the

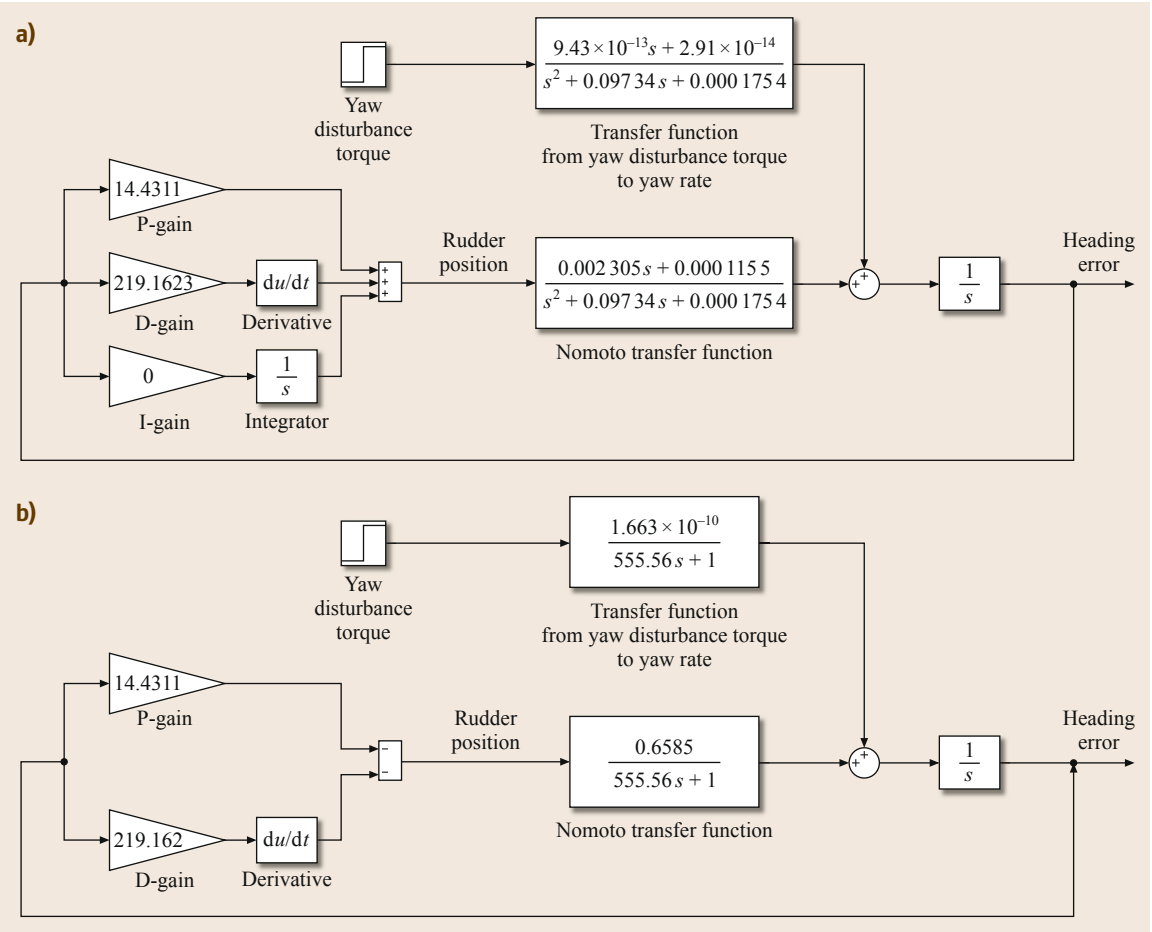

Fig. 10.49a,b Full-order (a) and reduced-order (b) model for ship autopilot design

estimation for x since the estimate $\hat{x}$ cannot approximate x any better.

Also note that (10.232) is essentially the state-space dynamic equation of the system augmented by term $\mathbf{L}\times(\psi - c\hat{x})$. This term is a correction since with a properly set $\mathbf{L}$ allows generating estimates $\hat{x}$ so that model (10.232) of the system approximates the actual system dynamics.

A Luenberger state observer obviously generates not just yaw rate r needed in PID autopilots but for the entire state vector including the sway velocity v. Therefore it can be used to implement advanced control schemes as well like pole placement with full-state feedback as presented earlier in the present chapter.

An autonomous ocean vehicle is a mobile system whose ability to accomplish a specific mission depends on the design and interplay among its seven principal subsystems: propulsion, sensors, energy, navigation, communication, control, and autonomy. The subsystems are coupled; a change in one impacts all the others in some way. The operating environment for an ocean vehicle is spatially complex, transient, and uncertain. The need for long duration measurements and the constraints of low bandwidth and intermittent communication dictate autonomous capability. Large-scale, three-dimensional, simultaneous coverage of the ocean requires concurrent deployment of multiple vehicles. Under such conditions, cooperative, adaptive vehicle behavior provides a competitive advantage in accomplishing most missions. Of the hundreds of types of unmanned ocean vehicles that have been built, only a few are viable, commercial products. Recent advances in component technologies and subsystem performance have combined to establish new thresholds of capability that are attractive and practical for many missions. This trend is likely to continue. The goal of Part B is to document the current state-of-the-art in some key areas and chart directions for future research and development.

Propulsion is clearly a distinguishing feature of mobile platforms. For subsurface vehicles, mechanical forces and buoyancy forces are the two prime movers. Propellers have dominated mechanical propulsion and are a mature technology, which is not reviewed here. There have been significant advances in biomimetic propulsors, which have great advantages for maneuverability. Chapter 11 reviews biology-inspired systems within a unifying framework of self-regulating nonlinear dynamics. Subsurface vehicles driven by buoyancy forces (gliders) have seen explosive growth in recent years. Chapter 12 reviews the underlying principles of ocean gliders, in which the net hydrodynamic force of lift and drag produced by a wing balances the net buoyancy. Various classes of gliders are categorized and new innovative designs are described.

Ocean surface vehicles play an important and unique role in an autonomous ocean sampling network by providing connectivity at the air-sea interface. Such connectivity includes near-surface sensing, communication links, energy re-supply, and carrying aircraft and subsurface vehicles. In the evolution of autonomous surface vehicles, there has been a tendency to simply adapt existing vessels, designed for other purposes, by removing the crew. Chapter 13 examines the characteristics of surface vehicles specifically designed for autonomous operation from the keel up, and discusses the potential of and need for such multi-functional platforms in an autonomous system of systems.

Precise navigation is essential for mobile platforms and is particularly challenging underwater. Improvements in performance in recent years are related to reduction in the cost and size of component sensors, and advances in algorithms such as simultaneous localization and mapping and cooperative positioning. Chapter 14 reviews the state-of-the-art in estimating the precise position of an autonomous ocean vehicle. The degree of autonomy of an ocean vehicle is inversely related to the continuity and handshaking of its communication link. Communication with an autonomous ocean vehicle is necessary to both acquire data and/or modify its behavior. Radio, sound, and light waves each have advantages and disadvantages in specific applications. Chapter 15 focuses on acoustic channel characteristics and modulation schemes used to provide wireless connection between nodes operating underwater. Networking protocols and peer-peer routing are important enablers for cooperative, adaptive behavior of multiple vehicles.

Onboard energy is always a limitation for autonomous ocean vehicles, as it is for all mobile vehicles. Efficient energy management is a function of subsystem duty cycles, payload demand, and operating technique. One approach is to design a vehicle to carry all the energy it needs to complete its intended mission (e.g., a nuclear submarine). This approach puts a premium on high-energy density power sources and tends toward large displacement hull forms for long duration missions. An alternative approach is to treat energy as a distributed resource in the operational domain (caches, renewable sources, replenishment vehicles, ambient kinetic energy advection), and plan missions to include re-supply and/or ambient exploitation. Most mature transportation systems use a distributed approach with some type of supporting infrastructure. Common features of re-supply are localization of the mobile vehicle relative to an energy source and physical connection (docking) to enable transfer. Chapter 16 reviews advances and trade-offs inherent in autonomous ocean vehicle docking.

Autonomous ocean vehicles are tools for intervention and/or data acquisition. One useful class of intervention is based on manipulators. Manipulation is a mature technology on tethered, remotely operated vehicles. The use of manipulators on autonomous platforms is more challenging. Chapter 17 reviews recent progress in autonomous manipulation. Data acquisition is a function of sensor payload, which determines the

perception of the vehicle. Sensor technology is advancing rapidly, driven by miniaturization, fiber optics, and low-power electronics. Sensors span a broad domain of transduction techniques and signal processing, and can be categorized in various ways. Non-acoustic sensors, in particular, have progressed significantly in recent years, and Chap. 18 reviews this field of development.

There are many advantages of using multiple autonomous ocean vehicles to collaboratively accomplish a mission. Four chapters (19–22) examine various aspects of this approach. Chapter 19 reviews cooperative control of autonomous ocean vehicles for environmental monitoring. An array of vehicles can act as a mobile, reconfigurable, large aperture sensor (antenna). Using feedback control to coordinate relative vehicle motion, such an array can adapt efficiently to a changing environment. The methodology and advantages of such cooperative control are described in two unprecedented field experiments in the coastal ocean. Chapter 20 describes the concept of nested autonomy as an architecture for distributed ocean sensing. Hierarchical, distributed command and control enables deployment of an array of autonomous ocean vehicles over a wide area for a long period of time with little or no human supervision. Effective coverage, limited communication range, safe operation, and environmental uncertainty are all primary constraints. This approach provides a mechanism for balancing autonomy with the periodic need for operator intervention. Chapter 21 focuses on time-optimal path planning and adaptive sampling for groups of ocean vehicles in realistic ocean conditions. Path planning optimization and adaptive sampling both involve prediction of ocean variables, and thus ocean modeling is essential. The state-of-the-art using dynamical models in feedback control of autonomous ocean vehicles is documented for both idealized and realistic environments. The goal is to improve the predictive skill of the continuous (space and time) ocean fields being measured. Optimal path planning and adaptive sampling can also be used to improve the predictive skill of detecting and tracking discrete objects (targets) in the environment. In many sport, military, and biological endeavors, cooperative strategies have proven themselves to be advantageous over non-cooperative ones. For a multi-vehicle team operating in the continuous and transient ocean, cooperative behavior involves optimizing a high-dimensional parameter space, even more so in cases when the target has the ability to make intelligent choices to avoid being tracked. Chapter 22 examines recent progress to construct a theoretical framework and initial applications for maritime surveillance. A methodology is developed that can help bridge the gap between a top-down view starting with theoretical concepts and a bottom-up view based on the details of real experimentation and execution at sea.

Deploying autonomous vehicles for extended periods in the coastal ocean requires safe and reliable operation in potentially congested waterways. The existing rules of the road for marine vessel operation are evolving to accommodate autonomous vehicles. Simultaneously, designers of such vehicles are developing advanced autonomy behaviors that exhibit *human-like* performance. Chapter 23 provides a snapshot of this rapidly changing operational environment, with particular attention paid to the software shaping high-level autonomy and on the legal framework for acceptable integration into public water space. In contrast to coastal ocean operation, where collision is a principal risk, the risk in deploying autonomous vehicles for extended periods in the open ocean lies more in their potential disappearance. Indeed, testing of true autonomy has often been limited by risk-of-loss aversion. When evaluating risks, various stakeholders may weigh consequences differently. For example, the owner may focus on the risk of vehicle loss, whereas the user on risk of data loss. Other risks, such as hazards to navigation, affect all stakeholders. Chapter 24 describes a risk management process using several methods tailored specifically to deployment of autonomous ocean vehicles.

11. Highly Maneuverable Biorobotic Underwater Vehicles

Promode R. Bandyopadhyay

After receiving only a trickle of interest over the past 50 years or so, biolocomotion has more recently attracted broader attention. In this chapter, biology-inspired highly maneuverable underwater vehicles (of ≈ 1 m length scale) that have achieved some degree of maturity are reviewed. Primarily, the Naval Undersea Warfare Center (NUWC) works are described. The nonlinear theoretical foundation of animal-inspired hydrodynamics and control is summarized. Low-speed propulsion (including hovering and maneuvering), control, and integration with sensors are considered. High-lift flapping-fin propulsion technology, cycle-averaged and olivo-cerebellar temporal control, integration with interaural time-differencing bio-sonar, and basin demonstration of utility are discussed. While numerous variables affect the mechanisms and integration of actuators, controllers, and sensors, the principles of self-regulating nonlinear dynamics provide a common and simplifying framework for the development of biorobotic vehicles. The salient features of these vehicles and their control design laws are tabulated. These emergent, low-speed platforms complement existing higher speed naval capabilities and are not substitutes for any existing mature system; in this sense, their utility depends on the imaginative nature of future operation concepts – a process that is unpredictable. The greater potential of the biorobotics approach is limited by a serious lack of progress in so-called strong artificial muscle technology, as well as by a lack of understanding of nonlinear temporal control and sensing and how they should be integrated. Application to utility has been facilitated where understanding of the underlying science has been mathematically formulated, and such formulation needs to be more widely emulated.

11.1 Biorobotics

The 1934 work of *Karman* and *Burgers* [11.1] laid the early theoretical foundation of biorobotics, followed in 1975 by *Lighthill* and others [11.2], who established a broader foundation. Karman and Burgers give the key insight into the hydrodynamic mechanism of biolocomotion [11.2, Fig. 8], which states that in a swimming fish, caudal fins need to flap just enough to produce vortex wakes to give rise to a thrust jet, and the Karman vortex street is present in reverse. However, energy is not wasted in excessive flapping in making the vortex wake and yet the jet cross-section is large, whereby *good efficiency* is achieved [11.2, p. 30].

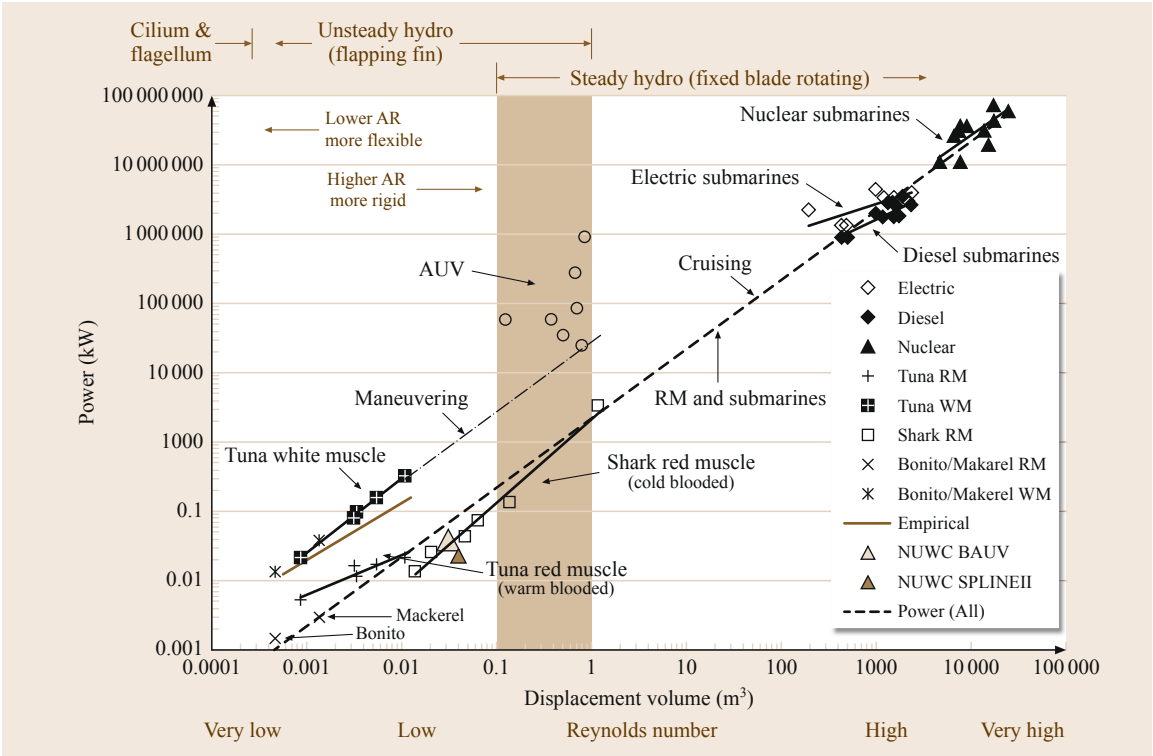

Fig. 11.1 Comparison of propulsion density of animal and manmade autonomous underwater swimmers; the latter shows both biorobotic vehicles (NUWC BAUV, and SPLINEII) and swimmers with conventional rotating propulsors. BAUV: biorobotic autonomous underwater vehicle; SPLINE: self-propelled line array; RM: red muscle (used for cruising); WM: white muscle (used for maneuvering, which follows a different trend (after [11.3])). For data source, see [11.3, 4]; the submarine data are from the open literature [11.5, 6] (reproduced after [11.4, Fig. 3] and after [11.3, Fig. 6])

Biolocomotion is now seen as more than hydrodynamics because animals are seen to be perfectly autonomous, with excellent maneuvering and sensing abilities – a perfect *unmanned underwater vehicle* so to speak. Reverse engineering of swimming animals is thus seen as instructive and the subject of biorobotics attempts to find utility in those animal properties. Here we review the more mature progress in this field.

Research on bio-inspired underwater vehicles seeks to expand the operational envelope by implementing *integrated* principles of hydrodynamics, control, materials, and sensing. The integrated nature of these principles and the differences between bio-inspiration and bio-mimicry are important aspects that we need to understand because success hinges on that understanding. The measure of success is readiness for demonstration on real missions (*transitionability* in naval context) to practical value, and realization of the potential depends on the maturity achieved over a period of 5–10 years, during which a substantial amount of investment will have been made. These aspects are considered below.

We are aware that in ocean engineering, bio-inspired vehicles are considered by some practically minded, influential people as just a curiosity. To rebut such notions, the focus in this review is on vehicles of emergent maturity, as described below. We do not consider the numerous biorobotic vehicles that have not made it out of the confines of the small tank or laboratory, including some of our own early works. Thus, this review leans more on our US Navy work over the last decade, and on the open literature in regard to others' work.

Figure 11.1 shows a meta-analysis of propulsive power (kW) versus displacement volume (m^3), extending over eight decades of these two parameters, has been carried out for engineering underwater vehicles and for animals [11.3–6]. Data from the open literature were utilized. For the animals, the propulsive power was separated for cruising and maneuvering; these functions are attributed to red and white muscles, respectively. The trend for cruising was identical between the engineering vehicles and the red muscles indicating that the drag levels are minimized. The ani-

mals shown use flapping caudal and/or pectoral fins for propulsion/maneuvering. Since the propulsive mechanism of these flapping lifting surfaces makes use of transitional vortex shedding, it must be that larger and larger biorobotic vehicles can also be built with flapping fin propulsion as long as the fin Reynolds number is within the critical range. From the graph in Fig. 11.1, this is a limit of displacement volume of the order of $1\,m^3$ (of the size of a large shark). (We have not been able to find animal data between 2 and $100\,m^3$, and a higher limit is not ruled out.) The tuna white muscle data shows that power required for maneuvering is 10 times greater than that required for cruising. Below, we review our biorobotic vehicles of displacement volume of the order of $0.05\,m^3$.

Let us begin with several important definitions. A *mature platform based on bio-inspiration or bio-mimicry* is one for which:

1. A user mission has been identified.
2. An instrumented version has been built and demonstrated both in the laboratory and in open/saltwaters.
3. Integration with mission sensors has been demonstrated.
4. Documentation or knowledge about improvements over conventional engineering solutions and mechanisms have been experimentally verified and theoretically backed.
5. The biology principle, mechanism, and design laws have been determined, are mathematically founded, and have been peer reviewed, and
6. Long-duration performance has been demonstrated.

Bio-inspiration is described as an undertaking in which the science has been distilled and implemented in a framework that is useful to a user where a bio-inspired platform does not necessarily resemble any animal. In contrast, *bio-mimicry* is an effort in which, first and foremost, biology is mimicked and whereby the resulting platform resembles the chosen animal. The latter, which tends to draw popular interest, may have value in camouflaging.

The subject of unmanned biorobotic underwater vehicles has been reviewed in the past [11.7, 8]. The underlying science and technology have been reviewed by several authors [11.2–4, 7–17]. From the larger biorobotic point of view ($\approx 1\,m$ scale), we separate the propulsive surfaces of animal swimmers in two categories as follows: smaller swimmers with highly flexible caudal and pectoral fins and with main bodies that are more on the flexible side (they have lower Reynolds number); generally larger swimmers whose fins are rather rigid (but not fully rigid) with bodies that are more on the rigid side (they have higher Reynolds number) [11.13]. An example of the former is sunfish (the kind of fish extensively studied in the laboratory [11.18]), and the examples of the latter are penguins, dolphins and whales (the fins are studied mostly biorobotically [11.3, 11, 14, 15, 19]). (Box fish with its rigid body and flexible fins straddles the two categories [11.20].)

Biorobotics received an early boost with the bio-mimicry of caudal fin swimming of tuna fish [11.21–23] in a similar flexible hull. This was followed by departure from bio-mimicry of form – by the application of flapping fin propulsion technology to rigid cylinders – the common engineering underwater hull forms of choice [11.19]. This chapter focuses mainly on flapping fin propulsion and control technology, and the fins are large and fairly stiff (or only slightly flexible).

In relation to swimming animals and from a practical point of view, the primary interest is in the hovering and maneuvering of flow-aligned cylinders or other platforms of about 1 m in length and 30 cm in diameter or depth. Hovering and other maneuverings such as yawing include station-keeping in sea states and in currents. Ideally, such platforms should have high efficiency, with minimal input of momentum into the water and very little acoustic radiation. It is also desirable to have novel requirements such as a built-in disturbance rejection capability (robustness) and rational integration of controllers, actuators, and sensors. Concepts that have a rigorous mathematical formulation are preferred, and a synthesis of bio-physical advances shows that this formulation needs to be nonlinear in character to achieve self-regulation and disturbance rejection properties. (Theoretical definition of self-regulation and why this is a nonlinear process is given in [11.15]; theory showing why the motion of animals is determined by olivo-cerebellar dynamics which is a nonlinear self-regulating process is given in [11.24–29]; and the theory of why sensing, control, and actuator hydrodynamics in swimming and flying animals are likely described by similar self-regulating equations, is given in [11.28].

Below, the flapping fin and the transitional vortices produced are treated as coupled nonlinear oscillators. The transitional (reverse Karman) vortex production process, which is the key to thrust, is shown schematically in Fig. 11.2 for a pectoral fin [11.15, 28]. A leading-edge vortex (LEV) on the fin (Fig. 11.2c) and a reverse Karman vortex train (Fig 11.2b) in the wake are produced when the Strouhal number (St) and pitch amplitude (and Reynolds number) are appropriate (Fig. 11.2f). Due to the motion of the stagnation point [11.15], symmetry is broken [11.29]. As a result, the lift force is enhanced and thrust is produced. This vortex becomes uniform along the span when an appropriate twist is applied (Fig. 11.2d,e). Figure 11.2f shows

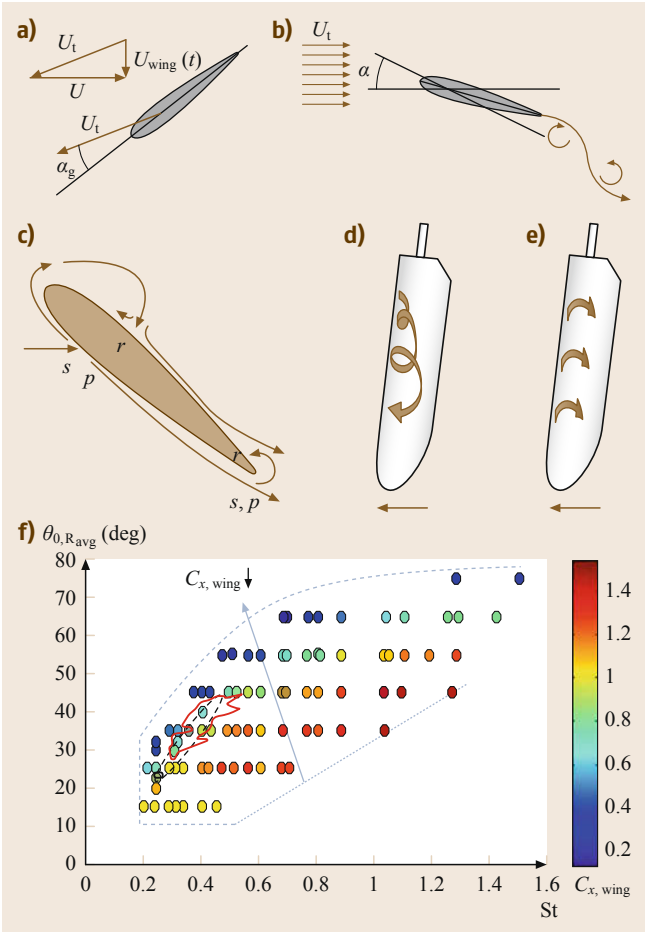

Fig. 11.2a–f Schematics of flow features in a penguin-like flapping pectoral fin: **(a, b)** fin–wake coupling; **(c)** flow bifurcations; and **(d, e)** leading-edge vortex (spirals on fins) in untwisted fins **(d)** and fins twisted spanwise **(e)**; the leading-edge vortex enhances lift force; **(a)** the geometric angle of attack of the fin α_g is determined from the forward fin velocity U and the wing velocity $U_{wing}(t)$, and U_t is total velocity; **(b)** the wake vortices, however, alter the motion of the stagnation points resulting in an effective angle of attack α ($\neq \alpha_g$), and the symmetry breaking by the motion of the stagnation point leads to thrust production; **(c)** streamline symbols are: s (stagnation point), r (reattachment), p (separation); **(d–e)** arrows: direction of fin motion. **(f)** Strouhal number (St) – pitch amplitude (θ_o) parameter space where cruising hydrodynamic efficiency in a single flapping and twisting fin is maximum (> 0.57; region marked by broken ellipse and red lines), or maximum forward thrust (deep red symbols) is produced; thrust is produced only in the region marked by the broken lines; the large arrow indicates direction where forward thrust ($C_{x,wing}$) drops (after [11.15, 29]) ◄

where a fin, hinged at one end, is operated for efficient cruising (area enclosed by red lines) or maximum thrust (red symbols). Efficiency and thrust reach maximum values at lower and higher values of St, respectively, while θ_o remains in the same range; the angle of attack is lower and higher, respectively. Note that the effects of the orthogonal fin roll (given by St) and pitch oscillations (θ_o) are coupled.

11.1.1 Flapping Fin Propulsion Technology

Flapping fins can impart a great deal of momentum to the water because the frequency of flapping can be increased without being constrained by the size of any internal reservoir. Rigid or nearly rigid fins can be scaled up better compared to highly flexible fins as in sunfish. Flapping fins when hinged at one end produce a LEV that remains pinned to the fin due to Coriolis forces [11.30]. As the measurements in [11.16, Fig. 9] show, due to delayed stall, higher lift forces are produced by flapping fins, which can operate at spatiotemporal angles of attack higher than the (first) stall angle. When the fin is flapped at the natural frequency of vortex shedding and the pitch amplitude is commensurate (between 20° and 40°) with the Strouhal number (St) in the range of 0.2–0.4, at a phase difference of about 90° between pitch and roll, efficiency reaches a maximum value (of about 0.60 in rigid fins of low aspect ratio) (Fig. 11.2f) [11.15]. Swim rules have been developed for optimal yawed swimming and yawing [11.3, 15–17, 19]; (the summary is presented later in Table 11.1). Further optimal swim rules have been developed by calibrating a cruising cylinder appended with six flapping fins in a tow tank [11.3]. The vehicle maturities considered here have been achieved by flapping the fins at these optimal conditions and by developing controllers to accomplish the flapping [11.14, 19].

In the vehicles considered here, there is no buoyancy control device because the multiple fins appended to the hull produce the required degrees of freedom with added simplicity. This is useful in rivers and estuaries where salinity can vary greatly. Forces and moments in all directions are controlled by phased oscillation of the flapping fins.

Table 11.1 Summary of flapping fin parameters for optimization of efficiency and thrust during cruising and yawing. Also included are characteristics of wall-shear stress (τ_w) patterns over the flapping fin for these flapping fin parameters: $\phi_0 = 30°$, $\psi = 90°$, $\theta_{t0} = 0°$

Cruising, hovering, or yawing	Fin kinematics: straight ($\theta_{Bias} = 0$), or yaw ($\theta_{Bias} \neq 0$) swim	Fin optimization parameters based on thrust or efficiency	Salient features of $\tau_w(t)$ on fin surface (blue: low, red: high wall-shear stress); both pressure and suction surfaces are shown; sinusoidal line: stagnation point trajectory; vertical axis: % chord, horizontal axis: time	
Cruising or hovering in straight path (that is, not yawing)				
Cruising: $U > 0$ $U_{wing}/U_t \to 0$ $Re_c = (30 - 130) \times 10^3$	$\theta_{Bias} = 0°$ $\phi_0 = 30°$ $\psi = 90°$ $\theta_{t0} = 0°$	$0.25 \leq St \leq 0.40$ $20° \leq \theta_0 \leq 45°$ $\eta > 0.57$ $C_{x,\eta} = fn(St, \theta_0)$ (higher θ_0 for higher St)	Spanwise bands of low τ_w near the leading edge, followed by high τ_w over the chord away from the leading edge when the stagnation point is advancing to the facing side of the fin during half the cycle of oscillation; during the remaining half of oscillation, as the stagnation point recedes to the other side, a thin band of high τ_w near the leading edge is followed by low τ_w over the remaining part of the chord	Hovering: $U = 0$ $U_{wing}/U_t \to 1$	$\theta_{Bias} = 0°$, $\phi_0 = 30°$, $\psi = 90°$, $\theta_{t0} = 0°$,	$C_x = fn(f^2)$ $\theta_0 = 45°$	Bands of low τ_w along oscillating stagnation line; this is followed by one pair of a band of low τ_w along the chord per cycle, followed by high τ_w over $s_c/c > 0.05$	Yawing while cruising or hovering				
Cruising: $U > 0$ $U_{wing}/U_t \to 0$ $Re_c = (30 - 130) \times 10^3$	$\lvert\theta_{Bias}\rvert < 20°$ $\phi_0 = 30°$ $\psi = 90°$ $\theta_{t0} = 0°$	$0.25 \leq St \leq 0.40$ $20° \leq \theta_0 \leq 45°$ $\eta > 0.57$ $C_{x,\eta} = fn(St, \theta_0)$ (higher θ_0 for higher St)	Oscillating leading-edge stagnation point for zero (top, 0°), positive (middle, 10°), and negative (bottom, −10°) pitch bias; bands of low τ_w for $0° < \theta_{Bias} < 20°$: spanwise near leading edge as for no yaw plus some chordwise patterns; for $0° > \theta_{Bias} > -20°$: mostly high τ_w and attached flow	
Table 11.1 (continued)

Cruising, hovering, or yawing	Fin kinematics: straight ($\theta_{Bias} = 0$), or yaw ($\theta_{Bias} \neq 0$) swim	Fin optimization parameters based on thrust or efficiency	Salient features of $\tau_w(t)$ on fin surface (blue: low, red: high wall-shear stress); both pressure and suction surfaces are shown; sinusoidal line: stagnation point trajectory; vertical axis: % chord, horizontal axis: time	
Yawing while cruising or hovering				
Hovering: $U = 0$ $U_{wing}/U_t \to 1$	$0° < \theta_{Bias} < 45°$ $\phi_0 = 30°$ $\psi = 90°$ $\theta_{t0} = 0°$	$C_x = fn(f^2)$ $\theta_0 = 45°$	With increasing positive pitch bias angles, regions of low τ_w increase; one pair of brief bursts of low τ_w extend over chord per cycle of fin oscillation; oscillating stagnation line is a band of low τ_w as when $U = 0$ and $\theta_{Bias} = 0°$	Hovering: $U = 0$ $U_{wing}/U_t \to 1$	$0° < \theta_{Bias} < -45°$ $\phi_0 = 30°$ $\psi = 90°$ $\theta_{t0} = 0°$	$C_x = fn(f^2)$ $\theta_0 = 45°$	With decreasing pitch bias angles below 0°, the chordwise bands of low τ_w partly become compact and shift mostly down chord	
Note: When τ_w is very low, the local fin boundary layer approaches separation. When τ_w is very high, the boundary layer is attached and may be accelerating. The topology of the near-wall flow over the fin can be defined by critical points such as saddles and foci; in the flapping fins, these flow bifurcation points can be identified: spatiotemporal stagnation point, separation and reattachment points [11.15]

11.2 Theoretical Foundation of Animal-Inspired Hydrodynamics and Control

Flapping fins are nonlinear oscillators. In the case of a drag-producing cylinder in a stream, the lowest order solution of the Navier–Stokes equation of the wake instability reduces to a van der Pol equation [11.31, Appendix]. The latter equation applies also when the cylinder is freely suspended and is galloping (at the natural frequency) [11.32]. Obviously, the cylinder can be replaced by a low-drag foil and the van der Pol form of the Navier–Stokes equation would still describe the lowest order solution of the wake instability. It has been shown [11.15] that the van der Pol solution can be extended to a flapping fin (i. e., if the fin wake is perturbed by a flapping fin motion) oscillating at the natural frequency when the drag wake is replaced by a thrust wake after symmetry breaking [11.29]. In other words, in the transitional range of Reynolds number, vortex-propelled animals can be described by nonlinear oscillators as indeed was implied earlier by *Karman* and *Burgers* [11.1] and *Lighthill* [11.2] and *Bandyopadhyay* et al. [11.15].

11.2.1 Hydrodynamics

As depicted in Fig. 11.2a,b, in the swimming animal, the oscillating surface and the vortex street couple [11.28]. The wake circulation alters the geometric fin angle of attack given by the forward velocity and the fin oscillation velocity. This mechanism allows a freely suspended flexible fin oscillating at the natural frequency and its wake vortex train to adjust to each other (lock-in) in terms of phase and energy, iterating to a low-energy system (minimal losses).

For a single fin hinged at one end that is also twisting and flapping in the optimal manner (Fig. 11.2d,e) near the natural shedding frequency of the wake instability of the nonflapping fin, the instantaneous fluctuating force F'_x produced agrees well – to a leading order particularly at high Reynolds numbers (fin chord and cruise speed-based $Re_c \approx 70\,000$) – with the van der Pol formulation given below,

$$\ddot{F}'_x - \omega_s G(F'^2_{xo} - 4F'^2_x)\dot{F}'_x + \omega_s^2 F'_x = \omega_s T R_{avg}\dot{\xi}\,, \quad (11.1)$$

where

$$\xi(t) = \phi(t) + \theta(t) \,,$$
$$\phi = \phi_0 \sin(2\pi f t) \,,$$
$$\theta(t) = \theta_0 \sin(\omega t + \psi) + \theta_{\text{Bias}} \,,$$
$$\omega_s = 2\omega\pi \frac{StU}{A} \,,$$
$$A = 2\phi_o R_{\text{avg}} \,.$$

F'_x is the fluctuation in force, and F'_{xo} is the amplitude of F'_x; $G(=0.02)$ and $T(=0.5)$ are constants (determined by trial) that affect the shape and the blur of the oscillatory solution (the limit cycle), respectively. In other words, the flapping (rolling and pitching) fin is a nonlinear oscillator and has a limit cycle oscillation (LCO) [11.15]. (The roll, pitch, and twist oscillation of the hinged fin may be seen to act as the $I_{\text{exti}}(t)$ term (see olivo-cerebellar control Sect. 11.2.2 below) to the nonlinear oscillator arising out of the natural vortex shedding of the nonflapping fin.)

Flapping Fin Parameters for Cruising and Maneuvering

Table 11.1 summarizes the fin kinematics that a controller (in the BAUV, SPLINE, and Razor vehicles, Sect. 11.3) uses for optimization of thrust and efficiency during cruising, hovering, and yawing. The total forward velocity is much higher than the wing velocity (which is cross-stream) during cruising, and these velocities are nearly equal during hovering (the forward speed is zero during hovering). Biasing the fin pitch at half the required yawing angle is the key fin setting required for yawing. For optimization of efficiency, the controller makes use of the observed direct coupling between Strouhal number St, whose definition includes roll oscillation amplitude ϕ_0 and pitch amplitude θ_0; a higher pitch amplitude of about 40° is used when St is near 0.40, and a lower pitch amplitude of 20° is used when St is near 0.25 (Fig. 11.2f) [11.15]. Also, note that in a single flapping fin, thrust is a function of the square of the flapping fin frequency f for given pitch amplitude and forward speed [11.15, 19].

The flapping fin mechanism can be understood by observing that the forces produced are describable by van der Pol (11.3) [11.15] or Stuart Landau nonlinear oscillators [11.28]. Using the equation for the latter oscillator, it has been shown theoretically that a coupling exists between the fin and the wake [11.28]. Table 11.1 can be viewed as tuning of the oscillator under various performance requirements. The rightmost column in Table 11.1 summarizes the wall shear stress on the fin for the fin kinematics given in the other columns. Characteristic patterns can be observed:

1. The point of stagnation oscillates, shifting from one pressure side of the fin to another pressure side as the pressure and suction roles of the fin surfaces alternate.
2. Downstream of the stagnation line and on the suction side, a generally spanwise low-wall-shear region develops, indicating the presence of a LEV.
3. Chordwise low-wall-shear bands appear in the suction side in hovering and yawing fins, indicating a complex and less efficient surface flow.

11.2.2 Animal-Like Motion Control Laws and the Principles of Integrated Design

We describe the unmanned underwater vehicle (UUV) design to be integrated when the actuators (fins), controllers, and sensors have similar laws of dynamics. In the case of animal-inspired swimming, these will be equations of nonlinear oscillators.

We assume that the principles of integrated design are derived from the olivo-cerebellar motion control laws [11.24–27, 33], as evidenced by the dynamics of the inferior-olive (IO) neurons that are responsible for motion and balance in all mammals, from rats to human beings [11.24, 25]. We first consider the motion control laws and then how the controller, actuator, and sensors are integrated in a common framework of dynamic systems mathematics.

The motion control laws are self-regulating. In such control, a sensor is not needed for error estimation with respect to a reference because a conventional closed control loop is not present. In other words, these controllers reject disturbances, which make them robust. (See [11.3, 28] for discussion of self-regulation.) Owing to this robustness, the controllers have remained unchanged in many animals.

The olivo-cerebellar dynamics of an IO neuron ($i = 1, 2, \ldots$) can be represented by two coupled nonlinear oscillators (u_i, v_i) and (z_i, w_i) as given below [11.26, 27],

$$\begin{bmatrix} \dot{u}_i \\ \dot{v}_i \\ \dot{z}_i \\ \dot{w}_i \end{bmatrix} = \begin{bmatrix} k(\varepsilon_{\text{Na}})^{-1}(p_{iu}(u_i) - v_i) \\ k(u_i - z_i + I_{\text{Ca}} - I_{\text{Na}}) \\ p_{iz}(z_i) - w_i \\ \varepsilon_{\text{Ca}}(z_i - I_{\text{Ca}}) \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ 0 \\ -\varepsilon_{\text{Ca}} \end{bmatrix} I_{\text{exti}}(t) \,, \tag{11.2}$$

where the variables (z_i, w_i) are associated with the subthreshold oscillations and low-threshold (Ca-dependent) spiking, and (u_i, v_i) describe the higher threshold (Na^+-dependent) spiking (this is similar to FitzHugh–Nagumo equation). The constant parameters ε_{Ca} and

ε_{Na} control the oscillation time scale; I_{Ca} and I_{Na} drive the depolarization levels; and k sets a relative time scale between the uv- and zw-subsystems. The nonlinear functions are

$$p_{iu}(u_i) = u_i(u_i - a)(1 - u_i) ,$$
$$p_{iz}(u_i) = z_i(z_i - a)(1 - z_i) .$$

The function $I_{exti}(t)$ is the extracellular stimulus, which can be used for the purpose of control, such as phase synchronization. Note that in a UUV, we do not need to be concerned with the ionic interpretations of the variables and constants; we are only concerned with the generic nonlinear dynamics [11.28].

The (u_i, v_i) oscillator can generate spikes (analogous to neural action potential), but this feature has not been used in the context of UUV maneuvering. The (z_i, w_i) oscillator, however, has been used successfully to synchronize the phase of a six-finned vehicle [11.33].

The salient features of this approach to control compared with conventional engineering controllers (i. e., proportional, integral, derivative (PID) controllers) are that no sensors are required, no reference is required, the controller has built-in disturbance rejection ability, and, in principle, the controller has no size or time scale limitation.

The lower oscillator in (11.2) can then be written as

$$\ddot{z}_i + F(z_i)\dot{z}_i + kz_i + \varepsilon I = 0 , \qquad (11.3)$$

where F is a cubic polynomial function and k is a constant if $I_{exti}(t) = 0$. Equation (11.3) resembles Lienard's oscillator (in contrast, the function F is a well-defined quadratic in the more familiar van der Pol oscillator [11.34, p. 13]). The oscillator exhibits a closed orbit Γ_i in the state space $(z_i - \dot{z}_i)$, that is, $(z_i - w_i)$, which is also known as LCO, with the constant parameters determining the form of Γ_i.

Below, we consider the notions of integrated design and nonlinear sensing because they are theoretically attractive.

Principles of Integrated Design

Swimming animals offer clue to homing, autonomy, and station keeping. The mechanisms are at a theoretical stage of understanding and we touch upon them notionally to spur future work. The principles of integration of the controller, actuator, and sensor are based on the hypothesis of *persistent synchrony with the environment* which after all should enhance mission effectiveness (pursuit of food, mating, and evasion in the case of animals). According to this hypothesis, not only the controller, but also the actuator and the sensor must follow similar dynamics as given essentially in (11.1)–(11.3). We have shown that the actuator does indeed follow laws similar to olivo-cerebellar dynamics [11.15]. It has been shown that it is beneficial for a UUV if olivo-cerebellar dynamics is a common principle of the three elements of the platform. In [11.28], it is shown that an integrated design accelerates homing if we build-in 10–15% of handedness.

Nonlinear Sensing as a Theoretical Requirement of Autonomy

Nonlinear acoustic sensing is another piece of the autonomy puzzle which however is the least developed of the three components, namely sensor, actuator, and controller. Most hydrophones are based on linear vibration of transducers which require lines of them for improved aperture. In [11.35], an alternative theoretical foundation is given based on nonlinear LCO of tiny three-dimensional transducer elements. (These are similar to cilium sensors – widely used by animals.) This transducer has a built-in disturbance rejection (of vibration, e.g.) property. Furthermore, by the use of the property of metachronism in a cluster of such nonlinearly oscillating transducers, acoustic sensing methodologies can be miniaturized and aperture can be increased.

The above rationale for the integration of actuators, controllers, and sensors, together with the need to develop nonlinear oscillatory versions of these three individual systems, gives a mathematically founded basis of autonomy.

11.3 Description of Biology-Inspired Vehicles of Emergent Maturity

Tables 11.2 and 11.3 summarize the salient features of the more mature bio-inspired and bio-mimicry vehicles, respectively. Brief descriptions of the bio-inspired vehicles and sample results are presented in Figs. 11.3 through 11.6. Table 11.4 summarizes the salient features of the engineering controllers (i. e., PID gain, adaptive, or cascading controllers) and olivo-cerebellar controllers that were crucial to demonstration of the low-speed maneuverability of the bio-inspired vehicles.

Figure 11.3a shows the first generation of the six-finned cylindrical BAUV; Fig. 11.3b shows the BAUV mated with a dolphin-inspired interaural time-differencing bio-sonar; and Fig. 11.3c presents representative results showing the tracks of the vehicle maneuvering around obstacles while pointing the bio-sonar at the target; these experiments were carried out in an acoustic test facility.

Figure 11.4a is a schematic of a cable with sensors (such as hydrophones and accelerometers) held taut between two flapping fin propulsion units. Figure 11.4b is a photograph of the components inside the self-propelled line array (SPLINE) hull. Figure 11.4c shows the cable being turned around a pole by one propulsion unit, while Fig. 11.4d gives representative measurements of turn radius, which can be held constant as desired.

In the meta analysis in Fig. 11.1, the trend line of the cruise data of the very large engineering vehicles and the red muscle data of the animals like sharks converge for displacement volumes from 0.01 to 1.0 m^3, although the force production mechanisms are different – steady-state lift properties of fixed blades in the former and pinned-LEV type modified dynamic stall of flapping fins in the latter. Based on this cue, a propulsor was

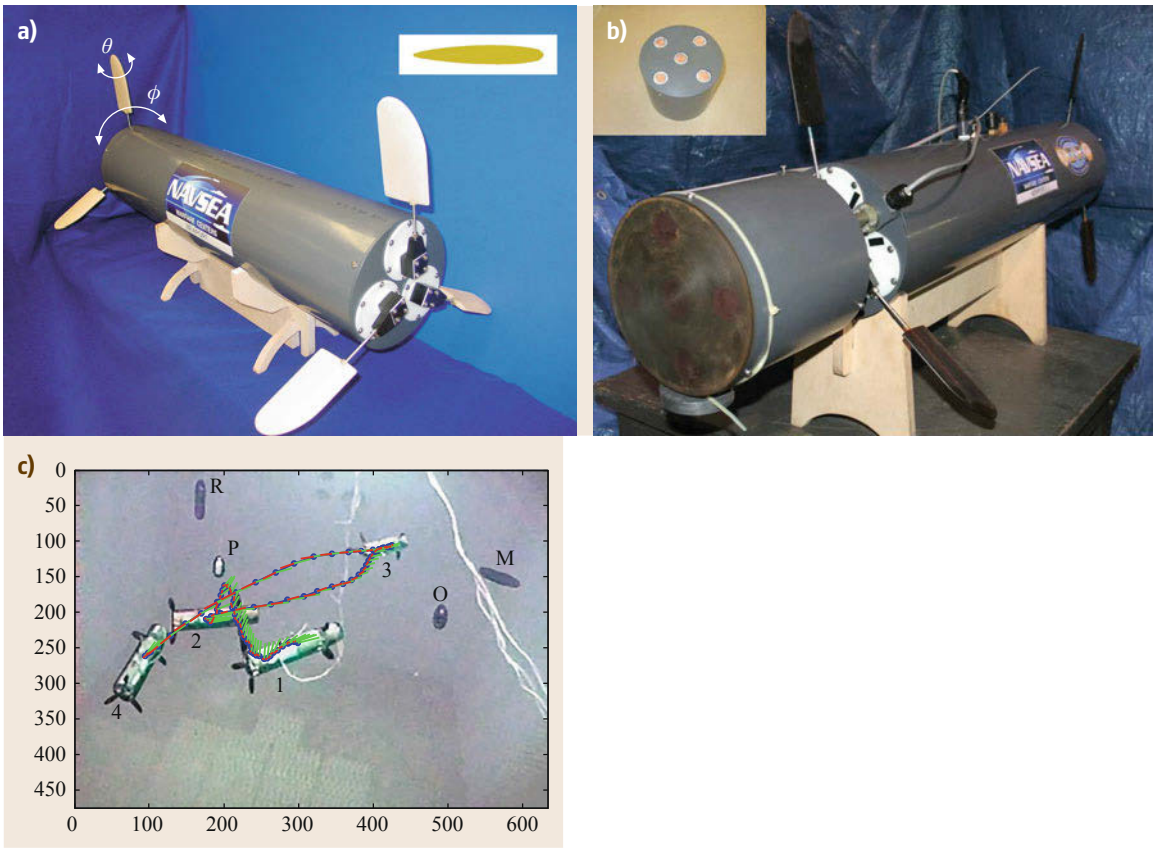

Fig. 11.3 **(a)** Photograph of BAUV, the first generation of the NUWC six-finned bio-inspired UUV. The inset shows the fin section (after [11.19]); fin pitch (θ) and roll (ϕ) oscillations are shown. **(b)** BAUV mated with approximated *bio-sonar* in front; inset shows the four (interaural) receivers and the central transmitter of the bio-sonar (after [11.36]). **(c)** Bio-sonar mounted BAUV navigating (1–4: increasing time) obstacles (M, O, P, R) in the NUWC Acoustic Test Facility (after [11.36]); water tank size: 10.6 m (depth) × 12.2 m × 18.3 m; axes: in pixels

Table 11.2 Summary of more mature bio-inspired underwater platforms

Platform name, institution, figure, and reference	Mission, purpose, comments	Typical dimensions	System and instrumentation	Biology principle, and modes of operation	Comparative performance statement with respect to conventional technology	Future work
BAUV, NUWC, Fig. 11.3 [11.19]	Exploratory development of flapping fin propulsion and olivo-cerebellar control technology	Cylindrical hull length 0.91 m, diameter 0.22 m; fin chord 7.5 cm, span 15 cm	Dolphin-inspired interaural time-differencing bio-sonar; depth sensor; onboard power source and data storage	Flapping fins: low-aspect ratio fins hinged at one end, pitches at 1/3rd chord from leading edge; LEV high lift (pinned-LEV type modified dynamic stall). Control: (a) olivo-cerebellar dynamics control – self-regulating dynamics (LCO); or (b) PID control using synthesis of cycle-averaged fin forces	Exquisite hovering and low-speed maneuverability; low cruise drag at low forward speeds; propulsion power/displacement is shark-like; more efficient than cross-tunnel thruster-based design	Mission-driven self-exploration of optimal maneuvering with olivo-cerebellar dynamics
SPLINE, NUWC, Fig. 11.4 [11.14]	Exploratory development of self-propelled line array concept of persistent surveillance	Cylindrical hull length 1.57 m, diameter 0.2 m; fin chord 9 cm, span 21 cm; cable length between propulsion units 7.3 m	Depth sensor, compass, inertial navigation unit, tilt sensor, line array tension load cell; onboard power source and data storage	Flapping fins: LEV high lift (pinned-LEV type modified dynamic stall); control: PID gain, adaptive, or cascading control using synthesis of cycle-averaged fin forces	Hovering and low-speed maneuverability; low cruise drag at low speeds; propulsion power/displacement is shark-like [11.3], Fig. 11.1; more efficient than cross-tunnel thruster-based design	Station-keeping in highly disturbed environment (high sea states)

Table 11.2 (continued)

Platform name, institution, figure, and reference	Mission, purpose, comments	Typical dimensions	System and instrumentation	Biology principle, and modes of operation	Comparative performance statement with respect to conventional technology	Future work
RAZOR, NUWC, Fig. 11.6 [11.8, 37, 38]	Multimission expeditionary autonomous UUV; harbor defense including swimmer interdiction, bottom surveys, hull inspection, and search, classify, and map missions with 360° sensor coverage of target; payload $> 0.0566\,m^3$; 100 m depth rating	Delta hull; modular design; overall length 1.7 m × depth 0.27 m × 0.76 m wide plus fin span; rear thruster; four rigid fins; two-man portable	Streaming of actuated imaging sonar and video camera; interdiction devices; radio frequency (RF) antenna, camera and global positioning system (GPS) on mast; depth sensor, doppler velocity log (DVL), inertial measurement unit (IMU), onboard power source, and data storage; onboard and tethered programming; field replaceable energy, endurance 6–20 hr with one-three batteries (1.5 kW/hr/tolerant lithium battery); WiFi 54 Mbs secure	Flapping fins: LEV high lift (pinned-LEV type modified dynamic stall); control: (a) hovering and low speed: PID control using synthesis of cycle-averaged fin forces; (b) higher speed: rotational speed control of conventional rotating propulsor; hull planform and fin layout bear similarity to turtles [11.39] but for the rear propulsor, the antenna, and the launch tubes	Exquisite hovering and low-speed maneuverability; more efficient than cross-tunnel thruster-based design; energy efficiency over conventional means of propulsion	Development of controller that transitions from flapping fins to rotating propulsion
SLOSHER, NUWC, Fig. 11.5 [11.40]	Platform mobility	Without shroud: NACA 0012-34 section fin chord 7.5 cm, 16 cm span, abstracted penguin wing planform; with shroud: 0.29 m internal diameter 7.5 cm chord shroud with 7.5 cm chord 8.9 cm span similar fin section	Power diagnostics for efficiency tracking	Fins can flap (roll and pitch) or spin as commanded; flapping fins: LEV high lift (pinned-LEV type modified dynamic stall); spinning fins: steady-state fin lift properties	Sloshing mode at hovering and low forward speeds complements high forward speeds with spinning mode	Simultaneous rolling, pitching, and twisting fins; vectored thrusting; integration with olivo-cerebellar dynamics controller

Table 11.3 Summary of more mature underwater platforms based on bio-mimicry

Platform name, institution, and reference	Mission, comments	Typical dimensions	System and instrumentation	Biology principle	Comparative performance statement with respect to conventional technology	Future work
Robotuna MIT [11.22, 23]	Purpose: Study of fish swimming in controlled manner; appears to support Gray's paradox that the drag of the swimming Robotuna (with oscillating tail) is less than that of the straight (that is, non-flapping, rigid) Robotuna	Seeks to mimic full scale fish: 70 km/hr; skipjack tuna (0.91 m × 35 lbs) – Blue fin tuna (4.27 m × 680 kg); Robotuna: six brushless DC servomotors, pulleys, and cable tendons drive eight discrete rigid vertebra; skin: *thin layer of flexible reticulated foam covered by a conformal Lycra sock*	Not available	Flapping caudal fin propulsion; flexible body shaped as Giant Dania; a wave of variable amplitude passes from nose to tail for propulsion	Directly demonstrated fish thrust production mechanism; tuna form has scalability	Burst of acceleration; fast start; understanding of hydrodynamic mechanism, reduction of power consumption due to the robotic drive; Robopike and GhostSwimmer are derivatives
Finnegan MIT [11.39]	Purpose: explore fin-based swimming in turtle-shaped vehicle configuration; 10 m depth operation	2 m × 0.6 m × 0.5 m; foils protrude 0.4 m from each side, 0.1 m average chord	Onboard power source and data storage; preprogrammed mission; inertial navigation; modified Rodrigues parameter linear control algorithm; open loop control; navigation sensor; pressure sensor; Doppler velocity logger	Mimics turtle; four flapping rigid fins for propulsion appended to a rigid turtle-like hull; linearized engineering control	Improvement in maneuverability by reduction in stability; banked and twisting turns (assisted by hull shape); exceeds turning performance of AUV by a factor of two; minimum turn radius = 0.7 times body length	Not available
GhostSwimmer Boston Engineering Corp. [11.21]	Reconnaissance; hull inspection; oceanographic mission	See Robotuna above	Compact electronics compared to that in Robotuna	Dorsal, pectoral, and caudal fins; flexible body shaped as blue fin tuna;	Small radius turning ability	Efficient actuation of flexible surface, speed enhancement

conceived where the blades could both flap and spin as needed. Figure 11.5a is a photograph of such a novel propulsor where the blades can spin as in conventional propulsors while holding the pitch angle fixed, or the blades can slosh (roll and pitch represented by ϕ and θ, respectively). Figure 11.5b shows the internal blade motor drives and controller housed in the hub. This version of the propulsor also shows a shroud normally used for reduction of acoustic radiation. In the configuration shown in Fig. 11.5a, the shroud is not present and the blades have a boundary layer fence on both sides near the tip. Figure 11.5c shows that thrust can indeed be produced in the spinning and sloshing modes – lower levels of thrust in the sloshing mode and higher levels in the spinning mode.

Figure 11.6a is an outer view of the RAZOR vehicle, and Fig. 11.6b is the RAZOR vehicle mated with the dolphin-interaural spacing bio-inspired sonar shown in Fig. 11.3b. This vehicle has undergone an extensive outdoor capability demonstration (Table 11.2 and Sect. 11.5).

Of the seven biorobotic platforms and devices in Tables 11.2 and 11.3, three disparate platforms – namely, the SPLINE, RAZOR, and GhostSwimmer – are more focused on missions. Judging from this small but varied sample, tentatively speaking, *uncommon low-speed mission in disturbed environments may be the forte of biorobotics* (these vehicles remain to be tested in challenging currents and sea states; Sect. 11.5 lists maneuverings that can be termed uncommon because regular UUVs propelled by rotating propulsors alone cannot undertake those motions efficiently and with minimal disturbance input to the water). Review of the controllers in Table 11.4 indicates that the self-referential phase reset (SPR) mechanism of olivo-cerebellar dynamics may have yet unexplored far-reaching potential in precision station-keeping and platform stabilization; this might facilitate the mat-

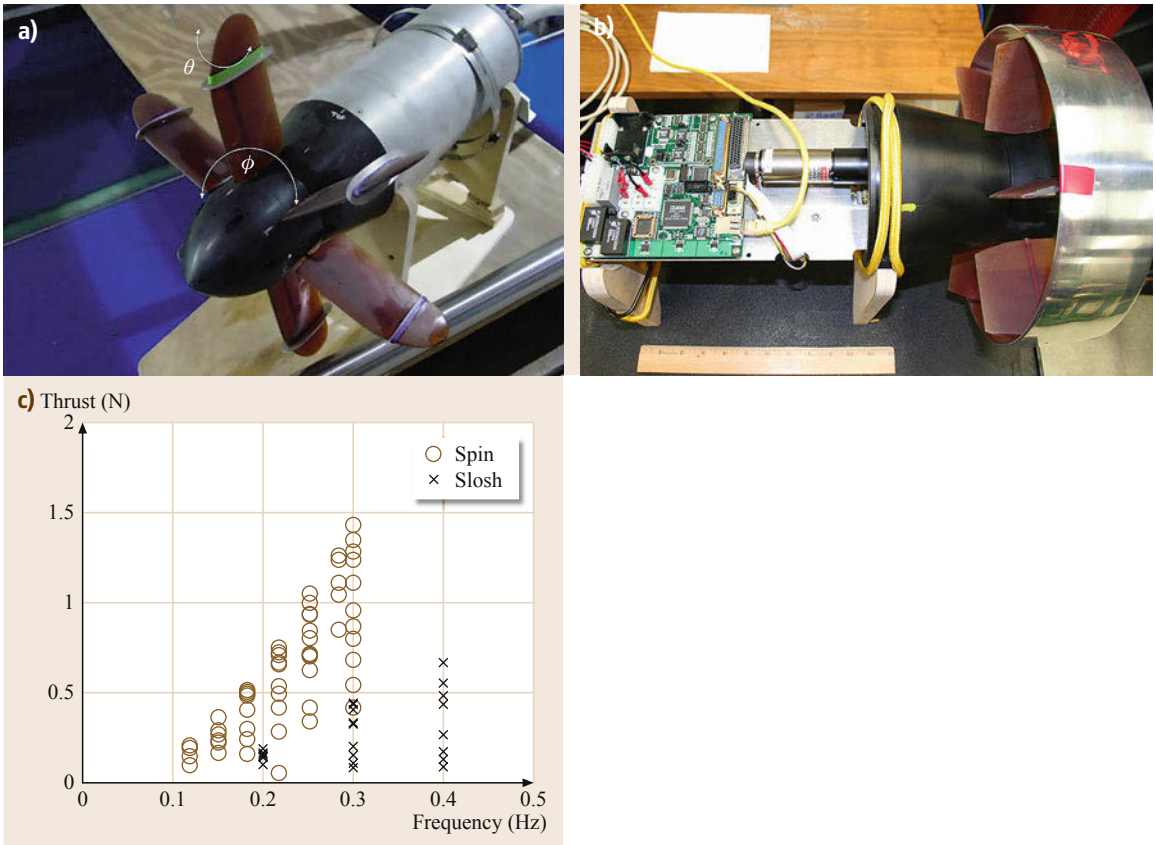

Fig. 11.5a–c Photographs of the slosher propulsor **(a)** and internal motor and controller **(b)**. Note the boundary layer fence in each blade in **(a)**. The shroud in **(b)** was not used in the experiments. **(c)** Thrust measurements when the fins are spinning, or sloshing (after [11.40]). The blade roll (ϕ) and pitch (θ) oscillations in the sloshing mode are shown in **(a)**

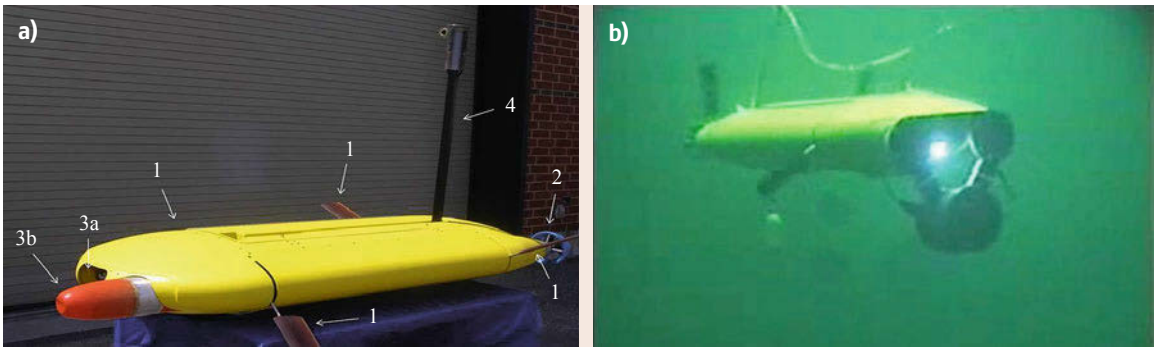

Fig. 11.6 **(a)** Photograph of the two-man-portable RAZOR. *1* – flapping fins, *2* – conventional rotating propulsor, *3a* – launch tube, *3b* – payload, and *4* – 0.76 m-long antenna). **(b)** RAZOR swimming with the approximated bio-sonar and front illumination (after [11.8, 37, 38])

ing of the platform with three-dimensional close-range sectional diagnostics of the target. Overall, the trend is what it should be for UUVs – that is, to provide a low-noise stable platform, in a disturbed environment, that can bring sensors in proximity to the target and make precise observations to assist bigger decision making – and, of course, do so in an autonomous manner.

11.4 Reliability, Low Power Consumption, and Disturbance Rejection of Bio-Inspired Propulsion

The six-finned SPLINE propulsor was operated in a water-filled tank held in position while pulling a fishing line. The line tension and energy consumption were recorded and are shown in Fig. 11.7. Nearly 450 h of continuous run is shown. The hull is capable of carrying the required batteries. The SPLINE propulsor has the ability to loiter at low speeds for several weeks.

The BAUV is a 40 W propulsor and the SPLINE is a 23 W propulsor. The extraordinarily low power consumption was further demonstrated by the trickle charge harvesting experiments described in [11.41, 42]. An electronic circuit was built to harvest very low levels of power available from benthic microbes in littoral basins. Power is stored in 58–450 F capacitors. Operation was automated, and once the capacitors were fully charged, the SPLINE propulsor fins were activated. The 58 F capacitor was able to operate the propulsor for 165 s in a tidal basin. While this is not a long duration, the amenability of bio-inspired propulsion to renewable energy sources opens up unconventional concepts of persistent autonomous operation in the littoral basin for discussion.

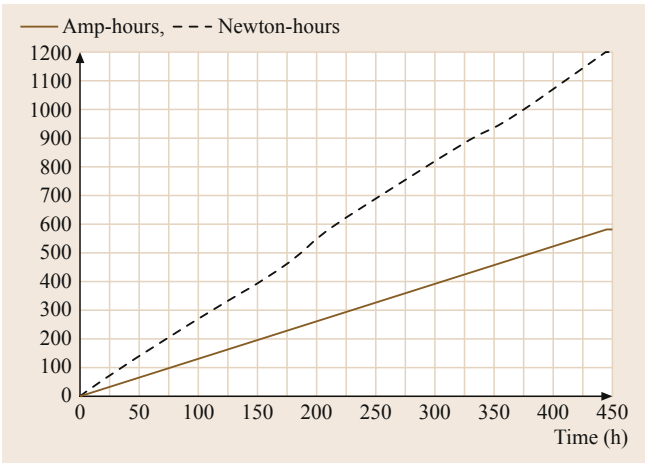

Fig. 11.7 Total energy consumption and cumulative force produced in the SPLINE propulsor, indicating long duration reliability

An experiment was carried out by driving the flapping fin roll and pitch oscillations using a van der Pol oscillator [11.33]. The fin was oscillated near the natural frequency of oscillation for maximum efficiency. The fin roll and pitch oscillation states exhibited a LCO. An artificial electrical disturbance (a square wave) was abruptly applied to the fin to dislodge it from the set LCO; this produced large levels of transient forces, causing the fin to visibly go off track momentarily (see video in [11.33]). Although no sensor was used and no error from the reference was estimated, the thrust force and fin motions autonomously returned to the states of the limit cycle after the disturbance was removed. This experiment demonstrated that a platform in which the actuator, controller, and sensors are integrated by the self-regulation principle (as discussed in Sect. 11.2) will be autonomously robust. *We therefore posit that autonomy in animals is a consequence of the self-regulation property of nonlinear oscillators and biorobotic platforms also need to have self-regulation property.*

11.5 Demonstrated Maneuverings of NUWC Bio-Inspired Vehicles

The NUWC bio-inspired vehicles have demonstrated a variety of precision maneuverings, as listed below. Video recordings of these maneuvering motions have been made and their precision has been determined. (Listed movement precision is in cm.) The unpublished video recordings of the maneuverings are available from the author.

11.5.1 BAUV

1. Near zero meter radius clockwise and counterclockwise horizontal plane turning [11.19]
2. Parallel parking in a narrow rectangular side chamber offset from a straight tank
3. Continuous pitch up and down motion keeping vehicle center at the same location [11.19]
4. Cruising broadside in a narrow tank with minor clearance between BAUV ends and tank walls
5. Cruising while remaining yawed
6. Cruising on water surface remaining partially submerged
7. Cruising, braking, and then making soft landing on tank floor
8. Making soft takeoff from tank floor and resumption of cruising
9. Braking after cruising
10. Swimming to commanded depth and holding that depth
11. Attaching and detaching of suction cups on walls [11.43]
12. Swimming among obstacles while pointing sensors at targets [11.36].

11.5.2 SPLINE

1. Tension and position control of a fishing line or cable [11.14]
2. Simultaneous tension and position control in a fishing line or cable [11.14]
3. Swimming of a 7.3 m-long cable to commanded depth, using two SPLINE propulsors, one at each end of the cable
4. Turning of a short-length cable while holding it taut and maintaining depth in a shallow water tidal basin [11.14].

Demonstrations (1–3) were carried out in large laboratory tanks; number of propulsors: one in one end only in (1–2, 4), and one at each end in (3).

11.5.3 RAZOR

1. Cruising and remotely operated vehicle (ROV)-like maneuvering, including hovering and station-keeping
2. Numerous demonstrations of underwater and surface maneuverings carried out in Narragansett Bay, RI, in more realistic mission environments than is possible in the laboratory.

11.6 Discussion

Exploratory transitioning to utility is a filtering process applied to basic research. The material in this chapter and the papers on the underlying science [11.9, 11, 12, 15] indicate the steepness of the transition pyramid, most being eliminated quickly. Anecdotally, the transition process of underwater vehicles appears to have attained greater maturity than that of flying vehicles, if non-biology-based micro air vehicles are excluded.

The section on integrated design principles shows how disturbance-rejecting nonlinear sensing, which is currently a large gap, should be built. In view of the infancy of nonlinear sensing, we are far off from the full potential of what biology-inspired integrated platforms can offer.

In our experience, the research that transitions to utility is that where understanding is developed to the extent that a mathematical formulation of the mechanism is possible. In our design and control, scaling laws and an understanding of the cycle-averaging process have been found to be useful. To develop reliable control laws, we have experimentally calibrated full-scale actuators in the operational range whenever possible. We have not used any computational fluid dynamics because, in practice, it is postdictive and not predictive.

The value of actuator materials such as strong artificial muscles has been emphasized in the past for actuation of shape deformation of animal-like propulsors [11.7, 44–48]. However, ionic polymer, or the much heralded carbon nanotechnology is yet to make an impact on platforms of 1 m scale.

The Naval utility of platform-length scales much smaller than 1 m has not been demonstrated. This may be due to boundary between the strengths of feasible actuation that is stiff versus highly flexible. System considerations indicate that some approaches such as jets (of squid) are inherently inefficient compared to flapping fins (of fish which impart more momentum to the water without the constraint of internal bladder size) and cannot be scaled up (the oxygen consumption rate of squid is five to seven times higher than that of fish) [11.49]. Furthermore, it does not seem to be useful to develop approaches that are vulnerable to saltwater corrosion and blockage due to biological growth, which always accompanies prolonged exposure to a natural oceanic environment. Caution is in order because, based on past experience of underwater research at NUWC, in some cases extrapolation of developments from clean water to oceanic environments can be fatal.

By many accounts, the NUWC flapping fin propulsion and control technology has matured. These technologies have been built in *affordable* modular form that is detachable/attachable to a platform. Future prospects include their evaluation for stabilizing (and recovering) platforms in distress and in high sea states, or for tautening towed cables. Future interest in biorobotics would be sustained if its mission value is continuously demonstrated to the users and if it is combined with conventional approaches. In basic research, an assessment needs to be made to identify the nagging obstacles to the development of strong muscle technology. In biorobotics basic research, integration of the SPR mechanism with flapping fins needs to be generalized. The results in Figs. 11.2 through 11.7 indicate that in the current stage of maturity, biorobotics is straddling between the laboratory and near-shore open waters.

11.7 Concluding Remarks

UUVs have wide-ranging naval utility. They are the main work horse for unmanned missions, and their long range, versatile payload capacity, and operational envelope offer advantage and value in many naval applications. However, our studies have documented that a large gap in turning ability exists between fish and tactical scale UUVs [11.50]. Advances in digital control have not been able to close this gap. As a result, the gap has been attributed to differences in the hydrodynamic mechanism of lift production – lift production in steady fins versus that in flapping fins – that is, attached fin flow versus pinned-LEV type modified dynamic stall. At NUWC, we have proceeded to implement the high-lift mechanism of flapping fins to naval utility in hovering and low-speed maneuvering, while others have proceeded to mimic swimming animals. These approaches to the development of biology-inspired UUVs have been reviewed by filtering those that we believe have matured the most.

The low-aspect-ratio, rigid flapping fin has been found to be the most successful actuator in the biology-inspired UUVs. We have also been able to mate the flapping fins to rigid cylinders – the most widely used underwater hull form, and also to noncylindrical sections.

Maneuverability and controllability have been demonstrated in both bio-inspired and bio-mimicry UUVs. Mission concepts, duration, payload capabilities, and sensor integration have been demonstrated, and the former type of UUV appears to be somewhat more advanced than the latter. A six-finned cylindrical UUV has demonstrated long-duration reliability, performing incessant swimming for nearly 3 weeks with low power consumption (Fig. 11.7).

While conventional PID controllers have been successfully developed for use with flapping fins, which produce oscillatory forces, control of the instantaneous unsteady forces due to flapping fins using olivocerebellar dynamics should make the UUVs more animal-like [11.24–26, 33, 51, 52]. This would give a more logical foundation to the integration of nonlinear sensors and would also make the UUV controller robust and most responsive to unsteady environmental disturbances. Autonomy is theoretically described as a consequence of the self-regulating property of nonlinear oscillators.

To date, significant progress has been lacking in the development of strong artificial muscles [11.44, 47, 48, 53, 54] and nonlinear sensing [11.35] for underwater application. When these developments move forward, their integration with flapping fins controlled by olivo-cerebellar dynamics would lead to radically new naval precision and other capabilities.

11.8 Nomenclature

A	Amplitude of fin oscillation
$C_{x,\mathrm{wing}}$	Coefficient of axial thrust in a single flapping fin [11.15]
F	Cubic polynomial function
F'_x, F'_{xo}	Instantaneous fluctuating force and force amplitude, respectively
f, ω, ω_s	Frequency of fin oscillation
G, T	Constants
I_{Ca}, I_{Na}	Factors driving depolarization level of inferior-olive neuron
$I_{\mathrm{exti}}(t)$	External stimulus
k	Factor that sets a relative time scale between the uv- and zw-subsystems
p_{iu}, p_{iz}	Nonlinear functions of u_i and z_i, respectively
R_{avg}	Average fin radius
$\mathrm{Re_c}$	Fin chord (c) Reynolds number Uc/υ
St	Strouhal number of a flapping fin, $\mathrm{St} = \frac{2f\phi_0 R_{\mathrm{avg}}}{U}$
U, U_{wing}, U_t	Cruise speed, wing speed, and total forward speed
u_i, v_i, z_i, w_i	States of oscillator i
α	Effective fin angle of attack considering fin–wake coupling
α_g	Geometric fin angle of attack (excluding fin–wake coupling)
Γ_i	Limit cycle orbit
$\varepsilon_{\mathrm{Ca}}$, $\varepsilon_{\mathrm{Na}}$	Factors controlling oscillator time scale of oscillation of inferior-olive neuron
$\theta(t)$, θ_o, θ_{Bias}	Pitch at time t, pitch amplitude, and pitch bias angle, respectively
$\xi(t)$	Combined roll and pitch angle
$\tau_\mathrm{w}(t)$	Temporal local wall-shear stress on the flapping fin surface
$\phi(t)$, ϕ_o	Roll angle at time t and roll amplitude, respectively
ψ	Phase difference between roll and pitch oscillations

12. Autonomous Underwater Gliders

Scott A. Jenkins, Gerald D'Spain

This chapter discusses the characteristics, design considerations, and performance of autonomous underwater (UW) gliders. These buoyancy-propelled, winged vehicles can be categorized as: (1) *profiling gliders* that traverse in bobbing trajectories to collect vertical profiles of ocean properties and (2) *cross-country gliders* designed for point-to-point horizontal transport efficiency. Horizontal transport efficiency is quantified by net transport economy and specific energy consumption. The latter metric for a glider is equal to its inverse lift-to-drag ratio (also called *finesse*) and is equivalent to the glide slope in steady-state, nonturning glides. Increases in efficiency can be obtained by:

1. Increasing the loaded mass (with larger buoyancy engines) and increasing the overall size of the glider, which increases the glider's speed and maintain sufficiently high Reynold's numbers to avoid the drag crisis.
2. Reducing the ratio of the total vehicle wetted area to wing area, via use of flying wing or blended wing body shapes, and
3. Increasing the wing aspect ratio, within structural strength and stiffness limitations.

Gliders have an intrinsic advantage in transport efficiency over conventional prop-driven autonomous underwater vehicles (AUVs) due to the simpler vortex dynamics of a wing versus a propeller. As a result, gliders can fly cooperatively with other winged vehicles or employ multielement wings to further improve transport efficiency. Although a glider must change depth to move forward, these depth changes not only allow the collection of vertical profiles of ocean properties, but also enable the extraction of energy from the ocean's vertical temperature gradients (*thermal glider*).

12.1 Concept

The underwater (UW) glider is a buoyancy-propelled, winged vehicle, analogous to a glider in air. The mechanical power of locomotion needed to overcome the drag on the vehicle as it moves through a fluid medium is supplied by gravity in the form of net buoyancy (positive or negative). Horizontal motion using the vertical force of gravity is made possible by the action of lift produced by a wing that acts perpendicular to the trajectory of the vehicle. Therefore, horizontal translation only occurs when the flight path is inclined at a glide angle (Fig. 12.1) that deviates from the horizontal plane in the direction of the vertical net force of gravity (upward for a positive net buoyancy and downward for negative net buoyancy). Inclination of the flight path along some glide angle allows the net hydrodynamic force of lift and drag to balance the net buoyancy in steady-state flight. The inclined flight path that produces this force balance also gives rise to a net vertical motion.

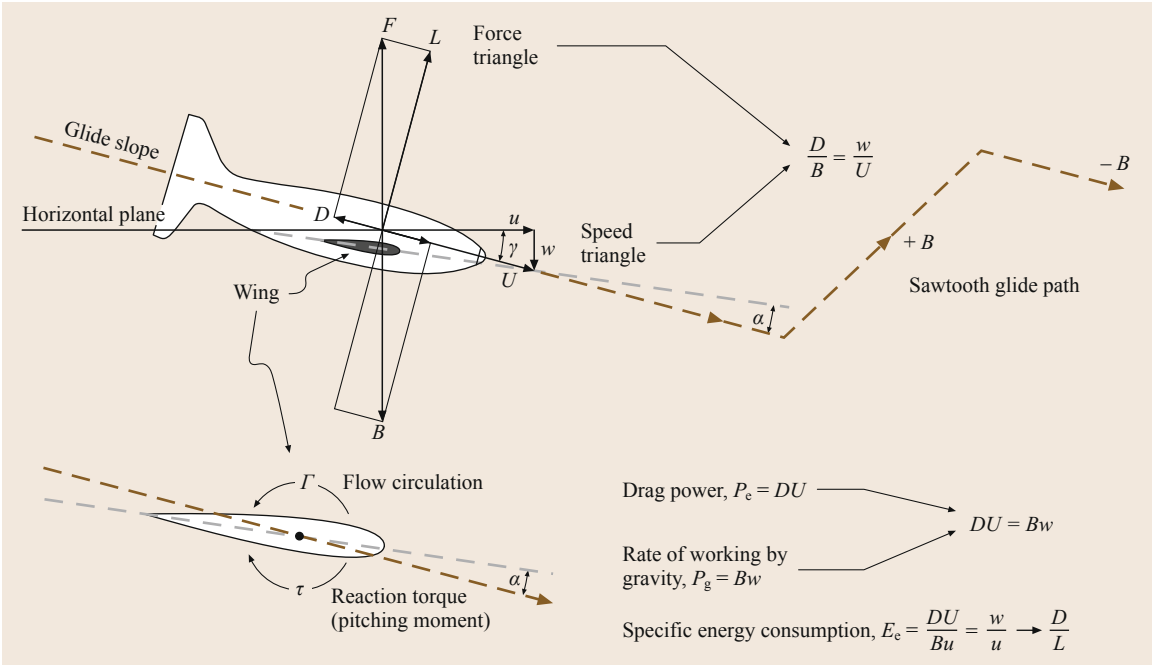

Fig. 12.1 Force balance and energetics for sawtooth glide path (after [12.1]). B = net buoyancy, L = lift, D = drag, F = resultant of lift and drag, u = horizontal speed, w = vertical speed, U = glide speed = magnitude of resultant of horizontal and vertical velocity, Γ = flow circulation, τ = pitching moment that is a reaction torque to the flow circulation, γ = glide angle from the horizontal, α = angle of attack, γ–α = pitch angle

Although analogous, a few differences do exist between air and underwater gliders. First, whereas an airborne glider only executes descending glides, and therefore must create lift only in the upward direction, a UW glider flies ascending as well as descending glides. In order to change the buoyancy between descending and ascending glides, a UW glider must be equipped with a buoyancy engine (Fig. 12.2) that effectively changes the displaced volume of the glider (equivalent to a change in average density for constant mass). This requirement to change the direction of lift – from upward on descending glides to downward on ascending glides – places constraints on the wing design (fixed camber usually is not designed into the wings of UW gliders) and additional demands on vehicle flight control. It also results in some interesting effects; for example, to turn to starboard, an ascending glider must bank to port, opposite the direction of a descending glider. These changes in buoyancy for an underwater glider occur about the point of neutral buoyancy, where the dry bulk weight is balanced by the weight of the water displaced by the vehicle. Therefore, the weight of an UW glider's loaded mass (its net buoyancy) can be remarkably different than its dry bulk weight, whereas these two weights are nearly the same for platforms in air. Another difference in flying in air versus underwater is the stability of the fluid medium. The troposphere, the lowermost 10 km of the earth's atmosphere, is a convective boundary layer with warmer, less dense air underlying colder, denser air. The resulting convective overturn causes turbulence which can make controlled flight very challenging. In contrast, the ocean is stably stratified for the most part, so that once an UW glider is traveling on its desired heading, very little additional flight control is required.

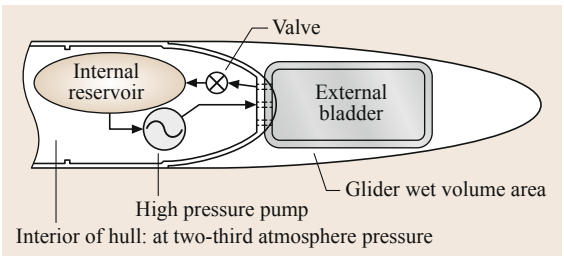

Fig. 12.2 Closed-loop oil-based buoyancy engine (after [12.2])

Underwater gliders originated in the early 1960s with the *Concept Whisper*, a prototype 2-man swimmer delivery vehicle (SDV) built by General Dynamics Corporation [12.5]. A prototype of Concept Whisper was built and tested in shallow dives in San Diego Bay in 1964. Concept Whisper was a classified project

and for several decades, nothing of its concepts and testing was known to the outside world. In the 1970s, analysis of the energetics of UW gliders and an evaluation of various applications was performed at the Naval Electronics Laboratory. At the end of the 1980s, *Stommel* independently proposed a fleet of autonomous gliders referred to as *Slocums* to profile the ocean's water properties [12.6]. Shortly thereafter, underwater gliders started being developed into useful sensor platforms as a result of sustained funding from the Office of Naval Research. These underwater gliders were developed and tested primarily for the purpose of profiling ocean water properties, commensurate with the role first envisioned by *Stommel* [12.6], and so are referred to herein as *profiling gliders* (Fig. 12.3).

The profiling gliders include *Spray*, *Seaglider*, and *Slocum* [12.2–4]. All three designs are based on a conventional winged body of revolution. Emphasis was placed on optimizing the performance of the profiling gliders to travel up and down through the water column at steep glide angles to obtain vertical profiles of water mass properties, rather than optimizing for cross country performance as with conventional gliders in air. The profiling gliders also were designed to accommodate the limited deck space available on small oceanographic vessels, and be two-person portable. As a result, all are similar in size and weight; order 2 m in length, 1 m in wingspan, 50 L in total vehicle volume, and operating at a net buoyancy of about 1–3 N. These three types of UW gliders have logged hundreds of at-sea days during a given mission, collecting ocean profiles. When running *down-wind* with western boundary currents such as the Kuroshio or Gulf Stream Currents, they have covered distances of 1000 km and more.

In the latter half of the 2000s, another type of UW glider, referred to as *cross-country gliders*, was developed for long horizontal range, long duration missions of passive ocean monitoring. These gliders have

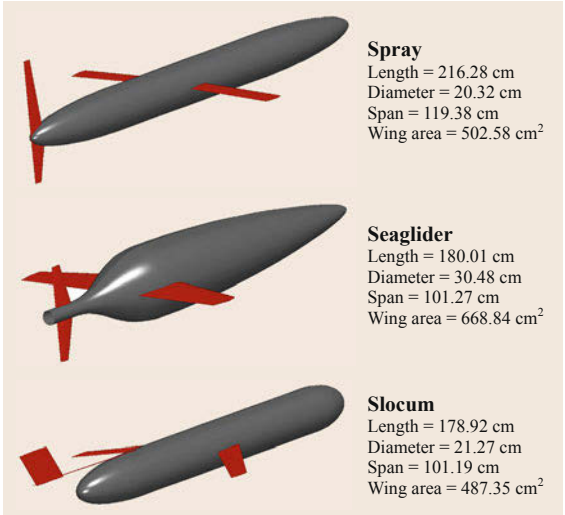

Fig. 12.3 *Profiling* underwater gliders, post *Concept Whisper*. Developed for vertical profiling of ocean water mass properties (after [12.2–4])

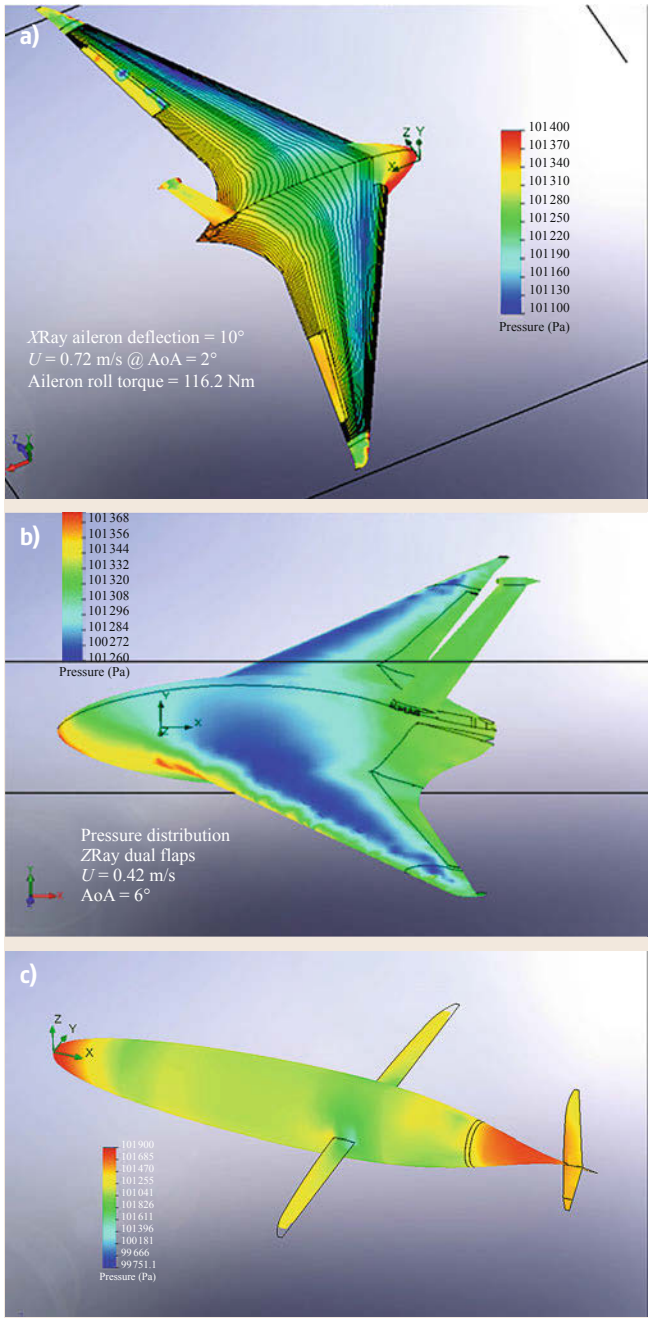

Fig. 12.4a–c Cross-country underwater gliders: Liberdade/XRay **(a)**, Liberdade/ZRay **(b)**, winged body of revolution **(c)**

larger payload and cargo-carrying capacity, and emphasize point-to-point, *cross-country*, transport efficiency. Various designs of these new cross-country gliders have been built and are currently undergoing sea trials, including two examples of flying wings, the Liberdade/XRay and Liberdade/ZRay gliders (Fig. 12.4). The XRay and ZRay designs use a seawater-based buoyancy engine analogous to the ballast system on submarines, while other cross-country glider designs use larger versions of the type of oil-based buoyancy engine diagrammed in Fig. 12.2.

As discussed earlier, underwater gliding is a buoyancy driven form of locomotion in which the power needed to overcome the drag (D) on the vehicle as it moves at a speed U through water is supplied by gravity in the form of positive or negative net buoyancy ($+/-B$). Horizontal translation using the vertical force of gravity is made possible by the lift (L) produced by a wing that acts perpendicular to the trajectory of the vehicle. Inclination of the glide slope from the horizontal gives rise to a horizontal component of lift that provides the force of forward propulsion. In steady-state flight, this force is balanced by the horizontal component of the drag, which yields the relationship that the glide slope is equal to the inverse of the lift-to-drag ratio. The lift-to-drag ratio (L/D) of a wing is also referred to as its *finesse* [12.7]. In the vertical direction, inclination of the glide slope from the horizontal also allows the net hydrodynamic force of lift and drag (F) to balance the net buoyancy in steady-state flight, but implies that a net vertical motion will result, (Fig. 12.1). This vertical motion is referred to as the sink rate (w). During each of the descending or ascending slopes of the sawtooth glide path, the power needed to overcome drag ($P_e = DU$) is equal to the rate of work by gravity acting down (or up) ($P_g = Bw$). Thus

$$P_g = P_e = DU = Bw\,. \tag{12.1}$$

Because the force triangle and the speed triangle in Fig. 12.1 are proportional, the power expenditure per horizontal distance traveled scales in direct proportion to the glide slope ($w/u \approx D/L$), or inversely with the lift-to-drag ratio (L/D). Therefore, by imparting the underwater glider with low drag and high lift properties, its energy consumed to produce locomotion in the horizontal direction can be minimized. In other words, almost all the energy in forward propulsion is consumed at the bottom of the dive cycle where the glider's displaced volume must be increased against ambient pressure. By decreasing the glide slope, i. e., increasing L/D, the number of times this change in displaced volume must occur is minimized for a given horizontal distance traveled.

The *buoyancy engine* generates a variable displaced volume increment, or net buoyancy volume $\pm V_b$; such that the total displaced volume of the glider is $V_d = V_s \pm V_b$, where V_s represents the volume of the glider's rigid body. By varying the net buoyancy volume, the buoyancy engine causes the net buoyancy force to alternate between positive and negative states, $B = \pm\rho g V_b$. Typically, the underwater glider is trimmed to be approximately neutrally buoyant in seawater when $V_b = 0$; so that the average density of the glider approaches the ambient seawater density, $\bar{\rho}_s \to \rho$, and the net buoyancy reduces to $B = \rho g(V_d - V_s) = 0$. In addition to the volume of the glider's rigid body and buoyancy engine displacement volume, the total volume of the vehicle, V_0, also includes void-space water V_{void}, that enters into the freely flooding internal spaces. Thus, the total volume of the vehicle is represented by: $V_0 = V_s \pm V_b + V_{void}$. Because the total vehicle volume is fixed, the void water is a function of the net buoyancy volume, $V_{void} = f(V_b)$, and the hull must accommodate ventilation of the void water with the outside water. Under neutral buoyancy, the total vehicle mass becomes $M_0 = \rho(V_s \pm V_b + V_{void})$. A variety of buoyancy engine technologies have been employed, including closed-loop liquid-based engines [12.2–4] for which buoyancy engine capacity is in the neighborhood of $0.1\% \le V_b/V_0 \le 4\%$; open-loop seawater-based buoyancy engines, as with XRay and ZRay having capacities typically ranging from $1\% \le V_b/V_0 \le 8\%$; open-loop compressed gas-based systems [12.8] having $5\% \le V_b/V_0 \le 20\%$; as well as the open-loop gas-based buoyancy engines that consume gas-generating compounds, such as those used in Concept Whisper [12.5] for which $11\% \le V_b/V_0 \le 28\%$. The profiling gliders use a closed-loop oil-based buoyancy engine as diagrammed in Fig. 12.2, while the cross-country gliders typically use open-loop seawater-based buoyancy engines. The closed-loop liquid-based engines have the disadvantage that the weight of the working fluid (oil) is always onboard, limiting the net buoyancy capacity to about half that of an open circuit buoyancy engine that uses seawater (e.g., as in a submarine buoyancy system). Also, oils can undergo phase changes from liquid to vapor under large decreases in pressure, which can occur in a closed-loop system when the oil is transferred from the external bladder to the internal reservoir to initiate ascent from deep depths. This phase change phenomenon limits the ability to evacuate all of the oil in the external bladder. Regardless, both close- and open-loop buoyancy engines typically are driven by small electric pumps that produce only low levels of intermittent self-noise, ideally suited for passive underwater monitoring applications or those requiring stealthy behavior.

12.2 Hydrodynamics of Wings Versus Propellers

Buoyancy-propelled winged vehicles are intrinsically more efficient than propeller-driven vehicles because the power needed to overcome drag (P_e) is minimized by the simplicity of the vortex system of the wing (Fig. 12.5). From the first law of thermodynamics, P_e is given by the rate of dissipation of the flow kinetic energy as a consequence of the generation of vorticity $\boldsymbol{\Omega} = \nabla \times \boldsymbol{u}$. On a winged vehicle, the preponderance of vorticity is generated during the action of making lift. From [12.11], P_e is given by

$$P_e = \iiint \mu(\boldsymbol{\Omega} \bullet \boldsymbol{\Omega})\,\mathrm{d}x\mathrm{d}y\mathrm{d}z\,, \tag{12.2}$$

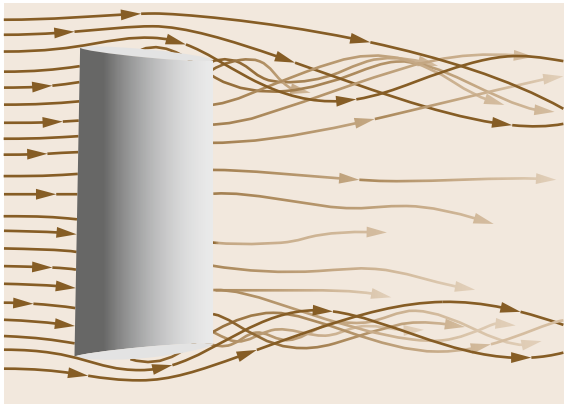

Fig. 12.5 Flow visualization shows the trailing line vortices shed from the wing tips of a constant chord wing as viewed from the top looking downward (after [12.9]). Flow is from *left* to *right*

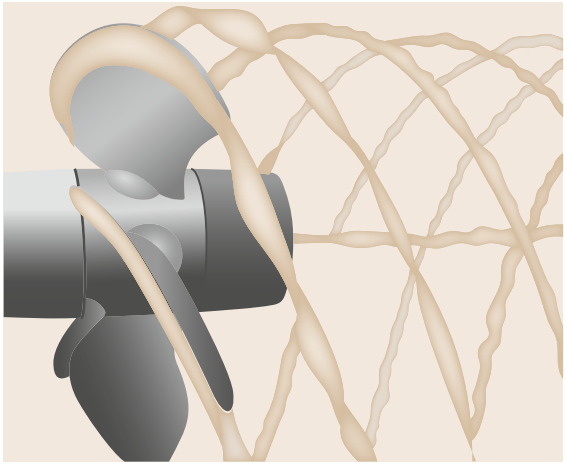

Fig. 12.6 Flow visualization of the trailing helical vortices shed from the tips of a propeller (after [12.9])

where (x, y, z) are the Cartesian coordinates fixed on the wing, with x being the horizontal coordinate in the chord-wise direction, y is the horizontal coordinate in the span-wise direction, and z is the vertical coordinate positive in the upward direction. The quantity μ is the dynamic viscosity, and the flow circulation, Γ, is related to the vorticity induced by a wing with vector airfoil sectional area $\bar{A}$ according to $\Gamma = \int \boldsymbol{\Omega} \bullet \mathrm{d}\boldsymbol{A}$. The vorticity released into the mean flow by a wing is at lowest order one-dimensional (1-D), in the form of a pair of trailing line-vortices shed from the wing tips (Fig. 12.5). In this case, the expression for the power needed to overcome drag reduces to

$$P_e = \mu \iiint \left[\left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}\right)^2\right] \mathrm{d}x\mathrm{d}y\mathrm{d}z \quad \text{(wing)}\,, \tag{12.3}$$

where (u, v, w) are the components of fluid velocity in the (x, y, z) directions, respectively.

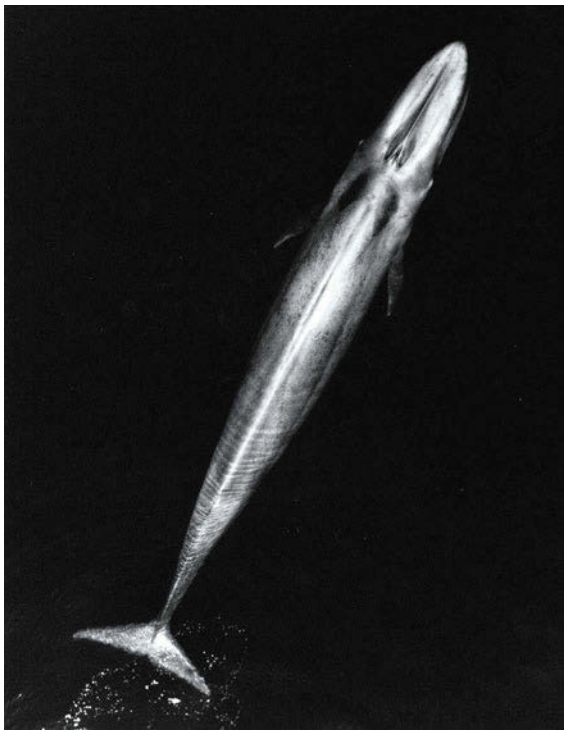

Fig. 12.7 The blue whale evolved winged tails (flukes), not propellers, for propulsion for their annual migrations over thousands of miles between feeding grounds and birthing grounds, as well as for endurance during high-speed pursuits from predators such as killer whales (after [12.10])

In contrast, a propeller is a rotating wing which releases the vorticity into the mean flow. It produces a more complex helical system of trailing vortices imparting swirl to the mean flow (Fig. 12.6). The trailing vortex system from a propeller is fully three dimensional; as a result, the power needed to overcome drag expression contains two additional terms

$$P_e = \mu \iiint \left[\left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \right)^2 + \left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \right)^2 + \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right)^2 \right] \mathrm{d}x\mathrm{d}y\mathrm{d}z \quad \text{(propeller)} . \tag{12.4}$$

From the additional vorticity components in the vortex trail of a propeller comes higher dissipation rates that require greater expenditures of onboard power to maintain a given vehicle speed through the water, U ($= |\boldsymbol{u}|$). The advantage in transport efficiency of a wing over a propeller in water is illustrated nature through the evolution of the propulsion systems for marine mammals, for example the blue whale (Fig. 12.7). Whales evolved winged tails (flukes) not propellers as the basis of their propulsion systems. Natural selection of winged tails did not occur for lack of a joint capable of 360° rotation, as the shoulder joint in primates clearly proves biomechanically viable.

12.3 Underwater Glider Attributes and Limitations

The most compelling attribute of an underwater glider from the point of view of other types of subsurface vehicles is its high endurance/long on-station time capability. This attribute arises because an UW glider can readily operate over its full flight envelope, from top speed to neutrally buoyant (determined by the net vehicle buoyancy created by its buoyancy engine). Therefore, it can conserve onboard propulsion energy by moving as slowly with respect to the surrounding medium as possible while still accomplishing its objectives. In addition, an UW glider has very low levels of self-noise (acoustically, electrically, and magnetically), because self-noise is created primarily by the buoyancy pump that is activated only episodically for short intervals. Once the underwater glider changes its net buoyancy, it can glide silently with no machinery or hydrodynamic noise until reaching the next reversal in the sawtooth glide path. (Again, the ocean's stable stratification minimizes disturbance from turbulence and so minimizes the need for actuating flight controls.) The intermittency of a glider's self-noise is in sharp contrast to the continuous self-noise emissions from propulsion of prop-driven vehicles. Finally, in contrast to prop-driven platforms, winged structures such as UW gliders can fly cooperatively to improve flight efficiency in horizontal transport. This point is illustrated later in this chapter.

The primary weakness of an UW glider compared with other types of underwater vehicles arises from its inability to maintain level flight in the water column – it must change depth to propel itself forward. This weakness actually is a strength when an objective is to collect vertical profiles of ocean properties.

As with all underwater vehicles, an UW glider is vulnerable to damage – from surface ship collisions, harsh weather, and entanglement – while on the ocean surface. For missions that require covertness, the probability of platform detection is also much greater at the surface; all of a glider's stealthy attributes are compromised during surfacing periods. However, wideband, inexpensive (energy-wise, size and weight-wise, and cost-wise), two-way communications can be achieved only after surfacing. In addition, most environmental sources of energy in the ocean – solar, wind, and wave – are available only at the sea surface. Once an underwater vehicle descends below the ocean surface, it must carry onboard all of the energy supplies required to accomplish its objectives (one exception is discussed in Sect. 12.5).

The characteristic of being *autonomous* for any underwater vehicle also imparts certain benefits and limitations. The primary benefit of autonomy is providing the platform with the ability to accomplish useful objectives (collection of ocean measurements, cargo transport, military-relevant missions, etc.) without direct human input. This ability almost always results in large cost savings, and enables transits in areas too dangerous or inaccessible for humans. The major limitation, on the other hand, is associated with this lack of direct human input. Once it leaves the ocean surface, an autonomous underwater platform must have onboard all of the artificial intelligence required to accomplish its goals. Improving the level of onboard intelligence is the primary challenge to future applications in underwater robotics.

Given these attributes and limitations, UW gliders (and autonomous underwater gliders in particular) are capable of performing a variety of functions and missions. These functions can be categorized as follows [12.1].

12.3.1 Depth Unlimited Roaming

In depth unlimited roaming, the glider is not confined to a particular depth regime while transiting cross-country in a deep ocean environment. Often such roaming will require trans-basin round-trip excursions. The Seaglider and Spray are among this functional class, being designed primarily for the role of gathering ocean vertical profiles of water mass properties. Design adaptations for such depth unlimited roaming require some or all of the following capabilities: long range, cruise speeds adequate to penetrate large-scale ocean circulation but otherwise kept to a minimum to conserve onboard propulsion energy, small-to-moderate payload volume, minimized hotel loads, and deep dive capability with neutral hull compressibility.

12.3.2 Depth Limited Roaming

This function requires cross-country capability within a limited depth regime. This constraint arises when operations are required in the shallow water regimes of the littoral zone, or when the vehicle must operate in a prescribed sector of the water column such as a sound channel or avoid penetration across the thermocline. The Slocum has design adaptations for this role such as its piston pump that allows it to rapidly reverse dive direction in close proximity to the free surface or seabed in confined shallow water areas. Useful design adaptations for this role include: flat glide slope (high L/D) which simultaneously maximizes range for a minimum number of dive cycles, high sprint speed capability to penetrate strong coastal currents, small to moderate payload volume, minimized hotel loads, rapid high-resolution pitch and roll response to avoid broaching or grounding in confined depth regimes, adequate flight control authority for suppressing ocean-surface-wave induced flight oscillations, and avoidance measures for fishing trawlers.

12.3.3 2-D Station Keeping

Station keeping requires the ability to maintain position at a prescribed point in the ocean. Other than the case of free drifting in stagnation flow or grounding on the seabed, underwater gliders must execute depth excursions in order to maintain station at a fixed latitude and longitude. Hence, the station keeping ability is two-dimensional (2-D) and is referred to as 2-D station keeping. All three profiling gliders have demonstrated 2-D station keeping, some within a watch circle of several meters for several weeks at a time. Some station keeping roles may require the glider to profile the water column at a fixed latitude and longitude, which might require maximum sprint and dive speed. Other station keeping roles may involve the glider maintaining station in a certain depth regime, which would benefit from the glider having minimum sink rate properties. In all cases, the glider needs adequate cruise speed to penetrate and hold station against ocean currents. In addition, the glider may be required to hold station on the seabed, in which case it must generate sufficient negative net buoyancy and/or have provisions in its hull and wing shape for anchoring against currents. Other vehicle qualities for station keeping would be long on-station capability, small to moderate payload volume, minimized hotel loads, rapid high-resolution pitch and roll response to execute grounding maneuvers or maneuvers near the seabed, adequate flight control authority when operating near the sea surface, and avoidance measures for fishing trawlers.

12.3.4 Payload/Cargo Delivery

The stealthy, high endurance (long distance combined with long duration) capabilities demonstrated by profiling gliders suggest that delivery of payloads and cargo would be logical function when rapid delivery time is not required. Among the most important characteristics for this breed of underwater glider would be the ability to move large payloads/cargo over significant horizontal distances while minimizing onboard energy consumption (i. e., using minimal numbers of dive cycles). Winged structures such can fly cooperatively to improve flight efficiency. Therefore, an UW glider can be equipped with cargo-carrying exterior compartments so that the total is *more* energy efficient in point-to-point transport than the glider alone, as discussed later in this chapter. This function may require both deep water and depth-limited operational capability (high L/D) with adequate cruise speeds to penetrate both large scale ocean circulation and coastal currents. In addition, large payload volume is required along with minimal hotel loads.

12.3.5 Level Flight Hybrids

This concept is posed to compensate for the major limitation of underwater gliders: the inability to maintain fixed depth in forward transit. This *motor–glider* is a glider with an auxiliary motor-driven screw. Prop-driven AUVs typically are ballasted for safety reasons to be slightly positively buoyant and use either vectored thrust or dive planes to achieve level flight. The motor–glider is a more efficient means for accomplishing the same force balance, using the lift from a high aspect ratio wing to provide the compensating trim

forces against buoyancy to maintain level flight. The concept is envisioned for circumstances where operations require short-term burst speed in very narrow depth regimes, or when level flight is required. Level flight capability may be required for proper operation of certain sensors like seafloor mapping sensors. High burst speed over a limited depth extent may be needed for certain avoidance maneuvers or for penetration in strong shallow water currents. This hybrid propulsion system approach provides the basis for a long range, high endurance prop-driven AUV (autonomous underwater vehicle). Design adaptations for this role require many of the same characteristics as depth limited roaming, with the addition of low drag at high cruise speed to maximize prop-powered flight performance.

12.4 Optimal Size and Shape for Horizontal Transport Efficiency

Transport efficiency varies inversely with the cost of locomotion. It is commonly measured in transportation science by *specific energy consumption* or *net transport economy*, which is equal to the energy consumed per horizontal distance traveled for each unit of vehicle weight [12.7, 12]. Specific energy consumption differs from net transport economy in that the former is based only upon the energy expended in propulsion, whereas net transport economy includes all forms of vehicle energy expenditure including the hotel loads (energy consumed by control systems, communications, payload power requirements, onboard data processing, launch and recovery systems, etc.). Similarly, the vehicle weight can be defined in various ways, for example in terms of total dry bulk weight of the vehicle (including payload), $F_g = \bar{\rho}_s g V_s$. In the next part of this section, it is defined as the weight (net buoyancy force) $Mg = B$, due to the loaded mass M applied to a wing (Fig. 12.1). An alternative weight normalization for specific energy consumption considers only that of the payload/cargo, to eliminate any potential bias toward larger underwater vehicles.

12.4.1 Net Transport Economy

Analytic surveys of natural and man-made fliers provide a starting point for identification of present operating regimes of the profiling gliders and rules of scaling to other performance regimes from those gliders. Design surveys in aeronautical design and bio-mechanics has produced a number of useful works for this purpose [12.7, 12–15].

Analytic flight survey literature reveals that a leading order variable controlling regimes of scale is the loaded mass. In an underwater glider, the loaded mass is supplied by the buoyancy engine. The loaded mass (net buoyancy/g) can be used as the normalization factor in the *net transport economy* (NTE)

$$\mathrm{NTE} = \frac{P}{(Bu)} = \frac{P}{(Mgu)} , \tag{12.5}$$

where P is the total time-averaged power consumed by the flier. The net transport economy is dimensionless and smaller values indicate more efficient transport. The dimensionless NTE is commonly compared to the loaded mass in kilograms [12.13]. Figure 12.8 plots NTE over 12 orders of magnitude variation in loaded mass, covering regimes of scale from insects to jet transports. The NTE values in Fig. 12.8 are based on total power consumption P including both the flight power spent overcoming drag ($P_e = DU$) as well as internal power consumption ($P - P_e$), which includes basal metabolic rates in the case of natural fliers and all subsystem energy consumption in the case of man-made fliers (hotel loads). In [12.13] and [12.15], estimates are made of the basal metabolic rates of birds based on the body mass, resulting in an empirical formulation of NTE

$$\mathrm{NTE} = 0.898(Mg)^{-0.227} \quad \text{(Tucker Fliers)} . \tag{12.6}$$

References [12.12] and [12.14] also examined a limited set of data on birds and derived a similar empirical relation

$$\mathrm{NTE} = 0.914(Mg)^{-0.293} \quad \text{(Schmidt–Nielsen Fliers)} . \tag{12.7}$$

These two empirical relations are indicated by the solid sloping lines in Fig. 12.8. The most apparent scale dependent feature of these empirical relations and the NTE data is that the energy consumed per meter traveled decreases as the loaded mass is increased – bigger fliers (greater loaded mass) are more efficient fliers. The profiling gliders presently operating in the range of 100–300 g of loaded mass are overlaid on Fig. 12.8 as a purple triangle. It appears that the profiling gliders are consuming relatively higher levels of energy per horizontal distance traveled than their bird/bat counterparts operating at equivalent loaded mass. Natural fliers are used as a standard for ultimate efficiency because natural selection tends to eliminates all but the most efficient mutations [12.13]. However, several factors

contribute to this apparent disparity in efficiency. First, the profiling gliders were not designed for efficiency in *horizontal* transport, but rather to move primarily up and down to collect vertical profiles of water column properties. For this case, then, a more useful form for (12.5) is to normalize by U, the speed along the glide slope, rather than the horizontal speed u. This change results in the net transport economy values from (12.5) being multiplied by $u/U = \cos(\gamma)$, where γ is the glide angle from the horizontal (Fig. 12.1). Since the profiling gliders are flown at glide angles of 20° to 30°, this factor results in only a 10% reduction in NTE. Second, rather than normalize the energy consumed per distance traveled by the weight of the loaded mass, NTE can be defined by normalizing by the dry bulk weight. Whereas this change in normalization usually has little effect on NTE for fliers in air (dry bulk weight usually is equal to the weight of the loaded mass), it causes a significant decrease in NTE for underwater platforms since the weight of the loaded mass can be remarkably different than the dry bulk weight due to the positive buoyancy of displaced water. Profiling gliders may be intrinsically less efficient relative to birds because of the extra energy that is consumed when gliding through ocean stratification, particularly when crossing the thermocline. Density changes in the ocean water mass cause corresponding changes in net buoyancy B, resulting in additional rate of working by gravity as defined by the right hand side of (12.1). A comparison of NTE for profiling gliders with (purple triangle) and without (yellow square) ocean stratification is provided in Fig. 12.8. Hull compressibility resulting from depth changes in the ocean cause additional changes in net buoyancy and in the work rates by gravity that ultimately factor against the total power consumption of the UW glider. No counterpart to this increment of energy consumption exists for birds flying in air. To minimize energy consumption due to hull compressibility, the optimal design solution is to match the hull compressibility with seawater compressibility. This match has been done on the deep-diving profiling gliders Seaglider and Spray that operate at very low values of loaded mass (net buoyancy), and where even small changes in net buoyancy can be critical to overall net transport economy.

For comparison, the NTE for the 6.2 m wingspan ZRay flying wing glider (presented later in Fig. 12.12), based on energy consumption measurements made at sea, is plotted in Fig. 12.12 as a red circle. Its NTE value of 0.65 is also somewhat above the Schmidt–Nielson Fliers curve, but approaches it if the ZRay payload is removed (NTE drops to less than 0.45).

To further reveal relative differences in efficiency of the flying shapes, *specific energy consumption* (E_e) can be used. It is a transport economy formulation based

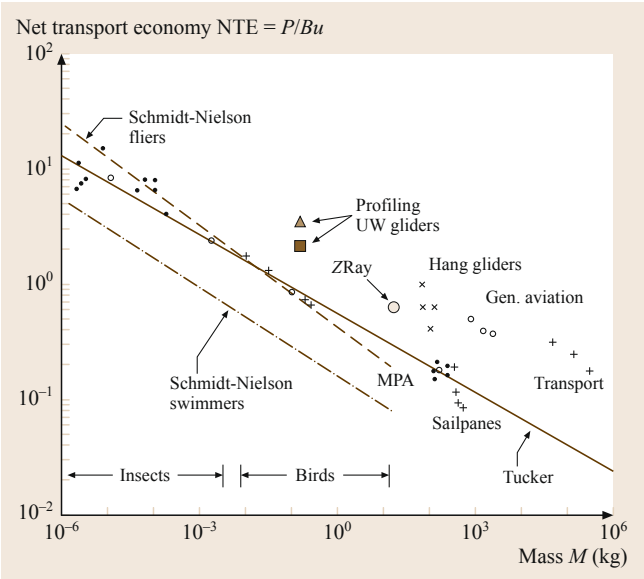

Fig. 12.8 Net Transport Economy (NTE) for natural and man-made fliers (after [12.12]) versus the profiling underwater gliders with (*purple triangle*) and without (*yellow square*) ocean stratification and the ZRay flying wing glider from at-sea measurements (*red circle*). NTE is based on total energy (propulsion plus hotel load and payload) consumption

only on the rate of expenditure of flight energy required to overcome drag ($P_e = DV = Bw$) ([12.7] and (12.1)). Energy is consumed by the buoyancy engine to generate a variable displaced volume increment $\pm V_b$, for forward propulsion. Only the horizontal component of the glide speed, u, results in horizontal distance traveled point-to-point. Consequently, the specific energy consumption (net transport economy) for horizontal transport of an underwater glider is

$$E_e = \frac{P_e}{\rho g V_b u} = \tan\gamma = \left(\frac{L}{D}\right)^{-1} . \qquad (12.8)$$

The glide slope, $\tan\gamma$, is equal to the reciprocal of the lift-to-drag ratio $(L/D)^{-1}$, and provides a physical metric of horizontal point-to-point transport efficiency. In other words, specific energy consumption is minimized by achieving the flattest possible glide slopes. A flat glide slope allows an underwater glider to travel the greatest distance point-to-point for a given number of buoyancy engine cycles. A flat glide slope also enables shallow water operations and other kinds of depth limited applications. Using the conventional quadratic formulation in the β-plane for lift L, and drag D, forces normalized to the wing area A_0 [12.16]

$$L = \frac{1}{2}\rho C_L A_0 U^2 \quad \text{and} \quad D = \frac{1}{2}\rho C_D A_0 U^2 . \qquad (12.9)$$

Here, C_L and C_D are the quadratic lift and drag coefficients, respectively. The drag coefficient is made up of two terms, a profile drag term C_{D0}, that depends on Reynolds number R_e, and an induced drag term C_{Di}, that increases with increasing lift coefficient and decreases with wing aspect ratio, N_R [12.17]

$$C_D = C_{D0} + C_{Di} = K_0 R_e^{-\xi} N_A + K_i \frac{C_L^2}{\pi N_R} . \quad (12.10)$$

In (12.10), K_0 is the profile shape factor, N_A is the ratio of the total wetted surface area to the wing area $N_A = A_t/A_0$, and K_i is the wing plan form factor. The aspect ratio is defined as $N_R = S/\bar{c} = S^2/A_0$ where S is the wingspan and $\bar{c} = A_0/S$ is the mean aerodynamic chord of the glider's wing. The power-law dependence of profile drag is $\xi = 1/2$ for completely laminar, unseparated boundary layer flow over the vehicle, and $\xi = 1/5$ for fully turbulent un-separated boundary layers. In (12.10), the Reynolds number is the size-dependent scale factor $R_e \equiv U\bar{c}/\nu$, where ν is the kinematic viscosity of the fluid. Since the glider is considered a streamlined body, the Reynolds number dependence of the profile drag term in (12.10) is an approximation of friction acting on the total wetted area, A_t. Specific energy consumption, E_c, can be explicitly examined for efficient gliders that achieve small glide angle during coordinated wings-level flight ($v = v' = 0$; $\beta = 0$). With the small glide angle assumption, the lift-to-drag ratio can be written after [12.18] as

$$\frac{L}{D} = \frac{C_L}{C_D} = \frac{u^2}{K_3 u^4 + K_4} = \frac{1}{E_e} , \quad (12.11)$$

where

$$K_3 = \frac{A_0}{2gV_b} K_0 R_e^{-\xi} N_A ,$$

$$K_4 = \frac{2gV_b}{A_0} \frac{K_i}{\pi N_R} .$$

Taking $\partial(L/D)/\partial u = 0$, the speed at which the lift-to-drag ratio is maximized becomes $U = (K_4/K_3)^{1/4}$ giving

$$\left(\frac{L}{D}\right)_{max} = \frac{1}{2}(K_3 K_4)^{-1/2} = \frac{1}{(E_e)_{min}} . \quad (12.12)$$

It can be readily shown that the small glide angle approximation ($L \approx B = \rho g V_b$) also reduces the Reynolds number to

$$R_e \equiv \frac{U\bar{c}}{\nu} \cong \frac{1}{\nu}\left(\frac{2gV_b}{C_L N_R}\right)^{1/2} .$$

Using this approximation to eliminate the Reynolds number in (12.10) and (12.11) gives the minimum specific energy consumption for nonturning, steady-state flight in (12.12) as [12.18]

$$(E_e)_{min} = 2\left[\frac{\nu^\xi K_i K_0 C_L^{\xi/2} N_A}{\pi (2gV_b)^{\xi/2} N_R^{1-\xi/2}}\right]^{1/2} = \left(\frac{L}{D}\right)_{max}^{-1} . \quad (12.13)$$

12.4.2 Size Factors

The minimum specific energy consumption from (12.13) decreases as $V_b^{-\xi/4}$, i. e., it decreases with increasing net buoyancy. Because net buoyancy is some fraction n_b of the total vehicle volume V_0, where $V_b = n_b V_0$, bigger buoyancy-driven vehicles generally are more transport efficient. Actually, surveys of natural and man-made fliers by [12.12] and [12.14] demonstrate that specific energy consumption monotonically decreases across 12 orders of magnitude of size increase. This size advantage is accentuated in an underwater glider because the buoyancy volume factor, n_b, increases with increasing vehicle volume approximately as $n_b \approx 1.2 \times 10^{-5} V_0^{7/6}$, due to economies of scale in packing efficiency [12.7]. Larger n_b permits higher glide speeds (speed increases as the square root of the increase in net buoyancy) and higher wing section Reynolds numbers, which results in higher wing section lift-to-drag ratios (Fig. 12.9).

Equation (12.13) also indicates that specific energy consumption decreases with increasing aspect ratio of the wing, as $N_R^{-(1-\xi/2)/2}$, favoring long tapered wingspans with relatively small wing chords. The aspect ratio of the profiling gliders varies from a maximum of $N_R = 9.75$ for Spray to a minimum of 4.4 for Seaglider. Specific energy consumption decreases as the lift to drag ratio (L/D) increases, but L/D suffers a precipitous decline if the wing section chord is made too small in an effort to achieve a high aspect ratio. Figure 12.9 shows that this L/D crisis occurs when the wing section Reynolds number drops into the mid 10^4 regime. This phenomenon arises because of laminar separation on the suction side of the wing section, which destroys a large percentage of the lift. Profiling gliders with their present 10–20 cm wing chords and 30 cm/s cruise speeds are operating within the laminar separation regime where their wings will not be able to realize a higher L/D and lower E_e by simply flying at higher angles of attack (Fig. 12.9). This laminar separation phenomenon suggests a need to go to bigger wing chords to get above the mid 10^4 Reynolds number regime in order to improve flight efficiency. A primary design philosophy of the larger cross-country gliders (Fig. 12.4) is to achieve

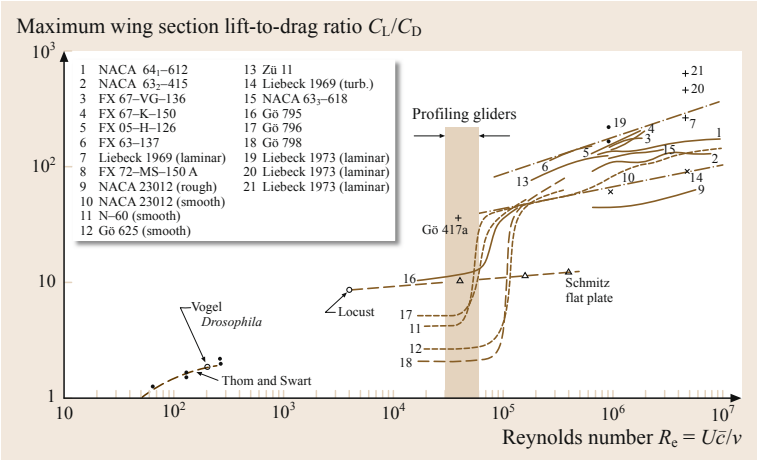

Fig. 12.9 Variation in maximum airfoil section lift-to-drag ratio with Reynolds number (after [12.12]). Numbered curves according to airfoil sections in the inset table

sufficiently large wing chords to avoid the L/D crisis shown in Fig. 12.9. Since Fig. 12.10 indicates that the wing area of profiling gliders is properly sized, larger wing section chords would reduce the wing aspect ratio ($N_R = A_0/\bar{c}^2$).

Increases in wing aspect ratio to reduce specific energy consumption are not only constrained by Reynolds number effects, but by material strength properties as well. As wing aspect ratio increases for a given wing area, the mean wing chord and so the Reynolds number of the wing section decreases, causing degradation of the maximum lift-to-drag ratio of the wing section according to wind tunnel measurements [12.19–21]. If the aspect ratio is increased by increasing the span, the weight of the wing, F_W, will increase as $F_W \approx S^{5/3}$. As the wing weight increases, the thickness-to-chord ratio of the wing section, $\bar{t}/\bar{c}$, must be increased as $\bar{t}/\bar{c} \approx S^{1/6} \approx V_0^{1/9}$ to provide adequate span-wise bending strength and torsional stiffness [12.22]. If $\bar{t}/\bar{c}$ is made excessively large to satisfy strength requirements of a high aspect ratio wing, then the maximum lift-to-drag ratio of the wing section will further degrade [12.19, 20] and [12.21]. For natural fliers, wing dimensions scale with total volume as $S \approx V_0^{1/3}$ and wing area as $A_0 \approx 0.165 V_0^{2/3}$ according to the *square-cubed law* originally proposed by Cayley, and critiqued later in [12.12]. Based on dimensional analysis, the basic square-cubed law specifies

- Wing semispan: $b \sim M^{1/3}$,
- Wing area: $A_0 \sim 0.165 M^{2/3}$, (12.14)

where M again is the loaded mass.

Figure 12.10 suggests that nature has found a compromise between transport efficiency and structural limitations at an aspect ratio of about $N_R = S^2/A_0 = 6.1$. Inspection of Fig. 12.10a indicates the wing semispan of the profiling gliders may be a bit excessive for the loaded mass at which they operate, but that the wing area of the profiling gliders in Fig. 12.10b compares closely with nature, fitting almost exactly the square-cube law formulation in (12.14), refined by Tucker (contained and discussed in [12.12]) from measurements of birds. Hence, the lack of comparable efficiency of the shapes of the profiling gliders appears not to be due to insufficient wing area, but rather because the loaded mass M is too small or the wetted surface area A_t is too big, or both. From analysis of observational measurements of birds in wind tunnels and in natural environments, Tucker has extracted an empirical relation for specific energy consumption of natural fliers [12.12]

$$E_e = 0.109(Mg)^{-0.185} . \quad (12.15)$$

Note that the exponent in this expression does not differ significantly from that in the empirical fit to NTE in (12.6); they only differ in the size of the leading exponent. From this empirical formulation, it appears that profiling gliders are less efficient fliers in horizontal transport (larger E_e when normalizing by loaded mass) than Tucker's equation would predict. Hence, it appears that horizontal transport efficiency can be further improved in profiling UW gliders (they were designed to profile vertically, not optimize horizontal transport efficiency). This improvement in E_e was a primary guiding factor in developing the larger underwater gliders shown in Fig. 12.4.

12.4.3 Shape Factors

Of all the geometric properties of the glider, the wetted surface to wing area ratio $N_A = A_t/A_0$, has the strongest influence on the specific energy consumption, increasing as $N_A^{1/2}$ (12.13). This result suggests that design focus on reducing N_A will achieve the greatest improvements

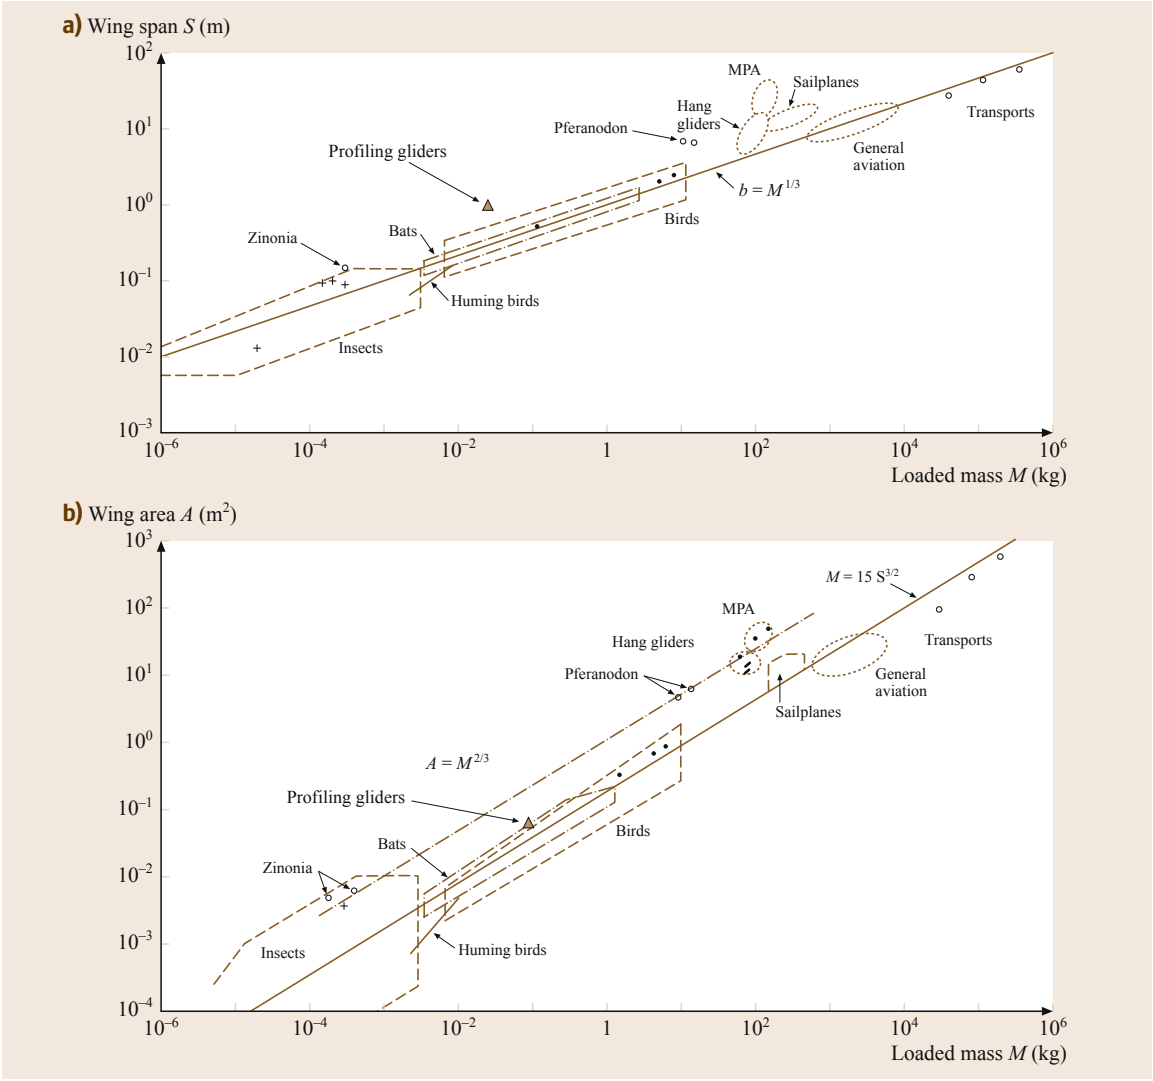

Fig. 12.10a,b Characteristic wing dimensions as a function of loaded mass. **(a)** Scaling of wingspan as a function of loaded mass; **(b)** wing area as a function of loaded mass for natural and man-made fliers (after [12.12, 18])

in horizontal transport economy. As a benchmark in underwater gliders, *Seaglider* has an $N_A = 21.1$ [12.3]. However, the smallest N_A values are associated with *flying wing* and *blended wing/body* geometries, such as utilized by birds, for which typically $N_A \approx 2.2$ to 2.4. The other benefit derived from concentrating the vehicle volume in the wing itself is a large wing area that reduces the magnitudes of C_L and the associated induced drag (the largest component of the drag at minimum E_e). Equation (12.13) indicates that specific energy consumption grows as $C_L^{\xi/4}$. However, increasing wing area indefinitely to achieve a low C_L becomes mutually exclusive with high aspect ratio, N_R. In (12.13), the factor $C_L^{\xi/2}/N_R^{1-\xi/2}$ indicates that a large N_R exerts a greater reduction in E_e than does a proportionally smaller C_L, subject to the structural limits mentioned above.

Another issue with concentrating vehicle volume in the wing is the effect on the profile drag shape factor K_0. Shape efficiency comparisons based on K_0 between a 2-D flying wing and a three-dimensional (3-D) winged body of revolution should be based on the same vehicle volume, V_0. Considering both shapes are streamlined bodies, K_0 scales in proportion to the wetted surface area relative to volume as $A_t/V_0^{2/3}$. Taking an ellipse as the canonical cross section for both 2-D and 3-D shapes, and following the assumption taken in [12.23] and [12.24] that the skin friction per unit area is the same for each shape, the shape factor ratio at con-

stant volume becomes

$$\frac{K_0(\text{2-D})}{K_0(\text{3-D})} = \frac{\pi}{4}\frac{A_t(\text{2-D})}{A_t(\text{3-D})} \approx \pi\sqrt{\frac{2(1-e^2)}{2-e^2}}\,, \quad (12.16)$$

where $e(0 \le e \le 1)$ is the eccentricity of the ellipse taken here as a proxy for the length-to-thickness ratio (*fineness*) of the body. Equation (12.16) is consistent with empirical data on drag of streamlined shapes at high Reynolds numbers (turbulent flow regime) [12.22]. These empirical data relatively show higher profile drag for 2-D shapes at small fineness ratios, as is the case in (12.10) when $e \to 0$. The data for 3-D shapes develop relatively higher profile drag at large fineness ratios, as occurs with (12.16) when $e \to 0.99$. Both the empirical data and (12.16) indicate a 2-D flying wing may suffer as much as a 3-fold increase in K_0 relative to a 3-D body of revolution. However, that increase is more than offset in (12.13) by a 9-fold reduction in N_A when a flying wing is compared to a winged body of revolution. For comparison, Fig. 12.11 shows a computational fluid dynamical (CFD) simulation of the Liberdade/XRay flying wing glider with vehicle volume of $V_0 = 1000\,\text{L}$ versus a Seaglider scaled up to a comparable size of $V_0 = 1000\,\text{L}$. The winged body of revolution in the 1000 L class of glider has about a 30% advantage in maximum cross country speed over the flying wing, but the flying wing is about 43% more efficient in horizontal transport.

Comparative analyses of transport economy in large subsonic transport aircraft concur with this conclusion, generally finding a 20–25% advantage in lift-to-drag ratio for the flying wing over conventional winged bodies of revolution, with additional benefits in gross takeoff weight, operating weight per passenger, and fuel consumption per passenger [12.25]. Other factors not immediately apparent in (12.13) that favor the 2-D flying wing geometries for underwater gliders are: higher Reynolds number on the wing section (due to larger wing chord), leading to higher maximum lift-to-drag ratios (thereby avoiding the 10^4 Reynolds number regime in Fig. 12.9) [12.12]; and increased structural depth of the center section allowing increases in wingspan (and aspect ratio) with fewer weight penalties compared to winged bodies of revolution [12.25, 26].

Together, (12.13) through (12.16) indicate four distinct adjustments that can be made to vehicle characteristics to get energetically more efficient in horizontal transport than the profiling gliders:

1. Increase the buoyancy engine volume to the maximum extent possible for the given internal volume
2. Make the underwater gliders bigger
3. Reduce the total vehicle wetted area A_t relative to the wing area, and

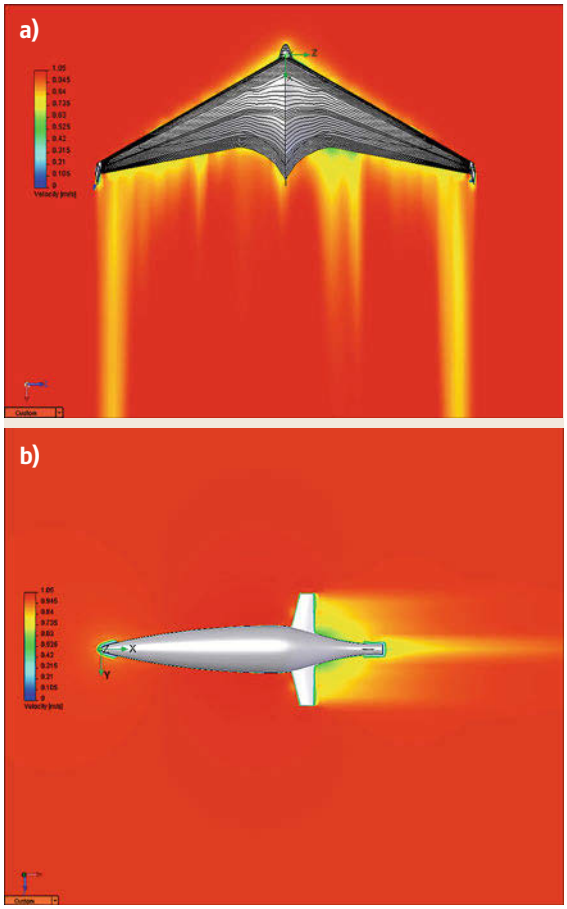

Fig. 12.11a,b Computational fluid dynamical (CFD) simulation of velocity field (using after [12.27]) in the horizontal plane for **(a)** Liberdade/XRay at $(L/D)_{max} = 19$, and **(b)** profiling-type Seaglider scaled up to $V_0 = 1000\,\text{L}$ at $(L/D)_{max} = 11$. The surface roughness is 10 μm in both simulations

4. Increase the wing aspect ratios to the maximum extent possible without reducing wing chord to such a degree that it operates in the mid 10^4 Reynolds number regime.

The wetted area could be reduced by copying birds and designing underwater gliders with flying wing or blended wing body shapes (Fig. 12.12). However, the form factors of such shapes have lower packing efficiency for the glider subsystems that typically fit more readily into cylindrical or spherical shapes.

12.4.4 Glide Polar

Glider flight efficiency is not only just a function of vehicle characteristics, but also a function of how the

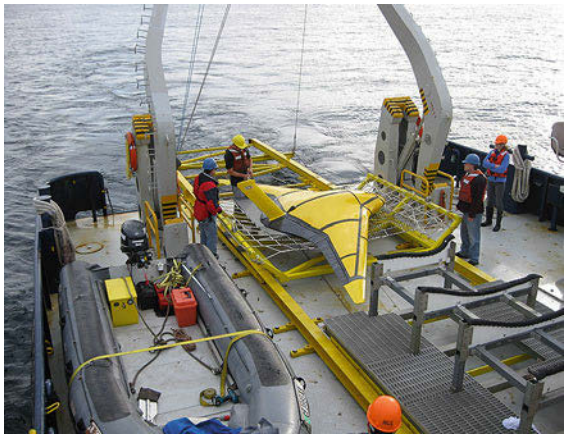

Fig. 12.12 Liberdade/ZRay blended wing body glider aboard R/V Sproul, January, 2011

glider is flown. The expression for specific energy consumption in (12.13) shows that flight energy consumption is minimized by maximizing the lift-to-drag ratio, L/D. From the proportionality between the force and speed triangles in Fig. 12.1, a relation exists between the maximum L/D achievable for a given glider and the angle of the glide path. Since the profiling gliders are flown at glide path angles between 20° and 30° in order to profile the ocean temperature and salinity fields, they will not achieve a specific energy consumption any better than $E_e \approx 0.3$ to 0.5 no matter how optimal their physical characteristics are made. In most ocean environments, the horizontal scales of variability are sufficiently large that vertical profiles of the water column can be collected at significantly shallower glide slopes. So the gliders in the functional class of *depth unlimited roaming* would benefit from improved horizontal flight efficiency, assuming their existing desirable characteristics (e.g., two-person portability) can be retained. However, in other functional classes, maximum flight efficiency in the horizontal is much more important. In particular, *depth limited roaming* requires a glider to travel long distances in a restricted depth interval, *payload/cargo delivery* vehicles must transport large payload and cargo over long distances point-to-point, and *level flight hybrids* must fly at a very flat glide path angle to minimize the expenditure of energy on auxiliary propulsion. All these types of applications for UW require minimum NTE and E_e, and hence maximum L/D. The specific energy consumption for the ZRay flying wing glider demonstrated at sea is 0.05 and the NTE less than 0.65.

While the L/D varies with glide path angle, a corresponding change occurs in the proportions of the speed triangle in Fig. 12.1. This proportional change in the speed triangle with changing glide slope angle yields a continuous relationship between the horizontal and vertical components (w versus u) of the glide velocity, U. This relation, known as the *glide polar*,is readily derivable by balancing the forces in the vertical and horizontal for steady-state flight. Based on the quadratic formulation of lift and drag in (12.9) and (12.10), it is given by

$$w = \pm \left(\frac{\rho g V_b \sqrt{1 + \tan^2 \beta_z}}{(1/2)\rho A_0 (1 + H^2(\alpha)) \sqrt{C_L^2(\alpha) + C_D^2(\alpha)}} \right)^{1/2} , \tag{12.17}$$

where the polynomial H is a function of angle of attack α

$$H(\alpha) \equiv \frac{L}{D} = \frac{C_L(\alpha)}{C_{D0}(\alpha) + C_{Di}(\alpha)} , \tag{12.18}$$

and β_z is the bank angle from [12.28] given as,

$$\beta_z = \arcsin[\cos\varphi \sin\beta \cos\eta + (\cos\alpha \sin\varphi - \sin\alpha \cos\varphi \cos\beta) \sin\eta] . \tag{12.19}$$

In (12.19), φ is the pitch angle, β is the roll angle, and η is the yaw angle. In coordinated flight, $\eta = 0$, the bank angle approaches the angle of roll at small pitch angles, i. e., $\beta_z \to \beta$ as $\phi \to 0$. Positive values of w in (12.17) correspond to ascending glides and $w < 0$ corresponds to descending glides. The corresponding expression for u is the same as (12.17) except that (a) only positive values of the horizontal speed are considered (the glider does not fly backward) and (b) $H^2(\alpha)$ changes to $H^{-2}(\alpha)$. The glide polars of the XRay flying wing glider (Fig. 12.11a) are plotted as solid lines in Fig. 12.13 for noncircling, wings-level flight at four different wing loadings within a potential range of net buoyancy volume, $n_b = V_b/V_0 = 3.8$ to 27.6%. The four polars in Fig. 12.13 (red, black, green, and blue curves) are representative of various buoyancy engine technologies, where the red curve ($V_b = 38.36\,L$, $n_b = 3.8\%$) is representative of the upper end of the closed-loop liquid-based engine technology [12.2, 3], the black curve ($V_b = 50.0\,L$, $n_b = 5.0\%$) represents the upper range open-loop liquid-based engine technology [12.1, 4, 29], the green curve ($V_b = 122\,L$, $n_b = 12.2\%$) is a proxy for the open-loop compressed gas-based systems [12.8], and the blue curve ($V_b = 275\,L$, $n_b = 27.6\%$) approximates the upper end of the open-loop gas-based buoyancy engines that consume gas generating compounds [12.5]. The magnitude of the glide velocity, U, and the velocity components (u, v, w) increase as the square root of the buoyancy engine volume increase and the associated wing loading (ratio

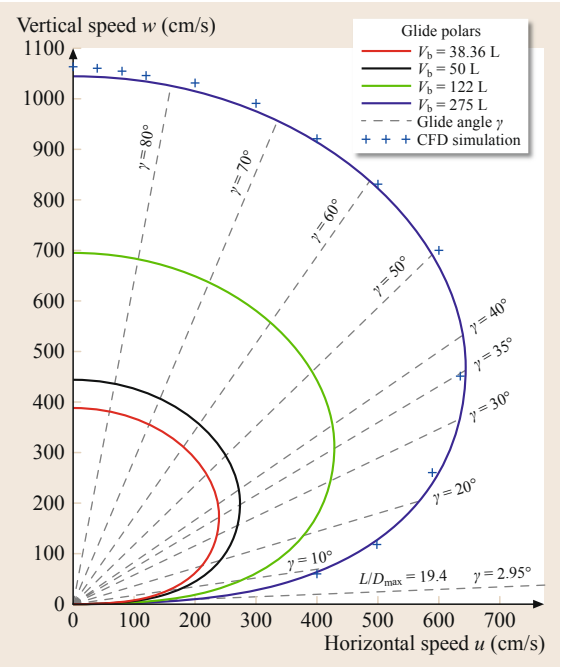

Fig. 12.13 Liberdade/XRay glide polars in the z-plane for wings level ($\beta = 0°$) attitude over a range of net buoyancy between 38.36 and 275 L. Glide angles γ shown as *dashed gray lines* are invariant with net buoyancy change. *Blue crosses* are derived from CFD simulations at $V_b = 275$ L using (after [12.27]). See also Fig. 12.11a

of net buoyancy to wing area) [12.28, 30]. The maximum lift-to-drag ratio over ground (minimum specific energy consumption) is given by the point of tangency on the glide polar to a straight line drawn from the origin [12.28, 30]. The dashed gray tangent line in Fig. 12.13 indicates XRay has a predicted $(L/D)_{max} = 19.4$, which corresponds to a best glide angle $\gamma = 2.95°$ and a specific energy consumption of $E_e = 0.051$. With 10 μm surface roughness, the CFD simulations like those in Fig. 12.11a gave approximately the same results, $(L/D)_{max} = 20.0$. At-sea results for ZRay without the use of trailing edge flaps to change camber confirm these maximum lift-to-drag ratio results.

For comparison, the published polar of the Seaglider [12.3] gives a $(L/D)_{max} = 7.0$, or $E_e = 0.143$. If the Seaglider with net buoyancy of $V_b = 0.33$ L was scaled up from its present volume of $V_0 = 66$ L to an equivalent volume of XRay of $V_0 = 1000$ L and given a net buoyancy $V_b = 38.36$ L, (Fig. 12.11b), then by (12.17), the maximum lift-to-drag ratio would increase by a factor of 1.81. This increase is based on the assumption of all laminar boundary layers ($\xi = 1/2$) in (12.17) and would give the scaled-up Seaglider a $(L/D)_{max} = 12.7$. For all turbulent boundary layers ($\xi = 1/5$), (12.11) gives a $(L/D)_{max} = 8.9$ for the scaled-up Seaglider. A CFD simulation (using [12.27]) for the scaled-up Seaglider (Fig. 12.11b) finds that about 60.5% of the boundary layer is laminar for a surface roughness of 10 μm, giving a $(L/D)_{max} = 11.1$.

When the XRay glider is flown at steeper glide angles (shown by the other dashed gray radial lines in Fig. 12.13 above the tangent line of the best glide angle $\gamma = 2.95°$), the cross-country speed, u, increases, reaching a maximum at a glide angle $\gamma = 35°$. This maximum arises because C_D is nearly invariant with C_L, when C_L becomes small at the small angles of attack during steep glides. In this case, an equation for u analogous to (12.17) reduces to u being dependent on $\sin\gamma \cos^2\gamma$, where $\gamma = \arctan(H^{-1})$. This expression has a maximum at $\gamma = 35°$ [12.1]. Within its range of possible buoyancy variation, the maximum country speeds of XRay can theoretically vary over a wide range, from $u_{max} = 241$ cm/s (4.7 kts) at a net buoyancy of $V_b = 38.36$ L (red curve), reaching $u_{max} = 644$ cm/s (12.5 kts) at a vehicle net buoyancy of $V_b = 275$ L (blue curve). XRay's glide speeds along the $\gamma = 35°$ glide slope, referred to as $\hat{U}$, are found in Fig. 12.13 to be $\hat{U} = 296$ cm/s (5.8 kts) at a net buoyancy $V_b = 38.36$ L, reaching $\hat{U} = 793$ cm/s (15.4 kts) at the maximum vehicle net buoyancy of $V_b = 275$ L. These numerical results, confirmed by at-sea tests, indicate that the XRay flying wing glider fitted with moderately sized buoyancy engines (the as-built XRay glider has $V_b = 30$ L) is capable of traveling point-to-point at horizontal speeds comparable to those of commercially available, mid-size prop-driven autonomous underwater vehicles (AUVs).

The glide polars for Seaglider [12.3] give $u_{max} = 46$ cm/s (0.89 kts) at a net buoyancy $V_b = 0.33$ L, ($n_b = 0.5\%$). For the scaled-up Seaglider at $V_0 = 1000$ L and $V_b = 38.36$ L, the wing loading is increased by a factor of 47, thereby increasing cross-country speed to $u_{max} = 315$ cm/s (6.1 kts) based on application of the wing loading relationship expressed in (12.17) to the published polar. As stated earlier, the winged body of revolution in the 1000 L class of glider has about a 30% advantage in maximum cross-country speed over the flying wing, although the flying wing is about 43% more efficient in horizontal transport.

Maximum along-coarse speed in still water is always obtained at a 35° glide angle regardless of vehicle shape or other hydrodynamic properties [12.1]. Figure 12.14 compares the potential cross-country speeds as a function of loaded mass (mass equivalent net buoyancy) of the four classes of underwater gliders when optimally sized for their intended missions. These include the winged body of revolution carrying single (small) payloads (*red*), the winged body of revolution carrying variable (large) payloads (*blue*), the flying

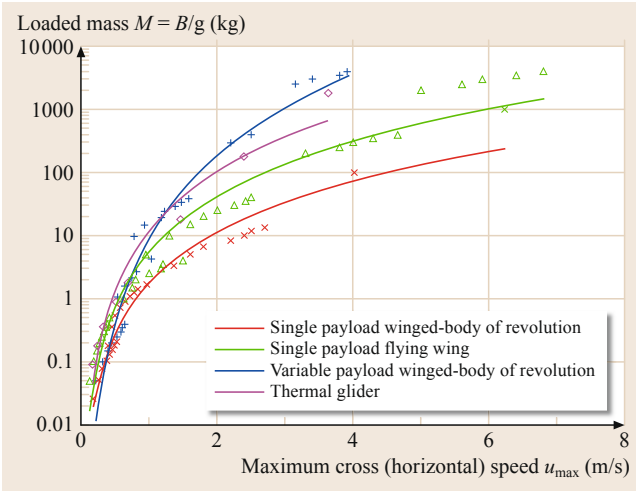

Fig. 12.14 Maximum cross-country (horizontal) speed for an underwater glider due to variation in the loaded mass for a winged body of revolution carrying single (small) payloads (*red*), a winged body of revolution carrying variable (large) payloads (*blue*), the flying wing carrying single (small) payloads (*green*), and a thermal glider in a winged-body-of-revolution configuration with single payload (*purple*)

wing carrying single (small) payloads (*green*), and the thermal glider in a winged-body-of-revolution configuration with single payload (*purple*). Winged bodies of revolution with maximum buoyancy engine capacity are the optimal combination for maximum speed (Fig. 12.15). For a given n_b, flying wings of equivalent vehicle volume are slower than winged bodies of revolution, but have superior transport economy, requiring fewer dive cycles (and less near surface exposure time) for a given distance traveled.

To exploit the superior horizontal transport economy of the flying wing for large payloads and cargo, vehicle packing must deal with the planar form factor of the flying wing and distribute the vehicle weight such that the critical vehicle balance factors that provide stability are met both before and after payload/cargo delivery. Those critical balance factors are (1) adequate vertical separation between the centers of buoyancy and mass, and (2) adequate horizontal separation between the centers of pressure and mass. A large payload/cargo concept for the flying wing glider is based on the use of multiple wing systems, and is referred to as the *Coanda triplane*, Fig. 12.16. The concept is based on adding two auxiliary wings to the basic ZRay flying wing glider hull form. To assure maximum vertical separation between the centers of buoyancy and mass, the lower wing carries the negatively buoyant payload/cargo while the upper wing carries buoyancy-compensating foam. This arrangement allows the glider to deliver the payload/cargo

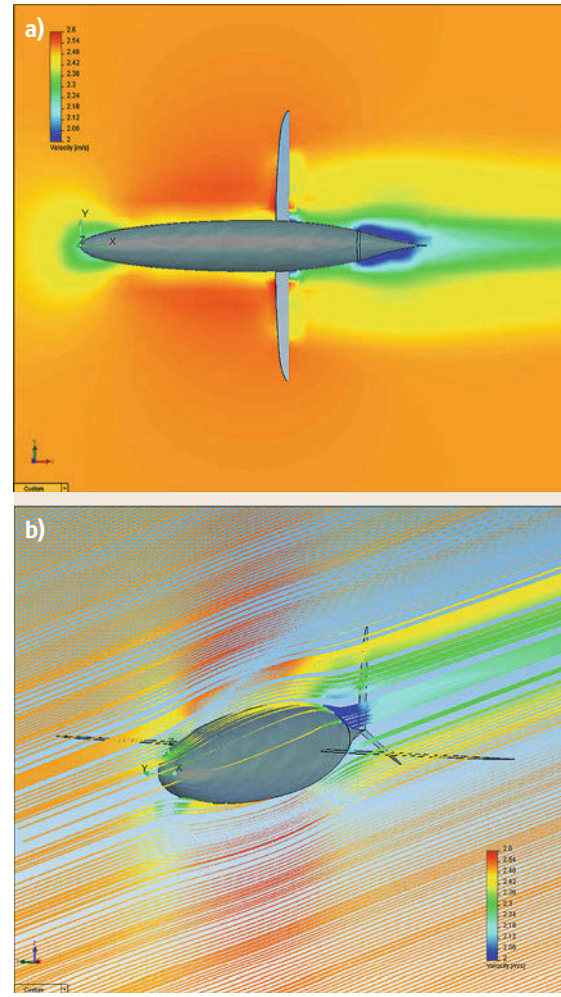

Fig. 12.15a,b CFD simulations of *The Bus* concept, a large winged body of revolution for carrying large payloads, used for creating the blue curve in Fig. 12.14. **(a)** Velocity contour plot in the horizontal plane; **(b)** streamlines in the vertical plane of *The Bus*

to the seafloor without having to perform unusual flight behaviors; upon arrival at the deployment site, the upper and lower wings are released, transforming the vehicle into a conventional ZRay glider.

The upper and lower external wings have high thickness-to-chord cambered airfoil sections. Computational fluid dynamical simulations (Fig. 12.17) show that for a particular-sized separation between these cambered auxiliary wings and the symmetric ZRay main-body wing section, remarkably high lift coefficients (large aggregate flow circulation) can be obtained at low angles of attack during both descent and ascent. This phenomenon is attributable to the *Coanda effect*, whereby the high velocity flow through the two gaps

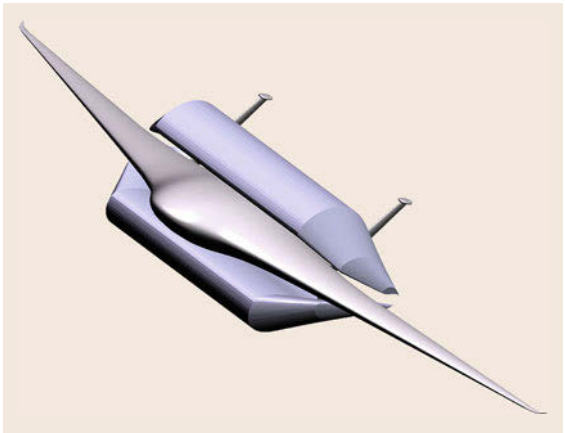

Fig. 12.16 The *Coanda triplane* is a large flying wing glider based on the ZRay glider (Figs. 12.4b and 12.12) for carrying large payloads and cargo to be delivered on the seafloor. The lower wing carries the negatively buoyant payload/cargo while the upper wing carries the foam for buoyancy compensation ◄

between the three wing sections remains attached in the diverging flow over the aft surfaces. This phenomenon results in a high degree of flow circulation in a closed-ended wake behind the aggregate three-wing system. The circulation is clearly visible by the vertical asymmetry of the velocity contour plots in Fig. 12.17 and by the progressive vector arrows. The lift coefficient that results from this circulation is on the order of $C_L = 2.8$, and translates into a near doubling of the L/D over that of ZRay alone. The glide polar for the Coanda triplane concept, computed from CFD simulations, is plotted as the dashed black curve in Fig. 12.18. A maximum L/D of 37.7 is achieved, equivalent to a ZRay glider using 10° of camber-changing, trailing-edge flaps. However, the triplane is about 10 cm/s to 20 cm/s slower than ZRay, and achieves its best L/D at a glide speed of only

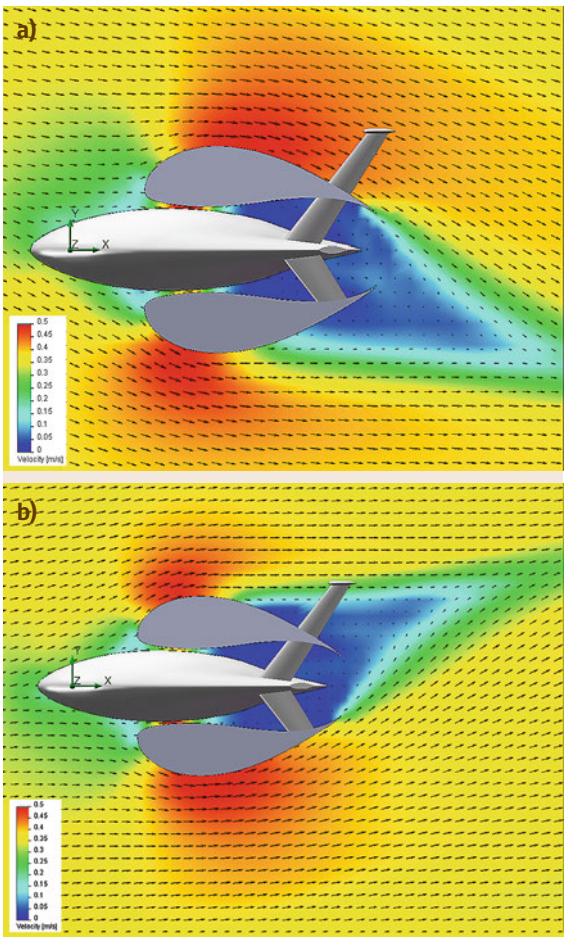

Fig. 12.17a,b A CFD study of the wing circulation for the *Coanda triplane*. **(a)** Shows the velocity contours during descending dives at negative angles of attack while **(b)** shows the velocity contours during ascending dives at positive angles of attack

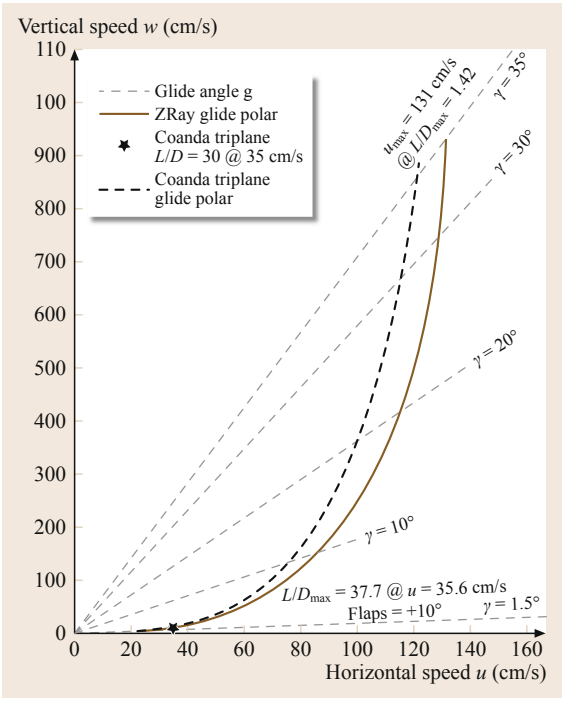

Fig. 12.18 Low-speed portion of the glide polar of the Coanda triplane concept (*dashed black curve*) and the ZRay glide polar (*red curve*). The glide polars are for wings level ($\beta = 0°$) attitude for a net buoyancy of 13.15 L. Glide angles γ are shown as *dashed gray lines*

35.6 cm/s. The low speed characteristics at maximum L/D are largely a consequence of the triplane's relatively high wetted surface area.

In summary, the ZRay glider becomes *more* energy efficient in horizontal transport of large cargo and payload than when flying by itself, although it does so at slower speeds. More generally, vehicles with wings can reduce their propulsion energy consumption by flying cooperatively with other wings, in contrast to prop-driven vehicles. Cooperative flight is enabled by the simplicity of the wing's trailing edge vortex system – Sect. 12.2.

12.5 Thermal Glider

This vehicle is applicable for ultra-long range, depth-unlimited roaming and for high endurance station keeping [12.4] (Table 12.1). The concept gives the glider the ability of renewing its onboard energy stores by harvesting environmental energy from the heat reservoir of the ocean, specifically from the temperature differences of the cold deep water and the warmer surface water (available in 80% of the world's oceans). Ranges of 30 000 to 40 000 km, circumnavigating the world, then become conceivable. Harvesting this thermal energy depends on the volume change associated with the state (phase) change of a material with a melting/freezing point in the range of ocean temperatures. Heat is absorbed from the warm surface water, causing a change of state from solid to fluid (melting), and released to the cooler, deeper water during the vehicle's transit through the thermocline, resulting in a state change back to the solid state (freezing). The heat exchange volume occurs inside tubes that run the vehicle's length and provide a large surface area for rapid heat flow. Almost all materials have a positive thermal expansion coefficient so that melting causes an increase in volume and freezing results in a decrease in volume (water below 4 °C is an exception). Because these volume changes are opposite to those required of a glider's buoyancy engine, they cannot be used directly for forward propulsion. Rather, the thermal buoyancy engine must include unique design features to account for the positive thermal expansion coefficient (as in Fig. 12.19) or the energy from expansion/contraction must be stored onboard over a half dive cycle to be useable for propulsion. The four stages of the thermodynamic cycle are shown Fig. 12.19. Environmental energy is harvested by heat flowing into and out of the working fluid in chamber 1, which contracts on freezing and expands on melting. The resulting work is transmitted around the system by the transfer fluid, typically mineral oil. Chamber 2 is an energy storage accumulator, with the transfer fluid pressurized by nitrogen at a pressure greater than the maximum external ocean pressure. In Fig. 12.19a, the vehicle is in stable thermal equilibrium in the warm surface water, N_2 is compressed, the external bladder is inflated, and working fluid is expanded. Descent begins by opening the three-way valve (Fig. 12.19b), venting the external bladder to the internal bladder. Maintaining the hull interior slightly below atmospheric pressure creates the pressure differential for this flow. As the vehicle reaches cold water, heat flows out of the working fluid, which freezes and contracts, and draws in mineral oil from the internal reservoir. The beginning of ascent (Fig. 12.19c) results from opening the three-way valve, the pressurized oil in the accumulator moves to the external bladder and the vehicle changes from negative buoyancy to positive buoyancy. During ascent (Fig. 12.19d), the vehicle ascends to warm waters, heat flows into the working fluid, which melts and expands, and oil flows to recharge the accumulator.

Because the thermal glider is nearly identical in shape and dimensions to the winged body of revolution for single payloads, the glide polar data from Fig. 12.14 can be used for hydrodynamic input to an analysis of

Table 12.1 Analysis results for the net transport economy of various sizes of a thermal glider designed for the ultra-long range, depth-unlimited roaming application (after [12.1])

energetics and transport economy. To make the transport economy analysis problem tractable, the following assumptions are made regarding a long range, depth unlimited roaming type of application:

- Range = 35 000 km
- Profile depth = 1300 m
- Dive angle = 33°.

The hull weight scales with volume. For thermal engines, the oil required and compensator scale with the drive force required. The drive force (provided by the net buoyancy, B) is a function of the glide angle and is the on-axis component of the buoyancy desired. The payload weight is fixed in the analysis. Energy consumption is based solely on hotel load, i. e., all propulsion energy is assumed to be harvested from the ocean temperature gradients. As a result, as the mission time decreases with increasing velocity, the onboard energy needed decreases. The volume is calculated for the scaled buoyancy, scaled thermal engines, and scaled oil in bladders and compensator. The velocity is then calculated based on the estimated volume and the C_D. Energy is recalculated based on the new velocity and the volume is readjusted. The results of taking these steps are in [12.1].

The NTE figures above for some of the larger thermal glider sizes demonstrate that the thermal glider is capable of transport economies unmatched by any existing man-made flier.

12.6 Discussion and Conclusions

Gliders occupy a unique niche in the universe of autonomous underwater vehicles. They have an intrinsic advantage in transport efficiency over conventional prop-driven AUVs due to the simpler vortex dynamics of a wing compared to a propeller. (Propulsion systems for long-distance persistence found in nature, e.g., birds and marine mammals, are based on wings, not propellers.) Due to a wing's simple vortex dy-

namics, gliders with wings can fly cooperatively with other winged vehicles and structures to further improve transport efficiency, in contrast to prop-driven vehicles. In addition, gliders are capable of readily operating throughout their full speed regime, from top sprint speed to creeping flight to free-drifting at neutral buoyancy in which no propulsion energy is consumed. Consequently, gliders offer a persistent, high-endurance solution for many ocean sampling and surveillance missions. Buoyancy-driven gliders also are silent (acoustically and electromagnetically) throughout most of the dive cycle, including when operating at top sprint speed. They create low levels of self-noise for a few percent of the total dive time due primarily to buoyancy engine operation. However, gliders are generally slower than prop-driven AUVs, typically operating in the speed regime below 3 kts. (Much of a glider's on-station persistence is attributable to these low operating speeds.) In addition, a glider must change depth in order to move forward and so is incapable of level flight. On the other hand, these depth changes allow vertical profiles of ocean properties to be collected and for energy to be extracted from the temperature gradients in the ocean.

In addition to being slower and an inability to conduct level flight, gliders are less maneuverable and more balance sensitive than prop-driven AUVs. However, possibly the greatest disadvantage is the additional vehicle interior volume consumed by, and the additional complexity of, a buoyancy engine compared to a prop-driven system.

The calculus of gliding has been explored for ways of increasing the horizontal point-to-point transport efficiency and speed of underwater gliders. An analytic solution for the minimum specific energy consumption (maximum L/D) indicates that increasing the net buoyancy volume of the vehicle V_b increases the speed as $\sqrt{V_b}$ while specific energy consumption E_e declines as $E_e \approx V_b^{-\xi/4}$, where $1/5 \leq \xi \leq 1/2$. Since buoyancy engine capacity is some fraction n_b of vehicle volume, V_0, this finding immediately argues for larger gliders for improved horizontal transport efficiency. The challenge therefore reduces to finding the most efficient geometries for large volumes. Of all the geometric properties of the glider, the wetted surface to wing area ratio, $N_A = A_t/A_0$, has the strongest influence on specific energy consumption, with E_e decreasing as $E_e \approx N_A^{1/2}$ with decreasing N_A. The flying wing glider offers a 9-fold reduction in the wetted surface to wing area ratio over existing profiling gliders, which offsets the 3-fold (at most) increase in profile drag resulting from the thick wing section of a flying wing. The other benefit derived from concentrating the vehicle volume in the wing is that a large wing area reduces the magnitudes of lift coefficient C_L required to support a given V_b, thereby reducing the associated induced drag, the largest component of drag at maximum L/D. However, increasing wing area indefinitely becomes mutually exclusive with high aspect ratio, $N_R = S^2/A_0$, where S is the wingspan. Specific energy consumption was shown to decline with decreases in the ratio of induced drag factors at a rate given by $E_e \approx C_L^{\xi/4}/N_R^{(1/2-\xi/4)}$.

Other factors that favor flying wing geometries for many classes of underwater gliders are higher Reynolds number on the wing section due to larger wing chord, leading to higher maximum lift-to-drag ratios and avoidance of rapid L/D degradation occurring in the 10^4 Reynolds number regime, and increased structural depth of the center section allowing increases in wingspan (and aspect ratio) with fewer weight penalties compared to winged bodies of revolution [12.31–33]. Analytic and numerical comparisons, supported by at-sea results, for large gliders ($V_0 \approx 1000$ L) of comparable net buoyancy demonstrate that a flying wing glider is about 43% more efficient in horizontal transport, but that a winged body of revolution glider has about a 30% advantage in maximum cross-country speed. All gliders designed for long-duration, long-distance flights certainly would benefit significantly from using a buoyancy engine that can harvest energy from the temperature gradients in the ocean.

13. Autonomous Sea Surface Vehicles

Stefano Brizzolara, Robert A. Brizzolara

Capitalizing on the experience and technology developments gained with underwater autonomous vehicles, the current research frontier in the field of autonomous marine vehicles has moved from under water to the sea surface, i. e., autonomous sea surface vehicles. Current and future perspectives of these types of autonomous vehicles are given in Sect. 13.1, with particular attention paid to US navy current interests. These were initiated a decade ago and still actively drive developments in this sector. The ability to design craft specialized for particular tasks to reach the best performance at sea, going beyond size and operational/safety limitations currently imposed by manned ships, offers unique opportunities to the naval architect. In this respect, the basic naval architecture principles that drive the selection of a type of hull with respect to operational requirements are given in the Sect. 13.3. The selection of the type of hull is a preliminary essential activity for the successful design or acquisition of an autonomous surface craft. Finally, as a practical example, Sect. 13.4 summarizes the main results of extensive research done at the MIT-iShip lab to develop a new class of autonomous unmanned surface vehicles, based on a highly specialized and optimized design of an unconventional SWATH (small waterplane area twin hull) hull, able to achieve superior performance and operational capabilities in real sea state conditions.

Unmanned surface vehicles (USVs) provide significant performance advantages relative to their counterparts in air and undersea domains. USVs have the ability to carry large, heavy payloads (or fuel) and maintain them on-station for long periods of time, for a platform of a given size and cost. Displacement and planing hulls typically used for USVs can be optimized for high payload fraction. Air-breathing propulsion means that the platform can be designed to have a long range and endurance or high speed. USVs can be designed to be quite stealthy or they can be designed for high speed. By virtue of being located on the sea surface, USVs are able to communicate with air and undersea platforms. Finally, the USV platform can and should be of low complexity and low cost.

USV development is still in its early stages, despite the fact that the use of unmanned boats in military operations is far from new. Some of the first uses of unmanned boats took place in 1946 for the collection of water samples following *operation crossroads* nuclear weapon tests [13.1] and subsequently in Vietnam for mine sweeping operations. Despite these early activities, concerted USV development did not begin until the late 1990s. This is typical of the development timelines for many complex technologies, which can be several decades long. For example, in the case of naval air power, it was almost four decades between the Wright brothers' first flight in 1903 and the first decisive uses of naval air power in World War II, with key milestones in between such as the first airplane takeoff from a warship in 1910 and the first aircraft carrier (early 1920s) [13.2, 3]. The first decisive military uses of radar occurred in World War II, for example in the Battle of Britain in 1940, following the seminal work on electromagnetic waves by Maxwell, Hertz, and others that occurred in the late 1800s [13.4]. Although very different to naval aviation and radar, the full capability of USVs will be enabled by solutions to technical issues that have a substantial degree of difficulty (for example, sensors, guidance and navigation, artificial intelligence, computer processing, and reduced size and weight of payloads of operational interest); these issues will still require time to be solved.

USVs have greatly advanced in capability over the past 10 years and can be of substantial use in missions today. As these developments continue, USVs are expected to soon have capabilities formerly seen only in much larger, manned vessels and aircraft. USVs are now being sold commercially, under development, used operationally, and are considered for operational use by a number of nations. The utility of USVs can be thought of as dependent on the complexity of mission they are called on to do, the complexity of environment, and the degree of involvement of human operators. Today, USVs are on the lower end of the mission and environmental complexity scales; therefore, a substantial degree of human operator involvement is required. In the future, as technology matures, operations with greater mission and environmental complexity will become possible and less human involvement will be required. For example, currently USVs generally operate in fair weather and low sea states, and in areas of little or no other maritime traffic. Capability is degraded in higher sea states, in part due to limitations of sensors and algorithms. In the future, USVs will be called on to operate in degraded weather conditions and higher sea states. Missions that require patrol and running tracks are fairly straightforward and can be undertaken today. Missions that require the USV to adjust on-the-fly to changing situations are still in the future. Today, the human operator is commonly responsible for hazard avoidance, controlling the USV remotely based on video streamed from the USV. As the autonomy matures, more functionality will be assumed by the autonomous control system, freeing the USV from the tether of a communications system and reducing the workload of the human operator.

USVs are a system composed of the platform, the navigation/maneuvering control system, and a payload. Additional system components may include, for example, subsystems for launch, recovery, and refueling. The following sections will address USV platforms and control systems; payloads are outside the scope of this chapter.

13.1 Platforms

The US Navy USV Master Plan has classified USVs into four size ranges: Fleet Class (approximately 11 m in length), Harbor Class (approximately 7 m in length), X-Class (small USVs deployable from an 11 m RHIB (rigid hull inflatable boat)) and Snorkler (semi-submersible platforms) [13.5]. All of these size classes are designed to operate from, and in close proximity to, conventional ships, or close to shore-based pier facilities. The USV mission is typically in support of conventional ships, and their size is limited by host ship launch and recovery constraints. In its anti-submarine warfare unmanned surface vehicle (ACTUV) (Fig. 13.1) program, the Defense Advanced Research Projects Agency (DARPA) is investigating the technical viability of a much larger unmanned naval vessel that will operate independently [13.6].

USVs platform design is constrained by the same *iron triangle* as manned boats and ships: the tradeoff between speed, range, and endurance. For example, an increase in the top speed of a particular craft design necessitates a decrease in payload capacity or endurance. In other words, every USV platform design, such as for manned craft, has been optimized for a particular set of performance parameters. USV platforms are developed by designing a purpose-built platform or by converting a manned platform to be unmanned (by adding a control system and payload). Purpose-built platforms have the advantage of being optimized for the intended mission and environment, while USVs that are based on converted manned platforms provide cost savings by obviating the need for new design activity and

Fig. 13.4 Remote multi-mission vehicle (RMMV) (courtesy of PEO LCS)

have readily available spare parts. Many developmental USVs and 7 m classes have used an existing manned platform, the rigid hull inflatable boat (RHIB). RHIBs are designed for high speeds in benign sea states; therefore, the RHIB may be an appropriate platform for missions that fit these parameters. However, many envisioned missions do not fit these parameters – they do not require such high speeds, but they do require operation in a seaway. For these missions, the RHIB is not the optimal platform and may, in fact, not be capable of performing the mission at all. To *optimize* the performance of the USV, for the intended mission and environment, the hull form must be optimized, which necessitates a purpose-built design. An example of a purpose-built design is the Office of Naval Research's (ONR) unmanned sea surface vehicle with high tow force (USSV-HTF) (Fig. 13.2), which was optimized for tow capacity and payload fraction, within particular structural constraints [13.7].

Currently, most USVs are monohulls, either planing or semi-planing. For example, the USV-HTF is a semi-planing craft and the RHIB has a planing hull. There are numerous alternative hull forms that might be considered. Each has advantages and disadvantages relative to planing hulls in terms of payload capacity, seakeeping, speed, launch and recovery considerations, and others. Depending on the particular mission and environment, an alternate hull form may be an effective choice. There have been a few examples of USV designs that explore the use of alternate hull forms. For example, ONR has designed and built a hydrofoil USV [13.7]. The unmanned sea surface vehicle–high speed (USSV-HS) (Fig. 13.3) is optimized to maintain its top speed in higher sea states than would be possible with a similarly-sized planing hull. As a semisubmersible, the remote multi-mission vehicle (RMMV) (Fig. 13.4) operates below the sea surface, which provides more stability [13.8]. Another hull form that provides improved stability and is being investigated for use in USVs [13.9, 10] is the small waterplane area twin hull (SWATH). Later in this chapter we will present an example of a purpose-built USV design based on a SWATH hull form.

In addition to the investigation of alternate hull forms, the pursuit of reduced lightship weight is a key area of research and development for USVs. Reduced lightship weight would result in the ability to carry additional payload or fuel, which would provide direct benefits to mission effectiveness. The use of advanced hydrodynamic computational tools to determine hull pressures, particularly during slamming events, as well as the computational prediction of extreme environmental structural loading may lead to optimized structural design and reduced structural weight while maintaining structural integrity [13.11, 12]. Computational fluid dynamical (CFD) methods for hydrodynamic performance prediction will be discussed later in this chapter.

13.2 Autonomous Maneuvering and Navigation

Most USVs today require substantial, remote human assistance to maneuver and navigate in anything but a very highly controlled environment. Consequently, a reliable, high-bandwidth radio link to transmit imagery from the USV to the human operator for hazard avoidance is required; they are not capable of autonomous operation. On the other hand, an autonomous USV (AUSV) is capable of perceiving its internal and external environment, capable of performing a task or function in a complex environment with minimal human intervention, and capable of responding effectively to a dynamic situation. A non-autonomous USV includes control approaches such as remote-control, waypoint navigation, and scripted operations, and has no organic perception – it is not capable of sensing or responding to its environment. In contrast, an AUSV is capable of hazard avoidance in compliance with the International Regulations for Preventing Collisions at Sea 1972 (COLREGs) without human assistance, can arbitrate between multiple, competing objectives, and can do planning/replanning based on changing mission objectives, situations, and resource levels.

The state-of-the-art for AUSVs is on-water demonstrations in good visibility with avoidance of fixed hazards for own ship speeds of > 20 kn, avoidance of moving hazards with COLREGs compliance for own boat speeds of > 20 kn, implementation of COLREGs for head-on, overtake, and crossing situations, and tactically relevant behaviors, including go-to-waypoint, avoid hazard, obey COLREGs, trail, intercept, and patrol. Real-time adaptive response to vehicle faults and dynamic re-planning have also been demonstrated on-water. An example of arbitration between multiple, competing objectives is the autonomous maneuvering and navigation of a USV in achieving a particular waypoint while avoiding hazards and complying with COLREGs.

The sea surface environment presents significant challenges for autonomous maneuvering and navigation. Issues include intermittent obscuration of sensors in rough seas by sea spray and wave slap, limitations of radar close to the USV, the effect of platform motions on sensor performance, the effect of sea surface topography on sensor line-of-sight, and limitations imposed by atmospheric weather conditions (fog, rain, snow, marine layer) on sensor performance. There is work underway to develop advanced autonomy for USVs and address the above technical challenges [13.13–15]. This is enabled by continuing advancements in technologies such as sensors (EO (electro-optic), IR (infrared), radar, LIDAR (light detection and ranging)), sensor processing, sensor fusion, perception capable of dynamically adjusting to environmental conditions, determination of intent (of other vessels), decision-making using uncertain and intermittent perception information, and look-ahead planning. A highly dynamic and unpredictable environment combined with mission complexity motivates a hybrid autonomy architecture [13.14–16] that includes a reactive decision-making component and a deliberative decision-making component. The reactive component provides a fast answer and is used for quick response to close-aboard hazards not detected by the perception system until the last moment and is necessary for safe operations in high risk environments. Deliberative decision-making uses more information and provides an answer that is valid over a longer period of time (unless the situation changes!), but it takes longer for the system to provide that answer. Deliberative planning is an enabler for long-duration operations. A hybrid autonomous architecture has been demonstrated on-water [13.14–16].

Widespread adoption of autonomous maneuvering and navigation will require that significant non-technical challenges be overcome to properly address safety/liability concerns. Yet to be defined are standard metrics of autonomy in terms of core competencies with associated proficiency tests. Approaches consisting purely of on-water testing to a high level of confidence in all conditions are prohibitively expensive; therefore, modeling and simulation will likely play a key role. Cultural issues will be more difficult for AUSVs than for unmanned systems. Non-autonomous unmanned systems have had to overcome the issue of taking the human out of the vehicle and locating him/her remotely from the platform, but still having a high degree of involvement with the operation of the platform. AUSVs will confront the issue of the human being much less involved in the operation, with the involvement being at a supervisory level only. Acceptance of this mode of operation will occur through a gradual approach in which AUSVs are initially used in an autonomous mode, but with a high degree of human supervision to establish trust in the system's performance. As confidence grows, the degree of human oversight will be decreased, allowing AUSVs to reach their full potential.

13.3 Naval Architecture of AUSV Design

This section will first define the general criteria used to select a hull form as a function of operational speed and size and then it will continue to describe in some detail the hydrodynamic design and performance of a new class of vehicles whose optimized design is to become a reference for the next generation of autonomous unmanned surface vehicles for ocean and coastal exploration.

13.3.1 Froude Number and Hull Typologies

Essential for selection of the hull form is the calculation of the relative speed of advance with respect to a representative dimension (the length) and weight (displacement volume) of the hull.

In non-dimensional form these two parameters are defined as the length Froude number Fr_L and the volumetric Froude number Fr_∇

$$\mathrm{Fr}_L = \frac{U}{\sqrt{gL}}\,, \quad \mathrm{Fr}_\nabla = \frac{U}{\sqrt{g\nabla^{1/3}}}\,, \tag{13.1}$$

where g is the acceleration of gravity, L is the submerged length of the hull, U, is the speed of the hull and ∇ is the hull displacement volume. The length Froude number is often used to qualitatively discuss the speed regime of a boat. From a purely physical point of view, the Froude number is the ratio between inertial forces due to the ship advancing at a certain speed U and the gravitational force, which are responsible for the free surface waves and the wave resistance. In fact, using the dispersion relation valid for first-order plane progressive (airy) waves, it can be demonstrated that the length-based Froude number is related to the ratio between the fundamental wavelength generated by the hull and its own length.

If we approximate the length of a transverse wave produced by a pressure region at the bow to that of regular wave traveling with hull speed, we obtain the following relation between the Froude number and the relative wave length

$$2\pi\lambda = gT^2 \rightarrow 2\pi\lambda = g\frac{\lambda^2}{U^2} \rightarrow \frac{\lambda}{L} = 2\pi\mathrm{Fr}_L^2\,, \tag{13.2}$$

where in addition to the variables appearing in (13.1), T is the period and λ is the length of the fundamental transverse progressive wave.

Figure 13.5 compares the fundamental wavelengths relative to the hull profile at four different Froude numbers representative of four different sailing regimes and related hull types. In naval architecture, the length Froude number is often used as an indication to select the most suitable hull typology for the particular application, as it is graphically presented with the shaded areas in Fig. 13.6. This is a preliminary distinction and must correctly consider the volumetric Froude number, especially to distinguish the regime of planing hulls from that of semi-displacement hull forms. This will be explained in more detail later on in this section. Slow speed heavier displacement hull forms operate in the lower Froude number range (Fig. 13.5a, upper panel), at which the fundamental wave length is much lower than the hull length and the resistance is dominated by viscous effects (friction and form drag). The shape of these types of hulls is optimized in order to reduce to a minimum the frictional and form drag components. Wavelength and wave resistance both increase with the Froude number. Typically, at $\mathrm{Fr} = 0.25$ the wave resistance and viscous resistance share the same relative importance in the total resistance. For $\mathrm{Fr} = 0.4$, the relative speed is representative of the limit speed for a fast displacement hull. Most fast naval units (destroyers, frigates) are at these Froude numbers. At this speed, the hull is running on its own wave length ($\lambda/L = 1$). Bulbous bows are very beneficial at these Froude numbers, since their generated waves can interfere directly with the aft wave train (Fig. 13.5b, lower panel). At $\mathrm{Fr} > 0.4$, the fundamental wavelength is larger than the hull length and the hull begins to severely squat and trim down at the stern. The ship literally climbs up the back of its own bow wave. At these speeds the flow along the convex geometry of the hull bottom develops large suction pressures that further increase the squat and trim of the vessel. The hull resistance begins to increase dramatically and becomes a practical barrier to further increases in speed. The wave pattern generated by a displacement hull is, of course, more complex as it derives from the continuously variable distribution of dynamic pressure along the hull (which depends on its shape), but to a first-order approximation, the final transverse wave pattern can be thought as a superposition of a series of transverse wave trains, each one generated at regions of the hull close to the free surface with high pressure gradients.

A sketch of two transverse and divergent wave systems created at the bow and stern of a displacement hull form (Fig. 13.7) is illustrative of the wave interference effect. A solution to the complex free surface wave pattern was first attempted by Lord Kelvin and solved for simple analytical hull shapes by *Michell* [13.17] and later by *Wigley* [13.18]. These studies led the way to the development of thin ship theory, which is the simplest theoretical or numerical method to predict ship wave patterns, based on the assumption that the ship

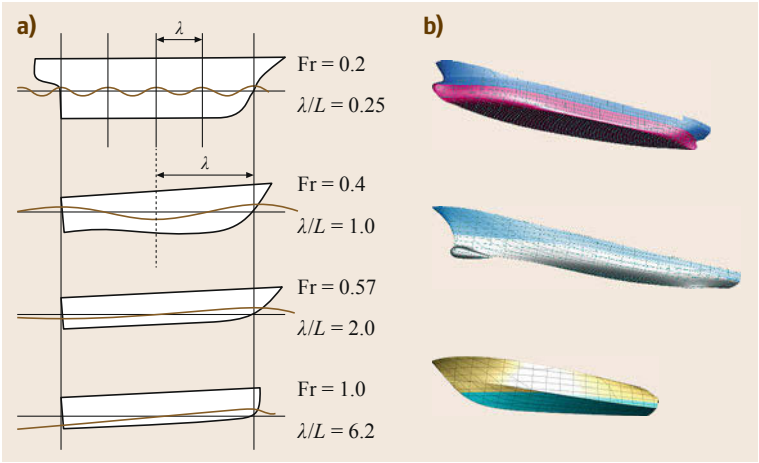

Fig. 13.5 (a) Fr = 0.2 corresponds to slow displacement hulls (e.g., large cargo ships ($L = 150-300$ m, 12–15 kn), but also to small (10 m long) boats at low speeds (3 kn). The weight of the vessel is mostly supported by buoyancy forces. For Fr $\lesssim 0.25$, the dominant resistance component is due to viscous effects, mainly friction and form drag, and the hull shape is normally adapted to this. ((b), top hull) An emblematic hull shape designed to operate at these speeds is a 160 m chemical tanker. For Fr = 0.4 ((a), second panel), the relative speed is representative of the limit speed for fast displacement ships. Most of fast naval vessels ((b), middle hull) operate in this Froude number range. At this relative speed, the hull is running on its own wave length ($\lambda/L = 1$). At Fr > 0.4 (e.g., (a), third panel), the fundamental wavelength is larger than the hull length. This Froude number corresponds to the so called *hull-speed*. Only semi-displacement and planing hulls ((b), lower hull), also characterized by lighter displacements, can overcome the speed barrier Fr = 0.4–0.5 and have a shape adapted to develop hydrodynamic lift force on their bottom surface. At Fr = 1, the hull starts to be supported primarily by hydrodynamic (instead of hydrostatic) forces, the transverse wave trains almost disappear, and the free surface flow around the hull significantly change its nature

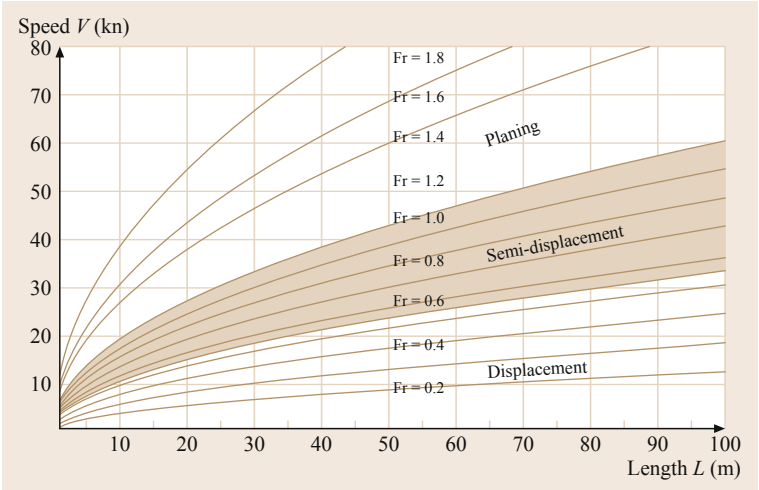

Fig. 13.6 Iso-Froude number curves in the ship speed–length plane and related hull typology

is a long slender body so the perturbation sources can be collapsed on the symmetry plane of the ship. The most recent applications of this theory with surprisingly good correlations were presented by *Tuck* [13.19], *Noblesse* [13.20], and *Doctors* and *Day* [13.21], who studied an appropriate extension of the theory for high-speed displacement hulls.

The approximations and inherent limitations of thin ship theory have been overcome by boundary element methods (BEM) or *panel methods*, which consider the real three-dimensional (3-D) shape of the hull as a boundary of the potential flow domain with linear [13.22, 23] or non-linear [13.24–27] free surface boundary conditions for the solution of the free

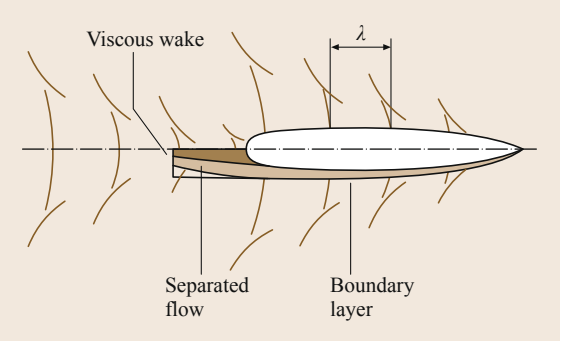

Fig. 13.7 Idealization of the of flow regions types around a ship advancing in calm water

wave patterns. Higher-order versions of these methods that use curved panels defined by B-spline surfaces [13.28] have been developed, and they have shown superior convergence and stability characteristics. Panel methods have been extensively tested and validated both in the case of slow and fast displacement hull forms [13.29] and for semi-displacement mono and multi-hulls, where the effect of dynamic trim and sinkage is essential [13.30–32].

Spectral analysis of wave pattern formation applied to experimental measurements [13.33] and to numerical simulations [13.30–32] has yielded insight into the wave generation characteristics of displacement hull forms, such as the relative importance of divergent and transverse wave trains at different speeds. In terms of energy, the relative importance of the divergent waves, negligible at low speeds with most of the energy concentrated in the transverse waves, progressively increases with the Froude number to become dominant for high-speed semi-displacement hull forms (Fr > 0.55). This ratio is directly dependent on the shape of the hull.

The solution of the viscous free surface flow around the hull is today possible with numerical methods that are able to solve the Reynolds averaged Navier–Stokes equations (RANS). The sharp free surface separating air with water was initially solved with surface tracking algorithms and level set methods [13.35] that are based on the assumption of a smooth and continuous surface on which dynamic and kinematic wave boundary conditions are satisfied, while more recent surface capturing algorithms, based on the volume of fluid technique [13.36] result in a simpler and faster numerical implementation and can inherently deal with wave breaking or spray flows. In recent validation studies, these methods have given good results both in cases of displacement hull forms [13.37] and for planing hulls [13.38–41]. Fully viscous free surface flow solvers avoid empirical estimation of the friction and form drag

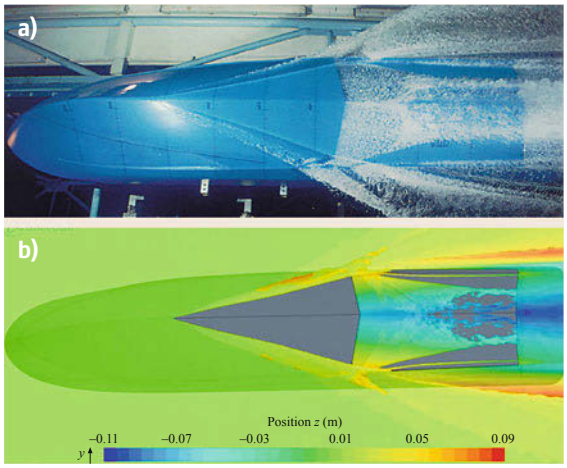

Fig. 13.8a,b Two-phase (air/water) flow field around a stepped planing hull with a partially ventilated afterbody. **(a)** Experiments, **(b)** numerical prediction with RANS solver (with permission from [13.34])

and include the possibility of simulating the non-linear interaction between the boundary layer flow and the flow induced by free surface waves, and they are general enough to be applied also to planing hulls (Fig. 13.8) for which the formulation of traditional boundary element methods, initially developed for displacement hulls, need to be radically changed to reproduce the different physics of the planing flow regime [13.42, 43].

Today it is possible to optimize the shape of the ship hull by means of CFD simulations (simulation based design and optimization). Some examples include fast displacement yachts [13.44, 45] and fast displacement navy hulls [13.46–48], but they are limited to local hull form optimization. More recently, global hull form optimization has been achieved on fast displacement monohulls with realistic design constraints [13.49] and on innovative types of fast catamarans with SWATH [13.50] or semi-SWATH shapes [13.51].

The effective power (defined as the product of the total resistance and the ship speed) normalized to displacement can be plotted as a function of the Froude number for different hull typologies (Fig. 13.9). The sharp increase in resistance for a displacement hull at $Fr_L > 0.4 \sim 0.5$ is sometimes called the resistance wall, beyond which speed is limited regardless of propulsion power. A substantial displacement reduction (Fnvol > 1.5) and specific semi-displacement hull shapes permit the resistance wall for a displacement hull (Fig. 13.9). However, at $Fr_L = 0.9 \sim 1.0$, the resistance of the semi-displacement hull increases very rapidly, delineating a practical upper limit for the operational speed of such hulls. At $Fr_L > 1$ and $Fr_\nabla > 3.0$, provided the hull

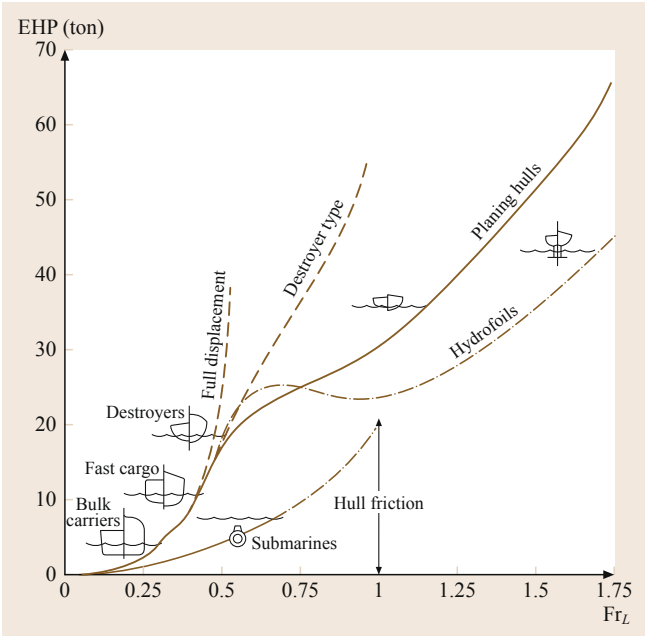

Fig. 13.9 Indicative effective horsepower (EHP) over ton of displacement as a function of the relative speed for different typologies of marine vehicles

shape is adequately changed (bottom hull in Fig. 13.5b), the planing regime occurs in which 80–90% of the weight is supported by the dynamic pressure of the high speed flow field around it. Although intended to operate at high Froude numbers, the planing hull must pass through the entire range of regimes prior to attaining its top speed. As confirmed by *Savitsky* [13.52], at $Fr_L < 1.0$, the planing hull has a somewhat larger resistance than displacement or semi-displacement hulls. This is attributed primarily to the sharp chines and submerged wide and sharp transom that promote flow separation and hence increase the form and wave-making drag component of the hull. The planing hull easily passes through the speed *barriers* for a displacement ship ($Fr_L = 0.4–0.5$) and the limit for a semi-displacement hull ($Fr_L = 1.0$). Within the three main hull categories described so far, naval architects have designed different families that can be distinguished by the shape and the typology of the hull. For example, in the last three decades the semi-displacement category, previously including only slender round bilge monohulls, has seen one of the largest unconventional design proliferations, with new hull shapes (deep-V, vertical or reversed stem, etc.) and typologies (multihulls such as catamarans and trimarans), which have caused a substantial performance increase at sea of this category of vessels compared to the previous state-of-the-art. An example of an unconventional hull form design, specifically for the application to a new generation unmanned surface crafts, is given in the next section.

13.4 Optimized Class of Autonomous Unmanned Surface Vehicles

While there has been a long history of vessels designed as manned platforms and a much shorter history of such vessels converted into unmanned vessels, vessels designed ab initio to perform optimally as AUSVs are an embryonic class. In addition to vessels designed for stand-alone missions, an AUSV is an essential, yet not often currently deployed, component of a persistent four-dimensional (4-D) ocean monitoring and surveillance system (Fig. 13.10).

The main characteristics of vessels in this sub-class are influenced by some key requirements:

- The ability to cover the assigned range (100 nmi) at design speed (12 kn) with onboard fuel and power generation, and conversion devices.
- Continuous operability up to sea state 3, corresponding to a significant wave height between 0.5 and 1.25 m and a wind speed up to 30 kn.
- The ability to transport, launch, and recharge subsurface AUVs (autonomous underwater vehicles) of lengths up to 2.2 m and maximum weights of about 100 kg.
- Sufficient static transverse stability to withstand 50 kn wind heeling moment without exposing the underwater hull or the propeller. Positive dynamic stability up to the heeling angle corresponding to the exposure of the underwater hull.
- Sufficient longitudinal metacentric height (greater than the transversal one) to reduce the dynamic trim

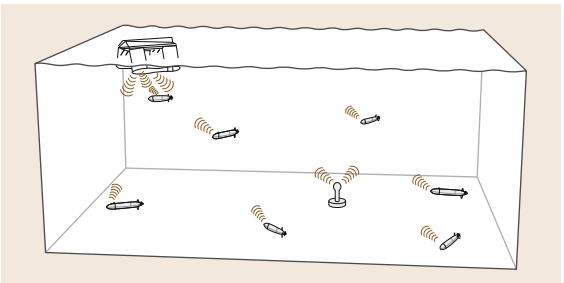

Fig. 13.10 The small AUSV-SWATH as a key element of an integrated, cooperative monitoring and surveillance system

by the bow, typical of high speed SWATHs, and withstand realistic shift of loads.
- The ability to serve as a launch, recovery, and recharging platform for unmanned aerial vehicles.
- Transportability inside a standard container (ISO LWH $12.2 \times 2.44 \times 2.59$).

The speed versus length relation of vessels belonging to this sub-class can be plotted along a constant Froude number (Fig. 13.11). We will consider one such a vessel here in detail as an example of the many design trade-offs involved. The principal geometric characteristics of this small unconventional ASV-SWATH hull are given in Table 13.1 (NURC), together with those of the dual mode hybrid hydrofoil SWATH (ONRG) and of another fast single-strut unconventional SWATH (NH04) optimized in [13.50]. To best satisfy the requirements, an unconventional SWATH hull form was selected, and a prototype was designed (Figs. 13.12–13.14). The advantages of a SWATH include superior seakeeping ability in high sea states with respect to other conventional displacement hull topologies (including catamarans or trimarans). The main drawback of SWATHs, however, has always been the higher powering requirement with respect to equivalent monohulls or catamarans, especially at the highest Froude numbers. This problem has been solved by adopting a particular unconventional shape of the underwater hull, described later in detail.

The new vessel configuration consists of a main central body with the keel line suspended more than 1 m above sea level by vertical struts that connect to the underwater hulls [13.55, 56]. The junctions between the top of the struts and the sides of the main body are fastened with removable and adjustable rods for easy disassembly and regulation of the strut inclination (canting angle). Two diesel generators, each 22 kW, provide the required propulsion power of 39 kW at the design speed as well as power for the estimated hotel load. Two fuel tanks, placed inside the middle of the underwater hulls, provide a range of more than 100 nmi (at full speed) as required for medium and short range missions.

Although the SWATH configuration offers superior seakeeping, the hydrostatic stability index must be evaluated carefully because of the high sensitivity to weight distribution. Particular attention has been paid to match the longitudinal position of the center of buoyancy and the center of gravity (LCB–LCG), with some trim control capability built in (ballast water tanks). Because of the high sensitivity to load changes, two mirrored ballast tanks have been fitted inside the underwater hulls, in the same position as the fuel tanks, to compensate

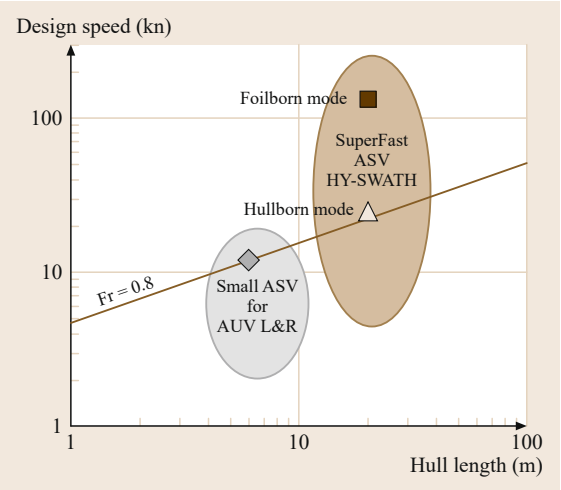

Fig. 13.11 Size and speed of two members of the AUSV class. The larger vessel (20 m long, *triangle*) has the same unconventional SWATH hull form in hull-borne mode, but it is designed to be convertible into a ultra-high speed hydrofoil to reach 120 kn (after [13.53])

Table 13.1 Main geometrical characteristics of unconventional SWATH designs with optimized underwater hull shapes. NURC and ONRG belong to the same family (twin canted struts) presented in Fig. 13.11. NH04 has a single vertical strut

	L/D	CP	$L/V_1^{1/3}$	$L/V_{tot}^{1/3}$	Fr	Fr_{V1}	Fr_{Vtot}

for the loss of weight and trim moment due to fuel consumption. The sensitivity is a consequence of the slender geometry of the struts in the horizontal plane, which do not offer much buoyancy reserve to counterbalance weight changes. To decrease sensitivity, the struts have been tapered just above the waterplane, increasing in width and length, to gain volume when subjected to a pitching moment. A similar approach has been adopted for forces and moments in the transverse plane.

Hydrostatic calculations indicate that the initial metacentric heights of the vessel in the transverse and longitudinal planes are in close proximity, in contrast to a conventional monohull, where the longitudinal metacentric height is in the order of the vessel length, while the transversal metacentric height is in the order of its draft. This fact implies no preferable direction of heeling for the vessel.

To manage the dynamic trim and sinkage of the vessel at high speed, as well as the dynamic stability of the vessel in waves, four active stabilizer fins have been installed, which will guarantee the optimal attitude when the vehicle is advancing and good damping while it is stationary. These two pairs of lifting surfaces are placed on the inner side and far ends of the hulls to obtain the maximum trimming moment.

The aft end of each hull houses an electric motor, gear box, and shaft, whereas the fore end is reserved for sensor payloads. The central body has been divided into three separate compartments by two transversal watertight bulkheads. Inside the fore and aft parts there are diesel generators, frequency converters, and control computers; in the mid compartment a docking space for AUVs has been constructed (Fig. 13.14). The weight of AUV recovery has been compensated by two additional seawater tanks with adequate reserve buoyancy. The framing consists of such a light metal shell (aluminum alloy 5083-H321, 2.7 kg/dm^3) with transverse main girders (Fig. 13.15). The diesel engines are mounted in a rubber mounted, highly damped cradle.

Several transverse, quasi-static (large angle) stability tests have been executed to verify the response of the vessel to the combined effect of wind and waves in terms of heeling righting moments versus heeling angle (Fig. 13.16). Worst case scenarios (tanks half full) were assumed. Three different strut design shapes were

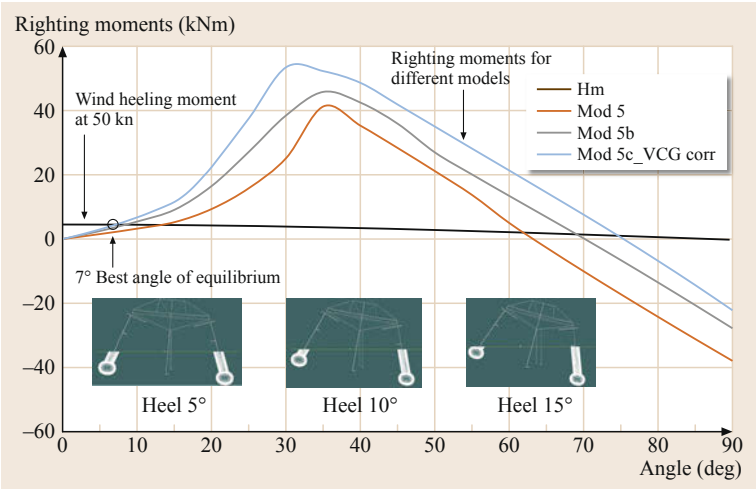

Fig. 13.16 Righting moment curves calculated for three different strut layouts and verification of the extreme wind stiffness heeling moment (after [13.55])

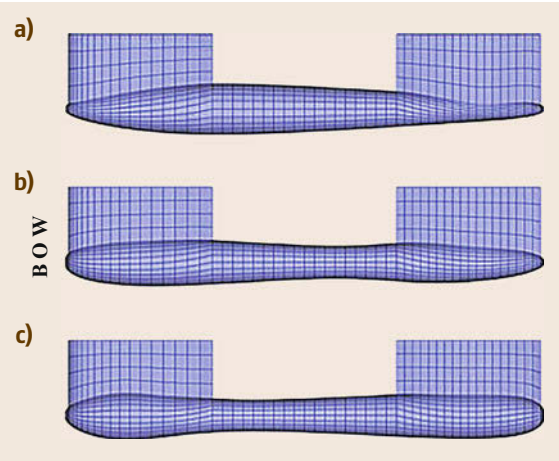

Fig. 13.17 Three different underwater hull shapes of the AUSV-SWATH considered during optimization: **(a)** conventional shape (no intermediate contraction), **(b)** unconventional reference design, **(c)** optimized unconventional shape

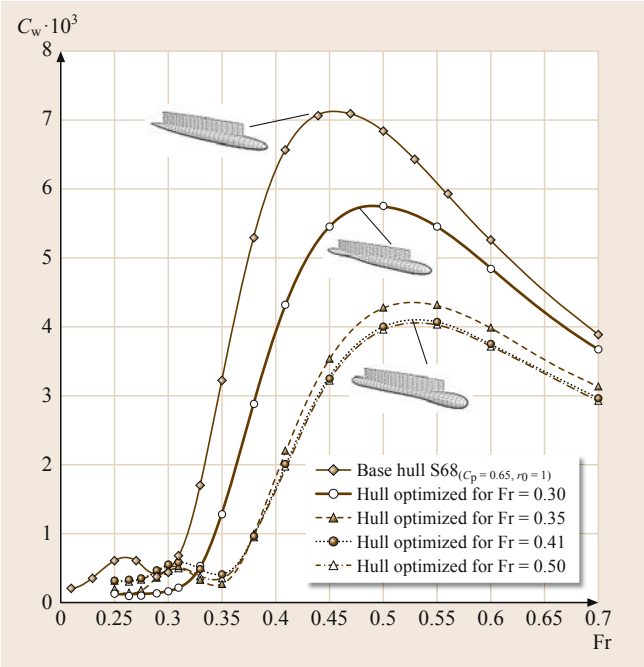

Fig. 13.18 Wave resistance reduction of unconventional SWATHs optimized according to *Brizzolara* [13.50]

considered. The lowest curve (Fig. 13.16) is for straight vertical struts, and the highest one for the final strut configuration with flared sides above waterline and longitudinal inclined stem profile.

For the second generation autonomous vehicles, an unconventional shape for the underwater hulls is utilized with two expanded main sections and an intermediate contraction (Fig. 13.17). Minimization of the resistance at a given design speed is primarily dependent on the position of the intermediate contracted section, as was first demonstrated by *Brizzolara* [13.50] for a single strut SWATH vessel. The optimum longitudinal position of the contracted section changes as a function of the Froude number. In general, for a single vertical strut SWATH, at lower speeds, the contracted section moves aft. This trend is maintained also for the twin canted strut SWATH design of the autonomous surface craft [13.57].

The advantages of shaping the lower hulls to reduce wave resistance (which in displacement mode is the main resistance component) can be as large as 50% as in Fig. 13.18, in the case of the single strut SWATH (NH04 in Table 13.1) and close to 35% as in Fig. 13.19 for the twin canted struts SWATH (NURC in Table 13.1),

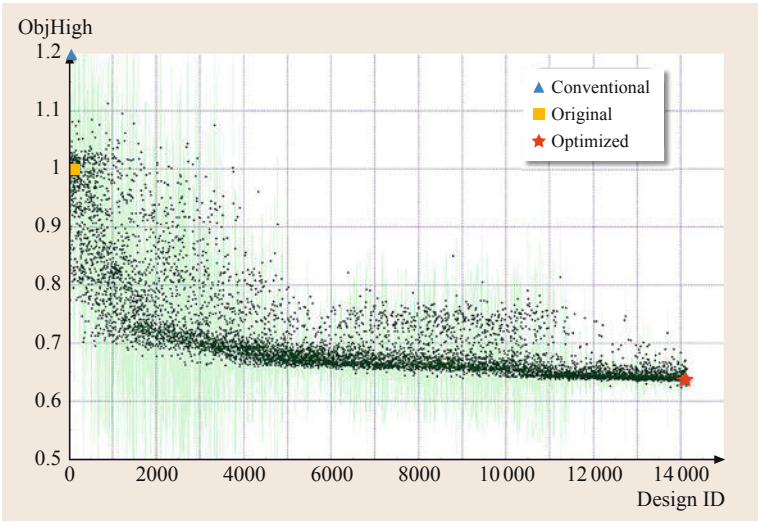

Fig. 13.19 Relative reduction of the wave resistance (function ObjHigh) during the optimization procedure for different hull shapes. The points corresponding to the original (first unconventional hull design), conventional (series-58 torpedo shaped hulls) and optimized hull forms are highlighted with different symbols. Each *black point* corresponds to a different hull geometry generated and evaluated by the optimization. The total considered cases are in excess of 14 000

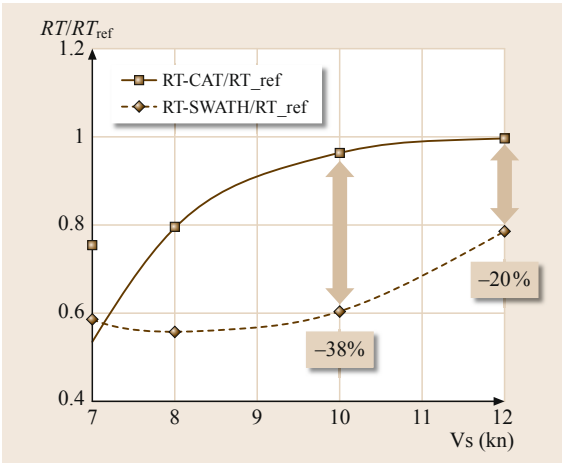

Fig. 13.20 Comparison of the total resistance predicted for the AUSV-SWATH and an equivalent catamaran. Values on the *y*-axis are relative to the total resistance of the catamaran predicted at 12 kn

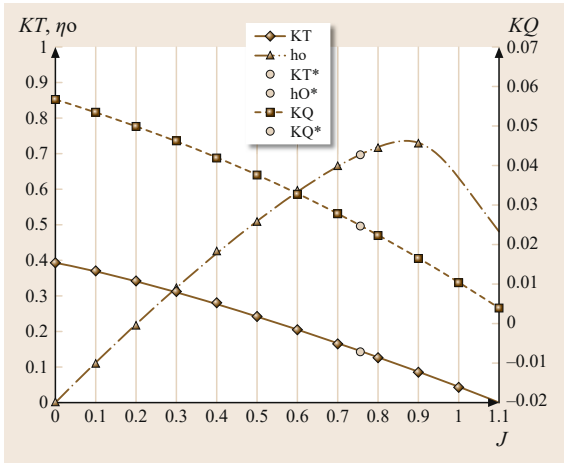

Fig. 13.21 Open water characteristics of the optimum propeller

similarly to its sister design variant in hull-borne mode (ONRG in Table 13.1). A fully automatic, computer driven, optimization procedure based on a new fully 3-D parametric model of the hull surface [13.57] was used to find the unconventional shape. This procedure is based on a viscous-inviscid flow solver for the prediction of the wave and viscous resistance of a SWATH vessel as validated in *Brizzolara* [13.50].

After the optimization of the underwater hull forms at the design cruise speed, the resistance–speed curve of the vessel was computed in a complete range of speeds by high fidelity CFD simulations with a fully turbulent, viscous, free surface flow model, validated against experimental tests in a towing tank on different occasions [13.58], also in the case of unconventional SWATH vessels [13.59]. At hump speed, a characteristic relative maximum of the resistance coefficient curve versus speed appears, which is typical of high speed SWATHs and corresponds to a critical bow-down dynamic attitude, which must be corrected by the action of active fin stabilizers. The two couples of fins, arranged at the bow and stern sections of the interior of the underwater hulls, are controlled to dampen roll and pitch motions in waves, as well as to regulate the attitude of the vessel at speed. Steep and high waves are generated at a hump speed corresponding to 5–6 kn for the AUSV presented in Fig. 13.12 ($Fr_L = 0.33–0.4$). This critical speed range, similar to the pre-planing regime of hard chine fast crafts, should be avoided during transfer. As a consequence of the hull form optimization for

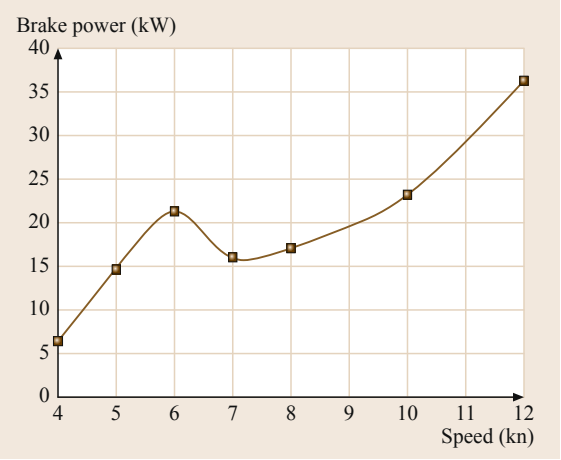

Fig. 13.22 Estimated total brake power with optimum propellers and twin shaft

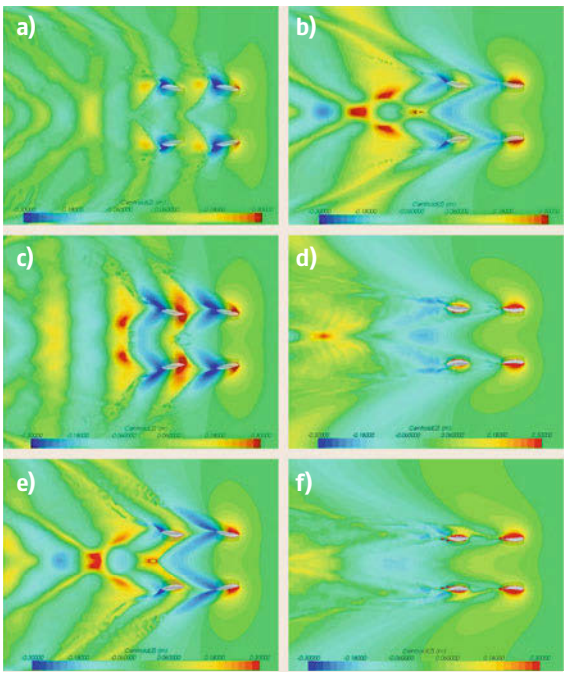

Fig. 13.23a–f Free near-field wave patterns calculated with the RANS solver for the optimized hull form at different speeds: **(a)** 5 kn, **(b)** 8 kn, **(c)** 6 kn, **(d)** 10 kn, **(e)** 7 kn, **(f)** 12 kn

higher speeds, the resistance drops considerably at 7 kn and then rises with a milder slope than equivalent conventional SWATH or catamarans (Fig. 13.20).

Figure 13.20 also presents the results of a comparison study with the resistance predicted for an equivalent conventional catamaran. The catamaran hull was obtained by transformation in affinity from the Marintek catamaran [13.60, p. 279], which is representative of a good high speed modern catamaran hull form. The original Marintek hull was non-uniformly scaled with two different scale factors, one for length and the second one for beam and draft, to reach an overall length of 7 m and the same displacement of the SWATH. Hull spacing of the catamaran was selected in order to reach the same deck area. The final catamaran hull is presented in Fig. 13.24, overlapped in 3-D onto the SWATH hull. The shape optimization procedure adopted to design the AUSV-SWATH hull allows for 38% drag reduction at 10 kn (the actual speed considered for the optimization) and 20% drag reduction at top speed (12 kn in this case). These are considerable values and imply a significant increase of endurance with respect to the current state-of-the-art.

On the basis of the effective power estimated with the RANS solver, selection of the optimum propeller of the Wageningen B-series was performed (Fig. 13.21). With the known load coefficient K_T/J^2, calculated at design speed, the optimum propeller has a diameter of 700 mm, a maximum rotational speed of 490 rpm at 12 kn, and an open water efficiency of about 70%, which is quite good for this size of craft. This high level of efficiency can be reached due to the relatively low rotational speed of the propeller, which is possible due to the reduction gear box fit in between the electric motor and the propeller.

The optimum propeller selection was based on a blade expanded area ratio of 0.45, calculated to satisfy standard cavitation criteria. An empirically derived thrust deduction factor of 0.95 and a wake fraction of 0.7 have been also assumed. The final brake power estimated on the basis of the predicted optimum propeller efficiency (Fig. 13.22) was used to select the characteristics of the two electric motors and the power of the two diesel generators, rated 22 kWe each (Fig. 13.13).

To examine seakeeping capabilities, unsteady RANS calculations [13.61, 62] with the SWATH free to heave and pitch but restrained in surge were systematically repeated for different incoming regular wavelengths, with values ranging from the SWATH hull length L, up to four times the SWATH length (Fig. 13.25, for example). All waves had the same height, nominally 3.5% of the SWATH hull length L, to be representative of extreme, non-linear conditions.

To compare the performance of the optimized AUSV-SWATH against an equivalent vessel, the seakeeping CFD simulations were repeated for a catamaran with a hard chine, deep-V hull form, previously also used for the resistance comparison and represented in Fig. 13.24 as overlapped on the SWATH.

Figure 13.25 shows a typical snapshot of the unsteady wave pattern predicted by the viscous flow solver

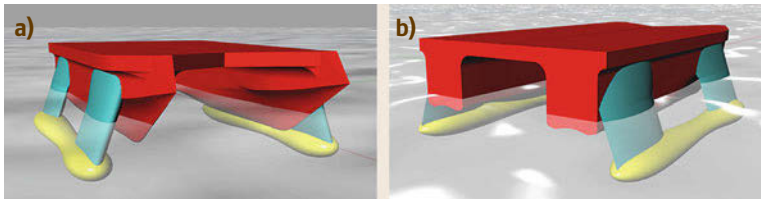

Fig. 13.24a,b Comparison by overlap of the AUSV-SWATH hull with the equivalent catamaran considered for resistance and seakeeping comparative studies. **(a)** Perspective view from bow quartering and **(b)** from stern quartering

around the AUSV-SWATH hull (superstructures are not represented) subject to an incoming wave with a length (λ) 2.5 times that of the SWATH hull length. Although the pitch and heave motions of the AUSV-SWATH, as presented later, are smaller than those of the catamaran, the radiated and diffracted waves are very well visible in the picture, consistently with the larger motion damping of the SWATH with respect to the catamaran. This is the result of the twin canted struts, which have a distinct capacity of dissipating the kinetic energy of the vessel moving in waves, by radiated waves and shed vorticity around the hull.

A hybrid strip theory method, based on two-dimensional (2-D) viscous non-linear free surface unsteady RANS calculation of radiated forces, demonstrated that the viscous effects responsible for vortex shedding are absolutely non-negligible for a correct prediction of the vertical plane motion of SWATH hull forms [13.62]. This study also confirmed that the peaks of heave and pitch response amplitude operators (RAOs) move to very high relative wavelengths (about $\lambda/L = 4.5$) in the case of this special SWATH design. At such low oscillation frequencies, the particular configuration of canted struts effectively limits the peak of the resonant response, which would be singular if evaluated with potential flow methods.

A comparison of the maximum motion amplitude during the simulations reveals that the SWATH heave and pitch motions are noticeably smaller than those of the equivalent catamaran over a wide range of incoming wavelengths (Figs. 13.26 and 13.27). As an example of the time history of the simulated pitch motion of the two crafts in the same incoming regular waves with $\lambda = 1.5L$ are given in Fig. 13.28. The heave RAO is calculated as the amplitude of the first harmonic of heave motion signal (elaborated with Fourier analysis) divided by the incoming wave amplitude. The pitch RAO is calculated as the ratio of the pitch first harmonic amplitude to the product of the wave number $k = 2\pi/\lambda$

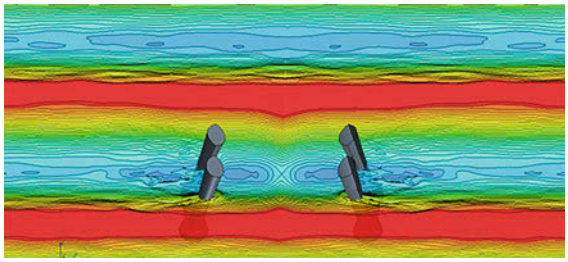

Fig. 13.25 Snapshot of the diffracted incoming regular waves around the SWATH predicted by the URANSE method ($\lambda/L = 2.5$)

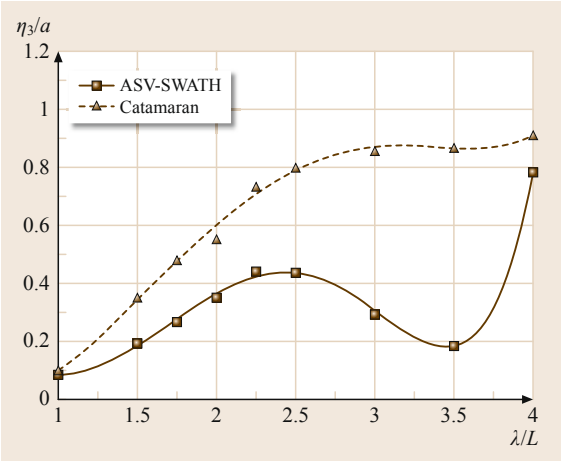

Fig. 13.26 Comparison of the heave RAO calculated for the two equivalent vessels

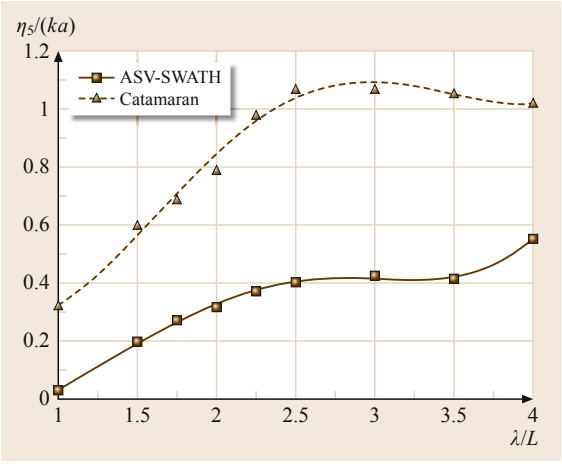

Fig. 13.27 Comparison of the pitch RAO calculated for the two equivalent vessels

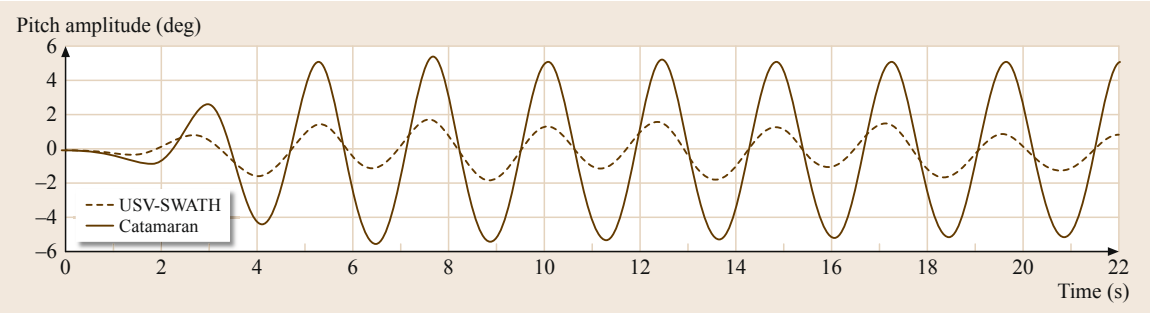

Fig. 13.28 Pitch angle time histories for the catamaran and the SWATH subject to the same regular progressing waves coming from the bow ($\lambda/L = 1.5$)

and the wave amplitude a. In the range investigated, a first relative maximum of the SWATH heave response happens for wavelengths between 2 and 2.5 times the hull length, but it still measures half of the catamaran heave amplitude. At the same time, the maximum SWATH pitch motion is less than 1/3 of that of the catamaran over the entire wave frequency range investigated. No distinct peak is noted in the pitch RAO for the SWATH; again this is a desirable effect consequence of the twin canted strut design of the unconventional SWATH, which smooths out and shifts the resonance peak towards very high relative wavelengths.

The calculated RAOs which correctly accounts for 3-D and viscous effects can be used to predict the motions of the SWATH design in irregular waves [13.62], according to linear seakeeping theory. This procedure can be conveniently repeated at different ship scales to evaluate the size of the unconventional autonomous vessel that best adapts to the particular sea state in the mission area.

13.5 Conclusions

With the advent of autonomous maritime systems, the opportunity exists to design a new class of surface vessels from the keel up to perform optimally as an integral component of such systems. Greater autonomy will enable the design of AUSV platforms for which no human will ever set foot on board. This will afford the opportunity to revisit approaches to platform design and naval architecture, and could result in radical changes to surface platforms [13.6]. Ships' hull and superstructure geometry, internal structure, and volume might be optimized for payload or fuel fraction rather than human habitability. Design limits and margins for structural adequacy, reserve buoyancy, stability, dynamics, and platform orientation might be different for AUSVs than for manned platforms, and result in additional mission capability. Higher risk mission profiles, untenable for human-inhabited ships, could be considered. New platform designs that result in increased platform performance may in the future lead to capabilities and missions not anticipated today.

As with all systems engineering, trade-offs abound, and mission requirements are necessary to constrain a design. Here, as an example, the requirements of a persistent, 4-D ocean monitoring and surveillance system have been defined, and an unconventional SWATH hull form has been designed to satisfy those requirements (Fig. 13.28). The advantages of a SWATH include superior seakeeping capability in high sea states with respect to other conventional displacement hull topologies, as well as better resistance and powering characteristics relative to conventional shapes. Such advantages are at a premium due to the functioning of this vessel as a critical interface between subsurface autonomous vehicles and unmanned aerial vehicles (thus the stability requirements). In addition to operating as a control node for such a network of autonomous platforms, the SWATH AUSV also functions as a long haul freighter for transport of such a system to its theater of operation (thus the efficiency requirements). In considering this requirement, transport efficiency comes into play (Fig. 13.29).

To compare the energy efficiency of different means of transport and assess the limit of a new technology, often a metric is used that was first introduced by *Gabrielli* and *von Kármán* in the middle of the last century [13.63]. It was defined as the specific power, relative to the vehicle displacement or the payload weight, and it was plotted versus speed in a logarithmic diagram. Such a diagram is useful to identify the technological efficiency limits of different types of vehicles (terrestrial, aerial, etc.) and hence to assess their transport efficiency at a glance. Different formulations

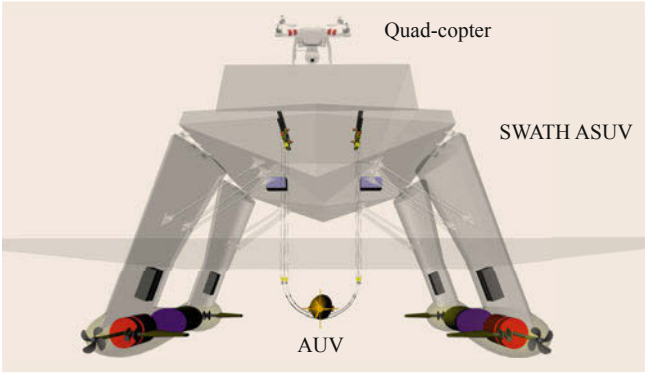

Fig. 13.29 Unconventional SWATH autonomous surface vessel as support platform of the 4-D autonomous ocean monitoring and surveillance system

of the diagram have been created since then and applied to different fast ship databases, for instance, *Papanikolaou* [13.64]. Here we refer to an updated version of the diagram, reported by *Almeter* [13.65], which is based on the most recent data for different typologies of marine crafts.

The transportation efficiency factor (TEF) in its non-dimensional form is defined as

$$\mathrm{TEF} = \Delta \frac{V}{P_\mathrm{B}} , \tag{13.3}$$

where Δ = vehicle weight, V = vehicle speed, and P_B = total brake power used to drive (propel and eventually sustain) the vessel at the given speed. All parameters are expressed in consistent units.

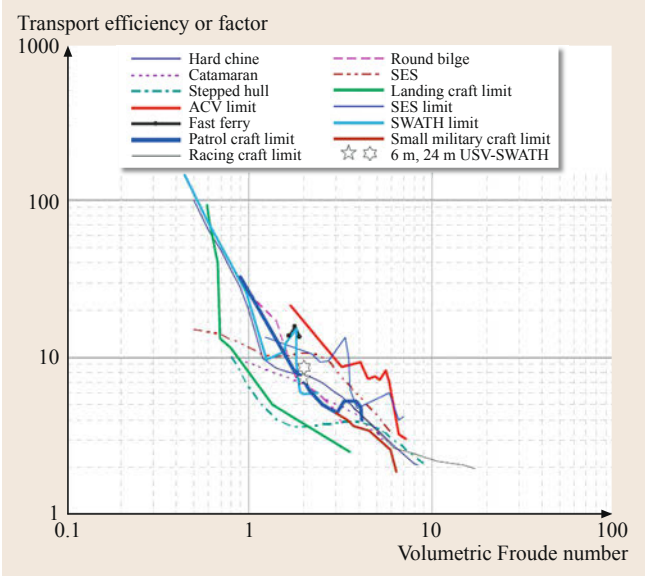

Fig. 13.30 Transport efficiency for different types of high speed crafts (after [13.65])

The transport factor is plotted versus the volumetric Froude number in the logarithmic chart of Fig. 13.30 for different technologies of high speed marine crafts. It should be kept in mind that the database of these crafts is composed of usually medium to large vessels and that the scale of the vessel has an impact (the smaller the worse) on the efficiency factor. Two different sizes of AUSV-SWATH designs – a 6 m long version briefly presented in the previous section and a larger scaled version 24 m long – are reported and compared in the figure with the other vehicle technologies. As is evident, at their design Froude number $\mathrm{Fr}_\nabla = 2.0$, the presented vessels have a higher efficiency than the conventional curve of high speed SWATH vessels, even though the considered sizes are surely smaller than the equivalent ones of the SWATH vehicles. In general, the efficiency index reduces when a ship is scaled to a smaller size according to Froude similitude; the Reynolds number, in fact, increases and with it friction resistance and form drag (relative to displacement). This is confirmed by the two different positions that the points representing the two AUSV-SWATH vehicle sizes assume on the graph of Fig. 13.29. The larger SWATH shows a higher efficiency getting closer to more sophisticated technologies such as surface effect ships. Generalizing, we can conclude that the transport efficiency attained by the optimized SWATH design is more than competitive with conventional monohull patrol crafts, catamaran, and fast planing hulls. This gap is expected to increase even further when added resistance in waves is considered. Experimental and numerical investigations are being carried out in this respect at MIT iShip lab.

However, the transport factor, although significant to assess the merit of the hull form optimization, is not the main performance goal for the autonomous surface craft, which has to be sought in the ability to perform launching and recovery missions in higher sea states than equivalent vessels. In this respect, the drastically lower RAO of pitch and heave motions of the unconventional SWATH design with respect to equivalent catamarans for a large range of incoming wave lengths, as previously presented, surely brings the particular design presented to a preferential place.

The AUSV, in turn, must interface with global scale transport infrastructure for cost-effective forward deployment. From here, the selection of the presented small size of particular unconventional SWATH design is oriented to compact (and standard) packaging requirements (ISO container size). The cost efficiency of the AUSV mainly derives from their easy and quick availability through the global transport infrastructure

network, which is nowadays based on standardized container modules. A highly portable, economically viable, persistent 4-D network based on the presented AUSV will be a major enabler for new and more extensive testing, leading to greater reliability and higher transition-to-operations potentials in many different marine offshore and coastal research fields. This revolution is not far away in time from us as it is envisaged at MIT.

14. Autonomous Underwater Vehicle Navigation

John J. Leonard, Alexander Bahr

This chapter surveys the problem of navigation for autonomous underwater vehicles (AUVs). Navigation is critical for the safety and effectiveness of AUV missions. The unavailability of global positioning system (GPS) underwater makes AUV navigation a challenging research problem. Recent years have seen considerable improvements in performance and reduction in the cost and size of the various sensor devices available for ocean vehicle navigation. In concert with these developments, advances in algorithms such as simultaneous localization and mapping, and cooperative navigation have enabled dramatic improvements in the navigation capabilities of AUVs. These improvements in AUV navigation have contributed to the successful deployment of AUVs for a wide variety of applications over the past decade.

This chapter surveys the problem of navigation for autonomous underwater vehicles (AUVs). We review the major types of sensors available for underwater navigation, and then describe some of the key techniques employed, including long baseline (LBL) navigation and simultaneous localization and mapping (SLAM) algorithms. Subsequently, we describe several example navigation systems utilized in recent AUV systems. Figure 14.1 shows some examples of the wide range of AUVs that are in use today. The selection of appropriate navigation sensors and algorithms, based on cost, power, size, and mission constraints, is a key element of AUV system design [14.1].

Navigation is an important requirement for any type of mobile robot, but this is especially true for AUVs. Good navigation information is essential not only for the safe operation and recovery of the AUV, but also for the data gathered by an AUV to be of value. For many types of AUV missions, such as seabed mapping and mine countermeasures, the quality of the data acquired by the vehicle depends critically on the accuracy of the vehicle's navigation system. Cost can be a major factor in AUV navigation system design. This is especially true for applications that involve the coordinated operation of multiple vehicles.

The absence of global positioning system (GPS) measurements underwater makes AUV navigation a difficult challenge. Without an external reference in the form of acoustic beacons at known positions, the vehicle has to rely on proprioceptive information obtained through a compass, a Doppler velocity logger (DVL) and/or an inertial navigation system (INS) to perform dead reckoning (DR). Independent of the quality of the sensors used, the error in the position estimate based on

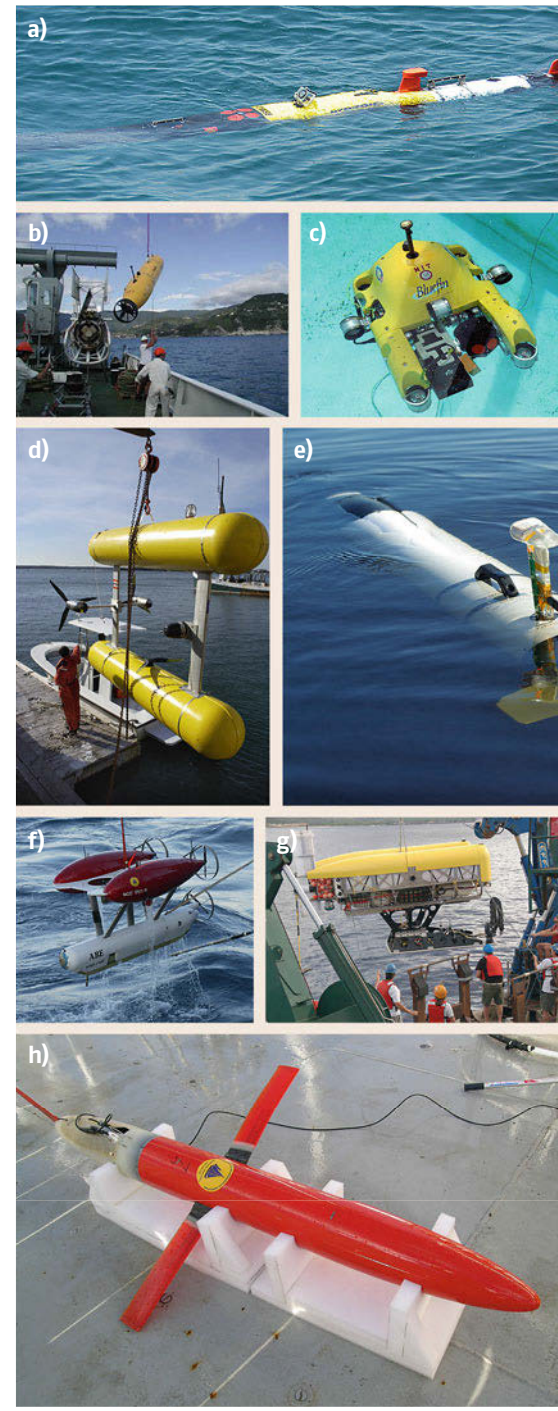

Fig. 14.1a–h The AUV systems that employ the diverse range of navigation sensors and algorithms described in this chapter include the REMUS [14.2], Bluefin 21 [14.3], HAUV [14.4], Seabed [14.5], Iver2 [14.6], ABE [14.7], and Nereus [14.8], AUVs and the Spray glider [14.9]. DR information grows without bound. Typical navigation errors are 0.5–2% of distance traveled for vehicles traveling within a few hundred meters of the sea floor such that their DVL has a lock on the bottom. Errors as low as 0.1% can be obtained with large and expensive INS systems, but for vehicles relying only on a compass and a speed estimate, the rate of error can be as high as 10%. By surfacing the AUV can obtain a position update through its GPS, but this is impossible or undesirable for many applications. The use of static beacons in the form of an LBL array limits the operation area to a few km^2 and requires a substantial deployment effort before operations, especially in deep water.

As underwater vehicles become more reliable and affordable, the simultaneous use of several AUVs has become viable, and it is anticipated that multivehicle deployments will become standard in the upcoming years. This will not only make entirely new types of missions which rely on cooperation possible, but will also allow each individual member of the group to benefit from the navigation information obtained from other members. For optimal cooperative localization, a few dedicated Navigation Aid-AUVs (NAs), which maintain an accurate estimate of their positions through sophisticated DVL and INS sensors, can enable a much larger group of vehicles with less sophisticated sensor suites to maintain an accurate position.

Navigation (along with communications, power, and autonomy) has been one of the fundamental challenges in the development of AUV technology. Underwater vehicle navigation is a challenging problem for several reasons. Due to the absorption of electromagnetic radiation in the ocean, GPS is only available at the surface. Unfortunately, there is no *silver bullet* solution for the AUV navigation problem. There are five primary technologies that an AUV designer has to draw upon in selecting an AUV navigation system:

1. Proprioceptive sensing
2. GPS
3. Acoustic transponder navigation
4. Map-based navigation
5. Cooperative navigation of multiple vehicles.

Proprioceptive navigation refers to using measurements of the vehicle's self-motion to deduce the vehicle's position. There are two major categories, based on price: (a) INS combined with DVL, and (b) magnetic compass/attitude heading reference systems. Integrated INS/DVL systems typically cost up to $100 000 and have been integrated on many large-scale, high-cost AUV systems. In the past two decades, the cost and

size of proprioceptive navigation sensors have reduced dramatically, making them available to smaller and lower-cost AUV systems. The performance claims of better than 0.1% of distance traveled have been made in the literature [14.10].

Regardless of sensor cost and quality, the problem with exclusive reliance on proprioceptive sensing is that the position error increases without bound as the distance traveled by the vehicle increases. The rate of increase will be a function of ocean currents, the vehicle speed, and the quality of dead reckoning sensors. If a vehicle can surface, then GPS can be used for a position fix. Indeed, many AUVs have demonstrated this capability. However, frequent surfacing is impractical for deep-water missions and is undesirable for other types of missions.

In acoustic navigation, transponders serve as *beacons* to constrain INS/DR error growth without the need for resurfacing. Two types of systems have been primarily employed [14.11–13]: LBL and ultra-short baseline (USBL). Both systems employ external transducers or transducer arrays as aids to navigation. Acoustic navigation is a well-established and widely used technique. However, in littoral waters, a number of sources of error occur. These include: multipath, drop-outs, fading, and reverberation. Further development is required to attain better outlier rejection and improve robustness for autonomous operations [14.14]. A longer term goal is to fully integrate navigation, communications, and tomography [14.15].

For many applications, deployment of acoustic beacons is undesirable, and map-based navigation presents an alternative. If an accurate a priori map of the environment is available, one approach to globally-referenced position estimation is to use measurements of geophysical parameters, such as bathymetry, magnetic field, or gravitational anomalies [14.16, 17]. In practice, an up-to-date, high-quality map may be unavailable in the operating area of interest. This motivates research into the problem of SLAM, in which the goal is for the AUV to build a map of its environment and to use that map to navigate in real time.

The structure of this chapter is as follows. Section 14.1 describes available sensors for measuring depth, heading, velocity, acceleration, acoustic range and bearing, and GPS. Section 14.2 describes the main navigation algorithms including DR and inertial navigation, LBL and USBL navigation, geophysical and map-based navigation, and cooperative localization. Section 14.3 summarizes the performance of several typical types of AUV systems in use today, and provides an outlook for future developments in this area.

14.1 Sensors

14.1.1 Depth

All submersible vehicles are outfitted with a pressure sensor [14.18] that allows an accurate determination of absolute depth using the known properties of sea water [14.19]. As a result, all other underwater navigation systems are only used to resolve the two-dimensional (2-D) position, (i. e., longitude and latitude) and underwater-vehicle-related localization problems are typically stated in 2-D. Quartz crystal pressure sensors can typically attain accuracies of 0.01% or better, but achieving full accuracy requires careful calibration and thermal compensation [14.1].

14.1.2 Compass

Like the pressure sensor, a compass is part of the basic navigation sensor suite of most underwater vehicles, as it is an inexpensive and low-power device. It provides the three-dimensional (3-D) vector of the local magnetic field. Before computing the heading from the magnetic field vector, it is necessary to carefully calibrate the compass each time the vehicle's area of operation changes, as the difference between the orientation of the 3-D magnetic field vector and the direction of true north (called *variation*) depends on the geographic location. In addition to the spatially slow variation, there are highly localized *magnetic anomalies*. The compass output is also affected by its position in the vehicle as electrical currents create magnetic fields which cannot be discerned from the earth's magnetic field. On-line compass calibration algorithms [14.3, 20] can substantially improve performance.

14.1.3 Gyroscopes

Gyroscopic systems measure changes in vehicle orientation by exploiting physical laws that have predictable effects under rotation [14.21]. Available sensors include mechanical gyrocompasses, ring laser gyroscope (RLG), fiber optic gyroscope (FOG), dynamically tuned gyroscope (DTG) and micro-electromechanical (MEMS) devices [14.22]. Optical gyroscopes have become popular as an accurate angular rate sensor, and operate on the SAGNAC principle [14.23]. However, sensible DR navigation requires high gyroscope performance increasing the associated costs significantly.

The power consumption and size of common optical gyroscopes have limited their use to larger and more expensive AUVs [14.1].

14.1.4 Attitude Heading Reference Systems

An attitude-heading reference system (AHRS) unit typically consists of a 3-axis gyroscope as well as a 3-axis linear acceleration sensor and a heading sensor (magnetic or gyrocompass). Combining the measurements from these sensors, the AHRS maintains a common algorithmic orientation estimate between the sensor cluster and the global world navigation frame. The orientation is maintained through integration of the gyroscope measured rotation rates. Long term pitch and roll stability of the orientation estimate is achieved through selective use of earth's gravity vector, which is measured by a triad of accelerometers. The long-term heading accuracy is maintained from either magnetic compass sensor readings or direct measurement of the earth rotation through the gyroscopes.

14.1.5 Inertial Navigation Systems

The sensors of an INS are the same as those of the AHRS described earlier. In addition to the AHRS, measured accelerations are rotated to the common navigation frame, as discussed above, and then double integrated to compute a position estimate for the vehicle. The initial position of the INS is obtained from an absolute position sensor (such as GPS or LBL). The process of inertial navigation is discussed in more detail in Sect. 14.2.1.

14.1.6 GPS

Almost all underwater vehicles today are equipped with a GPS receiver as it can be used to get a position fix before the start of the mission or during intermittent surfacings. GPS measurements obtained at different points during a mission can be used to constrain the error growth of position estimates derived from inertial and Doppler sensors [14.3]. Farrell provides a comprehensive summary of the mathematical techniques for integrating GPS measurements with high-rate inertial and acoustic sensors [14.24].

Fig. 14.2 (a) Doppler velocity log (DVL); (b) REMUS AUV with DVL

14.1.7 Doppler Velocity Log (DVL)

A DVL (Fig. 14.2) is a device which typically has four transceiver units that emit acoustic pulses. When a DVL is used for navigation purposes, it is usually mounted on a vehicle such that the transceivers are facing downward. If the DVL is close enough to the bottom, the transceiver will receive the reflected pulses (*bottom lock*) and as the transceivers are mounted at an angle with respect to the sea-floor plane, the received pulses will be subject to a Doppler shift if the vehicle is moving. Combining the measured Doppler shifts from all four sensors with the built-in roll, pitch, and heading sensors the DVL can then compute the vehicle's 3-D-speed vector $\boldsymbol{v}_v = (\dot{x}, \dot{y}, \dot{z})$ in a world-referenced frame.

The maximum distance between the DVL unit and the sea floor depends on the operating frequency of the transceivers. A low-frequency (150 kHz) DVL can obtain bottom-lock for ranges up to 500 m, while a high-frequency DVL (1200 kHz) can obtain bottom-lock up to 30 m.

The ranges indicated above can only be obtained under ideal conditions. A soft sea floor or vegetation can absorb most of the energy of the incoming pulse and thereby significantly decrease the maximum range. Another option is to mount the DVL in an upward-looking configuration such that the acoustic pulses are reflected at the water/air interface (*surface-lock*). Then, the vehicle measures its speed relative to the water surface, but this strategy may introduce errors in the case of significant surface currents. Figure 14.2 shows a REMUS 100-AUV with a double-DVL configuration. If bottom-lock cannot be obtained with the downward-looking DVL the vehicle tries to determine its speed using the upward looking unit. Recent developments greatly increased the accuracy of DVL-systems and errors as low as 0.2% (1200 kHz) or 1% (150 kHz) of distance traveled can be obtained.

In deeper waters, where the distance from the seabed is beyond the range of a DVL, an alternative is to use a correlation speed log sonar [14.25]. Whereas a DVL employs four angled beams, a correlation sonar utilizes a single widebeam transducer, pointing straight downward toward the seabed. By cross-correlating the received waveforms on two closely separated transducers, the displacement of the crosscorrelation peak provides a measure of the vehicle velocity. Correlation sonar navigation has been demonstrated by *Griffiths* and *Bradley* for performing long-distance under-ice excursions in deep water in polar regions with the Autosub AUV, achieving ranges greater than 1000 m [14.26].

14.1.8 Acoustic Ranging Methods

The most commonly used way to obtain absolute position information underwater is through the use of beacons. These beacons are at known locations and the AUV obtains the range and/or bearing to several of these and then calculates its position through trilateration or triangulation. Based on the location of the transceivers, we can identify three different baseline systems.

Electromagnetic energy cannot propagate appreciable distances in the ocean except at very low frequencies. Acoustic energy, however, propagates well in the ocean, and hence acoustic transponders can be used as *beacons* to guide the motion of an AUV without the need for resurfacing. Two types of system have been primarily employed [14.11–13]: LBL and USBL. Both systems employ external transducers or transducer arrays as aids to navigation.

Standard LBL

A typical LBL-configuration is shown in Fig. 14.3a. Two or more beacons are deployed around the perimeter of the area in which the AUV will operate. These beacons are anchored and float on the surface or, particularly in deeper water, a few meters above the sea floor. Each unit listens to acoustic query pings on a common receive channel. After receiving a query ping from an AUV, each unit waits for a unique turn around time (TAT) t^{TAT} and then sends out a reply ping on its individual transmit channel. The AUV then receives the reply pings. The transmit channel as well as the TAT are different for each unit. A unique TAT ensures that two beacons will not interfere by transmitting at the same time and by using different transmit frequencies the beacons provide a way for the AUV to identify from which unit a reply ping was sent. The time difference Δt_i between sending out the query ping and receiving a reply can then be used to determine the one-way travel-time (OWTT) t_i^{owtt}.

$$t_i^{\mathrm{owtt}} = \frac{\Delta t_i - t_i^{\mathrm{TAT}}}{2}$$

The distance d_i between a beacon i and the AUV is then given by

$$d_i = \frac{c}{t_i^{\mathrm{owtt}}} ,$$

where the speed of sound c is either a pre-programmed value or measured on-board. Using range measurements to several beacons and the beacon positions stored in the vehicle before deployment, the AUV can now trilaterate its position.

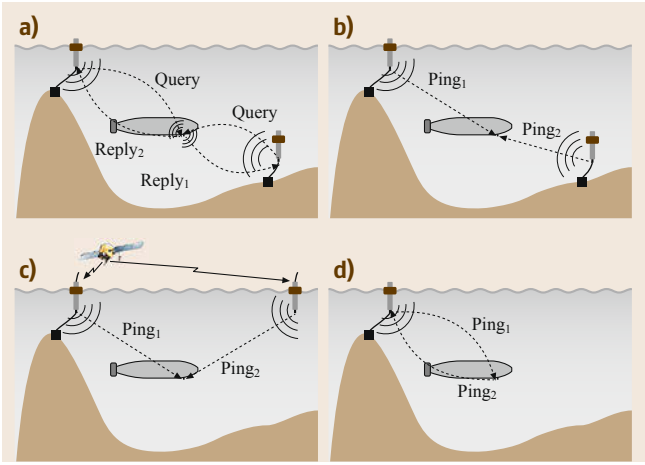

Fig. 14.3a–d Beacon-based underwater localization techniques. **(a)** Conventional (two-way) Long Baseline (LBL) navigation; **(b)** time-synchronized (one-way) LBL; **(c)** GPS-buoy navigation [14.27]; **(d)** ultra-short baseline (USBL) navigation

The maximum possible distance between the AUV and a beacon as well as the localization accuracy depends on the the frequency band used for query and reply pings. Long-range LBL-systems using the 12 kHz band work over distances as long as 10 km [14.28] and can provide an absolute position with an error between 1 and 10 m. Short-range LBL systems using frequencies up to 300 kHz band can achieve subcentimeter precision, but the maximum range is limited to 100 m [14.28]. The indicated errors assume that large outliers have been filtered out. These outliers, which can be seen in Fig. 14.4, are due to multipath and other acoustic propagation effects.

LBL Variants

Standard LBL systems such as the one described earlier are not well suited for large groups of AUVs because only one vehicle at a time can query the beacon network and get a position update. Thus, the position update interval increases with the number of vehicles. Newer LBL systems, like the one developed by ACSA [14.27, 30] and shown in Fig. 14.3b, have synchronized clocks in the beacons and the AUV transceiver units. The beacons broadcast a ping containing a unique identifier at fixed time intervals. When the AUV receives this ping, the beacon's known broadcast schedule and the synchronized clock's time ensure that the vehicle knows when a ping was sent and can directly compute the OWTT. The synchronized clocks thereby eliminate the need for query pings and allow all vehicles within the range of the beacons to get a range to the broadcasting beacon. As a result, the ping interval is independent of the number of vehicles relying on the beacon network.

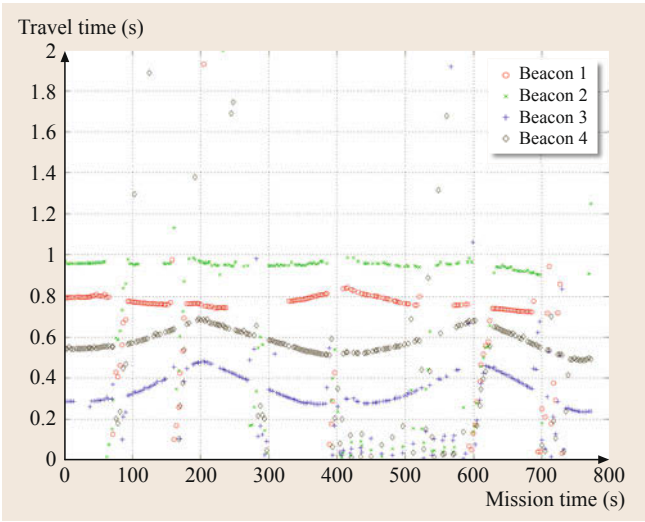

Fig. 14.4 Time-of-flight measurements obtained from four LBL beacons at the GOATS 2002 experiment (after [14.29]). The plot shows significant outliers for all beacons, particularly between 400 s and 600 s. This data illustrates the importance of techniques for outlier rejection in autonomous operations (after [14.7, 14])

Another improvement over conventional LBL is the system depicted in Fig. 14.3c. Building on the setup in Fig. 14.3b, beacons now transmit their GPS position along with the unique identifier. As with the system described previously, the vehicles do not need to query the beacons. With the position of the beacons embedded in the ping the beacons can float freely and it is not necessary to store their coordinates in the AUV before deployment.

USBL

Another variant of beacon-based navigation systems is USBL (Fig. 14.3d). Here the beacon is of the same kind as in a standard LBL system, but the transceiver on the AUV contains several receiving elements which are very close to each other. After querying the beacons, the reply ping is captured by all receiving elements. The phase difference between the signals coming from the different receiving elements allows the AUV to compute a bearing to the beacon. Combined with the beacon position stored in the AUV and the distance d obtained from the OWTT, the vehicle can compute its absolute position using only a reply from a single beacon.

Modern beacon-based systems, such as the ones shown in Fig. 14.3, significantly decrease the predeployment effort when compared to early beacon-based systems such as the standard LBL. However, all beacon-based systems confine the operating area of the vehicles to a polygon of beacons or, as in the case of USBL, to the coverage radius of a single beacon. Thus, beacon-based navigation is only feasible for operating areas of $\mathcal{O}$ (10 km^2) in size.

14.2 Algorithms

We now review some of the basic algorithms employed in AUV navigation. These are divided into:

1. Dead-reckoning and inertial navigation
2. Acoustic navigation
3. Map-based navigation
4. SLAM.

14.2.1 Dead-Reckoning and Inertial Navigation

The most obvious and the longest established navigation technique is to integrate the vehicle velocity in time to obtain new position estimates [14.31, 32]. This process is called DR. For low-cost vehicles, the measurement of the velocity components of the vehicle is usually accomplished with a compass and a water speed sensor. The principal problem is that the presence of an ocean current will add a velocity component to the vehicle which is not detected by the speed sensor. In the vicinity of the shore, ocean currents can exceed 2 km. Consequently, DR for power-limited AUVs, operating at small speeds (3–6 km), integrating water-relative speed measurements can generate extremely poor position estimates.

In inertial navigation, rotation rate measurements from gyroscopes are integrated to estimate the vehicle attitude, and measurements from accelerometers are integrated twice in time to compute the change in the vehicle position from a known initial location [14.33]. Inertial navigation is a widely studied field with a fascinating history [14.22]; *Titterton* provides a comprehensive description of inertial sensors and algorithms [14.34].

Position drift rates for current high-quality commercial grade INS units are of the order of several kilometers per hour. Initialization of the INS system for marine systems can be difficult. Cost and power consumption have historically made INS systems unattractive for small AUVs; however, this may change as systems get smaller and cheaper in the future.

As the linear and angular acceleration sensors are subject to noise, the position derived from these sensors in the absence of GPS or LBL is subject to a cumulative error and the obtained position will drift with respect to

the true position. The drift (error) e between the vehicle's true position x_{true} and the position obtained with DR x_{DR} are expressed as *drift over time* or *drift over distance traveled*

$$e = \frac{\|x_{\text{true}} - x_{\text{DR}}\|_2}{\Delta t} \quad \text{or} \quad e = \frac{\|x_{\text{true}} - x_{\text{DR}}\|_2}{\Delta x} .$$

Typically the heading and rate sensors of an INS are less noisy than those of a comparably inexpensive AHRS, which reduces the effect of accumulated drift. An INS that fits into the hull of a typical AUV shows typical drift rates of 1 km/h [14.35]. The exact performance of the most precise INS available are those developed for nuclear submarines; the drift rates for these sensors are not published but are expected to be $\mathcal{O}$ (0.01 km/h) [14.22].

For operations near the seabed, DVL sensors can be used to measure the vehicle's velocity relative to the ground. The integration of this information in the navigation Kalman filter can greatly improve the performance. For example, the DARPA Autonomous Minehunting and Mapping UUV developed in the early 1990s achieved a navigation performance of 0.01% of distance traveled using an integrated INS/DVL system [14.10]. The MARPOS system developed by Mariden A/S and the Technical University of Denmark for the MARIDAN series of AUVs represents a recent state-of-the-art commercially available AUV system, achieving 0.02% accuracy for site surveys and 0.10% accuracy for straight-line transits [14.36].

The problem with exclusive reliance on DR or inertial navigation is that the position error increases without bound as the distance traveled by the vehicle increases. The rate of increase will be a function of ocean currents, the vehicle speed, and the quality of DR sensors. Radio and satellite navigation systems can provide an accurate position update provided the vehicle can travel at or near the surface periodically for a position fix. The maximum vehicle travel time between surfacing for a position update will be governed by DR/inertial navigation accuracy. Poor quality DR will dictate an unacceptably high frequency of surfacing. Also, vehicles operating close to the coast are in appreciable danger of collision with surface vessels if they need to frequently approach the surface for position fixes. For deep water applications, the time and energy needed by a small AUV for transiting to the surface from near the bottom are very unfavorable. Finally, surfacing is impossible in ice-covered oceans.

14.2.2 Acoustic Navigation

When acoustic transponder measurements are available, a variety of algorithms are possible. Most techniques are based on recursive least-squares estimation, often with an extended Kalman filter. As described above, in an LBL navigation system, an array of transponders is deployed and surveyed into position. The array is usually calibrated through use of an additional acoustic transponder that is hung from a surface ship and interrogates the array from various locations.

The vehicle sends out an acoustic signal which is then returned by each beacon as it is received. Position is determined by measuring the travel time between the vehicle and each beacon, measuring or assuming the local sound speed profile, and knowing the geometry of the beacon array. With this information, the relative distances between the vehicle and each array node can be calculated. The two primary techniques are (1) to compute position fixes by locating the intersection point of spheres of appropriate radii from the beacons in the array, and (2) to integrate the raw time-of-flight (TOF) measurements into an appropriate Kalman filter.

The basic solution for computing a fix from spherical ranges to three transponders is as follows [14.14]. The local earth frame origin is at the surface. The x-axis points north, the y-axis points east, and the z-axis points down. The vehicle position in this frame is (x, y, z) and the coordinates of beacon i are (x_i, y_i, z_i). The measured round-trip travel times between the vehicle and the beacons are t_i and the associated distances are d_i. The distances are computed from the travel times by the approximate relation: $d_i = c(t_i - \tau_i)/2$, where c is the average speed of sound (Note: spatial variations in the speed of sound can be significant, especially variations with depth [14.11]).

The analytical solution based on measurements from three beacons consists of solving the following nonlinear system of equations for the vehicle coordinates

$$(x-x_i)^2 + (y-y_i)^2 + (z-z_i)^2 = d_i^2, \quad i = 1, 2, 3 . \tag{14.1}$$

In order to make the computations easier, we first compute the solution in an intermediate frame obtained by shifting the local earth frame at the location of beacon 1. The beacon coordinates in this frame are (x_i', y_i', z_i') and the vehicle position is (x', y', z'). The intermediate solution is then transformed back to the local earth frame. Advantage is also taken of the accurate knowledge of the vehicle depth, leading to a linear over-constrained problem (three equations known and two unknowns). The vehicle position is then

$$x = \frac{b_1 c_2 - b_2 c_1}{a_1 b_2 - a_2 b_1} + x_1 , y \quad = \frac{a_2 c_1 - c_2 a_1}{a_1 b_2 - a_2 b_1} + y_1 , \tag{14.2}$$

with

$$
\begin{aligned}
a_1 &= -2x_2' \,, \\
b_1 &= -2y_2' \,, \\
c_1 &= x_2'^2 + y_2'^2 + z_2'^2 - 2z'z_2' - d_2^2 + d_1^2 \,, \\
a_2 &= -2x_3' \,, \\
b_2 &= -2y_3' \,, \\
c_2 &= x_3'^2 + y_3'^2 + z_3'^2 - 2z'z_3' - d_3^2 + d_1^2 \,.
\end{aligned}
$$

When measurements from four beacons are available, least-squares minimization can be performed [14.37].

In more difficult acoustic environments, such as in shallow water or in the Arctic, it becomes difficult to distinguish between the direct arrival and multipath interference, and the rejection of outliers becomes a key issue, as shown in Fig. 14.4. In a fix computation scheme, one can rule out spurious fixes, whereas in a Kalman filter-based system, one can gate the raw TOF values [14.14].

A variant of this system is *hyperbolic navigation*, in which the vehicle does not actively ping but instead listens to an array of beacons whose geometry is known [14.38]. Each beacon pings in a specific sequence relative to the others at its specified frequency. By knowing which beacon pings when and the geometry of the array, the vehicle can reconstruct where it must be in space in order to hear the ping sequence as recorded. This system has the advantage of saving the vehicle the power expenditure of active pinging, and is especially useful for multiple AUV operations. With an active (spherical) LBL system, multiple AUV operations require careful sequencing of the pings between vehicles [14.39].

Most LBL systems work at a frequency of $\approx 10\,\mathrm{kHz}$ and provide position accuracy to within a few meters with a maximum range of the order of a few kilometers. Alternative systems operating at 300 kHz have been created that can provide positioning repeatability down to 1 cm resolution in a triangular operating area that is 100 m to a side [14.40].

In USBL navigation, the vehicle has a multielement receiver array that enables it to measure the angle as well as the range to an acoustic beacon. This system is a variant of a popular system for tracking an underwater vehicle from a surface ship [14.41]. By measuring the arrival time (phase) difference of a single sonar ping between two or more hydrophones, the bearing from the vehicle to the beacon can be determined. If the beacon responds to vehicle interrogation, then the time delay (and hence distance, as with an LBL array) can be calculated. Knowing the distance and direction to the beacon allows for local navigation [14.42]. Knowing the latitude/longitude of the beacon allows for geodetic navigation. This type of system is especially effective for homing and docking operations, which are important for Arctic [14.43] and autonomous ocean sampling network [14.44] deployments.

Errors in both LBL and USBL arrays come from many sources. The key sources of error can be broken down into two primary categories: errors in the assumed array geometry and errors in the assumed sound speed profile. Positioning error comes from inadequately or improperly surveying the relative and/or geodetic positions of the array beacons. In the event that only local navigation is desired, then only relative beacon positions are relevant. If the navigation is to be geodetic-referenced, then the beacons must be located globally as well. Sophisticated software packages are available for accomplishing this. Self-calibrating beacons simplify the task by reducing the surveying task to only one beacon with the others determining their own positions relative to the first. However, this raises the possibility of relative position errors due to errors in the assumed local sound speed.

A significant difficulty in acoustic navigation can be caused by an error in the assumed sound speed profile. An inaccurate sound speed profile will appear as a distance bias in the calculations. Reflection or multipath errors will result in incorrect TOF values and hence erroneous position fixes. Typically, LBL works well in deep water and with array separations of a few kilometers. Over longer distances in shallower water, more complex propagation effects come into play and increase the frequency of bad position fixes. If the topography is sufficiently severe, beacons may be occluded by rocks or other seabed formations. Even if the sound speed profile is known at the start of an AUV mission, the acoustic propagation environment can change during the mission [14.45].

Acoustic tomography refers to the goal of using travel time information between one or more vehicles and vertical hydrophone arrays to estimate the sound speed profile and other information at various places in the intervening water column [14.46]. These techniques are being investigated from scales of a few kilometers [14.47] to the global scale [14.48]. To perform moving source acoustic tomography with an AUV, one needs to know the location of the vehicle to a high precision. In addition, one needs to be able to identify the different propagation paths of the different arrivals received by each hydrophone [14.46]. This same information (effectively, knowing the channel impulse response of the environment) is vital for providing effective acoustic communications [14.49]. Hence, the problems of acoustic tomography, communication, and navigation are closely intertwined. An interesting idea

for future research may be to employ techniques from acoustic time reversal [14.50] to achieve higher accuracy in range estimation while concurrently estimating ocean acoustic propagation conditions.

14.2.3 Geophysical Map-Based Navigation

For some applications of AUVs, the use of acoustic beacons is undesirable or impractical. If an accurate a priori map of the environment is available, one approach to globally-referenced position estimation is to use measurements of geophysical parameters, such as bathymetry, magnetic field, or gravitational anomaly [14.16, 17, 51, 52]. These approaches are based on matching sensor data with an a priori environment map, under the assumption that there is sufficient spatial variation in the parameter(s) being measured to permit accurate localization.

All forms of map-based navigation are motivated by the desire to operate at an arbitrary location without the additional expense or problems associated with the installation of artificial beacons. In principle, the process appears straightforward: gather information about the surrounding terrain and match that information to an on-board map or database of terrain information. When the vehicle has a match to the database, then it knows its location on the map. This is analogous to the method which humans use to navigate; we find our way to our destination by locating and identifying landmarks which are familiar to us – either from past experience or via a map which has been constructed for our benefit.

In practice this form of navigation is not so simple. The vehicle is attempting to navigate by matching a set of sensed data with an a priori map or dataset of stored data. Two key problems are the cost and difficulty of generating the a priori maps and the computational complexity of searching for a peak in the n-dimensional correlation surface, where n is the number of dimensions in the map or sensor data set. Typically, map making expense is governed by both the type of data being collected and the desired resolution of that data. Determining the map resolution has a direct effect on the size and level of detail of the search needed to locate the vehicle in space. Since the vehicle could be in any of a large number of possible orientations relative to the original dataset, the search must be performed over all possible locations and orientations. This is a potentially large search space, necessitating some simplifications and/or simplifying assumptions in order to make the search more tractable. Typical simplifications are: restricting the types of map data stored (what sensor values, how many different sensors), lowering map resolution, *patchy* maps (maps of key areas only), restricting vehicle orientations (to reduce the correlation problem), and using inertial navigation or dead reckoning systems to limit the valid search area.

Evidence exists that geomagnetic navigation is employed by birds, fish, and other animals for migration and general navigation [14.53]. The magnetic flux density of the earth varies according to latitude, the presence of man-made and natural anomalies, and even one's depth in the ocean, increasing from 6 to 30 nT/km depth, depending on location [14.54]. Additionally, there are small but predictable variations in the earth's magnetic flux from day to night, and large arbitrary changes during magnetic storms; magnetic maps can be rendered useless for the duration of such storms. Useful magnetic maps, generated by satellites or surface ships, can be employed by underwater vehicles by accounting for the daily field variations and by calculating the effective magnetic field at depth using a Laplace field equation, setting the boundary conditions at the ocean surface [14.55].

Research into the nature of the earth's gravitational field has demonstrated that it is far from uniform and indeed possesses a varied topography [14.56, 57]. These variations are due to a variety of factors, especially the effects of local topography [14.58] and density inhomogeneities [14.59]. Variations in the earth's gravitational field on the ocean's surface relative to a regular ellipsoidal model have been measured to be on the order of 30–50 mgal [14.60]. Gravity maps were originally gathered on behalf of the US Navy for the purposes of INS calibration [14.61]. To an INS, the effects of a change in the local gravitational field are indistinguishable from accelerations of the vehicle itself. *Gerber* [14.62] proposed the use of a gravity gradiometer as an aid to INS. *Jircitano* et al. extended this idea to the AUV community, performing navigation simulations using a model of the Bell Aerospace Textron Gravity Gradiometer System [14.60] with good preliminary results. The drawbacks to such a system are the size, expense, and complexity of a gradiometer. In addition, the gradiometer must be mounted on an inertially stabilized and vibrationally isolated platform, making its use difficult on small, low-cost scientific AUVs.

Geophysical navigation algorithms have origins in techniques of navigating at sea using depth soundings that have been in use for centuries [14.31]. *Kamgar-Parsi* has developed techniques for performing geophysical navigation that are based on fitting contour lines to sensor data and matching these curves to an a priori map using matching techniques from computer vision [14.63, 64]. *Lucido* et al. have also investigated the segmentation and registration of bathymetric profiles [14.65]. *Tuohy* et al. have investigated geophysical navigation using maps of multiple geophysical parameters based on contour intersection methods [14.17]. The

reliability of any of these approaches will depend on the accuracy of the a priori map.

AUV navigation based on bathymetric data has been successfully achieved by *Bergem* [14.66]. In this system, depths are measured at different angles using a multibeam sonar. This gives an accurate profile of the sea floor, and the absolute position is determined by matching this profile against an a priori known detailed bathymetric map of the actual area. This idea is motivated by the successful employment of this technique to missile guidance systems.

14.2.4 Simultaneous Localization and Mapping

In practice, an up-to-date, high-quality map may be unavailable in the operating area of interest. This motivates research into the use of SLAM to enable an AUV to build a map of its environment while concurrently using that map to navigate in real time [14.67]. SLAM is a probabilistic estimation problem in which noisy sensor measurements are combined into a probabilistic representation of the state of the sensor and the observed surroundings. This model needs to be updated and extended sequentially by integrating new sensor measurements as they become available.

The variables to be estimated and the sensor measurements can be described in a graph [14.68] that captures their relation. We use a factor graph [14.69] as a general graphical model representation of the SLAM problem. Formally, a factor graph is a bipartite graph $G = (\mathcal{F}, \Theta, \mathcal{E})$ with two node types: *factor nodes* $f_i \in \mathcal{F}$ and *variable nodes* $\theta_j \in \Theta$. Edges $e_{ij} \in \mathcal{E}$ are always between factor nodes and variable nodes. A factor graph G defines the factorization of a function $f(\Theta)$ as

$$f(\Theta) = \prod_i f_i(\Theta_i) \,, \tag{14.3}$$

where Θ_i is the set of variables θ_j adjacent to the factor f_i, and independent relationships are encoded by the edges e_{ij}: each factor f_i is a function of the variables in Θ_i. Our goal is to find the variable assignment Θ^* that maximizes (14.3)

$$\Theta^* = \arg\max_{\Theta} f(\Theta) \,. \tag{14.4}$$

The general factor graph formulation of the full SLAM problem is shown in Fig. 14.5, where the landmark measurements m, loop closing constraints c and odometry measurements u are the examples of factors. Note that the factor graph formulation supports general probability distributions or cost functions of any number of variables, allowing, for example, the inclusion of calibration parameters.

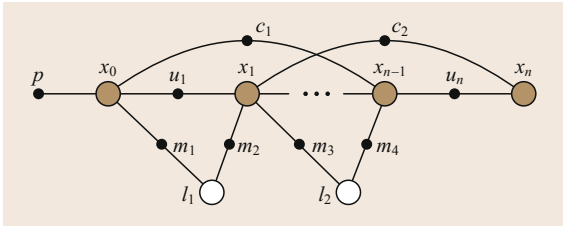

Fig. 14.5 Factor graph for the pose graph formulation of the SLAM problem

It is standard in the SLAM literature [14.70, 71] to assume Gaussian measurement noise models

$$f_i(\Theta_i) = \mathcal{N}(h_i(\Theta_i); z_i, \Sigma_i) \propto \exp\left(-\frac{1}{2}\,\|h_i(\Theta_i) - z_i\|^2_{\Sigma_i}\right) \tag{14.5}$$

because the factored objective function to maximize (14.4) reduces to a nonlinear least-squares problem

$$\arg\min_{\Theta}\,(-\log f(\Theta)) = \arg\min_{\Theta} \frac{1}{2}\sum_i \|h_i(\Theta_i) - z_i\|^2_{\Sigma_i} \tag{14.6}$$

for which efficient solutions are available. Here, $h_i(\Theta_i)$ is a measurement function and z_i a measurement, and $\|e\|^2_{\Sigma} \triangleq e^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}e$ is the squared Mahalanobis distance with the covariance matrix $\boldsymbol{\Sigma}$.

Recently, least-squares solutions to the full SLAM problem dominate, but many other solutions have been proposed in the past, mostly aimed at making computational complexity manageable. For example, Kalman filter solutions to SLAM achieve greater computational efficiency by keeping only the most recent robot pose (through marginalization of previous poses). However, this approach has been shown to be inconsistent [14.72] when applied to the inherently nonlinear SLAM problem, i. e., the estimate is biased and the error covariance is smaller than the actual one. State-of-the-art approaches achieve better performance by estimating the entire robot trajectory, which is known as full SLAM. The first solution to the full SLAM problem has been presented in [14.68] and a range of iterative least-squares solvers have been applied including relaxation [14.73], gradient descent [14.74], conjugate gradient [14.75], multilevel relaxation [14.76], and loopy belief propagation [14.77]. Exploiting the sparsity of the information form [14.78], Gauss–Newton type solvers using sparse matrix factorization have since become very popular [14.37, 79–81] because of their faster convergence rate. Full SLAM incurs a computational burden that grows in time with the duration

of the mission. Strategies to mitigate this are discussed in *Johannsson* et al. [14.82].

SLAM techniques have been used successfully on a wide range of AUVs, using sonar and image measurements. A key requirement for SLAM is to be able to extract and match features from measurements obtained from different vantage points, to extract constraints that can be used to constrain error growth. Figures 14.6 and 14.7 show an illustration of the constraint matching process for features extracted from consecutive camera images in a seabed mapping task [14.83]. Visual SLAM has been successfully applied by a variety of researchers, using either sonar [14.67, 84–86] or camera data [14.87–89].

14.2.5 Cooperative Navigation of Multiple Vehicles

An exciting development over the past fifteen years has been the integration of ranging and communication capabilities in modern undersea acoustic modems, such as the WHOI micro-modem [14.90]. Given recent advances in AUV communications technology [14.64], the technology exists now for two or more AUVS to establish communication links with each other. This new capability allows the development of fundamentally new approaches to navigation based on multiple cooperating vehicles. Improved position estimation via collaboration enables the development of cooperative behaviors, permitting teams of AUVs to perform adaptive and more efficient survey missions. Ultimately, one can envision a system in which one AUV can direct other AUVs to revisit targets of interest, using complementary sensors. Two or more vehicles can be used to establish a mobile transponder network to provide positioning support for each other and for a fleet of other vehicles [14.91].

If more than one AUV is available to carry out a task and these vehicles are at least occasionally within communication range, both vehicles can cooperate in order to improve their navigation accuracy. Generally speaking, cooperative navigation relies on the fact that one vehicle may have a more accurate position estimate than another one. It then broadcasts it's own position estimate, possibly along with additional information such as the uncertainty associated with that estimate. Other vehicles, which are within the communication range of the broadcasting vehicle and receive this information, are able to obtain a relative position estimate to the broadcasting vehicle (range and/or bearing) and can incorporate this information in order to improve their own position estimate.

Systems

One key advantage of cooperative navigation is that most AUVs are already fitted with the necessary gear. In order to exchange information, a standard acoustic modem, found on most of today's AUVs, can be used. The only other information required – a range and/or bearing to the broadcasting vehicle can be obtained by slightly modifying existing modem hardware. By adding several transducers to a modem, it can determine the incident angle of an incoming transmission through the small differences in the arrival time. In addition, all vehicles can carry a very accurate clock

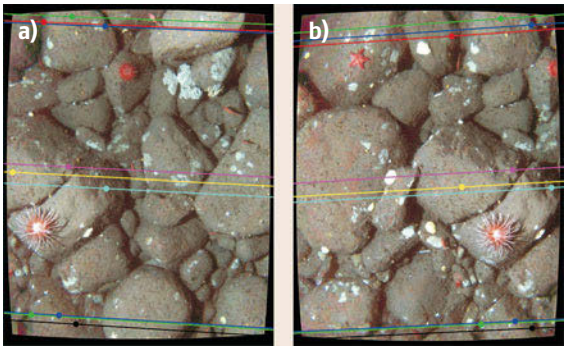

Fig. 14.6 Two consecutive pictures after being processed by the visually aided navigation (after [14.83]). From the several hundred features identified in each picture, only nine, marked by the *colored dots* have correspondences in both pictures and fit within the epipolar constraints (courtesy of R. Eustice)

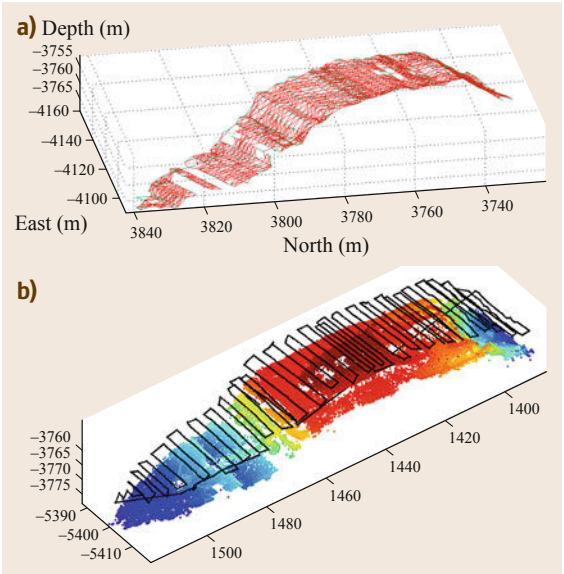

Fig. 14.7 Network of contraints **(a)** and estimated vehicle trajectory **(b)** for visual mapping of the RMS Titanic (after [14.87], courtesy of R. Eustice)

which is synchronized to a global clock via GPS on the surface [14.92–94].

Accurate time keeping has been central to precision navigation at sea throughout history [14.32]. Recent implementations of synchronous-clock one-way-travel-time acoustic navigation by *Eustice* et al. [14.92] and *Bahr* et al. [14.95] have been enabled by using a low-power temperature compensated crystal oscillator (TCXO), from SeaScan Inc., which has a typical drift of 20 ns/s, corresponding to a drift in position of approximately 2.6 m/day [14.96]. A common timebase and embedding a time-stamp indicating the broadcast time of each outgoing transmission allow a receiving vehicle to determine the time which the signal took to reach the receiver. With an accurate estimate of the speed of sound in water, the vehicle can then determine the distance to the broadcasting vehicle.

Strategies

Two different kinds of strategies can be employed for cooperative navigation. The first assumes a strict hierarchy where a group of AUVs acts as dedicated navigation aids (NAs). Their sole purpose is to provide navigation information to the mission AUVs (MAs). The NAs are thus equipped with very sophisticated sensors such that the drift of their position estimate is minimized. They may also operate very close to the surface such that they can easily surface to update their position using a GPS fix. In this scenario, only NAs broadcast navigation information and serve as mobile LBL-beacons to all MAs in communication range. As the sole purpose of the NAs is to maximize the MAs' navigation accuracy, their path can be adapted to best accomplish that goal [14.97].

The second strategy does not impose any particular hierarchy. Each vehicle occasionally broadcasts its position estimate and incorporates other overheard broadcasts. This approach does not require an extra set of dedicated vehicles, but due to the stochastic nature of received updates it is very difficult to predict, let alone guarantee, the performance of the navigation improvement of this cooperation strategy. In addition, the fact that each vehicle may transmit and receive navigation information may lead to cyclical updates. This occurs when a vehicle A incorporates information from a vehicle B and at a later point in time vehicle B then incorporates information from A. The dependencies arising between the position estimates may lead to overconfidence in the position estimate of each vehicle and must be carefully mitigated [14.98].

Algorithms

By treating the information received from a cooperating AUV as the noisy observation of landmark with an uncertain position, we can draw on a vast amount of algorithms and techniques developed by the SLAM community. Their work provides various frameworks to represent a state estimate (in this case a position) together with the uncertainty of this estimate. It also provides several methods to incorporate landmark observations, in this case received broadcasts from cooperating vehicles. Several of these SLAM techniques have been adapted for cooperative navigation [14.95, 99, 100].

14.3 Summary

Figure 14.8 shows typical navigation system performance for current AUVs based on five typical vehicle configurations. The sensor suite employed for an AUV depends on the navigation accuracy required for the mission as well as the available power, space, and the cost constraints.

14.3.1 Glider with Very Low Power Sensor Suite

Autonomous ocean gliders must operate for extended periods of time without being able to recharge their batteries [14.9, 101]. As a result, power consumption is the limiting factor for the selection of navigation sensors, and the navigation suite of a glider usually consists of a GPS, an AHRS, and a pressure gauge. While submerged the glider uses the AHRS combined with a vehicle model to estimate its heading and forward velocity and dead-reckon its position. The high noise and the unobservable variables in the vehicle model lead to a very high drift of 30% or even more if strong currents are present. On the surface, the vehicle resets its position estimate using GPS. The navigation accuracy achieved is typically more than adequate for providing data into ocean circulation models [14.102].

14.3.2 Low-Cost AUV Sensor Suite

A low-cost AUV such as the *IVER* uses a flow meter to obtain a measurement of their forward speed u_x^V. This information combined with an AHRS leads to a significant improvement of the navigation accuracy when compared to that of a glider.

14.3.3 Standard AUV Sensor Suite

The standard AUV adds a DVL to the list of sensors. When the DVL is able to obtain bottom lock a very accurate vehicle-referenced velocity vector $\boldsymbol{u}^V$ is available and the navigation accuracy improves by an order of magnitude. Drift rates as low as 1% of the distance traveled can be obtained with a well calibrated magnetic compass. Standard AUVs operating in a confined area are often outfitted with an LBL system. When operating within the polygon established by the position of the LBL beacons, the position drift will remain bounded.

14.3.4 High-End AUV

The dominant source of error in the standard AUV sensor suite described above is introduced during the transformation of vehicle-referenced velocities to world-referenced velocities as a result of errors in the heading measurements. Replacing the simple magnetic compass with an FOG improves the navigation by two orders of magnitude (0.1% of the distance traveled). When the DVL is not able to obtain bottom lock all of the vehicles described so far can only rely on the vehicle's linear acceleration sensors to obtain velocities. Due to the large noise introduced by these sensors the navigation accuracy decreases dramatically.

14.3.5 Special-Task AUV Using Visual SLAM

The special-task AUV has the same sensors as the standard AUV. Additionally, it uses a bottom-looking camera to take a series of pictures of the sea-floor. When revisiting a point it has taken a picture of before, it is able to recognize that fact and the navigation algorithm is able to reset the drift. As a result, the drift is bounded. An example, of this technique has been illustrated in Fig. 14.6. This method however requires the AUV to revisit points and stay close enough to the sea floor (< 10 m) to acquire the images.

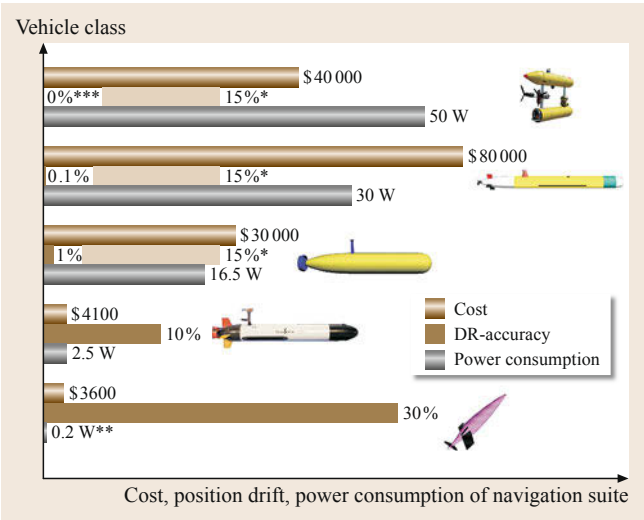

Fig. 14.8 Navigation accuracy, power consumption and price of various AUV sensor suites (*bottom to top*): (1) Glider with compass and attitude sensor; (2) low-cost AUV with compass, attitude sensor and flow meter; (3) medium-range AUV with INS, DVL and LBL; (4) high-end AUV with FOG-based INS, DVL and LBL; (5) special-task AUV with INS, DVL and SLAM. * Drift in mid water-column when DVL cannot obtain bottom or surface lock. ** Assuming a 10% duty cycle during which the navigation sensors are powered. *** Assuming that the vehicle was close enough to the sea floor throughout the entire mission to take pictures and revisit places.

14.4 Conclusion

In summary, the design of an AUV navigation system will depend on the mission requirements and cost constraints. For missions that are performed in shallow water, and for which frequent GPS surfacing is acceptable, a combination of GPS and dead-reckoning/inertial navigation will be acceptable in many situations. Cooperative navigation will become even more important in the future, as improved temperature compensated oscillators, and possibly even miniature atomic clocks, are anticipated to become widely available at low cost. This can greatly improve available options for hyperbolic and one-way time-synchronized AUV localization algorithms.

In deep water, the current state of the art is represented by the Nereus vehicle, whose sensor suite contains a Paroscientific pressure sensor, a Teledyne-RDInstruments 300 kHz Doppler sonar, an IXSEA Phins IMU, a WHOI LBL transceiver, a WHOI Micro-Modem, and a Microstrain gyro-stabilized attitude and magnetic-heading sensor [14.8]. Nereus navigates using the NavEst navigation software package developed by Woods Hole Oceanographic Institution and Johns Hopkins University, which integrates the DVLNav [14.103] package with the ABE LBL navigation suite [14.7]. This high-performance system embodies the current state of the art in deep ocean AUV navigation.

For further information on navigation sensor device performance, the reader is directed to a detailed survey by *Kinsey* et al. [14.1]. A tutorial introduction to SLAM is provided by the authors of [14.104, 105]. *Fallon* et al. gives a detailed presentation for several recent SLAM applications, including mine neutralization, real-time cooperative navigation, and ship hull inspection [14.106].

For future research in AUV navigation, a key challenge will be to develop techniques for Arctic and Antarctic operations. Polar regions pose major difficulties for AUV navigation including: high magnetic declination, inability to surface for GPS, infeasibility of deploying transponders, potentially moving ice canopy, and limited recovery options. Recent work in AUV navigation for polar regions includes the work of *Kunz* et al., who have deployed variants of the Seabed AUV in both the Arctic and Antarctic [14.107, 108].

Another ambitious goal for future research is to develop robust navigation techniques, combined with autonomous docking [14.44] and advanced communication networks [14.109], to enable long-term AUV deployments for persistent ocean sampling missions [14.110] using underice or deep ocean observatories [14.111, 112].

15. Acoustic Communication

Milica Stojanovic, Pierre-Philippe J. Beaujean

In this chapter, we discuss acoustic communication methods which are used to provide wireless connection between remote nodes operating in an underwater environment. We begin with an introductory overview of the history of acoustic communication, and an outline of current and emerging applications. We then provide a summary of communication channel characteristics, with an eye towards acoustic propagation mechanisms and the ways in which they differ from radio propagation. The main focus of our treatment is on two major aspects of communication system design: the physical link and the networking functions. On the physical link level, we discuss noncoherent and coherent modulation/detection methods, paying attention to both single-carrier modulation and multicarrier broadband techniques. Specifically, we discuss signal processing methods for synchronization, equalization, and multichannel (transmit and receive) combining. On the networking level, we discuss protocols for channel sharing using both deterministic division of resources (frequency, time, and code-division multiple access) and random access, and we also overview recent results on routing for peer-to-peer acoustic networks. We conclude with an outline of topics for future research.

15.1 **A Brief History** 360
15.2 **Current and Emerging Modem Applications** 360
15.3 **Existing Technology** 361
15.3.1 System Requirements 361
15.3.2 Commercially Available Modems 362
15.3.3 Field Tests 363
15.4 **Propagation Channel** 364
15.4.1 Attenuation and Noise 364
15.4.2 Multipath Propagation 365
15.4.3 Time Variability: Motion-Induced Doppler Distortion 369
15.4.4 Time Variability: Random Effects (Fading) 370
15.4.5 System Constraints 372
15.5 **Point-to-Point Links: Signal Processing** 374
15.5.1 Noncoherent Modulation/Detection 374
15.5.2 Coherent Modulation/Detection 375
15.5.3 Data Link Reliability 378
15.5.4 Turbo Equalization 378
15.5.5 Adapting to the Environment 379
15.5.6 Networks 379
15.5.7 Channel Sharing 381
15.5.8 Routing and Cross-Layer Integration 382
15.6 **Future Trends** 383
References 383

Wireless transmission of signals underwater over distances in excess of a 100 m relies almost exclusively on acoustic waves. Radio waves do not propagate well underwater, except at low frequencies and over extremely short distances (a few meters at 10 kHz) [15.1]. Optical signals, which are best used in the blue–green region (around 500 nm), also suffer from attenuation and do not propagate beyond about 100 m, although they do offer high bandwidths (on the order of MHz) [15.2]. Hence, sound is used for wireless transmission over anything but very short distances. Sound propagates as a pressure wave, and it can thus easily travel over kilometers, or even hundreds of kilometers, but to cover a longer distance, a lower frequency has to be used. In general, acoustic communications are confined to bandwidths that are low compared to those used for terrestrial radio communications. Acoustic modems that are in use today typically operate in bandwidths on the order of a few kHz, at a comparably low center frequency (5 centered at 10 kHz) [15.3]. While such frequencies will cover distances on the order of a kilometer, acoustic frequencies in the 100 kHz region can be used for shorter distances, while frequencies below a kHz are used for longer distances. Underwater acoustic communication over basin scales (several thousand kilometers) can be established in a single hop as well; however, the attendant bandwidth will be only on the

order of 10 Hz [15.4]. Horizontal transmission is notoriously more difficult due to the multipath propagation, while vertical channels exhibit less distortion [15.5]. Frequency-dependent attenuation, multipath propagation, and low speed of sound (about 1500 m/s), which results in a severe Doppler effect, make the underwater acoustic channel one of the most challenging communication media.

15.1 A Brief History

Among the first operational underwater acoustic systems was the submarine communication system developed in the United States around the end of the Second World War. This system used analog modulation in the 8–11 kHz band (single-sideband analog modulation AM) [15.6]. Technology has since advanced, pushing digital modulation/detection techniques into the forefront of modern acoustic communications. In the early 1980s, the advent of digital signal processing sparked a renowned interest in underwater acoustic communications, leading a group of scientists at the Massachusetts Institute of Technology and the Woods Hole Oceanographic Institution (WHOI) to propose a system based on frequency shift keying (FSK) [15.7]. The system became known as DATS (digital acoustic telemetry system) and provided a basis for the first generation of commercial digital acoustic modems [15.8]. Today, coded FSK is used in several acoustic modems, including the WHOI *micro-modem* and the Teledyne (formerly Benthos) *telesonar type B* modem [15.9]. While FSK relies on simple energy detection (noncoherent detection), and thus offers robustness to channel impairments, its bandwidth utilization is not efficient. Motivated by this fact, research in the 1990s focused on investigating phase shift keying (PSK) and quadrature amplitude modulation (QAM) for underwater acoustic channels. These modulation methods offer more bits/sec per Hz of occupied bandwidth, but require a receiver that can track the channel and compensate for the time-varying multipath and phase distortion (coherent detection). Work carried out at Northeastern University and WHOI resulted in a channel equalization/synchronization method [15.10], which forms the basis of a second generation of *high-speed* acoustic modems. Through the last decade, these modems have been used in operations involving both stationary platforms and autonomous underwater vehicles (AUVs), over vertical and horizontal links at bit rates of about 5 kbps. [15.11] gives an impressive account of a 2009 deployment near the 11 km deep Mariana Trench. A detailed summary of existing technology is given in Sect. 15.3.

Bit rates in excess of those available with operational modems have been demonstrated as well, but these results are in the domain of experimental research. At the time of this writing, research is active on improved, and ever more sophisticated channel estimation and equalization methods for single-carrier broadband systems, as well as on multicarrier modulation/detection techniques which hold a promise of reducing the implementation complexity of high-speed acoustic modems. The success of various communication techniques largely depends on our understanding of the acoustic communication channel, i. e., our ability to identify a proper model for signal distortion. We thus begin our treatment of acoustic communications links by outlining the channel characteristics in Sect. 15.4, and then move on to discuss the basic as well as the emerging concepts of signal processing in Sect. 15.5.

As technology advances, companies around the world engage more easily in modem development, and the legacy of US manufacturers such as Teledyne-Benthos, WHOI, and Link-Quest are joined by new ones such as the French Thales and the German Evo-Logics. As a result, standardization efforts are becoming necessary to ensure inter-operability between acoustic modems of different manufacturers [15.12]. While it is ultimately the need for a certain technology that will dictate the usefulness of its presence on the market, we must keep in mind that application-driven technology development is not the only way forward. More often than not, technology-driven applications arise – wireless radio industry being the prime example. In other words, as the acoustic modems' capabilities grow, applications that previously were not thought possible may start to emerge.

15.2 Current and Emerging Modem Applications

Modem applications range from ocean observation to the oil industry and aquaculture, and include gathering of sensor data from remote instruments for pollution control, climate recording and prediction of natural dis-

turbances, as well as the detection of objects on the ocean floor, and transmission of images from remote sites. Implicitly, wireless signal transmission is also crucial for monitoring and control of remote instruments, and for communicating with robots and AUVs, which can serve on isolated missions, or as parts of a mobile network. Applications involving AUVs range from search and survey missions to supervisory control and collection of mapping data, be they images, video, or side-scan sonar.

Autonomous systems are envisioned both for stand-alone applications and as wireless extensions to cabled systems. For example, a stand-alone 15 kbps acoustic link, intended to provide data transfer from bottom-mounted, battery-powered instruments such as seismometers to a surface buoy is described in [15.5]. A different example is that of ocean observatories, which are being built on decommissioned submarine cables to deploy an extensive fiber optic network of sensors (cameras, wave sensors, seismometers) covering miles of ocean floor [15.13]. These cables can also carry communication access points, very much as cellular base stations are connected to the telephone network, allowing users to move and communicate from places where cables cannot reach. Another example are cabled submersibles, also known as remotely operated vehicles (ROVs). These vehicles, which may weigh more than 10 metric tons, are connected to a mother-ship by a cable that can extend over several kilometers and deliver high power to the remote end, along with high-speed communication signals. A popular example of an ROV/AUV tandem is the WHOI's Alvin/Jason pair of vehicles that were deployed in 1985 to discover the Titanic. Such vehicles were also instrumental in the discovery of hydro-thermal vents, sources of extremely hot water on the bottom of deep ocean, which revealed forms of life different from any others known previously. The first vents were found in the late 1970s, and new ones are still being discovered. The importance of such discoveries is comparable only to space missions, and so is the technology that supports them. Today, vehicle technology, sensor technology, and acoustic communication technology are mature enough to support the visionary idea of an autonomous oceanographic sampling network [15.14]. Recent years have seen a proliferation of research on underwater sensor networks, which we discuss in Sect. 15.5.6.

15.3 Existing Technology

The field of underwater acoustic communication has become fairly mature. Many commercial units are available, along with a significant number of prototypes developed in research laboratories. The large number of configurations available complicates the selection process of a specific underwater acoustic modem. The purpose of this section is to offer some guidance in selecting an underwater acoustic modem. The authors do not recommend any specific product, rather they highlight what is important in the selection process. Following this, a brief overview of typical performance and field tests is presented.

15.3.1 System Requirements

Underwater acoustic modem users should always keep in mind that the performance of these systems changes dramatically depending on the application. For example, a system designed to operate at tens of kilometers will typically have a much lower throughput than a system designed to relay data at a few hundred meters. Also, some underwater acoustic modems are designed to operate in a complex network, while others are designed for point-to-point communication between two units.

The following list is by no mean exhaustive, but covers the main factors that should be used in selecting an underwater acoustic modem:

- *Application*: The user should always keep the application in mind when selecting an acoustic modem. Voice communication constitutes a category of its own, with well-proven technology specifically designed to relay intelligible voice with minimal delay and simultaneous two-way communication capability. Acoustic modems designed for the transmission of command-and-control messages operate more slowly, but very reliably. Image streaming can be achieved using the latest generation of high-bit rate (one-way) acoustic modems. Voice communication modems and command-and-control modems technology is much more mature than image streaming modems.
- *Cost*: Typically between $5,000 and $50,000 (US) per unit, depending on the complexity and performance.
- *Size*: Underwater acoustic modems are usually cylindrical in shape, with a pressure vessel containing the electronics and one or multiple transducers mounted on one end. The size varies from 0.05 m

diameter by 0.1 m in length, to 0.1 m in diameter by 0.5 m in length, depending on the frequency of operation (from a few to hundreds of kHz), maximum range and operating depth.

- *Power*: The power consumption depends on the range and modulation: traditionally, the total power consumption is of the order of 0.1–1 W in receive mode (depending on the receiver complexity), and 10–100 W in continuous transmission mode.
- *Data rate*: (1) underwater acoustic modems designed to operate very reliably in challenging environments, on moving platforms and over distances of several kilometers typically operate under 1000 bps; (2) in less challenging environments (e.g., vertical communications in deep waters), acoustic modems can operate at data rates well over 1000 bps.
- *Horizontal versus vertical transmission*: It is critical to understand that commercial underwater acoustic modems come in different versions depending on the type of operation. In particular, acoustic modems designed for vertical transmission in deep water use directional transducers and are capable of high data rates. A traditional mistake is to purchase this type of acoustic modems for horizontal transmission in shallow water, especially on moving platforms; in this case, acoustic modems with omnidirectional and a lower data rates should be selected.
- *Shallow water versus deep water communications (horizontal or slanted)*: In deep waters, fluctuations in sound speed (caused by changes in temperature, hydrostatic pressure, and chemical content) change the direction of propagation of sound (a phenomenon known as sound refraction). This often results in shadow zones: the sound produced by a modem will not reach the other modem, even if both modems are within operating range of one another. Echoes reflected off the sea surface and sea bottom may also be an issue at low frequencies, along with the presence of thermoclines or thermohalines. In shallow waters, the main source of limitation fades, which results from the many echoes reflected off the sea surface and sea bottom. As a result, underwater acoustic modems designed to operate in shallow waters are less likely to be in a shadow zone, but the received signal is often badly distorted and requires specific signal processing techniques (equalization, spread spectrum signaling, power, error coding) to operate reliably.
- *Range*: for the most part, the maximum operational range of an underwater acoustic modem depends on the operating frequency band of the acoustic modem, power, signaling (modulation, error coding, equalizing), environment, and transducer directivity. At low frequencies (a few kHz), commercial acoustic modems achieve reliable acoustic communications beyond 10 km horizontally, albeit at a low data rate (less than 400 bps). As frequency and bandwidth increases, some acoustic modems can transmit data at 10,000 bps or more, but the practical range is limited to 1000 m or less.
- *Operations in dynamic environments*: (1) surface activity causes Doppler spread, which limits the data rate and reliability; (2) platform dynamics cause Doppler shift, which limits the acoustic modem performance when excessive. Moving platforms usually require the use of omnidirectional transducers to avoid loss of acoustic communication.
- *Protocol for point-to-point quality of service* (*QoS*): reliability, delay, retransmission.
- *Networking capability*: Most acoustic modems are designed for point-to-point operation using a point-to-point protocol (PPP). Some series are also designed to support multiple access (MA), where two or more units can be operated within the same environment. In this case, the acoustic modems are usually operated sequentially and can be taken in and out of the water with minimal disruption to the other units. The most sophisticated acoustic modem now support routing capability between nodes, although this feature is rarely available commercially. In this case, one or more acoustic modems can operate together to relay messages over longer distances.
- *Compatibility requirements*: Interoperability between underwater acoustic modems produced by various manufacturers is still work in progress. Protocols and standards exist, but every manufacturer uses its own proprietary modem signaling and protocol. As a result, mixing and matching acoustic modems from different manufacturers is not recommended.

15.3.2 Commercially Available Modems

Figure 15.1 provides an overview of the nominal data rate versus range resulting from a large literature survey. In general, the high rate or high range results are for deep channels while the cluster of low range, low rate are for shallow channels. Modems developed by the research community are represented with diamonds, while stars denote commercially available systems. The range-times-rate bound represents an estimate of the existing performance envelope. While there are exceptions, most reviewed systems are bounded by this performance limit. Table 15.1 and Fig. 15.2 provide a few examples of state-of-the-art acoustic modems. The information is obtained from published technical specifications. Every acoustic communication system

Table 15.1 A few acoustic modems

Product name	Max bit rate [bps]	Range [m]	Frequency band [kHz]
Teledyne Benthos ATM-916-MF1 [15.15]	15360	6000	16–21
WHOI Micromodem [15.16]	5400	3000	22.5–27.5
Linkquest UWM 1000 [15.17]	7000	1200	27–45
Evologics S2C R 48/78 [15.18]	31200	2000	48–78
Sercel MATS 3G 34 kHz [15.19]	24600	5000	30–39
L3 Oceania GPM-300 [15.20]	1000	45000	not specified
Tritech Micron Data Modem [15.21]	40	500	20–28
FAU Hermes [15.22]	87768	180	262–375

presented here is of excellent quality and reputation and uses field-tested technologies. This short section cannot provide a complete description of the acoustic communications field. Many other acoustic communication systems have been developed over the past three decades that could not be included due to space limitations. Because underwater acoustic modems are very specialized pieces of equipment produced in limited numbers, standardizing hardware and protocols is a work in progress. Although most developers and manufacturers use proprietary hardware and protocols, a compact control language [15.23] has been developed to make optimal use of the limited acoustic modem data throughput installed on unmanned underwater vehicles. In addition, three frequency bands, common between a large number of underwater acoustic modems, have been identified. Finally, some efforts have been made in developing some level of inter-operability between underwater acoustic modems produced by different manufacturers. Although these efforts are encouraging, combining devices originating from different companies in the same network is usually not desirable.

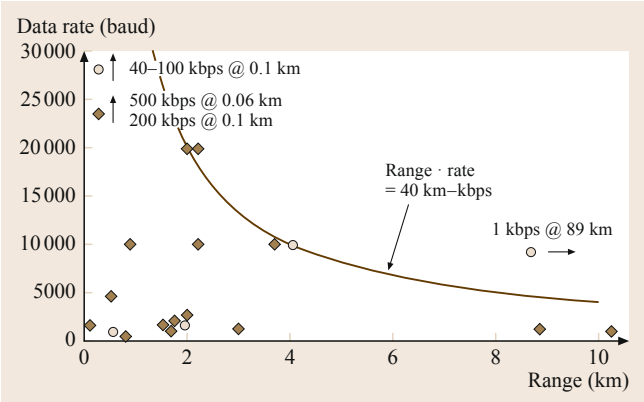

Fig. 15.1 Published experimental performance of underwater acoustic telemetry systems is summarized in this plot of rate [kbps] versus range [km] (after [15.24]). The channels vary from deep and vertical to shallow and horizontal

15.3.3 Field Tests

Field testing is a key step in evaluating the performance of an underwater acoustic communication system. Because of the extensive cost of such tests (especially in deep waters), numerous numerical models have been developed to predict the system performance and reduce the required in-water time for test and evaluation.

Underwater acoustic wave propagation is a complex combination of energy dissipation due to viscosity and chemical reactions, fluid–structure interaction, surface wave activity, biological activity, boat traffic, and source and receiver characteristics [15.25, 26]. The acoustic channel characteristics change with time, spa-

tial location, and frequency. The accurate representation of such a complex and dynamic system at any time, location, and frequency is simply not possible. As a result, even the most sophisticated models often display significant difference with measurements. Significant efforts are made to adapt the statistical models developed for radio communications, but much work remains in making these models sufficiently accurate.

Various scientific and governmental organizations (spearheaded by the United States Office of Naval Research), have developed series of comparative tests for existing technology and signal waveforms (Signal-ex, Modem-ex, KAM'11 [15.27]) and underwater acoustic networks (e.g., SeaWeb [15.28]). One key benefit of such tests is the careful monitoring of environmental characteristics during the test.

15.4 Propagation Channel

15.4.1 Attenuation and Noise

A distinguishing property of acoustic channels is the fact that the path loss depends on the signal frequency. This dependence is a consequence of absorption, i. e., transfer of acoustic energy into heat. In addition to the absorption loss, signal experiences a spreading loss which increases with distance. The overall path loss is given by [15.29]

$$A(l,f) = (l/l_{\text{ref}})^k \mathrm{a}(f)^{l-l_{\text{ref}}} , \tag{15.1}$$

where f is the signal frequency and l is the transmission distance, taken in reference to some l_{ref}. The path loss exponent k models the spreading loss, and its usual values are between 1 and 2, for cylindrical and spherical spreading, respectively. The absorption coefficient can be expressed empirically, using Thorp's formula, which gives $\mathrm{a}(f)$ in dB/km for f in kHz as [15.29]

$$10\log \mathrm{a}(f) = 0.11\frac{f^2}{1+f^2} + 44\frac{f^2}{4100+f^2} + 2.75\cdot 10^{-4} f^2 + 0.003 . \tag{15.2}$$

This formula is generally valid for frequencies above a few hundred Hz. The absorption coefficient is shown in Fig. 15.3. It increases rapidly with frequency, thus imposing a limit on the operational bandwidth that can be used for an acoustic link of a given distance.

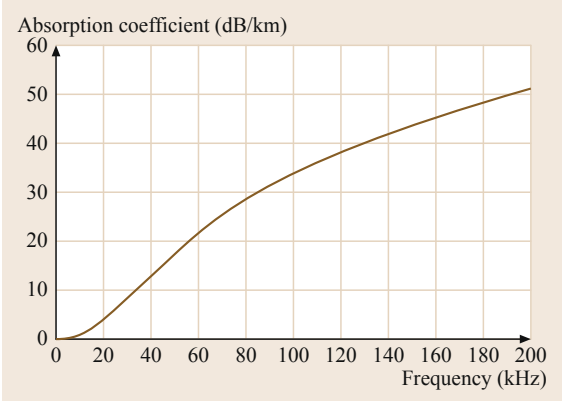

Fig. 15.3 Absorption coefficient, $10\log \mathrm{a}(f)$ in dB/km

Noise in an acoustic channel consists of ambient noise and site-specific noise. Ambient noise is always present in the background of the quiet deep sea. Site-specific noise, on the contrary, exists only in certain places. For example, ice cracking in polar regions creates acoustic noise, and so does shrimp snapping in tropical waters. Ambient noise comes from sources such as turbulence, distant shipping, and breaking waves, in addition to thermal noise. While this noise may be approximated as Gaussian, it is not white. The power spectral density (PSD) of the four noise components is given by the following empirical formulae in dB re μ Pa per Hz as a function of frequency in kHz

$$\begin{aligned} 10\log N_t(f) &= 17 - 30\log f \\ 10\log N_s(f) &= 40 + 20(s-0.5) + 26\log f \\ &\quad - 60\log(f+0.03) \\ 10\log N_w(f) &= 50 + 7.5 w^{1/2} + 20\log f \\ &\quad - 40\log(f+0.4) \\ 10\log N_{th}(f) &= -15 + 20\log f . \end{aligned} \tag{15.3}$$

Figure 15.4 shows the total PSD of the ambient noise for several values of the wind speed w (wind drives the surface waves which break and generate noise) and several levels of the distant shipping activity $s \in [0,1]$ (thousands of ships are present in the ocean at any time, and they generate distant noise, which is to be distinguished from the site-specific noise of vessels passing nearby). The noise PSD decays at a rate of approximately 18 dB/decade, as shown by the straight dashed line in Fig. 15.4. This line represents an approximate model for the noise PSD, $N(f) = N_0 \cdot (f/f_{\text{refx}})^{-\eta}$. The parameters N_0 and η can be fitted from the model, but also from the measurements taken at a particular site.

The attenuation, which grows with frequency, and the noise whose PSD decays with frequency, result in a signal-to-noise ratio (SNR) that varies over the signal

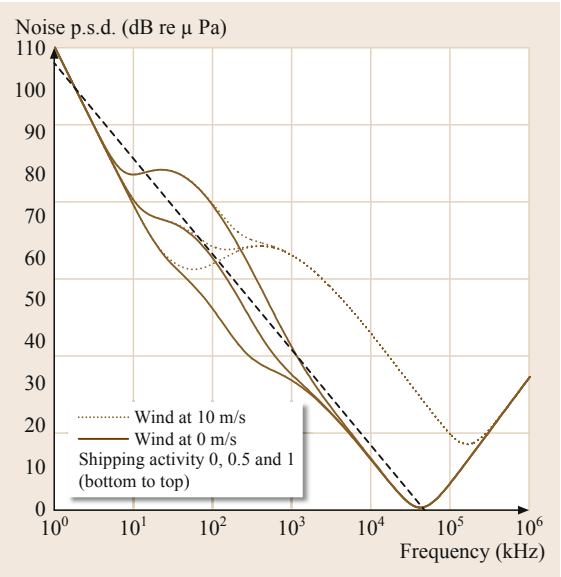

Fig. 15.4 Power spectral density of the ambient noise. The *dash-dotted* line shows an approximation $10\log N(f) = 50\,\text{dB re}\mu\text{Pa} - 8\log(f/1\,\text{kHz})$

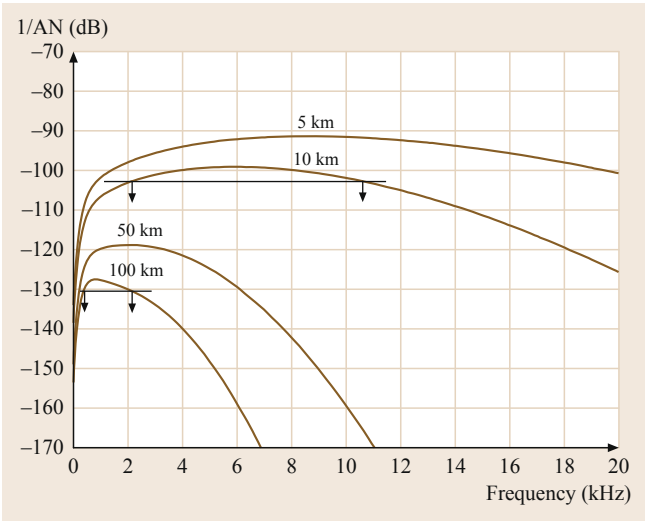

Fig. 15.5 Signal-to-noise ratio in an acoustic channel depends on the frequency and distance through the factor $1/A(l,f)N(f)$. This figure refers to the nominal SNR value that does not include variations induced by shadowing or multipath propagation

bandwidth. If one defines a narrow band of frequencies of width Δf around some frequency f, the SNR in this band can be expressed as

$$SNR(l,f) = \frac{S_l(f)\Delta f}{A(l,f)N(f)\Delta f}\,, \tag{15.4}$$

where $S_l(f)$ is the PSD of the transmitted signal. For any given distance, the narrowband SNR is thus a function of frequency, as shown in Fig. 15.5. From this figure it is apparent that the acoustic bandwidth depends on the transmission distance. In particular, the bandwidth and the power needed to achieve a prespecified SNR over some distance can be approximated as $B(l) = b \cdot l^{-\beta}$ and $P(l) = p \cdot l^{\psi}$, where the coefficients b, p, and the exponents $\beta \in (0,1)$, $\psi \geq 1$, depend on the target SNR, the parameters of the acoustic path loss, and the ambient noise [15.30]. The bandwidth is severely limited at longer distances: at 100 km, only about a kHz is available. At shorter distances, the bandwidth increases, but it will ultimately be limited by that of the transducer. The fact that the bandwidth is limited implies the need for bandwidth-efficient modulation methods if more than a bps/Hz is to be achieved over these channels.

Another important observation to be made is that the acoustic bandwidth B is often on the order of the center frequency f_c. This fact bears significant implications on the design of signal processing methods, as it prevents one from making the narrowband assumption, $B << f_c$, on which many radio communication principles are based. Respecting the wideband nature of the system is particularly important in multichannel (array) processing and in synchronization for mobile acoustic systems.

Finally, the fact that the acoustic bandwidth depends on the distance has important implications on the design of underwater networks. Specifically, it makes a strong case for multihopping, since dividing the total distance between a source and destination into multiple hops enables transmission at a higher bit rate over each (shorter) hop. Since multihopping also ensures lower total power consumption, its benefits are doubled from the viewpoint of energy-per-bit consumption on an acoustic channel [15.31]. Granted, by increasing the number of hops, the level of interference will increase, and packet collisions may become more likely, requiring, in turn, more re-transmissions. However, as shorter hops support higher bit rates, data packets containing a given *number* of bits will have shorter *duration* if the bit rate is appropriately increased, and the chances of collision will be reduced. This fact speaks further in favor of acoustic system design based on high-bandwidth, multihop links.

15.4.2 Multipath Propagation

While the basic propagation loss describes energy spreading and absorption, it does not take into account the specific system geometry and the resulting multipath propagation. Multipath formation in the ocean is

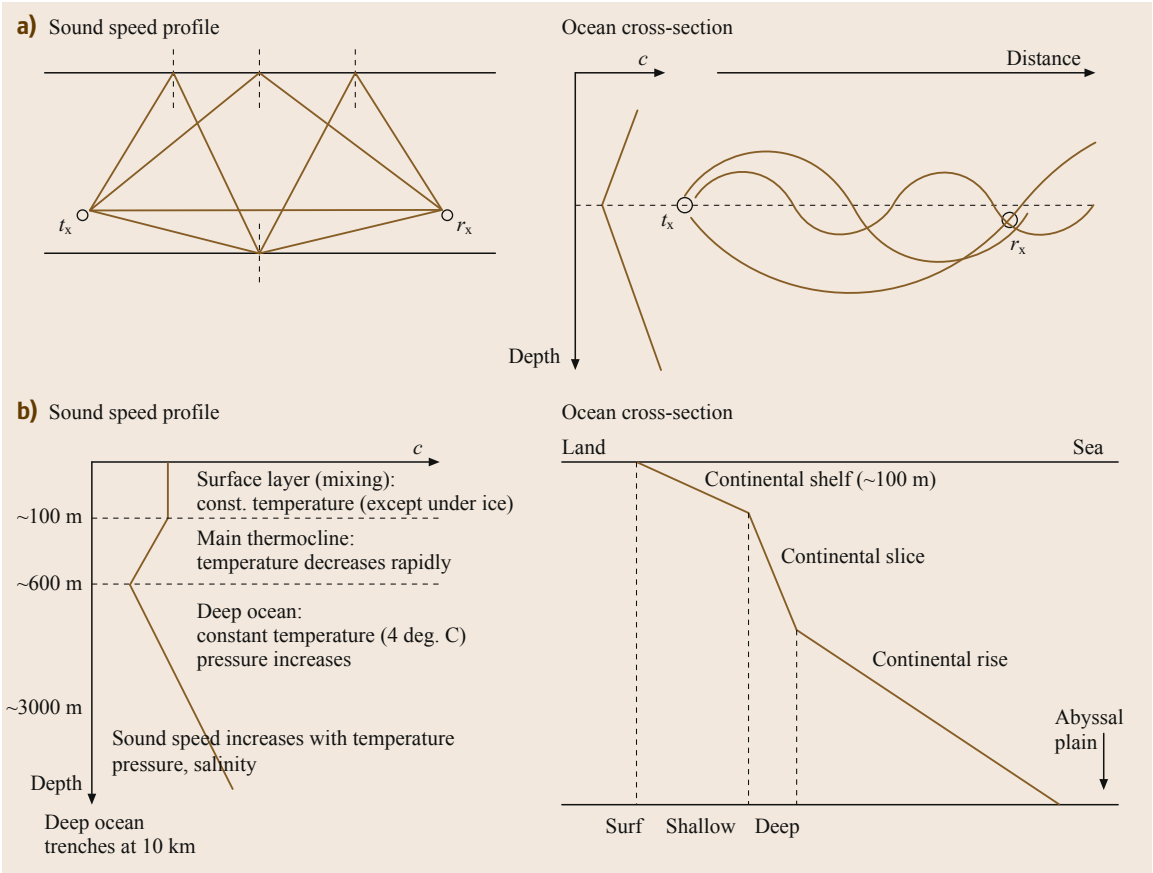

Fig. 15.6a,b Multipath formation in shallow and deep water **(a)**. Sound speed as a function of depth and the corresponding ocean cross-section **(b)**

governed by two effects: sound reflection at the surface, bottom and any objects, and sound refraction in the water. The latter is a consequence of sound speed variation with depth, which is mostly evident in deep water channels. Figure 15.6 illustrates the two mechanisms.

Sound speed depends on the temperature and pressure, which vary with depth, and a ray of sound always bends towards the region of lower propagation speed, obeying Snell's law. In shallow water, both the temperature and the pressure are constant, and so is the sound speed. As the depth increases, the temperature starts to decrease, but the weight of the water above is still not significant enough to considerably change the pressure. The sound speed thus decreases in the region called the main thermocline. After a certain depth, the temperature reaches the constant level of 4°C, and from there on the sound speed increases with pressure. When a source launches a beam of rays, each ray will follow a slightly different path, and a receiver placed at some distance will observe multiple signal arrivals. Note that a ray traveling over a longer path may do so at a higher speed, thus reaching the receiver before a direct, stronger ray. This phenomenon results in a nonminimum-phase channel response.

The first approach to modeling multipath propagation is a deterministic one, which provides an exact solution for the acoustic field strength in a given system geometry with a given sound speed profile. Because of computational complexity, approximate solutions are often used instead of the exact ones. An approximation that is suitable for frequencies of interest to acoustic communication systems is based on ray tracing. A widely-used package, Bellhop, is available online [15.32] (see also [15.33, 34]). Figure 15.7 illustrates a ray-trace obtained for a transmitter placed inside the circle to the left. Lighter colors in this figure indicate locations of higher received signal strength. If a receiver is placed at some distance away from the transmitter in this field, the signal strength will vary depending upon the *exact* location. In other words, two receivers (e.g., two circles to the right) placed at the *same* distance away from the transmitter, may experi-

ence propagation conditions that are quite different. In this example, shadowing is caused by ray bending in deep water. In shallow water with constant sound speed, signal strength can be calculated using simple geometrical considerations. Alternating constructive/destructive combining of multiple reflections will now form pockets of strong/weak signal reception. In either case, multipath effects make the signal strength location dependent, i. e., different from the value predicted by the basic propagation loss (15.1). If the transmitter or receiver were to move through this frozen-in-time acoustic field, the received signal strength would be perceived as varying. In practice, of course, neither the channel geometry nor the environmental parameters are frozen, and small disturbances cause the signal strength to vary in time even if there is no intentional motion of the transmitter or receiver.

The impulse response of an acoustic channel is thus influenced by the geometry of the channel and its reflection and refraction properties, which determine the number of significant propagation paths, their relative strengths and delays. Strictly speaking, there are infinitely many signal echoes, but those that have undergone multiple reflections and lost much of the energy can be discarded, leaving only a finite number of significant paths.

To put a mathematical channel model in perspective, let us denote by $\bar{l}_p$ the nominal length of the p-th propagation path, with $p = 0$ corresponding to a reference path (either the strongest, or the first significant arrival). In shallow water, where the sound speed c can be taken as constant, path delays can be obtained as $\bar{\tau}_p = \bar{l}_p / c$. The surface reflection coefficient equals -1 under ideal conditions, while bottom reflection coefficients depend on the type of bottom (hard, soft) and the grazing angle [15.35]. If we denote by Γ_p the cumulative reflection coefficient along the pth propagation path, and by $A(\bar{l}_p, f)$ the propagation loss associated with this path, then

$$\overline{H}_p(f) = \frac{\Gamma_p}{\sqrt{A(\bar{l}_p, f)}} \tag{15.5}$$

represents the nominal frequency response of the p-th path. Hence, *each path* of an acoustic channel acts as a low-pass filter. Figure 15.8 illustrates a reference path transfer function $\overline{H}_0(f) = 1/\sqrt{A(\bar{l}_0, f)}$.

For the distances and frequencies of interest to the majority of acoustic communication systems, the effect of path filtering is approximately the same for all paths, as the absorption coefficient does not vary much from its value at the reference distance and center frequency. Denoting this value by a_0, the transfer function of the

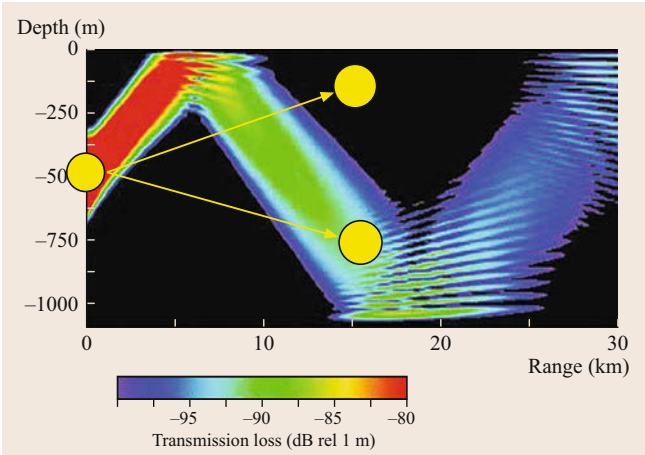

Fig. 15.7 A ray-trace shows areas of strong/weak signal reception. Sound reflection and refraction result in multipath propagation which favors some locations while placing others in a shadow

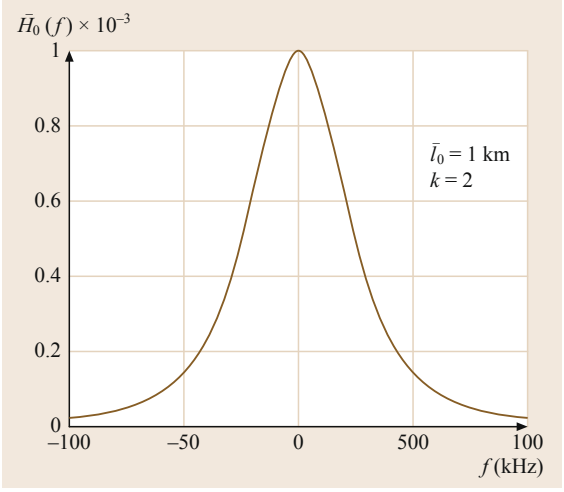

Fig. 15.8 Example of a reference path transfer function $\overline{H}_0(f)$

p-th path is modeled as

$$\overline{H}_p(f, t) = \overline{h}_p \cdot \overline{H}_0(f)\,, \tag{15.6}$$

where

$$\overline{h}_p = \frac{\Gamma_p}{\sqrt{(\bar{l}_p/\bar{l}_0)^k \mathsf{a}_0^{\bar{l}_p - \bar{l}_0}}} \tag{15.7}$$

is the real-valued (passband) path gain. Figure 15.9 shows an example of nominal multipath structure.

In an acoustic communication system, the channel can be observed only in a limited band of frequencies supported by the transducer. As a result, the observable response will be smeared, as illustrated in Fig. 15.10.

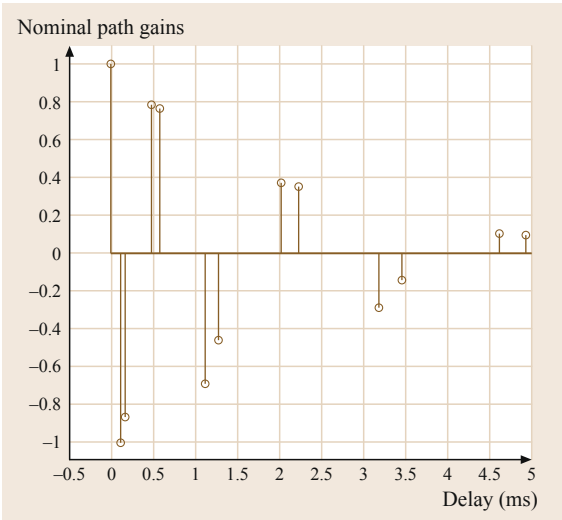

Fig. 15.9 Nominal path gains (15.7) for a channel with transmission distance $d = 1\,\text{km}$, water depth $h = 20\,\text{m}$, and transmitter/receiver height above the bottom $h_T = 10\,\text{m}$ and $h_R = 12\,\text{m}$. The surface reflection coefficient is -1; bottom reflection coefficients are calculated assuming speed of sound and density of $c = 1500\,\text{m/s}$, $\rho = 1000\,\text{kg/m}^3$ in water and $c_b = 1300\,\text{m/s}$, $\rho_b = 1800\,\text{kg/}m^3$ in the soft bottom. Those paths whose absolute value is above one tenth of the strongest path's are shown

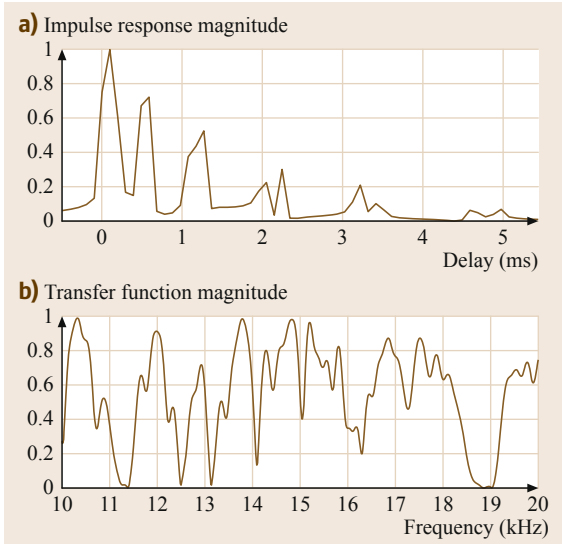

Fig. 15.10 **(a)** Impulse response (baseband) and **(b)** the transfer function for the nominal (time-invariant) channel geometry corresponding to the multipath structure of Fig. 15.9, as seen in $B = 10\,\text{kHz}$ of bandwidth centered at $f_c = 15\,\text{kHz}$. In a wideband acoustic system, multipath propagation creates discernible signal echoes and a frequency-selective channel distortion

It is important to make the distinction between the natural channel *paths* of the channel (Fig. 15.9), and the samples of the observable response (Fig. 15.10). The latter are often referred to as the channel *taps*. It is also important to note that the path gains can be very stable, while taps may exhibit fast variation. Such behavior is explained by the fact that each tap contains contributions from *all* the paths, wherein each path carries a pulse of finite duration and a different delay that varies in time. An example of tap variation is shown in Fig. 15.13, which we will discuss later when we address channel fading.

Multipath propagation creates a frequency-selective channel distortion, which is evident as the variation of the transfer function in Fig. 15.10. As a result, some frequencies of a wideband acoustic signal will be favored, while others will be severely attenuated. Channel equalization has to be employed to deal with this type of distortion.

The total delay spread between significant multipath arrivals or the *multipath spread* of the channel, T_{mp}, is an important figure of merit for the design of acoustic communication systems. Vertical links exhibit short multipath spreads, while horizontal channels exhibit multipath spreads that can range between a few milliseconds and hundreds of milliseconds. In single-carrier broadband systems, where the data symbols are short compared to the multipath spread, the meaningful figure of merit is the number of symbols that fit within the multipath spread. This number determines the extent of inter-symbol interference (ISI), which in turn dictates the length of the filters needed to equalize the channel. The fact that the multipath spread may be on the order of several milliseconds, or more, implies that the ISI may span tens or even a hundred symbol intervals; a situation very different from that typically found in radio systems, where ISI may involve a few symbols only. Multicarrier systems avoid this problem by transmitting in parallel on many carriers, each occupying a narrow subband. A meaningful figure of merit for these systems is the frequency coherence, $\Delta f_{\text{coh}} = 1/T_{\text{mp}}$. In a properly designed multicarrier system, carrier separation is kept well below this value.

The acoustic channel is often *sparse*, i. e., there are only several significant paths that populate the *total* and possibly long delay spread. This fact has an important implication on channel estimation and the associated equalization methods. Namely, while the entire multipath spread is represented by $L \approx T_{\text{mp}}B$ samples taken at intervals $T_s = 1/B$, fewer than L coefficients may suffice to represent the channel response. Ideally, only as many coefficients as there are propagation paths, $P < L$,

are needed. Channel modeling thus becomes an important aspect of signal processing, and sparsing has been investigated for decision-feedback equalization [15.36, 37], turbo equalization [15.38, 39], and multicarrier detection [15.40–42]. It is also important to note that although a greater bandwidth implies more ISI and more frequency selectivity, it also implies a better resolution in delay (less smearing in the observable channel response). Hence, although the attendant signal distortion is perceived as more severe, channel estimation will be more efficient if a proper sparse model is used, which may, in turn, lead to improved signal processing. In addition, signaling at a higher rate enables more frequent channel observations and, consequently, easier channel tracking [15.43].

15.4.3 Time Variability: Motion-Induced Doppler Distortion

There are two sources of the channel's time variability: inherent changes in the propagation medium, which contribute to signal fading, and those that occur because of the transmitter/receiver motion and contribute to the frequency shifting. The distinction between the two types of distortions is that the first one appears as random, while the motion-induced Doppler effects can be modeled in a deterministic manner and, therefore, compensated to some degree through synchronization.

Motion of the transmitter, receiver, or a reflection point along the signal path causes the path distances to vary with time. The resulting Doppler effect is evident as time compression/dilation of the signal, which causes frequency shifting and bandwidth spreading/shrinking. The magnitude of the Doppler effect is proportional to the ratio $a = v/c$ of the relative transmitter-receiver velocity to the speed of sound. Because the speed of sound is very low as compared to the speed of electromagnetic waves, motion-induced Doppler distortion of an acoustic signal can be extreme. AUVs move at speeds that are on the order of a few m/s, but even without intentional motion, underwater instruments are subject to drifting with waves, currents, and tides, which may occur at comparable velocities. In other words, there is always *some* motion present in the system, and a communication system has to be designed taking this fact into account. The only comparable situation in radio communications occurs in low Earth orbiting (LEO) satellite systems, where the relative velocity of satellites flying overhead is extremely high (the channel there, however, is not nearly as dispersive in delay). The major implication of motion-induced distortion is on the design of synchronization algorithms.

To model the Doppler distortion, let us focus on a single propagation path, assuming that the relative transmitter/receiver velocity v_p along this path stays constant over some interval of time. The path delay can then be modeled as

$$\overline{\tau}_p(t) = \overline{\tau}_p - a_p \cdot t \,, \tag{15.8}$$

where $a_p = v_p/c$ is the Doppler factor corresponding to the p-th path. If there is a single dominant component of velocity, these factors can be approximated as equal for all paths, $a_p = a, \forall p$; however, this is not the case in general [15.37]. To assess the effect of time-varying delay on the signal, let us focus on a particular signal component centered around frequency f_k in a narrow band $\Delta f \ll f_k$. The signal $s_k(t)$ and its equivalent baseband $u_k(t)$ are related by

$$s_k(t) = Re\{u_k(t)e^{i2\pi f_k t}\} \,. \tag{15.9}$$

Since the signal occupies only a narrow band of frequencies, its replica received over the p-th propagation path is given by

$$s_{k,p}(t) = \overline{h}_p \bar{H}_0(f_k) s_k(t - \overline{\tau}_p(t)) \,. \tag{15.10}$$

Defining the equivalent baseband component of the received signal via

$$s_{k,p}(t) = Re\{v_{k,p}(t)e^{i2\pi f_k t}\} \,, \tag{15.11}$$

we have the baseband relationship

$$v_{k,p}(t) = \overline{c}_{k,p} e^{i2\pi a_p f_k t} u_k(t + a_p t - \overline{\tau}_p) \,, \tag{15.12}$$

where

$$\overline{c}_{k,p} = \overline{h}_p \overline{H}_0(f_k) e^{-i2\pi f_k \overline{\tau}_p} \,. \tag{15.13}$$

The Doppler effect is evident in two factors: (i) frequency shifting by the amount $a_p f_k$ and (ii) time scaling by the factor $(1 + a_p)$. The situation of putting together all the signal components at frequencies f_0, f_1, etc., that span a wide bandwidth $B = K\Delta f$, and assuming only a single propagation path with the Doppler factor a is illustrated in Fig. 15.11. This figure offers an exaggerated view of the Doppler effect, but nonetheless one that illustrates the point: each spectral component in a wideband mobile acoustic system is shifted by a *different* amount, and the total bandwidth B is spread over $B(1 + a)$, i. e., a signal of duration T is observed at the receiver as having duration $T/(1 + a)$.

The way in which these distortions affect signal detection depends on the actual value of the factor a. For comparison, let us look at a highly mobile radio system: at 160 km/h (100 mph), $a = 1.5 \cdot 10^{-7}$. This value is low enough that compression/dilation can be neglected.

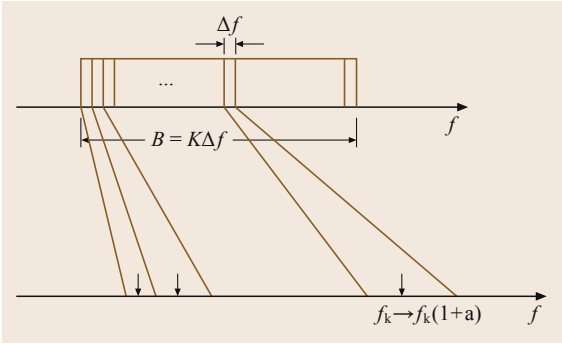

Fig. 15.11 Motion-induced Doppler shift is not uniform in a wideband acoustic system

In other words, there is no need to account for it explicitly in symbol synchronization. The error made in doing so is only 10^{-3} of a bit per 10 000 bit. In contrast to this situation, a stationary acoustic system may experience unintentional motion at 0.5 m/s (1 kt), which would account for $a = 3 \cdot 10^{-4}$. For an AUV moving at several m/s (submarines can move much faster), the factor a will be on the order of 10^{-3}, a value that cannot be ignored.

Nonnegligible motion-induced Doppler shifting and spreading thus emerge as another major factor that distinguishes an acoustic channel from the mobile radio channel, and dictates the need for explicit phase and delay synchronization in all but stationary systems [15.10]. In multicarrier systems, the Doppler effect creates a particularly severe distortion. Unlike in radio systems, where time compression/dilation is negligible and the Doppler shift appears equal for all frequencies within the signal bandwidth, in an acoustic system each frequency component may experience a markedly different Doppler shift, creating a nonuniform Doppler distortion across the signal bandwidth [15.44].

15.4.4 Time Variability: Random Effects (Fading)

Inherent channel changes range from the very large-scale, slow variations that occur seasonally (e.g., the change in sound speed profile from winter to summer) or daily (e.g., the change of water depth due to tides) to the small-scale, fast variations that are often caused by the rapid motion of the sea surface (waves) or the system itself. Many of these variations appear as random, and as such require an additional stage of modeling, namely statistical modeling.

The distinction between various scales is meaningful from the viewpoint of the duration of communication signals. While large-scale phenomena affect *average* signal power, causing it to vary over longer periods of time (many data packets), small-scale phenomena affect the *instantaneous* signal level, causing it to vary over shorter periods of time (few data packets, or bits of the same data packet). In light of system design, it is also useful to distinguish between those variations that are slow enough to admit a feedback by which the receiver can inform the transmitter of the change, and those that are too fast to be conveyed over the time it takes the signal to propagate from one end of the link to the other. In this sense, modeling of large-scale phenomena is meaningful for adaptive power control and modulation (which are performed at the transmitter in response to delayed feedback), while modeling of small-scale phenomena is important for adaptive signal processing at the receiver (channel estimation, equalization). It is also important to note that the apparently random channel variation can be a consequence of both the changes in the physical parameters of the environment (sound speed profile, surface scattering, internal waves) and the changes in the placement of the system within a given environment (transmitter/receiver displacement due to intentional motion or drifting with currents, etc.). Note also that these effects will differ across different environments, e.g., deep or shallow water, tropical, or ice-covered regions.

Large-Scale Effects

To assess the random variation of the channel, one can start by allowing the path lengths to deviate from the nominal values, so that

$$l_p = \bar{l}_p + \Delta l_p \,, \tag{15.14}$$

where Δl_p is regarded as a random displacement. This displacement models the large-scale variation which occurs because the channel geometry deviates from the nominal, either as the system is moved to a different location, or because the water depth has changed with the tide, etc. The deterministic, motion-induced delay variation which can be compensated through proper synchronization, is not considered as part of statistical channel analysis. The resulting transfer function of the channel, which is now *random* as well, is given by

$$H(f) = \overline{H}_0(f) \sum_p h_p e^{-i2\pi f \tau_p} \,, \tag{15.15}$$

where the path coefficients h_p can be calculated similarly as for the nominal case (15.7), using l_p instead of $\bar{l}_p$, and the delays can be calculated as $\tau_p = l_p/c - t_0$ in reference to some time $t_0 = \bar{l}_0/c$. The corresponding random path gains can also be approximated as [15.45]

$$h_p = \overline{h}_p e^{-\xi_p \Delta l_p/2} \,, \tag{15.16}$$

where

$$\xi_p = a_0 - 1 + k/\bar{l}_p \,, \tag{15.17}$$

and $\bar{h}_p$ is given by the expression (15.7). Note that one can also explicitly express the salient parameters h_p, τ_p as functions of time, i. e., $h_p(t)$, $\tau_p(t)$, if one is interested in their variation during a long-term deployment in the *same* area (deep/shallow water, etc.).

Small-Scale Effects

The above model accounts only for the variations induced by the path length displacements, i. e., it does not include the effects of scattering. Scattering, which causes micro-path dispersion along each propagation path, can be modeled through an additional factor that accompanies the path gain $h_p(t)$. An overall channel model is now obtained in the form

$$H(f,t) = \bar{H}_0(f) \sum_p \gamma_p(f,t) h_p(t) e^{-i2\pi f \tau_p(t)} \,. \tag{15.18}$$

In this model, the factors $h_p(t)$ account for the slower-changing process caused by deviations of the system geometry from the nominal, while the factors $\gamma_p(f,t)$ represent the faster-changing scattering process. In other words, during a typical communication transaction of several packets, the path gains can be considered fixed, $h_p(t) = h_p$, but the additional factors $\gamma_p(f,t)$ cannot. Assuming a relatively large number of micro-paths, these factors can be modeled as complex-valued Gaussian processes, with some mean and variance. In general, scattering in an acoustic channel depends on the signal frequency, making each macro-path experience a different, possibly independent filtering effect. Note, however, that the transfer function $H(f,t)$ will in general exhibit correlation in both frequency and time (as well as across the elements of a transmit/receive array).

Statistical Characterization

Because of the different dynamics of the two types of processes, statistical channel analyses are typically conducted in two forms: one that targets the locally-averaged received signal power, and another that targets the instantaneous channel response. Specifically, large-scale statistical modeling focuses on the channel gain defined as

$$G(t) = \frac{1}{B} \int_{f_c - B/2}^{f_c + B/2} E_\gamma \left\{ \left| H^2(f,t) \right| \right\} \mathrm{d}f \,, \tag{15.19}$$

where the expectation is taken over small-scale fading. In contrast, small-scale modeling focuses on the processes $\gamma_p(f,t)$, as well as the effects of random Doppler shifting.

A complete statistical model for either large or small-scale phenomena must specify the probability density function (PDF) and the power spectral density (PSD), or the correlation properties of the random process of interest. These functions can be assessed using an analytical approach that relies on a mathematical model such as the one outlined above, a repeated application of a propagation model such as the Bellhop ray tracer for a large number of slightly disturbed channel conditions, or an experimental data analysis. All approaches have been considered in the literature, which abounds in statistical models that were found to adequately match the channels observed in different locations, at different time scales, and in different frequency bands. As of this time, however, the jury is still out on establishing standard models that would concisely describe the statistics of *typical* underwater acoustic channels. Crucial to that effort is identification of the scales of stationarity for the different processes at hand.

As far as the large-scale modeling goes, recent experimental results offer some evidence in support of a log-normal model for the channel gain [15.45–47]. Figure 15.12 illustrates such a model. Several of these studies also find that the path gains, and consequently the overall large-scale channel gain, can be well modeled as auto-regressive processes, at least on the time scales of several seconds, which are meaningful for implementation of packet-level feedback schemes.

Experimental studies on small-scale fading have offered evidence of Ricean [15.46, 48, 49] as well as Rayleigh phenomena [15.50]. Figure 15.13 illustrates an experimental data set that exhibits traits of Ricean fading. Combining the effects of large and small-scale fading leads to a mixture of log-normal and Ricean distributions, which can be approximated in closed form by the compound K-distribution. Experimental evidence to this effect is provided in [15.51]. Less is known about modeling the time-correlation functions of the small-scale processes, but it is generally understood that coherence times on the order of 100 ms can be assumed for a general-purpose design. Frequency-correlation, as well as space-correlation, as they pertain to communications systems, also remain to be addressed in a systematic manner.

The importance of statistical channel modeling is twofold. On the one hand, it enables the design of practical adaptive modulation methods which rely on identifying those channel parameters that can be *predicted* via delayed receiver-transmitter feedback [15.52]. On the other hand, it will enable the development standardized simulation models, thus allowing performance analy-

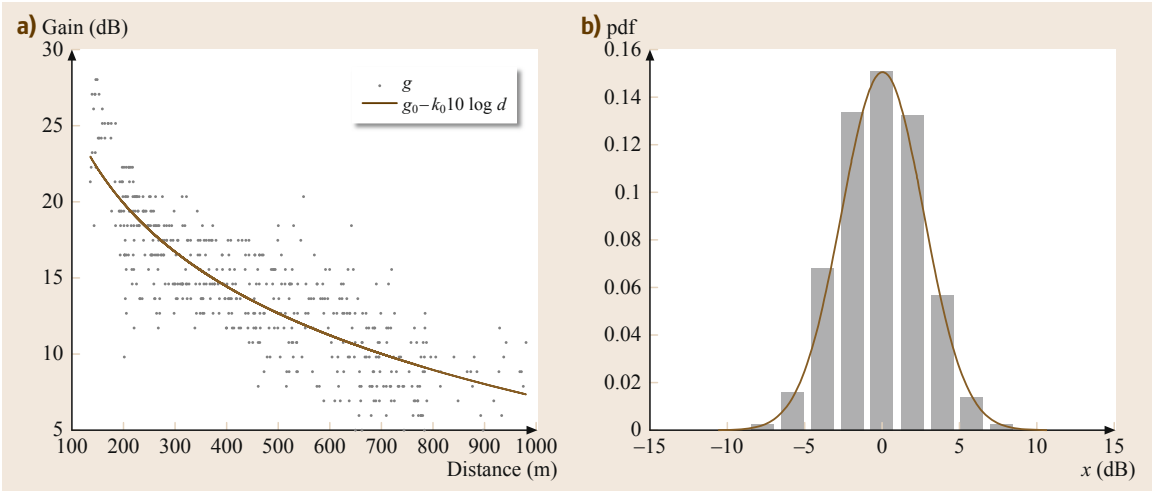

Fig. 15.12a,b During an experiment off the coast of Northern California, an acoustic signal occupying the 8–12 kHz band was transmitted between a fixed station and an AUV, and the strength of the signal received by the WHOI micro-modem was measured over a period of time during which the transmission distance changed. **(a)** shows the recorded signal strength, an estimate of the channel gain (15.19), as a function of distance (*dots*) and the accompanying trend which exhibits a log-distance dependence (*solid*). **(b)** shows the histogram of the difference between the recorded gain and the nominal trend, which is well described by a Gaussian distribution on the dB scale, i. e., a log-normal distribution on the linear scale

sis not only of signal processing methods, but also of network protocols and system-level design strategies, without the need for actual system deployment. Currently available simulators, such as the World Ocean Simulation System [15.53], use accurate ray tracing models, but they lack the statistical aspect of assessing the system performance. Statistical channel modeling was addressed recently in [15.45].

15.4.5 System Constraints

In addition to the fundamental limitations imposed by acoustic propagation, there are hardware constraints that affect the operation of acoustic modems. The most obvious of these constraints is the fact that acoustic transducers have their own bandwidth limitation, which constrains the available bandwidth beyond that offered by the channel. Additional constraints include power efficiency (transmitter amplifiers are often nonlinear, imposing a limit on the *peak* signal power), and the fact that acoustic modems operate in half-duplex fashion. These constraints do not only affect the physical link but all the layers of a network architecture. For example, the half-duplex mode of operation, combined with the low speed of sound, challenges the throughput efficiency of acoustic links that require automatic repeat request (ARQ) [15.54].

In an acoustic system, the power required for transmitting may be much greater than the power required for receiving. Transmission power depends on the distance, and its typical values are on the order of tens of Watts. (An acoustic signal propagates as a pressure wave, whose power is measured in Pascals, or commonly in dB relative to a micro Pascal. In seawater, 1 W of radiated acoustic power creates a sound field of intensity 172 dB re μPa 1 m away from the source.) In contrast, the power consumed by the receiver is much lower, with typical values ranging from about 100 mW for listening or low-complexity detection, to no more than a few Watts required to engage a sophisticated processor for high-rate signal detection. In hibernation mode, from which a modem can be woken on command, no more than 1 mW is required.

Underwater instruments are often battery-powered, and, hence, it is not simply the power, but the energy consumption that matters. This is less of an issue for mobile systems, where the power used for communication is a small fraction of the total power consumed for propulsion, but it is important for networks of fixed bottom-mounted nodes, where the overall network lifetime is the figure of merit. One way to save energy is by transmitting at a higher bit rate. For example, the WHOI modem [15.55] has two modes of operation: high rate at 5 kbps and low rate at 80 bps. This modem will require about 60 *times* less energy per bit (18 dB) in the high-rate mode. The receiver's energy consumption will also be lower, although it requires 3 W for detection of high-rate signals as opposed to 80 mW for detection of

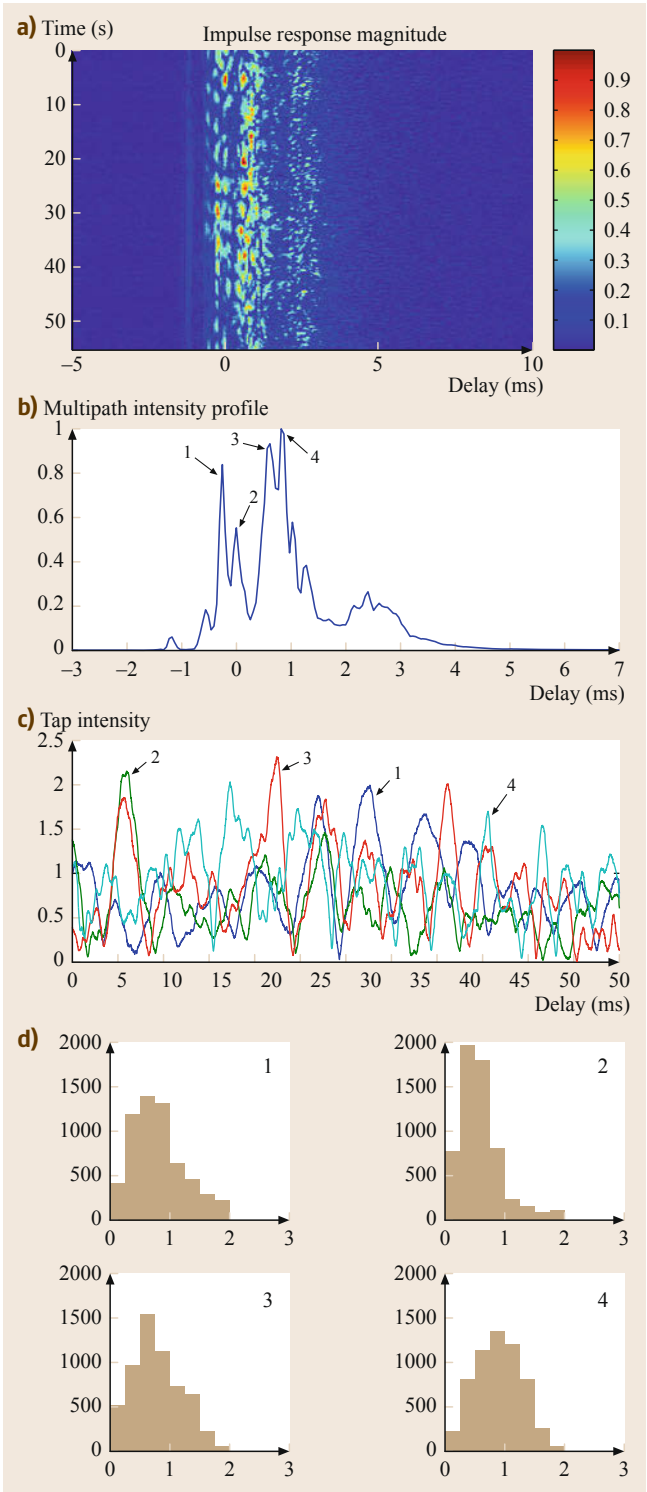

Fig. 15.13a–d During an experiment that took place in Narragansett Bay, near the coast of Rhode Island, the transmitter and the receiver were mounted on fixed tripods at 4 and 2 m above the bottom, at a distance of 1 km, with the channel depth ranging between 9 and 14 m. The sea condition was calm. A pseudo-random binary sequence of length 4095, modulated onto a 13 kHz carrier, was transmitted repeatedly at a rate of 10 kbps. The received signal was digitally down-converted, and correlated with the replica of the transmitted signal to yield an estimate of the channel response. Channel responses (magnitude) are shown in **(a)**. The multipath intensity profile **(b)** represents the average of magnitude-squared channel responses observed from 132 consecutive sequences. Shown also is the time-variation of several channel *taps* **(c,d)**. These figures reveal a channel consisting of multipath arrivals whose amplitude varies in time in a such a manner that there is no clearly defined strongest arrival. The phase (not shown) exhibits a random behavior around a constant slope, corresponding to a small but different Doppler shift on each of the arrivals, while the histograms of the tap magnitudes indicate Ricean fading

low-rate signals (the difference is about 2 dB). Another way to save the energy is by minimizing the number of retransmissions (we discuss the relevant protocols in Sect. 15.5.6). Finally, energy spent in idle listening over a longer period of time is not to be neglected. Having modems that are capable of hibernation, or instituting intentional sleeping schedules for those that are not, can help to control this type of power expenditure [15.56].

15.5 Point-to-Point Links: Signal Processing

15.5.1 Noncoherent Modulation/Detection

Noncoherent signaling is commonly used to relay data and to transmit command-and-control information at low bit rates. Frequency-hopped m-ary frequency-shift-key (FH-MFSK) modulation is widely accepted as a reliable albeit inefficient choice for such modems. FSK modulation uses distinct tonal or frequency-modulated pulses to map digital information. Frequency-hopping is a spread-spectrum technique, which alternates portions of the frequency band over fixed periods of time, so that successive FSK-modulated symbols use a different portion of the frequency spectrum, thus minimizing inter-symbol-interference (ISI) caused by reverberation. Many commercial suppliers offer several versions of FH-MFSK acoustic modems. In the case of a combination of N tones transmitted simultaneously, the symbol transmitted during the m-th signaling interval ($mT_s \le t < (m+1)T_s$) is

$$s_m(t) = A_m d(t) \sum_{n=1}^{N} g_{m,n} c_{m,n}(t), mT_s \le t < (m+1)T_s\,, \tag{15.20}$$

where, in the simplest case, $c_{m,n}(t)$ is a tone (either real or complex),

$$c_{m,n}(t) = e^{2\pi i f_{m,n}(t-mT_s)}, mT_s \le t < (m+1)T_s\,. \tag{15.21}$$

A_m is the peak acoustic pressure of symbol $s_m(t)$, $d(t)$ is the pulse shape (e.g., Gaussian), T_s is the pulse duration in seconds, $f_{m,n}$ is the carrier frequency of tone n for symbol $s_m(t)$. The binary information $b(m)$ is coded in symbol $s_m(t)$ as a combination $g_{m,n}$ of frequency bands centered at $f_{m,n}(n = 1, \ldots, N)$. $g_{m,n} = 1$ if the frequency band is used, otherwise $g_{m,n} = 0$ (at least one band is used for every symbol $s_m(t)$). If $s_m(t)$ uses only one of N bands and N is a power of 2, $\log_2(N)$ bits can be coded simultaneously within a single symbol. For example, if $N = 4$, $s_m(t)$ will contain $log_2(4) = 2$ bits of binary information ($b(m)$ =(0,0),(0,1),(1,0) or (1,1)). If $g_{1,n} = 1$ and $g_{2,n} = g_{3,n} = g_{4,n} = 0$, then $b_m = (0, 0)$. If $g_{2,n} = 1$ and $g_{1,n} = g_{3,n} = g_{4,n} = 0$, then $b_m = (0, 1)$, and so on. Figure 15.14 shows a section of an FH-MFSK modulated signal and the corresponding periodogram.

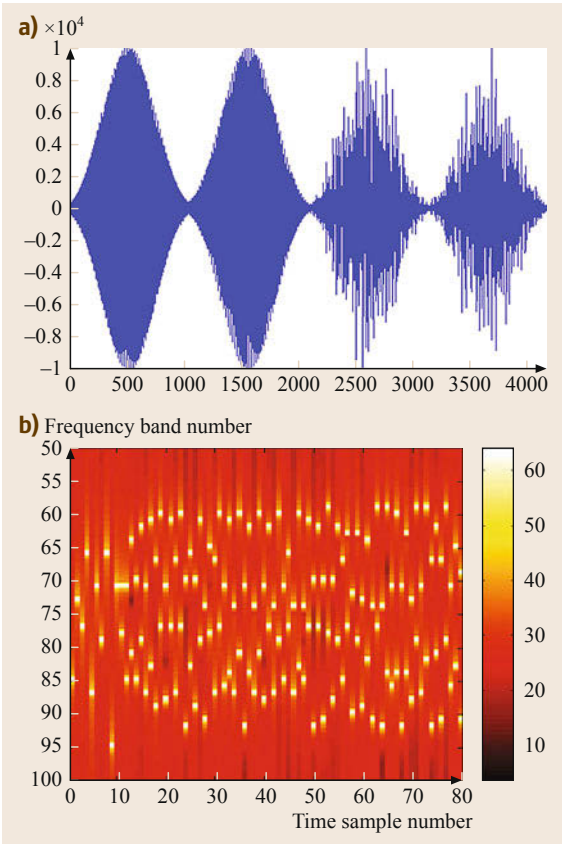

Fig. 15.14 (a) The first four symbols of a FH-MFSK sequence. (b) Spectrogram of a FH-MFSK sequence

At the receiver, the incoming message is first detected and synchronized using a short FH-MFSK modulated sequence. Following this, each data symbol is processed individually. First, the cross-correlation between the incoming faded symbol and a set of reference symbols $c_{m,n}(t)$ is computed,

$$R_{r_m,c_{m,n}}(\tau) = \int_{-T_s}^{T_s} r_m(t) c^*_{m,n}(t+\tau)\mathrm{d}t\,, \tag{15.22}$$

where * denotes the complex conjugate. For every received symbol $r_m(t)$, we retain the peak of correlation

within each band centered at $f_{m,n}$,

$$Z_{m,n} = \max_t \left\{ R_{r_m,c_{m,n}}(\tau); mT_s \le t < (m+1)T_s \right\} . \tag{15.23}$$

If we assume once more that $s_m(t)$ uses only one of N bands and N is a power of 2, we identify the frequency band that contains the most energy by comparing the coefficients $Z_{m,n}$,

$$n_{\max}(m) = \max_n \{Z_{m,n}; n = 1, \ldots, N\} . \tag{15.24}$$

Note that $n_{\max}$ is a function of the symbol index m. Under the same assumption, $g_{m,n} = 1$ if $n = n_{\max}$, otherwise $g_{m,n} = 0$. For example, if $n_{\max} = 1$, then $g_{m,1} = 1$ and $g_{m,2} = g_{m,3} = g_{m,4} = 0$. Therefore, $s_m(t)$ contains the couple of bits $b_m = (0, 0)$. If $n_{\max} = 2$, then $g_{m,2} = 1$ and $g_{m,1} = g_{m,3} = g_{m,4} = 0$, so that $s_m(t)$ contains the couple of bits $b_m = (0, 1)$, and so on.

15.5.2 Coherent Modulation/Detection

Coherent modulation methods include phase shift keying (PSK) and quadrature amplitude modulation (QAM). These methods offer bandwidth efficiency, i. e., the possibility to transmit more than 1 bit per second per Hertz of occupied bandwidth. However, because the information is encoded into the phase of the signal, precise knowledge of the received signal's frequency and phase is required in order to perform coherent detection. This fact presents a major challenge because an acoustic channel introduces a rather severe phase distortion on each of its multiple paths. A coherent receiver thus needs to perform phase synchronization together with channel equalization.

Coherent systems fall into two types: single-carrier and multicarrier systems. In single-carrier systems, a broadband information-bearing signal is directly modulated onto the carrier and transmitted over the channel. A typical high-rate acoustic signal occupies several kHz of bandwidth over which it experiences uneven channel distortion (Fig. 15.10). This distortion must be compensated at the receiver through the process of equalization. Multicarrier modulation bypasses this problem by converting the high-rate information stream into many parallel low-rate streams, which are then modulated onto separate carriers. The carriers are spaced closely enough such that the channel appears as frequency-flat in each narrow subband. After demodulation, each carrier's signal now only has to be weighted and phase-synchronized, i. e., a single-coefficient equalizer suffices per carrier. Each of these methods has its advantages and disadvantages when it comes to practical implementation: single-carrier systems are capable of faster channel tracking but they need high-maintenance equalizers; multicarrier systems are efficiently implemented using the fast Fourier transform (FFT), but they have high sensitivity to residual frequency offsets. In what follows, we review the basics of both types of systems as they apply to phase-distorted frequency-selective acoustic channels, and we outline the current research trends.

Single-Carrier Modulation/Detection

The problem of joint phase tracking and equalization in single-carrier broadband systems was addressed in [15.10]. The basic receiver structure [15.10] was extended to multichannel (array) configuration [15.57, 58] to enable diversity combining, which is often essential on acoustic channels. The resulting multichannel decision-feedback equalizer (DFE), integrated with a second-order phase-locked loop (PLL), provided the benchmark design for the high-speed acoustic modem [15.55]. It also became a de-facto standard for the development and comparison of future techniques, which focused on replacing the basic DFE with more sophisticated equalization and channel estimation schemes (e.g., turbo equalization and sparse channel estimation [15.39]), or inclusion of multiple transmitters, be it in the form of multiuser systems [15.59, 60] or multi-input multi-output (MIMO) structures for spatial multiplexing and/or diversity [15.38, 61].

The block diagram of a multichannel DFE is shown in Fig. 15.15. The receiver includes several stages: precombining (which may or may not be used, depending upon the array structure), phase correction, and multichannel equalization. The receiver is designed to process an incoming signal of the form

$$v(t) = \sum_n d(n) g_c(t - nT) e^{i\theta(t)} + w(t) , \tag{15.25}$$

where $d(n)$ are the data symbols transmitted at the rate of one symbol per T; $g_c(t) = g_T(t) * c(t) * g_R(t)$ is the composite impulse response of the transmitter, channel, and receiver (all in equivalent baseband with respect to the carrier frequency f_c); $\theta(t)$ is the carrier phase, and $w(t)$ is the noise. The channel response $c(t)$ and the phase $\theta(t)$ are unknown (and possibly different across the array elements), necessitating an adaptive receiver. Adaptive equalization has been considered in two forms: direct, which does not perform explicit channel estimation, and indirect, in which the channel is first estimated and then used to adjust the equalizer. In either form, the data symbols are estimated as

$$\hat{d}(n) = \sum_{p=1}^{P} \boldsymbol{a}_p^H(n) \boldsymbol{x}_p(n) e^{-i\hat{\theta}_p(n)} - \sum_{i>0} b_i^*(n) d(n-i) , \tag{15.26}$$

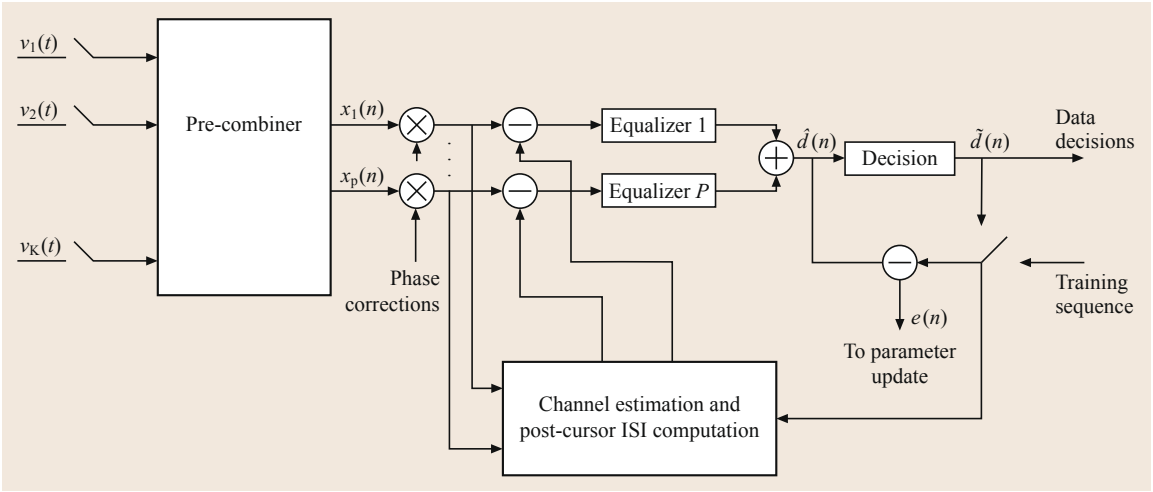

Fig. 15.15 Multichannel decision feedback equalizer

where the input vector $\boldsymbol{x}_p(n)$ to the p-th equalizer branch consists of the sampled precombiner output

$$x_p(t) = \sum_{k=1}^{K} c_{p,k}^{*} v^{(k)}(t) \, .$$

The samples are taken at the Nyquist rate, e.g., two per symbol interval for signals band-limited to $\pm 1/T$. The precombiner coefficients $c_{p,k}$, the feedforward equalizer vectors $\boldsymbol{a}_p$, the feedback equalizer coefficients b_i, and the phase estimates $\hat{\theta}_p$ are adjusted adaptively so as to minimize the mean squared error (MSE) in data detection. Each of these parameters is thus driven by the input signal and the error $e(n) = d(n) - \hat{d}(n)$. Adaptive operation begins with a training sequence of known data symbols $d(n)$ until convergence has been established, after which the symbols $d(n)$ in (15.26) are replaced by the decisions $\tilde{d}(n)$ made on the estimates $\hat{d}(n)$. The details of various algorithm variants can be found in [15.36, 57, 58].

Performance of the multichannel DFE is illustrated in Fig. 15.16. The excellent performance achieved by this receiver in many environments testifies to the benefits of careful algorithm structuring that caters to the acoustic channel. While a propagation-ignorant design may result in an unnecessarily large number of receiver parameters (many equalizer branches with long filters), which will, in turn, cause increased sensitivity to noise and numerical errors, results similar to those of Fig. 15.16 show that one may not need more equalizer branches than there are significant propagation paths; that each of these branches may not need an excessively long filter, and that the feedback filter may only need to activate a select subset of coefficients, although its

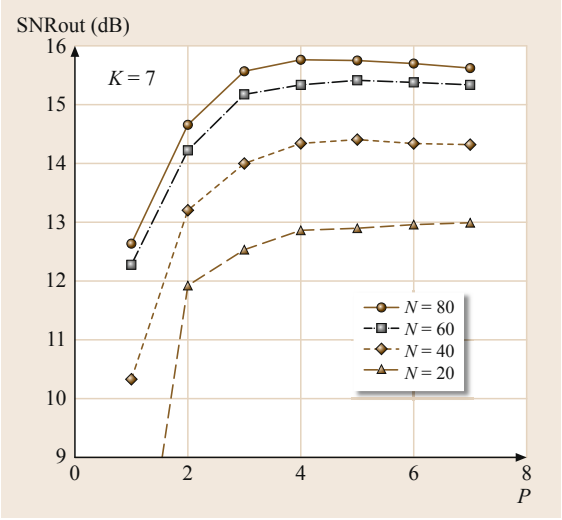

Fig. 15.16 Performance of the multichannel DFE on an experimental channel: output SNR (inversely proportional to the MSE) as a function of the number of equalizer channels P for a fixed number of input channels K. The parameter on the curves is the length N of each feedforward filter used. The total span of the feedback filter is 100 symbols. Real data used for this study correspond to quadrature amplitude modulation (QPSK) signals modulated at a rate of 2 kbps onto a carrier of 1 kHz, and transmitted acoustically over an 85 km long channel in about 50 m of water. The signals were received using a vertical array with inter-element spacing of 1 m. The signals were processed using a double recursive least squares (RLS) algorithm integrated with a second-order decision-directed PLL ►

total span must match that of the multipath. In other words, respecting the *physical* aspects of acoustic propagation in developing a concise channel representation is the key to successful signal processing. Identification of *significant* channel components has attracted due interest in the acoustic community over the past several years, and much attention has been devoted to the topic of sparse channel estimation. [15.37] gives an excellent primer.

Multicarrier Modulation/Detection

Multicarrier modulation in the form of orthogonal frequency division multiplexing (OFDM) has been adopted as a standard for many of the emerging wireless radio systems – wireless local area networks (WLAN), digital audio and video broadcast (DAB/DVB), and long-term evolution that supports the fourth generation (4G) and future generations of cellular systems. However, it has only recently come into the forefront of acoustic communications research, and at the moment, there appears to be little effort to implement this technology in a commercial modem (e.g., by the French Thales).

The appeal of OFDM lies in the computational efficiency of FFT-based processing, and in the fact that it easily scales to different bandwidths (unlike with single-carrier systems, where the equalizer length has to be adjusted in accordance with the bandwidth B because it determines the symbol duration and hence the extent of ISI, with OFDM it simply suffices to increase/decrease the number of carriers K, i. e., the size of the FFT, while keeping the same carrier separation $\Delta f = B/K$). Namely, the demodulated signal is simply represented as

$$y_k(n) = H_k(n)d_k(n) + z_k(n)\,, \qquad (15.27)$$

where $d_k(n)$ is the data symbol transmitted on the k-th carrier during the n-th OFDM block of duration $T = 1/\Delta f$; $H_k(n)$ is the channel transfer function $H(f,t)$ evaluated at the k-th carrier frequency at the time of the n-th block, and $z_k(n)$ is the noise. This signal admits a very simple detector, and extensions to multiple receiving elements are straightforward. In addition, by virtue of having a narrowband signal on each carrier, OFDM is easily conducive to MIMO processing [15.40, 62], adaptive modulation [15.63], and differentially coherent detection [15.64]. However, its sensitivity to frequency offset and time-variation of the channel demands special attention. Issues related to power efficiency also need to be kept in mind, as OFDM is sensitive to nonlinear distortions [15.65].

OFDM signal processing encompasses two stages: pre-FFT synchronization and post-FFT data detection. To account for motion-induced Doppler frequency shifting, which can amount to more than a full carrier spacing, front-end resampling is often necessary. A simple method for estimating the needed resampling rate is to measure the time between two synchronization preambles that frame several OFDM blocks and compare it to the expected frame duration [15.66].

Since the Doppler factor is relatively large to begin with (e.g., on the order of 10^{-3} for a relative velocity of 1.5 m/s), Doppler shifting that remains after initial resampling cannot be neglected. Two approaches have been pursued to address this issue: one is based on the assumption that residual Doppler shift is the same for all carriers [15.66], while another allows for nonuniform frequency shifting across the signal bandwidth [15.44].

Channel estimation for OFDM systems has been addressed in different forms: in one, each OFDM block is processed independently of the other blocks, thus allowing for the possibility that the channel changes completely from one block to another [15.41, 62], while another form exploits correlation between adjacent blocks [15.40, 67], which makes it advantageous on slowly varying channels. Similarly as in single-carrier systems, accurate channel estimation is the key to successful data detection in OFDM, and it benefits greatly from proper channel modeling to reduce the number of unknown parameters that need to be estimated. Methods for identification of sparse systems, such as matching pursuit (MP) and basis pursuit (BP), which improve upon traditional least squares (LS) estimation, were found to be beneficial and well suited to channel estimation in acoustic OFDM. These methods have been applied to both block-individual channel estimation that uses pilot carriers only [15.41], and to block-adaptive, decision-directed channel estimation [15.68].

The effect of time variability is a subtle one when it comes to acoustic OFDM systems: if the channel can change from one block to another, then perhaps it will change within each block. If this variation is nonnegligible, inter-carrier interference (ICI) will arise at the demodulator output, and carrier-by-carrier detection will no longer be optimal. ICI equalization then becomes necessary. Such a situation is somewhat counter-productive, as it destroys the original motivation of using OFDM for the simplicity of its implementation. Nonetheless, it may arise from pushing the limits of bandwidth efficiency: the more carriers in a given bandwidth, the better the bandwidth utilization, but the narrower the carrier spacing $\Delta f = 1/T$, the longer the OFDM block duration T, and the channel variation may become nonnegligible. The problem of ICI equalization is analogous to that of ISI equalization in single-carrier systems, except that the equalizer now operates across

carriers, and typically involves fewer interfering terms. Methods based on one-shot linear equalization of a full block of carriers [15.41, 69], as well as recursive linear or decision-feedback equalization [15.70], have been investigated. Further improvements are available from front-end (pre-FFT) filtering, which extracts the information about the time-varying channel before it has been lost in the process of FFT demodulation. A receiver that mimics the operation of an optimal, channel-matched filter was proposed in [15.71], while one that follows the analogy of fractionally-spaced equalization in the frequency domain was investigated in [15.72].

Virtually all acoustic OFDM systems addressed to date have focused on coherent detection and the attendant issues of channel estimation and Doppler tracking. However, a properly designed OFDM system (one in which there is no ICI) is well suited to differentially coherent detection as well. Differential encoding can be performed either across blocks or across carriers. In the latter case, differential coherence is naturally satisfied with tight carrier packing, which simultaneously supports bandwidth efficiency. Preliminary experimental results [15.64, 73] have demonstrated the benefits of differentially coherent OFDM, whose computational complexity is by far lower than that of any coherent system, and whose performance can surpass that of coherent detection when channel estimation fails.

15.5.3 Data Link Reliability

Channel coding or forward error coding (FEC) in a crucial feature of underwater acoustic modems. By introducing a redundancy part in the transmitted message, error correction codes allow for detection and correction of the bit errors caused by noise and inter-symbol interference. Generally, the ability to correct the errors is achieved by adding redundancy, which in turns reduces the effective data rate. Therefore, a proper coding scheme for a communication system is chosen based on the trade-off between the desired data bit rate and error rate performance.

Traditional FEC techniques are divided into convolutional codes (usually decoded with the ubiquitous Viterbi algorithm) and block codes (e.g., Bose-Chaudhuri-Hocquenghem or BCH, Reed–Solomon or RS) [15.74, 75]. Concatenated codes usually combine convolutional and block codes to improve the reliability of the acoustic modem even further. More recently, turbo codes [15.76, 77] and low-density parity-check (LDPC) codes [15.78] have become part of the field of telecommunication as they offer near Shannon error correction capability. Having inherently a low coding rate and a potentially large decoding latency, turbo codes have emerged as a good choice in communication systems where achieving a very low error rate performance is a top priority. A communication link designed for the transmission of the command-and-control messages to a remotely operated robot or vehicle is such a system. Since control messages do not contain a large number of bits that need to be transmitted in a short time, high bit rates are not required.

Even the most sophisticated error codes cannot ensure complete link reliability. To guarantee an error-free communication link (if it is physically possible), the acoustic modem must include a quality of service (QoS) feature, typically in the form of an automated retransmission query (ARQ) process implemented between two acoustic modems [15.54, 79]. This operation requires a communication protocol that includes acknowledgments and may dramatically reduce the overall data rate. The optimization of the QoS protocol is a key feature of modern acoustic modems. Acoustic modem users should be aware that commercially advertised throughputs (data rates) assume a single message transmission and do not include any retransmission.

15.5.4 Turbo Equalization

Turbo equalization is a very powerful method used to improve the removal of inter-symbol interference and additive noise. This technique can be implemented with single-carrier and multiple-carrier signaling. In particular, extensive research in combining turbo equalization and OFDM has taken place over the past decade. The simplest and best explanation is provided in the seminal work published in [15.80]. In short terms, turbo-equalization jointly optimizes adaptive equalization and channel decoding in an iterative process. The result is a dramatic improvement of transmission quality, even for high spectral efficiency modulations and time-varying fading channels. Modern underwater acoustic modems make growing use of this technique, which is powerful but processor intensive.

At the heart of this process is interleaving and error coding. The binary information at the source is carefully error-coded, modulated, and interleaved before it is pulse-shaped and transmitted through the water channel. In a traditional equalized receiver, the distorted signal is equalized, deinterleaved, converted to the binary domain, and the error-coded binary information is decoded and, hopefully, every binary error is corrected.

The obvious issue with this method is the fact that some error may remain. The turbo-equalizer goes two steps further in using this information. First of all, it modulates and interleaves the error-corrected binary information (which may still contain errors), thus cleaning the signal of some (or most of the) inter-symbol interference. The original signal is equalized

once again, but this time the *cleaned* signal is used as a new reference in the decision feedback portion of the adaptive equalizer. The second step is to repeat the entire operation again and again, so that the original signal is equalized against an ever *cleaner* reference signal.

The statistical properties of the acoustic channel, the type of interleaver, error coding, and decoding have a significant impact on turbo-equalizers. However, the same can be said of every equalized communication system, and overall this technique can lead to significant improvements in data transmission quality over a more traditional equalizer approach. Therefore, turbo-equalizers are becoming increasingly more common in underwater acoustic communication systems [15.38, 39, 69].

15.5.5 Adapting to the Environment

Adapting to the communication environment involves not only receiver-end channel estimation, but transmitter adaptation as well. This task is much more challenging in a time-varying environment which hinders the feedback from the receiver to the transmitter. In an acoustic channel, the situation is exacerbated by the long propagation delay which may make the feedback obsolete by the time it arrives. It is thus imperative to identify those environmental parameters that can withstand the feedback delay, and focus on the related transmitter functions.

In light of the large-scale and small-scale channel variations discussed in Sect. 15.4.4, adaptive mechanisms that have been considered include large-scale power control and small-scale waveform control. The first refers to adjusting the total transmitting power regardless of the modulation/detection method used, while the latter refers to adjusting the shape of the signal spectrum, i. e., distribution of the total available power over a given bandwidth. While the former targets power savings over extended periods of time (e.g., hours or days), the latter targets improved signal detection in a particular communication session (several data packets).

Neither type of adaptivity has been implemented in a commercial system, although research suggests significant benefits. Specifically, large-scale power control was shown to have significant benefits both in the sense of power savings [15.45] and in the sense of interference control in networked systems [15.81].

The work on small-scale adaptation has been versatile, including active time-reversal [15.82], single-mode excitation [15.83], and adaptive modulation [15.63]. Time reversal (or phase conjugation in the frequency domain) has in particular been extensively studied as an adaptive matched-filtering technique for acoustic communications [15.82], both in the sense of receiver adaptivity and transmitter adaptivity. It uses a time-reversed replica of a received signal waveform to implement a filter matched to that waveform, and can operate either passively or actively. Passive time-reversal resides at the receiver side only, where its role is to acquire a probe signal and use it to perform low-complexity front-end filtering prior to equalization or interference cancelation [15.84, 85]. In contrast, active time-reversal operates at the transmitter side, where its role is to time reverse the feedback signal and use it as the basic pulse (basic transmit waveform) that will best match the channel. By doing so, the transmitter, typically equipped with a large array, focuses its energy not only in time, but also in space ([15.82] and references therein). In repeated actions of this type, both ends of the link can focus their energy.

Adaptive modulation has been considered in the context of single-carrier MIMO systems [15.61], and, more recently, in the context of multicarrier systems [15.63], where adaptive power and/or rate control (adaptive bit loading) can be implemented easily by adjusting the amplitude and/or the modulation level of each carrier separately. The performance improvement available from these techniques is contingent on the quality of the channel state information that is fed back to the transmitter. Recent results [15.63], which report on the first experimental demonstration of this type, suggest the possibility to isolate the more slowly varying channel parameters (i. e., the predictable propagation path gains) from the more rapidly varying ones (phases) and use them to design an adaptive modulation system.

15.5.6 Networks

With the technological advances in acoustic modems, vehicles, and sensors, the concept of an underwater network of distributed autonomous nodes [15.14] is coming closer to realization. Experimental deployments are well underway, demonstrating the existing hardware capabilities in series of experimental deployments supported by the US Navy, such as the SeaWeb that uses telesonar modems [15.28], or deployments that use WHOI micro-modems [15.86]. Recently, efforts have begun to standardize acoustic network protocols with the goal of ensuring inter-operability between different modems. In particular, an international NATO-led effort is active in establishing JANUS [15.12], a standard that specifies data packet structures, acknowledgement (ACK) mechanisms, bit rates, etc., for use in given frequency band/transmissison distance configurations. Simultaneously, research is steadily advancing on the design of multiple-access methods, medium

access control (MAC) and routing protocols for underwater acoustic networks. The fundamental aspects of underwater acoustic networking have been highlighted in several survey articles [15.87–90]. At the moment, there is a solid base of custom-designed protocols that are suitable for poor-quality, interference-prone, delay-challenged acoustic channels, and are ready for testing in the field.

A full spectrum of network applications is not yet obvious, as integrated system capabilities depend on many aspects whose proof-of-concept, in turn, depends on in-situ testing. Unlike with signal processing, testing of networked systems cannot be performed off-line. Network simulation tools have thus started to emerge; an example is the World Ocean System Simulator (WOSS) [15.53], which integrates the Bellhop ray tracer with digital ocean maps and the NS-2 network simulator.

Due to a lack of *typical applications*, we tend to think about two types of networks: one with fixed, bottom-mounted nodes deployed for longer periods of time (e.g., sensor networks for environmental monitoring), and another with mobile nodes deployed on shorter missions (e.g., fleets of *cooperating* AUVs, where vehicles have the capability to respond to one another and make decisions, not only to be guided by supervisory commands from a central authority that amounts to *switch from mission A to mission B*). Interactions between mobile and fixed sensors are, of course, also of interest. Large-scale integration of autonomous systems includes the typical cross-layer network optimization at the boundary of two adjacent layers (i. e., routing and data link layer, or data link and physical layer). More importantly, it extends all the way from the application to the physical link, and includes external system functions such as localization and navigation (which themselves are challenging tasks as there is no global positioning or timing underwater).

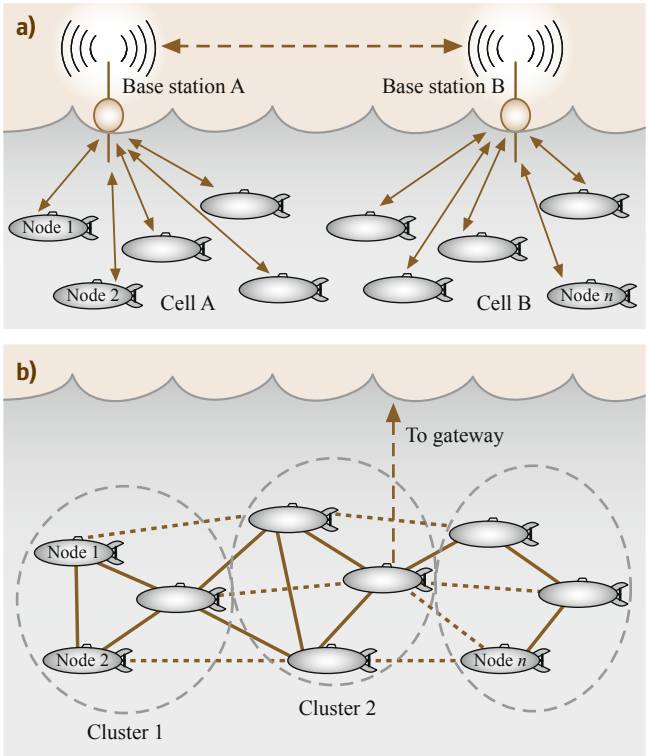

Fig. 15.17a,b Network topologies and the associated architectures come in various forms: in a centralized network of a cellular type, nodes communicate through a single-hop connection to the base station, while base stations are connected to a common infrastructure **(a)**; in a de-centralized network of an ad-hoc type, nodes communicate over multihop, peer-to-peer links **(b)**

The design of underwater networks is daunted by the constraints of acoustic propagation: limited, distance-dependent bandwidth, high bit (packet) error rate, and high channel latency. The fact that acoustic signals propagate at 1500 m/s, while bit rates supported by the (half-duplex) acoustic modems are on the order of a kbit/s, makes the propagation delay anything but negligible with respect to the packet size – otherwise a common assumption in the design of many channel access schemes. As a result, direct application of protocols developed for terrestrial sensor networks may incur a serious penalty in efficiency, requiring instead a careful re-design for acoustic applications. Energy efficiency is an important aspect in bottom-mounted sensor networks, since re-charging the batteries of submerged instruments is to be postponed for as long as possible. In contrast, mobile systems are already constrained to several-hour missions before they have to re-charge, and power usage for communications is not a major issue (unless self-propelled gliders are in question). It must also be kept in mind that underwater instruments (sensors, modems, vehicles) are neither cheap nor disposable. This fact may be the single most-important feature that distinguishes underwater networks from their terrestrial counterparts, fundamentally changing many network design principles that are usually taken for granted. Finally, the questions of network topology optimization and the associated capacity analysis remain open.

In terms of system topology and architecture, two extreme situations are illustrated in Fig. 15.17. In a centralized network, distributed nodes communicate through a base station in whose footprint they are. Coverage can be extended in this type of network by replicating the cells across space, similarly as in terrestrial cellular systems (except that the *infrastructure* that connects the base stations can consist of radio links). In a de-centralized network, the nodes communicate di-

rectly with each other. There is no central authority such as a base station, although the nodes can form clusters, and the end goal may as well be to transmit all the data to a common node (a surface sink). The network nodes can either have pre-established routes over which to send the packets (as would be the case in fixed bottom-mounted networks), or they can do this in an ad-hoc manner, learning the routes as they go (which would be the case in a mobile network). Between these two extremes lie various hybrid architectures.

15.5.7 Channel Sharing

Channel sharing is the major design issue for band-limited acoustic networks. Methods for channel sharing can be divided into two types: deterministic and random. In deterministic access, resources such as frequency bands or time slots are allocated to particular nodes. This type of multiple access is well suited to systems in which the nodes transmit continuously, since the a-priori allocated resources are then well utilized. If the nodes instead transmit in a bursty manner and not too often, random access may be the preferred choice. The nodes now transmit more-or-less at their own will and in the same frequency band, risking a loss if their packets collide at the receiver. Medium access control (MAC) protocols can then be used to orchestrate the nodes' behavior and reduce the chances of collision. Random and deterministic access can also be combined in a reservation-based channel sharing scheme. Nodes now first contend by transmitting short reservation packets in a random access fashion. The central authority chooses the winners, and deterministically allocates them fixed resources for the duration of the data transmission phase.

Deterministic Access

Deterministic access for acoustic networks has been considered in various forms – frequency, time, and code-division multiple access (FDMA, TDMA, CDMA) [15.91]. Typically, FDMA is considered inefficient on account of the fact that the already limited bandwidth will be wasted if allocated permanently to a node that does not transmit, while those nodes that transmit will be doing so at a lower bit rate, thereby increasing the energy consumption. This reasoning is justified in today's applications where the nodes typically do not stream continuously, but only report to the base station upon request. A polling mechanism is then put in place via time-division duplexing (TDD). Although this method may resemble TDMA (and is often called that) a network based on polling is not a true TDMA network, as it involves a two-way propagation delay for each transaction, whereas in a true TDMA network nodes schedule their transmissions so that they arrive back-to-back to the central node. In an acoustic setting with variable propagation delays, guard times are needed to ensure that there is no overlap of packets at the base station. Acoustic modems that are currently in use are well conducive to such an implementation [15.92].

An alternative that has been considered for small multiuser systems is CDMA based on direct-sequence spread-spectrum (DS-SS) modulation, which simultaneously provides the low probability of detection (LPD) needed for operation in hostile environments. It may be worth noting that the usual assumptions involved in the design of radio DS-SS systems do not hold in an acoustic channel, because it requires chip-rate (as opposed to symbol-rate) adaptive processing to take advantage of the available spreading gain [15.60]. Passive time reversal has also been used for multiuser detection [15.85].

While today's applications do not require more than a single cell, spatial frequency reuse across multiple cells offers the key to large area coverage with a limited bandwidth. Acoustic propagation, however, dictates cellular design principles that are more complex than those used in terrestrial networks, and makes the system capacity heavily dependent on the center frequency [15.93]. Specifically, moving to a higher frequency region than that dictated by simple SNR maximization (Fig. 15.5) improves the signal-to-interference ratio and yields a greater capacity.

Random Access

Random access has been used for acoustic networks in which the nodes transmit infrequently [15.28, 86]. This type of access is also suitable for networks with many nodes, so long as the their aggregate traffic does not exceed a certain limit. The simplest form of random access is the Aloha mechanism whereby each node transmits whenever it wants to, and if it becomes aware of a collision (via an acknowledgement/negative acknowledgement (ACK/NAK) feedback from the intended receiver), it re-transmits after a random back-off time. This simple mechanism can be augmented by carrier sensing multiple access (CSMA), which imposes an additional condition that a node can transmit only if it senses the channel to be free. Compared to radio systems where propagation delay is negligible compared to the packet duration, this listen-before-transmitting principle has fewer benefits in acoustic systems, where the packets propagate slowly, and the fact that none are overheard does not mean that some are not present in the channel. Multiple-access collision avoidance (MACA) introduces a hand-shaking procedure to secure the link using short control packets of

the request-to-send/clear-to-send type (RTS/CTS) prior to transmitting the longer data packets.

In the past years there have been major developments on the medium access control (MAC) layer, with focus on protocol design that is not ignorant of the high acoustic latency, but strives to overcome it in an efficient manner or even take advantage of it. Examples of such protocols include the distance-aware collision avoidance protocol (DACAP) [15.94], T-Lohi [15.95], propagation-delay-tolerant Aloha [15.96], and many others, e.g., [15.97, 98]. For example, DACAP is based on a standard control packet exchange to secure the link for data transmission, with the addition of a warning signal that interrupts an on-going transmission that is bound to fail. T-Lohi uses dedicated collision-avoidance tones to announce data transmission, thus enabling all those who overhear the tones to count the number of active nodes, which, in turn, is used to optimize channel access.

15.5.8 Routing and Cross-Layer Integration

Work on higher layer protocols has focused in particular on routing. Geographical routing, which exploits the knowledge of the nodes' locations to determine the best next relay so as to minimize the total energy consumption, was addressed in [15.99]. A distributed geographical routing protocol with integrated power control was proposed in [15.81]. Distributed routing for delay-sensitive and delay-insensitive applications was investigated in [15.100], while a distributed procedure for initial neighbor discovery was proposed in [15.101]. Transport control protocols have been considered to a much lesser extent, since end-to-end retransmission suffers greatly from long delays and high packet error rate.

Cross-layer design plays an important role in acoustic systems, both between adjacent network layers and between adjacent system functions. Examples of cross-layer design include frequency allocation and power control integration with MAC and routing [15.81]; topology/sleep control for energy-efficiency in fixed networks [15.56, 98, 102]; packet size selection for optimizing the throughput/energy performance of MAC protocols [15.103], and optimization of rateless packet coding (network coding) for use with half-duplex acoustic links [15.104]. An example of cross-*function* design is integration of localization/navigation with acoustic communications. The use of acoustic modems as traveling beacons that help to localize AUVs by measuring the relative propagation delays in a network is described in [15.92]. Such localization may, in turn, support geographical routing protocols in which location information is used to find the best routes through the network.

The issues of mobility and delay-tolerance have received particular attention. Channel access in a network composed of both fixed and mobile nodes was studied in [15.102], via a simulation analysis that compares the Aloha and the DACAP protocols. Both were found to provide satisfactory performance, which is further enhanced for mobile applications by simple modifications such as back-to-back repetitions. [15.105] investigated routing in a delay-tolerant network (DTN), comparing two classes of protocols, one based on spray-and-wait principle and the other based on resource allocation for intentional DTN. In conditions of high load, the latter was found to outperform the former as well as basic flooding in terms of packet delivery ratio regardless of mobility conditions, while the former showed better performance in terms of average delivery ratio. [15.106] considered a swarm of free-floating mobile sensor nodes that need to report their measurements to a central station. [15.107] considered location-based routing in a mobile network. To improve the performance, the nodes do not use the current knowledge of the destination's location, but instead form a prediction based on the history of motion. [15.108] also investigated location-based routing, which it enhanced by inclusion of a link quality metric into the decision-making process. Finally, [15.109] explored the idea of waiting for a favorable link to present itself before forwarding a packet. In other words, an AUV may not wish to waste its energy transmitting to a relay far away, but may instead want to wait for a better opportunity. Once such an opportunity presents itself, highly directional transmission is exploited to focus the energy in a desired direction.

These references offer a valuable first step towards understanding the network behavior in the presence of long acoustic delay and frequency-dependent attenuation. They identify vulnerable points of existing protocols and offer clever solutions to recover the performance. However, although there is a common understanding that mobility needs special care in an acoustic setting, the analysis is often conducted via simulation, using a time-invariant propagation model. This fact emphasizes the need for *statistical* channel models that will reflect temporal as well as spatial variability of acoustic channel and enable the development of more accurate simulation tools.

15.6 Future Trends

As underwater acoustic modem technology keeps evolving, new research trends appear. The most obvious trend is the development of message format and protocols optimized for a specific application. A good example is the development of the compact control language (CCL) for unmanned underwater vehicle (UUV) applications [15.23]. Another example is digital diver modems. In addition, data compression algorithms tailored for underwater acoustic modems have now been developed, as traditional compression routines are often not well suited to this type of communication system. The integration of underwater acoustic modems in larger system now includes the combination of multiple functions in order to reduce cost, size, and power consumption. For example, several underwater acoustic modems also include long-baseline and/or ultra-short baseline acoustic positioning capability [15.110, 111].

Some of the most innovative research in underwater communication now combines various modalities, such as optics (laser, lidar), and magnetic and electromagnetic signaling with broadband acoustics [15.112]. In particular, excellent work is taking place in combining short-range, high-bit-rate underwater communications with slower, longer-range underwater acoustic communications. Finally, one should not overlook the extensive research work taking place to develop better acoustic propagation models and statistical performance models [15.113]. For example, great efforts are being made in modeling and optimizing network operations using underwater acoustic modems, possibly in combination with surface radio communication devices. Also, integrated underwater acoustic communications and localization are increasingly being combined to improve data routing [15.114].

16. Autonomous Underwater Vehicle Docking

James G. Bellingham

This chapter describes the practical challenges of docking autonomous underwater vehicles (AUVs) in the ocean environment and approaches undertaken to create working docking systems. Early docking work was motivated by the desire to operate AUVs for multiple sorties without recovery or human servicing of the AUV. To accomplish this, the docking system provides a method for the AUV to find the dock, to physically attach, to recharge AUV batteries, to establish a communication link, to wait in a low power state for a new mission, and to undock. A variety of homing methods, dock configurations, power transfer approaches, and communications links have been employed to achieve these respective needs, and are described herein. While the original applications driving docking were oceanographic in nature, present interest is broader, driven by commercial and military applications as well. Docking has been demonstrated, but has not been deployed as an operational capability, in part because docking requires an infrastructure for the dock that provides physical mounting, a source of power, and communication connectivity. The advent of cabled and mooring-based observatories, and subsea infrastructure for oil and gas production, create a foundation supporting docking system deployment. Consequently, the prospects for operational docking systems seem promising.

Autonomous underwater vehicle (docking AUV) is the process whereby an AUV purposefully transitions from a state of free flight to being physically connected to another device or platform, called the dock. One driver for the development of AUV docking stems from the desire to decrease reliance of AUV operations on ships and thus enable persistent AUV operations. In effect, if the AUV batteries can be recharged, mission data retrieved, and a new mission initiated without recovering the AUV to a ship, then the potential exists to dramatically reduce operational costs and increase deployment duration. Examples of docks designed to support extended deployment include docking systems integrated on moorings [16.1] or attached to cabled observatories [16.2]. The advent of a growing number of scientific observatories directly enables such AUV docking concepts, a circumstance recognized early in the seafloor observatory planning process [16.3].

One of the earliest observing system concepts to employ docking as a key element was the autonomous ocean sampling network (AOSN) paradigm [16.4]. AOSN proposed the use of a heterogeneous mix of vehicles to synoptically characterize dynamic ocean processes. The system used a mix of buoyancy-driven

vehicles (*gliders*) and propeller-driven AUVs. Docking was invoked as a method to extend the endurance of the propeller driven vehicles and to collect and report observed data. It is worth noting that at the time of the AOSN paper, propeller driven AUVs had typical endurances of a fraction of a day, buoyancy-driven systems (gliders) did not exist yet, and satellite communication systems like Iridium were still in the future. The AOSN concept attracted significant effort, and a range of docking technologies were developed and demonstrated [16.5–8].

With growing acceptance of survey-class AUVs in the commercial sector, interest is growing in the use of AUVs for activities such as periodic inspection of subsea equipment installations [16.9] and the use of AUVs for maintenance and repair activities [16.10–12]. Many scenarios envision an AUV that is resident with the undersea equipment, thus creating a docking requirement. Another scenario uses an AUV to deliver a package, such as an ROV (remotely operated vehicle) [16.13, 14] to the equipment requiring servicing. In this scenario, the delivered ROV, once attached, can be tele-operated using connectivity through the dock and undersea infrastructure, allowing ROV operations without a ship.

The demands of launch and recovery often limit the operational use of AUVs. Consequently docking has been identified as an enabling capability to support off-board operation of AUVs from submarines [16.15, 16], autonomous surface vessels [16.17], other AUVs [16.18], ships [16.9], and under ice [16.19, 20]. Even in circumstances where humans are available to handle recovery, safety factors will limit deck operations as sea conditions deteriorate. Expanding the weather window for AUV operations can have important financial benefits for commercial operations, and can be enabling for military operations. Consequently, automating launch and recovery is attractive.

The diverse uses of docking systems lead to equally diverse design strategies. The steps include: navigating the AUV to the docking device vicinity, approaching the dock with the appropriate velocity and orientation, and achieving physical linkage of the AUV and the dock. In addition, some docking systems integrate communications and power transfer functions into their design, and in these cases the process of physical linkage is also associated with establishing communications and power links. Factors influencing the nature of the docking include: is the vehicle docking with a fixed or moving object? Will the dock provide power to the AUV, or vice versa? Will a human operator intervene in the process at any stage? Are there reasons to minimize the amount of hardware required for docking on either the AUV or the dock? Even this brief list of questions demonstrates how different applications might drive a docking system design in very different directions.

16.1 Technical Elements of Docking

To understand the elements of docking, it is useful to review an example docking scenario. Consider a dock attached to a cabled observatory that provides power and high-bandwidth communication to a docked vehicle. The dock itself is a funnel structure (Fig. 16.1) into which the torpedo-shaped vehicle (Fig. 16.2) will drive in the docking process. The docking process starts with the vehicle at a considerable distance, and following sequence:

- *En route*: the first phase of docking is for the vehicle to navigate to the vicinity of the dock so that it can directly sense the dock with onboard sensors. During the en route phase of operations, the vehicle typically navigates relative to the Earth.
- *Approach setup*: once the vehicle is in the general vicinity of the dock, it must position itself for an approach to the dock. For example, the vehicle might use an ultrashort baseline (USBL) acoustic system that can measure the direction and range to an acoustic transponder mounted on the dock to position itself in front of the dock cone, aligned for an approach.
- *Approach*: once the vehicle is positioned appropriately, it can make its approach to the dock. Approach techniques range from the simple strategy of simply pointing directly at the dock, to more sophisticated methodologies which attempt to compensate for currents to follow a specific trajectory.
- *Terminal homing*: the last segment of the final approach, as the vehicle closes to within a few vehicle lengths of the dock, is referred to as the terminal homing phase. The accuracy of the final approach to the docking funnel can be improved by using a terminal guidance sensor with very high update rate and high accuracy, for example, an optical homing system.
- *Capture*: a successful final approach terminates with the vehicle impacting inside the docking funnel. The vehicle will continue to thrust forward, driving the nose of the vehicle to the center of the

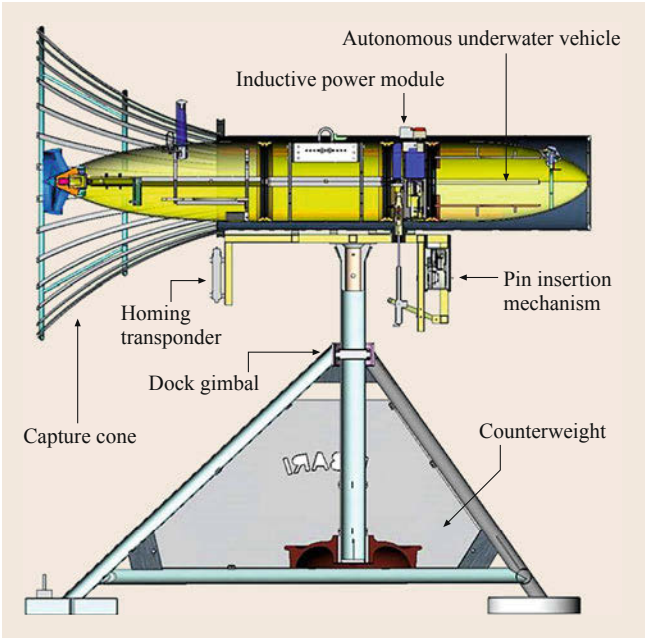

Fig. 16.1 A solid model of a docking station with an AUV captured within the dock (after [16.2]). This docking system is made to rest on the seafloor and be connected to a cabled observatory. The system includes a flared capture cone, which increases the capture aperture of the dock, and a cylindrical housing section, which encloses the docked AUV. A power connection is created by inserting a pin containing an inductive coil into the vehicle, enabling inductive power transfer. The pin also serves to restrain the vehicle within the dock. Communication is provided by an 802.11 ink, supporting short-range communication through seawater. The entire cone assembly is mounted on a gimbal and counterweighted so that the dock will self-level on deployment. Solid works drawing by Jon Erickson, MBARI ►

funnel, where the vehicle will be guided to a capture mechanism.

- *Missed approach*: a robust docking system must anticipate the chance that the final approach will not result in a successful capture. In this case, the vehicle must be capable of detecting that it has missed the dock and repositioning itself for another attempt. This is called executing a missed approach.
- *Connection*: following successful capture, power and communication connections can be made. These may involve actuation by either the vehicle or the dock to make electrical, inductive, or (in the case of communications) electromagnetic/optical connection.
- *Servicing*: once attached, the AUV can connect to the cabled observatory network through the dock. Its batteries can be recharged, data can be downloaded, new missions uploaded, software updated, and so on.
- *Undocking*: to start a new mission, the process must be reversed. Electrical and power connections must be broken. The vehicle capture mechanism must release the vehicle. The vehicle must extract itself from the dock. Once the vehicle is clear of the dock, it can begin its new mission.

The common elements of docking include sensors that allow the AUV to home on the dock, mechanisms for mechanically connecting the vehicle and the dock, and software controlling the overall process. In some cases, the docking system also includes one or more communications links between the vehicle and the dock, and power transfer systems to power and recharge the vehicle.

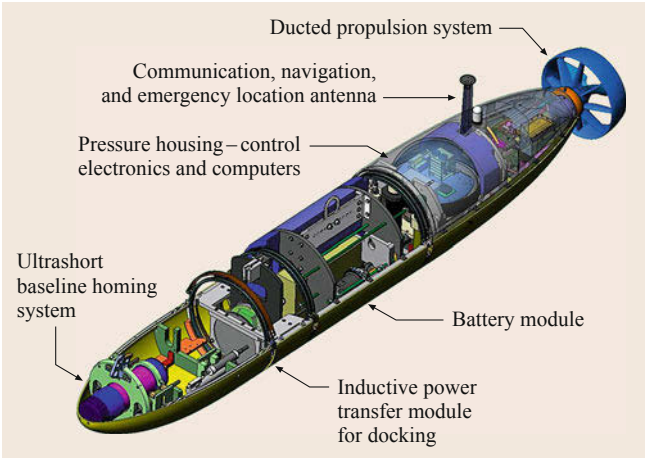

Fig. 16.2 Autonomous underwater vehicle (AUV) configured to dock with docking station of Fig. 16.1 (after [16.3]). Elements of the vehicle are labeled. Docking-related components include the ultrashort baseline homing system, mounted in the nose, and the inductive power module. Other features of the system facilitating docking include the absence of external appendages on the forward portion of the vehicle, which would hinder capture and insertion of the vehicle into the docking enclosure. This system is one of the Dorado vehicles (after [16.21]). Jon Erickson, MBARI ►

16.2 AUV Characteristics

The design and operational characteristics of a docking system are intimately connected to the characteristics of the AUV. Important parameters include the controllability of the platform, its external characteristics, its size, and its ability to withstand impacts. For example, some docking methodologies involve a slow and careful approach to the dock, while others achieve docking by running the vehicle into the dock at or close to its maximum speed. The reasons behind these different strategies largely revolve around the nature of the AUV.

16.2.1 Vehicle Configuration and Controllability

Perhaps the most common type of propeller-driven AUVs are designed like torpedoes; they are propelled by a single propeller, and their attitude controlled by control surfaces at the stern (Fig. 16.2). Such platforms are optimized for efficient movement through the water, but are unable to hover or operate at low speed. They are analogous to aircraft, which are controllable only as long as they move forward. For most torpedo-like vehicles, the minimum controllable speed is usually greater than 0.5 m/s, setting a lower bound on docking approach speed. Examples of torpedo-like vehicles used for docking include: Odyssey [16.22], REMUS [16.23], and Dorado [16.21].

Other vehicles are hover-capable, using multiple thrusters to allow control at low and zero speed (Fig. 16.2). For example, the Endurance AUV, used to explore an Antarctic lake [16.24], is an ellipsoidal vehicle with six thrusters, and is able to move independently in x, y, and z axes and rotate in yaw. While Endurance has little control of pitch or roll, it can pivot in place and exert fine control of its horizontal position while rising vertically. The Seaeye Sabertooth hybrid ROV-AUV [16.25] has vertical and lateral thru-hull thrusters, and forward thrusters at its stern. The SWIMMER AUV developed by IFREMER has an ROV-like configuration [16.13]. The important characteristic of these hover-capable vehicles is that they can make controlled, low speed approaches to a dock, and thus are amenable to precision docking. The ability to operate at low speeds is also attractive when the dock is located in the vicinity of other equipment that might be damaged by the impact of a fast-moving vehicle.

16.2.2 Vehicle Size

The size of the vehicle and dock has a substantial effect on design of the docking system, as size influences the sensors that can be accommodated, the impact velocities that can be sustained, and the forces the vehicle can generate. A small dock size brings obvious disadvantages from the perspective of accommodating the hardware associated with docking. Mechanisms for making mechanical connections between vehicle and dock, for power transfer and communications, all have minimum-size requirement. Further, sensor performance is most often a function of size as well. For example, the direction finding performance

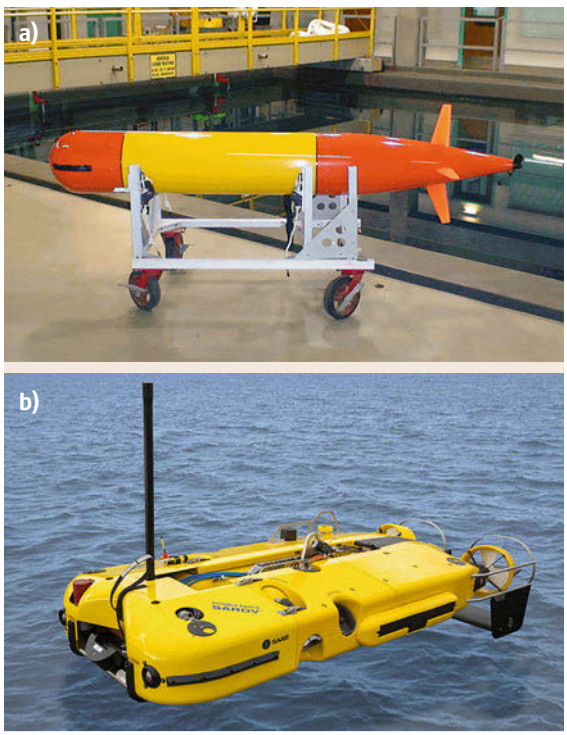

Fig. 16.2a,b Two different configurations of AUVs. **(a)** Torpedo-like AUVs are particularly common as the torpedo shape can support low drag and efficient propulsion, which is attractive for AUV operations in which covering long ranges is important. The vehicle depicted here is the *Tethys* AUV (after [16.26]). The flight characteristics of torpedo-like AUVs encourage docking solutions where the vehicle flies into the dock at some appreciable speed, usually greater than 1 m/s. **(b)** The *Double Eagle SAROV* is characteristic of AUVs that have large numbers of thrusters allowing the vehicles to pivot, and to control forward, lateral, and vertical motion at very low speeds. This allows docking strategies involving slow, precision approaches to docking stations. From SAAB Center Images, reproduced with permission (photos by J. Bellingham) ◄

of an acoustic array for homing is dictated by its aperture compared to the acoustic wavelength at the operating frequency, with smaller arrays having poorer directionality.

However, small size has benefits as well, for example, generally allowing impacts at higher speeds. Consider the docking of a torpedo-like vehicle weighing 200 kg, impacting a dock at 1.5 m/s. The dock and vehicle must absorb 225 J of kinetic energy, not counting added mass of entrained water. If the linear dimension of the system is scaled up by a factor of 2, the vehicle will weigh 1600 kg, and the dock must now dissipate eight times the energy. If, on the other hand, the approach speed can be dropped by half, then the quadratic dependence of kinetic energy on velocity drops the energy dissipated by a factor of 4. Consequently, as vehicle size increases, the speed of docking needs to decrease, and this, in turn, drives larger vehicles to multi-thruster configurations that can be controlled at lower speeds.

The vehicle's ability to apply useful force to the docking process using its propulsion system is likely also to be a function of size. Use of the vehicle's propulsion system to create a force that can complete physical elements of docking is attractive because it minimizes the number of additional actuators that are required. A useful metric, therefore, is the thrust to weight ratio for a given vehicle. Propulsion systems are typically sized to overcome vehicle drag and drag scales with the area of the vehicle. In contrast, mass scales as the vehicle volume. Consequently, if all other factors are held constant, then shrinking a vehicle by two in length will double the vehicle's thrust to mass ratio. Thus smaller vehicles have higher accelerations and are able to apply significantly more force as compared to their mass in the docking process.

16.3 Sensors For Homing

The homing sensor provides the AUV with the information necessary to find and connect to the dock. The ideal homing sensor would allow the AUV to reliably sense the relative location of the dock at any distance with high accuracy, and would update that information many times a second and with no latency. In practice, there is no such technology. Consequently, homing systems for docking are either a combination of different technical approaches with complementary characteristics, or have non-ideal characteristics that must be mitigated by other aspects of the docking system design.

The primary information provided by the homing sensor is the relative position of the two platforms. This provides the vehicle with the information required to approach the dock in a controlled manner. While the AUV presumably has some knowledge of its own location and that of the dock in Earth coordinates, this knowledge is unlikely to be sufficiently accurate for the AUV to achieve physical connection to the dock. Thus the approach and terminal homing phases of docking require accurate relative position information.

Drivers for the homing system key characteristics are as follows:

- *Acquisition distance*: how far away can the AUV acquire information on the relative location of the dock? A homing system that operates at a great distance greatly minimizes the chance that the AUV will not be able to find the dock and/or provides a larger margin for maneuvering the vehicle to position for final approach.
- *Accuracy*: how accurately can the vehicle measure the relative position of the dock? The importance of accuracy increases as the vehicle gets closer to the dock. The simplest homing sensors provide only left–right, up–down cues, without providing accurate relative bearing, elevation, and range. While these systems are adequate for head-on approaches to a homing target, they can be less attractive in more complex situations, for example, when there are currents or when the homing target is offset from the dock.
- *Environmental sensitivity*: many sensing modalities in the ocean have highly variable performance. The range of a particular optical sensor might vary from sub-meter to greater than 100 m, depending on water properties. Methods depending on acoustic signals are sensitive to acoustic conditions, including refraction due to sound speed variations and reflections from the sea surface and seafloor. The severity of performance variability is highly location dependent, and, consequently, the choice of homing system can be heavily influenced by the nature of the environment in which the dock will be deployed.
- *Update rate*: the more frequent the update rate, the more rapidly the vehicle can correct a non-optimal approach. For example, a vehicle traveling 1.5 m/s traverses 3 m between updates given an update rate of 2 s. Under ideal conditions, this might not be a problem; however any cross-currents, dock motion, or errors in the homing system measurement can cause a missed approach.

- *Latency*: some homing methodologies introduce significant latency to the relative position measurement. This increases the ambiguity of the current state of the vehicle, and delays the vehicle's ability to correct for disturbances. In many cases, latency is introduced by signal processing inside the sensor rather than the physics of the sensing technology.

An accurate navigation system onboard the AUV can be particularly useful for docking, allowing the vehicle to navigate between homing system updates, to compensate for latency, and to detect environmental influences like currents.

16.3.1 Acoustic Homing

Acoustic signals propagate over long distances under water and, consequently, are the basis of homing for a number of docking systems. Numerous acoustics navigation methodologies exist, and are often grouped by the size of the transducer array required to achieve a position fix, e.g., long baseline, short baseline, and ultrashort baseline navigation systems. The most commonly used configurations are transponding in nature, in that one system (usually the vehicle) emits an interrogation ping, and the other system (usually the dock) replies. Range is determined by measuring the round trip travel time of the acoustic signal. Practical homing systems used by AUVs have acquisition distances ranging from a fraction a kilometer to many kilometers. The performance depends on both the characteristics of the acoustic homing systems, principally its operational frequency, and the nature of the environment.

The physics of sound in the underwater environment creates a range of challenges. These include the speed of sound, sound refraction due to sound speed variations, interactions of sound with the seafloor and sea surface, ambient noise, and the absorption properties of seawater [16.27]. In complex environments, like shallow water, reverberation and the time varying nature of the ocean surface and interior may cause individual pulses in the received signal to fade or amplify from ping to ping. In signal processing terms, the channel impulse response function is both complicated and time varying. The net effect is that measured properties of a received ping, for example, time of arrival of the leading pulse, may appear to jump in a non-Gaussian way [16.28]. This is a well-known problem for undersea acoustic navigation systems, and a variety of methods have been developed, ranging from methods to reject the jumps [16.29] to other approaches that seek to use the complex nature of the arrival as a probe of the undersea environment sound speed environment [16.30]. Most often, however, the appearance of a multi-path as the separation between source and receiver increases, which becomes yet another factor limiting the useful range of the system.

The update rate and latency of an acoustic system homing are bounded by the finite speed of sound underwater. For the case when the AUV interrogates the dock, and the dock replies, the round-trip for a vehicle at 1.5 km is approximately 2 s. While the latency cannot be improved, the update rate can be increased by simply accelerating the update rate as the vehicle gets closer to the dock. After all, a fast update rate is really only necessary in the terminal stages of homing.

Ultra-Short Baseline Acoustic Systems

Ultra-short baseline (USBL) acoustic homing systems make a phase-sensitive measure of the difference in time of arrival of an acoustic pulse at several hydrophones [16.31]. The difference in time of arrival can be used, in turn, to compute the direction of propagation of the pulse. The phase-sensitive nature of USBL allows comparatively small hydrophone arrays, employing hydrophone separations less than half a wavelength of the pulse. The small size of the hydrophone array, for example, less than 7.5 cm for a 10 kHz signal, allows practical systems with arrays that could fit in the palm of a person's hand. By combining USBL with standard acoustic ranging methods, a vehicle carrying a small USBL can measure the distance and direction to a dock equipped with a transponder. Consequently, a wide number of AUV homing systems have used USBL as the primary homing sensor, including *Light* [16.32], *Singh* et al. [16.5], *Stokey* et al. [16.8], *de Goede* et al. [16.33], *Allen* et al. [16.34], and *McEwen* et al. [16.2].

USBL system integration on an AUV can require careful calibration. Commercial USBL arrays are usually characterized in acoustic facilities to quantify the as-built performance of the array. It is not unusual to require an additional calibration step once the USBL system is mounted on a vehicle, and even to require the addition of materials like acoustical absorbing foam to ensure adequate performance [16.35]. Sources of error include acoustic refraction by any enclosure used for the USBL array, as well as interfering acoustic reflections from vehicle components.

Short Baseline Systems

In contrast to ultra-short baseline systems, short baseline systems (SBL) dispense with the phase comparison and only determine arrival time difference. For monofrequency pulse detection systems the electronics are simple, most often an in-band energy detector of a hard-limited acoustic signal. However, the accuracy of such arrival-time schemes are not as good as phase-sensitive

methods, and, consequently, array sizes must be significantly larger to get usable accuracy. For this reason, homing methods using SBL methods have been implemented on docks rather than on vehicles.

An *inverted* SBL scheme was implemented by *Cowan* [16.36] in which three radially distributed hydrophones on a dock measure the azimuth of a pulse arriving from the vehicle. The resulting measurement is encoded in two reply pulses, separated in frequency and time. The time separation of the two pulses communicates the azimuth information. The attractive aspect of this system is that it minimizes the complexity of the system on the vehicle, reducing the job of the vehicle to simply measuring time-of-arrival of the two pulses. However, some small latency is introduced by the round-trip time. Latency is minimized both by making the system highly integrated and by operating it at short ranges. Cowan's system was intended to be used at ranges of approximately 300 m or less.

Another inverted SBL system was tested by *Smith* and *Kronen* [16.37] for application to docking. The commercial Desert Star Dive Tracker system introduced sufficient latency, even at short ranges; Smith concluded that the approach was unattractive for vehicles making a fast approach (a meter per second or more). However, the approach was deemed useful for slower moving vehicles.

Acoustic Imaging as a Docking Aid

Acoustics can be used to map undersea structures, thus providing a potential cue for docking. The SWIMMER vehicle, which is an AUV that delivers and connects an ROV to subsea infrastructure, used an acoustic imaging system for the final approach of the SWIMMER vehicle to a dock [16.38]. The preliminary tests used an imaging system consisting of two orthogonally mounted scanning sonars. The target consisted of the docking station of which the vehicle was provided with the CAD (computer-aided design) model. The imaging system compared the actual sonar return to a simulation of the sonar return, generated with an estimated position, the CAD model, and a sonar model, to generate updated positions. The system was demonstrated with a mockup of the docking system in shallow water at Cybemetix' Marseilles harbor facilities.

16.3.2 Optical Homing

The advanced state of light sources, sensors, imaging systems, image processing algorithms, computation, and associated technologies provides a strong foundation for a variety of optical homing methods. Optical systems can be roughly divided into some simple categories: systems that home on active lighting systems, systems that home on structured patterns, and systems capable of homing on arbitrary objects. The complexity of the different approaches varies tremendously. Homing on an active light source can be one of the simplest homing systems available, while software intensive vision-based homing methodologies require substantial computational capability, and even then may be limited in update rate.

The acquisition range of optical systems is, in general, greatly limited compared to acoustics in natural ocean environments. Attenuation of optical signals occurs due to scattering and absorption of light by both seawater itself, and the particulate and dissolved constituents of seawater [16.39]. The optical properties of natural seawater are highly wavelength dependent, with the best clarity coinciding roughly with those of human vision. The presence of particulates and dissolved chemicals greatly changes the absorption and scattering properties of water, and can increase attenuation many order of magnitude. As a consequence, light propagation in the ocean is highly location and depth-dependent. Proximity to coastal runoff, phytoplankton blooms, seafloor sediment, and other sources of particles and dissolved compounds can dramatically change optical properties and, therefore, the performance of optical homing systems.

Homing on Active Light Sources

Cowen et al. [16.7, 36] demonstrated an elegant optical homing system using a chopped light source as the homing target and a quadrant detector on the AUV to provide homing cues. The system provided right–left and up–down cues to the vehicle. The directional nature of both the light source and the detector meant that the vehicle needed to approach the dock towards the light source in order to detect the source. Despite water clarity so poor that the vehicle was not visible at a depth of 2 m, acquisition distances of the optical system were 10–15 m. The performance of the optical homing system in Buzzard Bay demonstrated acquisition distances of roughly 28 m. The author assisted with these tests and observed that when the Odyssey AUV acquired lock on the light source at sufficient distance (more than a few meters), it always hit the cone dock target.

Ambient illumination from the sun or other light sources poses a potential source of confusion when homing on the light source. The system described by *Cowen* discriminated against ambient light using two techniques. By modulating the light source at 40 Hz the system could reject the more slowly varying ambient light using a high-pass filter. The more spatially constant ambient light could also be rejected, as compared to the point source target, by using a differencing

scheme with quadrant detectors to reject uniform lighting [16.7]. In tests in San Diego Bay, when water clarity reportedly obscured the yellow Odyssey AUV submerged at depth of 2 m, the homing system was only confused when submerged very shallowly (about 1 m or less) and pointing towards a setting sun.

The use of multiple lights on the dock and a vision system on the AUV allows more sophisticated homing. With the appropriate configuration of lights, the vehicle can compute the vehicle position in dock coordinates. This is particularly useful if the dock is a cone or some other system that requires the vehicle to approach from a particular direction. *Hong* et al. [16.40] proposed a system using five lights arranged around the perimeter of a docking cone, and a sixth light in the same plane as the other five, but outside of the cone. This arrangement allowed the vehicle to compute its position and orientation relative to the dock when all dock lights were in the field of view of the AUV imaging systems.

The five-light system implemented by *Park* et al. was tested in a Korea Ocean Research and Development Institute (KORDI) engineering basin [16.41]. Park eliminated the sixth light, focusing on extracting a directional cue and a range measurement. The environment provided challenges such as interfering light sources, including reflection of the dock lights off the water surface. Docking was initiated with the ISiMI AUV [16.42] at a distance of 15 m pointing at the dock. The authors report successful docking without using range estimation, but also provide a range of suggestions for improving the image processing and control algorithms.

Murarka et al. [16.20] used light-source homing for recovery of their Endurance AUV through ice holes in the Antarctic. This system used a flashing light, reminiscent of *Cowen* et al. [16.7], to guide the AUV to the ice hole. However, the AUV was equipped with a vision system rather than a simple quadrant detector. The light source was suspended to the bottom of the ice hole, where it would be detected by an upward looking camera on the AUV. Endurance is capable of hovering and moving vertically. Once the flashing optical target was detected, Endurance navigated to the ice hole entrance, and then ascended through the 2 m-diameter, 3 m high ice hole. The vision base systems accomplished both approach to and ascent through the ice hole. The authors report using the algorithms for eight descents and ten ascents through the ice.

Homing on Patterns and Arbitrary Structures

Vision systems can also be used to home on passive targets. These targets may be patterned to have specific visual signatures useful to the vision processing algorithm. For example, *Maire* et al. [16.17] tested a vision-based system for homing on black and white striped poles. The system depended on ambient light for illumination, and was tested in an outside diving pool with the Starbug AUV. The vision processing algorithms were able to recognize and distinguish between two different poles by the differing width of the black and white stripes. The docking concept in this case consisted of landing on the bottom between the vertically oriented poles.

Kushnerik et al. [16.43] describe a vision-based docking system using a passive visual marker on the bottom as the homing target. They explored a number of potential marker patterns, finally selecting nested rectangles, as they provided orientation information. They report using the tunnel sea lion (TSL) autonomous vehicle to demonstrate detection, servoing, and landing on the markers using a down-looking camera in natural light at a water depth of 8 m in Peter the Great Bay.

16.3.3 Electromagnetic Homing Systems

Electromagnetic methods face a special challenge in the ocean environment due to the conductive nature of seawater. Not only are radio frequencies strongly attenuated, but the effects are frequency dependent. Below gigahertz frequencies, attenuation goes as the inverse of the root of the frequency. At a frequency of 1 MHz, the $1/e$ attenuation distance, also called the skin depth, is 0.3 m. However, at 1 kHz the skin depth increases to approximately 10 m. Consequently, homing systems using electromagnetic techniques must function at low frequencies. Although the speed of propagation of electromagnetic signals is greatly slowed in a conducting medium, it is still effectively instantaneous in the undersea environment. Thus the latency of an electromagnetic homing system is largely determined by the implementation of the homing system, rather than the physics of electromagnetic propagation in the ocean.

Magnetic Dipole Systems

Feezor et al. [16.6] developed an electromagnetic homing system for docking, using an oscillating magnetic dipole to generate a homing signal. Since magnetic fields are vector quantities, a sensor that fully resolves magnetic components can determine the direction of the magnetic field. By aligning the homing dipole with the docking system, the magnetic measurement, in effect, conveys the orientation of the dock. Thus the magnetic dipole system is attractive for docks that require a directional approach, but whose orientation might be unknown.

The oscillating nature of the magnetic homing signal creates a problem in that while the alignment of the magnetic field can be determined, its absolute direction

is ambiguous. To resolve this ambiguity, an additional dipole source was introduced to transmit a timing signal, allowing synchronization of the homing signal. The source coil for the timing dipole field was oriented vertically at the dock, so that a vehicle approaching in the plane of the dock would see a vertically oriented timing magnetic field. The homing dipole was oriented so that its axis aligned with the axis of the docking funnel. The vertical source coil generated a dipole timing field for the AUV oscillating at 1 kHz, while the homing dipole field oscillated at 2 kHz. The two signals were locked such that a frequency doubled signal generated by the timing field would be synchronized to the homing dipole field.

A three-axis magnetic sensor on an Odyssey IIb AUV was employed to detect and home on magnetic signals generated by the dipole fields. On the AUV, a vertical detection coil was used to measure the magnetic field generated by the vertical source dipole, following which a phased-lock-loop captured the phase information in the timing signal. The frequency-double output of the phase-locked-loop provided a reference for a lock-in amplifier style detection of the homing signal. The provision of a reference signal, generated from the timing signal, allowed determining both the amplitude and the direction of the homing field. Because the AUV had a three-axis sensor, the homing field could be completely resolved in the coordinate frame of the AUV. The AUV homing algorithm commanded the vehicle heading to align the vehicle with the homing field. In effect, the AUV followed the field lines into the dock. Tests of this system on Odyssey II AUVs in Buzzards Bay, Massachusetts, were highly successful with the caveat that the vehicle needed to approach to a range of approximately 30 m to detect the magnetic dipole fields.

16.3.4 Constraining Vertical Position

Homing can be reduced to a two-dimensional horizontal homing problem if the vehicle knows the vertical location of the dock. This can be particularly attractive when there is the potential that the homing signal may suffer from degradation in the vertical plane, for example, when the dock is near a reflecting surface such as the sea surface or seafloor. In general, the vehicle will have at least a rough knowledge of the dock depth, for example, that it is near the seafloor or in a particular depth range in the water column. However, to use depth as a cue for the terminal phase of homing requires the vehicle to know the dock depth to an accuracy better than the vertical capture aperture of the docking system.

Pressure can be used as a cue for vertical plane homing, effectively allowing homing at a constant depth, if the vehicle knows the depth of the dock. However, pressure as a cue can be complicated by factors such as tidal variations in water depth, changing atmospheric pressure at the surface, inaccuracies and hysteresis in pressure sensors, and changes in the density of the water column. For example, tidal variability can cause the depth of the dock to change as local sea level rises and fall if the dock is secured relative to the seafloor. Environmental factors can be mitigated by providing a method for the dock to communicate its pressure depth to the vehicle, but at the cost of added complexity.

Altitude is a particularly robust vertical plane cue if the dock is mounted in a way that keeps its height over the seafloor constant. For example, the docking system in Fig. 16.1 uses a rigid tripod, holding the dock a constant 3 m over the seafloor. For this system, the AUV uses its altimeter to maintain a constant 3 m altitude during the final homing phase, resulting in highly accurate homing in the vertical plane.

16.4 Capture and Connection Mechanisms

Capture is the process whereby the AUV becomes physically attached to the dock. Connection describes the activity of securing the vehicle and making any links, for example, for power or communications. Typically, the capture mechanism guides the vehicle into alignment, brings the vehicle into its final docked position, and latches the vehicle and dock together to ensure that the vehicle will stay connected. The connection mechanisms establish electrical or optical connection between the vehicle and the dock, and may secure the vehicle within an enclosure that protects the vehicle against the environment while docked.

Chief among the goals associated with design of the capture mechanism is to simplify the homing problem. Considerations include providing a large capture aperture in the horizontal and vertical planes, and reducing constraints on approach direction and attitude. This is simplest to understand in the context of a dock shaped like a funnel, into which the vehicle will attempt to drive. If the funnel is very small, then both homing sensors and vehicle control must be very accurate to ensure that the vehicle impacts the interior of the funnel. The funnel also requires that the vehicle approach the mouth of the funnel along the axis of the funnel. Thus, the funnel dock requires the vehicle to know the orientation of the funnel and be able to achieve an orientation to make a final approach along the funnel axis.

The concept of a capture aperture is a useful abstraction for comparing docking methodologies. This is best understood in the context of a simple model of a dock as an area in space which defines the region the vehicle must encounter during final approach for a successful capture. Typically, there are constraints on the alignment of the vehicle with the dock as well.

16.4.1 Directional Docks: Funnels

Funnel docks are designed to provide a large cross-section with which to capture the vehicle and guide it to a capture mechanism. In some cases, the funnel guides the vehicle to a cylindrical structure which encloses all or part of the AUV. In most cases, the vehicle drives into the dock under propulsion power. Examples of funnel docks include the early Odyssey docking systems [16.6, 7], the REMUS docking system [16.34], the Dorado docking system [16.2], and the UUV (unmanned underwater vehicle) Docking and Recharge System designed to accommodate multiple vehicles [16.18]. Cone docking systems are most often used with torpedo-like AUVs.

Attractive features of funnel-type docks include the potential for a large capture aperture. Further, funnels can be constructed to fully constrain the AUV after capture, for example by placing a cylindrical vehicle *garage* at the base of the funnel (Fig. 16.1). This simplifies the subsequent problem of establishing connections for power and communications. Further, if the dock completely envelops the AUV, then the AUV is better protected while it is docked, which can protect the vehicle against biofouling or other environmental hazards. Finally, the funnel dock can be constructed to support most of the docking functionality, minimizing the amount of additional hardware the vehicle must carry.

The funnel dock imposes constraints on the approach direction, as the funnel is fundamentally directional in nature. This creates the need that an approaching vehicle be aware of the docking orientation. In cases in which the orientation of the dock is fixed on deployment, the vehicle only needs to know the dock alignment. In other cases, the dock orientation is not fixed; for example, it may be allowed to weathervane to align with prevailing currents. If the orientation of the dock is variable, then the orientation of the dock must be communicated to the vehicle.

Most funnel docks are either bottom-mounted (*McEwen* et al. [16.2]) or designed to be connected to a large platform of some sort [16.1, 18]. In the first case, the orientation of the dock can be fixed during

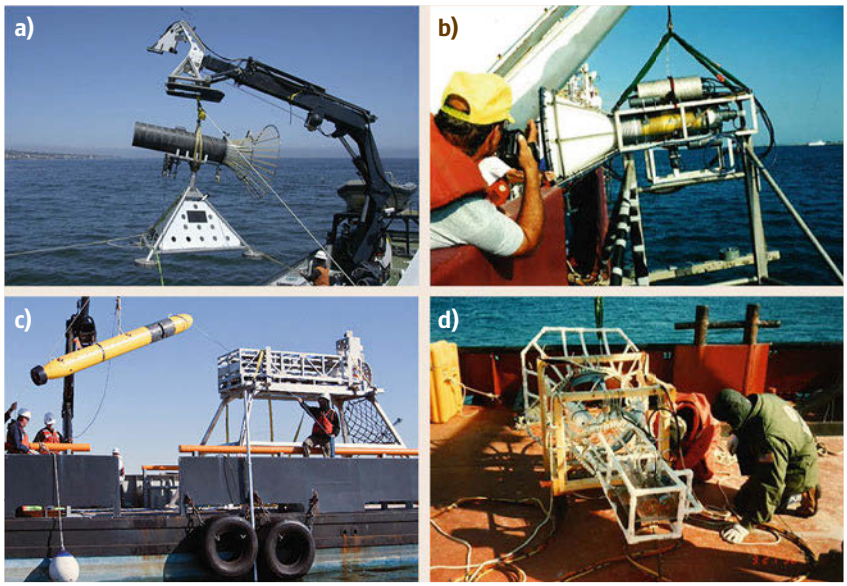

Fig. 16.4a–d Four cone-type docking stations. **(a)** Docking station depicted in Fig. 16.4 supporting the Dorado AUV docking (after [16.2]). The system is depicted as it was deployed on the MISO cabled observatory in Monterey Bay. **(b)** REMUS docking station described by *Stokey* et al. (after [16.8]). **(c)** A docking station built by Bluefin Robotics and Bettelle Memorial Foundation, in which a single cone can be aligned in front of a rectangular enclosure containing several vehicle garages (provided by Jeff Smith, Bluefin Robotics, reproduced with permission). Thus the system is unique in its ability to support multiple AUVs. **(d)** A docking system using a unique electromagnetic homing system, used with the Odyssey IIb AUVs, described in the text (after [16.6])

deployment. In the second case, the dock orientation is determined by the platform hosting the dock. Since almost all dock homing methodologies assume a constant or near constant depth approach, assuring the dock is level is an important consideration in design and deployment. For example, a bottom-mounted system might be placed on an uneven surface, causing the dock to be tilted. The Dorado dock [16.2] gimballed the dock on the support structure, using a large counterweight to hold the dock upright and level. Various funnel docks are depicted in Fig. 16.4.

16.4.2 Omnidirectional Docks: Poles

Pole docks are vertical structures, usually rigid poles or cables under tension, to which the vehicle attaches with some latching device. In effect, the vertical aperture of the dock is defined by the length of the docking segment of the pole, and the horizontal aperture is defined by the width of the capture mechanism on the AUV. The capture mechanism is often a fork on the nose of the AUV (Fig. 16.5) or tines which extend from the side of the vehicle that can capture the pole as the vehicle sweeps by. Pole docks are a solution when a dock must be integrated into a mooring. An early pole dock was developed and successfully demonstrated during the AOSN project [16.5].

A key feature of a pole dock is that an AUV can approach from any direction, eliminating the need to control the dock orientation in the horizontal plane or communicate the orientation to an AUV. This means, for example, that a vehicle can always approach into

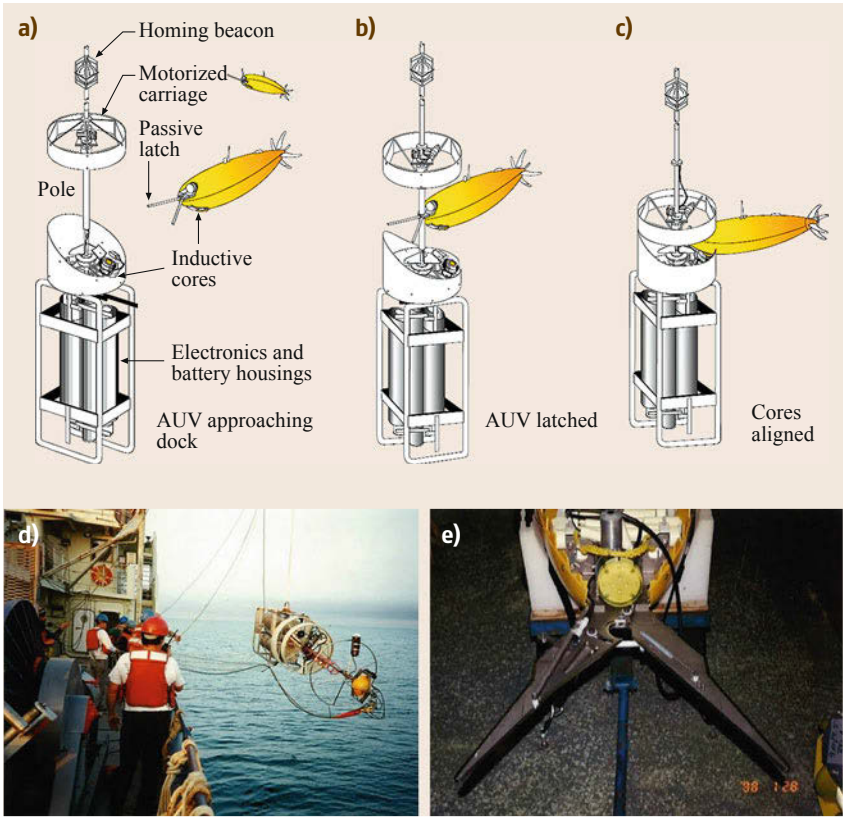

Fig. 16.5a–c This pole dock system (after [16.5]) was built to be an integral element of a deep-water mooring (after [16.1]) and used with an Odyssey IIb AUV. **(a–c)** The function of docking station is demonstrated, consisting of approach, capture, and engagement. The final step, where the vehicle is clamped by the motorized carriage, brings inductive cores on the AUV and the dock onto alignment, enabling both power and communication connectivity. This docking methodology has the advantage of allowing an approach from any horizontal direction (after *Singh* et al. [16.5]). **(d)** The docking station being deployed. **(e)** The front of the AUV, with the capture fork extending towards the photographer, and the ultrashort baseline homing array disk positioned just behind the above the docking fork. The top fairing of the vehicle is removed for the photo. Photos by the author J. Bellingham

the current, provided the vehicle can measure current direction. Pole docks can also support a larger vertical aperture fairly easily by simply making the docking segment of the pole long. This feature significantly simplifies homing in the vertical plane. However, pole docks have the disadvantage that the vehicle must carry some sort of mechanism for attaching itself to the pole, thus adding to vehicle size and weight, and possibly to drag.

Although omnidirectional in the horizontal plane, pole docks can be more complicated homing targets in the vertical plane, despite their large capture aperture. It is not simple to place a homing target like an acoustic beacon or a light source in the middle of a pole. Singh placed the homing beacon at the top of the docking pole. In such a configuration, the AUV must home on a location offset from the homing signal emitter. This complicates vertical plane homing, as a simple dead-ahead homing strategy does not work. Options include constraining vertical plane homing by pressure or altitude, or using a homing system that provides good off-axis navigation.

Ensuring a pole dock stays vertical can be difficult or impossible, depending on the structure hosting the dock. For example, if the pole is part of a mooring, then a current can introduce a tilt into the mooring and by extension to the dock. If the dock is not upright, the vertical offset between the pole and the homing target introduces a horizontal offset for approach directions perpendicular to the tilt. Further, a tilted dock can complicate engagement of the vehicle with the dock.

While pole docks simplify the AUV approach phase, they complicate making power and communications links between the dock and the vehicle. The ability of the vehicle to attach to the dock from any direction means that any communication or power connection to the dock must either be omnidirectional, or the vehicle and the dock must be aligned. In the case of the Woods Hole Oceanographic Institution (WHOI) dock, a mechanism nicknamed the *juicer* was used to clamp the vehicle into place and align the vehicle with the dock's communications and power transformer [16.5]. However, clamping the AUV to the pole also creates potential problems. The clamped AUV is potentially subject to rotating currents imposing a winding motion of the AUV around the mooring axis. One could allow the AUV to twist the entire mooring, or put some sort of electrical slip-ring somewhere between the mooring and the AUV, but such additions increase system complexity and compromise reliability.

16.4.3 Soft Docking Approaches

Soft docking methodologies use a low approach speed during the final approach, and thus require a vehicle equipped to be controllable at low and no speed. Motivations for soft docking include removing constraints on the nature of the docking structure, achieving greater control of alignment of the vehicle and dock during capture, and minimizing docking forces. For example, AUV servicing of subsea infrastructures may require that the vehicle attach itself to a subsea control panel [16.44] similar or identical to those designed for servicing by an ROV. Thus the AUV must be able to approach the panel in a similar manner to a ROV. Another motivation for soft docking is to allow simpler dock design. For example, some docking work has simply used a cradle on which the AUV *lands* [16.43].

Soft docking implies a vehicle with control over four or more degrees of freedom at zero and near zero speed. For example, ROVs can control surge, heave, sway, and yaw, but usually not roll or pitch. Thus, soft-docking AUVs are typically multi-thruster vehicles. Examples of vehicles used for soft docking work include the Australian Starfish and the SAAB Double Eagle SAROV in Fig. 16.2.

16.4.4 Other Docking Mechanisms

In the methods described above, the vehicle is the active element that achieves a mechanical connection between the vehicle and the dock. At most, the dock actuates mechanisms to engage to the vehicle after the initial connection has already been established. However, there is a class of approaches that involves the dock actively grappling the vehicle. Examples include a vehicle recovery scheme in which a towed vehicle homes and grapples with a free swimming AUV [16.45, 46]. An under-ice docking scheme [16.19, 47] involved a multi-step process whereby an AUV (the Explorer) autonomously homed to the vicinity of an ice-mounted dock and came to rest on the under-ice surface, where a small ROV attached lines used to pull the AUV into the dock.

Yet another approach is discussed by *Smith* and *Kronen* [16.37], who evaluated a tail-hook docking system suitable for bottom mounting and *full speed* approaches. The tail hook deployed by the AUV contained a puck at its end, which was captured by a slotted capture mechanism. The capture mechanism allowed entry of the puck from any of four directions. Like the cone and pole docks, the tail-hook concept in principle allows a vehicle to approach at full speed.

16.5 Coupling Power and Communications

As outlined previously, many docking scenarios are motivated by the desire to extend undersea deployment of an AUV. Initially such scenarios were oceanographically driven, however, as outlined in the introduction, commercial and military operational scenarios are incorporating docking as a way to extend deployment durations of AUVs. The need to recharge AUV batteries and to extract data and send new commands is common to almost every extended deployment scenario. Furthermore, when the dock is connected to the shore, the dock provides the physical portal through which an operator can interact with the vehicle. For example, docking tests of the Dorado AUV [16.2] used the Naval Postgraduate School (NPS) Monterey Inner Shelf Observatory (MISO) cabled observatory, allowing video monitoring of the docking and undocking process in real time from the shore. Once docked, the vehicle effectively became a part of the shore network, with all the advantages such connectivity brings.

Even when the dock is not connected to the network, there are strong motivations for enabling the vehicle to download data to the dock. In effect, the dock is usually the *safe* part of the system, so it is the logical location in which to save data. The alternative, in which the vehicle simply accumulates data, creates a situation where each successive operation of the vehicle puts at risk both the vehicle, and all previous data taken by the vehicle. At some point, the risks of operation will outweigh the potential benefit of additional data.

The ability to recharge an AUV's batteries at sea is a key feature of many docking systems. AUVs that carry power hungry payloads like mapping sonar are most often attended by a ship and recovered on a daily schedule for servicing. Recharging an AUV at a dock creates the opportunity to simultaneously support a power hungry payload and remain deployed for extended periods.

16.5.1 Establishing a Communications Link

Communication techniques that have been employed for connecting an AUV and a dock include optical, inductive, radio frequency, and direct electrical connection. Each of these technologies is driven by large commercial markets, and thus the technical foundation is constantly evolving. Factors influencing the choice of communication link include the amount of data that will be transferred; the nature of the engagement and capture mechanisms; the role of communications in the docking and undocking process; the characteristics of the dock environment; and the type of AUV being employed.

Bandwidth requirements for communication connectivity is largely driven by the intersection of data download and operational duty cycle needs. Communication between the AUV and the dock is employed for a variety of reasons, including:

- Downloading mission data from the vehicle to the dock
- Uploading mission scripts from the dock to the vehicle
- Commanding the vehicle to start a mission
- Modifying the vehicle software configuration.

Interacting with the vehicle to upload and start new missions and to modify vehicle software can be accomplished over comparatively low bandwidth connections. In contrast, high bandwidth sensors like multibeam sonar and sidescan sonar generate on the order of 300 kb/s. So if the vehicle can download data at 1 Mb/s, the vehicle must spend roughly 1 h downloading data for every 3 h of mission. Camera systems can generate even more data. Consequently, high-bandwidth connection between the vehicle and the dock can be critical if rapid turn-around of the vehicle between missions is important.

Optical communications was used by the Flying Plug docking system [16.36], inductive coupling by the Odyssey IIb [16.48], radio frequency communications by the Dorado [16.2], and direct electrical connection by the REMUS [16.8]. The advantage of both optical and inductive communications is that no electrical connection need be exposed to seawater or mated via an underwater connector. The advantage of the direct electrical system is that it is relatively simple and uses off-the-shelf hardware and software. The radio frequency (RF) communication system used by the Dorado employed off-the-shelf 802.11 hardware and provided 10 Mb/s communications through seawater at separations up to 6.25 cm.

The RF-based communication link used by the Dorado offered the particular attraction that the dock and the vehicle established a communication link while the vehicle was not yet fully docked. When the dock is cabled to shore, as in the Dorado tests that occurred at the MISO cabled observatory [16.49], the potential exists for human intervention in the docking process. For example, the Dorado tests could be monitored by a video camera on the dock, and when the dock established a communication link with the vehicle, that communication link by extension allowed operator interaction with the vehicle. With the appropriate interface to the vehicle, this allows the operator to take control of the vehicle and manually control docking should the need arise.

16.5.2 Power Transfer

The primary objective of many docking scenarios is to extend AUV deployment times by recharging AUV batteries. Consequently the ability to transfer power through the dock to the AUV is a key feature of many docks. Being able to recharge batteries quickly allows a higher operational tempo of the AUV, and thus the power capacity of the dock is a critical characteristic. The total energy capacity of a smaller AUV might be only a few kilowatt-hours, while larger 21″ diameter AUVs might have battery packs with capacities on the order of 10 kilowatt-hours or more. Other considerations include reliability, alignment, mating force, complexity, power capacity, efficiency, size and weight.

There are a number of ways to establish a power connection between the vehicle and the dock. These include underwater mateable electrical connectors, inductive electrical coupling, transfer of material, or mechanical coupling. Docking systems to date use the first two approaches, direct electrical connection or inductive coupling. In principle, transfer of material might include physically swapping batteries or fueling chemical reactants. These might be attractive for faster recharge of a vehicle, but have not been implemented. Mechanical coupling might be as simple as letting the vehicle's propeller windmill in a current, and using the resulting power generated by the spinning propulsion motor to charge the battery. No mechanical power transfer methods have been reported in the literature.

Wet mateable electrical connections are conceptually simple, but require careful alignment, significant mating forces, and can have a limited lifetime. A survey of six wet mateable connectors [16.50] reports mating forces ranging from approximately 7–55 N per circuit. Most connectors were rated for 100 mate cycles, with two commercial connectors claiming greater than a thousand cycles. A unique wet mateable connector described by *Stokey* et al. [16.8] takes advantage of the fact that only two connections are required. The connector establishes a two-contact electrical connection between the vehicle and the dock, but only insulates one of those connections from seawater. Electrical isolation of the power system from the vehicle hull prevents anodic dissolution of the hull.

Inductive power transfer systems have the advantage of no exposed electrical contacts and can be designed to be less sensitive to alignment, and have low mating force. Reliability is typically limited by the lifetime of the electronics associated with the inductive process, rather than the number of mate/demate cycles. Power capacity and size and weight are related, as efficient high power transfer requires a larger inductor, and the high-permeability materials that make high efficiency power coupling possible are quite dense. Systems developed by *Feezor* et al. [16.48] and *Granger* et al. [16.51] used inductive coupling for both communication and power transfer. The Florida Atlantic University (FAU) inductive power system developed by *Coulson* et al. [16.52] was used for the Dorado docking system.

Autonomous recharging requires a sophisticated battery management system that can maximize energy stored in the batteries while simultaneously minimizing battery failures [16.53]. Examples of battery failures include the destruction of the advanced swimmer delivery system by a battery fire. Lithium-ion battery fires on the Boeing 787 grounded that aircraft's commercial operations for months. In the undersea environment, where batteries might be in a pressure vessel, a battery fire is a catastrophic event.

16.6 AUV Control Considerations

In most AUV control systems, AUV control is segregated by the level of abstraction. At the lowest level, dynamic control systems command actuators to achieve desired orientation, speed, and position. At a higher level, algorithms attempt to accomplish a particular task by commanding the dynamic control system. Above the task level, software monitors the state of tasks, and manages sequencing of activities. While a variety of software architectures are used on operational AUVs, most conform to some semblance of this hierarchy. In principle, even more capable systems might include yet another level that could create plans to achieve user defined goals, and replan when circumstances change; however, in practice this level of autonomy has not been used in docking AUVs thus far.

16.6.1 Navigation, Currents, and Arriving at the Dock

Control algorithms for bringing an AUV to a dock have diverse levels of sophistication, depending on the demands of the docking process. Perhaps the simplest are *pure pursuit* algorithms, which simply point the vehicle directly at the homing target. These are appropriate for docking systems that can be ap-

proached from any direction, like pole docks. Slightly more sophisticated homing control is required when the dock must be approached from a particular direction, as is the case for a funnel-type dock. Control becomes more demanding for the directional approach when there is a significant cross-current. Even more complex homing is required in circumstances where there are obstacles, and soft docking is required.

Pure pursuit, in which the vehicle always points directly at the dock, is the simplest homing method. In the event of a cross-current, pure pursuit results in a hooked trajectory, in which the vehicle is *blown* to one side of the dock. This can result in the vehicle missing the dock, and also means that the final approach direction depends on the speed and direction of the current. This makes pure pursuit unattractive for docking systems that require the direction of approach to be controlled. A variation on pure pursuit is to estimate the current and use the current estimate to compute a heading correction that cancels the cross-current component (the current orthogonal to the direction to the dock). *Wu* et al. [16.54] described simulations of docking approaches in currents. This removes the *hook* from the approach trajectory. Two-phase approaches are possible as well, for example, using an initial line of sight approach and converting to controlled orientation in the terminal phase, as simulated by *Jantapremjit* and *Wilson* [16.55]. A fuzzy-behavioral approach was proposed by *Smith* et al. [16.56] and *White* et al. [16.57] that drove the vehicle towards a virtual funnel to arrive at a docking station.

The ability to measure the current environment in the vicinity of the dock can substantially improve docking skills. An AUV equipped with a Doppler velocity log will be able to measure current by computing the difference of dead reckoned speed and measured speed over bottom. For example, *Yakimenko* et al. [16.58] describe a trajectory generation approach that can incorporate currents in planning the approach to the dock. Docking methods that are omnidirectional in nature, like the pole dock, can use knowledge of the current to approach into the current so as to minimize cross-current and reduce approach speed. If the current cannot be measured directly by the AUV, an alternative approach is for the dock to be free to rotate and align with the current. If the AUV can sense or interrogate the dock orientation, the near-field docking trajectory will always be directly up-current, avoiding the necessity for a crab angle of approach to compensate for a cross-current. While this necessitates a method to communicate the dock orientation to the vehicle, some homing techniques like the electromagnetic homing method described by *Feezor* et al. [16.6] carry the information with the homing signal.

16.6.2 Managing State: AUV Control

From a control perspective, docking of the AUV can be understood as a sequence of tasks that culminate with the vehicle connected to and secured by the dock. Each of these tasks has specific sensing and control challenges, and in some cases actions by the vehicle must be coordinated with actions by the dock. Overall management of the process involves sequencing between tasks, possibly communicating with the dock, detecting failures, and invoking contingency activities when a failure occurs. To achieve the individual tasks, and to sequence between tasks, many operational systems employ some variant of behavior-based control [16.59, 60].

The building blocks of behavior-based control are the individual *behaviors*, which are control laws that can be combined to accomplish tasks, which in turn can be conditionally connected to achieve more complex missions or respond to contingencies. *Bellingham* and *Leonard* [16.59] describe a behavior-based architecture, illustrating an implementation of homing as used for under-ice homing and recovery. Docking work reported by *McEwen* et al. [16.2], *Feezor* et al. [16.6], and *Singh* et al. [16.5] employed the same behavior-based architecture. Successful docking depends on the vehicle carrying out a sequence of activities such as setting up for the approach, making an approach, and perhaps activating actuators upon contacting the dock to secure itself and make connections for communications and power. Figure 16.6 illustrates the state transition table for an AUV for both docking and undocking, as adapted from McEwen.

16.6.3 Managing State: Coordinating AUV and Dock

Docking involves the coordination of two distinct entities, the dock and the AUV. Consequently, successful control strategies for docking must address both platforms and contend with the reality that communications between undersea systems are unreliable. Some docking designs require significant interaction between the dock and the AUV, and consequently each platform must be aware of the state of the other system in order to execute the appropriate action. Docking systems that demand coordinated activities on the part of both the vehicle and the dock introduce failure modes associated with the communication and coordination process. Consequently, contingencies for failures must encompass the entire system.

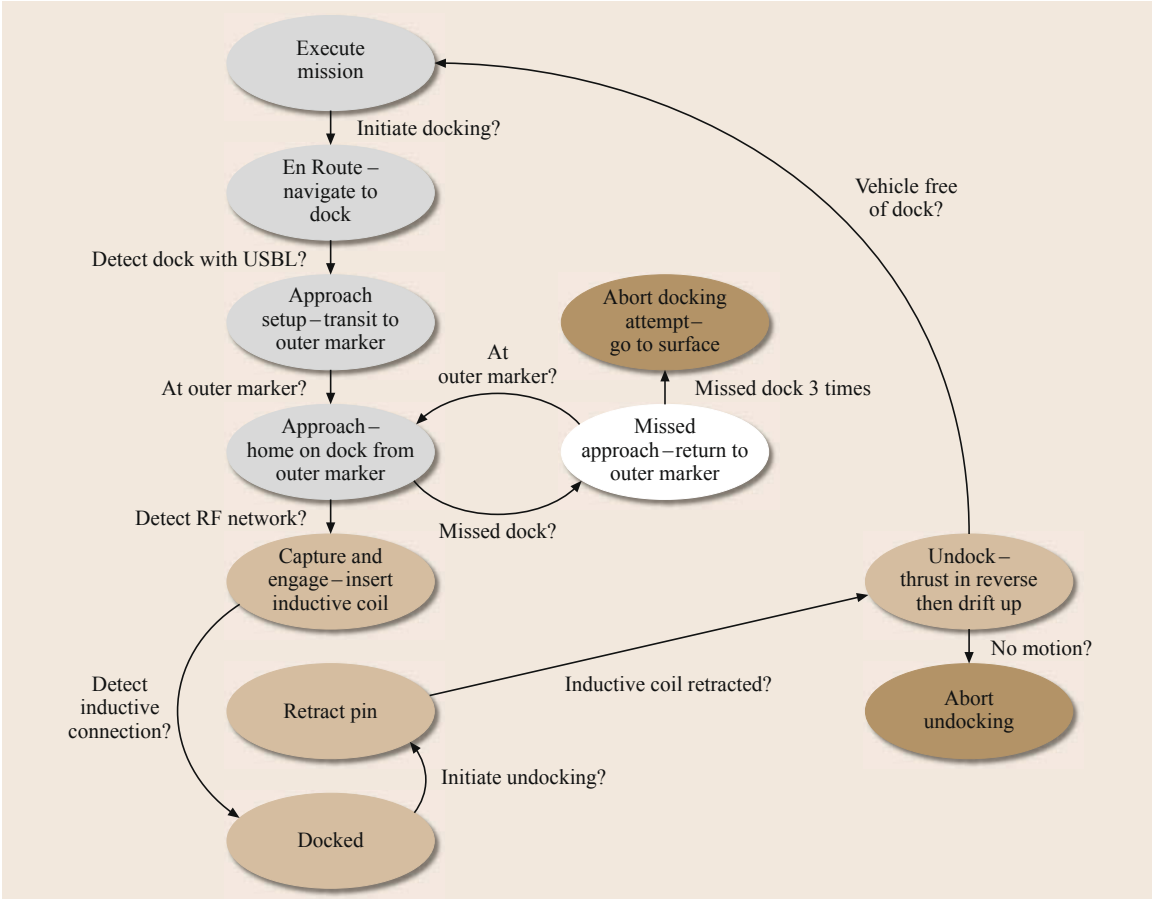

Fig. 16.6 State diagram for docking, undocking, and handling more common failures, derived from *McEwen* (after [16.2]). Starting from the *top* is the sequence whereby the AUV progressively navigates to a position in front of the dock (the *outer marker*) and docks with the dock. If the vehicle misses the dock in its final approach, a missed approach procedure is executed, which repositions the vehicle for another approach from the outer marker. Missing from this diagram is the dock logic, which must recognize that the vehicle is captured in the dock so that it can insert the inductive power pin into the vehicle. Logic for undocking the vehicle is also shown

Examples of AUV-dock interactions that must be managed during the docking process include the following:

- The pole dock (Fig. 16.5) described by *Singh* et al. [16.5] uses a carriage (the *juicer*) to clamp the vehicle in place after the vehicle has attached itself to the pole. Should the clamps activate without an attached vehicle, the dock effectively closes itself to the vehicle, precluding docking.
- The funnel dock described by *Stokey* et al. [16.8] guides the AUV to a cylindrical chamber, in which the vehicle is clamped for electrical connection.
- *McEwen* et al. [16.2] also described a funnel dock that guides the vehicle to a cylindrical chamber. In this system, the dock drives an inductor into the side of the AUV, pinning the vehicle in place and engaging the inductive power transfer system.

In the systems above, the dock must take certain actions at the right time. If the dock attempts to engage the vehicle too soon, they make it impossible for docking to succeed. For example, if the pole dock attempts to clamp the vehicle, it effectively blocks the docking pole, preventing the vehicle from attaching. Although the undocking process has not been discussed much, it should be clear that extracting the vehicle from the dock requires that the dock and the AUV proceed in synchrony as well.

Operator control of elements of the docking process is possible under some circumstances, as described earlier. For example, docks attached to a cabled ob-

servatory are likely to have a very high bandwidth connection with the shore. This provides the potential for operator monitoring and control of dock, and to the extent that the vehicle is in communication, monitoring and control of the vehicle as well.

16.6.4 Detecting and Recovering from Failures

Failures are inevitable with autonomous systems, particularly when deployed for extended periods in a hostile and unpredictable environment. The robustness of a system is thus a function of both its inherent ability to avoid failures and its ability to recover from failures when they do occur. Typically the first is achieved through overdesign, which is expensive, and the second remains a research topic. For most complex engineered systems in use today, robustness is achieved largely through experience; by having processes in place to learn from failures and to implement the lessons learned. The few docking systems that have been tested in the ocean, have been in use only briefly. Consequently, it seems likely that only the most common failure modes have been experienced.

The large number of discrete control functions involved with docking, and the sensitivity of many of these activities to environmental conditions or disturbances, makes failures difficult to predict. Consequently, the overall docking process must be robust to failure of individual steps. For example, a missed approach, where the vehicle attempts to home on the dock but misses, is a particular class of failure that is likely to occur many times. This might be caused by currents, poor sensing conditions, turbulence, or anomalies in vehicle performance. The appropriate response for the AUV may be quite different, depending on the root cause of the missed approach. This leads to both a classification problem and a contingency management problem. It is not enough to know that an approach has failed, because the reason for failure is important as well. However, to the degree that contingency responses are created for different failure modes, mission management becomes more complex. In effect, each contingency response creates the potential for unintended consequences that must be anticipated and mitigated. At present there is no good way to do this.

Handling of some simple failure modes is discussed by both *Singh* et al. [16.5] and *McEwen* et al. [16.2]. The state transition diagram in Fig. 16.6 describes the vehicle response to some simple failures. For example, the missed dock transition leads to a state of which the goal is repositioning the vehicle for another approach. If the vehicle misses the approach three times, it aborts the docking attempt and goes to the surface.

16.7 Conclusions and Future Prospects

Of the activities attempted with AUVs, docking is among the most challenging. The literature reflects this difficulty, with most papers testing some element of docking, and only a few reporting results from a deployed system in the ocean. Most tests focus on homing. Those that deploy and exercise a full docking suite, including battery recharge, data dump, and initiation of new vehicle missions, report results for comparatively brief deployments. Consequently, one must conclude that docking has not made the transition from demonstration to operations. This prompts the questions: why has docking not become an operational capability, and what are the conditions that might allow this event to occur?

In the early 1990s, when the AOSN paper first proposed AUV docking as an integral part of an ocean observing system, little attention was given the infrastructure required to support and power a docking system. However, docking does imply the existence of an infrastructure. For example, if the objective is to support ten AUV full missions from the dock, then the dock must be able to supply power levels equal to ten times the battery capability of the vehicle (assuming the vehicle missions uses the full battery capacity each mission). Early attempts to use docking to support field programs thus had to invest in their own infrastructure, such as moorings with satellite communications and large quantities of batteries [16.1]. This created a significant barrier to the adoption of AUV docking. Not only does a team have to master the most difficult aspect of AUV operations, it must also be capable of building from scratch the dock and the infrastructure supporting the dock.

The deployment of cabled observatories, which adapt subsea telecommunications technology to provide high bandwidth, low-latency communications and high power to nodes in the ocean interior, provide an ideal infrastructure to support docked AUVs. Early scientific cabled observatories include a system deployed off Japan in the late 1970s [16.61] and the LEO-15 system, installed a few kilometers off the coast of New Jersey in the 1990s [16.62]. Since then, a wide number of cabled systems have been installed, supporting *plug and play* instruments on the deep seafloor

connected by many hundreds of kilometers of cable to the internet [16.63, 64]. While one of the more ambitious cabled observatories efforts is funded in the United States (Ocean Observatories Initiative (OOI)), a number of countries are developing and operating cabled observatories [16.65]. It should be noted that AUVs provide a useful complement to cabled systems, the former being mobile and capable of deploying instruments to locations of interest, the latter being fixed in location.

AUV reliability is also an important factor driving adoption. Most AUV operations today are attended by a ship, or at least have ships in the vicinity. Should there be problems, the vehicle can ascend to the surface, where it can be recovered and serviced. A docked AUV is most likely far from rescue and must carry out a particularly complex sequence of activities for every mission. Consequently, operating a docked AUV entails some risk. While one might argue that the risk associated with docking is a necessary part of the docking development process, the ability of the vehicle to successfully complete repeated missions without human servicing is demanding. While buoyancy driven systems are routinely deployed for months at a time, propeller-driven AUVs are typically deployed on the order of a day. However, the advent of a class of very long endurance AUVs, operating up to 3 weeks at a time per deployment [16.26, 66] offers encouragement that AUV reliability can support extended dock deployments.

A final factor moderating docking adoption stems from the comparatively high cost of scientifically equipped AUVs. In effect, there is an opportunity cost associated with committing an AUV to a docked deployment. The owner of the AUV has the choice of keeping the AUV close at hand, or deploying a vehicle at a remote dock at sea. While the sea-deployed system is positioned to respond rapidly to opportunities in the vicinity of the dock, it is effectively unavailable for operations that are beyond operational range of the vehicle from the dock. When the AUV must support a variety of scientific goals, this creates an inherent conflict between users, which is simplest to handle by keeping the vehicle on shore where it is equally available to all potential users. This calculus breaks down, however, when the dock location is remote and unique. For example, science associated with a docked system in winter in the Arctic Ocean removes the AUV from ready access, but also places the vehicle in a location where it is uniquely capable of making observations, as the Arctic Ocean is all but inaccessible during winter. It is worth noting that such remote deployments place a high premium on autonomy, including adaptive capability such as event detection capabilities for triggering AUV missions.

In summary, while AUV docking has been experimented with since the 1990s, only recently has the needed combination of supporting infrastructure, vehicle reliability, and operational need emerged for docking to transition to an operational capability. In the science domain, the emergence of cabled and mooring-based observatories provides a framework that can both support and benefit from docked AUVs. In the commercial domain, the rising interest in inspection, repair, and maintenance (IRM) capabilities for offshore structures offers an application domain where the problems associated with infrastructure and the risk-reward calculation are tipping in favor of resident vehicles. The drivers for adoption of docking capability are growing, encouraging hope that docking will become an operational capability supporting a more permanent presence of mobile platforms in the ocean.

17. Underwater Vehicle Manipulators

Tae Won Kim, Giacomo Marani, Junku Yuh

This chapter covers current commercial developments and major research activities for underwater vehicle-manipulator systems. It briefly describes the dynamics of underwater vehicle-manipulator systems to show the level of its complexity. The teleoperation of the underwater vehicle-manipulator system and sensor-based underwater vehicle manipulator controls, such as force control and visual servoing are discussed. Furthermore, it describes coordinated motion controls of underwater vehicle and manipulator systems and presents the results of recent developments in autonomous manipulation for autonomous underwater vehicles.

17.1 Underwater Vehicles for Intervention Missions

As about 70% of our planet is covered with water, the importance of the ocean cannot be overemphasized. A great deal of effort has been put into acquiring living and nonliving resources in the ocean. Most marine activities have worked on the ocean surface or shallow water, and deep-sea research activities have been limited due to economic and technological reasons. However, recent advancements in deep-sea technologies such as unmanned underwater vehicles (UUVs), have made it more feasible to exploit deep-sea resources, such as mining for seabed minerals, collecting marine organisms for pharmaceutical applications, and extracting oil and gas. There are basically two types of UUVs: remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs) [17.1–3]. While many of them are just fly-by-type vehicles for survey and monitoring, some of them are equipped with manipulators for intervention missions. While there have been some recent developments and breakthroughs in underwater manipulator technologies for AUVs (so called *autonomous manipulation*), most commercial UUVs with manipulators are ROVs. A typical work-class ROV for intervention missions has a 7 degrees-of-freedom (DOF) manipulator and a 5 DOF grabber. The manipulator is used for interactive manipulation by a human operator on the supporting ship, whereas the grabber is used to maintain a relative position of ROV to the target object by grabbing a target structure in the presence of an underwater current or wave. Most heavy-duty underwater manipulators are designed for ROVs and are actuated by hydraulic drivers. They are also designed for teleoperation rather than autonomous manipulation. Table 17.1 lists samples of heavy duty underwater manipulators currently available in the market.

A typical work-class ROV for intervention missions requires two individual operators: one steering the vehi-

cle and the other operating the manipulator. One of the main tasks of the vehicle operator is to keep the ROV as steady as possible (station-keeping) since the manipulator is attached to the vehicle, and the vehicle motion can disturb the manipulator and greatly affects the accuracy of its end-effector interacting with the environment. The accuracy of the end-effector would be greatly improved if the manipulator controller could compensate for any disturbance due to the motion of the vehicle. However, most commercial ROV systems do not use vehicle motion compensation control for the manipulator that is directly teleoperated by a human operator. Due to the increase in demand for more dexterous and precise underwater manipulation, many researchers have performed advanced studies for dynamics and control of underwater vehicle manipulators. Considering the vehicle and the attached manipulator as one multibody system, several researchers have studied coordinated motion control of the vehicle-manipulator system to improve the accuracy of the end-effector. The coordinated motion control automatically compensates for any disturbance due to the motion of the vehicle and also takes advantage of the redundancy of the overall vehicle-manipulator system. Many underwater tasks require the position accuracy of the end-effector of the order of a centimeter or subcentimeter, whereas most sensors for the vehicle position have accuracy of the order of a meter. Therefore, in order to effectively implement the coordinated motion control in practice especially in autonomous mode, the sensor accuracy of the vehicle position must be improved. In the past, very few AUV systems for intervention missions have been reported and most of them were used as a testbed for developing autonomous manipulation or as a working model for research.

17.2 Dynamics of Underwater Vehicle Manipulators

The analysis of the dynamics of underwater vehicle manipulators is much more complex than that of regular manipulators on the factory floor. For example, it is difficult to accurately introduce the effects of the added mass and the added moment of inertia in the modeling process for multiple links of the manipulator. The frictional force and the drag force due to the velocity of the manipulator itself, waves, and currents are also complex in modeling. The modeling and control of underwater manipulators were studied by several researchers, including *Kato* and *Lane* [17.9], *Dunningan* et al. [17.10], *Levesque* and *Richard* [17.11], *Mahesh* et al. [17.12], *McMillan* et al. [17.13], *McLain* et al. [17.14], *Tarn* et al. [17.15], *Ioi* and *Itoh* [17.16], *Schjølberg* and *Fossen* [17.17], *Leabourne* and *Rock* [17.18], *Lee* and *Choi* [17.19], and *Ryu* et al. [17.20]. In this section, it is not our intention to derive details of the full dynamic equations of the underwater vehicle manipulators. Instead, we would like to point out several specific elements that differentiate underwater vehicle manipulators from regular manipulators.

The hydrodynamic forces acting on a rigid body moving in fluid can be found in *Patel* [17.21] and *Troesch* and *Kim* [17.22]. Similar to the vehicle main body, each link of the manipulator will be influenced by hydrodynamic forces including added mass, buoyancy acting at the center of buoyancy (COB) of the link, the fluid acceleration force resulting from the acceleration of the fluid itself, and the fluid drag forces exerted on the link.

As the profile drag forces are dominant for slowly moving objects, the drag force exerting on an infinitesimal element of the ith link and the total drag force on the link can be expressed as

$$\mathrm{d}D_{fi} = \frac{1}{2}\rho C_{\mathrm{D}} b_i v_{r_i} |v_{r_i}| \mathrm{d}x \,, \tag{17.1}$$

$$D_{fi} = \frac{1}{2}\rho \int_0^l C_{\mathrm{D}} b_i v_{r_i} |v_{r_i}| \mathrm{d}x \,, \tag{17.2}$$

where C_{D} is the drag coefficient, ρ is the fluid density, v_{r_i} is the relative velocity of the element to the fluid flow velocity, $b_i \mathrm{d}x$ is a projected area of the element, and l is the link length.

Considering the effects of the hydrodynamic variables above and assuming that the vehicle is stationary during the manipulation, the dynamic model of an underwater manipulator having a series of links and joints can be represented by the following equations

$$\begin{aligned}\mathbf{M}_m(\boldsymbol{q})\ddot{\boldsymbol{q}} + \boldsymbol{C}_m(\boldsymbol{q},\dot{\boldsymbol{q}}) + \boldsymbol{D}_m(\boldsymbol{q},\dot{\boldsymbol{q}}) + \boldsymbol{F}_m(\dot{\boldsymbol{q}}) \\ + \boldsymbol{G}_m(\boldsymbol{q}) + \boldsymbol{\tau}_d = \boldsymbol{\tau}_m \,,\end{aligned} \tag{17.3}$$

where $q \in \boldsymbol{R}^{n\times 1}$ is a joint angle vector, $\boldsymbol{\tau}_m \in \boldsymbol{R}^{n\times 1}$ is a joint torque vector, $\mathbf{M}_{\boldsymbol{m}}(\boldsymbol{q}) \in \boldsymbol{R}^{n\times n}$ an inertia matrix including added mass terms, $\boldsymbol{C}_{\boldsymbol{m}}(\boldsymbol{q},\dot{\boldsymbol{q}}) \in \boldsymbol{R}^{n\times 1}$ is a nonlinear vector arising from centrifugal and Coriolis effects including added mass terms, $\boldsymbol{D}_{\boldsymbol{m}}(\boldsymbol{q},\dot{\boldsymbol{q}}) \in \boldsymbol{R}^{n\times 1}$ is a nonlinear vector due to hydrodynamic forces such as drag forces, $\boldsymbol{F}_{\boldsymbol{m}}(\dot{\boldsymbol{q}}) \in \boldsymbol{R}^{n\times 1}$ is a nonlinear vector due to friction at the manipulator joints, $\boldsymbol{G}_m(\boldsymbol{q}) \in \boldsymbol{R}^{n\times 1}$ is a nonlinear vector due to gravity and buoyancy forces, and $\boldsymbol{\tau}_d \in \boldsymbol{R}^{n\times 1}$ is a vector of unknown signals due to unmodeled dynamics or external disturbances such as current.

During the manipulation, the end-effector or tool of the manipulator could be in contact with the environment, and forces and moments would occur at the end-effector. In this situation, (17.3) must be modified by adding the reaction torque to the end-effector force on the right side of (17.2).

$$\boldsymbol{\tau}_r = \mathbf{J}_m^T(\boldsymbol{q}) f_e \,, \tag{17.4}$$

where is $\mathbf{J}_m \in \boldsymbol{R}^{6\times n}$ the manipulator Jacobian matrix, $\boldsymbol{f}_e \in \boldsymbol{R}^{6\times 1}$ a vector of forces and torques at the end-effector.

The dynamics of the underwater vehicle manipulator is quite complicated as shown in (17.2), highly nonlinear, and involves coupled equations with unknown parameters and disturbances. It is almost impossible to accurately model the dynamic equations and to operate the manipulator at a nominal speed using a conventional controller. However, when the manipulator moves very slowly in the friendly environment of no or minimal current or wave, the dynamics of the manipulator could be represented by the simplified linear version of (17.3) since the effect of velocity-dependent terms in (17.3) becomes negligible. In fact, during the actual operation in the field, most commercial underwater manipulators move very slowly (much less than 1 rad s^{-1}) for safety and other reasons, and they use conventional joint controllers for the master–slave teleoperation.

17.3 Teleoperation of Underwater Vehicle Manipulators

A typical setup for teleoperation involves the operator sitting in the control room located on the mother ship and holding a master arm that is a miniature of the actual underwater vehicle manipulator (slave arm) attached to the ROV. The operator controls the slave arm by moving the master arm whose motion is followed by the slave arm. During the operation, the operator relies on the visual information of the work site in the form of a series of 2-D video images that are captured by cameras on the vehicle's main body and the slave arm and then transmitted to the control room monitors by an underwater cable. Not only the view of the work site is limited but also the visual information especially for the deep-sea operation is often delayed. If the vehicle is not holding or sitting on an underwater structure, the ROV operator must try to control the vehicle for station-keeping during the manipulation. However, even if there is no current or wave during the station-keeping, the vehicle moves like free-floating within the accuracy of the vehicle position sensors in the order of a meter or so. Therefore, it is difficult to achieve the accuracy at the end-effector since underwater vehicle manipulators are attached to the vehicles that are constantly moving, unlike industrial manipulators whose bases are fixed on the factory floor. As *Hildebrandt* et al. [17.23] state, many simple tasks on the ground such as plugging become very difficult to perform by the underwater vehicle manipulator. Underwater plugging tasks, done on a trial-error basis since the required precision could not be achieved by the ROV manipulator system, take hours to complete. Therefore, operator fatigue often becomes a critical issue in teleoperating the underwater vehicle manipulator.

Several researchers have addressed the issues mentioned above and have improved the accuracy of the manipulator in teleoperation. Among them include *Sayers* et al. [17.24], *LaPierre* et al. [17.25], *Zhang* et al. [17.26], *Bowen* et al. [17.27], *Hildebrandt* et al. [17.23], *Hildebrandt* et al. [17.28], and *Shim* et al. [17.29]. *Zhang* et al. [17.26] developed a virtual model-based teleoperating system and experimentally showed a good performance of moving target tracking with up to a two second time delay. They used on-line parameter estimation and showed that the manipulator could be continuously controlled with a low bandwidth network. *Hildebrandt* et al. [17.23] implemented precise manipulator position control by compensating for errors due to the ROV movement. The overall scheme was divided into:

1. Prediction of vehicle movement
2. Calculation of manipulator compensation movement
3. Compensating motion with the manipulator.

The prediction of vehicle movement relied on a position sensor in the vehicle and a mathematical model of the vehicle. The manipulator compensation movement was calculated by the difference between the current position and the predicted position. The compensation position in the Cartesian space was then transformed into a joint space position to be given to the manipulator. They showed that the ROV movement compensation algorithm considerably increased the position accuracy of the end-effector of the commercial hydraulic underwater manipulator, Schilling Orion 7P (Fig. 17.1). Notably, *Hildebrandt* et al. [17.28] and *Shim* et al. [17.29] have developed additional computer control systems to the top of a commercial underwater vehicle manipulator system, Schilling's Orion

Fig. 17.1 Schilling's Orion 7P (courtesy of FMC technologies schilling robotics)

7P, and presented experimental results. *Hildebrandt* et al. [17.28] added two new controllers (a second position controller and an adaptive speed controller) to the top of Orion's position controller to improve the joint position accuracy at the level of less than 1° without changing the original hardware or the respective hardware-near software/firmware. The second position controller has the desired subdegree precision and the adaptive speed controller makes it possible to have very slow but precise movements. Experiments were conducted for the plugging of a Gisma Series 80 connector. The plugging procedure consists of three steps: the manipulator's end-effector with the plug is positioned in front of the receptacle within an accuracy of 1 mm and 1°; the plug is precisely aligned with the receptacle until the top of both parts touch; and then the plugging process is completed by having a linear movement of 100 mm. Results show that their control approach can improve accuracy and plugging was successfully done in 50% of all trials. *Shim* et al. [17.29] developed a new master system that allows the operator to control the slave arm in workspace. Instead of using the master arm, a joystick is used for a velocity input of the end-effector in workspace and the new master system's computer computes the desired joint angles by solving forward and inverse kinematics of the slave arm for the desired velocity of the end-effector. The computed desired joint angles are then sent to the slave arm controller. The master system also offers a graphic model of the slave arm, which follows its actual motion based on the joint signals. In addition to the limited video images of the slave arm at the work site, this graphic model view of the slave arm's motion helps the operator.

It is worthwhile to note the Woods Hole Oceanographic Institute (WHOI)'s Hybrid-ROV, also known as Nereus [17.27], which operates in two different modes. For broad area survey, the vehicle can operate untethered as an autonomous underwater vehicle capable of exploring and mapping the sea floor with sonars and cameras. For close-up imaging and sampling, Nereus can be converted to operates at sea as a tethered ROV, using a lightweight, micro-thin, fiber-optic tether. Nereus uses its manipulator by teleoperation via the fiber-optic tether while the vehicle could be considered an AUV. In May 2009, Nereus explored the Mariana Trench, being the first vehicle to explore the Mariana Trench since 1998.

17.4 Sensor-Based Manipulator Control

Various sensors are used for manipulator control. Among them, force and vision sensors are discussed in this section. They are widely used for manipulator control in terrestrial or space environments [17.30–33]. As demand on the high performance of the underwater manipulation is increased especially for applications in deeper water like subsea oil/gas industry, archaeological or scientific studies, force and visual-based manipulator control received more attention. However, their use for underwater manipulator control has been limited due to environmental conditions. The performance of a force sensor would be influenced by the change of the operating depth, whereas the performance of an optical vision sensor would be dependent on the turbidity of the water. In this section, the current use of force and visual feedback for underwater manipulator control is briefly reviewed and the future direction toward autonomous manipulation is discussed.

Force feedback contains information about contact force between a manipulator's end-effector and an underwater environment. This information helps an underwater robot or operator determine how much power is needed to perform a given task such as handling a fragile object. A few force control methods that have been implemented to control underwater manipulators (are/include) bilateral force feedback [17.6], back-electromotive force (EMF)-based motor force feedback [17.34], and direct force control with underwater force–torque (FT) sensor [17.35].

The bilateral force feedback control has been developed for master–slave teleoperation [17.30, 36, 37]. Its

basic concept is to keep the joint angles of both master and slave arms the same so that the operator feels the contact force from any changes in (master/slave) arm positions. To achieve a 1 : 1 direct mapping of both arms' angular positions, a motor-driven active master arm is needed for duplicating the slave arm's position. Kraft Telerobotics [17.6] has commercialized a bilateral force control-based deep-sea underwater manipulator for ROVs such as WHOI's Hybrid ROV Nereus.

Back-EMF feedback is another way of (measuring/assessing/mapping) the force on the underwater manipulator [17.34]. It uses back-EMF voltage of electric motor in the manipulator to calculate reaction force. Since the back-EMF voltage is proportional to the motor speed and has relatively low noise [17.38], it can be used to measure the motor speed and position without a direct sensor. An obstruction of the robotic arm or an object inside the gripper could be detected by calculating a feedback force on each motor from the command voltage and back-EMF voltage. This method can be implemented only on electric motor-driven manipulators. *Kerdels* et al. [17.34] showed the performance of the back-EMF-based force control of the gripper by grabbing a light bulb with a 3 DOF Sub-Atlantic 123 DC-manipulator (rated for a depth of 300 m).

An FT sensor-based force control scheme for autonomous underwater manipulation was developed by *Marani* et al. [17.35]. Actual contact forces and torques on the manipulator are directly measured by the underwater FT sensor and used to control the manipulator. However, as mentioned above, accuracy and precision of most FT sensors in the market are heavily influenced by the operating pressure. Developing FT sensors for deepwater applications would be useful.

Visual feedback control schemes use a noncontact sensor like a low-light charge-coupled device (CCD) camera. However, the performance of visual feedback control depends on environmental conditions such as light and visibility. One good example of using a vision sensor for robot manipulator control is visual servoing. It has been used to control a robot manipulator with visual information, mostly with relative pose (position and orientation) between a camera and an object in a hostile environment [17.32, 33, 39–42]. With the visual servoing concept, the target object can be kept within the camera field of view (FOV), so that a manipulator maintains its relative pose with respect to a static or moving object.

It is well known that visual servoing has two types of control methods: position-based and image-based ones [17.43]. The position-based visual servoing is used to calculate the relative pose of an object with respect to the camera, which is used to control the manipulator. In this method, the camera calibration is very critical to get accurate relative pose. The image-based method uses image features such as size or orientation of the object in the camera space to calculate control commands making the current features match desired ones that were precalculated. While it is free from the camera calibration, it requires control commands mapping from image features to real world control space since it does not use the position information.

One commercial position-based visual servoing for underwater manipulator control was recently developed by FMC Technologies Schilling Robotics for autonomous hot stab insertion [17.44]. The hot stab insertion task is an underwater version of traditional peg-in-hole task with a manipulator, and is more difficult than the traditional one due to very tight (almost zero) mechanical clearance between a hot stab plug and a receptacle (port) and the unstable base of the manipulator. In addition, the main body of the vehicle that is the base of the manipulator is continuously moving due to underwater current and buoyancy unless the vehicle is sitting on the ocean floor or fixed to an underwater structure. Due to the aforementioned difficulties, it usually takes 30 min to 1 h for well-experienced operators to complete the task. Furthermore, failure occurs often, causing serious damage to the plug or the port. The visual servoing helps making the operation much faster than the human operator, completing the task before it fails to keep the target object within the camera FOV. The visual servoing is more efficient than the human operator in completing the operation. To overcome drawbacks in using an optical camera in turbid water, a high-frequency acoustic imaging sonar camera has been developed [17.45, 46]. Acoustic imaging is a valid alternative for a human operator to get information about the object, but it requires further research to make a computer automatically recognize the object [17.47–49]. A sensor fusion scheme for autonomous underwater manipulation was developed for the SAUVIM project, using various sensors such as an imaging sonar, a dual-frequency identification sonar (DIDSON), optical cameras, and an underwater FT sensor [17.50, 51]. Details are described in Sect. 17.6.

17.5 Coordinated Motion Control of Underwater Vehicle–Manipulator Systems

The vehicle's movements affect its manipulator's and vice versa, unless the vehicle is completely stationary during the manipulation by holding or sitting on an underwater structure. The effect of the manipulator's motion on a large underwater vehicle main body is negligible, compared to the effect of the vehicle's motion on the accuracy of the manipulator's end-effector. For a small vehicle, the coupled effect of the movements from the vehicle main body and the manipulator is substantial and must be considered in the overall control system design. This issue can be addressed by the coordinated motion control of the vehicle and the manipulator.

The overall underwater vehicle-manipulator system could be seen as a multibody system with redundant degrees-of-freedom. The redundancy can be used to assign additional motion without impeding the end-effector's performance, and the motions of the vehicle and the manipulator can be coordinated by redundancy resolution of the overall system with optimizing an index. Therefore, the coordinated motion control of the vehicle-manipulator system could be advantageous by having additional degrees-of-freedom in manipulation. The coordinated motion control system should have a planning module capable of generating trajectories for the vehicle and the manipulator for given tasks and a control module capable of generating control signals for the vehicle and the manipulator to accurately track the trajectories in the presence of coupled effects and uncertainties.

Several researchers have studied modeling and coordinated motion control of underwater vehicle-manipulator systems and showed that the coordinated motion control approach could improve the accuracy of the end-effector [17.12–15, 17–20, 43, 52–67]. Some of these previous studies are described below.

Schjølberg and *Fossen* [17.17] derived the dynamic equations of an underwater vehicle-manipulator system, and applied feedback linearization for transforming the nonlinear system dynamics into a linear system for controller design. *Antonelli* [17.52] proposed an adaptive control scheme that keeps the advantage of model-based adaptive control while limiting the computational load. The control algorithm was designed as a modular structure by applying the virtual decomposition approach [17.68]. *Han* et al. [17.59] proposed a performance index for redundancy resolution. Redundant DOFs of the vehicle and manipulator were used to optimize the index by applying the gradient projection method. In addition, the inverse optimal nonlinear H-infinity control was developed to guarantee tracking performance under uncertainty caused by modeling or identification errors, or unmodeled dynamics.

One must note that most commercial UUVs with manipulators are heavy-duty large ROVs. They do not have coordinated motion controllers for the vehicle and manipulator systems and their manipulator controllers do not automatically compensate for errors due to the vehicle motion. It is partly because the current state of the art in positioning sensors such as long baseline (LBL) does not offer the accuracy required for a high performance of the manipulator, especially its end-effector. The vehicle and the manipulator may also operate in different bandwidths, mainly due to the difference in size and dynamic characteristics. The actual position of the vehicle remains within the accuracy of the vehicle position sensor. For example, the accuracy of the vehicle position sensor of the order of a meter could mean that the actual vehicle keeps moving within a meter and yet the sensor reads the same position value. Since the vehicle is the base of the manipulator, the required accuracy of the end-effector cannot be achieved without accurate sensory information about the vehicle position. However, recent developments in integrated navigation sensor technologies show very promising results for more accurate position control of the vehicle, which would improve the precision and accuracy of the end-effector. *Panish* and *Taylor* [17.69] experimentally demonstrated that both the Kearfott T-24 and the IXSEA PHINS III [17.70] provide exceptional navigation accuracies, exceeding the published specifications–position drift of less than 0.1% of distance travelled, CEP that refers to the circular error probability, or a circle about a mean value which includes 50% of the population. A drift of 0.1% of distance travelled CEP means that the position drift of less than 1 m for travelling 1 km between global positioning system (GPS) fixes is expected for 50% of the time. Such developments could make the practical use of the coordinated motion control possible.

17.6 Underwater Autonomous Manipulation

Autonomous manipulation on a moving base, such as terrestrial mobile robots, humanoids, and underwater robotic vehicles, is a very challenging task in the area of robotics in general, especially in unstructured environments, such as underwater. It refers to the capability of a robot system that performs intervention tasks requiring physical contact with unstructured environments without continuous human supervision. Unlike industrial manipulators having fixed bases on the floor, autonomous manipulation requires a system capable of assessing a situation, including self-calibration based on sensory information, and executing or revising a course of manipulating action without continuous human intervention. Therefore, developing a system capable of fully autonomous manipulation would be a great achievement and make a substantial impact on a variety of application areas with significant economical, societal, and scientific importance [17.71].

Let us look at one scenario of cutting an underwater cable. With given information about the cable's location and shape, the vehicle has to navigate to the location, identify the cable, position itself, and cut the cable. It may sound like a very simple task. However, it would not be so simple if it has to be done in autonomous mode. Even in teleoperation mode, it would not be an easy task without the coordinated motion control if the vehicle is floating in water. In fact, the low bandwidth and significant time delay inherent in acoustic subsea communications represent a considerable obstacle to remotely operate a manipulation system, making it impossible for remote controllers to react to problems in a timely manner. Nevertheless, robots for autonomous underwater intervention would pave the way for a different range of new operations, such as deep-ocean and under-ice exploration, tasks in hazardous areas, tasks in natural or man-made disastrous regions, automated searches, surveillance missions, to name a few.

In the past, many researchers have studied advanced control of AUV itself as reported by *Carreras* et al. [17.72, 73], *Zhao* and *Yuh* [17.74], *Hanai* et al. [17.75], *Kim* and *Yuh* [17.76], *Lee* et al. [17.77], *Yuh* and *Nie* [17.78], and *Yang* et al. [17.79], but only a few AUVs with manipulators were introduced. OTTER is an AUV equipped with a single degree-of-freedom arm, which was designed to be used as a testbed for autonomous technologies at the Stanford Aerospace Robotics Lab. in 1996. It is a hovering-capable underwater vehicle, which operates in a test tank at the Monterey Bay Aquarium Research Institute (MBARI). Various research topics were studied with OTTER, including precise, high-speed underwater manipulators, task-level programming with an advanced finite-state machine paradigm, underwater video navigation, station-keeping, tracking, and automatic objects retrieval [17.80]. Another intervention-AUV (I-AUV), namely Autonomous Light Intervention Vehicle (ALIVE), was developed by Cybernetix in 2003. The aim of the EU-funded ALIVE project was to develop an intervention-I-AUV capable of docking to a subsea structure, which has not been specifically modified for AUV use. A description of the ALIVE vehicle was given by *Evans* et al. [17.81]. The most recent effort in developing an AUV for intervention missions is the TRIDENT FP7 EU research project funded by the European Commission for 3 years, since March 2010. The consortium is made up of eight partners: Universitat Jaume-I, University of Girona, University of the Balearic Islands, University of Bologna, University of Genova, Heriot-Watt University and Instituto Superior Tecnico, and company Graal Tech. The long-term objective of the project is the design and implementation of a new methodology enabling multipurpose underwater intervention missions with a very high autonomy level [17.82–84]. A team of two cooperative heterogeneous robots with complementary skills, an autonomous surface craft (ASC) and an intervention-AUV (I-AUV) endowed with a dexterous manipulator, are used to perform underwater manipulation tasks. The proposed methodology is based on two steps. First, the I-AUV cooperates with the ASC performing path to survey an area of interest, gathering opto/acoustic data from the seafloor. During this phase, the I-AUV performs accurate path following and terrain tracking, to maximize bottom coverage and data quality. The motion of the ASC is coordinated with that of the I-AUV to achieve precise USBL (ultra short base line) positioning and reliable acoustic communications. After the survey, a multimodal two-and-a-half-dimensional (2.5-D) elevation map of the environment is built consisting on a photomosaic rendered over an accurate bathymetric map, both being jointly and globally optimized. At the second step, I-AUV is launched to search for an object of interest manually selected by the user over the constructed map. When the object (the target of the intervention) is found, the I-AUV switches to free floating navigation mode. An optimization algorithm is used to decide how to move the arm, the vehicle, or both together in order to satisfy a set of constraints, such as keeping the object within the camera FOV, keeping a desired altitude, and avoiding arm singularities. The manipulation of the object takes place through a dexterous three-fingered hand attached to a redundant robot arm (7 DOF) and assisted with proper percep-

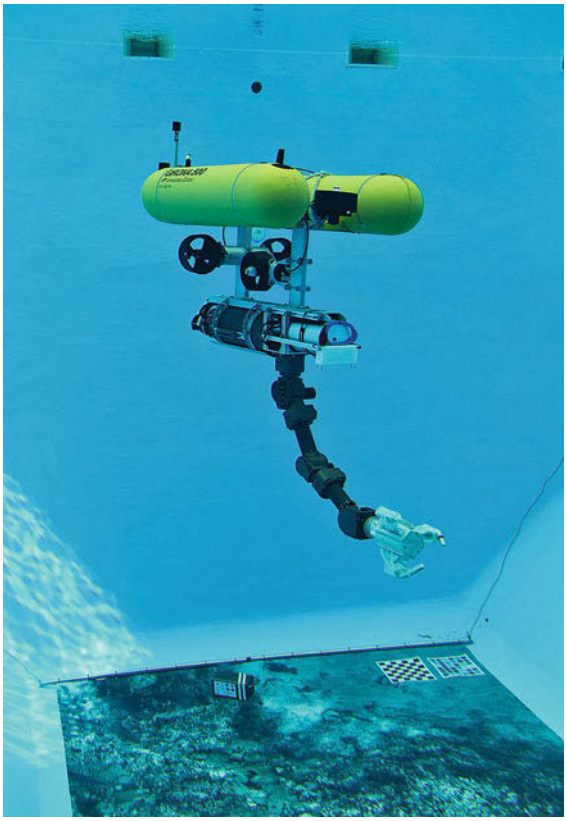

Fig. 17.2 Girona 500 I-AUV

tion (a stereo pair). The intervention task is seen as a semiautonomous process where the target is manually selected over the map built during the survey phase, but then it is automatically recognized and manipulated by the robot in a completely autonomous way. Girona 500 I-AUV is shown in Fig. 17.2.

The key technology in underwater intervention performed with autonomous vehicles is autonomous manipulation. In the literature, no such system fully functional for autonomous manipulation was reported until recent developments with a semi-autonomous underwater vehicle for intervention missions (SAUVIM) [17.50, 51]. Therefore, this section describes underwater autonomous manipulation based on the results of SAUVIM.

Autonomous underwater intervention is the primary objective of the SAUVIM research team. SAUVIM (Fig. 17.3) funded by the US Office of Naval Research was jointly developed by the Autonomous Systems Laboratory (ASL) of the University of Hawaii, Marine autonomous systems engineering (MASE), Inc. in Hawaii, and Naval undersea warfare center division(NUWC) Newport in Rhode Island. The first fully autonomous manipulation in an unstructured ocean environment was demonstrated with SAUVIM at Snug Harbor, Honolulu, Hawaii on January 20, 2010.

Fig. 17.3 The SAUVIM vehicle (Sand Island, Hawaii, 2008)

SAUVIM was built with the primary goal of performing autonomous underwater intervention. Navigation and hovering movements are precisely actuated with eight thrusters located around the center of mass (COM). The sensor navigation equipment includes a photonic inertial navigation system (PHINS) unit from IXSEA, a differential GPS, a Doppler velocity log (DVL), and depth sensor. The above navigation sensor system is capable of providing a stable and precise feedback of the vehicle position, velocity and acceleration on all the six degrees of freedom. The stability and precision of the vehicle, SAUVIM, during station-keeping was tested by experiments with a six DOF model-based dynamic controller, active on position and orientation. The inertial navigation system (INS) was aided only by the DVL, since the GPS antenna was, in this case, submerged. The vehicle was able to maintain the target position, over a 15 min period, with a standard deviation of the order of 0.01 m, for the translational part. This was confirmed by the manipulator camera output, which was looking toward an Earth-fixed target. During the experiment, only a slow change was noticed in the vertical position, which was due to the tide activity. In fact, while the target was fixed with respect to the earth, the INS used a depth sensor to correct errors in the Z-coordinate.

SAUVIM is equipped with a 7 DOF robotic manipulator, MARIS 7080 (Fig. 17.4). The arm, unlike the classical hydraulic technology in use for ROVs, is actuated by electromechanical components, to meet low-power requirements and high accuracy in manipulation tasks. Each joint is actuated by a brushless motor with a reduction unit (harmonic drive). A force/torque sensor, installed between the wrist and the gripper, senses the amount of the force and torque acting on the gripper. Designed for underwater applications at extreme depths, it is internally compensated with appropriate oil. The sensor devices of SAUVIM are the most critical components of a generic intervention mission, since at the task-execution level the system must be capable of acting and reacting to the environment with the extensive use of sensor data processing. SAUVIM is equipped with a dual frequency identification sonar camera DIDSON (Fig. 17.5), a digital multifrequency scanning sonar, several video cameras with image-processing computational unit and a special ultrasonic device for tracking the position of a generic target in 6 DOF.

Fig. 17.4 MARIS 7080 underwater manipulator (ASL, Hawaii, 2004)

Finally, the hardware architecture is composed of several on-board computers and peripherals for sensor data acquisition, enabling the following capabilities: for the vehicle, 6 DOF dynamic control, 6 DOF position feedback, extended Kalman filter (EKF) for parameters identification, target identification with DIDSON, and ability to correct absolute position with the DIDSON; for the manipulator, advanced multipriority task space control, collision avoidance, workspace optimization in conjunction with the navigation control, and optical vision with 6 DOF target position recognition.

Autonomous manipulation on SAUVIM is described by illustrating different phases during its final demonstration conducted on January 20, 2010. It consists of the following six phases that would be a major part of the typical procedure for underwater recovery tasks:

- Phase 1: Undock from the pier and navigate to a search area
- Phase 2: Search for the submerged platform
- Phase 3: Navigate and dive toward the platform
- Phase 4: Hover (station keeping)
- Phase 5: Hook a recovery tool to the target object (autonomous manipulation)
- Phase 6: Return to the pier.

Fig. 17.5 The DIDSON sonar (courtesy Sound Metrics)

Each phase was executed with no human intervention. The following information was known in advance and given to the SAUVIM computer:

1. Shape of the platform
2. Shape of the target to recover
3. Search area for the platform
4. Directional information about the target's location on the platform (frontal area of the platform).

17.6.1 Phase 1: Undock from the Pier and Navigate to a Search Area

The surface navigation, in this undocking phase, was aided by the differential global positioning system (DGPS), with an accuracy of about 2–3 m. This accuracy is sufficient enough for SAUVIM to move to a target area where to begin the search for the platform (Fig. 17.6). After detecting the platform by the scanning sonar, SAUVIM aligned itself to the platform and became ready to dive toward it.

17.6.2 Phase 2: Search for the Submerged Platform

After arriving at the search area, SAUVIM started searching for the main platform using the DIDSON sonar (Fig. 17.7) with acoustic lenses that operates at two frequencies, 1 and 1.8 MHz, with an operative range up to 40 m [17.85]. Target localization in the mid-range using the DIDSON sonar is still a challenging task under development. Very few studies on target identification and localization with the DIDSON have been presented in the literature. A preliminary study on target identification has been developed by *Yu* et al. [17.47] and *Yu* [17.48] while a possible use of the DIDSON imagery for SLAM has been investigated by *Walter* et al. [17.86]. The SAUVIM approach to determining the pose estimation with the DISDON sonar was presented by *Marani* and *Choi* [17.87]. Here, a recursive model estimator was implemented: at a fixed frequency, a model of the target, as ideally seen from the DIDSON, was built according to object dimension (a-priori information) and DIDSON orientation with help of the inertial navigation system and the pan/tilt modules on-board SAUVIM vehicle. Maximum (white color) acoustic reflection from the object surface, no reflection (black color) from the object edge and average reflection (gray) from the background are the object model hypothesis. Then, for the target identification, a bi-dimensional convolution-based approach was implemented using high-performance libraries.

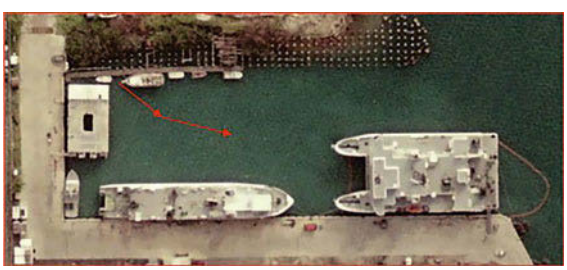

Fig. 17.6 Experimental area (SNUG harbour, Hawaii, courtesy Google Earth)

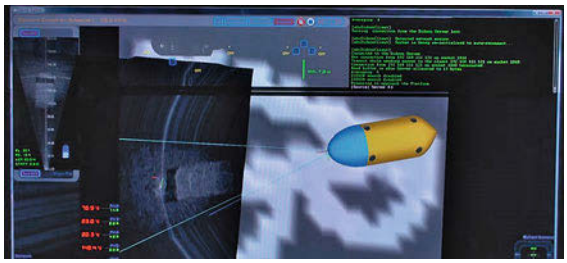

Fig. 17.7 Search of the underwater platform

17.6.3 Phase 3: Navigate and Dive Toward the Platform

After the platform was located in phase 2, the vehicle initiated diving toward the platform. Using the PHINS corrected by the DVL, SAUVIM performed dead reckoning in order to position itself just 30 cm above the platform. Here, the vehicle used the ballast for diving, enabling the COB identification when beyond a depth of 1 m.

In order to practically quantify the standard deviation of the vehicle position over the platform, a predefined experiment of positioning the vehicle in the same hovering configuration was repeated several times. In this experiment, the relative Cartesian coordinates of the platform with respect to the vehicle were computed using DIDSON imagery taken at a distance of 10 m from the target area. Successively, the vehicle performed dead-reckoning navigation from the target area to the hovering configuration. This experiment confirmed an excellent repeatability, and the global standard deviation of the position error was confined within a few centimeters in the successive trials.

17.6.4 Phase 4: Hover (Station Keeping)

SAUVIM is equipped with an advanced navigation control system capable of precise station-keeping (hovering). This is accomplished with a 6 DOF dynamic controller and an EKF for the real-time identification of the COB.

This is another important capability necessary to optimally set a roll and pitch configuration, as presented by *Marani* et al. [17.50]. In fact, optimal positioning for an I-AUV should minimize the energy consumption and improve the stability in orientation. In general, during an intervention task, the vehicle is maintained in a hovering configuration, thus requiring a 6 DOF control of the vehicle positioning. The choice of roll and pitch, if done arbitrarily, can severely impact the power efficiency of the vehicle. This is especially significant in heavy systems, since the COB may not be necessarily aligned over the COM. An EKF was used to identify the location of the COB relative to the COM, making it possible to compute the working orientation that maintains the COB vertically aligned above the COM. The EKF was implemented online to detect any change in the COB caused by various reasons, such as ballast operations. This approach helped achieve very precise position control of the order of subcentimeter in translation.

17.6.5 Phase 5: Hook a Recovery Tool to the Target Object (Autonomous Manipulation)

The manipulator started searching for the target object by using its optical camera mounted on the manipulator for short-range optical vision. Once the target object and its location (6 DOF) were detected, the arm started a tracking mode. After successfully locking on the target object, it physically connected the recovery tool to the target object. One important feature during this phase is the workspace optimization. The vehicle is set to adjust its position in real time in order to optimize the manipulation. In this approach, the entire vehicle-manipulator system is regarded as a unique open chain with multi-degrees of freedom joint. In particular, the vehicle position is modeled as a 6 DOF (free) joint (Fig. 17.8).

SAUVIM uses the concept of task reconstruction [17.88–90] along with the appropriate choice of primary and secondary tasks, which makes it possible for SAUVIM to autonomously reposition itself to increase the manipulability only if needed. The choice of the tasks was set in the following order of priority:

- Task 1 (3 DOF): Cartesian position of *Link 8* (the end-effector)
- Task 2 (3 DOF): Orientation of *Link 8* (the end-effector)
- Task 3 (6 DOF): Generalized velocity of *Link 1* (the vehicle main body).

Tasks 1 and 2 were set to track the relative position and orientation of the target object measured by using the optical camera system, whereas the generalized velocity of the vehicle (task 3) was set to zero.

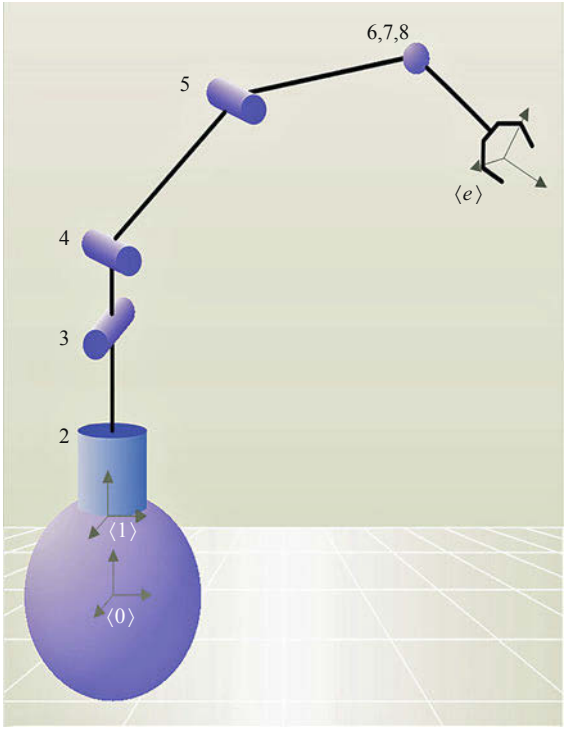

Fig. 17.8 Modeling of the SAUVIM vehicle-manipulator system

17.6.6 Phase 6: Return to the Pier

Finally, SAUVIM returned to the docking pier. Precise docking was performed using feature-based relative navigation. After surfacing, SAUVIM went to the central area and looked for the submerged platform. Then, using the relative position of the docking pier with respect to this reference, SAUVIM navigated to its home. The measured standard deviation of the final position was about 10 cm, which is accurate enough for precise-docking.

From the above six phases, we have implicitly identified the complexity of problems encountered in autonomous underwater interventions. Among those, the following are most noticeable:

- *Target area navigation*. Without the help of advanced underwater imaging technology, it would have been impossible to autonomously locate and navigate toward the target area. The above is one of the first attempts to use the DIDSON sonar as multi-DOF pose sensor to guide autonomous navigation.
- *Vehicle positioning*. While in classical ROV operation, it is the responsibility of the operator to position the ROV in the target area and an autonomous system must be capable of performing some kind

of workspace optimization. For SAUVIM, a large effort has been devoted to develop automatic optimization algorithms capable (as seen in phase 5) to precisely correct the hovering position in order to maximize the manipulability of the arm during its operations.

- *Arm control system*. Many problems commonly encountered in robotics such as kinematic singularities, collisions, and joint limit and motor saturation, are no longer handled by the robot operator. An autonomous robotic control system must be able to intelligently assess all the above situations in order to allow a successful completion of the task when it is, at least theoretically, possible. This was another area in which SAUVIM research was devoted for.
- *Future development* in autonomous underwater manipulation should be able to provide robust improvements of all of the above issues. It is important to increase the general confidence of all the organizations toward such systems, and to initiate a gradual transition from human-teleoperated ROVs to a new level of autonomy of intervention AUVs.

17.7 Conclusions

This chapter presented basic materials about underwater vehicle manipulators that are essential for underwater intervention missions, such as underwater sampling, construction, and recovery. Most commercial underwater vehicle manipulators are hydraulic-driven and used for ROVs. They are teleoperated by human operators using the master–slave configuration, which often causes operator fatigue since most underwater manipulator operations are done on a trial-and-error basis due to the vehicle movement and delayed sensory feedback. In order to minimize the presence of human operators and maximize the advantage of vehicle autonomy, the coordinated motion control of the vehicle and manipulator system and autonomous manipulation are key technologies for future underwater vehicle manipulators. The US Navy funded the underwater vehicle, SAUVIM, which has experimentally demonstrated autonomous manipulation. Following its success, more underwater vehicles having the capability of autonomous manipulation are expected to develop in the near future.

Among some exemplar underwater intervention tasks are object recovery/rescue, and maintenance/repairing of underwater facilities. Therefore, one may consider a task like *Black box recovery-grasping an object of interest and placing it at a desired location* for benchmarks in future development. One recent development after SAUVIM is the TRIDENT project in Europe. They performed an autonomous underwater intervention task, *Black box recovery* in Port de Sóller's harbor (Mallorca) in October 2012 [17.91].

18. Non-Acoustic Sensors

David Fries, William Kirkwood

The focus of the chapter is to provide a cross section of progress in the area of non-acoustic sensors for underwater mobile platforms and to provide a framework for structuring the subject of oceanographic non-acoustic sensors. State-of-the-art non-acoustic sensor systems are a summation of five areas: advanced analytical detectors, distributed computing, network technology, automation and power systems. The current state of sensor technology is partitioned and reviewed using a chemical, biological and physical sensing systems approach. A commentary on future directions for the three classes of sensor systems is also provided. Sampling technology with programmable fluidic processing systems capable of sampling with offline or online detectors is additionally presented to augment real-time non-acoustic sensor technology. The packaging of these types of sensor is briefly presented. Applications of ocean engineered AUV-based (AUV: autonomous underwater vehicles) sensing and sampling systems are also mentioned throughout the chapter to highlight the emergence of this class of ocean technology.

18.11 The Essential Need for Sensors 437
References 437

Scientists and engineers concerned with ocean changes that result from process dynamics work to investigate and design solutions for measuring the environmental systems observed. Process dynamic measurements and spatial-temporal observational abilities of the ocean historically are enhanced by the developmental evolution of physical, chemical, and biological sensor technologies. Historically, we would argue that field research activities in the ocean beyond diver depths, with the exception of sample collection, has been dominated by the research vessel paradigm using acoustics.

Predominantly the acoustic sensors for ocean science came from the development of sonars that have been focused on acoustic sensing for navigation as well as communications. Acoustic sensors are a primary instrument in the ocean observations and ongoing advances are well documented in the acoustic engineering happened rapidly over 50 years and literature. Fundamental advancements in acoustics continue, albeit incrementally, in comparison to the rapidly advancing methodologies in chemical, biological, and specialty physical sensing. Consequently, the focus of this chapter is to provide a cross-section of progress in this latter class and to provide a framework for structuring the subject of oceanographic non-acoustic sensors.

18.1 Non-Acoustic Ocean Sensors: Sourcing and Classification

The key to outlining the state and composition of non-acoustic ocean sensors is to consider the advancements of sensor technologies from larger sensor application spaces. Adapting technologies for ocean

Table 18.1 Sensor *space* based on stimulus to identify existing sensor system types

Stimulus	Applications
Acoustic	Wave amplitude, phase, polarization, spectrum, wave velocity
Biological	Bio-species (types, conc. states)
Chemical	Compositions (identity, conc. states)
Electric	Charge, current, potential, voltage, electric field (amplitude, phase, polarization, spectrum), conductivity, permittivity
Magnetic	Magnetic field (amplitude, phase, polarization, spectrum), magnetic flux, permeability
Mechanical	Positions (linear, angular), acceleration, stress, pressure, strain, mass, density, speed of flow, rate of mass transport shape, architecture, stiffness, viscosity, other
Radiation	Type, energy, intensity, other
Thermal	Temperature, flux, specific heat, thermal conductivity
Optical	Wave amplitude, phase, polarization, spectrum, wave velocity, refractive index, emissivity, reflectivity

applications from the terrestrial and space fields has greatly contributed to what is now considered part of an oceanographer's toolbox. For example, advanced analytical chemical systems, microelectronics, computers, and satellites are now commonly included as available ocean technologies. Innovations have and will continue to be brought over from the medical, military, and water treatment fields as they develop aquatic and parameter measurement sensors. Grouping the current state of sensor technology within the chemical, biological, and physical classes is adequate for a snapshot of the current state; however, in general, any of the sensors can be lumped into either radiation, fields, or mass transfer-based systems.

As a starting point, the treatment of non-acoustic ocean sensor solutions using a function classification scheme based on stimulus may be a reasonable starting point to categorize and organize existing sensors. Table 18.1 provides a summary of the stimuli and the composition of applications space. The generic sensor space categorization by stimulus leads to more specific non-acoustic sensor systems that most are familiar with, for example, non-acoustic current/flow meters, optical systems, thermistors, dissolved oxygen, plankton samplers, fluorometers, radiometers, magnetic current/flow meters, seismometers, mass spectrometers, and laser Raman spectrometers.

State-of-the-art non-acoustic sensor systems are a summation of five areas: advanced analytical detectors, distributed computing, network technology, automation and power systems. All of these areas are critical towards the advancement of more capable ocean sensing and observatories. However, new analytical functions are our focus and the basis for organizing the non-acoustic sensors space. Consider, for example, the question as to what scale the sensor system of interest needs to operate at. Spatial and temporal elements of the environmental continuum versus the spatial and temporal continuum of the sensor system have to be contemplated when looking to derive appropriate sensor-AUV selections.

18.2 Classical Non-Acoustic Ocean Sensors

Acoustics have been a dominant technology in ocean studies such as mapping and surveys. However, many ocean spatial and temporal process phenomena require other sensory modalities to properly access the space, time, and composition. In the case of particle characterization for size, form, and temporal dynamics, acoustic systems provide sensing abilities for longer temporal and spatial scales. In contrast, non-acoustic ocean optical systems provide similar time–space coverage but also extend to both longer and shorter characterization time scales. Depending on the platform selected for sensor deployment, optical systems can also extend into different spatial scales (Fig. 18.1).

Traditional non-acoustic sensors have matured primarily in the physical sensing area. The measurement of temperature is a great historical example of this maturity process, and it is still prevalent today. Examples of temperature sensing include the thermistor, thermistor string, and electronic reversing temperature sensor. Temperature measurement systems of all types, both general and high precision, are considered mature technologies.

Depth or water column pressure is another common measurement. Examples of pressure measurement systems include quartz pressure sensors, solid state diaphragms designed as submersible pressure transducers, such as piezoresistive sensors with an isolated stainless steel diaphragm in a stainless steel or titanium package. Their uses include wave and tide gauges, tsunami detection, ocean current surveys, and seabed subsidence.

Salinity is widely perceived as a fundamental variable in the regulation of natural marine systems. It is a key parameter in determining seawater physical

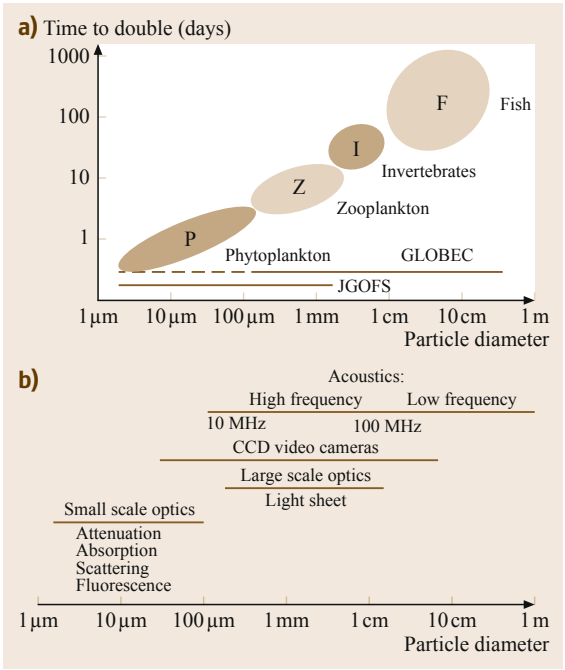

Fig. 18.1a,b Comparison of acoustic sensory range versus non-acoustic optical sensing for particle analysis and associated ocean function or phenomena. **(a)** Range of ocean *particles* and the timescale to functionally double relevant to acoustic and optical sensing modes, **(b)** Partitioning of the light and acoustic based measurements relative to spatial scale

characteristics such as density, conservative element concentrations, and solubility of gases [18.1]. In addition, as a conservative water mass tracer, it is critical to descriptive modeling of oceanic circulation, mixing, and climate processes. Salinity is an important ecological factor as it influences functional and structural properties of some organisms through changes in total osmotic concentration, relative proportions of solutes, coefficients of absorption, and saturation of dissolved gases, density, and viscosity [18.2].

Because of the global significance of salinity in marine systems, oceanographic researchers are continually exploring new tools, such as instrumenting animals, in order to study the physical, chemical, and biological structure of oceans [18.3]. Salinity is determined by electrical conductivity, temperature, and depth (CTD) instrumentation [18.4]. Electromagnetic inductive cell type conductivity and a platinum thermoresistance temperature are common sensors in CTD. There are high precision and miniaturized versions that are low cost with high precision for in-situ applications [18.5]. Additionally, towed-CTD instrument chains exist for accurate two-dimensional data sets of temperature and salinity in the upper layer of the ocean.

Fluid motion measurements are core instrumentation in classical ocean sensor systems. Currents, tides, and turbulence characterizations are needed for real-time forecasting and physical oceanographic model updates. Measurements are made from various platforms such as moorings, ships of opportunity, and autonomous underwater vehicles (AUV). Examples other than acoustic Doppler current profilers (ADCPs) include drag meters, electromagnetic current sensors, mechanical styles based on rotors, propellers, and electrode pairs using time-of-flight techniques. Wave and tide sensors provide additional information by recording wave speed, height, and direction using technologies like quartz pressure transducers, electrostatic capacitance, micro-machined silicon pressure chips, and semiconductor strain gauges, plus tri-axial accelerometers with three orthogonal rate gyros.

Seawater subsurface ocean optical properties comprise a history of rich instrumentation development to perform in-situ light measurements. Optical instrumentation allows the temporal and spatial surveying of light intensity, wavelength, reflectance, radiance, UV radiation, dissolved solids, bioluminescence, backscatter coefficients, beam attenuation, fluorescence, light transmittance, ocean color, chlorophyll concentration, absorption, angular distribution, and photosynthetically active radiation (PAR) irradiance sensors for the study of marine photosynthesis.

The distribution of optical energy in the upper ocean and ocean variable imaging are the drivers pushing advancement of ocean optical sensors for oceanography. Optical radiation sensors come in numerous configurations and target a variety of optical parameters. Systems based on absorbance, scattering, fluorescence, irradiance/radiance, and transmittance are all in operation in oceanography. Additionally, most of these optical instruments have been demonstrated on AUVs and other mobile platforms. Mobile spatial mapping has been accomplished using transmissometers, fluorometers, and radiometers.

18.3 Chemical Sensor Systems

Describing the state of chemical sensor systems is an enormous task and could easily be the basis for an entire volume dedicated to the subject. In this chapter we provide examples of technologies that represent aspects of chemical instrumentation and hopefully will provide a snapshot of the chemical instrumentation migration to maturity within the environment and mobility using AUVs. In general, key drivers for evolution of chemical instrumentation come from the ability of chemical sensors to provide trace detection and spatial/temporal chemical dynamics in water and within chemical ecology. Previous literature reviews have covered and summarized in-situ chemical sensors into two volumes on chemical sensor systems for aquatic sciences and chemical and biological sensors for time-series focused research [18.6, 7]. These reviews describe a variety of continuous flow analyzers, electrochemical sensors, and optical sensors for in-situ measurements of dissolved chemical species.

Chemical sensors need to have excellent detection limits to be desirable. Attributes such as precision, selectivity, response time, a large dynamic concentration range, low power consumption, robustness, and less variation of instrumental response with temperature and pressure are the most advantageous. Also, instruments that stay free of fouling problems are highly attractive to end users. It is also important to note that some chemical sensors are deployed in several different oceanic environments for the detection of targeted chemical species, whereas others are useful in only one environment because of various configuration limitations. There are a number of chemical sensors that can be used as stand alone in-situ sensors, whereas a greater number involve water being brought from the environment into an analytical cell or chamber via tubing, either aboard ship or onboard a mobile platform such an AUV. Multi-element sensors that measure several chemical species from the same water sample are an area that researchers are pushing for further development. These multi-function sensors will increase the capability of AUVs (for example) to characterize spatial ocean chemical composition and diversity.

At present, most sensors need further refinement to perform measurements at very high acquisition rates without a loss of precision or sensitivity. Fundamental inorganic compounds and ions (oxygen, basic nutrients, hydrogen sulfide, pH, carbon dioxide, NOx, SOx, Fe, Mn, and trace metals) are good candidates for continual AUV-based integration. Nitrate, a key nutrient, as a sensor system has seen major advancement in the last few years. Nitrate sensors are a current example of instrumentation that will see increased usage for nutrient mapping, particularly in AUV coastal surveys. Current commercial nitrate sensors can be accessed as either by the use of automated wet chemistry or ultraviolet (UV) spectroscopy performed in situ. Optical UV techniques function to detection levels of $\approx 0.5\,\mu$M, but for levels below that wet chemistry is required at present. UV nitrate sensors are, therefore, suitable for use in the ocean surface except for some rare areas. For work below the micromolar level there are wet chemical systems that can achieve nanomolar levels of detection [18.6]. At the time of writing this we are not aware of any having been deployed on an AUV. Additionally, wet chemical systems are evolving to measure ammonia, nitrite, orthophosphate, silicates, and iron at desired levels and acquisition rates for waters and sediments. We expect that these instruments will in time be in a format that is tractable for insertion on AUV platforms.

The study of boundaries and interface environments are important in ocean dynamics. Boundary layers include atmosphere-to-water, water-to-sediment/soil, as well as the boundaries between fluid masses with sharply different characteristics. These different contexts all require the measurement of fluxes. Additionally, deterioration of water quality, ocean acidification, and unknown processes have resulted in a tremendous decline of ocean communities [18.8]. Quantifying the fluxes of chemicals is of great importance to understand these local, regional, or global biogeochemical processes. These include fluxes of key carbon species such as CO_2 and CH_4, nitrogen species such as NH_4^+, N_2O, and NO_3^-, many important metals and trace molecular species, sulfur, and other measurements of CO_2 system parameters (pH, CO_2 fugacity (f_{CO_2}), total dissolved inorganic carbon (CT), total alkalinity (TA), and carbonate ion concentration [CO_3^{2-}]). An illustrative system is the spectrophotometric elemental analysis system (SEAS) [18.9]. Differently from the single-purpose instruments available on the market, SEAS offers a platform for CO_2 parameters, nutrients, and trace metals. In its third generation, the in-situ chemical sensor can be configured for a wide variety of chemical measurements, including trace metals, nutrients, and inorganic carbon system variables in different sample environments and deployment modes. Automated wet chemical analyzers such as these will see increased use in AUVs and possibly in combinations with AUV swarms to provide informative data on flux in different oceanic contexts.

Oxygen chemical sensors [18.10, 11] are in high demand, especially for AUV mapping studies of anoxic environments. Standard oxygen sensors such as oxygen electrodes, galvanic O_2 micro-sensors, and Clark

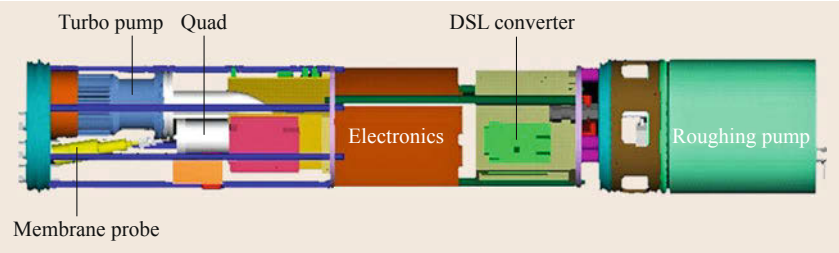

Fig. 18.2 Underwater mass spectrometer consisting of three primary subsystems: a high-pressure membrane inlet with a small-volume seawater pumping system; a quadrupole mass spectrometer and oil-less vacuum pumping system; and underwater housing. The membrane inlet assembly consists of a circular sheet or tube of polydimethylsiloxane (PDMS) membrane material

polarographic sensors are frequently being replaced by the rise of optode-based O_2 systems. Optode devices have lowered the cost of making oxygen measurements while they have also extended reliability and maintainability. Related to these types of sensors are membrane-covered amperometric sensors, a renewable reagent fiber optic sensor for measuring partial pressures, and membrane transport of analytes into reactive solutions for conductance detection. Pure optical systems such as non-dispersive infrared absorption and cavity ring down laser systems have emerged especially in the area of CO_2 sensing. Underwater methane sensors based on IR optical absorption and mass spectrometry have gone through rapid ascension driven by the need for assessment of their role in climate studies. We expect these systems will migrate over to mobile vehicle platforms from the initial demonstrations or be optimized further for more numerous placements.

Underwater mass spectrometer technology has been adapted from its lab-based origins to AUV-based field deployments [18.12]. For the detection of organic pollutants and other toxic chemicals, this evolving technology provides non-parallel analytical performance and allows the possibility of access to the entire chemical space. The technology (Fig. 18.2) can detect organic compounds of small molecular mass (< 300 Da) and large molecular mass (> 300 Da). Small molecules include methane, xenobiotics (e.g., halogenated hydrocarbons), and toxins. Large molecular mass compounds, which have been largely ignored, include dissolved organic compounds (DOC), dissolved organic nitrogen compounds (DON) and can in time be characterized with the evolution of the technology.

The initial demonstration of an underwater mass spectrometry on AUVs was membrane inlet mass spectrometry (MIMS) [18.12]. This same design has also proven to be an effective tool for measuring complex mixtures of dissolved gases (volatile organic compounds (VOCs), CO_2, etc.) in non-AUV applications also. MIMS has also been used to study metabolite flux and dissolved gases in surface waters and continuously aboard ships [18.13, 14]. The recent adaptation of MIMS to in-situ environmental analyses demonstrates the utility of such an instrument operating while underway at sea, allowing continual monitoring of many gas species in real time. This approach allows potent analytical monitoring of spatially explicit biogeochemical changes.

The possibility of accessing the entire chemical space is a unique feature of mass spectrometry and the rise in mass spectrometry in the lab over 2 decades will mostly likely be replicated in the field/ocean analytical sensor space. Awaiting the expansion of mass spectrometry in the ocean is the increase in demonstrations of ion sources beyond the membrane inlet method that has been used to date by all underwater mass spectrometers (quad, ion trap, cycloidal). Atmospheric ion source developments for liquid chromatography mass spectrometry (LC-MS), which are numerous in lab settings suggest new source designs that will take a liquid sample and apply vacuum/gaseous-based mass analysis. The use of mass spectrometry on AUVs will most certainly see a rise in use in the coming decade, with the need for oil and gas field pipeline monitoring and exploration activities using the MS/AUV combination. The rise in chemical ecology and the need to understand non-point source chemical pollution and natural products will also drive the need for spatial chemical mapping.

Laser Raman spectroscopy is another class of spectrometer for ocean science. Raman spectroscopy has the frequently desired capability of being non-destructive. Raman spectroscopy also has the ability to discern structural information many other systems lose when analyzing the sample. For example, Raman spectroscopy easily differentiates calcite from aragonite, which are the same calcium carbonate material but have different lattice structures. Raman spectroscopy uses a monochromatic laser to irradiate a spot on the target causing vibrational modes which return a portion of the photons returned are frequency shifted. The original

light frequency is filtered out and the resulting spectra collected is rich with information other sensors and instrument systems cannot provide. In addition, Raman spectroscopy looks at a spectrum of chemical compounds simultaneously, as long as they are within the laser beams' spot size. Raman systems are also capable of scanning a prescribed area or watching a reaction occur over time. Therefore, Raman spectroscopy is a very strong instrument for use in situ.

Natural gas hydrates occur within sediments and outcrops around the world; hydrates are an excellent target for Raman investigation [18.15]. It is helpful that hydrates, composed of 85% water and 15% gas, are ice-like and semi-transparent. The excitation laser can thus be focused within the specimen without the exact positioning strictures required for a fully opaque surface. Raman instruments have been evaluated for detection limits on a number of gas species. Samples of 1 atm CO_2, 0.7 atm N_2, 0.2 atm O_2, or 0.01 atm H_2O vapor contained in an Erlenmeyer flask were successfully tested using the excitation laser focused through the wall of a glass vessel. One experiment collected 64 acquisitions of 10 s each and determined the following detection limits: 0.2 bar CO_2, 0.1 bar N_2, 0.1 bar O_2, 0.01 bar CH_4, and 0.01 bar H_2O vapor [18.16]. The results observed are consistent with the well-documented Raman scattering cross-sections for CO_2, N_2, and O_2, where the scattering cross-section for CH_4 is almost an order of magnitude greater [18.17]. The detection limit for CH_4 is, therefore, about 10× greater than that for CO_2, N_2, and O_2. In addition, although seawater itself is of little interest for direct spectroscopy, one species peak is usually dominant, that this that of SO_4^{2-} at a near constant 28 mM concentration. In the normal oxygenated ocean, SO_4^{2-} varies with salinity; therefore, it is possible to use this prominent peak to provide a quantitative marker. Acquiring a seawater spectrum at depth serves as a valuable quantitative system check [18.18].

Current trends indicate a high likelihood that autonomous vehicles may in the near term be capable of successfully hosting instruments such as a Raman spectrometer. When suitable, autonomous target locating and sensing strategies can be devised; the detection of a chemical signature from gas plumes emitting from the seafloor are one potential example. Although autonomous operation is commonplace in industry, there are current technical barriers that inhibit long-term at sea operations for Raman spectroscopy in an autonomous mode, namely a suitable cost effective power source. In remotely operated vehicle (ROV) operations Raman spectroscopy has no limitations with the abundance of power, nominally 10 W continuous with today's technology.

In-situ fluorometers are another class of AUV compatible sensors that see almost routine use on AUVs and will see increased use over time (Fig. 18.3). Spectral sensors such as fluorometers have been developed for chlorophyll a in algal and cyanobacterial populations, largely related to trophic support (biomass) and primary productivity. The configurations of fluorometers have evolved over time into more simultaneous spectral wavelengths, extending the range of sensing wavelengths while reducing the packaging size and costs of the systems. This has largely been enabled with the enormous growth in solid-state opto-electronic devices, such as high power light-emitting diode (LEDs). One example of fluorometers moving beyond physiological flourometers is the application as hydrocarbon spill monitors. AUV deployments using UV flash lamp configured fluorometers have taken place, but with the rise of low cost UV LEDs in combination with market growth of lower cost and smaller form factors this class of oil sensor is becoming readily available from industrial sources. Continual improvement of antifouling systems for optical sensors is also actively under development, and we expect to see improvements that will be critical for long duration AUV studies.

Trace metal sensors are a type of chemical sensor suitable to perform in-situ metal analysis. Several analytical approaches exist, such as fractionation. Spectroscopic techniques such as laser-induced breakdown (LIBS) use emission spectrometry and are good candidates for future AUV inclusion. However, LIBS may need some form of chemical separation, such as preextraction to augment the utility. Traditional techniques use the electrochemical properties of metals and are divided into two major analytical classes, voltammetric and potentiometric systems. These electrochemical techniques have been used over the past 3 decades. Low power requirements with small form factor electronic packaging make electrochemistry a compatible chemi-

Fig. 18.3 Field fluorometer system using a xenon pulsed UV lamp in an underwater housing. The unit has detection capabilities for hydrocarbons (e.g., carbazole) in sub-ppb levels

cal sensor system for AUVs. Direct reduction methods and adsorptive styles, such as anodic stripping voltammetry illustrate the analytical performance and size of these sensors [18.19]. Potentiometric sensors are also applicable to AUV deployment, however the individual capability of a system is coupled to the performance of the ion selective coating that separates the sample from the medium. Further development of new ion-selective coatings is critical for the expansion of the chemical *vision* of these electrochemical metal species sensors for AUVs.

Automated wet chemical analysis has a proven history in aquatic observations, in particular for metals relevant to micronutrient activity. Continuous flow injection instrumentation has been used for profiling and surface ion detection mapping of specific metals (Fe, Co, Mn, Cu, Zn). As was mentioned prior, wet chemical systems have the ability to be tuned to different chemical species and in many ways can be viewed as *hardware processors* that are *programmed* to different chemicals based on the reaction chemistry used. This applies to electrochemistry applications and beyond. Insertion on AUV platforms will become more prevalent over time as form factors shrink and the cost of components is reduced.

Many chemical instrument systems benefit from the incorporation of microelectronics, which results in significant miniaturization. The realm of AUVs should substantially benefit from developments occurring in these miniaturized engineered instrument systems. An example of this is the water-stable organic transistor, which has already been developed and applied to chemical sensors [18.20]. The development of low-cost, organic thin-film transistor (OTFTs) devices capable of converting an analyte binding event to an easily read electrical signal is already leading to new chemical specific devices with reduced size and cost. OTFT sensors have been demonstrated in aqueous solutions with concentrations as low as ppb for trinitrobenzene, methylphosphonic acid, and other chemicals. This work indicates reliable OTFT operation in aqueous media, hence opening new possibilities of chemical sensing with OTFTs chemical sensors and on mobile platforms. OTFTs are ideal for inexpensive, chemical sensors because of their compatibility with flexible, large-area substrates, simple processing, and highly tunable active layer materials.

Nanomaterials also show promise in aquatic chemical analysis mainly due to their highly tunable size and shape-dependent chemical and physical properties [18.21]. Although a broad definition, nanomaterials are structured components materials that have at least one dimension less than 100 nm. Furthermore, they exhibit unique surface chemistry, thermal stability, high surface area, and large pore volume per unit mass that can be exploited for ocean chemical sensor fabrication. Nanoscale materials can be implemented as scaffolds for chemosensing. Nanomaterials have proven to be useful for the fabrication of sensors and have compositions including metals, metal oxides, chalcogenides, and polymers. Their structures range from nanoparticles, nanorods, and nanowires to nanoporous structures and core-shells. A few nanomaterials have been functionally altered to work with various kinds of ligands and active groups that produce sensitive and selective sensors for specific analytes. The ever expanding group of nanocomponents has the potential to allow chemical sensor designers to create highly selective chemoreception systems able to function within the complex background of ocean waters. Migration of this technological toolbox into ocean chemical sensor systems will emerge over time as they are implemented in industrial and medical applications and adapted to ocean research.

18.4 Biological Sensor Systems

Similar to the chemical research space, biosensor research and monitoring is fragmented in such a way that at best we can provide a broad overview of important AUV amenable sensors. The spectrum of sensors available, however, can address biogeochemical cycles, primary and secondary production, species distribution, animal movements, habitats, and pollutants. It is impossible to discuss all relevant systems or to provide appropriate detail for all of those discussed in this chapter. Therefore, this is an introduction to the sensor technologies currently in process or soon to be, and what variables are quantified.

The advancement of instruments has frequently preceded many major discoveries in the field of science and technology. The microscope is a classic example of the influence of scientific instrumentation on sensing within the biological sciences. Efforts in engineering ocean instrumentation and developing the associated sensors must take into consideration the inherent environmental limitations encountered in underwater applications. Environmental issues include the corrosive nature of seawater, bio-fouling, limited energy resources, pressure tolerant enclosures, data transfer reliability and the dynamic nature of the ocean itself.

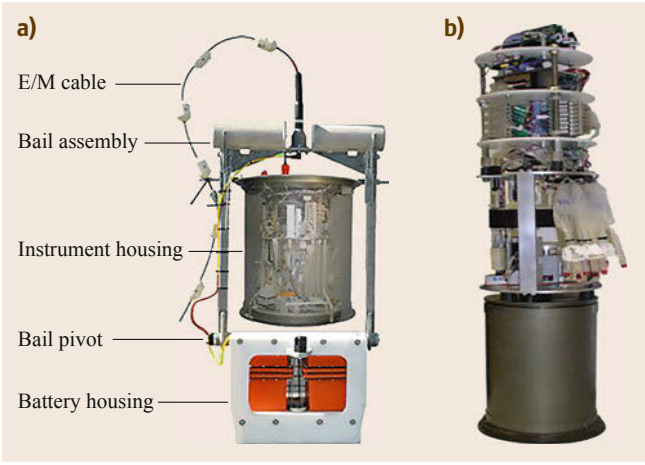

Fig. 18.4 (a) Environmental sampler processor (ESP) and (b) autonomous microbial genosensor (AMG), automated wet chemical analyzers that collect sample, homogenize, and filter the lysate and apply DNA/RNA probe arrays or amplification probes for nucleic acid detection and in the ESP case provide protein/toxin arrays for detection (images courtesy of MBARI and University of South Florida, respectively)

Biological sensor technology for underwater can be divided in one perspective as acoustic and non-acoustic based sensing. The major problem of acoustic-based sensors is that they are very prone to noise. Since this chapter is focused on non-acoustic sensors, we shall ignore the issues associated with those sensor technologies. With regard to non-acoustic sensors, they are not generalized instruments for the most part and must be tailor made for the specific application.

Biological, non-acoustic sensors can be further broken down into sensors for the visible (optical, imaging, etc.) and those for the microscopic (microbial, genetic, microscopy, etc.). In the microscopic realm sensors onboard AUVs are needed in order to measure biological reactions and physiological function in variable ecosystems. Biological sensors are, perhaps, the least developed of the sensor types but can provide key information on the function and structure/composition of biologically-influenced ecosystems in real time. As with chemical and physical sensor types, the signals produced by biological sensors need to be processed in a manner that allows for the future to perform adaptive sensing. To accomplish this they will need to be capable of long-term deployment and they should be suitable for integration with other sensing devices in an effort to provide a complete characterization of ecosystem structure over time. Although some aspects of sensor deployment may vary when implemented across different media (air, water, sediment), the general needs assessment for AUV-based sensor development is considered to be similar for all sensor types. The only real distinction between sensor types being the method to access and process a sample may change. These sensors need to be developed for monitoring all levels of biota, from microbiological to the highest levels in the eukaryotic domain.

Interdisciplinary research between engineering and biological cultures in many cases has spurred the development of sensors for AUVs and the ability to contribute to bio/eco function determination, including prediction. A working knowledge of modern molecular biological techniques synthesized with engineering approaches to sensor development is required to advance the biosensor ability of AUVs. In addition, bioinformatic data management and aquatic environmental engineering will contribute to these developments.

Areas where AUVs equipped with the latest biosensing technology can make inroads using environmental genomics and sensors for microbial viability (environmental viability of pathogens and indicators) to detect total microbial communities and identify emerging microbial problems before they create ecosystem deterioration. AUVs can help identify toxins in the environment, both toxin production and pathways. In many emerging biosensor systems computational biology and bioinformatics will be needed to manage the tremendous data streams generated from genomic and genetic sensors.

Fully operational genomic sensors (Fig. 18.4) on AUVs are still awaiting definitive demonstrations. Improvements for field deployment of AUV capable gene sensing systems are under development. These biosensor developments will benefit from an emerging complementary bio-analytical approach, namely, automated sampling onboard AUVs with post shore analysis in the lab using the highly developed genomics analytical systems. Using automated real-time sampling followed by near real-time analysis may be the first viable approach to significantly identify community structure through phylogenetic fingerprinting methods and to ground truth future biosensors.

Currently unattended genetics sensors, which can be classified as wet chemical analyzers, are the leading candidates for transfer onto AUVs. Both the environmental sampler processor (ESP) [18.22] and autonomous microbial genosensor (AMG) [18.23] are leading candidates for AUV deployments capable of species specific detection. The ESP and AMG are portable water laboratory systems that provide onsite biological analysis of water samples. These electromechanical fluidics systems are designed to collect and concentrate discrete water samples, autonomously apply molecular probes to identify microorganisms, including their DNA or protein products. Data gen-

erated are available by remote transmission and autonomous analysis in real time for adaptive sampling. Assay detection chemistries are available for many biological targets. These assays enable the sensor system to be tunable or programmable for different targeted species. This capability could be integrated into AUVs outfitted with them to act as a control function in the vehicle's control loop. Aquatic microbial detection technologies combined with AUV marine technology will provide near real-time sensing and detection capabilities to protect shellfish, beaches, coastal resources, groundwater, and drinking water sources. Polymerase chain reaction (PCR) amplification technology is the enabling technology being incorporated into the AUV compatible genetic sensor to bring down power requirements and scale while extending deployment time and the number of samples analyzed.

One aspect of these devices is that they can be configured with a variety of genetic probe arrays [18.24, 25] at one time. The probes are on small filters that have matching genetic markers which capture their genetic match when the assay of material is passed over them. Using a system of false positives and photosensitive chemistry, the identity and relative concentration can be captured in situ and in near real time. The probes can also be fixed and stored for later analysis in the lab.

Mass spectrometry and molecular biology-type systems [18.25] are demonstrating detection that indicates the presence of proteins and toxins. Real-time proteomic-based sensors that measure expression patterns in biota proteins using automated methods is a complex technical problem. Proteins are the functional elements in cells that are amenable to significant post-translational modifications not captured by functional genomic sensors. As such, proteomic-based sensors are expected to yield information that better relates to functionality at the macro-scale ecosystem. Real-time AUV sampling combined with a post-analysis approach may benefit the elucidation of the proteomics spatial-temporal dynamics in the immediate future. Similarly, metabolomic-based sensors that measure metabolic byproducts produced by functional biota will emerge on AUVs with the growth of mass spectrometry and the advancement of automated sampling methods. Detection and monitoring of known metabolic byproducts, or metabolic fingerprints, generated in response to perturbations within the environment will be highly informative to researchers as well as the general public.

Optical sensors, both spectral and imaging (Fig. 18.5) (beyond fluorometry and intrinsic properties ocean optical systems), are natural candidates for AUV missions. Optical sensors that measure biotic

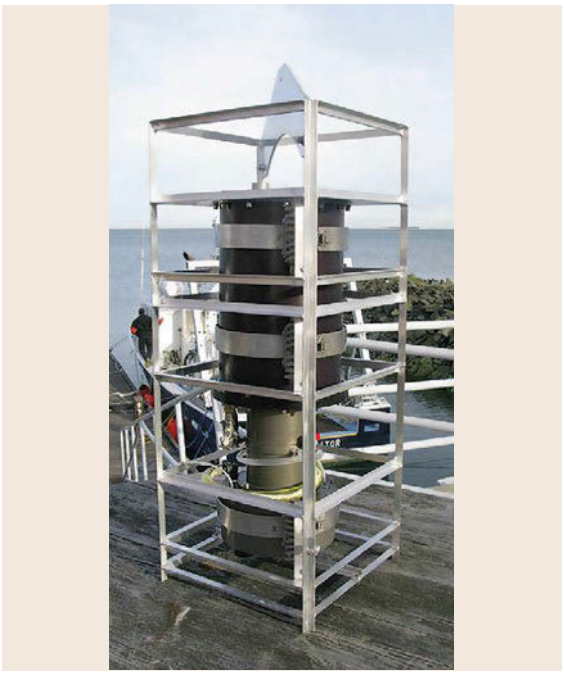

Fig. 18.5 Submersible FlowCAM acquires digital images of each particle passing through its flow cell along with up to 26 different measurements for each particle. Statistical pattern matching techniques enable automatic classification of taxonomic groups from libraries of known particle images. Particle size measurement range from 10–600 μm, deployment modes include moorings, as vertical profilers and on unmanned vehicle with a matched AUV housing (courtesy of MBARI)

morphology, and the shape and look of the organism, can be used to relate to biotic function and abundance measurements. An illustrative system for the spectral sensing pathway to measure microbial organisms is the optical phytoplankton discriminator, also known as BreveBuster [18.26]. BreveBuster was conceived and designed the using optical absorbance characteristics of particles in the water to assess the fraction of phytoplankton biomass made up by *Karenia brevis* (a red tide pathogen). An existing pre-production version of the instrument tolerates water pressure to 200 psi for deployments on AUVs and towed vehicles. The output parameter, the similarity index, represents the degree of similarity between the optical absorbance of particles in the sample under test and that of a target organism.

Flow cytometry is a biological particle imaging and counting system for morphological and abundance measurements. Flow cytometers developed from earlier efforts to count cells and particles in liquid suspension as they passed through a sensing region of the flow chamber. A primary example is the Coulter counter,

which was developed in the mid 1950s for counting and sizing red blood cells. In modern flow cytometers, cells are typically analyzed at rates up to a few thousand per second. Sensors measure cellular features and the corresponding signals are processed. These instruments have revolutionized automated cell analyses in that measurements are made at high speed. Miniaturization of the systems is rapidly occurring and shipboard, flow-through versions are now commercially available. The analysis of the intrinsic fluorescence profiles of individual marine algae can be used in general classification of organisms based on cell size and fluorescence properties.

Commercially available ocean deployable systems exist, including FlowCAM from Fluid Imaging Technologies. These instruments preform continuous imaging particle analysis, monitoring phytoplankton, zooplankton, and fluid borne particulates. The FlowCam is available in submersible models which can measure particles from 1 μm to 3 mm in size, which make it a good candidate for adoption onto AUVs. The FlowCytobot is a separate system that uses diode-pumped 532 nm lasers and can measure scattering and fluorescence of bio-particles. The FlowCytobot is currently designed for operation in coastal observatories with a connection to the shore for power. A next generation system has evolved, which is an imaging FlowCytobot version for imaging with a higher sampling throughput. The work to move these systems into more portable formats, capable of being carried on vehicles, is occurring outside the traditional ocean engineering field. Currently, lab-based engineering developments of optofluidic flow cytometers are underway primarily within the medical or clinical diagnostics arena. The field of optofluidics is comprised of optics and microfluidics working together to create novel functionalities within a small chip. These chips hold great promise for lab-on-a-chip flow cytometry and for the further miniaturization of the flow cytometer [18.27]. The Microflow cytometer has been developed on a chip for the characterization of phytoplankton. The Microflow cytometer measures distinct side scatter and fluorescence properties of various microorganisms. This device proved sensitive enough to detect and characterize picoplankton with diameters $\approx 1\,\mu m$ and larger phytoplankton up to 80 μm in length. The wide range in size discrimination coupled with the detection of intrinsic fluorescent pigments suggests that this Microflow cytometer should be able to distinguish different populations of phytoplankton as a miniaturized system on unmanned underwater vehicles.

It is hoped that highlighting these systems indicates the emergence of biological sensor technologies on mobile platforms. A large number of microbial biosensors have been developed for environmental, food, and biomedical applications, which we can expect to transition over to systems engineered for the ocean. The fabrication of microbial biosensors based on amperometry, potentiometry, conductometry, voltammetry, microbial fuel cell, fluorescence, bioluminescence, and colorimetry, is occurring and will be applied in the field. Sensors that provide reliable quantitative information related to growth rates are coming with the expansion of low cost, high performance embedded microscopy systems. Detection and data presentation of kinetic information allows direct and indirect indicators for quantitative predictions for the ecosystem being monitored. Sensors such as spectral optical instruments continue to evolve and help detect the initiation and extent of primary production. These spectral instruments are successful in connecting environmental perturbations and variations with primary production events in real time. The increased number and quality of underwater mobile imaging systems (beyond acoustics only) is helping track levels of predation to tease out changes in population numbers. These predation data give insight into the ecosystem's structural dynamics and helps researchers to better understand the impacts of environmental changes. For many of the biosensor designs outlined in this section the utilization of micro electro-mechanical (MEMS)-based underwater sensor system designs should be a major part of the future scope for research. MEMs-based sensors will optimize the cost of materials and energy in particular. One other potential dimension of underwater biosensor development is the bio-inspired system approach, which uses the existing biological system around us. The oceans in particular are a rich depository of ideas and solutions ready for adaptation to our man-made systems. Bio-inspired sensor systems, like bio-inspired AUVs, are not just about trying to imitate the living system but to synergize the currently available technology with nature to optimize any given sensor design.

18.5 Physical Sensor Systems

Physical sensor technologies for energy, heat, water, salt, and particulate phases in general are more mature than either chemical or biological sensor technologies. A large industrial base exists for the manufacture of

temperature, pressure, and physical property sensors. Consequently, there are more examples for these types of sensors than those in other areas [18.28]. Classical depth or pressure measurements in the ocean (highlighted earlier in this section) are a direct example of the progression of physical sensors. These developments as state-of-the-art changes are more evolutionary and usually are not revolutionary steps in progress. Water column measurements are of utmost importance to better understand ocean processes by setting the normal background conditions and, for instance, are required to perform tsunami wave detection. A specific example is the work on the reinforced piezoresistive pressure sensor, which employed double diaphragms with a Wheatstone bridge. The double diaphragm design achieved higher sensitivity, a wider operating range, and better temperature compensation for ocean depth measurements compared to conventional single diaphragm piezoresistive designs [18.29].

For AUV mounted current metering, one cannot avoid the strength of acoustics to deliver flow information. Acoustic current Doppler profilers (ACDPs) are available currently for roving current observations. Modern ADCPs are also employed as acoustic Doppler velocimeters (ADVs) looking at over ground velocities, and when using a specific configuration the water velocities can be estimated while the vehicle is flying mid water. The advancement of AUV adaptive oceanographic sensor networks, combined with 2-D and 3-D imaging techniques, should be able to assist in mapping the fluxes across scales in environmental volumes and interfaces. For example, atmospheric turbulence sensing requires 3-D flow field measurements that are within 10 cm of the air–water interface; the sensors must be environmentally robust for persistent observations and be accurate to $0.1\,\mathrm{cm\,s^{-1}}$. Water column sensing requires 3-D flow field levels quantified within 5% throughout the water column to better understand the turbulent transport and flux of gases.

Transport in the water column includes chemicals as well as biomass in water and at the water–air interface. Combining optical and acoustics sensors on mobile platforms may provide some of the functionality needed for simultaneously measuring ocean chemistry and biology across a variety of scales. As physical sensors have advanced in moored ocean observatories over the last decade, one should see opportunities to transfer the sensing functions onto AUVs. Modifications will be needed in areas of computation, power, and packaging to accommodate the unique features of mobile platforms.

Instruments to quantify the relationship between turbulence in water coupled with turbulence in the air directly above would provide major changes in physical oceanographic observations. This requires surface sensors for fluxes through the sea surface interface. To accomplish these turbulence goals, new capabilities for AUVs that advance mapping of 3-D flow field (transport, fluid velocity) systems are one focus, as well as microturbulence sensors. Standardization for field physical sensing devices will be required on AUVs, just as it has been on observatories and drifters. Continued miniaturization in physical sensors, electronics, and packaging will be driven by new unmanned system designs. A new area of rising research interest is the discrimination of nanoparticles and aerosols, manmade and naturally occurring. Particle size distribution and shape sensors with near real-time response for mobile surveys are areas in need of development for AUV-based event response. Sensor systems must be able to accurately establish the sensor/AUV orientation within the environment. Physical location and altitude is the largest uncertainty in mobile hydrological observations as one example. As submersible robots become increasingly available, knowledge of their exact position in four dimensions will become more and more critical. An error of alignment within ± 0.1 degrees or 0.5 cm will substantially degrade the utility of bio-geochemical observations.

Multi-parameter systems are commercially available (DO, pH, ORP, chlorophyll, rhodamine, turbidity, conductivity, temperature, salinity, specific conductivity, depth) and inclusion of these is becoming the backbone of AUV deployments; we expect this to expand in the future. Mini bio-optics packages: chlorophyll, beam transmittance, angular scattering, conductivity, temperature, depth etc., are available and further expand the ocean optics and bio-optical data streams. Maps generated with these data parameters will provide richer physio-chemical information sets to real-time circulation models and fisheries management. Greater optical sensing capability can be expected in both the spectral and imaging realms. Using imaging technologies from micrometer to the meter scale is and will further improve details on particles of benthic biota and fish [18.30, 31].

Several instruments for optical detection are already available; this is not a complete list and new developments are underway. A number of existing instruments have already been successfully adapted to AUVs. Sensors for bioluminescence, particle counting and imaging are available off the shelf from a number of manufacturers.

The underwater bioluminescence assessment tool (UBAT) from Wet Labs provides measurements of mechanically stimulated bioluminescence of continuously flowing samples for potential bioluminescence in units of photon per second per liter. UBAT is a small

bioluminescence sensor specifically designed for deployment on multiple platforms, including shipboard profilers, AUVs, and long-term deployment on moorings. The photomultiplier tube (PMT) and flow meter that together comprise the core of the UBAT system are calibrated to the appropriate National Institute of Standards and Technology (NIST) specifications. The current UBAT system operates to depths of 600 m at present and uses mechanical stimulation, not unlike the wake of a ship, necessary to obtain maximum bioluminescence potential from bioluminescent organisms entrained in the flow. Stated sample rates of 60 Hz are specified with a data output rate of 1 Hz. Laser in-situ scattering and transmissometry (LISST) instrumentation include a series of submersible devices that are configured for a number of applications, including AUVs. All employ the small-angle forward scattering principle, also called low-angle laser scattering or laser diffraction. Sequoia Scientific is a manufacturer of several LISST laser sediment/particle/bubble/droplet sensing instruments, which can be purchased currently. Some of these instruments deliver the optical volume scattering function (VSF) of interest to optical oceanographers. One variant of the LISST instrumentation is the LISST-hologram (LISST-HOLO). The optics end of the LISST-HOLO consists of a 5 cm optical path using a red (658 nm) laser beam to traverse the optical path, overfilling a charge-coupled device (CCD) array, thereby creating a hologram. This instrument is particularly well suited to the measurement of large, complex biological particles. The LISST-HOLO creates in-situ images of particles, using in-line digital holography to overcome the depth of field issues other particle imaging systems are limited by. The digitally recorded holograms yield images of particles from 25 μm to 2.5 mm throughout the entire sample volume (≈ 2 ml). The sampling frequency is adjustable, with a maximum sampling frequency of 0.2 Hz or a hologram every 5 s. Others are considering use of the LISST-HOLO to augment sensing capabilities in interdisciplinary research applications using AUVs.

Laser optical particle counters (Fig. 18.6) (LOPCs) are another variation of particle profiling instruments. LOPC instruments can be purchased as off-the-shelf equipment configured for installation on an AUV from Odim Brooke Ocean. The operational principle of the LOPC is a combination of laser diode and line generator producing a divergent linear beam ≈ 1 mm in width. The beam is focused through a cylindrical lens producing a parallel beam subsequently reflected by a mirror and directed through an air–water interface window into the sampling volume. At a selected distance from the window, a mirrored prism is used to redirect the beam back to the window on a parallel path directly below the emerging beam. The light beam and optics of the LOPC are designed to address the probability of two or more particles occurring in the beam simultaneously and being counted as one particle. The reduction in coincidence probability is essentially the ratio of the two smallest detection areas. The LOPC utilizes a laser diode line generator producing a narrow beam that is broader in height that impinges on a linear array photodiode. The cross-sectional effective area of the beam results in a reduction of coincidence by a factor of 80×. This effectively increases the LOPC operational capability in large particle concentrations. The LOPCs high speed processing and improved plane provide detection counts at higher resolutions and higher concentrations with lower coincidence. The resolution achievable with the LOPC is a significant improvement over existing technologies, allowing an improved lower detection limit. The design of the LOPC instrument allows it to add on components and optional equipment.

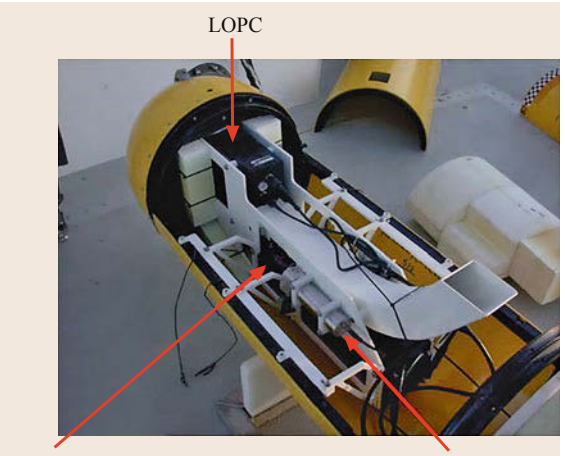

Fig. 18.6 AUV configured with laser optical particle counter and real-time flow imaging and classification (REFLICS) sensor concurrent with the embedded CTD system. Simultaneous deployment of both optical instruments permits geospatially defined particle quantitative and morphological characterizations (image courtesy of MBARI)

An accurate analysis of a large dynamic system like our oceans requires spatially fine and temporally matched data collection methods. The real-time flow imaging and classification (REFLICS) instrument offers higher resolution but at a lower frame rate than the LISST instruments. REFLICS is a method developed to estimate fish stock size from pelagic (marine) fish egg abundance taking point samples. REFLICS enhances

fish egg sampling by obtaining continuous, accurate information on fish egg abundance in the area of interest. REFLICS images the dynamic flow with a progressive-scan area camera and a synchronized strobe that provides backlighting. The strobe illumination allows the camera to acquire a sharp (no motion blur) image of the flow. Digitization and processing occur onboard using an image processing computer. REFLICS is capable of working as an integrated system built up with a number of modules, frequently a CTD, working together to achieve the objective of imaging, detecting, and classifying. REFLICS is also multi-platform capable and has been installed on AUVs. REFLICS is proving to be a cost-effective tool for oceanographers and marine ecologists who need high-resolution real-time data on fish egg distribution and abundance. REFLICS can be improved in several ways, such as integrating a classifier, to be more robust.

18.6 AUV-Based Physical Sensors – Horizons

Historically, physical sensor technology has matured at a faster pace than either chemical or biological sensor technologies. A large industrial base exists for the manufacture of temperature, pressure, and physical property sensors, and consequently there are more examples of these types of sensors on AUVs. However, current AUV-based physical sensor technology does not provide 3-D parametric physical information for water, sediment, and groundwater over spatial scales ranging from the micro to kilometer scale volumes. One particular topic in need of new sensors is fluid transport and fluid velocity for better characterization and understanding of the phenomenon within the associated fields of research. Specifically, there is a need for improved 1-D (one-dimensional) and 3-D flow field information in water and sediments. Additionally, there is also a need to improve the capability of AUV sensors to provide the proper orientation of the sensor in the environment; micro-turbulence measurements are an example of the need for further advancement in this area. Current developments in low power optical systems within the ultra-violet (UV) spectrum for particle detection and characterization are the type of technologies that may be an area of opportunity for the import of innovation in AUV oceanographic research. Discrimination of particles and nanoparticles, including the discrimination of non-biological and biological composition with particle size distribution and shape sensors, in particularly with near real-time response is an example of what is further expected to emerge in AUV sensors systems over time.

18.7 AUV-Chemistry Sensors – Horizons

The categorical space of chemistry is characterized by high level segmentation into classes of compounds and is further fragmented into a vast repository of individual compounds which elude detection by specific chemical sensors. Thus, unlike the physical sensor space, the chemical sensor space is highly fragmented and requires many different instrument configurations to access the variety of challenges associated with the field. A major factor in the lag of chemical sensor maturation relative to physical sensors is a continual issue. Consequently, there will be a continual call from the ocean research community to develop AUV-based chemical sensors for a wide range of compounds in the chemical space for organic, inorganic and biochemical samples within all environmental media, i. e., atmospheric aerosols, sediments and sub-surface waters in and around fresh and marine water systems. To date, there are few sensors that are capable enough to measure multiple chemicals at high acquisition rates, with suitable precision and sensitivity. There is a current need for sensors that can directly detect organic compounds of varying molecular mass along with the structural context, such as lattice cages. Small molecules include methane, halogenated hydrocarbons, and toxins. CO_2 sensors, either optical or chemical, and mass spectrometry are an example of sensing systems that have garnered substantial attention recently and have been placed on AUVs. Sensors having multi-element and/or chemical speciation capability at similar spatial and temporal resolutions will be highly desirable to elucidate environmental processes in 3-D. Multi-sensor packages for simultaneous physical and chemical parameters are essential to future AUV oceanographic research. It is reasonable to believe miniaturization will occur over time with widespread use driving investment from manufacturers. Sensors that can serve as chemical proxies for biological processes are also expected to emerge over time and to help the adoption rate of chem sensors on AUVs.

18.8 AUV-Based Biological Sensors – Horizons

Biological sensors to date have been developed for productivity measurements, species-specific detection, and organism mobility, among other targets. In order to measure biologic reactions and physiological function in ocean ecosystems, additional biosensors will need to emerge. Biological sensors can provide key real-time information on the function, structure, and composition of biologically influenced ocean ecosystems. AUV biosensors will evolve for monitoring all levels of biota, from microbiological (microscopy and imaging) to apex levels in the eukaryotic domain (passive acoustics tags). Future and existing technologies that need to be improved for AUV field deployment include: genomic-based sensors that identify community structure through phylogenetic fingerprinting methods or biological function by detecting gene expression and transcription; and proteomic-based sensors that measure protein expression patterns in biota. Metabolomic-based sensors that measure functional biota metabolic byproducts are a topic area ready for additional AUV-sensor systems development. Similarly to chemical sensors, the bio-space is largely fragmented and will require some revisions for specialized applications. Sensors that measure ocean biotic morphology, the shape and look of the organism in question, as well as sensors that provide reliable quantitative information related to growth rates are opportunities for transport of solutions from terrestrial life science microscopy innovations to the AUV sensing arena. New AUV sensor formats that detect the initiation and extent of primary production, as well as detection of predation levels and additional pathogens, will yield meaningful solutions in time. These would include invasive species and stress indicators along with toxicological responses.

18.9 Autonomous Sampling Systems – Extending Real-Time AUV Sensors

Higher content information of the ecosystems biotic layer is needed and desirable [18.31–33], along with simultaneous chemical and physical measurements. For those biological and chemical measurements that are not feasible by in-situ sensors (for example, isotope tracer measurements), modular high-resolution collection devices provide an approach to supply these difficult measurements. Configurable automated sampling/archiving modules on AUVs provide a solution that combines adaptive field sampling with subsequent analysis of acquired samples on established laboratory instruments using established assays. This sampling-AUV methodology enables complex chem/bio/physical measurements that compliment current and emerging AUV sensors.

Sampling technology will yield programmable systems capable of sampling with offline or online detectors while providing correlated high content information. The methodologies and automated systems can be targeted towards selected targets but with simple modification should be able to capture a wide range of intended chemical/biochemical/particulate material. One example of an adaptive sampling strategy would be the control of high end analytical fluidic sample processors triggered by a co-resident sensor that is commonly available – e.g., a nitrate sensor triggers sampling for isotopic analysis, or a bio-optical or physical sensor triggers the initiation of a confirmatory gene sampler.

This approach is a technology solution for persistent (temporal) and long-range (spatial) AUV derived automated/mobile/adaptive screening and sampling. It can be used for establishing baseline, responding, monitoring, and controlling ecosystems. This single technology can provide a range of adaptive and intelligent support for characterizing indicator chemistry, microbiology, and micro-particulate matter of an ecosystem, before, during, or after some time period. The sampling-AUV is based on three advanced technology components brought together into a unified approach:

1. Autonomous underwater vehicle
2. Adaptive real-time sensing module
3. Robotic fluidic sampler/archival unit.

Such a sensor-triggered robotic sampling system can either augment ship-based surveys or completely eliminate the need for expensive research vessel time while opening the access to the sea further to AUV technology.

18.10 Non-Acoustic Sensor Packaging

Non-acoustic sensors for ocean environment can be more highly affected by ocean deployment conditions than acoustic sensors (Table 18.2). Harsh environment salts, corrosion, vibration-motion, and biofouling will

Table 18.2 Listing of environmental problems and associated solutions for packaging of non-acoustic sensors

Marine environment problem	Approach/solutions
Rapid temperature change	Temperature isolation and compensation
Corrosive medium	Use of ceramics, special plastics, regenerable surfaces
High pressure	Spherical packages: pressure compensation
Bio-fouling	Acid reservoirs and pumps, Cu plating, regenerable surfaces
Energy source-volume limited	Seawater-Al cells for electrical energy
Ingestion	Inert outer casing, no strings or probes
Limited sample concentration	Bio-amplification, plate-strip-detect
Limited radio frequencies (RF) or optical communications range	Acoustic (piezo-based) communication
Limited reagent reservoir	On-board synthesis, microchem. reactors
Particulate concentrations/clogging	Bio-filtering/expendable samplers

affect non-acoustic sensors to a greater degree. Space efficiency is mandated for high packing density of mechanisms and minimal reagent storage, thus 3-D design is important. Heterogeneous materials are typically required for the complex systems: metals, ceramics, polymers, glasses, and composites and synergistic interferences such as electrical-RF-noise, motors, and light sources all become complications in non-acoustic sensor design. Lastly, the internal volume of the pressure vessels that house non-acoustic sensors in many instances also require some gases or solids to maintain a fixed air quality inside the pressure vessels.

18.11 The Essential Need for Sensors

Sensor-AUV-based observations combine the estimation of spatial-temporal distributions and trends for targeted environmental variables. From the sampling perspective, the introduction of new sensor types enables new observational vistas and truer representation of the water column dynamics. Sensors can further help influence the choice of sensing locations and dynamic redeployment of AUV monitoring resources in response to new observations and predictions. Consequently, sensors guide the selection and repositioning of vehicles to improve the estimation of spatially distributed fields under resource and environmental constraints.

Historically, acoustic sensors and non-acoustic optical sensing have been the primary and secondary development areas for sensor-AUV systems beyond physical sensors such as temperature and salinity. Greater space–time coverage and (chem-bio-physical) composition knowledge of the ocean is needed and new non-acoustic sensor technologies will be necessary to address this need.

The state of the ocean faces complex stressors and challenges to its valuable resources [18.34]. These include deterioration of water column and surface water quality, the emergence and increased intensity and duration of events such as harmful algal blooms and hurricanes, microbiological contamination of beaches, loss of reef habitats, and chemical contamination resulting from water usage and coastal runoff. There is a need to understand the processes that are responsible for these changes and to provide potential strategies that might mitigate these problems. Ocean-engineered AUV-based sensing and sampling systems can assist in the effort [18.35]. Automated mobile sensing and mapping of the oceans will have to circumvent the unique challenges related to the heterogeneity of this domain. Further non-acoustic sensors, automatic analyzers, and in-situ monitoring systems (and the associated deployment apparatus) are in an ongoing state of development, field deployment, and validation. However, AUVs augmented with acoustic and non-acoustic chemical/biological and physical sensors continue to be the leading candidate in platform technology to quantify and understand the true composition of the ocean's and its sustainability.

19. Cooperative Vehicle Environmental Monitoring

Naomi Ehrich Leonard

This chapter reviews cooperative control of autonomous vehicles for environmental monitoring with a focus on methodologies that have been designed, deployed, and proven to provide efficient, reliable, and sustained monitoring of the uncertain and inhospitable ocean environment. Vehicles that communicate their state or measure the relative state of other vehicles in the team can cooperate by using feedback control to coordinate their motion as a mobile, reconfigurable sensor array, responding efficiently to changing signals, scales, and conditions in the environment. In a variety of contexts, a vehicle team with judiciously designed cooperative control can outperform the same team with each vehicle controlled independently. For example, cooperative control methodologies have been developed to improve the richness of information in the data that the vehicles collect, their accuracy in feature detection and tracking, and the robustness of their decisions to uncertainty and failures. The chapter begins with a survey of early work on ocean sampling and environmental monitoring, cooperative control, and collective motion. The theory, methodology, and field deployment are then highlighted for two projects on cooperative vehicle monitoring in the coastal ocean that demonstrated the applicability and associated performance advantages of cooperative control. The chapter concludes with a presentation of more recent developments as well as future directions in cooperative vehicle environmental monitoring.

19.1 Motivation

Over the last decade, methodologies for automated cooperative control of robotic vehicles have been designed, deployed, and proven to provide efficient, reliable, and sustained monitoring of the uncertain and inhospitable ocean environment. Unprecedented data sets have been collected from deployments of cooperative vehicles in the field, and both real-time and post-deployment analyses have led to new understanding of the environment. This first decade of success in cooperative vehicle environmental monitoring sets the stage for new opportunities and future gain, especially as the development of cooperative control methodologies can continue to leverage ongoing technological and scientific advances in underwater communication and sensing, energy and computational efficiency, vehicle size, speed, maneuverability and cost, and ocean modeling and prediction.

Indeed, the demonstrated potential of cooperative vehicle control has led to increased demand for fleets of autonomous underwater vehicles (AUVs) for use in measuring ocean physics, biology, chemistry, and geology to improve understanding of natural dynamics and human-influenced changes in the marine environment. Further, methodologies for cooperative control of robotic vehicles in the ocean are readily adaptable to applications on land, in the air and in space; likewise, there is much to be learned from developments in these other domains. The recent explosion in research on networks and complex systems, including investigation of mechanisms that explain a *collective intelligence* exhibited by animal aggregations on the move, are also being leveraged to advance design of cooperative vehicle dynamics.

For environmental monitoring to be successful, physical, chemical, and biological variables must be

measured across a range of spatial and temporal scales; in the ocean the monitoring strategy must also contend with a harsh, three-dimensional physical space that is highly uncertain and dynamic. Small spatial and temporal scales associated with the measured variables typically make a stationary sensor array impractical because a very large number of sensors would be needed to get sufficient resolution in space and/or time. An array of mobile sensors, however, may be very well suited to such a challenge since mobility can be exploited to dynamically distribute fewer sensors according to the spatial and temporal scales.

The underlying principle of cooperative control of vehicles for environmental monitoring leverages mobility of sensors and uses an interacting dynamic among the individual sensors to yield a collective behavior that performs better than the sum of the parts. If the vehicles can communicate their state or measure the relative state of others in the team, then they can cooperate and the cooperative vehicle dynamics can provide coordinated motion of the team as a whole. The resulting vehicle network functions as a dynamically reconfigurable sensor array with a capability for high performance in environmental monitoring not available at the level of individuals. High performance has been demonstrated with cooperative vehicle groups in the ocean in terms of richness of information in measurements, accuracy in feature detection and tracking, and robustness of decisions to uncertainty and failures.

Methodologies for systematic generation of feedback control laws that yield provable collective dynamics have been critical to the successful design of high-performing cooperative vehicle networks. Feedback control refers here to the automated changes that each vehicle makes in response to its measurements of the sampled fields, the relative state of other vehicles in the network, and any additional available measured or computed signals.

Consider, for example, the task of tracking high-density phytoplankton patches in the ocean with a team of AUVs that carry optical sensors for measuring phytoplankton concentration. Suppose also that when any two vehicles in the team are not separated by too great a distance (call them neighbors), they can measure or communicate to each other their relative position and/or velocity. Then, each vehicle can apply a feedback control law, at its sampling or communication frequency, that moves it in the direction of a combination of its best estimate of:

1. The direction of increasing concentration
2. The direction toward its neighbors that are farther than a prescribed separation distance
3. The direction away from its neighbors that are closer than a prescribed minimal separation distance

In ideal conditions, the vehicles will move as a regularly spaced array up the phytoplankton concentration gradient; in real conditions, feedback will provide robustness to noise, uncertainty, and disturbance within bounds. An augmentation to this feedback law to further reduce error due to noisy measurements has each vehicle compute a local estimate of the optimal vehicle array resolution for gradient climbing accuracy and then adapt the prescribed separation distances between neighbors to achieve this resolution.

Consider, as another example, the task of providing dynamic sampling coverage of the changing phytoplankton patches over a fixed region with this same team of AUVs. The goal is to enable the vehicles to efficiently sample the patches across the region so that the data can be used to map the phytoplankton patches with minimal mapping error. Each vehicle can apply a feedback control law in response to where its neighbors are collecting data and in accordance with priors on spatial and temporal scales associated with the phytoplankton patches. The feedback control law moves it toward a location that is easily accessible, is away from others, and has not been recently sampled. In this case in ideal conditions, the vehicle network will cooperatively perform dynamic sampling coverage of the patches over the region; in real conditions, feedback will provide robustness to some noise, uncertainty, and disturbance. An augmentation to this feedback law has each vehicle compute a local estimate of changing spatial and temporal scales to update its priors and adapt how far from other vehicles to move and how frequently to re-sample previously sampled locations.

Feedback has also been used to *close the loop* between cooperating vehicle networks and advanced ocean models when data collected by the vehicle network can be made available for assimilation into the ocean models and the ocean model predictions can be made available to one or more of the vehicles. In the first example of tracking high-density phytoplankton patches, the feedback with ocean models allows individual vehicles to modify their gradient climb based on predictions of high-density locations. In the second example of dynamic sampling coverage in a fixed region, the feedback with ocean models provides enhanced estimates of uncertainty so that individuals could bias their motion toward sampling locations with the greatest possibility of minimizing uncertainty in the mapping. Forecasts of ocean currents are also useful for navigation.

Cooperative feedback control makes possible a vehicle network that is autonomous, versatile, and robust to noise and uncertainty. Further, when each vehicle has the same feedback law, the vehicle network has an added robustness to vehicle failures or additions since an ordering of the vehicles is unnecessary and in particular the system does not depend on any special individuals. Other promising opportunities have been explored with a heterogeneous group of vehicles. In these cases, feedback can be used for cooperative subtask allocation or coordinated complementary actions: for example, slow-moving autonomous underwater gliders can provide coverage and fast-moving propelled underwater vehicles can be allocated to relay information and to move to *hot spots* at great speed. Similarly, unmanned aerial vehicles (UAVs) can provide large-scale mapping of sea-surface fields and AUVs can complement with in-depth feature tracking below the surface. In this chapter, we describe two projects in cooperative vehicle environmental monitoring with extensive field deployment in the coastal ocean that demonstrated for the first time at large scale and over several weeks the applicability and associated performance advantages of cooperative control methodologies for mobile sensor networks in the ocean. The first of these was the autonomous ocean sampling network (AOSN) II project [19.1, 2] with its field experiment in Monterey Bay, CA, over the month of August 2003 and the second was the adaptive sampling and prediction (ASAP) project with its field experiment in Monterey Bay, CA, over the month of August 2006 [19.3].

For AOSN-II, a methodology was designed [19.4] and demonstrated [19.5] that featured small networks of autonomous underwater gliders cooperating to compute temperature gradients and track cold upwelled water. The gliders were also used to demonstrate autonomous coordination of their motion to sample along the path of drifters and thus increase measurement density along fronts. For ASAP, a methodology was designed [19.6] and demonstrated [19.3] that featured a network of 10 gliders (of two types) to optimize dynamic sampling coverage, minimizing uncertainty for estimation of temperature, salinity, and currents in a large coastal region just north of Monterey Bay. In both field experiments, three numerical ocean models ran in near real time, assimilating data collected by the gliders and providing estimates and predictions that were used in the gliders' adaptive motion planning. Additional real-time data were provided by a research aircraft, satellite imagery, high-frequency radar, moorings, drifters, and propelled vehicles. In the ASAP experiment, the cooperative behavior of a network of six gliders ran autonomously without failure for almost 24 days straight.

An important factor in the success of the AOSN-II and the ASAP projects was the strong multidisciplinary collaboration among researchers with expertise in ocean science, vehicle dynamics, and control and dynamical systems theory. The methodologies developed drew inspiration from earlier work in ocean sampling and environmental monitoring, cooperative control, and collective motion; we present background and history on these subjects in Sect. 19.2. The AOSN-II and ASAP programs in cooperative vehicle ocean monitoring, from theory through full-scale ocean deployment, are reviewed in Sect. 19.3. More recent developments and future directions in cooperative vehicle environmental monitoring are described in Sect. 19.4.

19.2 Background and History

The autonomous oceanographic sampling network (AOSN) was introduced in 1993 by *Curtin* et al. [19.7] as an approach for dynamic measurement of the ocean environment and resolution of spatial and temporal gradients in the sampled fields. At that time most oceanographic data were collected from satellites, ships with towed underwater profilers, and arrays of moorings and floats. The AOSN concept was to deploy AUVs to take measurements that would complement those from distributed point sensors such as moorings and from remote sensors such as satellites, and enable adaptive sampling to improve forecast skill; the AOSN system would operate successfully with the use of acoustic and radio modems for communication and docking stations for recharging AUV batteries. It was anticipated that control would be critical for the AUVs to accomplish complex missions in the presence of uncertainties and real-world constraints, and that coordinated control of the multiple vehicles would lead to system efficiency and endurance. *Bellingham* described in [19.8] how nested approaches would allow sampling the ocean over a range of spatial and temporal scales.

The vision of an integrated ocean monitoring system was made possible with the development of small, relatively inexpensive AUVs. Propelled AUVs such as the autonomous benthic explorer (ABE) [19.9], the Odyssey [19.10], and the REMUS [19.11] were designed to provide maneuverability and speed. Buoyancy-driven autonomous underwater gliders, including the Slocum [19.12], Spray [19.13]

and Seaglider [19.14], were designed to provide endurance [19.15, 16]. ABE was used to map the sea bottom and to search out and study deep-sea hydrothermal vent sites and volcanoes [19.17–20]. The Odyssey vehicle was used in experiments under the ice in the Arctic [19.21]. REMUS was equipped with optical sensors and used to measure bioluminescence [19.22, 23]. Seagliders were sent on 5-month-long missions to measure physics, biology and chemistry off the coast of Washington and in the Labrador Sea [19.15]. Slocum gliders were introduced as an integral part of the long-term ecosystem observatory (LEO), an integrated observatory off the coast of New Jersey [19.24–26].

An early example of a control architecture design for multiple AUVs was described in 1987 by *Albus* and *Blidberg* in [19.27]: the architecture was designed to enable two AUVs to perform cooperative search, approach, and mapping using cooperative maneuvers such as *fly-formation*, *circle-split-and-rendezvous*, and *leader-follower*. In [19.28] the objective was to use multiple AUVs as an imaging system. Virtual chains of AUVs were considered by *Triantafyllou* and *Streitlien* in [19.29]; a technology for one vehicle to track another in a chain-like fashion using an ultrashort baseline (USBL) acoustic tracking system was demonstrated by *Singh* et al. [19.30] in Buzzards Bay off Woods Hole, MA in March 1996. In June 1996, two Odyssey vehicles were used along with an acoustic tomography network for mapping in the Haro Strait region of British Columbia [19.31]. *Stilwell* and *Bishop* presented a decentralized control framework for a cooperative platoon of AUVs in [19.32]. Formation flying to map salinity fronts was tested in the North River in North Carolina using the Ranger micro-AUV [19.33].

A 1997 survey by *Cao* et al. [19.34] described cooperative mobile robotics as a still emerging field rich with opportunities. The robotics community became heavily engaged in the late 1980s first with a focus on simulation [19.35, 36] and then physical implementations [19.37, 38]. Collective behavior in animal groups was an early inspiration [19.39], with a behavioral-based approach becoming popular in the 1990s [19.40]. However, according to [19.34] in 1997, *few applications of cooperative robotics* had been reported, and supporting theory was *still in its formative stages*.

Interest in very large-scale stationary sensor networks surged with advances in wireless communication technology and microsensors, and environmental monitoring was an early, important application driver for development of network architectures and algorithms in this context [19.41–44]. Energy considerations were used to justify the use of large numbers of stationary sensors over mobile sensors. However, the balance tipped the other way in the case of undersea sensing due to the challenges of undersea communication and the emergence of relatively inexpensive, high-endurance vehicles such as the autonomous underwater gliders.

Bretherton et al. [19.45] in the 1970s applied the technique of objective analysis (OA) [19.46], which uses classical linear estimation theory to compute objective maps, to address the problem of deployment design for an array of stationary or passively drifting sensors in the ocean where the aim was to provide coverage and minimize uncertainty in the estimates made from the data collected. Adaptive ocean sampling, as in [19.47], built on this concept to consider the design of a trajectory for a mobile sensor platform, complementing another sensor platform moving along a predetermined track, in order to minimize uncertainty in an ocean forecasting model. A performance metric that accounts for both spatial and temporal sampling requirements was derived by *Wilcox* et al. [19.48]; it was used to evaluate oceanographic survey performance with AUVs in [19.49]. A methodology for control of multiple sensor platforms based on information theory was presented in [19.50] and sampling strategies driven by distributed parameter estimation were described in [19.51, 52].

Motivated by the many potential applications and the rich theoretical possibilities, researchers in the control theory community began a significant effort in the early 2000s to use systems theoretic approaches to design and study cooperative control. Artificial potentials presented an attractive methodological basis for cooperative control of network formations [19.53–58] both because convergence and performance could be proved using Lyapunov stability theory (see early work on robot navigation and obstacle avoidance [19.59, 60]) and because control laws derived from artificial potentials resembled the distributed, cohesive, and repulsive forces used to model animals that move together [19.61, 62].

Artificial potential methods were also used to design cooperative gradient climbing strategies for a group of vehicles that could each only take a scalar measurement at a time of the field of interest (e.g., ocean temperature) [19.63]. Capitalizing on this idea and building on the methods of [19.55, 56], *Ögren* et al. [19.4] developed a provable methodology to control the shape of the formation as well as the rotation, translation, and expansion of the formation [19.64]; this was used to design control strategies for a network of vehicles to adaptively climb gradients in the sampled field and thus robustly find peaks (Sect. 19.3.1 below reviews the implementation of this methodology in the field). These ideas were extended further by *Zhang* and *Leonard* [19.65, 66] to design provable control laws for cooperative level set tracking, whereby small

vehicle groups could cooperate to generate contour plots of noisy, unknown fields, adjusting their formation shape to provide optimal filtering of their noisy measurements. Related work addressed environmental boundary tracking [19.67, 68], coverage control [19.69, 70], target tracking [19.71, 72], and maximization of information [19.50].

Researchers in control also took a strong interest in the dynamics of consensus within a network; the topology of the sensing and communication interconnections among agents was encoded using graphs, and the convergence of consensus dynamics was proved with approaches that exploited graph theory allowing for time-varying communication graphs and time-delayed communications [19.73–77]. Consensus in the positions of agents was used to address a variety of other problems including formations [19.78] and rendezvous [19.79].

In most of this consensus literature the dynamics are linear, and yet the problem of consensus on direction of motion that mobile robots must make is nonlinear, since the space of directions in the plane is a circle (and not a line). Consensus on the circle is called synchronization, and it has been studied extensively in the context of coupled phase oscillators used to model a variety of interconnected periodic processes in biology and physics (firefly flashing and neuron firing) [19.80, 81]. *Justh* and *Krishnaprasad* developed a geometric framework to design steering control laws to coordinate the motion of vehicles in [19.82]. This approach was generalized in the work of *Sepulchre* et al. [19.83, 84] using a model that extends coupled oscillator dynamics, in which the phase of each oscillator represents the direction of motion of a vehicle, to include the spatial dimensions, which represent the positions of the vehicles. These works provided a systematic methodology for designing provable, distributed control laws that stabilize motion patterns in the plane ([19.85–87] for 3-D); each vehicle uses a feedback law that depends only on what limited measurements it can make, and the controlled system can cope with a time-varying communication network and with real-time changes in the number of vehicles in the group. Because the methodology is systematic and robust and because distributed control of vehicle motion patterns is central to environmental monitoring, the methodology of [19.83, 84] was developed into an adaptive sampling methodology for mobile sensor networks in the ocean [19.6] (Sect. 19.3.2 below reviews the implementation of this methodology in the field).

19.3 Advances in Cooperative Vehicle Ocean Monitoring

The AOSN II and ASAP projects were driven by an interest in developing sustainable, portable, adaptive ocean observing and prediction systems for use in coastal environments. The projects used cooperating AUVs carrying sensors to measure the physics and biology in the ocean together with advanced ocean models in an effort to improve the ability to observe and predict ocean dynamics. A central focus was on reliable, efficient and adaptive coordinated control strategies for mobile sensor platforms to collect data of high value. Both the AOSN II and ASAP experiments were designed to bring together new techniques in sensing, forecasting and coordinated control; see [19.88] for a summary of goals and progress. The 2003 AOSN II experiment brought these techniques together for the first time, yielding an unprecedented data set. The 2006 ASAP experiment fully integrated these techniques to even greater benefit, demonstrating their potential in a versatile and high-performing adaptive coastal ocean observing and prediction system. The methodologies derived, integrated, and demonstrated are adaptable to a wide variety of environmental monitoring problems and settings.

19.3.1 Cooperative Gliders in AOSN II

In summer 2003, a multidisciplinary research group as part of the AOSN II project produced an unprecedented in-situ observational capability for studying upwelling features in Monterey Bay over the course of a month-long field experiment [19.1, 2]. A highlight was the simultaneous deployment of more than a dozen, sensor-equipped, autonomous underwater gliders [19.15], including 5 Spray gliders (Scripps Institution of Oceanography, La Jolla, CA) and up to 10 Slocum gliders (Woods Hole Oceanographic Institution (WHOI), Woods Hole, MA). Autonomous underwater gliders are high endurance, buoyancy-driven vehicles that move up and down in the ocean by controlling their net buoyancy using pumping systems. Their fixed wings and tail give them lift, which helps them make forward progress by following sawtooth-shaped trajectories. To control their attitude, gliders actively redistribute internal mass. The Slocum uses a rudder to control heading, and the Spray shifts mass to the side to roll, bank, and turn. During the field experiment, the gliders were operated to achieve a fixed velocity relative to the flow. Their effec-

tive forward speed was of the same order as the stronger currents in and around Monterey Bay: $\approx 25\,\mathrm{cm\,s^{-1}}$ in the case of Spray and $35\,\mathrm{cm\,s^{-1}}$ in the case of Slocum. Thus, when the currents were too strong, the gliders did not make progress if they were moving against the currents.

As part of the field experiment, sea trials were run with groups of three Slocum gliders controlled into triangular formations [19.5]; see also [19.6] for a survey. Feature-tracking capabilities of the glider formations were demonstrated under the challenging conditions of limited communication and limited feedback as well as a strong flow field. Two sea trials tested strategies for cooperative motion control and cooperative gradient estimation for the gliders at relatively small scales in the region, i. e., on the order of 3 km. In a third sea trial, a Slocum glider was used to track a Lagrangian drifter in real time and collect data in a volume surrounding the path of the drifter. This demonstrated the utility of a glider, and the possibilities for a network of gliders, to track Lagrangian particle features such as a water mass encompassing an algal bloom [19.5].

The Slocum gliders were operated to 200 m depth and were deployed far enough from the coast to avoid shallower water. Each glider surfaced every couple of hours, although the gliders did not surface synchronously. At the surface, each glider got a global positioning system (GPS) fix for navigation, and using Iridium satellite and ethernet, sent back to shore the data it had collected and received updated mission commands from the shore computer. Since the gliders were not equipped with underwater communication, the communication with the shore computers was the only means for (indirect) communication between gliders.

The strategy for coordinated motion control was based on the *virtual body and artificial potential* (VBAP) methodology for control of multiple vehicles described in [19.4]. VBAP is a general coordinated control strategy that stabilizes the translation, rotation, and expansion of a formation of autonomous vehicles; it is especially well suited to missions that require a changeable mobile sensor array such as gradient climbing in a scalar, sampled field, where expansion and contraction of the network modify the resolution of the array. The virtual body refers to a collection of moving reference points, each with dynamics that are computed centrally and made available to the autonomous vehicles. Spring-like control forces for the vehicles, and the virtual body, are derived from artificial potentials between the vehicles and the virtual body; they are designed to stabilize the dynamics of the vehicles and the virtual body into a formation. In the computation of its control law, each vehicle uses a measurement of the relative position of neighboring vehicles and nearby reference points on the virtual body.

The local gradients of a sampled scalar field can be estimated on-board or centrally, if the samples taken on-board the vehicles can be communicated among them or to a central computer. The group will control its motion in the direction of the gradient if the virtual body dynamics are designed to move it in the direction of the gradient; for example, if the dynamics of the virtual body move it toward the coldest water, as determined from an estimated temperature gradient, the vehicle group will move toward the coldest water as well since it moves with the virtual body in formation. In the VBAP methodology, stability and convergence of the vehicle formation is guaranteed with a feedback control on the speed of the virtual body.

Ideal assumptions, including continuous communication and feedback for the autonomous vehicles, were used to prove the control theory and algorithms described in [19.4]. Thus, in order to make the control methodology applicable to the conditions of the cooperative control sea trials of 2003, the VBAP control methodology was modified in a few key ways. For example, the algorithms were integrated with the on-board glider waypoint tracking routine and adjusted to accommodate the constant speed of the gliders, the high-speed ocean currents, the asynchronous surfacings of the gliders, as well as other latencies [19.89]. The approach was later systematized as part of the ASAP project in a fully automated software suite, the glider coordinated control system (GCCS) [19.90]. The GCCS automates the decentralized coordinated control methodology of [19.6] for adaptive sampling motion patterns.

The main idea behind the integration of VBAP with waypoint control was to use VBAP to produce waypoint lists, corresponding to coordinated glider trajectories, that the gliders would then follow using their on-board waypoint control [19.5, 89]. Accordingly, VBAP was run in a *planning* mode using a simulation of the gliders with initial conditions defined by the gliders' most recent GPS fixes and average flow measurements. The VBAP-planned trajectories were discretized into waypoint lists. Each Slocum glider uploaded its waypoint list when it surfaced, and followed those waypoints for the subsequent 2 h until its next surfacing.

For the Slocum vehicles, a waypoint is prescribed as a vertical cylinder in the ocean since it refers to a position in the horizontal plane and a radius that sets how close the vehicle should come to the waypoint position. Thus, when a sequence of waypoints is prescribed, the glider follows the waypoints by passing through each of the corresponding cylinders in the prescribed sequence. To follow a sequence of waypoints, each glider uses its on-board low-level heading control which depends

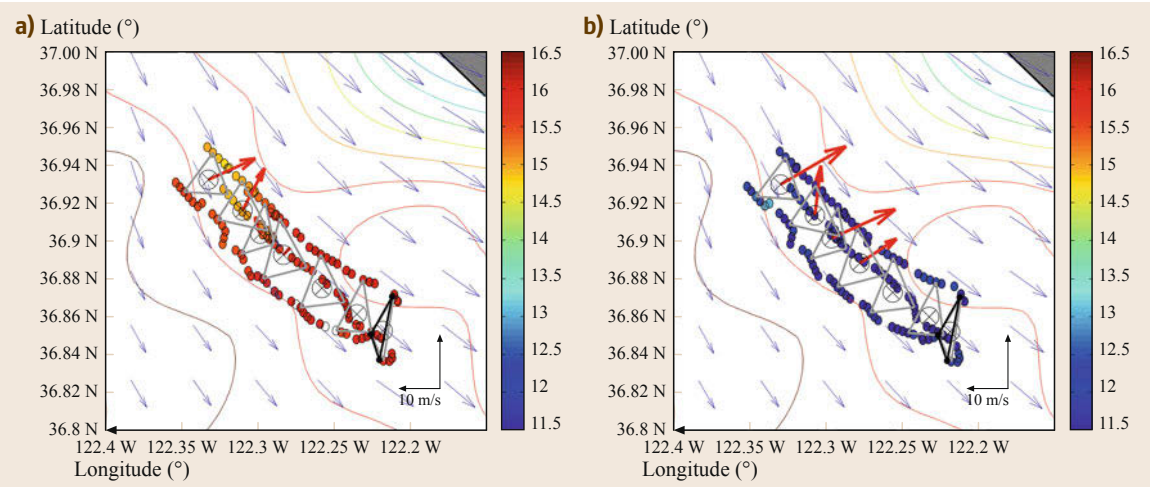

Fig. 19.1a,b From [19.2]. Three gliders moving northwest in triangular formation (*gray lines*) from 18:00 GMT August 6 into late morning August 7, 2003. *Colored dots* indicate the temperature in degree Celsius (see color scale) at **(a)** 5 m depth and **(b)** 30 m depth. *Black circles and lines* show initial position and formation, and *open circles with a cross inside triangles* illustrate the path of the center of the triangle formation. *Red arrows* correspond to estimate of the negative gradient of temperature in the horizontal plane along the path of the center of the triangular formation. The *color contours* indicate sea-surface temperature in degree Celsius (see color scale) as sampled by the Naval postgraduate school's TWIN OTTER aircraft

on its own heading (measured on-board) and a deduced reckoning estimate of its own position [19.91]. The deduced reckoning position is computed by integrating an estimate of horizontal speed using the most recent GPS fix as the initial condition. The horizontal speed is estimated from depth and vertical speed, which are estimated from on-board pressure measurements. The method also uses the glider's estimate of average flow, computed from the difference on the surface between its GPS and its deduced reckoned position.

The first sea trial in which three Slocum gliders coordinated their motion in an equilateral triangle formation was run over a period of 16 h on August 6–7, 2003, with asynchronous 2-hourly surfacings. The distance between gliders was prescribed to be 3 km and the formation prescribed to move along a linear path heading northwest to measure the incipient upwelling front. In the first half of the sea trial, there was no prescription on the orientation of the formation so that it could most efficiently maintain array resolution and follow its path. In the second half of the sea trial, to test the orientation control feature of the methodology, the orientation was prescribed such that one edge of the triangle would always be normal to the path of the center of mass of the group. The stable tracking of prescribed glider array resolution and linear path made it possible for in-situ estimates of gradients to be computed in near real time from the gliders' scalar measurements. The results suggest that the gliders could successfully be programmed to autonomously follow their estimate of the gradient if so desired.

Figure 19.1 shows a sequence of snapshots of the triangular glider formation over the August 6–7, 2003 sea trial. Temperature measurements are shown on 19.1a at 10 m depth and on 19.1b at 30 m depth. As shown, the three vehicles stayed in formation moving along the desired linear path despite relatively high-speed currents. The red arrows on the plot show a few example glider estimates of the negative gradient of temperature. These vectors point in the direction of the cold water, as verified from independent temperature measurements. The resolution corresponding to 3 km between gliders led to remarkably smooth gradient estimates over time.

Three gliders again coordinated their motion in an equilateral triangle formation in a second sea trial on August 16–17, 2003. This time the distance between gliders was prescribed to start at 6 km and then contract to 3 km. This was meant to demonstrate the expansion and contraction feature of the methodology and test the effect of the different glider array resolutions on the gradient estimates. The formation was prescribed to move along a zigzag path heading southwest across the upwelling front. Despite facing currents with magnitude as high as the Slocum's effective speed of 35 cm s^{-1}, the glider formation moved and contracted remarkably well. The results suggest that the gliders could successfully be programmed to autonomously adapt their

formation size in response to changing scales in the sampled field.

In the August 6–7 sea trial, the coordinated glider network measured the front close to its inception, while in the August 16–17 sea trial, the network measured the front after it had been advected further to the south across the mouth of Monterey Bay [19.2]. As a result, the data collected from these two sea trials added new insight into the evolving vertical structure of the upwelling plume. Notably, the gradient estimates from the glider networks would not have been possible using conventional profiling floats or drifters. Since frontal dynamics are typically nonlinear, precise gradient estimates are critical in forecasting frontogenesis and evolving instabilities.

In the third sea trial on August 23, 2003, a single glider followed a surface drifter in real time, making zigzags across and below its projected path. This demonstrated yet another opportunity for environmental monitoring with coordinated vehicles, namely that a glider or glider formation could collect scalar samples and thus estimate gradients both across and along tracer paths.

19.3.2 Cooperative Gliders in ASAP

In summer 2006, a multidisciplinary research group as part of the ASAP project performed an unprecedented field experiment, building on the successful efforts of the AOSN II project. The ASAP project demonstrated a full-scale adaptive ocean sampling network featuring a coordinated network of gliders controlled autonomously over the course of a month to efficiently sample a $22 \times 40\,\mathrm{km}^2$ and up to more than 1000 m-deep region of coastal ocean just northwest of Monterey Bay as shown in Fig. 19.2 [19.3]. The coordinated sampling of the gliders was integrated with an assortment of additional mobile and stationary sensing platforms, three real-time numerical ocean models, numerical optimization and prediction tools, a virtual control room, and a participating team of scientists.

When gliders move without taking into account, for example, through feedback, the relative position or motion of other gliders in the group, they are susceptible to strong currents driving them into clumps. In the AOSN II experiment current-driven clumping was observed and shown to lead to sensor redundancy with negative impact on sampling performance [19.6]. This motivated the development of coordinating feedback control laws that enforce dynamic distribution of vehicles to enhance sampling performance. The methodology proposed and justified in [19.6] provides this coordinated feedback control with two components: (1) the design of coordinated motion patterns for high-performance sampling and (2) the design of feedback control laws that systematically and automatically stabilize vehicles onto the desired coordinated patterns. The methodology of [19.6] was implemented in the 2006 ASAP experiment, which provided a proof of concept for the applicability of the methodology to the field.

The methodology proposed in [19.83, 84] was used for the second component, the systematic generation of feedback control laws for stable coordination of a network of autonomous vehicles to a family of motion patterns. The patterns, which consist of vehicles moving on a finite set of closed curves, are distinguished by a small number of parameters that encode synchrony. For example, two vehicles that move in parallel around two separate curves have synchronized heading directions, while two vehicles that move around the same curve but always on opposite sides of the curve have anti-synchronized heading directions. The corresponding feedback laws the vehicles use are likewise distinguished by control gains that depend on the same small number of synchrony parameters.

The control laws are distributed, which means that each vehicle applies its own control law that depends on its own measurements. Furthermore, the control laws are reactive, they do not require a prescription of where each vehicle should be as a function of time, but rather each vehicle moves in response to the relative position and direction of its neighbors. Each vehicle is constantly adjusting what it does to keep moving, to stay close to its assigned curve, and importantly to maintain the desired spacing with respect to the other vehicles, as encoded by the synchrony parameters. Because the responsive behavior of each individual can be defined as a function of the state of a small number of other vehicles, independent of the total number of vehicles, the control methodology is scalable. And because there are no leaders or special individuals in the network, the methodology is robust to vehicle failure.

The GCCS software infrastructure described in [19.90] and tested in [19.92] was used to implement the methodology in the field. In the ASAP experiment, it was observed that vehicles maintain their prescribed relative spacing in the presence of strong currents by moving off their assigned curve as needed: when a vehicle was slowed down by a strong opposing flow field, it cut inside its curve to make up distance, while its neighbor on the other side of the curve that was sped up by the strong current cut outside the curve to avoid overtaking the slower vehicle and compromising spacing.

There are several advantages to designing the coordinated motion patterns independently from the design of control laws to stabilize vehicles to those motion patterns. First, the patterns can be independently chosen to

optimize a sampling performance metric. Second, the pattern can be chosen for minimal performance sensitivity to disturbances in vehicle motion. Additionally, the pattern can be chosen to account for design requirements and constraints, such as avoiding or focusing on certain regions, leveraging information on the direction of strong currents so vehicles move with them rather than against them, and accommodating additions or removals of vehicles. Human-in-the-loop supervisory control, which can be critical for highly complex settings, can be fairly easily integrated when it is warranted. In the ASAP experiment, a team of scientists made supervisory decisions based on visualizations of observational data, modeling output, system performance, and availability of vehicles. A method was in place to translate these decisions into formal adaptations of the desired motion patterns, which could be refined using numerical optimization tools. To implement an adaptation, an intermittent, discrete change in the pattern was input to the GCCS and the vehicle network responded accordingly.

The sampling metric used to design motion patterns [19.6] is computed from the mapping error of the data assimilation scheme known as OA [19.45, 46]. OA provides a linear statistical estimation of a sampled field, and the mapping error measures the residual uncertainty. OA mapping error is a sampling performance metric since reduced uncertainty implies better measurement coverage. The mapping error at a given position and time is the error variance at that position and time. It can be computed from an empirically derived model of the covariance of fluctuations of the sampled field about its mean and from where and when data are taken. The OA mapping error is plotted in gray scale in Fig. 19.2b on the sampling domain. The sampling metric is computed as the negative log of the integral of the mapping error over the sampling region. In the ASAP experiment, the mapping error was computed in real time so that humans making adaptation decision could evaluate sampling performance.

An examination of the oceanographic and atmospheric conditions during the ASAP experiment using data and model output is described in [19.93]. The oceanographic focus of the ASAP experiment was the [19.3]

> *three-dimensional dynamics of the coastal upwelling frontal zone in Monterey Bay and the processes governing the heat budget of the* $22 \times 40\,\mathrm{km}^2$ *control volume during periods of upwelling-favorable winds and wind relaxations.*

An objective for the coordinated glider sampling was to be responsive to the dynamics of intermittent upwelling events.

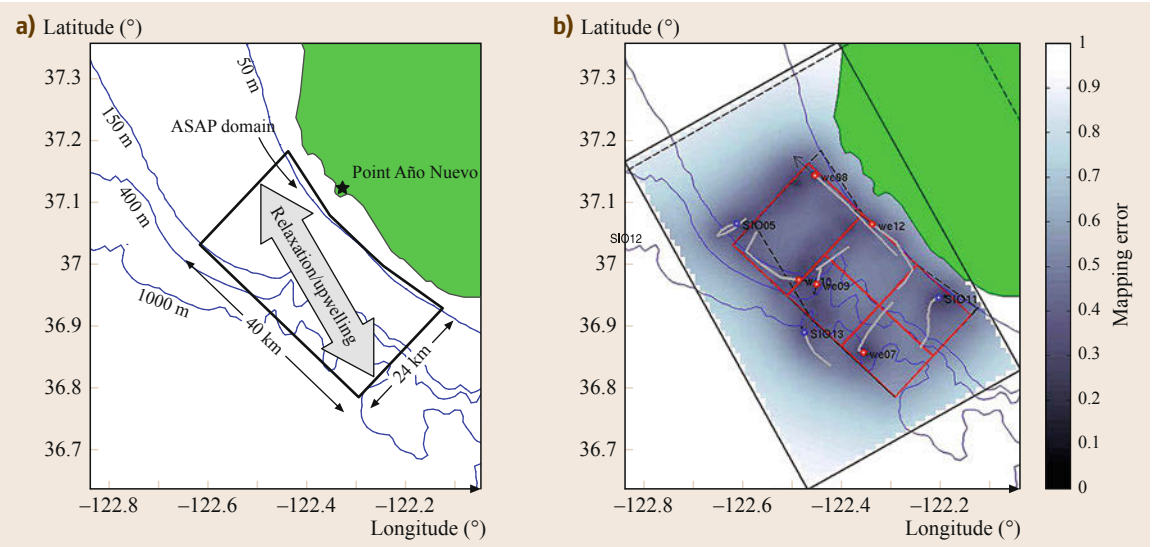

Fig. 19.2a,b From [19.3]. **(a)** Region of glider fleet operations in the 2006 ASAP field experiment, just northwest of Monterey Bay, California. The summertime ocean circulation in Monterey Bay oscillates between upwelling and relaxation. During an upwelling event, cold water often surfaces just north of the bay, near Point Año Nuevo and tends to flow southward across the mouth of the bay. During relaxation, poleward surface flow crosses the mouth of the bay past Point Año Nuevo. **(b)** Objective analysis mapping error plotted in *gray scale* on the ASAP sampling domain for July 30, 2006 at 23:30 GMT (Greenwich mean time); see text for details on the mapping error. Eight gliders are shown; their positions are indicated with *red* (Slocum) and *blue circles* (Spray)

Data were collected during the experiment from other sources as well as the gliders. These include a Naval postgraduate school research aircraft, satellite imagery, high-frequency radar, and several moorings, drifters deployed by the Monterey Bay Aquarium Research Institute (MBARI) and other ships and vehicles outside the control volume. Three different high-resolution ocean models regularly assimilated data: the Harvard Ocean Prediction System (HOPS) [19.94], the Jet Propulsion Laboratory implementation of the Regional Oceanic Modeling System (JPL/ROMS) [19.95] and the Navy Coastal Ocean Model/Innovative Coastal Ocean Observing Network (NCOM/ICON) [19.96]. Each model produced daily updated ocean predictions of temperature, salinity, and velocity. A central data server at MBARI was used to run a virtual control room (VCR) and to make all observational data and model outputs available in near real time. The VCR, developed for the 2006 ASAP field experiment, made it possible for participants to remain at their home institutions throughout the experiment but still be fully informed and connected team members [19.97]. There were a number of different panels on the VCR including those for team decision making and voting.

Virtual pilot experiments were run in advance of the field experiment to get experience with the coordinated control and adaptive sampling implementation. The virtual experiments were run as if they were real field experiments except for the replacement of real vehicles in the real ocean with simulated vehicles moving in the currents of a virtual ocean defined by a HOPS re-analysis of Monterey Bay in 2003. The simulation mode of the GCCS was designed to allow for virtual experiments with control of gliders, communication paths, and data flow exactly the same as what was used in the 2006 field experiment [19.90, 98].

For the ASAP experiment, the Slocum gliders were allocated to mapping the interior volume using automated coordinated sampling defined by motion patterns on a finite set of closed curves, with properties between measured paths inferred using interpolation. The automated feedback control laws for the Slocums were implemented with the GCCS. The Spray gliders were allocated to mapping the periphery of the volume. The boundary was divided up into segments and each Spray glider was assigned to move in an oscillatory manner along a segment of the boundary. A separate control law was implemented for this oscillatory behavior so the gliders were well distributed. The experiment started with a default coordinated motion pattern, and as the environment and operating conditions changed, the coordinated motion pattern was re-designed and updated.

The input file to the GCCS that defines a coordinated motion pattern is called a *glider coordinated trajectory* (GCT). As an example, GCT #2 used for the Slocum gliders in the ASAP experiment is illustrated in Fig. 19.3a. A GCT defines the curves that serve as tracks for the gliders as well as the synchronization of the motion of the gliders on and across the different curves. For example, the GCT #2 shown in Fig. 19.3a defines a pattern in which a pair of gliders, denoted with red circles, moves around the red curve with maximal intervehicle spacing and is synchronized with another pair of gliders, denoted with green circles, that moves around the green curve with maximal intervehicle spacing. The glider planner status panel of the VCR on July 30 at 23:10 GMT, when GCT #2 was active, is shown in Fig. 19.3b. The glider planner panel for OA mapping error at roughly the same time is shown in Fig. 19.4.

Pseudoelliptical curves were selected for the Slocums since they had nearly straight long sides. The curves were oriented to ensure that the gliders would repeatedly cross over the shelf break, each time sampling a cross-section of the dynamic ocean processes that propagate parallel to the shelf break. The shelf break refers to the end of the continental shelf characterized by a markedly increased slope toward the deep ocean bottom [19.3]:

> *By constructing a time sequence of cross-section plots, it would then be possible to reconstruct, identify and monitor ocean processes even before assimilating the glider profile data into an advanced ocean model.*

The distribution (synchronization) of the gliders relative to one another around the curves, as well as the dimensions and position of the curves, were selected to maximize the sampling performance metric. An on-line optimization tool was available for locally optimizing any candidate motion pattern. Additionally, candidate coordinated motion patterns were often pretested using the GCCS in simulation mode using one or more of the forecast ocean fields. Because the simulations of gliders moving in the forecast ocean could be run in faster than real time, it was possible to obtain predictions of glider performance in the predicted real ocean.

To implement an adaptation to sampling plans, a new GCT was prepared to replace the existing GCT. This was initiated manually by briefly interrupting the GCCS, swapping the new GCT file for the old one, and then re-starting the GCCS. Over 24 days of the ASAP experiment, 14 different GCTs were used to adapt the Slocum glider plan (Fig. 19.4a). Some of the adaptations were made in response to changes in the ocean involving strong and highly variable flow conditions. Other adaptations were made in response to changes in scientific objectives, for example, to add sampling over the head of the canyon and to chase an eddy moving off-

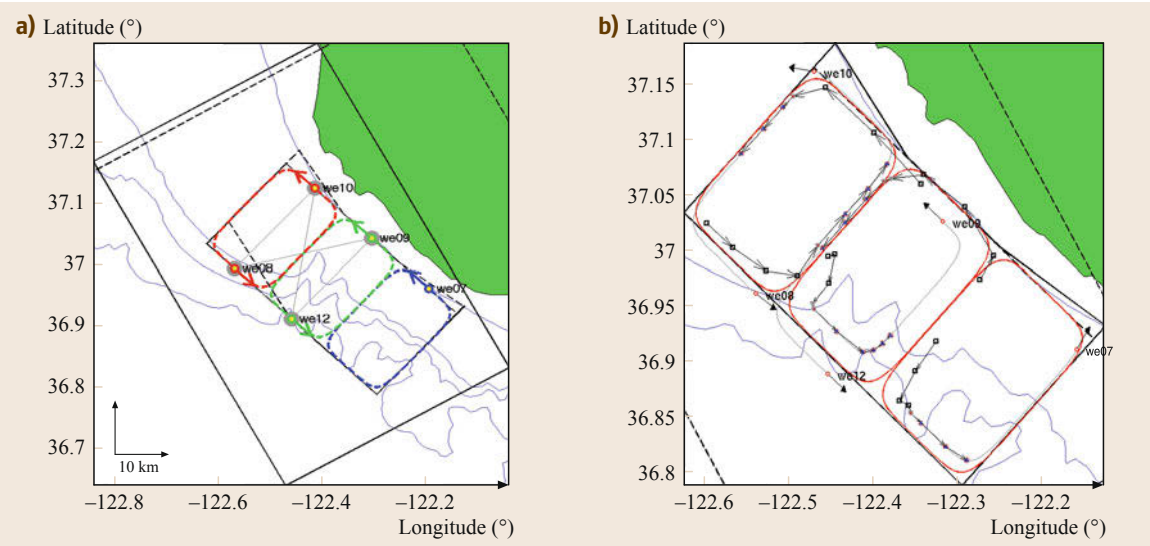

Fig. 19.3a,b From [19.3]. **(a)** The coordinated pattern for four of five Slocum gliders already in the water at the end of July 2006, with the pair we08 and we10 to move on opposites of the north track (*red*), the pair we09 and we12 on opposites of the middle track (*green*) and the two pairs synchronized on their respective tracks. Glider we07 should move independently around the south track. The *dashed lines* show the superelliptical tracks, the *circles* show a snapshot of the glider positions. The *thin gray lines* show the feedback interconnection topology for coordination and the *arrows* show prescribed direction of rotation. **(b)** A snapshot of one of the VCR panels, which was updated every minute. It presents, for each glider, surfacings over the previous 12 h (*black squares*), waypoints expected to be reached before the next surfacing (*gray triangle*), next predicted surfacing (*gray circle with red fill*), new waypoints over the next 6 h (*blue triangles inside red circles*), and planned position in 24 h (*hollow red circle*). Each glider is identified with a label at the planned position in 24 h

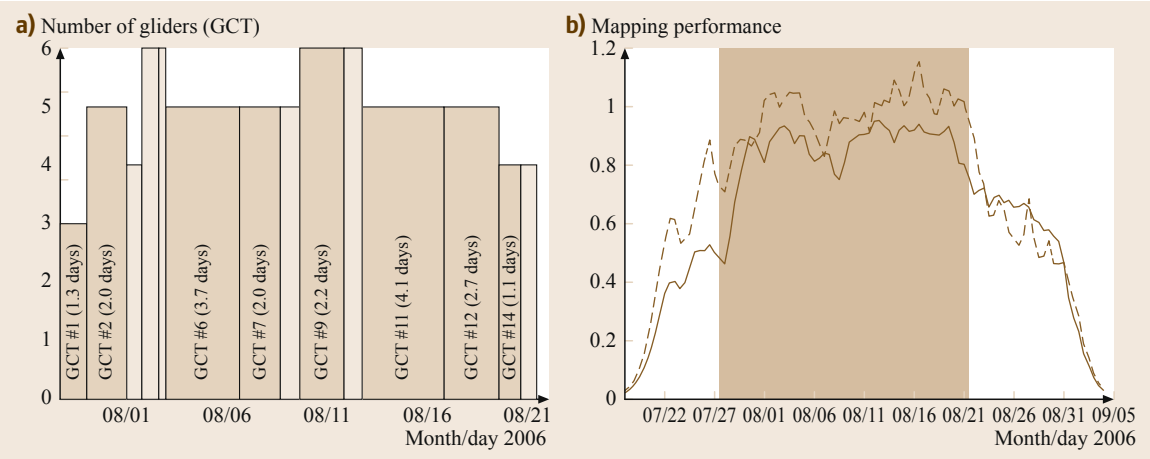

Fig. 19.4a,b From [19.3]. **(a)** Time of GCTs for Slocum gliders. **(b)** Slocum glider sampling performance over the interior of the sampling region (*solid line*) and along the boundary (*dashed line*). The portion of the plot that is *shaded* corresponds to the period of time during which the GCCS was actively steering the Slocum gliders

shore. The influence of these adaptations are reflected in the Slocum glider sampling performance, which is plotted as a function of time in Fig. 19.4b. In particular, poor coordination of gliders resulted in a decline in sampling performance. On August 6, during GCT #6, the sampling performance experienced its steepest decline as a result of flow conditions impairing coordination. Recovery of performance after a subsequent adaptation

of motion pattern demonstrated the positive impact of coordinated control on sampling performance. Details on the ocean conditions, adaptations, and performance of the gliders during the field experiment are described in [19.3].

The methodology of [19.6] was successfully implemented in the challenging coastal ocean environment of Monterey Bay, CA in August 2006, demonstrating a new capability for ocean sampling. The implementation points to the feasibility and versatility of the method for adaptation of motion patterns and integrated human decision making to address a complex multi-robot sensing task. The glider network coordination was autonomous and sustained with glider motion patterns adapted to meet the requirements of the changing ocean sampling mission and the changing dynamic state of the ocean. The methodology can be applied to collaborative robotic sensing in other domains.

19.4 Recent Developments and Future Directions

Recent years have seen an acceleration of theoretical developments and field testing of cooperative vehicle environmental monitoring; these have both motivated and leveraged advances in sensors, energy efficient and versatile mobile sensing platforms, communications, environmental modeling and estimation techniques, and control theory for cooperative exploration by networked mobile agents. It has become clear that robotic vehicles are especially useful for monitoring in remote and hostile environments and that their potential is much enhanced when they perform in cooperative teams [19.99]. A recent survey of robotics for environmental monitoring, including a discussion of cooperative systems, is provided by *Dunbabin* and *Marques* [19.100]. *Redfield* surveys works on cooperative underwater vehicles in [19.101]. Many of the recent advances are opening up further opportunities and avenues for continued research.

Further, new infrastructure developments, such as the cabled ocean observatories, provide significant resources that could potentially enhance the versatility of cooperative autonomous vehicles, most particularly with respect to data, communication, and power. For example, the NEPTUNE regional cabled ocean observatory boasts continuous high-power and high-bandwidth data transfer in real time between a large expanse of the ocean sea floor and the shore. Without having to surface, any autonomous vehicle could make use of sea floor nodes to send its data back to shore, or to share its location and data with other vehicles in the team, which would improve coordination among vehicles. A vehicle could also use the infrastructure to calibrate its location for its on-board deduced reckoning and to leverage the data collected in the cabled observed for its on-board (and thus collective) decision-making. Further, if docking stations were available, autonomous vehicles could recharge their batteries. Leveraging cabled observatories in this way would be most advantageous if dynamic sampling coverage were needed to complement the existing coverage from the sea floor nodes. Otherwise, there would be a tradeoff for the autonomous vehicles between moving into areas already well covered and exploring new areas where no cabled observatory exists.

Examples of recent field-tested methodologies for cooperative vehicle environmental monitoring include a decentralized strategy for coordinated harbor patrol using the theory of Gaussian processes implemented on three AUVs in Lisbon harbor by *Marino* et al. [19.102]. *Schofield* et al. [19.103] describe a number of field tests including a test of remote coordination of an array of acoustically networked AUVs and the coordinated sampling of underwater gliders and the space-based Hyperion imager flying on the Earth Observing-1 spacecraft. Using decentralized data fusion and control, two UAVs were used to demonstrate cooperative localization of ground-based features by *Cole* et al. [19.104]. *Techy* et al. [19.105] implemented a strategy for coordination based on speed modulation to synchronize two autonomous UAVs for tracking long-distance movement of plant pathogens above crop fields. *Maczka* et al. [19.106] demonstrated an efficient method for cooperative navigation of underwater vehicles from time-synchronized acoustic data transmissions. *Hollinger* et al. [19.107] demonstrated on a single AUV in the Southern California Bight a probabilistic planner that uses uncertainty in ocean current prediction based on an interpolation variance. *Merino* et al. [19.108] presented a cooperative perception system for multiple UAVs with different kinds of sensors and showed experimental results of forest fire detection with cooperating UAVs. *Alvarez* et al. [19.109] described methodology that estimates volumetric distribution of the geostrophic current field from glider measurements merged with satellite altimetry data; this methodology was validated using data collected from three Slocum gliders and one Spray glider moving along predefined paths during a field experiment in August 2010 in a coastal region of the Ligurian Sea. *Alvarez* and *Mourre* [19.110] examined optimal sampling strategies for a single underwater glider sampling in the presence of a mooring.

Lekien et al. [19.111] presented a method that uses Lagrangian coherent structures to coordinate vehicles robustly in the presence of very strong currents. Other methods to coordinate gliders and AUVs to maximize information in the data collected, taking explicit account of challenging ocean currents have been studied, [19.112–116].

Strategies for coordinated sampling that optimize information-based metrics have also been further explored [19.117–123].

Advances have been made in decentralized cooperative control strategies that improve or leverage the communication network structure of mobile robotic teams. These include new algorithms that use graph theoretic approaches [19.124] for computing, maintaining or maximizing connectivity [19.125–127], controllability [19.128], and robustness of coordinated motion to uncertainty [19.129]. Techniques from algebraic topology have also been applied to problems in multivehicle sensing [19.130]. Advances in cooperative routing and motion planning for multiple autonomous vehicles have been extensive, see, for example [19.131, 132].

Another source of inspiration for cooperative control design comes from mechanisms of collective behavior in animal groups such as fish schools and bird flocks. In these animal groups, remarkable collective behaviors result without centralized direction from relatively simple individuals who sense and respond to their local environment, including the relative position, heading or speed of *neighbors* in the group [19.133–136]. Mathematical models have been used to explain individual decision-making and interactions that lead to high-performing group behaviors [19.137–141]. These models can potentially be used to design provable decision-making feedback laws for individual robotic vehicles so that robotic teams inherit some of the critical group-level properties observed in nature, notably the ability of the group to forage efficiently (for information) despite individual-level limitations on sensing and communication and significant uncertainty in the environment. *Torney* et al. [19.142] showed how animal groups could apply a performance-dependent interaction to efficiently move to the source of a chemical gradient in a turbulent environment, and *Wu* et al. [19.143] turned this into a provable algorithm for efficient cooperative search in a noisy distributed field. In [19.144], *Young* et al. applied system-theoretic techniques to understand interactions in starling flocks that yield robustness of consensus to uncertainty, and used these in [19.129] to design decentralized feedback laws that enable networks of vehicles to improve their robustness to uncertainty.

Design of dynamics of decision-making teams of robots and humans is yet another important direction of research that has the potential to impact the success of cooperative vehicles in complex tasks. Humans are capable of intelligent and adaptable decision-making in response to reasoning about real-world information in real time, and robotic systems are capable of significant computational speed and memory. Challenging problems in complex settings, for example, with multiple scales and significant uncertainty, can be well served by solutions in which humans and robotic systems participate in complementary ways. Benefits and possible pitfalls of such human and robot collaboration were evidenced in the AOSN II and ASAP experiments. Indeed, with the data visualization tools, computational aids, and communication mechanisms accessible through the GCCS and ASAP's virtual control room, the ASAP field experiment demonstrated collaboration between a distributed team of humans and an automated group of underwater robots to perform adaptive ocean sampling in an uncertain environment with multiple objectives subject to a variety of safety and operational constraints. While the autonomous vehicles moved continuously in coordinated patterns, the human participants contributed in ways the automated system could not by making rapid decisions in response to critical environmental changes (sudden excessively strong currents or unanticipated shallow water) and operational failures. The human team also made important longer term decisions in response to observed or predicted indications of change in the environment, such as new features or locations of interest, or decline in performance with respect to one or more performance metric. And yet, opportunities may have been missed when the human participants had difficulty assessing the likelihood of risk in proposed scenarios or balancing the many competing objectives. Likewise, human supervisory strategies may have been less than optimal given that the autonomous robots had no opportunity to provide direct feedback to their human supervisors.

In this vein, progress has been reported on humans and robots in exploration [19.145–149] and on humans working together in search tasks [19.150–153]. Progress has also been made on algorithm development using what cognitive scientists understand about human decision-making. For example, decision-making algorithms with provable performance in search tasks were derived in [19.154], drawing on research on the heuristics humans use to trade off between exploiting well-known alternatives and exploring uncertain but possibly better alternatives. It has been shown in [19.155] that humans use their ability to learn correlation structure when it exists among decision alternatives, as in the case of alternatives representing different locations in a spatially distributed resource. The knowledge

of correlation structure has been shown to be critical to enhancing performance in the search algorithms of [19.154]. This suggests approaches to systematize means for robots to benefit from human input, for example, by using observations of human choices to estimate correlation structure and updating decision-making strategies accordingly. Further work that builds on research on human decision-making and behavior may allow derivation of engineering models and provable strategy design for well-integrated human–robot teams in complex missions such as cooperative vehicles for environmental monitoring.

20. Nested Autonomy for Distributed Ocean Sensing

Henrik Schmidt, Michael R. Benjamin, Stephanie M. Petillo, Raymond Lum

Nested autonomy is a new control paradigm for distributed undersea surveillance, specifically designed for the layered communication infrastructure provided by the low-bandwidth underwater acoustic communication and the intermittent RF connectivity. Implemented using the open-source MOOS-IvP behavior-based, autonomous command and control architecture, it provides the fully integrated sensing, modeling, and controlling that allows each platform to autonomously detect, classify, localize, and track an episodic event in the ocean, without depending on any operator command and control. The prosecution of an event, such as the detection and tracking of a subsea volcanic plume or an oceanographic feature, may be initiated by the operators or entirely autonomously by an onboard detection capability. The event information collected by each node in the network is reported back to the operators by transmitting an event report, using a dedicated command and control language. Collaborative processing and control is exploited when the communication channel allows, for example, collaborative tracking of a coastal front, or the tracking of manmade sources or marine mammals.

References 479

The primary motivation for designing a distributed command and control architecture for undersea monitoring and observation is to achieve the ability to deploy a fleet of autonomous mobile marine platforms over a wide area of the ocean environment and over a long period of time with little or no human supervision. Concerns over effective coverage, communication range, and safe operation of the platforms are all primary motivations of an effective form of autonomous control. The long duration of missions and unpredictable nature of the environment require the vehicles to adapt their missions and behave autonomously as events unfold. Conversely, practical concerns of marine operations over large areas require an element of operator intervention over the course of time. These two characteristics can be at odds with each other in practice, but can be tempered by effective periodic communication through a network of fixed and mobile nodes co-deployed in a coordinated manner designed to balance individual platform and network objectives. The connectivity with and between the submerged assets of such networks is almost entirely dependent on underwater acoustic communication, except for rare and time-limited surfacings. Consequently, the undersea network nodes must operate with a communication infrastructure with severely limited bandwidth. Current underwater communication technology can robustly provide a point-to-point channel capacity in shallow water of less than a few hundred byte km/min, close to ten orders of magnitude smaller than modern electromagnetic communication

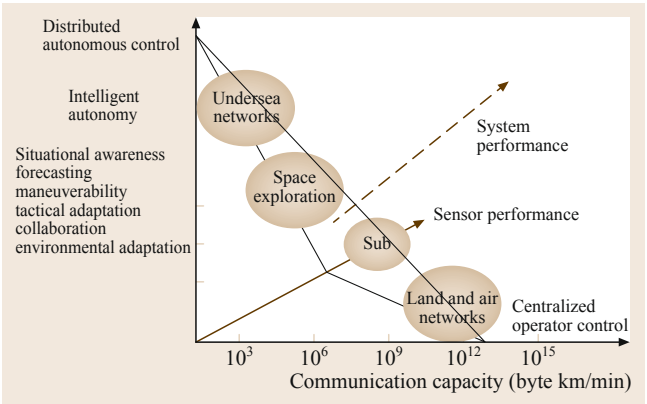

Fig. 20.1 Performance trade-off between sensor performance, communication channel capacity, and autonomy for net-centric sensing and observation systems

protocols used for land- and air-based distributed, net-centric systems. Equally critical is the high latency and short communication windows inherently associated with communication between the human operator and the submerged assets, more severe than that experienced in interplanetary space exploration. Operational constraints for some applications prohibit the existence of permanent surface assets which can provide a high-speed communication link with the operators. The connection of the operator to such systems is instead restricted to gateway vehicles, such as underwater gliders, which occasionally surface for a limited time and quickly relay short messages received acoustically from the submerged network nodes, and receive command and control commands which will subsequently be transmitted via the acoustic channel to the other nodes. The latencies using such a gateway vehicle on the continental shelf will typically be on the order of 10–60 min.

A typical acoustic or optical sensing system will generate data at a rate of the order of megabytes per second, for which the acoustic communication capacity of the undersea environment is totally inadequate for the transmission of raw data back to the operators. Therefore, in contrast to the air- and land-based equivalents, the data processing cannot be performed centrally but must be largely distributed to the individual nodes. Similarly, real-time *tethered* control of the underwater assets is made impossible by the latencies imposed by the use of occasionally surfacing gateway nodes. Consequently, real-time command and control decisions must be made locally on the nodes, in turn requiring that not only the data processing, but also the analysis and interpretation, traditionally performed by human operators, must be performed locally on the nodes. This requires fully integrated *sensing, modeling*, and *control*, a significantly higher level of autonomy than required in most current applications of autonomous underwater vehicles (AUVs) – where the data collection and the control have been handled independently.

In addition to allowing for autonomous reaction to sensor input, the higher degree of autonomy enables the adaptive control of the mobile nodes to take optimal advantage of the environmental and tactical situation through modeling and forecasting. As illustrated in Fig. 20.1, such onboard intelligent autonomy may compensate for the reduction in performance associated with the limited sensing capabilities of small underwater vehicles and the limited undersea communication channel capacity and latency.

For ocean monitoring and observation systems, an important mission objective for the network is the detection, classification, and tracking of episodic – usually unpredictable – events. Such events include chemical plumes from undersea volcanoes or man-made systems, and biological phenomena such as algal blooms. Another important application of undersea sensing systems is the detection and tracking of marine mammals and man-made sources of sound in the presence of ambient noise. Without the possibility of transmitting large amounts of data back to the operators, the on-board autonomy must be capable of fully completing the mission objective of sampling and characterizing the event entirely autonomously, without any human intervention or assistance.

In addition to autonomously *adapting* to such episodic events, the individual nodes may take advantage of *collaboration* with other nodes, again without requiring the human operator in the loop [20.1]. Thus, a cluster of network nodes within – at least occasional – acoustic communication range with each other may fuse its own data collected for the event with those obtained by and broadcast by other network nodes in the vicinity. For example, two AUVs with acoustic arrays may each track a marine mammal and collaboratively create an accurate localization solution by triangulation.

20.1 Nested Autonomy

To enable effective and fully autonomous adaptation and collaboration for an undersea network with its inherently severe communication constraints, MIT has developed an operational *nested autonomy* architec-

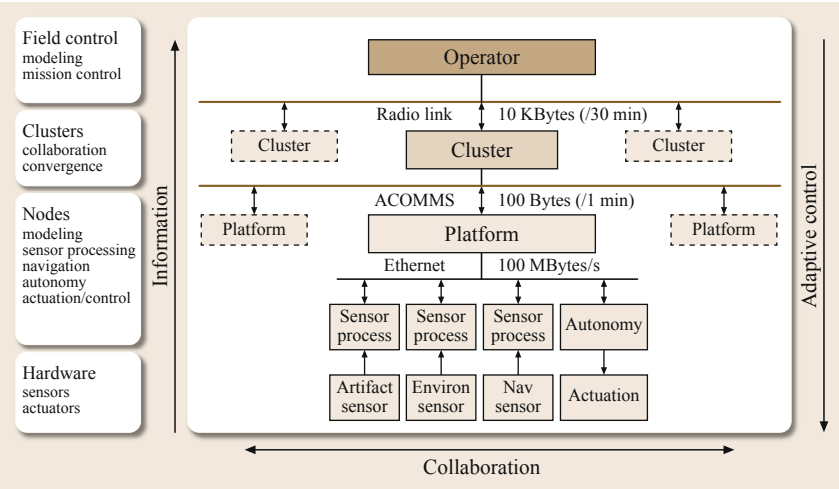

Fig. 20.2 Nested Autonomy. The field operator is communicating with clusters of autonomous nodes through gateway assets occasionally surfacing for transmitting target reports and receiving network commands. The node and cluster autonomy are designed accordingly

ture with fully integrated sensing, modeling and control within each AUV, clusters of assets, and the entire network [20.2].

The *nested autonomy* paradigm is exploiting the inherent layering of the communication infrastructure, illustrated in Fig. 20.2. The underwater network connectivity is being provided by low-bandwidth acoustic communication (ACOMMS), while the above-surface networking is handled by high-bandwidth, but latent, radio frequency (RF) communication through a regularly surfacing gateway node. On-board each node, the computer bus and Ethernet networking provides very high-bandwidth communication between the sensing, modeling and control processes. The three layers of horizontal communication have vastly different bandwidths, ranging from 100 byte/min for the inter-node ACOMMS to 100 Mb/s for the on-board systems. Equally important, the layers of the vertical connectivity differ significantly in latency and intermittency, ranging from virtually instantaneous connectivity of the on-board sensors and control processes to latencies of 10–60 min for information flowing to and from the field control (human) operators. As a result, adaptive control of the network assets with the operator in-the-loop is at best possible on an hourly basis, allowing the field operator to make tactical deployment decisions for the network assets based on, for example, environmental forecasts and reports of interfering shipping lane distributions, etc. Shorter time scale adaptation, such as autonomously reacting to episodic environmental events or a node tracking a marine mammal acoustically must clearly be performed either at the *node* level, or, if collaborative sensing is feasible, at the *cluster* level.

The *nested autonomy* concept of operations (CONOPS) does not entirely eliminate the operator from the decision process. Thus, whenever a communication opportunity arises, the operational paradigm will take advantage of any information that can be received from the operator or collaborators in the cluster. On the other hand, the intermittency of the underwater acoustic communication channel makes it imperative that each node is capable of completing the mission objectives in the total absence of communication connectivity.

20.2 Concept of Operations (CONOPS)

20.2.1 Field Level

The layered and clustered communication infrastructure illustrated in Fig. 20.2 naturally leads to a nested or layered concept of operations, which, as mentioned earlier, provides some optimal mixture of distributed autonomy and centralized control. Figure 20.3 shows a possible field-level concept of operations for an oceanographic observation system for capturing an episodic event, such as a chemical plume released by an undersea volcanic event. The target area is populated by a number of clusters, each with a number of mobile assets such as AUVs and gliders.

One of the adaptive responsibilities of the operators is to deploy the finite number of clusters in a pattern which is optimal for the current environmental situation and with the highest probability for capturing the episodic event of interest. The time scales for deploy-

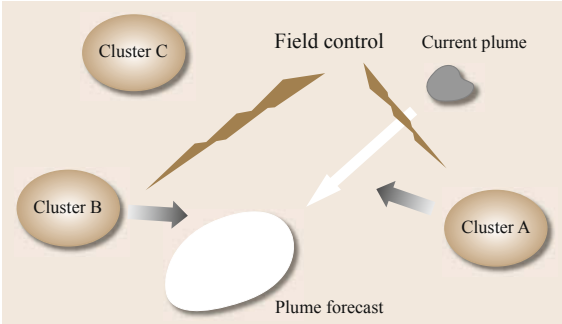

Fig. 20.3 Field-level CONOPS. The field control is dispatching clusters to autonomously prosecute a chemical plume with a forecast path and expansion. Cluster A is instructed to initiate prosecution immediately since it is closest to the projected path. The *downstream* cluster B is alerted to be ready for action, while field control decides not to activate cluster C, which is not in the path of the plume

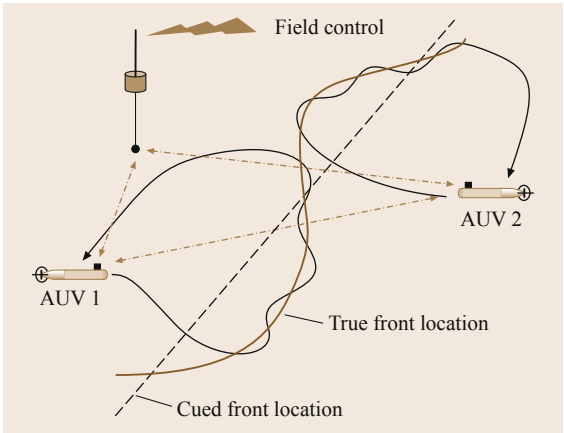

Fig. 20.4 CONOPS for a cluster of AUVs with oceanographic sensors, and a gateway buoy for communication with field control

ment and re-deployment are inherently long – on the order of hours to days – and is therefore highly dependent on reliable environmental and situational forecasts, often requiring a significant modeling and data assimilation infrastructure. Once deployed, it is assumed that each cluster is capable of autonomously detecting, classifying, localizing, and tracking (DCLT) the episodic event of interest. This event *prosecution* may be either cued by the operators through a surface communication gateway or performed fully autonomously. Once a tracking solution and the nature of the event are determined, the result of the prosecution will be reported back to the operators in the form of an *event report*. The human operators may then cue other clusters in the projected path of the event with whatever information is available, packaged into the format suitable for transmission through the network, for example, using the dynamic message coding scheme DCCL (dynamic compact control language) [20.3]. The final crucial role of field control is the fusing of the *event reports* from the various clusters in the path of the event, gradually building up a more and more complete event track and description.

20.2.2 Cluster Level

Depending on the available assets, a wide spectrum of cluster compositions is conceivable, including gliders and propelled AUVs with chemical, biological, and acoustic sensors. Figure 20.4 schematically shows how such cluster assets may be applied in response to an event cueing message from field control. The message identifies a front with a location and heading indicated by the dashed line. After the message is received by a surface gateway buoy, it is broadcast using the acoustic modems. Nearby nodes, such as dormant, drifting, or bottomed AUVs which pick up the message, will initiate a prosecute behavior sequence – in this case the detection and subsequent mapping and tracking of a frontal boundary. Depending on the level of autonomy authorized by field control, the AUV may decide not to pursue the target event if there is little probability that it will come within detection range.

If two or more nodes are prosecuting the event, each node may fuse the event information from the other nodes to produce a more accurate event characterization, and to optimize the coverage or resolution. Thus, in Fig. 20.4 the two vehicles coordinate their survey in order to not overlap and to increase coverage. Another example of collaborative control is a node which did not receive the original *prosecute* command, but which, following the receipt of an event report from a prosecuting node, will determine whether the target event is likely to come within the range, and then autonomously initiate a Prosecute sequence. All event reports generated by the prosecuting nodes are then collected by the communication gateway and transmitted back to field control via RF communication.

20.2.3 Node Level

A suite of node-level CONOPS has been developed for both single node and collaborative detection and tracking of a variety of episodic events, such as the adaptive mapping of a front or a thermocline, and for tracking an acoustic source, such as a marine mammal or a man-made source of sound.

As an example, Fig. 20.5 shows the core adaptive prosecute sequence developed for a propelled AUV for

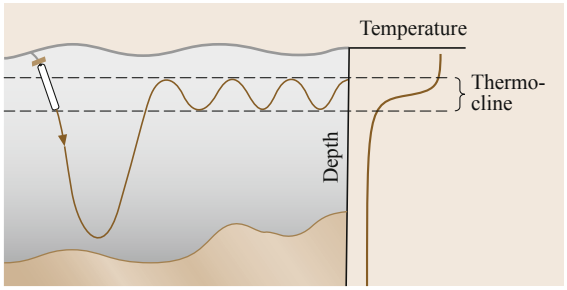

Fig. 20.5 Concept of operations for an AUV detecting, classifying, and tracking a coastal thermocline (after [20.4], courtesy of *Petillo* et al.)

DCLT a shallow water thermocline. The node level, CONOPS are described here for the tracking of a thermocline, but they can be directly mapped onto any other episodic event in the ocean environment, for example, the tracking of a plume, where the collaborative, adaptive cluster autonomy is even more important by providing simultaneously the resolution and coverage required for accurately localizing, classifying, and tracking the event. Thus, the network must first detect and localize the plume, and then adaptively track its boundaries, a mission which obviously requires the vehicles to collaborate to cover the expanding spatial extent of the plume.

20.3 Autonomy

20.3.1 MOOS-IvP Autonomy Architecture and System

The core of the nested autonomy paradigm is MOOS-IvP (the mission-oriented operating suite, with interval programming (IvP)): the autonomous, integrated sensing, modeling, and command and control framework on each individual platform. In combination with the collaborative cluster autonomy, the integrated node autonomy enables the adaptation which may compensate for the reduced physical sensor apertures of the unmanned underwater vehicles. The design of the autonomy system is based on three basic architectural components, extending the nesting into each individual sensor node:

- *Payload/Backseat vehicle architecture*: Low-level vehicle control is separated from the platform autonomy software, with the latter operating on a separate payload computer. This allows the same payload software and payload hardware to be integrated in vehicles of different size and different vehicle manufacturers.
- *Publish and subscribe software application architecture*: The payload software system is comprised of several distinct applications. The decision-making, sensor processing, communications handling, data logging, and many other applications are coordinated by the MOOS publish–subscribe middleware. The core MOOS middleware is lightweight, having no external dependencies and less than 1 Mb compiled size. The 2012 release, MOOS V10, allows for improved high-bandwidth and low-latency communications, suitable for use on the Oxford autonomous car project. Hundreds of MOOS applications have been written for use on at least 20 different marine vehicle platform types. Applications are largely independent, defined only by their interface. Any application is easily replaceable with an improved version with a matching interface. Core MOOS and many common applications are publicly available along with source code under an open source LGPL license (GNU Lesser General Public License).
- *Behavior-based decision-making architecture*: The IvP-Helm is a single MOOS application containing its own architecture of modular components – behaviors. The mission mode determines which behaviors are active, and competing behaviors are coordinated using multiobjective optimization using interval programming [20.5]. Several common and powerful behaviors are available at www.moos-ivp.org, but users may augment this core capability with their own public or proprietary behaviors to suit new mission objectives.

20.3.2 The Payload Autonomy Paradigm

To allow the MOOS-IvP network control to be applied on a variety of fixed and moving nodes with different control software, a *payload autonomy* paradigm was adopted and integrated with the MOOS-IvP control software infrastructure, and has subsequently been integrated into a wide variety of autonomous underwater vehicles and surface craft. This is achieved by adopting a hardware and software architecture that physically separates the sensing, communication, data processing, and associated adaptive autonomy from the basic platform control, illustrated schematically in Fig. 20.6. The idea is that all high-level control including the adaptation to measured and estimated parameters, is performed on a payload computer (PLC) running MOOS middleware, and including the IvP-Helm autonomous decision-making engine. The payload will also handle all communication with the network, ei-

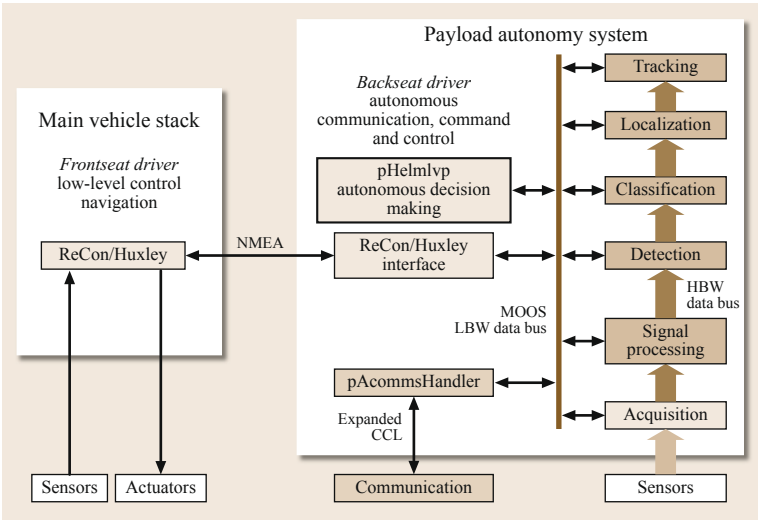

Fig. 20.6 Schematic representation of the payload autonomy paradigm, where higher level adaptive control and network communication are handled by MOOS-IvP on the payload computer, while lower level control, navigation, and vehicle safety are handled by the main vehicle computer using the native control software

ther through a radio link while surfaced, or an acoustic modem when submerged. All lower level control, and basic navigation and platform safety tasks are handled by the native vehicle control software running on the main vehicle computer (MVC), for example, *Huxley* on Bluefin vehicles and *Recon* on Remus vehicles. The communication between the PLC and the MVC is performed over a manufacturer-specific NMEA-type interface (National Marine Electronics Association), operated by a dedicated MOOS process. The commands passed from the PLC to the MVC are simply continuous updates of desired heading, speed, and depth, which the MVC then translates to desired rudder, thrust and elevator signals to the tail cone. The MVC will provide the PLC with a data stream containing all relevant navigation data. Thus, in a traditional ship analogy, the PLC represents the bridge, the radio room and the sensing infrastructure, while the MVC represents the engine room and the navigation resources of the ship. In the same analogy, the Helm represents the *Captain*, while the interface MOOS module represents the *Helmsman*.

The MVC will also perform a series of basic safety tasks, including mission aborts due to bottom altitude limit violations, lack of commands from the PLC within a specified time, or an overall mission timeout. Higher level safety tasks such as exceeding the specified operational area, and individual behavior timeouts or failures, are handled by the PLC.

20.3.3 The MOOS-IvP Autonomy Architecture

The *nested autonomy* paradigm for distributed undersea sensing inherently involves reaction to situations and events that are deterministically unpredictable. Thus, the autonomy architecture cannot be based on the availability of a world model that can form the basis for the autonomous decision making. Instead, it requires a capability of fully autonomously adapting to the environmental and tactical situation associated with the phenomenon it is intended to measure. As such, it forms a clear example of the type of robotic system for which the IvP model for multiobjective behavior coordination was intended and developed. Thus, for example, an underwater vehicle tasked with detecting and tracking an acoustic source is faced with several, often conflicting objectives. It will likely have been assigned a station point, from which it should not move too far, while at the same time having to get close to the source to develop a reliable tracking solution. Also, depending on its sensing capability it may have a preferred heading for achieving tracking resolution. Also, if other vehicles in the vicinity are already tracking the target event, it may not be desirable for it to pursue the same source aggressively, but instead preserve power for future sensing tasks. MOOS-IvP provides exactly the flexibility and inherent multiobjective capability for implementing such high-level autonomy with adaptive and collaborative capabilities.

The MIT-LAMSS group's implementation of the *nested autonomy* concept of operations is using the MOOS middleware, supporting the modular *star* software architecture illustrated in Fig. 20.7. As in all MOOS communities, the MOOS Database (MOOSDB) process is the core of the MOOS architecture and handles all communication between the processes (applications) using a publish-and-subscribe architecture. The various MOOS processes include all necessary control functions as well as sensing and processing modules, with the MOOSDB providing the unified interface standard that enables the fully autonomous integration of

sensing, modeling, processing, and control. MOOS ensures a process executes its *iterate* method at a specified frequency and handles new mail on each iteration in a publish-and-subscribe manner. The autonomy (IvP) helm runs as the MOOS process pHelmIvP.

The fundamental architecture of the IvP-Helm autonomy configuration at the core of the nested autonomy paradigm is illustrated in Fig. 20.8. Because of the inherent latency and intermittency of the underwater communication environment, the mission-dependent autonomy configuration defines a finite set of autonomy *modes* in which the autonomy will remain perpetually until specifically reassigned through a high-level transition command, either from the topside command and control or an onboard mission control process. The autonomy mode structure is configured in a hierarchical tree structure, with the mode transitions achieved by a simple change in a MOOS control variable, thus requiring very limited communication from the operators. Note that this paradigm is in distinct contrast to traditional *scripted* autonomy, where mode transitions are in general predefined.

Another fundamental architectural principle illustrated in Fig. 20.8 is that each mode has a preconfigured set of *behaviors*, each of which defines a set of objective functions for *speed*, *heading*, and *depth*, representing the utility of all allowed values for these variables. As in the case of the modes, the behaviors are perpetual, which means that they are running throughout the mission whenever the mode is active, although they may not contribute an objective function unless certain conditions are met. For example, the vehicles will continuously run a collision avoidance behavior, but it will not be active unless the node to avoid is within a configurable spatial envelope. The central IvP algorithm (the *captain*) will then continuously calculate and publish an objective compromise, which will be passed on to the MVC via the MOOSDB and the interface process (the *Helmsman*).

The *nested autonomy* paradigm in general allows the mode transitions to be entirely arbitrary, which makes it inherently suited to sensor-adaptive mission execution. Thus, for example, an underwater vehicle operating in a *deploy* mode such as a hexagonal loiter will use its onboard sensor processing to *detect* and subsequently *classify* an episodic event to which the node must respond. Once the processing is confident in assessing the desired nature of the event, it will simply change a MOOS variable which will trigger a mode transition in the Helm to a *prosecute* mode, which will activate a set of behaviors that allows the vehicle to map and track the event.

Mode transitions may alternatively be triggered by a simple command from the operators, received via the

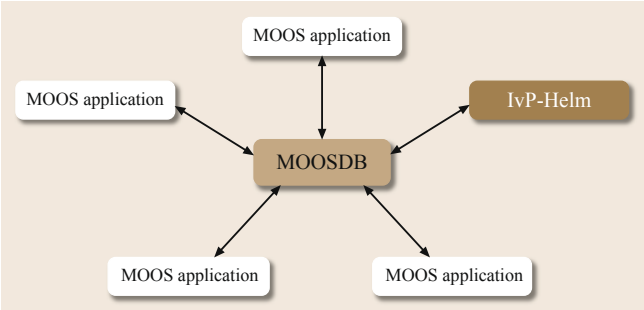

Fig. 20.7 Modular software architecture based on the MOOS middleware

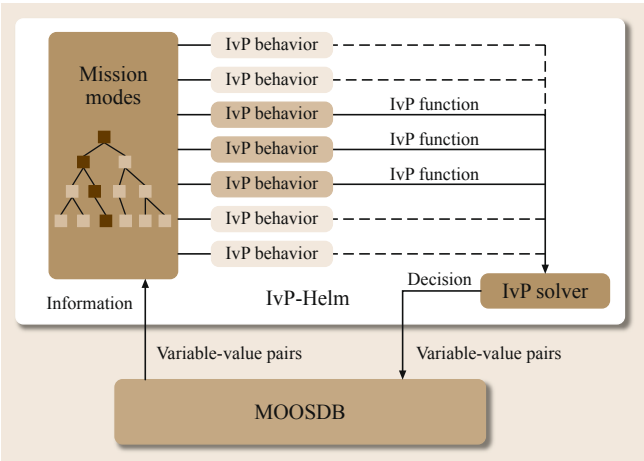

Fig. 20.8 IvP-Helm autonomy architecture

communication infrastructure. Also, depending on the configuration, transitions may be initiated by an *event report* issued by a collaborating fixed or mobile node or the operators. The fact that mode transitions can be initiated through various channels is a key feature ensuring robustness. Thus, for example, a node which has not itself been able to detect an event can be alerted through one of the other channels and consequently participate fully in the event prosecution.

An example autonomy mode hierarchy for vehicles in a network deployed for capturing episodic oceanographic events is shown in Fig. 20.9. During a mission, a vehicle will always reside in one of the modes at the end of a branch, and it will as a fundamental principle remain in that mode until it is commanded, internally or externally, to transition to another mode. Each mode defines a set of behaviors, most of which are generally available off-the-shelf. A typical behavior set is shown in the table in Fig. 20.9.

The perpetual mode/behavior architecture provides an extremely effective basis for executing field missions. Thus, except for configuration variables such

	IvP behavior	Station Keep	Loiter	Search	Classify	Track

Fig. 20.9 Autonomy mode hierarchy for autonomous detection, classification and tracking of an episodic oceanographic event such as a coastal front

as the operational area and initial deploy location, the autonomy software, in general, does not require modifications before each individual launch, and even the sensing mission itself may be modified after deployment because of the capability of issuing the vehicle a high level, simple command which switches the mode, modifies variables such as waypoint locations, or activates and de-activates onboard sensing resources. Thus, for example, a vehicle executing a sonar survey can with a single command be switched to a mission mapping the temperature and salinity over depth, as long as that particular survey mode and the associated behaviors (race track, depth-yoyo, etc.) have been defined in the autonomy configuration.

20.4 Acoustic Communication Infrastructure

The nested autonomy paradigm is inherently autonomy centric, with the objective of making it robust to the severely constrained undersea communication environment with low bandwidth, high latency, and most importantly, severe intermittence imposed by the underwater acoustic environment. However, the operation of the observation network is still dependent on occasional communication to the vehicle in the form of commands changing the platform mode and configuration variables. Also, there is a need to send *status*, *contact*, and *track* reports to the operators to allow them to make informed decisions regarding progress of the mission. Finally, for many ocean sensing missions, the environmental assessment performance can benefit significantly from collaborative platform behaviors because it has the potential of breaking the space-time ambiguity inherent to measurements made by individual moving platforms.

The MIT nested autonomy operational paradigm is using the Goby [20.6] communication infrastructure and a highly flexible dynamic compact control language (DCCL) (*Schneider* et al. [20.3]), which together with a new Goby-Acomms communication marshalling, queuing and link layer [20.6, 7] provides a highly portable and efficient, unified command and control architecture. This allows field deployments of undersea networks of modem-equipped AUVs with MOOS-IvP autonomy to become routine exercises [20.2].

With each network node being directed by the MOOS-IvP platform autonomy system, the operational

paradigm enables fully autonomous adaptation of the mobile network nodes to the environmental and tactical picture, collaborative target event tracking by multiple platforms, and safe and efficient operation in uncharted environments without the need for re-programming. Once deployed, the entire network is operated using only the DCCL messages for communication between nodes and human operators for changing mission objectives and platform states. The Goby-DCCL is interfaced to the MOOS-IvP platform autonomy by the process *pAcommsHandler*, as shown in Fig. 20.6, providing the following capabilities and properties to the autonomy system:

- Highly portable with most of the software being hardware independent, with generic message handling all the way down to the physical modem driver.
- The DCCL encoding/decoding provides highly efficient data compression through a user-defined message composition with arbitrary value intervals and resolution.
- Dynamic queuing allows for high-priority messages to move to the head of the queue, with the priority of less time critical low-priority messages such as *status* reports increasing with time. This ensures that the message queue not be saturated by high-priority, short-time validity messages such as *track* reports.
- User defined time division multiple access (TDMA) communication scheduling, either using a centralized polling scheme, a fixed slotted scheme, or a dynamic self-discovering slotted scheme.

20.5 On-Board, Real-Time Signal Processing

A key to the autonomous, adaptive sampling of chemical, biological, physical, or acoustic fields in the ocean is an efficient on-board implementation of a data analysis package that allows for real-time feedback to the platform control, allowing for the sensor-adaptive autonomous control of the platforms. MOOS-IvP provides a very effective infrastructure for achieving this due to its modular structure and well-defined communication infrastructure. Thus, as illustrated in Fig. 20.6, separating the signal processing chain into a sequence of MOOS processes will allow each step in the processing to not only take advantage of the navigation information available in the MOOSDB, but also have the possibility of providing feedback to the Helm for optimizing the processing performance. This real-time, closed-loop feedback is the key enabler of environmentally *adaptive* sampling by making processed event data immediately available to the autonomous control. Also, it allows the data processing to take advantage of information arriving from other network nodes and published in the MOOSDB, enabling more effective *collaborative* sampling when the communication environment allows.

20.6 Application Examples

In a collaborative effort between the NATO Undersea Research Centre (NURC), MIT, Woods Hole Oceanographic Institution (WHOI), and the Naval Undersea Warfare Center (NUWC), a series of experiments were carried out between 2008 and 2010, with the primary objectives being the demonstration of the performance of a network of underwater vehicles as receiver platforms for multistatic active sonar tracking, and their communication and control networking. In these experiments, up to seven AUVs were deployed, six of which were equipped with towed hydrophone arrays and operating in a common underwater acoustic communication network [20.2]. These experiments provided a unique opportunity for testing and demonstrating the performance of the nested autonomy control paradigm under realistic underwater communication constraints. The experiments were designed, in addition to the multistatic acoustic data collection, to allow the demonstration of fully autonomous oceanographic mapping and adaptive autonomous behaviors for optimal acoustic sensing and communication. They also provided a comprehensive testbed for the MOOS-IvP platform autonomy in general.

20.6.1 Unified Command, Communication, and Control Infrastructure

The GLINT'08, '09, and '10 experiments were carried out as part of a joint research project (JRP) on undersea sensing network technology (NURC project 4G4), involving NURC, MIT, WHOI, NUWC, and several Italian organizations. The experiments had several scientific objectives, relating both to the sensing

concepts, communication networking, and distributed, autonomous control.

The principal objective was to demonstrate the communication, command, and control of a hybrid platform suite, using a common communication infrastructure based on the WHOI Micromodem, and a common autonomy system for operating all mobile and fixed assets, based on the *payload autonomy* paradigm and the MOOS-IvP behavior-based autonomy software suite. The architecture had previously been integrated and demonstrated on the SCOUT kayaks, the Bluefin BF21 AUVs (Fig. 20.10), and several land robots at MIT. In preparation for and during GLINT'08, it was successfully integrated into the NURC OEX AUV and the NUWC Iver2 AUVs, both deployed in the experiment towing hydrophone arrays for multistatic acoustics. In addition, the architecture was partially integrated into the NUWC Folaga environmental sampler and two bottom moorings equipped with micromodems for undersea networking. The hybrid network with these assets is schematically shown in Fig. 20.11.

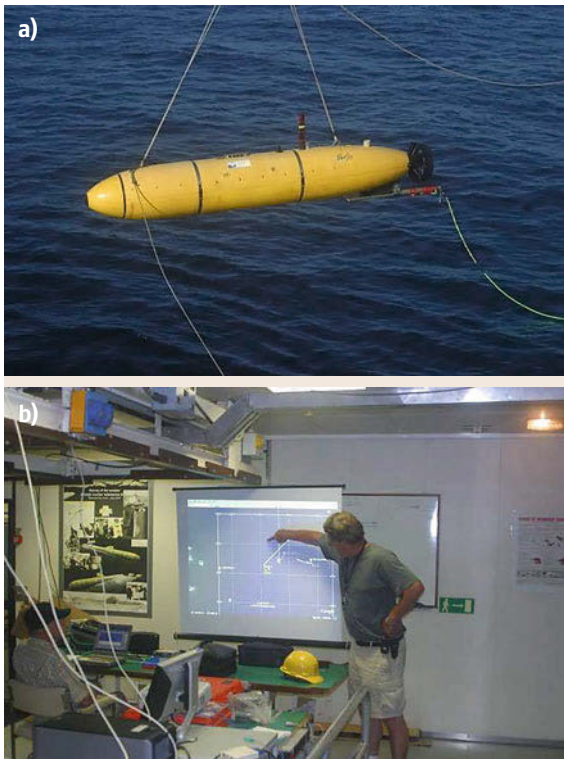

Fig. 20.10a,b GLINT'08 experiment, Pianosa, Italy, July–August 2008. **(a)** The Unicorn BF21 AUV with towed DURIP array (out of photo) being deployed from the NRV (NATO Research Vessel) Alliance. **(b)** The command and control center on the NRV Alliance with situational display

The principal scientific objective of GLINT'08 was to collect a comprehensive multistatic active dataset using three AUVs with towed hydrophone arrays, which will support the development of robust multistatic active processing approaches suited for operation in the limited computational environment of AUVs. The three vehicles were the NURC OEX with the 48-element SLITA array, the MIT Unicorn BF21 with the 32-element DURIP array, and the NUWC Iver2 vehicle towing a 16-element hydrophone array. The two large vehicles – the OEX and Unicorn – had fully integrated MOOS-IvP autonomy systems early in the experiment and were routinely used in coordinated data collection missions. On the last day of the experiment, all three array-towing vehicles were operated together. Also, the MOOS-IvP-DCCL communication infrastructure [20.2] allowed several demonstrations of fully autonomous obstacle and collision avoidance to be performed by Unicorn and OEX, as illustrated in Fig. 20.12, which shows the topside real-time situational display, which graphically displays all status and contact information transmitted from the vehicles via the undersea communication network.

A major accomplishment in GLINT'08 was the development of an enhanced report and command structure which allows for dynamic, optimally compressed, encoding and decoding of messages [20.2]. This new dynamic compact control language (DCCL, [20.3]) communication handler was implemented in MOOS-IvP and demonstrated for the real-time interleaved transmission of regular low-bandwidth FSK (frequency shift keying) messages with high-rate PSK (phase shift keying) coded messages, for up to 2 kb messages at 5.4 kb/s, allowing for the real-time transmission of CTD (conductivity, temperature and depth) (measurements and array signal processing products such as beam-time records (BTR) for real-time display on the topside situational display. The real-time topside display of BTR data from an AUV had not previously been achieved in the field. Acoustic communication messages from Unicorn and the other AUVs were assimilated with a heterogeneous mixture of other data sources (AIS, ship's NMEA, etc.) to give a unified situational display available to both the science crew and the ship's captain, as illustrated in Fig. 20.10b and Fig. 20.12a. Figure 20.12a shows an example of the usefulness of the situational display in a case of a run-away of one of the NUWC Iver2 AUVs. The last reported navigation for the vehicle was extrapolated in the topside command center to determine a possible grounding site on the island of Pianosa. The workboat was subsequently sent to the predicted site at the northern tip, and the vehicle was recovered from the rocks within 10 m of the predicted location.

20.6.2 Adaptive Thermocline and Acousticline Tracking

One of the primary applications of this nested autonomy system is the autonomous and adaptive detection and tracking of oceanographic features with AUVs. To this end, algorithms for autonomous and adaptive thermocline tracking have been developed and extensively tested in field experiments, demonstrating the feedback loop between AUV sensor measurements and adaptive motion using the nested autonomy system.

To implement adaptive thermocline tracking onboard AUVs, a MOOS application named pEnvtGrad was written to interface thermocline detection algorithms with the MOOS and IvP-Helm autonomy system. pEnvtGrad's final output simply consists of the upper and lower depth bounds of the thermocline region, as well as the depth at which the thermocline's temperature gradient ($|\Delta T/\Delta z|$) is largest. The upper and lower bounds of the thermocline are then used by an IvP-Helm behavior (BHV_ToggleDepth) to bound the vertical motion of the AUV, producing a depth-adaptive yo–yo pattern in depth and effectively tracking the thermocline depth (Fig. 20.5). In fact, pEnvtGrad also allows for similarly tracking the acousticline and pycnocline with the same algorithms, where sound

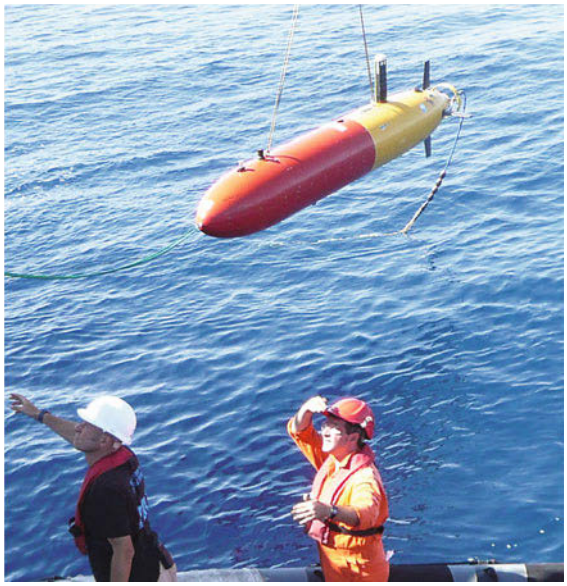

Fig. 20.13 The NURC OEX AUV during GLINT'09. This AUV uses acoustics to communicate with the ship while underwater and gets position updates via global positioning system (GPS) when surfacing (after [20.4], courtesy of *Petillo* et al.)

speed and density values are based on temperature and salinity measurements from the AUV's on-board CTD. The details of the thermocline detection algorithms and pEnvtGrad are given in [20.4].

Adaptive thermocline and acousticline tracking were demonstrated during the GLINT'09, Champlain'09, and GLINT'10 field trials, which are described below. The GLINT'10 experiment in particular used adaptive thermocline tracking missions in the broader context of collecting a synoptic multi-AUV data set displaying evidence of internal waves.

Acousticline Tracking (GLINT'09)

The GLINT'09 experiment was a collaborative effort between MIT and the NATO Undersea Research Centre (NURC, based in La Spezia, Italy) that took place in the Tyrrhenian Sea near Porto Santo Stefano, Italy. Adaptive acousticline tracking missions took place on 13–14 July, 2009, using the NURC OEX AUV (Fig. 20.13) running MOOS and IvP-Helm autonomy. The AUV was deployed from the NRV Alliance, where the topside AUV operators monitored the AUV's status via acoustic communication systems.

In preparation for at-sea testing, pEnvtGrad underwent development and testing in a simulation environment constructed from CTD data collected by the AUV in the same region earlier in the cruise. In developing pEnvtGrad, the acousticline was defined as the depth range over which the sound speed changes most rapidly per unit depth. For the associated in-water acousticline tracking missions that took place, the AUV was commanded into a north–south 1 km × 200 m racetrack pattern and performed the acousticline tracking as an adaptive-depth yo–yo pattern determined and autonomously updated by pEnvtGrad.

The actual depth history of the OEX AUV over its ≈ 2-hour acousticline tracking mission is shown in Fig. 20.14. The initial yo–yo is apparent as the deep dive from 7 to 70 m (*B*), which is followed by the adaptive acousticline tracking between 9 and 28 m depth (*C*). The vertical resolution of the acousticline tracking is based on sound speed values averaged over depth bins to smooth out any higher frequency variations in sound speed. In this case, the depth bins were chosen to be 1 m deep (given a water depth of about 105 m). As the AUV collected more sound speed measurements, these got averaged into the acousticline depth determination algorithms to update the acousticline bounds autonomously and adaptively. To avoid smoothing out all sound speed variations over time, a 30 min periodic reset was implemented to essentially restart the algorithm with a new initial yo–yo (*D*).

The postprocessed vertical sound speed and temperature profiles from the full 2+ hours of data collected during the acousticline tracking mission are plotted in Fig. 20.15a,b, respectively. The *solid vertical blue lines*

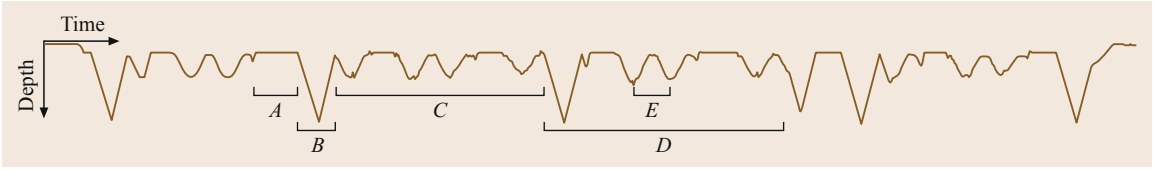

Fig. 20.14 Depth history of the OEX AUV during an adaptive acousticline tracking mission. (*A*) Default shallow turning and transiting depth (7 m). (*B*) Initial yoyo (7–70 m) performed by the AUV to ensure sampling of the entire water column down to the vehicle's maximum dive depth. (*C*) Adapted yo–yo tracking the acousticline between 9 and 28 m depth. (*D*) Is a 30 min tracking period after which the AUV re-initializes the yo–yo through the full water column to account for acousticline depth variation over space and time. (*E*) Is the 400 m period (length) of a single yo–yo (after [20.4], courtesy of *Petillo* et al.)

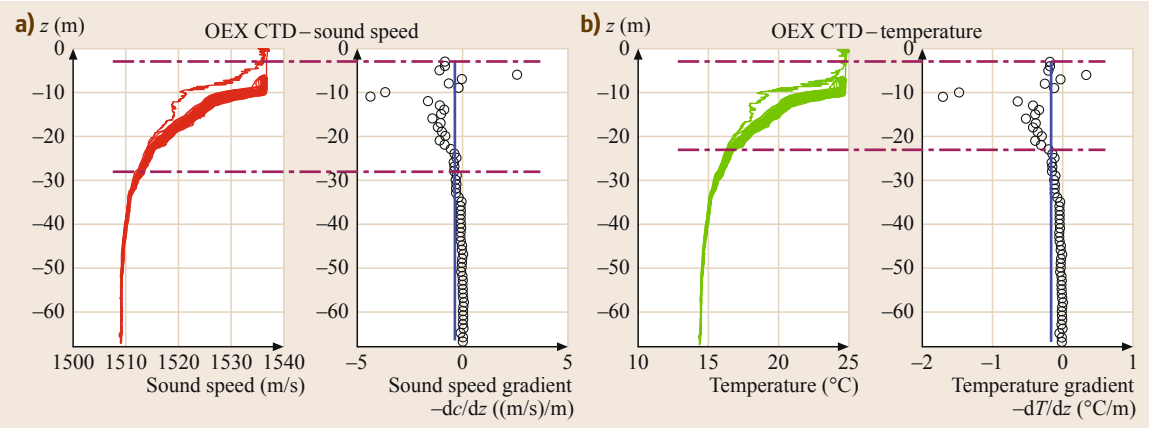

Fig. 20.15a,b Postprocessed sound speed **(a)** and temperature **(b)** profiles with acousticline and thermocline regions delinieated by the dashed lines in **(a)** and **(b)**, respectively (after [20.4], courtesy of *Petillo* et al.)

(on the gradient plots) represent the threshold values (average gradient over all sampled depths). A gradient greater in magnitude than the threshold magnitude is determined to be within the depth range of the acousticline or thermocline, respectively. The acousticline and thermocline regions are bounded by the *dashed lines* shown. When calculating the sound speed with the *MacKenzie* sound speed equation [20.8], the sound speed is dominated by temperature in shallow water (as it is here) and by pressure deep in the ocean. This results in similarities in the shapes of the temperature and sound speed profiles in Fig. 20.15. A thresholding method was used to delineate the acousticline and thermocline depth range, where the threshold was defined as the average of the sound speed and temperature gradients, respectively, over all depth bins. The threshold total average sound speed gradient from postprocessing $(\Delta c/\Delta z)_{\text{tot_avg}}$ was 0.427 (m/s)/m and the average acousticline depth range was calculated to be 3–28 m, where c is the sound speed through the water in m/s and z is the negative of depth in meters. Similarly, the threshold total average temperature gradient from postprocessing $(\Delta T/\Delta z)_{\text{tot_avg}}$ was 0.162 °C/m and the average thermocline depth range was calculated to be 3–23 m, where T is the temperature in °C.

The discrepancy between the minimum depth boundary from postprocessing and that calculated on board the AUV during acousticline tracking (3 m versus 9 m, respectively) is due to the depth range over which the calculations are being bounded (3–70 m versus 7–70 m, respectively), where the postprocessed data additionally include measurements taken during the AUV deployment and surfacing for GPS that skew the upper acousticline depth shallower by slightly decreasing the threshold value.

Fig. 20.16 The NUWC *Hammerhead* Iver AUV used during Champlain'09. This AUV carries a complete environmental package in its nose and communicates with the ship via RF (on the surface) and acoustics (underwater). It also carries a GPS and Doppler velocity logger (DVL) for positioning (after [20.4], courtesy of *Petillo* et al.)

Thermocline Tracking (Champlain'09)

The Champlain'09 experiment took place in Lake Champlain, VT, USA from 3rd to 5th October, 2009. A combined group from MIT and the Naval Undersea Warfare Center (NUWC, based in Newport, RI, USA) deployed an Iver AUV (Fig. 20.16) running MOOS and IvP-Helm autonomy software into this freshwater lake to test adaptive thermocline tracking missions. Since the Iver is a human-portable AUV, it was deployed off the side of a small motorboat and communicated with the operators on the boat via a 25 kHz WHOI Towfish acoustic transducer and Micromodem system. Lake Champlain was chosen due to its proximity to MIT and NUWC and for its deep center channel (> 100 m), which helps it support a stratified thermal structure that allows a thermocline to develop over the warmer months.

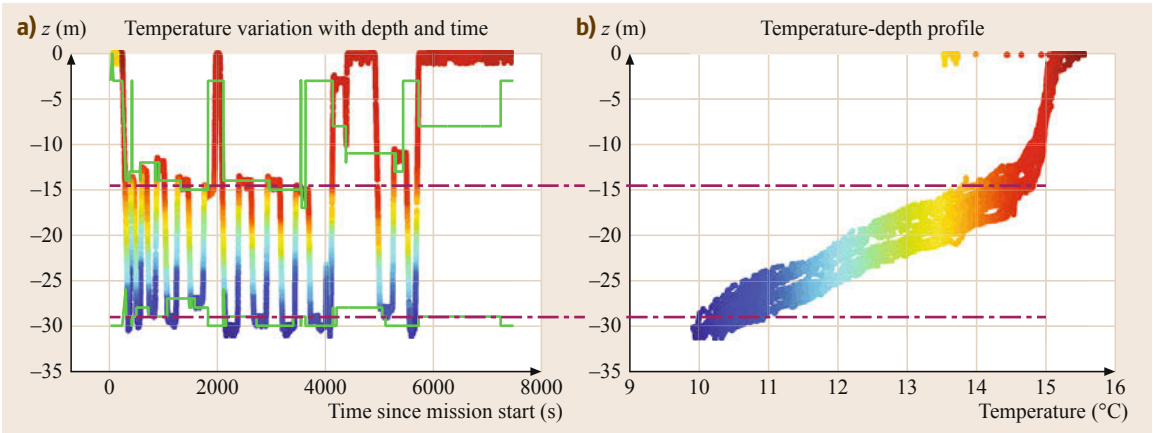

Fig. 20.17a,b Data taken from the real-time topside CTD display showing temperature variations over depth and time. (after [20.4], courtesy of *Petillo* et al.)

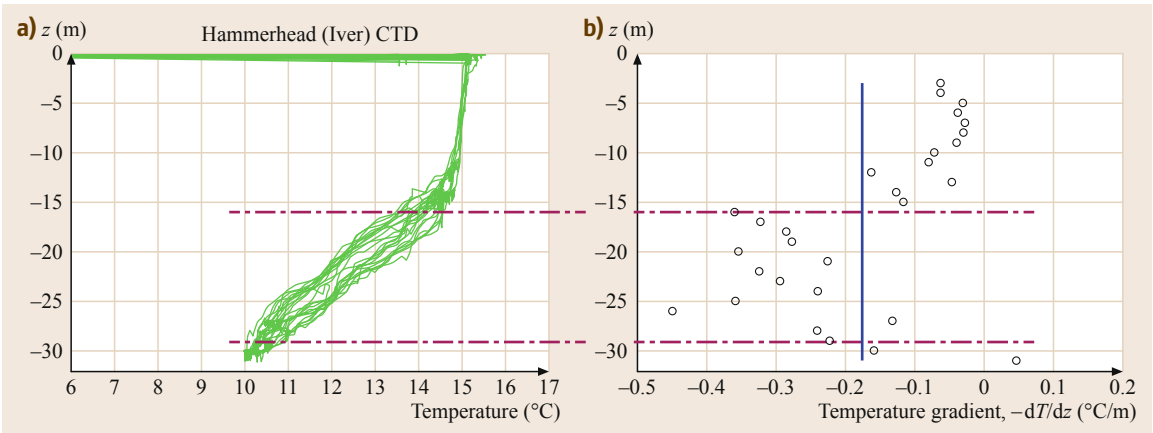

Fig. 20.18 **(a)** Temperature-depth profile over the entire mission (multiple dives), and **(b)** vertical temperature gradients averaged over 1-meter depth bins. (after [20.4], courtesy of *Petillo* et al.)

Champlain'09 was the second field trial of pEnvtGrad, where it underwent further testing and improvement while conducting adaptive thermocline tracking missions. In the horizontal plane, the AUV was deployed into a northwest–southeast straight line transect 1 km long. In the vertical, the AUV performed a depth-adaptive yo–yo pattern across the thermocline depth, which was determined autonomously by pEnvtGrad.

The results of one of these thermocline tracking missions are shown in Fig. 20.17, where the AUV was deployed for about 2 h total and was deployed into a thermocline tracking mission for the first 1.5 hours. Figure 20.17a shows the actual depth of the Iver AUV (multicolor points), with the colors corresponding to the temperature at the given depth, time, and location along the horizontal transect (not shown). The associated temperature values are plotted in the temperature-depth profile in Fig. 20.17b with the same color scale. In Fig. 20.17a, the AUV performs an initial yo–yo from 3 to 30 m as the first dive, gathering temperature data, and then determines autonomously that the thermocline is between about 14 and 29 m depth (smaller amplitude undulations) and starts tracking the thermocline. The thermocline depth bounds actively calculated on the AUV by pEnvtGrad are plotted as the green lines in Fig. 20.17a, which demonstrate the ability of the AUV to actively and autonomously adapt to changes in the thermocline depth boundaries (as small as 1 m) in real time. We chose 1 m depth bins because the water depth at the deployment location was of the order of 100 m, and the periodic reset was set at 30 min. The *dashed red lines* in Fig. 20.17 approximate (by inspection) the average thermocline bounds as determined by pEnvtGrad.

The postprocessed temperature data from the entire mission in Fig. 20.17 is shown in Fig. 20.18.

The average thermocline depth range was calculated as about 16–29 m (dashed lines, Fig. 20.18a,b) in postprocessing, with the total average temperature gradient $(\Delta T/\Delta z)_{\text{tot_avg}}$ of 0.168 °C/m set as the threshold value for bounding the thermocline range (solid vertical line, Fig. 20.18b). A gradient greater in magnitude than this average value's magnitude is determined to be within the depth range of the thermocline. When comparing the thermocline ranges determined by inspection of the AUV's actions in real time versus those calculated in postprocessing (dashed lines, Figs. 20.17a,b and 20.18a,b, respectively), it is apparent that they are very similar (within a couple of meters), verifying the effectiveness of the real time calculations and adaptation.

In this experiment, the muddy lake bottom at an imprecisely known depth posed a risk to the recovery of the AUV, thus we could not let it dive deeper than about 35 m. This directly bounded the range of depths over which we could collect temperature data, which affected the threshold value used to bound the thermocline. Thus, it is likely that we did not capture the full range of the thermocline during the mission. However, since the thermocline range was determined by pEnvtGrad to extend down to 30 m in the real-time data (for safety the maximum thermocline depth was bounded at 30 m from the initial yo–yo settings), this demonstrates the ability of the AUV to detect the majority of the sampled thermocline range with pEnvtGrad algorithms even in cases where data are unavailable over part of water column.

Thermocline Tracking for Internal Wave Detection (GLINT'10)

On August 13, 2010, MIT and NURC conducted the internal wave detection experiment (a single-day experiment in the larger GLINT'10 experiment) in the northern coastal basin of the Tyrrhenian Sea bordered by the Tuscan Archipelago and the western coast of Italy (Fig. 20.19). This experiment aimed to use nested autonomy and multiple AUVs to detect the presence of internal waves (or lack thereof) in this region of the Tyrrhenian Sea.

This experiment took a novel approach to internal wave detection by tasking two collaborating AUVs to autonomously adapt their motion in relation to each other and to their dynamic environment, resulting in a greater efficiency of sampling given a restrictive mission duration and in collection of fully synoptic data sets capturing internal waves.

The internal wave detection experiment involved two AUVs running the MOOS autonomy system guided by the IvP-Helm. These AUVs used acoustic communication during the experiment to send and receive real-time data and status updates, which they used to autonomously coordinate their motions in the horizontal plane through a track-and-trail behavior, as seen in the topside display in Fig. 20.20. In the vertical axis, the Unicorn AUV autonomously adapted to changes in the environment using the adaptive thermocline tracking behavior while the Harpo AUV (which would have also adapted, if the thermocline depth allowed for more reliable acoustic communication) swam just below the thermocline. A thermistor

Fig. 20.19 The region of the Tyrrhenian Sea bounded by the western coast of Italy and the islands of the Tuscan Archipelago. The Tuscan Archipelago basin is outlined by the dashed line. The GLINT'10 AUV operation region is delineated by the box. The numbering shows the five inlets of the basin (after [20.9], courtesy of *Petillo* and *Schmidt*)

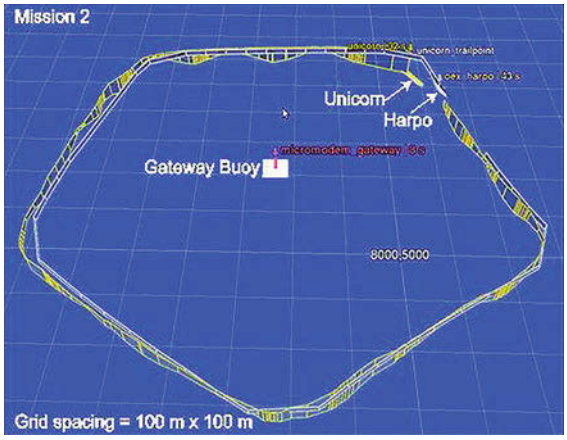

Fig. 20.20 Mission 2 loiter pattern around the gateway buoy, as seen from above, at an angle to the horizontal. Harpo performs a horizontal loiter pattern at constant depth (12 m) just below the thermocline. Unicorn trails directly behind Harpo while performing an adaptive yo–yo pattern through the thermocline depth range. *Vertical bars* along the loiter indicate the AUVs' depths (*yellow* is Unicorn's track, *white* is Harpo's track), and their current positions are shown by the *arrows* (after [20.9], courtesy of *Petillo* and *Schmidt*)

chain was also deployed for the duration of the experiment.

In examining the resulting AUV and thermistor data sets from this experiment, there is strong evidence of internal wave propagation along the thermocline near the buoyancy frequency of the thermocline interface ($N_{max} = 0.05747\,\mathrm{rad/s}$). Internal waves with nearly identical and lower frequencies were seen in the Unicorn, Harpo, and thermistor data collected near the thermocline depth. The 12 −m depth AUV and 11 −m depth thermistor results suggest the presence of buoyancy-supported internal waves along the thermocline (about 11 m depth) in the AUV operation region throughout the day on August 13, 2010. This conclusion may also be extrapolated to say that internal waves are likely detectable along the thermocline throughout the rest of the Tuscan Archipelago basin during the summer, when the thermocline is fairly well defined. Given the lack of previous literature regarding internal waves in the Tuscan Archipelago basin, this finding is rather significant to the scientific groups that conduct acoustic (and other) experiments in this region. See [20.9] for more detailed results and analysis from the internal wave detection experiment.

Overall, this experiment was novel in its use of multiple AUVs collaborating autonomously with each other and autonomously collecting environmentally adaptive data sets for more synoptic spatiotemporal data coverage. Not only does this increase the efficiency of data collection (environmentally-adaptive autonomy behaviors allow us to collect the exact data set we need without a human in the loop), but it also gives us the ability to collect the specific data set a scientist is interested in by using AUVs running autonomy. The use of intelligent acoustic communication networking also allows the AUV operators and scientists to monitor (from the topside on a ship or shore) the data collected in near real time. These abilities are invaluable when ship time for data collection is so expensive, and we hope that such improvements in AUV autonomy, adaptive environmental sampling techniques, and acoustic communications will allow us to further reduce necessary ship time for scientists and engineers to collect the specific data sets they need in the future.

20.6.3 Bistatic Target Tracking (GLINT'10)

As part of the GLINT experiment program and associated research, the nested autonomy paradigm was extended to the bistatic tracking of underwater targets. The concept of this application can be illustrated by the two-dimensional bistatic geometry in Fig. 20.21. The passive acoustic receiver (denoted as R), constructed as a hydrophone array, is towed by an AUV in this application. The active acoustic source (denoted as S) is deployed to transmit known sonar pulse signals at time t_k, where $k = 1, \ldots, N$ denotes the sonar ping number. The sonar pulse signals reach the receiver as two distinct dominant signals – the direct blast is the signal traveling straight from the source to receiver, and the indirect blast is the signal traveling from the source to receiver via acoustic scattering at the target (denoted as T). These signals are then recorded as hydrophone array data on the receiver. By processing the data, the target state – consisting of the Cartesian position and velocity – can be accurately estimated.

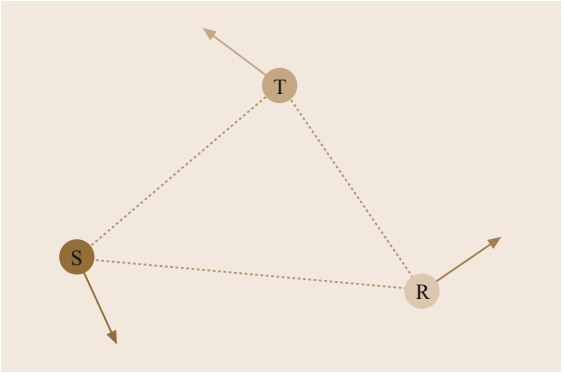

Fig. 20.21 Two-dimensional (2-D) bistatic geometry involving source (S), target (T), and receiver (R). The directional arrows indicate the velocities of the corresponding bistatic assets

Integrated Perception, Modeling, and Control

A new *integrated perception, modeling, and control paradigm*, as shown in Fig. 20.22, has been introduced for the AUV/receiver to solve the bistatic tracking problem [20.10, 11]. The *automated perception*, on the

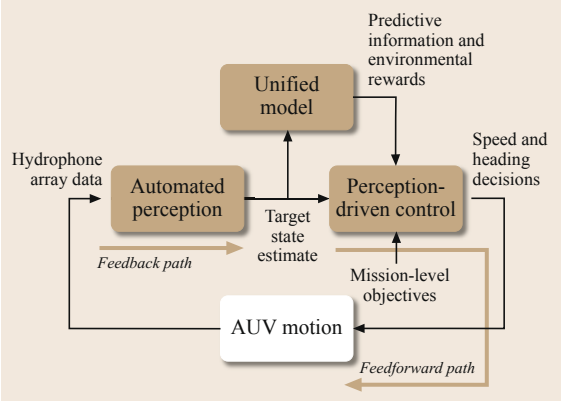

Fig. 20.22 Integrated perception, modeling, and control paradigm for the AUV/receiver to solve the bistatic tracking problem

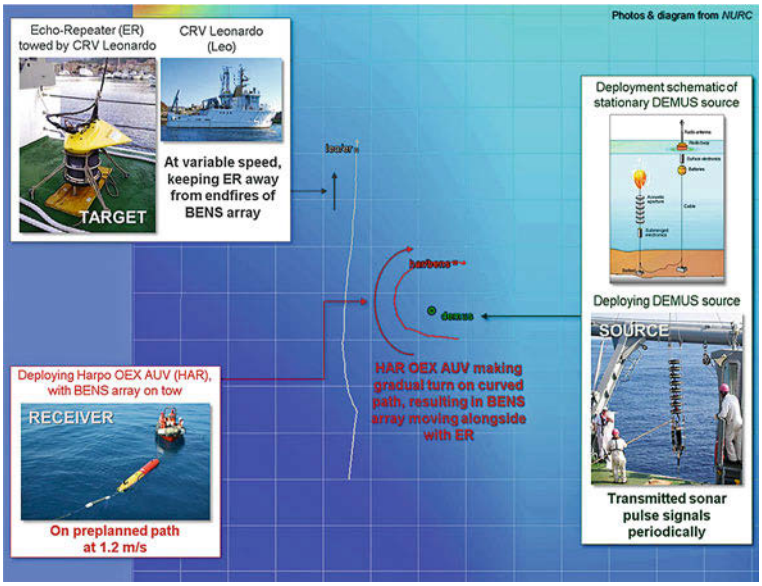

Fig. 20.23 Ground truths of bistatic assets for a GLINT'10 experimental run with photos and schematic diagram. The DEMUS source is plotted in *green*, the Harpo OEX AUV towing BENS array is plotted in *red*, and the CRV Leonardo towing the echo repeater (ER) is plotted in *gray*. The historical Cartesian positions of bistatic assets are depicted, with their current speed and heading indicated by the length and direction of the *arrow* at their current positions. The AUV was commanded to move along a preplanned path at 1.2 m/s – heading west first, before making a gradual turn on the curved path, and then heading east. CRV Leonardo was cruising northward at variable speed, trying to keep the target away from the endfires of the receiver

feedback path, is used to process the hydrophone array data from the receiver, and provide the target state estimate. This perception is performed using sonar signal processing and target tracking algorithms. The estimate is the perceptive feedback in the closed-loop control system for driving both the *perception-driven control* and *unified model*. The *perception-driven control* then deliberates the perceptive feedback against the mission-level objectives to make unsupervised decisions on the speed and heading for the *AUV motion* in the feed-forward path. No depth decision is considered here since Fig. 20.21 is dealing with two-dimensional geometry. By controlling the *AUV motion*, the vehicular path is adjusted adaptively. A new *bistatic behavior* has been developed in the *perception-driven control* to execute, in real time, a new nonmyopic and adaptive control for the vehicle. The predictive information and environmental rewards from the *unified model* are used to provide the IvP function for this new behavior. The *unified model* is amalgamated from both information theoretic and environmental acoustic models. These models are then used to predict the pertinent information and acoustic characteristics of the target state estimate for the particular bistatic geometry. The pertinent characteristics predicted for different future bistatic geometries, resulting from different discrete speed and heading decisions at the current target state estimate, are then encapsulated in the predictive rewards. In essence, the control formulation presents a new vehicular control that applies both information-theoretic and environmental-based controls concurrently.

AUV on Preplanned Path

To demonstrate the advantage of this new *integrated perception, modeling, and control paradigm*, the bistatic tracking results of the underwater target are compared with the AUV operating with and without this new paradigm. We will first examine the tracking results without this paradigm. The data we use are from the GLINT'10 experimental run, conducted jointly between MIT and NURC, in the Tyrrhenian Sea off the coast of Italy. The ground truths of the bistatic assets utilized for this experimental run, together with their respective photos and schematic diagram, are depicted in Fig. 20.23. The deployable experimental multistatic undersea surveillance (DEMUS) source was deployed as stationary asset, and transmitting sonar pulse signals. The echo-repeater (ER) was used to simulate a target by retransmitting the recorded sonar pulse signals from the source. It was towed by the CRV Leonardo (Leo). The receiver was the BENS (Broadband Environmental Networked Sensor) array, towed by the

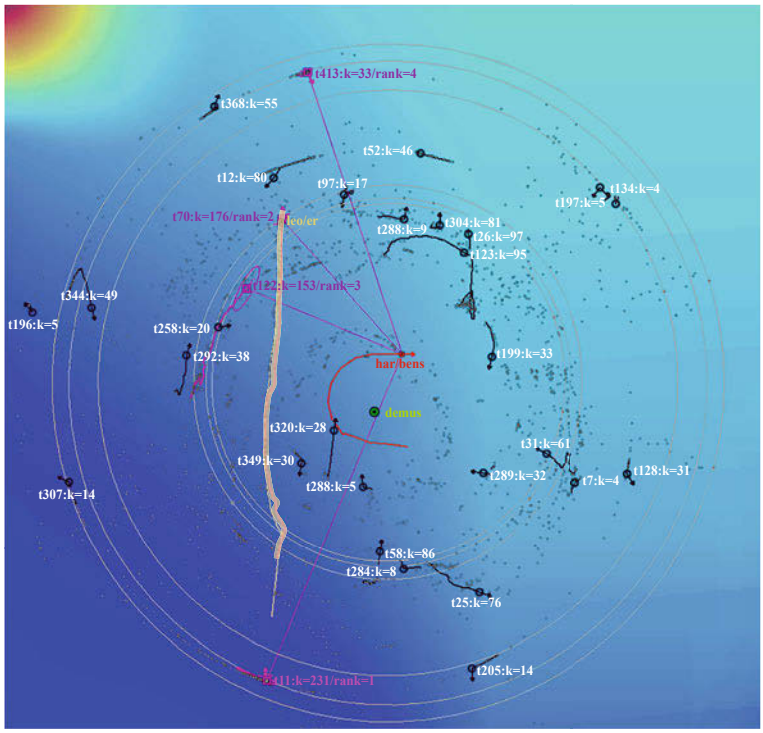

Fig. 20.24 Bistatic tracking results from *automated perception* for the GLINT'10 experimental run at ping $k = 234$. The ground truth of the DEMUS source is plotted in *green*, the Harpo OEX AUV towing the BENS array is plotted in *red*, and the CRV Leonardo towing the ER is plotted in *gray*. Confirmed tracks are plotted in *magenta*, terminated tracks are plotted in *black*, and information pertaining to these tracks is depicted

Ocean Explorer (OEX) AUV. The AUV was commanded to move along a preplanned path at 1.2 m/s, for the entire run from ping $k = 1$ to 235, without adopting the new paradigm. The AUV headed west first, before making a gradual turn on a curved path, and then headed east. The *automated perception* was used to process the hydrophone array data from the receiver and provided the target state estimate. However, this estimate was not used in the control. CRV Leonardo was cruising northward at variable speed, trying to keep the target away from the forward and aft endfires of the receiver array. This was done to ensure good tracking results on the target.

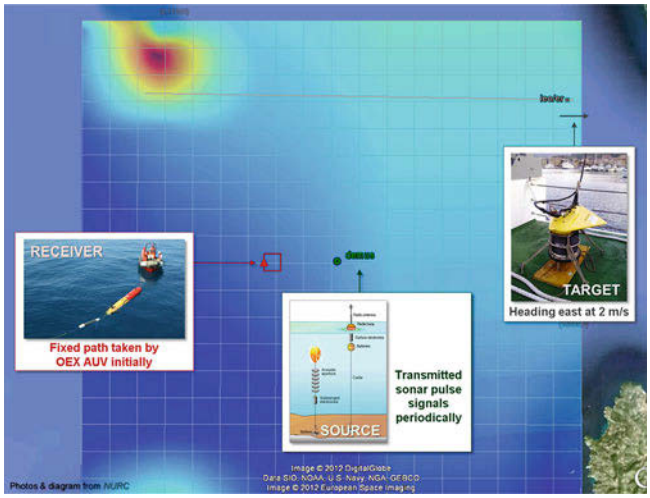

Fig. 20.25 A simulated tactical scenario with the stationary DEMUS source plotted in *green*, the initial fixed path taken by the OEX AUV plotted in *red*, and the CRV Leonardo towing the ER plotted in *gray*. CRV Leonardo was simulated to head east at 2 m/s

The bistatic tracking results from the *automated perception* for this experimental run at ping $k = 234$ are shown in Fig. 20.24. Both the confirmed and terminated tracks are clearly plotted, and the information pertaining to these tracks is depicted. For the confirmed track due to the ER, the information $t70 : k = 176/\text{rank} = 2$ implies that track #70 has been active for 176 pings since initiation and is ranked #2 in the active track priority. This track depicts the state estimated for the target over the past 176 pings. Track #122 is due to the ghost of the ER. This is caused by the starboard/port side ambiguity of the BENS array. However, this ghost is not well tracked because the constant maneuvering by the AUV, particularly during the gradual turn on the curved path, causes the track to violate the nearly constant velocity (NCV) target dynamic model assumed in the *automated perception*. Tracks #11 and #413 are due to the prominent fixed but unknown underwater objects that were persistently present since the start of the experimental run. With the target speed, good target tracking results are obtained for track #70.

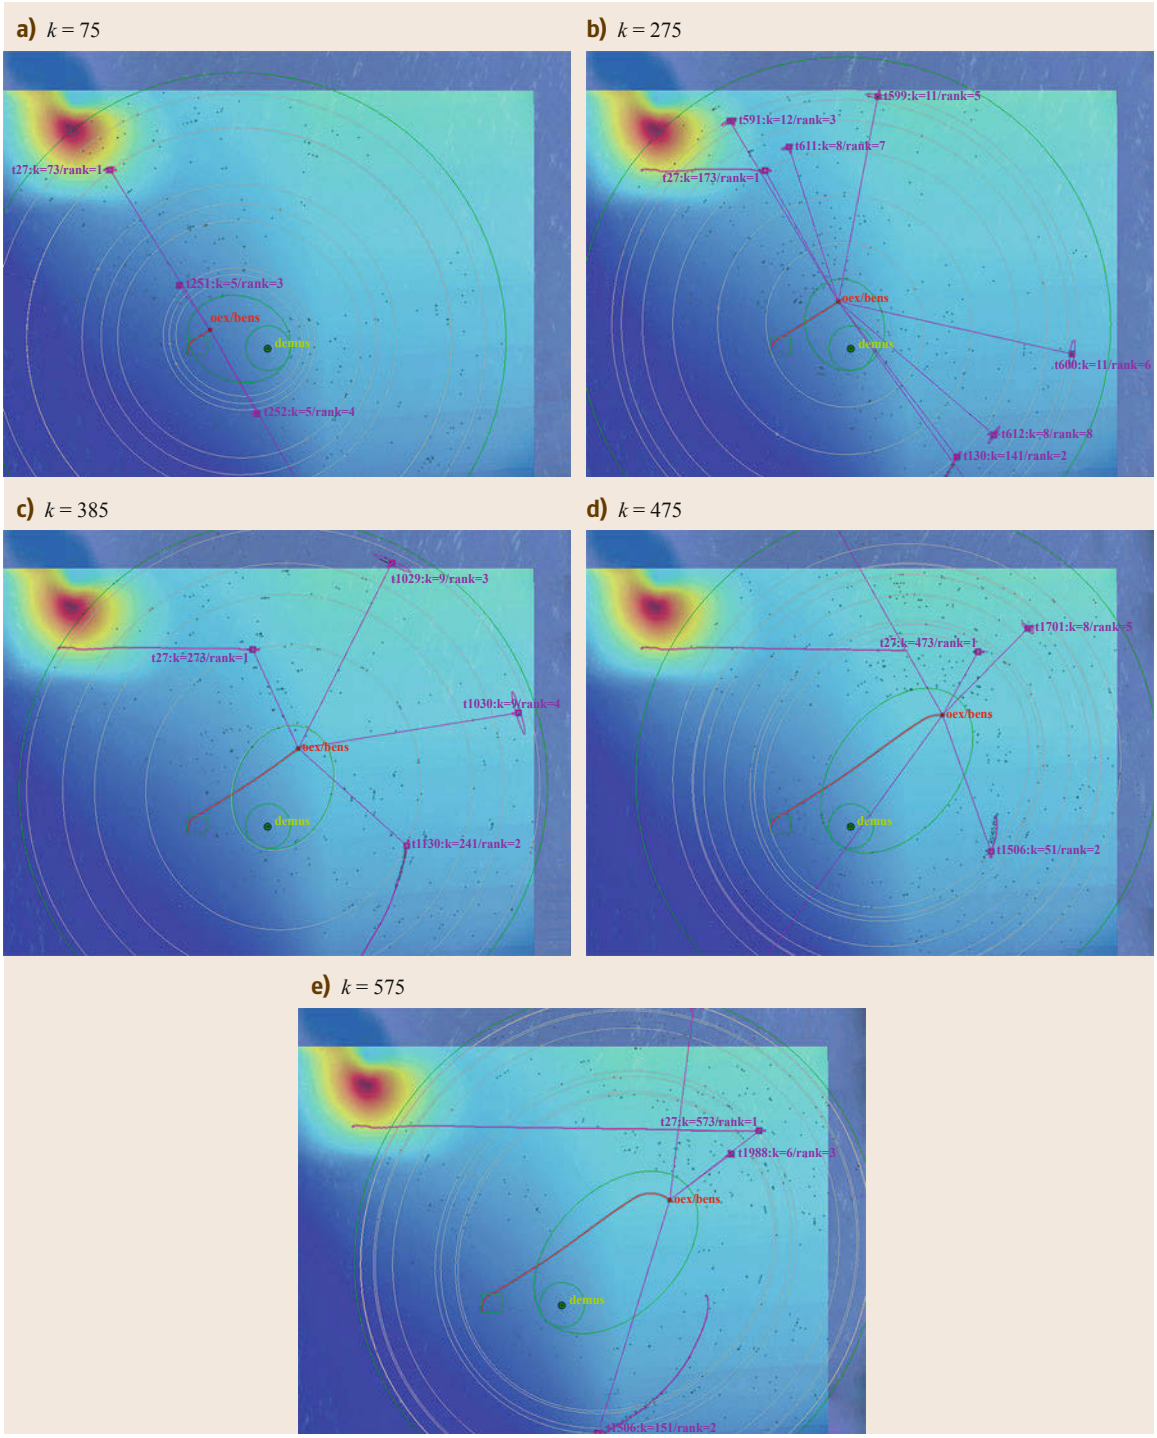

Fig. 20.26a–e Simulated results of a tactical scenario at pings $k = 75$ **(a)**, $k = 275$ **(b)**, $k = 385$ **(c)**, $k = 475$ **(d)**, and $k = 575$ **(e)** with the *bistatic behavior* applied on the OEX AUV and driven by target state estimates of the confirmed track #27 from the ER. The stationary DEMUS source is plotted in *green*. The OEX AUV towing the BENS array is plotted in *red*. The OEX AUV was initially moving on a fixed path, but switched to an adaptive path upon tracking the entry of the ER. The moving ER, towed by the CRV Leonardo, is plotted in *gray* (not visible) and was heading east. Confirmed tracks are plotted in *magenta*

AUV on Adaptive Path

In the previous section, the bistatic tracking results were obtained with the AUV on a preplanned path. The AUV was not reacting to the target state estimate obtained from the *automated perception*. The target speed was adjusted to keep the target away from the endfires of the receiver. This was done to ensure good tracking results on the target. Operationally, this is not realistic since the target is never cooperative. In this section, we will implement the *integrated perception, modeling, and control paradigm* on the AUV. The synthetic data, generated from a high-fidelity simulator, is used here with the same bistatic assets as the experimental data in Fig. 20.23. The simulated tactical scenario is shown in Fig. 20.25. For this scenario, the stationary DEMUS source was simulated to transmit sonar pulse signals. The ER, towed by the CRV Leonardo, was used to simulate a noncooperative target cruising eastward at a fixed speed of 2 m/s from ping $k = 1$ to 650. The OEX AUV, towing the BENS array, was commanded to move along the fixed path initially. With the new paradigm implemented on the AUV, the target state estimate of the ER from the *automated perception* is now used to drive both the *perception-driven control* and *unified model*.

The simulated results of the tactical scenario at different pings k are obtained in Fig. 20.26. The target state estimates of the confirmed track #27 due to ER from the *automated perception* were used to drive the *perception-driven control* and *unified model*. The AUV was initially moving on a fixed path, but switched to an adaptive path upon tracking the entry of the ER. This adaptive path was planned with the *bistatic behavior* in the *perception-driven control*, with the objective of maximizing the information and acoustic performance of the target state estimate. With the adaptive path taken by the AUV, good target tracking results are obtained for track #27.

From the results obtained in Figs. 20.24 and 20.26, it is clear that the *integrated perception, modeling, and control paradigm* allows the path of the AUV to be adaptively adjusted in reaction to the target state estimated from the tactical situation. The path has been planned with the objective of optimizing the target tracking performance. Such methodology can be easily extended for distributed nodes in an AUV network.

20.7 Conclusion

Being dependent on acoustic communication with a channel capacity many orders of magnitude smaller than the air- and land-based equivalents, the operation of distributed ocean sensing networks requires a much higher level of autonomous, distributed data processing, and control than land- and air-based equivalents. The *nested autonomy* paradigm and its underlying principle of *integrated sensing, modeling and control* described here are inherently suited for the layered communication infrastructure provided by the low-bandwidth underwater acoustic communication and the intermittent RF connectivity. Implemented using the open-source MOOS-IvP behavior-based, autonomous command, and control architecture, nested autonomy allows each platform to autonomously detect, classify, localize and track (DCLT) an episodic ocean event without depending on operator command and control. The prosecution of a particular event may be initiated by the operators through an acoustically transmitted compact command message, cued by other sensing systems, such as satellite remote sensing, for example, or fully autonomously by an on-board detection algorithm, but the fundamental principle of the paradigm is that each network node shall be capable of completing its missions objectives, irrespective of communication connectivity. The inferred properties of the event are reported back to the operators by transmitting a compact *event report*, using a dedicated command and control language. Collaborative processing and control may be exploited when the communication channel allows, for example, for collaborative tracking of extended features such as plumes and fronts. The nested command and control paradigm has here been demonstrated for the fully autonomous, adaptive tracking of the space- and time-varying coastal thermocline and acousticline, using relatively simple onboard signal processing, but the highly modular MOOS-IvP architecture allows the event characterization and tracking algorithms to be exchanged with customized and advanced processing software without altering the operational functionality of the autonomy system.

21. Science of Autonomy: Time-Optimal Path Planning and Adaptive Sampling for Swarms of Ocean Vehicles

Pierre F.J. Lermusiaux, Tapovan Lolla, Patrick J. Haley Jr., Konuralp Yigit, Mattheus P. Ueckermann, Thomas Sondergaard, Wayne G. Leslie

The science of autonomy is the systematic development of fundamental knowledge about autonomous decision making and task completing in the form of testable autonomous methods, models and systems. In ocean applications, it involves varied disciplines that are not often connected. However, marine autonomy applications are rapidly growing, both in numbers and in complexity. This new paradigm in ocean science and operations motivates the need to carry out interdisciplinary research in the science of autonomy. This chapter reviews some recent results and research directions in time-optimal path planning and optimal adaptive sampling. The aim is to set a basis for a large number of vehicles forming heterogeneous and collaborative underwater swarms that are smart, i. e., knowledgeable about the predicted environment and their uncertainties, and about the predicted effects of autonomous sensing on future operations. The methodologies are generic and applicable to any swarm that moves and senses dynamic environmental fields. However, our focus is underwater path planning and adaptive sampling with a range of vehicles such as autonomous underwater vehicles (AUVs), gliders, ships or remote sensing platforms.

Ocean observing is the process of collecting ocean measurements to provide the most useful information about the ocean systems and dynamics of interest. Such marine sensing is expensive and challenging. In the ocean, not everything can be measured on a sustained basis. Ocean modeling is the process of developing and utilizing theoretical and computational models for the understanding and prediction of ocean dynamics. Similar to ocean observing, ocean modeling is challenging, and not every naval and environmental process can be modeled exactly. Stochastic ocean modeling explicitly acknowledges these uncertainties in modeling and thus augments deterministic predictions with probabilistic information. Data assimilation is the process of quantitatively estimating dynamically evolving fields by combining information from observations with those predicted by models, hence limiting uncertainties. With stochastic predictive capabilities and data assimilation, one can estimate future conditions and their uncertainties, and make informed decisions and complete desired tasks. Systems that integrate some of these activities without continuous human guidance are often referred to as autonomous systems.

The science of autonomy is the systematic development of fundamental knowledge about autonomous decision making and task completing in the form of testable autonomous methods, models, and systems. In ocean applications, it involves varied disciplines that are not often connected. For example, ocean dynamics, sensing, robotics, communications, predictions, and uncertainty, as well as varied types of human–computer–vehicle interactions are inputs to ocean autonomy. There are two important ocean modeling feedbacks to autonomy. The first one is the use of models to predict optimal

paths for swarms of ocean vehicles and the second is the use of models to predict the sensing expected to be most useful. Prediction of optimal paths for ocean vehicles is referred to here as *path planning*. This search for optimality often focuses on time-optimal or energy-optimal paths. The prediction of optimal sensing strategies is referred to as *adaptive sampling*. We note that in both cases, the prediction of paths can itself be improved adaptively in the sense that observations collected along the path can be utilized to update the predictions. Such updates can be completed onboard vehicles in the form of *onboard routing* or by central/hierarchical computational entities for *high-level routing*.

Recent autonomous marine activities have started a revolution that was possibly first imagined by *Henry Stommel* in his now famous article, *The Slocum mission* [21.1]. Today, the number of autonomous platforms used in semi-coordinated sea operations can be larger than 10, and this number is increasing. This new paradigm in ocean science and operations motivates the need to carry out interdisciplinary research in the science of autonomy. This chapter reviews some recent fundamental results and research directions in time-optimal path planning and optimal adaptive sampling, setting a basis for a large number of vehicles forming heterogeneous and collaborative underwater swarms that are smart, i. e., knowledgeable about the predicted environment and their uncertainties, and about the predicted effects of autonomous sensing on future operations. The methodologies are generic and applicable to any swarm that moves and senses dynamic environmental fields. However, the focus of this chapter is underwater path planning and adaptive sampling with a range of vehicles such as AUVs, gliders, ships, or remote sensing platforms.

When compared to related control and robotics problems of large dimensions, the differences with the present focus on ocean applications are that:

- Naval platforms are heterogeneous and their data are gappy but multivariate.
- Marine fields can strongly affect vehicles' operations, are dynamic on multiple-scales, and have very large dimensions, but are predictable to some degree.
- The measurements to be collected affect these future predictions.

Therefore, there are feedbacks between optimal planning, sampling and predicting, in time and space, and across variables. The field of ocean autonomy thus uses guidance from ocean flow and acoustic propagation modeling, information theory, dynamical system theory, uncertainty prediction, decision-making under uncertainty, machine learning, bio-inspired algorithms, and distributed computing. In all cases, our focus here is to predict global dynamic swarm patterns and perform high-level optimization. This is not the detailed fully-resolved control of a single robot. In our focus, a global objective function defines the optimal dynamic and collaborative autonomy. In general, objective functions depend on the predicted environment, on the predicted values and positions of the expected measurements, and on the feedbacks between measurements and predicted dynamics.

In what follows, we focus on the science of autonomy results obtained by our multidisciplinary simulation, estimation, and assimilation systems (MSEAS) group and recent collaborators. We first outline and present a subset of our results on time-optimal path planning for swarms of ocean vehicles (Sect. 21.1). This is followed by an overview of some of our results in adaptive sampling (Sect. 21.2). Our objective is to outline overall schemes and approaches, and to illustrate their applications in idealized and realistic ocean conditions. For detailed descriptions of the algorithms and methodologies we developed and utilized, we refer to references cited in each of these sections. For general reviews on oceanic path planning, we refer to [21.2] and [21.3], and for general reviews on oceanic adaptive sampling, to [21.4–8], and [21.9]. Brief conclusions and outlook are given in Sect. 21.3.

21.1 Time-Optimal Path Planning for Swarms of Ocean Vehicles

Our new level-set based method for time-optimal path planning of vehicle swarms in time-varying uncertain velocity fields (ocean currents) was developed and described in [21.2, 3, 10–14]. To forecast the time-optimal trajectories of large numbers of robotic vehicles navigating in strong and dynamic flows, our approach first evolves the reachable sets from the starting points. A reachable set is the set of points that can be visited by a vehicle at a given time. The boundary of such a set is called the reachability front. Our approach keeps track of the reachability front at all times, so that we can determine when the front first reaches the end point. A path traced by a point on the reachability front that first reaches the end point is an optimal path that we wish to compute.

We obtained a modified level set (21.1) for ϕ^o, the scalar field that governs the evolution of reachability fronts [21.3, 10, 11, 14], linking it to the Hamilton–

Jacobi equation governing the minimum-time navigation problem in dynamic flows. The reachability fronts are evolved from the vehicle start points y_s until they reach the desired end points y_f, combining nominal vehicle motions due to steering and advection by the dynamic flow environment, as shown by (21.1). An optimal trajectory $X_P^*(y_s, t)$ and the corresponding vehicle heading directions are then extracted from the evolution of the reachability fronts. This is done by solving the backtracking (21.2) where the solution ϕ^o is differentiable, starting from an end point y_f and integrating backward in time to the start point y_s

$$\frac{\partial \phi^o}{\partial t} + F|\nabla \phi^o| + v \cdot \nabla \phi^o = 0\,, \tag{21.1}$$

$$\frac{\mathrm{d}\, X_P^*(y_s, t)}{\mathrm{d}t} = -v(X_P^*, t) - F\frac{\nabla \phi^o(X_P^*, t)}{|\nabla \phi^o(X_P^*, t)|} \quad \text{with } X_P^*(y_s, T^*(y_f)) = y_f\,. \tag{21.2}$$

We also extended the methodology to the case of coordinated motions of swarms of vehicles and to the case of uncertain stochastic flows. Coordinated motion in this context refers to maintaining swarm formations of specific geometrical shapes by the vehicles, regardless of the ocean currents. Accounting for uncertainties in the predicted ocean fields allows us to yield the paths that best compromise between least uncertainty and least total travel time.

Our approach is interdisciplinary: It is inspired by ideas in fluid and ocean sciences, computational sciences, numerical methods, and uncertainty quantification, and applies them to path planning, which has roots in robotics and optimal control. The methodology is based on solving (stochastic) partial differential equations. In this sense, it is rigorous and obviates the need for heuristics. To compute the level set evolution, i. e., the viscosity solution to the Hamilton–Jacobi equation, we either use our finite-volume code for partial differential equations (PDE) (with varied orders, limiters, etc.) or narrow-band level set and fast marching methods for efficient computations. For the uncertain flow case, we employ our stochastic PDEs solvers [21.15]. In all cases, the computational cost increases only geometrically with the number of grid points (and not with the path length). We refer to the above-mentioned references for descriptions of numerical algorithms. Next, we illustrate results under diverse fluid and ocean conditions, as well as diverse vehicle behaviors.

21.1.1 Canonical Steady Flows

We first evaluated our level-set-based methodology by computing time-optimal paths in canonical steady ocean flow features. Such problems include, for example, determining how to time-optimally enter or leave an ocean eddy, cross an ocean jet, or maneuver in a meander/wave field [21.13]. The results can be very useful as rules-of-thumb for time-optimal operations.

To exemplify such canonical steady flow problems, we consider idealized 2-D-in-space (x, y) non-dimensional *highway* scenarios (2-D: two-dimensional), as illustrated in Fig. 21.1 [21.13]. In the first case (Fig. 21.1a), the vehicle is deployed from $(0, -0.4)$, with the goal of reaching the point at $(0, 0.8)$. The speed of vehicle is 1. The flow consists of two different jets, both flowing in the positive y direction. The first jet (narrow band with black arrows on the left) has a higher speed, $v_1 = 2$, than the vehicle. The second jet (narrow band with red arrows on the right) has a constant speed equal to that of the vehicle, $v_2 = 1$. From (Fig. 21.1a), the optimal path takes advantage of the higher jet flow on the left to reach the goal point. In the second case (Fig. 21.1b), the vehicle is deployed from $(-0.6, -0.6)$ and the goal point is at $(0.6, 0.6)$. The speed of the vehicle is 1. In this case, we have two different jets flowing in opposite directions, both with a speed of 1.5 (faster than the vehicle). The first jet (upper narrow band with black arrows) flows in the negative x direction. The second jet (lower narrow band with red arrows) flows in the positive x direction. As can be seen from (Fig. 21.1b), the vehicle rides the first jet to an upstream position of the second jet in order to compensate for the unfavorable flow of the lower jet. Then, the vehicle crosses the second jet as quickly as possible to reach its goal. In another *highway* test (Fig. 21.1c), the vehicle is deployed from $(-0.6, 0.6)$ and the goal point is at $(-0.6, -0.6)$. The speed of the vehicle is 1. In this case, we have two different jets flowing with a speed of 1.5 (faster than the vehicle). The first jet (upper narrow band with red arrows) flows in the positive y direction. Therefore, it is infeasible to use any trajectory crossing this jet flow. The second jet (lower narrow band with black arrows) flows in the positive x direction. As can be seen from (Fig. 21.1c), the vehicle first skirts the upper flow on the right-hand side. Then it moves to an upstream position of the second jet and crosses it as quickly as possible to reach the goal.

21.1.2 Time-Dependent 2-D Flows

Time-dependent flows are now considered. To evaluate robustness, a large number of 2-D flows were utilized, including flows at the exit of a strait, flows behind islands, and wind-driven flows. Such flows have also been utilized to evaluate our approach for the path planning of swarms of vehicles [21.3, 10–12, 14].

Next, we present three examples of time-optimal path planning for swarms of vehicles in the context of

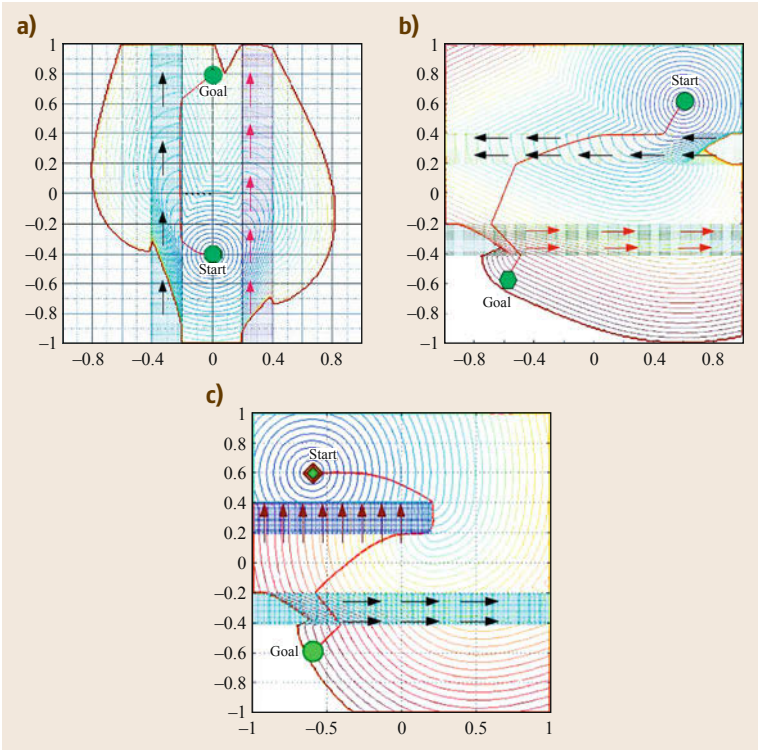

Fig. 21.1a–c Highway test cases. **(a)** 2 ideal jets. Faster jet on left (*black arrows*). Level-set optimal path rides the faster jet. **(b)** Two ideal jets in opposite directions. Level-set optimal path first rides top jet to get to an upstream position of opposing lower jet. It then crosses the opposing jet as quickly as possible to reach goal. **(c)** This case includes one truncated jet (at twice the vehicle velocity) that is effectively an impenetrable obstacle. The second jet is a transverse jet, similar to the bottom jet in **(b)**. Here the level-set optimal path moves around the truncated jet to reach an upstream position of lower jet. It then crosses the lower jet as quickly as possible to reach the goal (after [21.13])

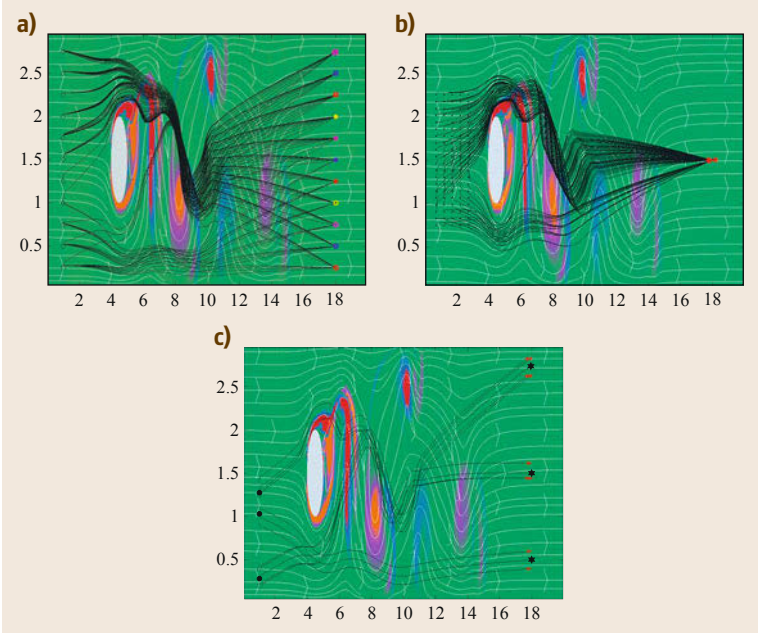

Fig. 21.2a–c Vorticity of the flow past an island (*gray oval*) overlaid with white streamlines. **(a)** *All-to-all broadcast* with swarms while crossing strong eddy field in optimal time – 11 swarms of 11 members each, avoid island, utilize eddies/wakes, reform swarms, and communicate. **(b)** *All back to ship* optimal recovery of large swarm formation of vehicles – formation of 100 vehicles to return to ship for pick up, avoid island, utilize eddies/wakes to return in shortest time. **(c)** *Maintain swarm formation* with coordination based on local gradients or dynamics – 3 swarms of 2–4 members (*line*, *triangle*, *square*), avoid island, shortest time (after [21.10, 12, 14])

flows past an island. The circular island is an obstacle to both the flow and to the vehicles. The flow is fast enough to cause the shedding of vortices off the leeward side of the island.

The first swarm example is an *all-to-all broadcast* to swarm leaders, in which 11 swarms of 11 members each optimally cross the strong eddy field in the wake of the island while exchanging information with each other:

Specifically, one member of each swarm switches to another swarm and all subsequently reform the swarms in fastest time at 11 target locations (Fig. 21.2a). In other words, we start with 11 swarms of 11 vehicles each at the 11 starting points upstream of the island (shown by open circles). Each of the initial swarms is to break up and distribute one member to each of the 11 target points downstream of the island (shown by colored markers), resulting in 11 new swarms, each made up from 1 member of each of the original 11 swarms. The goal is to achieve the new configuration in minimum time, communicating data to each swarm leader, while avoiding the island. The optimal paths computed by our level-set-based method are the black curves in (Fig. 21.2a). We see three classes of paths. Most paths go above the island and get a boost from the first shed eddy. A second group goes below the island and intercepts the eddy at a later point. The final grouping remains below the island and avoids the eddy.

The second example is an *all-back-to-ship* fastest-time recovery scenario (Fig. 21.2b). A formation of 100 vehicles starts upstream of the island (black dots). The goal is to find the quickest paths to bring all the vehicles to a single pick-up point (18, 1.5) downstream of the island, utilizing wakes and eddies while avoiding the island (simulating the recovery of a swarm of AUVs by a single ship). The optimal set of paths are found by the level-set-based method and are shown as black curves in Fig. 21.2b. Roughly three quarters of the vehicles are sent over the island to take full advantage of the first eddy. Most of the remaining vehicles avoid the eddy by passing under the island, although some go under the island and catch the eddy later.

21.1.3 Maintain Swarms Formations

Building on the above, we created algorithms for *maintaining swarm formations*. The first example consists of three swarms of two to four members each, organized in the shape of a line, triangle or square, coordinating their paths based on gradients or dynamics (Fig. 21.2c). For the algorithm illustrated, the coordination is based on local gradients (Fig. 21.2c), using a local control algorithm.

Here, the goal is to bring each of the three swarms from their start locations to their target locations in minimum time while maintaining their formation and avoiding the island. We utilize our level-set-based method to compute the optimal paths for the center of mass of each swarm (black curves starting from black dot and finishing at black star). Around each center-of-mass-path we construct the swarm paths by using the headings for the optimal center-of-mass-path and adding a velocity component at each step to maintain each vehicle position relative to the center of mass. To prevent the vehicle paths from diverging, we allow the center of mass to move at a speed lower than the maximum vehicle speed (i. e., the center of mass moves with a velocity that is a function of the instantaneous flow).

A drawback of this local control approach is that the allowable separation between vehicles depends on the flow dynamics. The distance between vehicles has to be small if the flow speed is highly variable in space (large flow gradients). The smoother the flow in space, the larger the spacing between vehicles can be. In [21.12], we develop a more powerful methodology based on local level-sets which allows maintaining complex shapes in large flow gradients; a time optimal path is computed for the group leader and finite-time local level sets are computed continuously in time for the other vehicles in the swarm. The latter provide reachable sets for each of these vehicles for each finite-time horizon (which could be a time step) and allow a subsequent shape optimization algorithm to find and sustain an optimal swarm formation.

21.1.4 Forbidden Regions

Forbidden regions are areas which are denied to the vehicles (for safety reasons or security restrictions) but do not affect the flow field [21.3]. In the example that follows, this constraint information is provided to the vehicles ahead of time, just as restricted regions or forecasts of hazardous weather can be provided to an aircraft. In these conditions, the goal is still to compute time-optimal paths, but under the additional constraint of avoiding the provided or forecast forbidden regions.

For example, consider a uniform barotropic jet exiting a strait or estuary (sudden expansion or 2-D coastal flow), as illustrated in Fig. 21.3. The non-dimensional speed of the vehicle is 0.5, while the largest current speed is 2.5 (Fig. 21.3a,b). The width of the inlet is one third of the total width of the channel. In the simulation (Fig. 21.3c), nine vehicles are released from the lower edge of the inlet (black dot) and are required to achieve a triangular formation (colored dots). The unconstrained time-optimal paths constructed from the level-set-based algorithm are shown by colored lines. The vehicle heading for the tip of the triangle rides along the central jet, while the vehicles targeting the four endpoints closest to the inlet use the upper and lower recirculation eddies. Overall, we can see from Fig. 21.3c that the algorithm correctly predicts the shapes of the optimal paths.

In the companion case (Fig. 21.3d), two forbidden regions are added (gray shaded area), which block seven of the nine paths in the free run (Fig. 21.3c). The

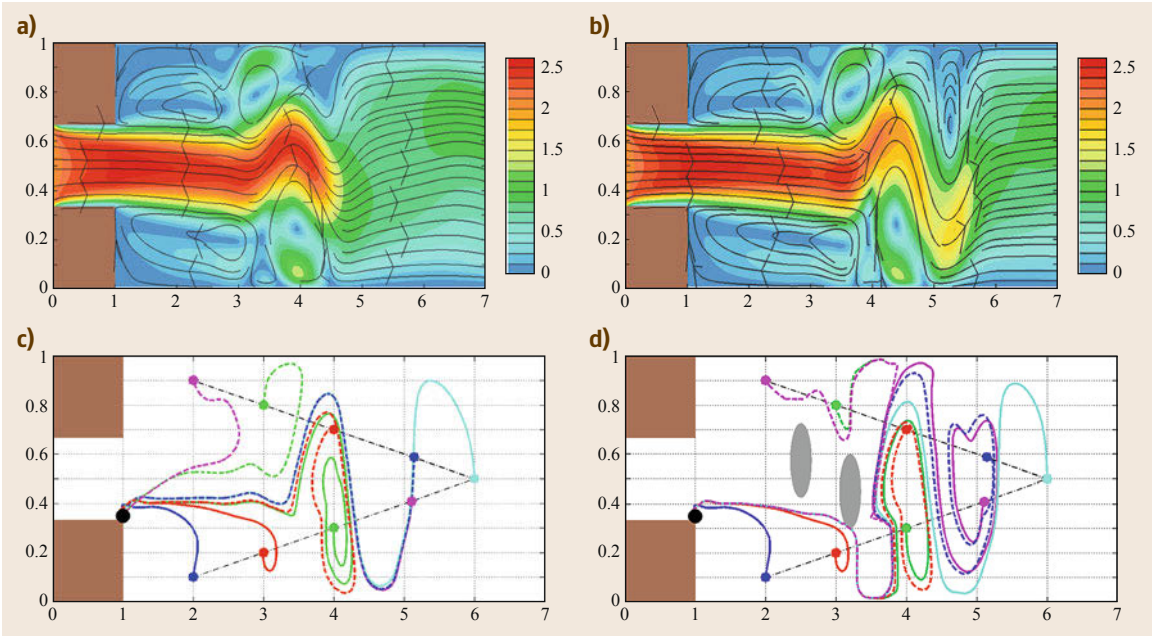

Fig. 21.3a–d Time-optimal paths without **(c)** and with **(d)** forbidden regions. **(a,b)** Snapshots of flow field for a jet exiting a strait or estuary (sudden expansion flow) **(a)** At time of initial vehicle deployment and **(b)** at final time of vehicle maneuvers in **(c)**. **(c,d)** Optimal vehicle paths for nine vehicles deployed from a single point (*black dot*) in the flow field of **(a,b)**. Results for two situations: **(c)** no constraints or forbidden regions. Vehicle paths take full advantage of the evolving jets and eddies to reach their final positions (*colored dots*) in the shortest times. **(d)** Two forbidden regions. Vehicles are denied access to the *gray shaded* regions. The level set algorithm provides seven new time optimal paths for the paths computed in **(c)** that are blocked while correctly leaving unchanged the two paths that are not blocked (after [21.3])

new optimal paths for these seven vehicles all ride the lower edge of the main jet, just skirting the bottom of the second forbidden region. They then ride down one eddy and up an adjoining eddy (Fig. 21.3a), to rejoin the main jet behind the forbidden regions. The two paths from Fig. 21.3c that did not pass through the forbidden areas remain unaffected.

We note that forbidden regions can be learned by vehicles as they progress, using onboard routing (Sect. 21.2.1). In that case, data about forbidden regions are collected by the vehicle along its optimal forecast route. As these new data are utilized, optimal paths are re-computed, leading to a new optimal forecast route for the remaining travel plan.

21.1.5 Uncertain Flow Fields

It is well known that ocean predictions are limited in accuracy because of the predictive capabilities of present modeling systems [21.16, 17] and also due to fundamental limits of predictability for nonlinear dynamics. As a result, the practical horizon for skillful forecasts of time-optimal paths is also limited. In addition, some paths will be more uncertain than others, for example, some fast paths may be very uncertain, while some somewhat slower paths may be very certain. The path planner can thus aim to find a compromise between time optimality and certainty of arrival.

To illustrate this compromise, we consider the case of time-optimal path planning in a 2-D stochastic wind-driven double-gyre flow with large uncertainties (Fig. 21.4), [21.10]. This is a strong flow field in which the uncertainties are predicted using dynamically orthogonal (DO) stochastic PDEs [21.15, 18, 19]. Questions that we consider include:

- What are the effects of flow uncertainties on the time optimal path?
- Which path should be selected?
- Is there a path which is both fastest and least uncertain (most robust or most likely)?

For the chosen start and end points, the shortest-distance path is against the jet flow that is stronger than the vehicle speed. We thus expect at least a bi-modal behavior for the probability density functions (PDFs) and

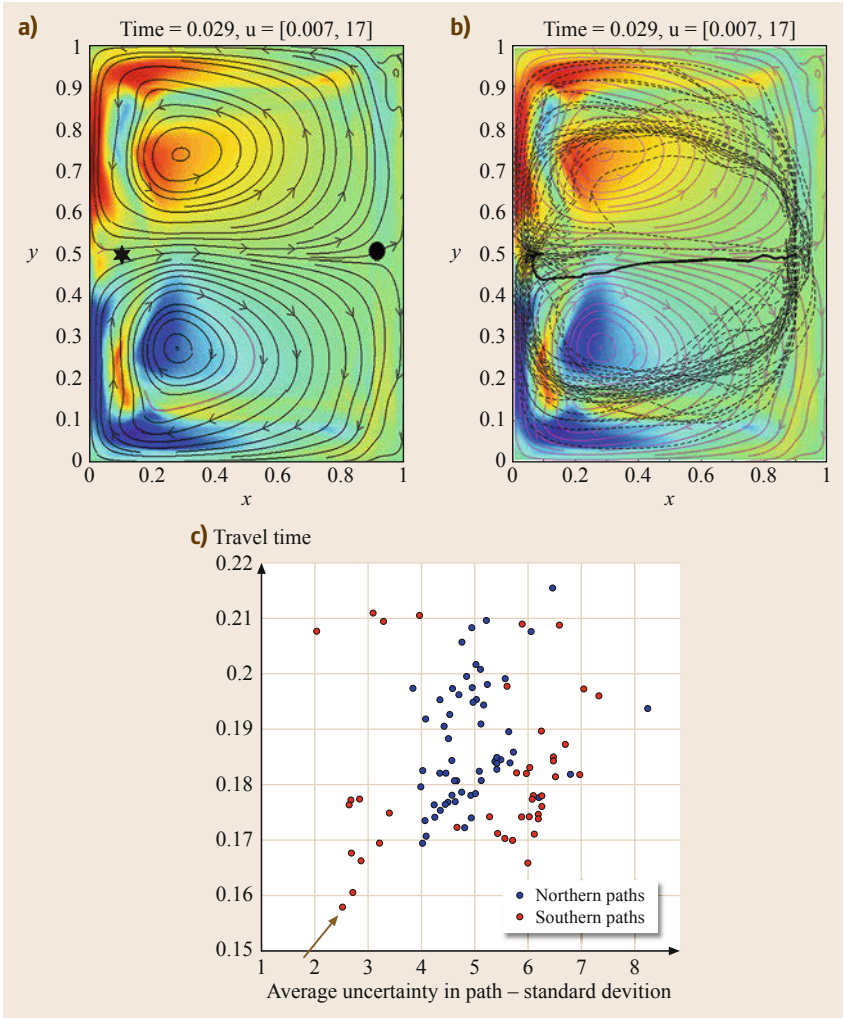

Fig. 21.4a–c Path planning in uncertain flow. **(a)** One realization of strong wind-driven, double-gyre flow. Vehicle starting point indicated by *filled circle*. End point indicated by *black star*. Wind forcing is stochastic. **(b)** Ensemble of optimal paths for different winds shown by *dashed lines*. Mean path shown by *solid line*. The mean path is unrealizable; the ensemble of paths is close to a bi-modal distribution (either following northern or southern gyre). **(c)** Travel time vs. uncertainty of ensemble of gyre paths. Most probably path follows southern gyre (*green arrow*)

sensitivity to initial conditions. We use the DO equations to quantify the uncertainty and the level-set-based path-planning (21.1)–(21.2) to solve for optimal paths for a number of realizations of the DO simulation. As is shown in Fig. 21.4b, as expected, we find that the mean path is not realizable as the paths generated are close to a bi-modal distribution (the flow field PDF leads to a PDF for the paths). For each path, we integrate the standard deviation of the flow velocity along the path, which provides a measure of the extent of *uncertainty* along the path. We then plot the travel time versus this uncertainty (Fig. 21.4c), providing a Pareto-like quantity. This plot indicates that a fast and least uncertain path is a path to the south. We note that this preferred south path arises mainly because the initial mean and PDF conditions are not symmetric with respect to the shortest-distance (horizontal) path between the start and end points.

21.1.6 Realistic Ocean Conditions: Three-Dimensional Multi-Scale Flows

Our level-set-based method has also been employed for path planning in realistic (data-driven) three-dimensional (3-D) ocean flow fields [21.13], as illustrated in Fig. 21.5. In this example, the MSEAS ocean prediction system provides the three-dimensional currents. The simulations are realistic (data-driven) ocean reanalyses based on the real-time exercises that occurred during August–September 2006 in the New Jersey Shelf/Hudson Canyon region [21.20, 21], specifically the autonomous wide aperture cluster for surveillance (AWACS) and Shallow Water-06 (SW06) exercises. The simulations employ nonlinear free surface primitive equations with fully implicit two-way nesting (Fig. 21.5a,b) and tides. The larger domain (Fig. 21.5a)

Note the strong flow opposing path. **(d)** 80 m flow during path planning. Weaker flow with some flow into goal from NE. **(e)** 3-D optimal path initially dives deep to weaker flows. The final approach to goal is from NE along the favorable flow (after [21.13])

is a 522×447 domain with 3 km resolution and 30 vertical levels, while the smaller domain (Fig. 21.5b) is a 172×155 km domain, with 1 km resolution and 30 vertical levels. The ocean initial conditions utilize real data gathered by gliders, AUVs, ship deployed conductivity temperature depth (CTD) and historical data taken from the World Ocean Database, Gulf Stream feature analyses, National Marine Fisheries Service, etc. The duration for this real-time simulation was 43.5 days. Here, we focus on the period during which Tropical

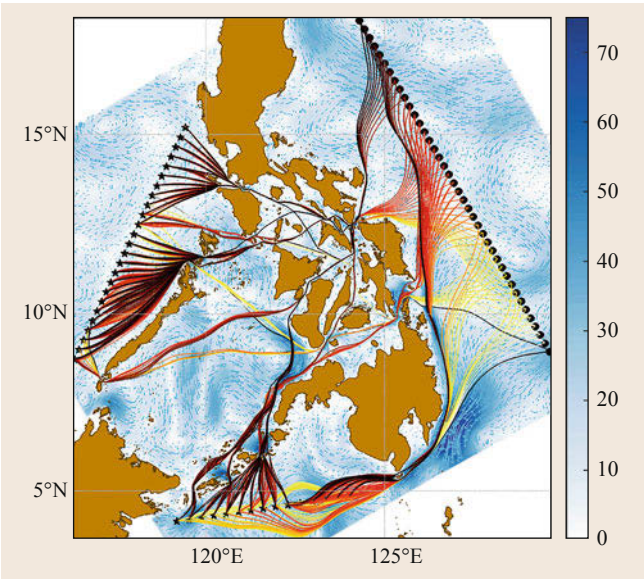

Fig. 21.6 *Time-optimal path planning in the Philippines Archipelago for vehicle swarms*: time-optimal paths of 1600 vehicles deployed from 40 different release points in the Pacific (marked by *circles*, in the east of the picture). The vehicles cross the Philippines Archipelago from east to west in the fastest time. Most of the paths are indirect as they take advantage of currents and other multi-scale ocean features ►

Storm Ernesto passed by the region (late August to early September 2006).

In order to simulate realistic and most practical conditions, we set our vehicle speed to $0.25\,\mathrm{m\,s^{-1}}$, which is often a maximum speed for most currently operated underwater gliders. The vehicle is deployed at the ocean surface (white open circle in Fig. 21.5c) and needs to travel to a second, offshore surface location (white circle with cross, Fig. 21.5c). During the path planning exercise, Tropical Storm Ernesto generates a strong, opposing, onshore current of around $0.8\,\mathrm{m\,s^{-1}}$ (Fig. 21.5c). Therefore, the glider cannot use the straightforward surface trajectory from the starting location to its offshore goal. However, the level-set algorithm finds a time-optimal 3-D path (Fig. 21.5e) in which the glider initially dives and *meanders* in 3-D to take advantage of the weaker flow field in the deeper ocean region (Fig. 21.5d).

21.1.7 Realistic Ocean Conditions: Swarms in Multi-Scale Flows with Complex Geometries

Our level-set-based methodology has been parallelized to efficiently plan optimal paths for swarms of vehicles in realistic multi-scale ocean flows with complex geometries. To illustrate this, we consider tidal-to-mesoscale ocean simulations for the Philippines Archipelago [21.22]. In this example (Fig. 21.6), there are 40 different swarms of vehicles, each released at a different location in the Pacific (east of the Archipelago). Each swarm and location consists of 40 different vehicles, one vehicle per swarm is the leader and aims to reach one of the end points in the west while the other vehicles aim to reach another of the 39 end points. When all vehicles reach their final destination, vehicles in the reformed-swarms are close to each other and can communicate underwater to exchange all needed information from their previous swarms. In other words, at the final time, an information exchange among all swarms can occur, in the form of an *all-to-all broadcast* (as in Fig. 21.2, but for realistic complex flows). The key is that each of the vehicles is navigated in fastest time to its specific end point, to the west (South China Sea) and the south (Sulawesi Sea) of the Archipelago. To do so, each vehicle optimally combines the following behaviors for time-optimality:

- Accounting for the wind events and the corresponding strong currents
- Waiting for favorable strong tidal flows in the many straits
- Taking the major currents in the region, following their meanders and eddies
- Looping in rings as needed or avoiding them all together, depending on their final destinations and variability of the 3-D ocean flows.

Figure 21.6 shows the fastest paths for all the vehicles overlaid on the map of the Philippines [21.14]. In this example, paths for 1600 vehicles have been planned by efficiently parallelizing the level-set-based algorithm. As observed, none of the vehicle trajectories is a direct path to its target. Vehicles clearly utilize ocean currents and multi-scale features to reduce their travel time.

21.2 Adaptive Sampling for Swarms of Ocean Vehicles

With our collaborators, we have developed a range of adaptive sampling schemes and applied them in varied coastal regions. In what follows, we start by outlining some of the schemes that were first applied in real

ocean situations, as well as the results of these schemes (Sect. 21.2.1). The constraints of the realistic ocean forecasts and the computational capabilities of the last decade led to a range of approximations necessary to issue optimal sampling paths forecasts in real time. After these results, we have started new theoretical research towards schemes and methods that are both rigorous and applicable to real ocean systems. This progress is summarized in Sect. 21.2.2.

21.2.1 Early Results: Approximate Schemes for Realistic Applications

During the last decade, we have developed and applied a range of adaptive sampling and onboard routing schemes for optimal sensing in varied regions of the world's oceans. They include:

- Adaptive sampling via error subspace statistical estimation (ESSE) with nonlinear predictions of error reductions [21.5, 23]
- Mixed integer linear programming (MILP) for optimal-sampling path planning [21.24]
- Nonlinear optimal-sampling path planning using genetic algorithms [21.25]
- Dynamic programming and onboard routing for optimal-sampling path planning [21.26]
- Command and control of surface kayaks over the Web, directly read from model instructions [21.27].

These schemes and results are outlined next.

Real-Time Adaptive Sampling via ESSE

The results of the ESSE adaptive sampling scheme [21.20, 28] utilized in real time are illustrated in Fig. 21.7. For data assimilation, the ESSE scheme integrates an ensemble of nonlinear simulations and assimilates data by Kalman updates in the adaptive error subspace obtained from this ensemble. For adaptive sampling, the same is carried out, but in a forecast sense and for many candidate sampling plans, since the goal is the nonlinear prediction of the ideal future sampling. Specifically, a set of candidate sampling plans (data locations and sensor types) was chosen a priori to reduce computational costs and directly satisfy operational constraints. For each plan, a nonlinear ESSE prediction and data assimilation was then carried out. This estimated the error reduction for each plan and so determined the candidate plan with the best impact.

Adaptive Sampling with Routing Schemes

Predictive adaptive sampling and onboard adaptive routing have been combined for thermocline tracking and adaptive sampling for acoustic fields with AUVs [21.26], as illustrated in Fig. 21.8. The method consists of two complementary steps. First, data assimilative environmental and acoustic propagation ESSE ensemble modeling provides input to a dynamic scheme that computes parameter values for autonomous sensing behaviors, with the goal of optimally reducing the forecast acoustic uncertainties. Behavioral parameters include, for example, the dive angle or the times to switch depths. Second, these parameters for the autonomous sensing behavior are refined onboard the vehicle in realtime, in response to the data sampled.

A related approach consists of computing the high-level routing remotely (in a centralized computer). A vehicle is then guided by downloading remotely-computed optimal waypoints from a website. During

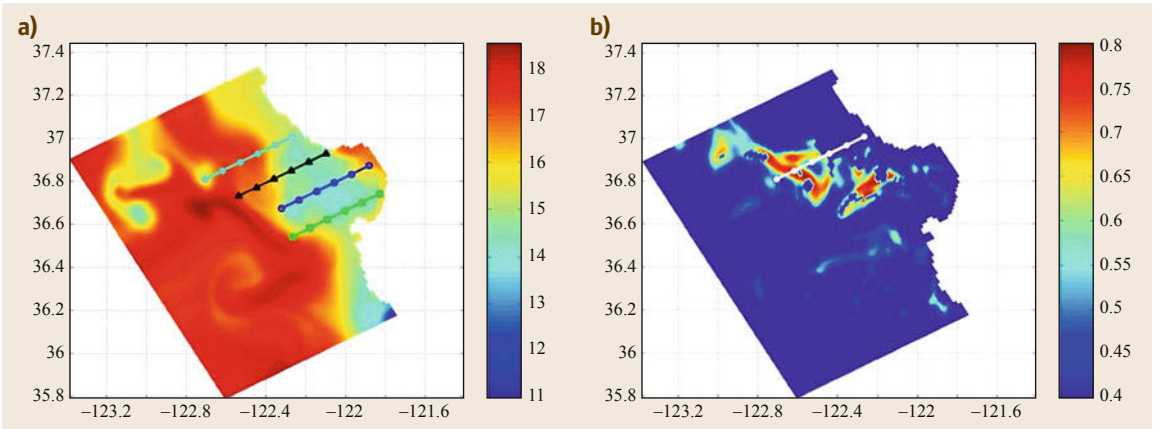

Fig. 21.7a,b Adaptive sampling via ESSE, for an 24–27 August sample forecast. **(a)** Central forecast of the surface T for August 26, overlaid with the four candidate tracks. **(b)** Predicted optimal track for August 26 and its relative error reduction for August 27 (after [21.5]). The question answered is *which of the four sampling track tomorrow will reduce uncertainties the most the day after tomorrow?*

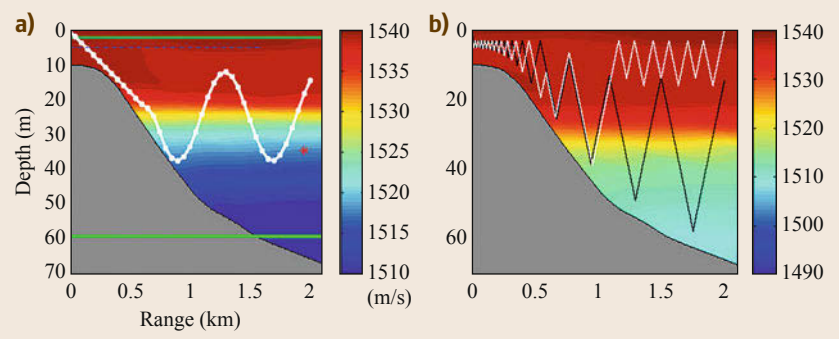

Fig. 21.8a,b Simulated adaptive thermocline tracking using yo-yo adaptive sampling and onboard routing, overlaid on sound–speed ($m\,s^{-1}$). **(a)** AUV path; *green lines* are the minimum and maximum depths allowed. **(b)** The optimized AUV automatically captures the *afternoon effect* on the surface thermocline, i. e., the warming of the upper ocean layers due to the strong daylight sun (after [21.26])

the Persistent Littoral Undersea Surveillance Network 2007 exercise (PN07) in Dabob Bay [21.27, 29]; such a website was used to optimally guide kayaks at sea, directly based on data-assimilative ocean model predictions of the optimal sampling plans, without humans in the loop. Computers ran the ocean model forecasts and adaptive sampling forecasts and then wrote the waypoints file on a website that was read by a kayak, all without human input. This was a technical achievement compared to other larger and more extensive exercises, e.g., Monterey Bay 06 [21.8, 9, 30], where humans were intermediaries between ocean models and vehicles, e.g., entering waypoints or interpreting ocean model forecasts and then selecting waypoints.

Path Planning for Fixed-Uncertainty Optimal Sensing

Path planning for fixed-uncertainty optimal sampling aims to answer the following type of questions: Assuming the error field is not dynamic during the sampling, which sampling path is optimal? This approach often assumes simple updates of field estimates due to data but more importantly neglects how dynamics over time evolves future observations, evolution which affects the truly optimal adaptive sampling. The planning then amounts to the optimization of a fixed objective function whose solution often amounts to visiting the locations of highest uncertainty. Here, we outline two schemes for such planning. The first one solves the optimization using MILP [21.23, 24, 31], as shown in Fig. 21.9. The solution is obtained by a *branch and bound algorithm*, which provides exact and globally optimal solutions. The path is segmented by waypoints, and the goal is to solve for their coordinates. The number of waypoints is a parameter fixed as a function of vehicle range and grid dimensions. An extension of this approach for time-dependent fields has been obtained [21.32].

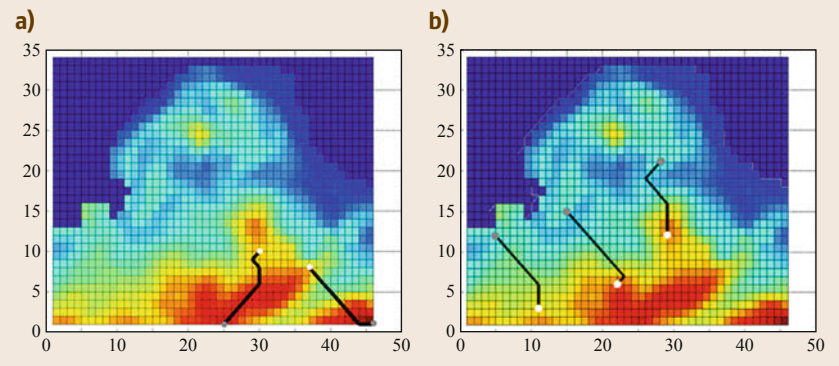

Fig. 21.9a,b Generation of sampling paths for fixed objective fields using mixed-integer programming (MIP). Fields are the ESSE T error standard deviation averaged over 0–50 m. *Gray dots* are starting points for the AUVs and *white dots* are the MIP optimal termination points. **(a)** Optimal path of two vehicles. **(b)** Optimal path of three vehicles (after [21.24]). The question answered is *assuming the error field remains constant for the next day, on which path do I send my AUVs?*

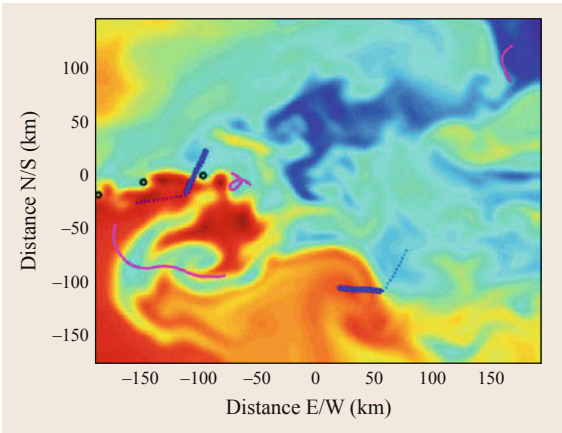

Fig. 21.10 Optimal sampling path solution computed by a genetic algorithm (GA) in the Middle Atlantic Bight and Shelfbreak Front regions (after [21.25]). The plan is computed for three moorings, three gliders, and two REMUS vehicles. The GA places all moorings (*black circles*) directly within the Shelfbreak Front, which passes over them during the simulated 5 days of deployment. The REMUS vehicles (*blue tracks*) pass over Shelfbreak events and fronts, and the gliders (*magenta tracks*) track large gradients with time. A distance-potential constraint maintains the paths of platforms apart by at least a Rossby radius (key horizontal length scale for mesoscale ocean dynamics, 15 km in this example)

The second scheme uses genetic algorithms to solve the optimization problem [21.25]; the results are illustrated in Fig. 21.10. With genetic algorithms, one can carry out nonlinear path planning for any type of cost function, which is a significant practical advantage. The weights of each term in the cost function are chosen by users. However, a disadvantage of the genetic algorithm solution is that one cannot always theoretically guarantee that it is at, or is near, the optimum. In the results illustrated, the cost function includes terms representing ocean variability, acoustic transmission loss sensitivity, and temperature uncertainty. Results illustrate that the temporal dependence of the ocean fields strongly influences the optimal location of the moorings that are fixed in space and the gliders that are slowly drifting. The remote environmental monitoring unit (REMUS) vehicles move quickly and are less sensitive to time-dependent ocean effects.

21.2.2 Recent Progress: Towards Rigorous Schemes for Realistic Applications

Our recent research in adaptive sampling has been motivated by the ESSE examples presented above. The first research theme that we investigate is to increase the number of candidate sampling paths towards functional paths covering the whole physical domain and to increase the durations of look-aheads towards durations up to the end of the experiment or the predictability limit. Ideally, there should be no limitation on the candidate paths other than the operational constraints. A second theme is to continue the utilization of nonlinear uncertainty evolution and estimation of future data impacts, but replace the ESSE ensemble approach by our DO PDEs and replace the ESSE Kalman updates by non-Gaussian updates, including Gaussian Mixture Models updates [21.33, 34]. Mixture models are semiparametric frameworks consisting of a sum (mixture) of parametric distributions whose parameters and number (total number of distributions themselves, referred to as mixture complexity) are commonly fit to an ensemble of realizations. A third theme is to extend the adaptive sampling optimality criterion to information theory (mutual information schemes) and to include nonlinear smoothing effects. In what follows, we outline a subset of results related to these research themes.

Adaptive Sampling Using Partially Observable Markov Decision Processes (POMDPs)

Computational research has begun on the use of POMDPs as a means of adaptively sampling fields of interest in the ocean. A POMDP in this case is a mathematical framework that allows one or more agents to optimize an objective function under uncertainties both in sensing and knowledge of the field dynamics. We have demonstrated its use on two simplified dynamical model testbeds. The first is a stochastic game of life where a robot aims to optimally reach an end goal while sampling minor rewards and avoiding minor losses along the way. The second is the prediction of optimal sampling paths for two vehicles operating in the idealized Lorenz-95 atmospheric model [21.35]:

1. *Stochastic game of life*: We have adapted John Conway's game of life [21.36] by including stochasticity in the governing equations, as described in [21.37]. As such, we consider this to represent a (simplified) discrete flow model. Figure 21.11 shows one time instant in that game, all actors of the game are dynamic: the black circle is the AUV; the green circle is a slowly moving global feature of high reward; blue plus signs are minor rewards; and red crosses are minor cost/loss. Both of the latter fields evolve independently according to the rules of the game. The route of the AUV (not plotted in the snapshot) is being optimally planned. The domain is discretized such that all motions are restricted to be up or down, or left or right. The AUV applies the POMDP-like algorithm, intelligently maneuvering

through the field such as to maximize its reward. Specifically, it seeks to approach the green circle, primarily sampling blue dots along its path. This test bed naturally extends to multiple vehicles. The game of life results (Fig. 21.11) may also directly apply to real ocean fields in the sense that green, blue, and red regions could be specific ocean field properties or discretized regions of instability or of interesting dynamics that one wishes to sample.

2. *Lorenz-95 model*: The system studied is the Lorenz-95 atmospheric model, which is a time-varying one-spatial dimension model, as illustrated in Fig. 21.12. The Lorenz-95 model replicates a number of phenomena observed in geophysical fluid dynamics, and as such lends itself well to this analysis. Each vehicle (i. e., adaptive observation) locally predicts future consequences of proposed sampling paths, independently of other vehicles, given current knowledge of the system. In this test bed, the adaptive DO equations are used to predict the PDF of the Lorenz-95 state and artificial potential-like functions are employed to ensure that adaptive vehicles remain sufficiently apart from each other. We implemented a POMDP-like algorithm for adaptive sampling, using a GMM-DO (GMM: Gaussian Mixture Model) filter for data assimilation [21.33, 34]. With this example, we show that adaptively sampling the field using the POMDP approach outperforms the case in which the adaptive observations remain fixed in location (see the bottom left plot of Fig. 21.12).

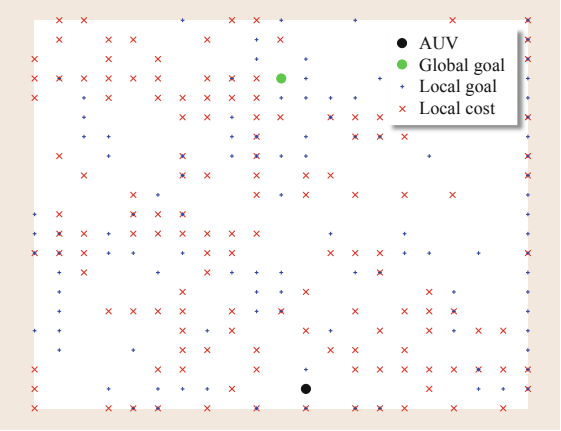

Fig. 21.11 Stochastic game of life with intelligent sampling using POMDPs. A fixed-time snapshot in the time-dependent game is shown. The route of the AUV is being optimally planned. The domain is discretized such that all motions are restricted to be up or down, or left or right. The goal for the AUV, *black circle*, is to track and reach the *green circle* as fast as possible and, if efficient along the way, sample the *blue plus signs* (e.g., food) and avoid the *red crosses* (e.g., predators), so as to increase the total reward

While POMDPs are computationally expensive, techniques are being developed that continually allow their use in domains of increasing complexity. In the future, with a detailed probabilistic description of the currents via the adaptive DO equations, one could derive novel metrics using information theoretic measures (specifically *mutual information*) to represent rewards. Our scheme may effectively be applied among multiple agents, where each agent locally applies a POMDP, communicating across a subset of its information to neighboring vehicles. Knowledge of the ocean fields, derived from the MSEAS ocean prediction model, is naturally of significant advantage. By subdividing the POMDP framework into a set of hierarchies, itself inspired by biological swarming formations, one could optimize the sampling behavior of the team of AUVs. Then, a top layer POMDP controls a number of lower layered POMDPs, themselves controlling a group of AUVs.

Adaptive Sampling with Limited-Time Look-Ahead POMDPs and ESSE in 2-D Fields

We now extend the above approach to two-spatial dimension and time-dependent problems and evaluate it on simulated ocean fields. We still employ DO equations for uncertainty prediction and a limited time look-ahead POMDP approach to select the sampling paths. However, we now use ESSE for data assimilation instead of the GMM update.

As shown in Fig. 21.13, we consider an uncertain flow behind a circular cylinder/island. The uncertainty arises due to the initial conditions and is evolved in time using the DO equations. Assuming that we have access to a single sampling vehicle (a glider), we predict a trajectory for this asset that optimally reduces the uncertainty in the estimated velocity field (horizontal components: u and v). In Fig. 21.13a, we plot the field of variance in u and v along with the vehicle trajectory obtained using a three-time-steps look-ahead approach for adaptive sampling. Figure 21.13b shows the time evolution of the variance of two stochastic DO modes. Initially, the variances of the modes are large (order 1). As the vehicle makes measurements at integer times, the variance of each of the modes is reduced. With time, the variance of the modes eventually decreases to an order of 10^{-1} for the first mode and 10^{-5} for the last mode.

Figure 21.13c,d shows the true solution for the velocity field and the mean of the adaptive-sampling-based estimate of that velocity field at two different times. At time $t = 6$ (Fig. 21.13c), we see that the mean of the estimated solution is still very different from

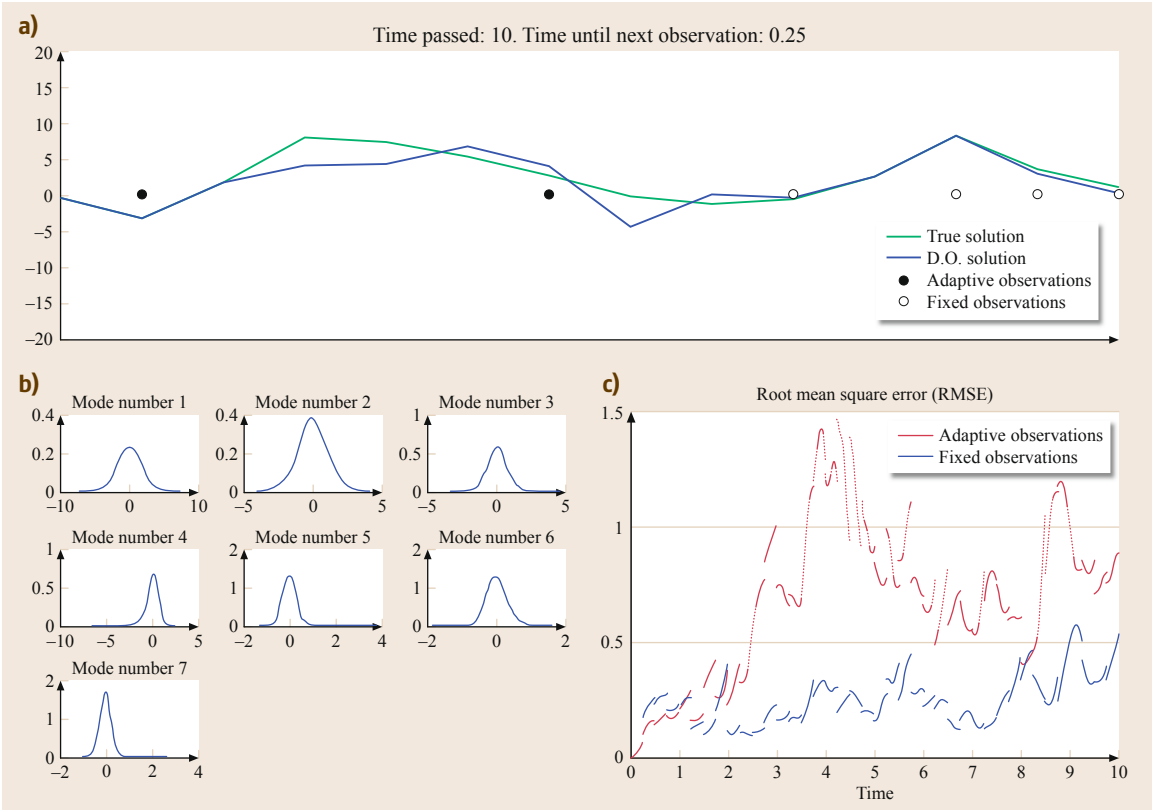

Fig. 21.12a–c Adaptive sampling one-dimensional (1-D) example: the Lorenz-95 application. The adaptive sampling is based on: i) non-Gaussian data assimilation (GMM-DO Filter) combining Gaussian Mixture Models (GMMs) with the DO equations; ii) three-step look-ahead POMDPs to decide which direction (left or right) to sample for each of the two adaptive observations; and iii) an artificial potential-like function to ensure the two adaptive observations remain separated in space. **(a)** True (unknown) and estimated solutions at final non-dimensional time 10. The latter estimated solution is obtained by adaptive sampling by GMM-DO, three look-ahead POMDPs and artificial potential-like functions. Three routine observations are fixed in space (*open circles*) while two observations have paths that are forecast by the adaptive sampling (*black circles*). **(b)** Marginal PDFs for the seven DO modes active at final time 10. **(c)** Comparison between the time-evolution of the averaged true error of the estimates obtained using adaptive sampling or not using it (i. e., assimilating data but keeping the two *black circle* observation locations fixed in place). The true error reduction obtained by predicting the best sampling location is substantial (about 100% better)

the true solution because very few measurements have been collected so far. As time progresses (Fig. 21.13d) the mean of the estimate matches quite well with the true solution, and the algorithm correctly predicts the shape, phase, and frequency of vortex shedding behind the island. Another interesting result in this example is that the vehicle automatically navigates towards the cylinder, indicating that it is the optimal location where measurements must be made to gain maximum information about the field. It also follows the locations where eddies are shed. Clearly, the dynamics of the problem, the limited-time look-ahead POMDP behavior and the assimilation scheme govern the track of the vehicle.

21.3 Conclusions and Outlook

Some of the results obtained by our MSEAS group and recent collaborators have been summarized here. We first presented a subset of our results on time-optimal path planning for swarms of ocean vehicles. We then

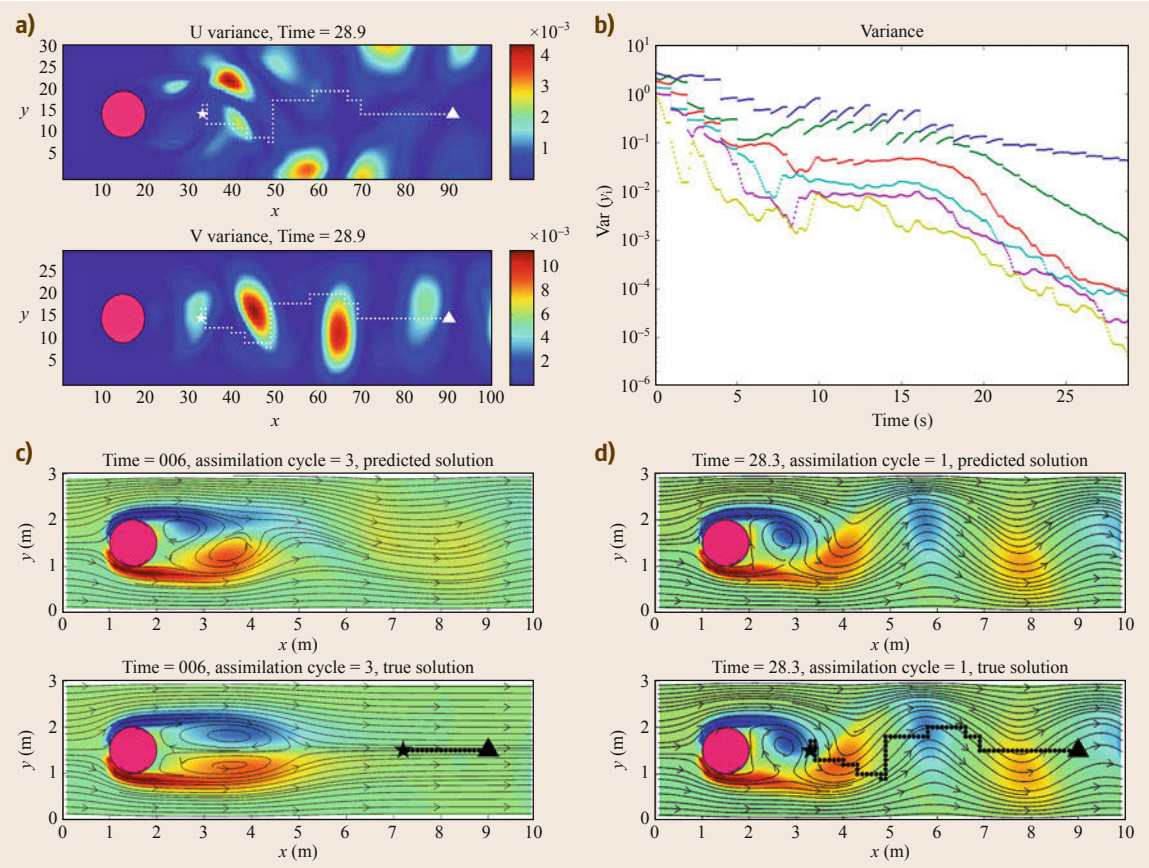

Fig. 21.13a–d *Adaptive sampling for flow past a circular island.* We predict the trajectory of a vehicle that makes measurements in the field so that the uncertainty in the field is optimally reduced. The uncertainty due to initial conditions is propagated forward in time by the DO equations and an ESSE update is used for the assimilation. **(a)** Variance in the u and v velocities of the flow field. **(b)** Reduction of variance of each of the DO modes due to the measurements made by the vehicle. **(c)** The mean of the predicted solution compared with the true velocity field. The predicted solution is significantly different from the true solution at this time. **(d)** As the vehicle measurements become more effective, the predicted solution is driven towards the true solution and eventually, both these fields match up well

reviewed some of our research in adaptive sampling. The path planning and adaptive sampling schemes and approaches presented were illustrated by their applications in idealized and realistic ocean conditions.

Of course, many more results, complementary to ours, have been obtained, both in optimal path planning and adaptive sampling. Even if we were to limit ourselves to oceanic and atmospheric applications, the depth and breadth of these complementary results are significant. For general reviews on oceanic adaptive sampling, we refer the reader to [21.4–9]. For general reviews on oceanic path planning, we refer the reader to [21.2], as well as to Chaps. 14, 19, and 20 of this Handbook.

In coming decades, in light of the growing human population on earth, the ocean, with the water and life it contains, is likely to become increasingly important. Since data collection and operations at sea are expensive, utilizing all of the knowledge we have to plan such collections and operations is logical and important. Useful knowledge here combines science and engineering, including observation, modeling, prediction, estimation, and control. The science of autonomy will necessarily play an increasing role in ocean applications. This is because sustaining healthy interactions between the ocean and humans is vital to life on earth. These interactions will have to be intelligently and autonomously managed.

22. Cooperative Vehicle Target Tracking

Frank Ehlers

As autonomous ocean vehicles become more affordable and reliable, applications of multivehicle teams become more feasible. Cooperative vehicle target tracking is a promising application since in many sport, military, and biological endeavors cooperative strategies have proven themselves to be advantageous over noncooperative strategies. The sophistication of winning human team interactions indicates the challenge inherent in programming a fleet of autonomous vehicles to work cooperatively to effectively and efficiently accomplish a goal. For a multivehicle team operating in the continuous and transient ocean environment, meeting this challenge involves optimizing a high-dimensional parameter space, even more so in cases when the target has the ability to make intelligent choices to avoid being tracked. In this chapter, recent progress to construct a theoretical framework and recent applications for maritime surveillance are presented. A methodology is developed that can help bridge the gap between the top-down view starting with theoretical concepts and the bottom-up view dealing with all details of real experimentation and execution at sea.

22.1 General Theoretical Framework

Target tracking in surveillance applications is essentially a problem of connecting signature dots (glimpses of a target) in a noisy, uncertain environment. Cooperative vehicle target tracking is a method in which multiple sensing platforms (vehicles) jointly react to a target's behavior, which may or may not be evasive, to maintain contact and extend previously observed tracks. The maritime environment is noisy, uncertain, and spatially extensive. In maritime surveillance applications noise and uncertainty can be reduced through persistence and adaptability. For operations over large areas, the scalability of any target-tracking methodology is an important practical consideration. Autonomous ocean vehicles are useful tools for maritime target tracking since they enable both persistence and adaptive, scalable approaches [22.1, 2].

Teamwork can be efficient and effective in successfully completing difficult tasks. Teamwork is a cooperative effort by a group of individuals or agents to achieve a common goal, wherein individual team members contribute different skills, knowledge, and interests to the effectiveness of the group. In a game setting, targets are modeled to make locally optimal decisions based on their established tactics (or internal *mental state*) independently (from their perspective) of the activities of the surveillance team. Constrained by established tactics, the target's dynamics can be expressed by a control algorithm that formulates the objective of the chosen *mental state*. For example, if the *mental state* is to drift to save energy, the target dynamics can be linked to the oceans dynamics. The surveillance team's goal is to track the target with distributed mobile sensors under centralized and/or distributed control in a coordination scheme that may be called *synchronized covertness*.

In this chapter, the advantages (or even necessity) of teamwork for target tracking using autonomous ocean vehicles are investigated. A *trading methodology* is described which enables the generation of coordination

schemes for cooperative target tracking with measurable effectiveness. This *trading methodology* can be used to evaluate the effectiveness of different schemes, and to predict the effectiveness of a given scheme under changing environmental and operational constraints. The trade-offs are, in general, effectiveness versus efficiency (for a specific scenario, time to find a target versus number of assets). Applying the methodology to a specific scenario avoids the computational limitations of brute-force processing methods. Two example scenarios are discussed stemming from multistatic sonar and maritime surveillance.

Cooperative target tracking using autonomous ocean vehicles is a multidisciplinary endeavor that benefits from recent progress in distributed sensor networking, networked robotics, collaborative signal processing, control and game theory, and interactions of multiagent communities [22.3–11]. However, maritime applications have unique challenges including transient environmental conditions, high noise levels at sensors, sparse coverage over large areas, intermittent and low bandwidth communication channels, navigation uncertainty, and limited energy availability.

Communication is essential for coordinating the behavior of individuals or agents. Communication can be preplanned or adaptive. To minimize communication bandwidth, two questions must be answered: What information should be shared and with whom should this information be shared? More specifically, for the target-tracking task: How much information is sufficient to allow data association and pattern recognition? Given the assumption of intelligent targets with detection and avoidance capability, communication events should be as rare as possible. From a system design point of view, the communication process should minimize interdependency, since interdependency can result in unpredictable and perhaps uncontrollable system behavior.

Here, the target-tracking team consists of an array of mobile sensors distributed throughout an ocean domain of interest. If the spatial domain is large, and the number of mobile sensors relatively small, then part of the solution for robust tracking is determining curves of intercept for sensors along a projected track. Such curves can be mapped covertly with minimal target reaction to the sensing or they can be manipulated through deliberate interaction with the object. The tracking process can be divided into two phases:

- A search phase (I) in which the cooperative sensor interaction is used to fuse measurements in time and space to increase the signal-to-noise ratio of potential target signatures.
- A holding phase (II) in which the highest ranked signals from the first phase are correlated with tracks and the tracking team adapts to best follow the tracks.

In Phase I, the performance of a single sensor can be enhanced to increase range, or multiaspect measurements made to better determine a signature.

In Phase II, a track can be followed with a single-sensing system whose speed and maneuverability matches that of the target (*track and trail*), or with a network of sensors distributed over the domain in a *handoff* mode.

In both phases, if the sensors are stationary and the detection ranges are modest relative to the domain size, the number of sensors must be large. If instead the sensors have mobility and can adapt to the environment and to the projected tracks, then their effectiveness increases and the number of sensors is reduced. Further effectiveness gains can be achieved if the sensors can adapt to one another (cooperative behavior). This chapter focuses on the latter approach to tracking performance enhancement.

When the target is reactive (perceives the tracking and maneuvers evasively), cooperative target tracking becomes a game. Each player in this game has a given system capability. Both must be modeled consistent with the stochastic nature of the control and estimation processes operative during game execution.
