Cooperative target tracking over realistic maritime time and space scales is a complex adaptive system. The specific application dictates the level of cooperation needed:

- From situations where the cooperation is not really necessary to achieve sufficient performance, and the built-in cooperation dependencies introduces an overhead which hampers the overall system. *Divide and conquer* is rather the better heuristic then. Stated differently: If the cooperation introduces interdependencies, the risk that these interdependencies produce is that an unstable and unpredictable overall system should be monitored.
- To situations where cooperation is mandatory, especially against stealth targets, in nonstationary environmental conditions. In this case, single sensors or platforms are not capable of detecting targets or holding tracks, and collaboration is the only way to achieve a sufficient overall system effectiveness. The interconnectivity between the collaborating platforms is key to achieving the gain in effectiveness: One system is helping the other or one platform is covering the potential poor performance of another platform. This covering can be done simply (but not very efficiently) by adding more assets, scanning, and acting independently. Or it can be done by implementing synchronization

or coordination with careful attention to interdependencies that may lead to an unstable overall system.

For realistic scenarios, the quantitative evaluation of the effectiveness of cooperative target tracking systems with tractable decision rules for their operation is a subject of current research. Rigorous analytical solutions exist only at the level of methodological ideas, rather far from implementations, and numerical simulations are challenging. To gain insight into the performance advantages (or disadvantages) of such systems and assess trade-offs and sensitivities, a simplified framework must be constructed that models essential features at tractable levels of complexity. Repeatable experimentation within this simplified framework provides sensitivity analysis and uncertainty estimation. When transitioning from single-sensor systems to distributed, mobile systems, an essential feature is the coordination mechanism between spatially separated sensors that may not have the same information due to limited communication between them. The behavior of complex adaptive systems is often nonlinear. A small change in one specific variable, such as the coordination mechanism, may result in large changes in system performance. Modeling the behavior of the overall system as a function of this specific variable is critical for assessing system stability and determining overall measures of effectiveness (MoE) from component measures of performance (MoP).

Four approaches are commonly used for analysis of cooperative target tracking:

- Control and estimation (CE)
- Multiagent systems (MAS)
- Cellular automata (CA)
- Probabilistic graphical models (PGM).

22.1.1 Control and Estimation Approach

In a state space approach, there is a model for the evolution over time of the state of each player. This evolution is corrupted by noise which randomly pushes the player in uncontrolled directions [22.12]. For cooperative target tracking, there is a coupling among all state variables, modeled by a set of stochastic differential equations. In addition to the motion or control equations in the state space mode, there is a set of estimation equations describing the uncertainty of each player about the state of all state variables of all players. Control design and estimation design can be separated, that is, each control equation is conditioned by the result of the estimation process for each state variable [22.13]. For example, the state of a member of the surveillance team will probably change when a target is detected nearby. How each player reacts to the knowledge about the states is defined by the control equations. The performance of the system is modeled by a multiple-objective cost function with multiple constraints. Such a cost function can be expressed in terms of risk. For cooperative tracking of a reactive target, the surveillance team will try to minimize the risk of the target passing undetected, while the target will act such that its own risk of detection is minimized.

Mathematically this risk can be calculated as a function of the MoP of the components of the systems. MoPs can be combined into *attributes* of the system specific to a task. The degree to which overall risk is minimized can be defined as the system's MoE. The art of system design is to create from expert knowledge of the system the attributes which are then used to optimize the setting of free parameters, including parameters that govern coordination. The proof that a chosen combination of MoPs is a good cost function to increase the MoE is possible for mathematically tractable setups [22.14], for example, for linear-quadratic forms [22.12]. However, this simplification is unrealistic since the main features of the motion, control, decisions, and estimation cannot be represented accurately by linear-quadratic equations. A coupled physical-mechanical-fluids control model is a better choice [22.15]. Tools from applied physics can then be used for further analysis including simplification and approximation techniques for the analytical treatment of stochastic differential equations. Other approaches to generating a proper functional representation of the risk are via learning (trial-and-error or more sophisticated reinforced learning [22.16, 17]).

MoE values for specific scenarios can be statistically derived through Monte Carlo simulations. A large number of degrees of freedom in realistic scenarios make such simulations a formidable task, and one that is more likely to yield insight into the sensitivities of specific constraints in specific scenarios rather than the impact of different coordination mechanisms for more generalized application classes.

The impact of coordination mechanisms can be appreciated by noting the advantages of complete data exchange between two sensing platforms. The sensors could exploit the received signals in a coherent or semicoherent manner. Collaborative coherent signal processing allows for an increased signal-to-noise ratio. Semicoherent techniques could, for example, exploit complementary Doppler and target strength features of a target. Joint estimation and classification can lead to higher localization accuracy and a lower false alarm rate. Collaborative signal-processing techniques can be adaptive, or the motion of the sensing platforms preselected [22.18, 19].

An important output of a mobile vehicle controller is path planning [22.20, 21], especially for distributed sensors in a surveillance mission [22.22]. Path planning can be myopic (with receding horizon) or nonmyopic. The planning horizon in an energetic ocean environment is highly variable, and targets are often unpredictable. Executing initially good plans without adapting to new conditions is risky. Thus, extrema in the cost function solution surface, which is a formulation of the risk, will vary with time in the absence of adaptive pathways.

22.1.2 Multiagent Approach

In a surveillance scenario, targets and target trackers can all be viewed as agents. Some agents may communicate and cooperate, some may be passive, some reactive. The agent paradigm is helpful because it explicitly encapsulates features that in the CE representation are implicit. In a cooperative system, each agent seeks to maximize a joint global reward function.

Cooperative target tracking can be formally described as a decentralized partially observable Markov decision process (DEC-POMDP). Since standard procedures for solving POMDPs are computationally intractable for scenarios of large dimensions, approximations play a major role (as in the CE approach), and the art is in adapting the way approximations are made to the structure of the interactions [22.24–28]. The local policy for agent I is a mapping from the local history of observations made by agent I to an action. To program the autonomy in the cooperative target-tracking team members, this local policy has to be found. This is equal to finding the control design in the CE approach.

The tracking of reactive targets is the field of multiagent partially observable stochastic games (POSG). POSG formulations can be found in [22.29]. Formulated for noncooperative multiagent systems, they allow each agent to have a unique reward function. Further analysis of Bayesian games can be found in [22.30].

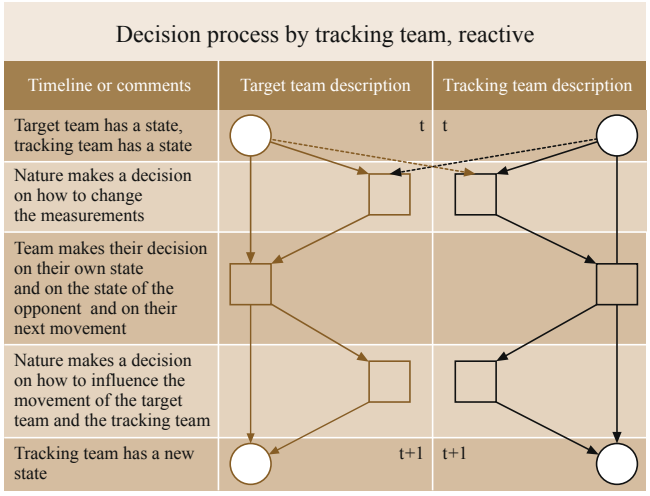

Fig. 22.1 An influence diagram (a special type of PGM) contains nodes that represent chance variables (*circles*), decisions (rectangles), and utility values (the utility values are similar to the attributes discussed in the CE representation) (*diamonds*) (after [22.23])

22.1.3 Cellular Automata Approach

A cellular automaton consists of a regular grid of cells, each in one of a finite number of states. The grid can be in any finite number of dimensions. For each cell, a set of cells called neighborhood is defined relative to the specific cell. An initial state is selected by assigning a state for each cell. A new generation is created by some fixed rule which can include stochastic and asynchronous elements. When analyzing systems for cooperative target tracking by cellular automata (CA), simplifications are made on the internal activities, and the focus is set on the interactions in the neighborhood of the cell. Often these interactions generate group behavior that allows each member to be maximally independent of the target.

Linking the CA approach to the MAS approach, each tracking agent has interactions with the other agents and the target. For many agents, such interactions result in a complex system. Self-organization methods like random graphs and finite state machines are used for discrete event control in distributed surveillance [22.31, 32]. A general description of such complex, nonlinear systems gives a useful insight, in emergent or swarming behaviors of the entire system [22.33]. Starting with many CAs, which are all independent of each other, but depend on the target, they trade their independence among each other, to become more independent of the target. In CA language, this is a formulation of the main idea behind the *trading methodology* discussed in the introduction. In a swarm of fish, for example, the individuals have a strong dependency to their nearest neighbors, but in the swarm the individuals are well protected against enemies.

22.1.4 Probabilistic Graphical Models Approach

The power of this approach is best described by a citation [22.34]:

> *Probabilistic graphical models (PGM) encode our domain knowledge declaratively, using a representation that has its own inherent semantics. Thus the*

conclusions induced by the model are intrinsic to it, and not dependent on a specific implementation or algorithm. This property gives us the flexibility to develop a range of inference algorithms, which may be appropriate in different settings. As long as each algorithm remains faithful to the underlying model semantics, we know it to be correct. The existence of a declarative representation allows us to separate out the two sources of error, modeling error and algorithmic error, and consider each separately.

Influence diagrams (Fig. 22.1) are able to represent agents beliefs and decision-making processes [22.35]. The reason they are well suited is that it is possible to implement factored reasoning (which is exploiting independence) for monitoring team formations [22.36]. They can also be applied to implement decision making in open mixed networks [22.37]. In [22.38], a graph-based model of distributed cooperative navigation for multirobot measurement is presented. Solving the task of cooperative target tracking could start with similar mathematical tools, expanded to include targets acting in a noncooperative manner. The influence diagrams can be used to explicitly visualize the steps of the *trading methodology*. This will be further discussed in Sect. 22.5.

22.2 Distributed Sensing, Control, and Decisions

If the data fusion is performed correctly, multisensor measurements have a better detection performance than the best single sensor among them [22.39]. For example, spatially distributed sensors resolve target ambiguity by providing different aspects of the target. Not all information has to be sent to a fusion center. Depending on the setup, it might be sufficient to send only selected information to specific team members (optimally, this should be the most important information). This links the distributed sensing task to a local decision rule that specifies which data should be sent to whom to increase the overall utility function with the constraint of limited bandwidth.

Based on the incoming data, either from own measurements or via communication channels, each team member has to fulfill its specific control tasks, which again (although individually executed) are to increase the team utility function with the constraint of achieving consensus among team members on sharing the workload [22.41, 42].

Thinking about control as an activity to be done by each team member, distributed decision making is understood as the method to generate agreement on a specific state inside the team (e.g., switching from target search to target trail). It is possible to generate consensus (distributed decision making) within the team without a central controller.

In a distributed architecture, two types of communication are necessary:

1. To establish the data fusion, and
2. To coordinate the sensing activities (Fig. 22.2).

Molinares [22.43] describes a data link layer in support of swarming of autonomous underwater vehicles which would support both types of communication.

In the maritime domain, different communication methods exist: underwater acoustic, underwater laser, underwater cable, underwater electromagnetic, and above water radio (high frequency (HF), very high frequency(VHF), ultra high frequency (UHF), satellite communication (SAT)). An important design task is to find capable and reliable communication links, including knowledge about the probability of errors associated with these links. All channels have different ranges and bandwidths. For maritime applications over large areas, satellite communication offers the highest bandwidth channel to share data over long ranges to enable a centralized network architecture for data fusion. However, underwater vehicles must come to the surface in order to communicate via satellite communication channels. As communicated sensor information by team members is a measurement, the accuracy of this measurement has to be taken into account for fusion.

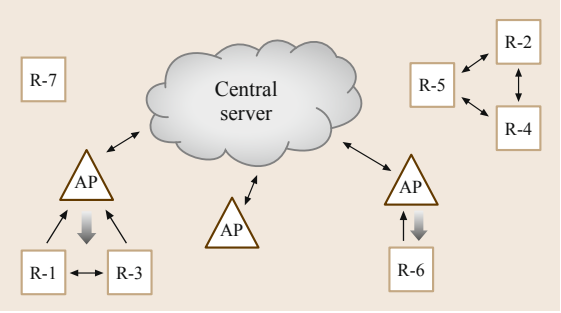

Fig. 22.2 Diagram of the network structure. Robots (*squares*) are able to communicate on a peer-to-peer basis with nearby robots as well as access the central server through access points (*triangles*). The communication links originating from robots are all relatively low bandwidth while the downlink from the server may be higher bandwidth (after [22.40])

To adapt to inherent uncertainties, various learning methods can be employed. Machine learning with reinforcement is a powerful tool; however, its extension to multiagent and large dimensions is not trivial. The mathematics for reinforcement learning are similar to the CE approach. Learning is also equivalent to the setting of specific parameters in a POMDP. Learning for CAs can be executed via genetic algorithms. Learning in Influence Diagrams is formulated as an optimization and/or fixed point problem (i. e., solvable by iterative application of an optimization operation).

In general, learning works better if the parameter space is smaller and if the free parameters can be treated independently in the optimization process. An open research question is whether best preplanned collaboration exists. From a coordination expert system point of view it could be a decision algorithm on what to do under specific situations. This implies that for a large number of specific situations, a large number of coordination settings have to be stored, which becomes impractical in realistic scenarios. A possible solution is the creation of a *team template library* as an algorithmic version of the *trading methodology* mentioned in the Introduction. The algorithmic approach first identifies critical parameters for a specific situation. Optimization with respect to coordination is then performed at this identified *criticality ridge*. Since situations are constantly changing, both a similarity measure for situations (*this situation is similar to the one we had yesterday where we successfully applied the following coordination scheme*) and a fast identification method for critical parameters are needed. For the construction of such a fast identification method, the heuristic of blind separation techniques could be applied: a critical parameter changes the system behavior independently of the value settings of other parameters. Information science offers the tools to design, store and implement situational and process-specific details in ontologies. Ontologies represent all bottom-up (*the devil is in the detail*) information. The *team template library* is where all detailed specific bottom-up information is linked to the criteria of applicable coordination schemes (which can also be described as algorithms representing the top-down approach to cooperative tasks). Sections 22.3–22.5 further elaborate on the *trading methodology* that incorporates both heuristic and expert knowledge to generate and evaluate coordination schemes.

Coordination for cooperative target tracking is a tool to allow cooperation. Coordination methods differ in the amount of data transfer they need, the speed of convergence, and the sensitivity to error.

Coordination schemes applied in cooperative systems (multirobot, human societies, business processes, and information science) are:

- *Divide and conquer*: no interaction necessary after planning phase.
- *Decentralization due to a limited sensor range* [22.44].
- *Decentralization due to limited control access*.
- *Auction*: bidding for a task. An auction is a process of buying and selling services by offering them up for bid, taking bids, and then selling the item to the highest bidder. The auction procedure has to be set up before the execution of the auction.
- *Voting*: recommendations based on ratings or rankings collected from many sources. Voting is a method for a group such as a meeting or an electorate to make a decision or express an opinion. The majority wins in a typical voting procedure.
- *Consensus*: recommendations based on ratings or rankings collected from many sources, Consensus decision making is a group decision-making process that seeks the consent of all participants. Consensus may be defined as an acceptable resolution, one that can be supported by all, even if not the *favorite* of each individual [22.45, 46].
- *Game theoretic*: an equilibrium state in which each player has achieved the maximum that can be achieved (i. e., any further move will decrease the payoff).
- *Bio-inspired*: similar to ants forming teams for transporting heavy pieces of food, bio-inspired cooperative target tracking can be interpreted to be a trial-and-error approach on the information gathering task of finding and holding track of a target.
- *Adaptive hierarchy*: explicitly allowing changes of hierarchical structures at run time leads to coordination schemes adaptive to specific situations the team is facing in cooperative target tracking, for example, the surveillance units can reason about a reorganization of the team structure in the case of a sudden loss of target contact [22.47].
- *Synchronized covertness*: the design idea is to exploit the covertness of receivers, but at the same time allows for coordinated activities among them. The covertness of receivers is important when dealing with stealth targets which can avoid detection only in a limited number of geometric setups. If the stealth targets have no knowledge about the receivers positions, they cannot adjust their path planning to exploit their stealth design in these geometric setups. The mixed architecture which results from the design idea of synchronized covertness

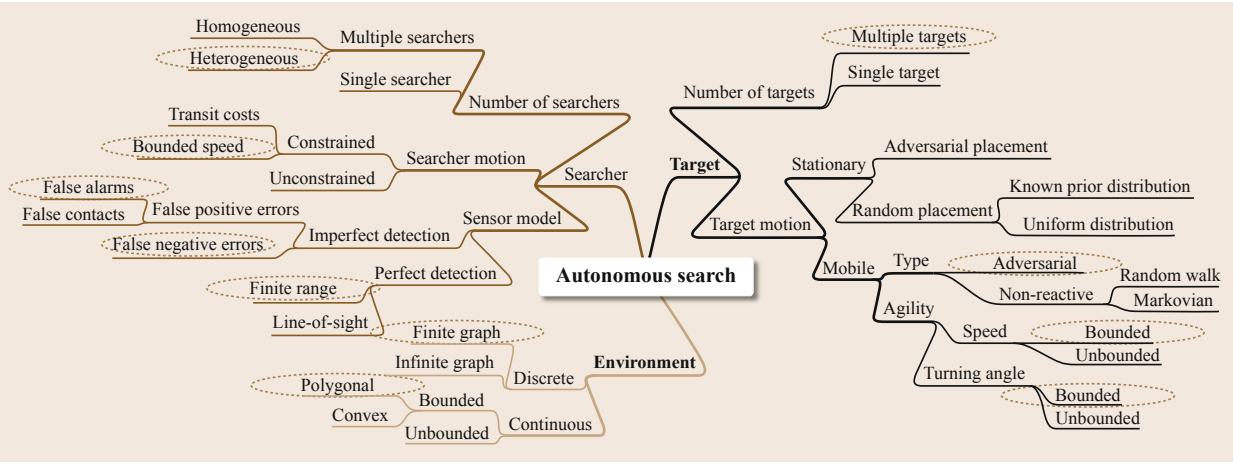

Fig. 22.3 Parameter space for autonomous search models (after [22.48]). Applications discussed in this chapter are indicated by *dotted ellipses*

is developed by the *trading methodology* described in this chapter. The *trading methodology* allows to balance the need for synchronization (or interdependence) with the benefit of covertness (or independence).

Most desirable is a coordination architecture that is a mixture of centralized elements, for example, for synchronization and startup phases, and decentralized elements that are robust, delay, and disruption tolerant. Multilayer architectures developed in the robotics community are able to support cooperative target tracking with operator interaction. Publish and subscribe (e.g., MOOS [22.49], ROS (and, e.g., PRACSYS built on it [22.50])) techniques minimize the interdependencies between the various processes within such a multilayer, multisensor, and multiplatform network. A cooperative architecture for information-theoretic search and track has been examined in [22.51]. Multiple robots are used for cooperative target tracking in [22.52]. Energy management is always an important consideration [22.53].

Few multirobot systems have been tested on the scale necessary to demonstrate pursuit evasion in complex environments such as the ocean (Fig. 22.3). In addition, a reliable communication infrastructure is required to guarantee that a plan will be executed successfully. Decentralized architectures and methods capable of utilizing new information as it becomes available can reduce these requirements, but the development and evaluation of such algorithms remains an active research area [22.48].

The probability of detection of a target depends on the target motion, particularly on the target strength for specific aspects of the target relative to the detector, or on the anomaly of its behavior with respect to many other neutral agents in its vicinity. Systems designed to exploit these two detection methods are discussed below: multistatic sonar target tracking and maritime surveillance.

22.3 Multistatic Sonar

In this section, we describe multistatic sonar from its implementation point of view (the bottom-up description), then we switch to the top-down view of describing the objective for the application of multistatic sonar. Within the top-down view, we review standard concepts for cooperative tracking that could be applied. We specify then a benchmark problem which explicitly includes the main features identified by the expert evaluation of the bottom-up view. We formulate the benchmark problem as a fair game and describe a solution methodology.

Detection and tracking of objects in the ocean by passive acoustic means are ultimately limited by emitted sound source levels. In noisy, multipath environments, passive approaches tend to be inadequate. Active acoustic systems, on the other hand, offer sufficient performance, especially when operating in multistatic mode, using multiple, spatially distributed sources and sensors to activate and receive signals. In shallow water areas (< 100 m), applying data fusion and tracking algorithms to multistatic sonar data are challenging due to noisy and fading channels, reverberation and clut-

ter [22.54, 55], but can be solved [22.56]. A simple and surprisingly well-performing approach in the signal and contact processing for multistatic tracking is to sequentially process the incoming contacts. The motion model inserted in the tracking algorithm (by Kalman filtering) is implicitly concatenating the contacts together with their uncertainties. Sequential handling of contacts has less performance than a full fusion, but in many applications and simulations this procedure is adequate.

For multiple tracking platforms, the data fusion process increases track accuracy and track length, and minimizes track latency. For long-range applications, sequential target tracking can be used as a method for data fusion [22.56]. If the sequential target tracking is not feasible due to too low probability of detection, data fusion before tracking or a multisensor track-before-detect may be possible. [22.57, 58].

Multistatic sonar enables false alarm classification by evaluating hypothesis on the existence or nonexistence of contacts in different source receiver geometries depending on the size and structure of the objects or larger underwater features. These geometric considerations lead to a very important feature of multistatic sonar: It is antistealth, in the sense that the target has less degrees of freedom in deciding what to do next without being detected, which relates directly to a decrease in the number of internal *mental states* available to the target. Multiple acoustic sources can be used to localize autonomous receivers automatically [22.60], resulting in a very high precision of target position estimation. Any mobile array of receivers can be used for spatially adaptive target tracking. Sensor performance is related to the overall aperture and element spacing. System performance is determined by a combination of both sensor performance, networking capabilities, and platform agility.

Multistatics with autonomous systems is advantageous because it allows low-risk sources and receivers in close proximity to the target, resulting in a higher signal excess [22.61]. The fusion of contacts has to account for the quality of each measurement correctly. To improve the measurement of each sensor, two MoPs have to be combined: the detection probability (related to the expected signal-to-noise ratio of target returns) and the accuracy of the localization. How these two MoPs are combined depends on the situation (states of all assets and of the environment). Measurements that are uncorrelated provide maximal information. Information theoretic metrics (e.g., Renyi entropy [22.39]) can be used to calculate the information added by using multiple sources and receivers.

Multistatic sonar can be understood as a semantic sensor network (Fig. 22.4). The realization of such multistatic sensor networks [22.59] reveals the need to specify and implement all elements of ontology. Specific field trials in the ocean have demonstrated that the complete chain from detection (glint detection), communicating, and simultaneous track holding is pos-

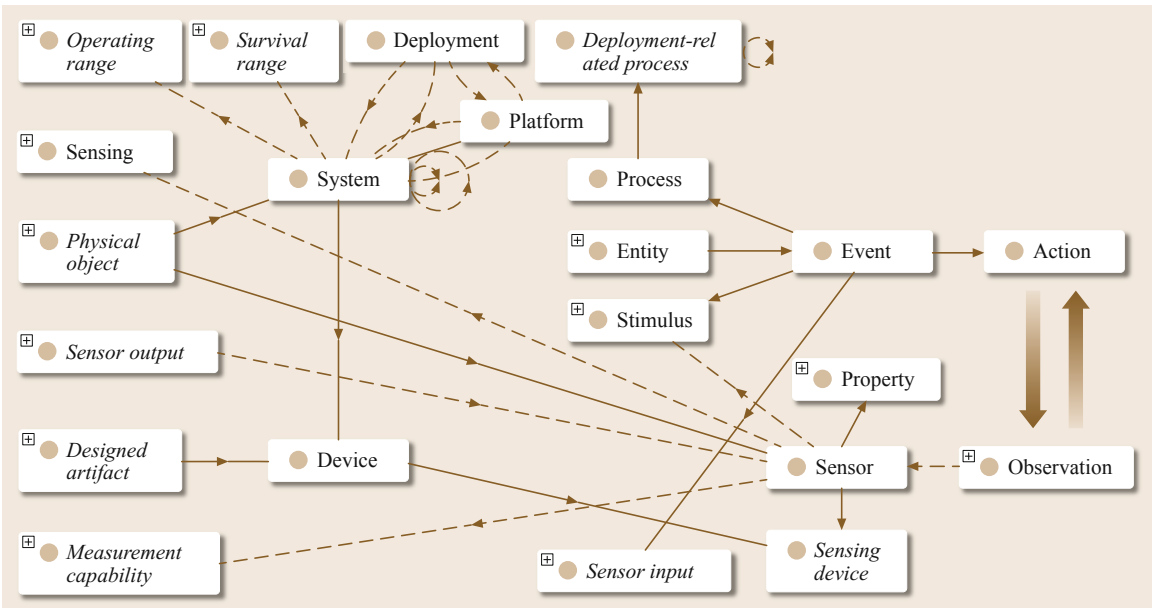

Fig. 22.4 The semantic sensor network (after [22.59]) with the focus on the link between observation and action that has to be statistically separated (become independent) from each other for target's actions and surveillance's observations in order to generate a fair game

sible [22.62–65]. The multistatic approach has also been demonstrated in other domains [22.66, 67], and multirobot patrolling has been applied to other areas, like harbor patrolling [22.68].

Experimental experience provides a valuable estimation of costs to the elements of the ontology. Efficient cost accounting will be needed later (Sect. 22.5) when in the *trading methodology* the ontology design must be changed.

Scenarios for cooperative target tracking using low-cost autonomous vehicles for surveillance in a predefined area covered by several stand-off sources are depicted in Fig. 22.5. We call this scenario *low-frequency cooperative target tracking* (LFCTT). This implementation is a distributed, mobile sensor network with limited inter-platform communication. We assume that the stand-off sources can be used to continuously distribute a small amount of coordination information via the acoustic underwater channel. The receivers should be kept covert as much as possible to limit target adaption, but have the capability of transmitting over the low-frequency acoustic channel information on specific confirmed tracks. This information can be encapsulated into a few hundred bytes every minute.

For these scenarios, we develop a coordination scheme and outline how to evaluate its parametric settings.

A possible approach from control theory is to model the target as a worst-case target, meaning that in every time step of the game, the target is reacting noncooperatively to the maximum extent, trying to avoid detection as much as possible [22.12]. Inserting the resulting reward matrix into the control equations of the surveillance leads to a set of equations dealing separately with the controller and with the observer design of the surveillance team. In the linear-quadratic control case, this leads to closed-form equations for how to handle the observations and how to react after analyzing them.

The worst-case scenario makes a high demand on quality of sensors and number of assets in the surveillance team. The resulting strategy of the surveillance team is probably close to the scenario where all possible target tracks lead to the detection of the target (independent of its strategy). For example, the target might guess that the surveillance team is preparing for its most clever move; hence, it is taking a (from the perspective of the surveillance team) less clever, but (with the surveillance team having expected a different move) at the end successful move. As a result, the surveillance team has to be prepared for everything, which means organizing itself to detect targets under all circumstances, an extreme scenario that is likely to be unrealistic.

To approach cooperative target tracking in a more realistic way, we choose a heuristic generally used for the analysis of complex adaptive systems: avoid interdependencies, strengthen interconnectivity. Following this heuristic, the resulting network becomes more tractable (phase transitions are less complex) [22.69].

Complex phase transitions lead to unpredictable chaotic behavior of the entire system. Interconnectivity is maintained in LFCTT by the use of multiple acoustic sources and receivers. Greater signal diversity (aspects of the target illuminated) results in increased detection probabilities [22.56]. Interdependencies are avoided by the tendencies of both the target and the surveillance team to operate independently under their own control.

We assume that the LFCTT scenario has two different subtasks: subtask 1 where the target's position is unknown to the surveillance team, called search task; subtask 2 in which the surveillance team has made a definitive decision on the target's position and tries to hold the track as long as necessary to initiate an appropriate action [22.39].

In the search task, if the surveillance team is acting such that the target cannot predict its behavior over a longer time frame, an appropriate strategy for the target is to act optimally in the current situation, but to avoid situations in the near future in which it might be trapped.

At this point in the design process, it makes sense to use a benchmark problem to highlight the most im-

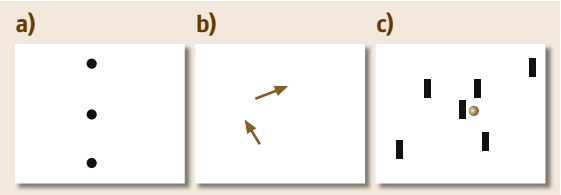

Fig. 22.5a–c Scenario consisting of (c) a surveillance area, and areas for (b) autonomous receivers and (a) stand-off acoustic sources. For low-frequency active sonar, the actual distances between the boxes can be large, especially for the sources (*dots*) which are operating as stand-off illuminators of the surveillance area. The goal of the target (*dot*) is to reach the left side of the surveillance area. It can hide at clutter points (*black rectangles*). The coordination necessary in this LFCTT game is for the receivers (*arrows*) which have to have a simultaneous good view on a specific patch in the surveillance area to make optimal use of the multisource and multireceiver setup. Since the discrimination of clutter and target detections is difficult because of nonstationary fluctuations, we assume that the best data for such discrimination is generated if the sound transmitted from all three source is hitting the same patch to which the receivers are focussing

portant features of the scenario. We further assume that the cellular automaton modeling the target consists of a small number of *mental states* (reckless, offensive, defensive, cautious, conservative) (Fig. 22.6) that influence how the actual path planning of the target is executed. We postulate that each action possible in a *mental state* leads to independence from the surveillance team in the near future. Changing the *mental state* is only possible for the target when:

- The target certainly knows that it is undetected on some time scale.
- The target has reached a point to hide, for example, within known clutter fields in the environment.
- The target has reached a safe point far enough away to be not affected by the surveillance team.
- The target has reached a point in which there are still many *mental states* (and therefore actions) available to be finally successful and the surveillance team is still acting randomly and independently of the target actions.

We explicitly model clutter that can be from databases or from an in-situ clutter analysis. Clutter plays a major role in the LFCTT game, influencing the measurements of the surveillance team and influencing the target movements. We assume that classification is best when three sources converge on one target. This is analogous to the saccades, movements of (human) eyes in surveillance mode, where the two eyes coordinate their focal point quickly within the scene

To simplify the calculations, we model sensor performance crudely, taking only grid cells into account that are under best surveillance conditions. This approach is similar to the *winner-takes-all* (WTA) methodology in artificial neural networks. We call these grid cells the WTAs of the surveillance team.

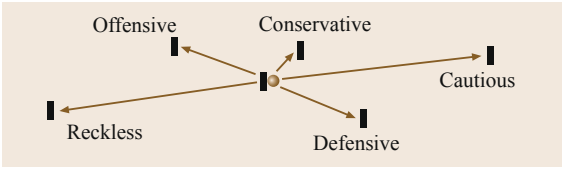

Fig. 22.6 An example for the decision-making process, modeled as a celluar automaton (CA), inside the target (*dot*) on which clutter point (*black rectangles*) to reach next. It is deciding depending on its *mental state* on how the path for the near future actions is calculated. Since clutter points are genarally a place to hide, in the example of Fig. 22.6 we depict a one-to-one mapping of *mental state* (reckless, offensive conservative, defensive, cautions) and actual path. The reality in LFCTT is much more *stochastic* in the sense that uncertainty about positions, resolutions and performance of tracking processes by the surveillance team have to be taken into account. But these effects are understood in the sense that they can be adequately modeled to extend this simplified CA model

The simplification for sensor performances by WTAs helps to infer that the best performance is generated if the crossing beams of the receivers are located in the area defined by the sound sources. This leads to a coordination scheme in which the sources also coordinate the movement of the receivers which might be autonomous underwater vehicles (AUVs) equipped with towed hydrophone arrays (Fig. 22.7).

In the game, the target does not know which actions the receivers are taking. However, it is reasonable for the target to assume their existence (otherwise the game-theoretic setting would not apply). The receiver positions are only unknown until they participate actively in long range communications. Hence, the target's planning horizon should include an evasive reaction on this detected communication event. Maximizing independence means for a receiving platform to keep its covertness as long as possible.

Subtask 1 of the game is finished if either the target transits through to its goal undetected or the surveillance team passes a persistent track to subtask 2.

The benchmark problem just described leads to a game that can be further analyzed. Percolation theory as an instance of renormalization methods can be used to analytically predict the game outcome when pa-

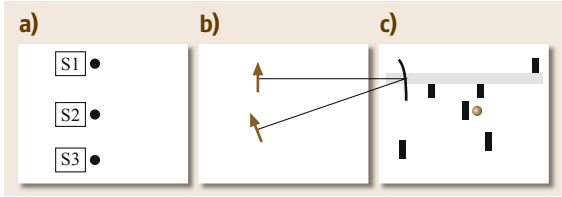

Fig. 22.7a–c Scenario from 22.5 with coordination scheme: The sources are located in **(a)**, the receivers are positioned in **(b)**, and **(c)** is the surveillance area. The three sources coordinate their ping transmission scheme in such a way that a patch in the surveillance area is hit by the sound simultaneously. For example, if the two sources S1 and S2 are pinging at the same time, the area filled with *dots* is specified. The source S3 can arrange a further focus with its ping timing (e.g., the *curve* crossing the the *shaded gray area*). Regardless on their own position, the receivers (*arrows*) can quickly change heading to point with their broadside beam to this patch. By the coordination between the sources, the receiver movement is also specified without any further communication between the sources and the receivers being necessary. If the receivers are AUVs equipped with towed arrays, the changes in heading can be performed within a short time frame

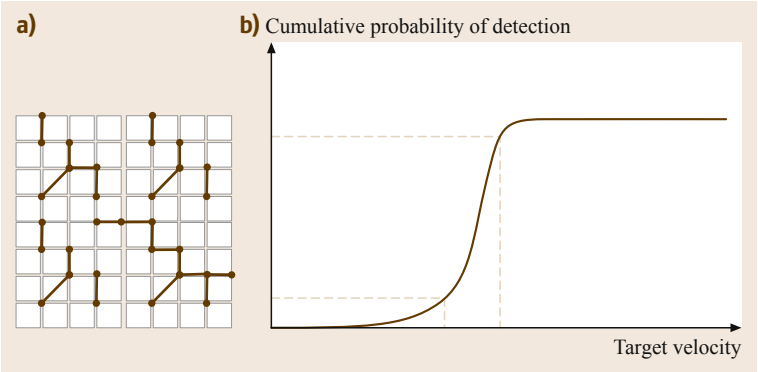

Fig. 22.8a,b **(a)** Percolation theory to describe whether a target breaks through a barrier. Each leg corresponds to a possible path of the target with associated probability of detection. **(b)** Depending on the velocity of the target the probability of the barrier to be open or close goes through a critical phase. The sigmoid shape of the cumulative probability of detection is a typical example for the behavior of complex adaptive systems. The system is transitioning from one phase (barrier open) to another phase (barrier close). The *dashed lines* mark a critical parameter interval around the critical value of the cumulative probability of detection of 0.5

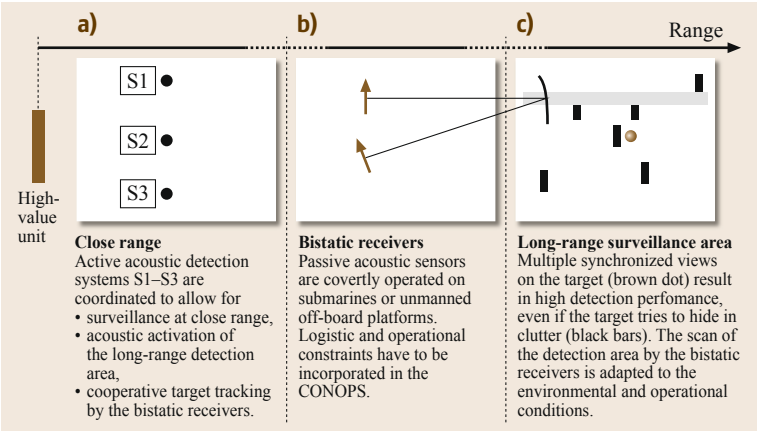

Fig. 22.9a–c Layered defense setup for the scenario from Fig. 22.5. The long-range surveillance in area **(c)** is described by the synchronized covertness process in Fig. 22.7. In area **(b)** the covert receivers can simultaneously act as passive receivers. In area **(a)** the additional installation of standard active sonar protection of the High Value Unit is possible by just adding receivers to the stand-off sources

rameters are chosen to be outside the fair game setting (Fig. 22.8).

Furthermore, once understood at this analytical level, benchmark problems can be combined, in a layered defense setup (Fig. 22.9). The more the layers are designed to be independent from each other, the better can the analysis of the resulting multilayer system inherit elements of the analytical evaluation of the benchmark problem for the long-range detection area (Fig. 22.9c).

Summarizing the approach outlined in this section, we can identify two major steps:

1. An *understanding phase* in which a fair game is constructed as a benchmark problem. The benchmark problem deals only with the important features of the cooperative target-tracking application in multistatic sonar. It separates critical functionalities or agents in the description. These simplifications and compact descriptions allow a further analytical treatment and an extension of the findings by this treatment to larger, multilayer structures.
2. A design phase for multilayer systems where coordination plays a major role for the construction of both effective and efficient systems. Effectiveness and efficiency can be predicted by re-using the results from the analytical treatment of the benchmark problem in the *understanding phase*. This design phase can follow a *trading methodology* as further explained in Sect. 22.5.

22.4 Maritime Surveillance

Marine traffic is one of the backbones of the world's economy. Together with fishing and industrial exploration and recreation activities, an enormous amount of uncorrelated movements take place. The amount of data is tremendous; sensors are erroneous and cannot always been trusted. For example, AIS (automatic identification system) is a locating signal which all large commercial ships must carry, though many vessels transporting illicit cargo turn off their AIS transmitters in order to avoid cooperatively reporting their status. Turning off the AIS transmitter however is an anomalous behavior which can be detected.

For information gathering tasks, the evaluation of sampling strategies depends on the ability to produce quantitative metrics for system performance, which in turn depends on having a clear sense of what aspects of the observed field are important. Much recent effort has been directed toward *anomaly* detection. The concept of an *anomaly* or *anomalous behavior* is dependent on baseline statistics that are problematic when regimes can only be sampled sparsely. In such cases, the role of feedback will be even more critical with perhaps active probing (sending an UAV (unmanned aerial vehicle)) necessary to elicit a response. False positives (the false alarm problem) and their associated costs are typically the most serious limitation of a highly sensitive system. When risk is included as a metric, state variables may have different associated utility and expected values. In the case of systems for anomaly detection, consider a large sensor network including UAVs, AUVs, ships, radars, etc., for the detection of smuggling, or otherwise anomalous behavior in coastal waters. The system would not only detect anomalous behavior, but it could also access databases about vessels, their cargo and crew in order to estimate risk for the particular observation. This imposes high levels of uncertainty in the system as public databases might be inaccessible, or UAV assets not available at the time. The system has to constantly reconfigure in order to deduce the information relevant to the operators. An adaptive architecture is necessary for the coordination scheme to cope with this variability. The implementation of autonomous ocean vehicles could potentially be a game changer.

In maritime surveillance, there are many innocent players who are following the rules but run into strange situations (by equipment failure or environmental conditions). Surveillance of all these players is not possible. Practically, the target always risks being under surveillance (the covert receiver is the general case). Instead of trying to be invisible (which is not possible), the objective of the target is to make only its illegal activities invisible.

The aim of maritime surveillance is to check the sequence of decisions made by the target to see whether this sequence is designed to be maximally independent. That is an anomaly because decisions of the target should be normally following another strategy (the one written in the AIS log or inherently given like bringing goods from A to B, finding fish, etc.). The strategy for the surveillance team is to gather as much data as possible for this task. Coverage is an attribute for the search phase. A quick reaction capability of requesting more data if an anomaly has been detected is an attribute for Phase 2 (verification and hold). More than in the multistatic scenario, the maritime surveillance scenario will be demand based in order to avoid the transmission of all collected data. Demand-based data sharing might look like: *Something is strange here. Do you have more information?* An implementation of this network should build upon the features of a publish and subscribe architecture.

In this case, we are not only gathering information about positions, but about processes. Position information is still important because it can be, for example, the start position of a process or a constraint for a process, but in general we are looking for a measured sequence of positions and activities which is then used to estimate the target's intention. A decision on whether the target's behavior is inside or outside normal bounds is called an anomaly detector.

The target's goal is to disguise the illegal intention as much as possible for a sufficiently long time. The target is modeled to have a small number of mental states, as before, and determines how much probability of letting the surveillance detect its behavior is acceptable. The coordination architecture is again a mix between centralized synchronization and distributed decision making and the coordination method is synchronized covertness (letting the target know that you might be watching, but not whether you are really there or not). This can be visualized as a separation in the related probabilistic graphical model.

22.5 Effective Coordination Schemes

An important aspect of a cooperative target tracking system is measuring its overall performance [22.70]. In particular, connecting MoPs (and their probability density functions (PDFs)) with MoEs requires integration of specific performances into overall effectiveness in achieving objectives and goals (Fig. 22.10).

Simulations or standard reinforcement learning methods [22.17] are not feasible for large parameter spaces. The expert choice of attributes linking MoPs and MoEs is a viable method, but is not rigorous enough to test the effects of different coordination methods.

Complex nonlinear systems often show critical behavior: small changes in parameter settings lead to completely different behavior of the system. Renormalization methods have been used to analyze the criticality of systems with many degrees of freedom [22.69, 71]. Renormalization can mathematically bridge between bottom-up and top-down perspectives. Essentially, gradients in the system are analyzed from the critical point in parameter space. The parameter space is, in fact, of infinite dimension if beliefs have to be handled. This means that the *parameters* are functionals, and it is necessary to find independent subprocesses in order to handle the overall complexity. Equality of processes has been investigated and found to be challenging [22.72]. A sensitivity analysis to initial conditions is the key to allow a qualitative evaluation of the effectiveness of a coordination scheme. A quantitative evaluation becomes possible by high-fidelity simulation for a limited number of parameter settings in small domains previously identified by the qualitative evaluation.

We divide the design process into two parts:

- Creation of benchmark problems to calibrate and standardize the mapping between MoEs and MoPs is the *understanding phase*.
- Constructing an efficient cooperative team by inserting coordination into layers of originally independently operating surveillance assets (and thereby creating efficient and suffciently effective functionalities) is the *trading methodology*.

22.5.1 The *Understanding Phase*

Benchmark problems are simulations characterized by an unbiased initial condition for each team and positioned at a critical point in the parameter space. The likelihood of one team prevailing over the other is initially equal. Benchmark problems are simplifications of the real world that distil key aspects of a system to clarify and calibrate the underlying dynamics. Often the simplifications allow analytic solutions against which more comprehensive (but opaque) numerical models can be tested for fidelity.

In benchmark problems for the evaluation of the effectiveness of coordination methods, the critical design aspect is the transition from one to many agents as a means to achieving the objectives. For example, in multistatic surveillance, cooperative target tracking enables the detection and tracking of targets hidden in clutter by increasing the effective antenna aperture and thus narrowing the focus and increasing the signal-to-noise ratio. In the detection of anomalous behavior, cooperative sensing synchronized with a global observation network enables the construction of a time dependent, multidimensional vector whose magnitude and direction can reveal a target's hidden process. These two scenarios share the common features of multisensor data fusion and a smart adversary.

Approaches to generating benchmark problems vary:

- The heuristic of looking for independent subprocesses or functionalities. Numerical simulations governed by analytical considerations on the importance of these functionalities gives as a by-product the formerly unknown functional connections between components in the entire process. This functional relationship represents the link between the a-priori MoPs and the posterior MoEs.
- A game scenario constructed by experts. Idealistically, the game is set up such that each side has an equal chance of winning at the start. Alternatively, the initial conditions can be deliberately biased to test specific hypotheses. Fundamental to target detection and tracking problems is the process of minimizing uncertainty. Teams that best succeed in such minimization (through cooperative behavior) will have a better chance to win the game.

22.5.2 The *Trading Methodology*

In the *understanding phase* explicitly separated (independent) agents or functionalities are generated. The *trading methodology* starts with uncoordinated independent layers of these agents. From this starting point with a specific position in the effectiveness-efficiency plane and a guaranteed minimal effectiveness the risk harming the effectiveness of the system by inserting dependencies is traded with the predicted gain of efficiency by inserting these dependencies. For example, using the same acoustic sources in the layered defence

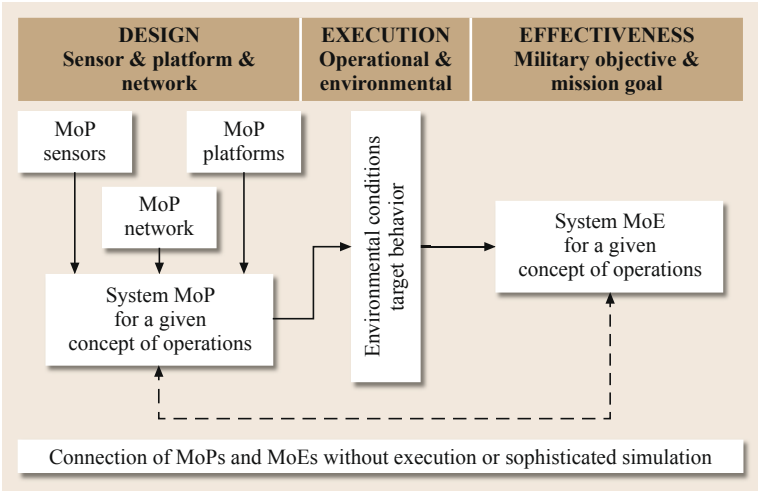

Fig. 22.10 Schematic showing pathways connecting measures of performance with measures of effectiveness

system in Fig. 22.9 for the execution of operations in all three layers is more efficient than having extra sources for each layer, but the risk is introduced of losing all three layers if the single set of sources breaks.

In the context of a probabilistic graphical model, the *trading methodology* is connecting the agents of the cooperative team. By applying the *trading methodology*, the system design takes a path on the effectiveness-efficiency surface. Connections made can be similar to already known coordination schemes (Sect. 22.3). For example in an auction scheme there will be many connections representing the process of bidding and bid evaluation. Inserting this in the multistatic framework would result in a loss of covertness and in a loss of the ability to counter stealth targets with a low number of surveillance assets. In the synchronized covertness applied to a layered defence scheme, there will be less connections due to the preplanned spatial separation of the layers and the covertness of the receivers. Both coordination schemes lead therefore to two different positions in the effectiveness-efficiency plane, relative to the started point, hence, a comparison of both becomes possible.

Instead of comparing complete packages of coordination schemes, as discussed in the paragraph above, the *trading methodology* can also be understood as an iterative process, inserting, or deleting single or small sets of connections between agents. Since inserting or deleting connections results in principle in the necessity to completely re-analyze the entire model, methods are needed to quickly recalculate the effectiveness and efficiency predicted for the updated version of the model. The analytical knowledge gathered in the understanding phase can govern finding such methods by checking the importance of the update made relative to the critical behavior of the entire system. Similarly, maintaining substructures (hierarchies) invariant to chances, which could be, for example, clustering as proposed in [22.73], leads to fast re-evaluation of systems, too. The identification of critical (important) and independent (invariant to changes elsewhere) agents or functionalities is prepared in the *understanding phase*.

22.6 Conclusions and Recommendations

Many practical applications in the maritime domain deal with stealthy targets and large scale, three-dimensional transient environments. Cooperative vehicle target tracking offers the best solution to many surveillance and search/pursuit tasks in this domain. Successful implementations of cooperative vehicle target tracking can be found in multistatic sonar operation and in maritime surveillance systems. The cooperation is important because single sensor, single-platform systems do not provide the necessary persistence, coverage and environmental adaptability. In maritime surveillance, tracking is not plotting positions on a geographic grid, but following a trajectory in a space of behavioral parameters particular to the target.

A distributed coordination architecture is desirable in the implementation of cooperative target tracking with autonomous ocean vehicles. Coordination is advantageous in both the search and tracking phases.

Synchronization of the team in a centralized manner is necessary in large areas with sparse communication,

leading to a hybrid coordination scheme called synchronized covertness.

A methodology to generate coordination schemes has been developed, stemming from a heuristic bias toward independence. Coordination schemes generated with this methodology allow evaluation of the effectiveness of coordination.

Benchmark problems provide a useful way to quantify and compare the effectiveness of coordination schemes on a common basis (Fig. 22.11).

A recommended way forward would be the creation of a library of benchmark problems in realistic maritime environments together with the results of the *trading methodology*, that is, the produced coordinated behavior. Such a library could serve to gauge advances in coordination approaches on a common and understood basis. The scenarios could also serve as training tools for interactions between humans and multirobot systems.

23. Rules of the Road for Unmanned Marine Vehicles

Joseph A. Curcio

The growing use of unmanned marine vehicles (UMVs) demands safe and reliable operation in order to assure acceptance and integration into public water space. By looking at the evolution of unmanned aerial vehicles (UAVs) and unmanned ground vehicles (UGVs) and examining the existing legal structure related to safe maritime operations, we explore the path ahead for UMVs. The existing COLREGS (rules of the road) for marine vessel operation may be undergoing modifications in order to accommodate UMVs, while simultaneously, designers of UMVs are working on developing advanced autonomy behaviors that exhibit *human-like* on-water performance by UMVs. This paper presents a snapshot of the rapidly changing field of UMV operation, with particular focus on software technology shaping higher level autonomy behavior and on the legal landscape providing the framework for acceptable operation in public water space.

23.1 COLREGS 517
23.2 Sensing the World 518
23.3 Proper Behaviors Yield Compliance 519
23.4 Integrating UMVs into Public Water Space 523
23.5 Developing Standards 524
23.6 The Road Ahead 525
23.7 Conclusion 525
References 526

Unmanned marine vehicles (UMVs) operating in populated waterways may require compliance with existing rules such as the collision regulations defined by the convention on the international regulations for preventing collisions at sea (COLREGS) [23.1] as published by the International Maritime Organization (IMO) and widely accepted by individual nations through international treaty agreements. Every mobile marine platform carries the risk of becoming involved in a collision with both stationary and mobile objects and vehicles. This risk exists regardless of whether the platforms are manned or unmanned. Owners and operators of mobile robotic marine platforms must take certain responsibility and action by designs intended to mitigate risks associated with the potential for collision and errant conduct by these platforms. This notion suggests that UMVs may need to operate in a very *human-like* manner so that their maneuvering will be recognizably executed and accurately interpreted by other vessels operating in their vicinity.

Rules and regulations pertaining to the operation of UMVs in public water space are evolving topics. The existing marine COLREGS *rules of the road* may themselves need to change in order to accommodate UMV interoperability with other manned and unmanned vessels. We will explore here the current state of technology associated with keeping UMV operations compliant with the existing COLREGS requirements and discuss the natural evolution of both the technology and the legal framework that will be necessary in order to keep pace with this technological development.

23.1 COLREGS

COLREGS establish a set of standard procedures that mariners are expected to follow. Comprised of approximately four dozen rules, they cover fundamental vessel maneuvering, vessel markings, situation awareness requirements, and signal specifications. In nautical terms these rules prescribe proper procedures for maneuvering a vessel and specify additional requirements for light and sound signals that alert other mariners to

a vessel's location, heading, intentions, and maneuvering constraints. Safe operation in crowded public water space is achieved through compliance to this widely accepted standard set of rules by all vessel operators.

At the core of the numerous COLREGS regulations are three fundamental driving rules. These three rules form the basis for most of the behaviors necessary for safe operation in the presence of other vessels. In no particular order, these three rules consist of the *head-on*, *overtaking*, and *crossing* situations. In general, the rules provide for specific actions suitable for avoiding collision when two or more vessels are operating in proximity of each other. Typically, in most crossing, overtaking, and approaching situations, one vessel will be the *stand-on* (privileged) vessel and the other the *give-way* (burdened) vessel, but as the rules clearly state, this is not always the case. In addition, there exists a *catch all* rule (rule 2 – responsibility) that requires a last chance to avoid collision by any and all vessel operators, regardless of rights.

As these rules were originally written to be interpreted and acted upon by humans, there exists room for interpretation and a notion of good helming and common sense is required in operating under these rules. In addition, COLREGS do not afford operators a clear *right of way* over other vessels, but rather dictate the accepted standard for safe maneuvering in order to avoid collision. Rule 2 along with rule 7 (risk of collision) are in place to clearly indicate that safe helming is mandatory, and regardless of perceived *rights of way* as defined by the rules, operators must take every precaution to avoid collision.

Fundamental to the rules is that they were originally written for humans to interpret and act upon, as evidenced in the use of terms such as *proper look-out* and the use of sight and sound signals to alert other mariners. Even today with the availability of AIS (automatic identification system), radar, and other navigation aiding devices, the role of the human lookout remains embedded in the rules. It is unlikely that completely automated navigation and vessel control will be accepted and implemented within the existing set of COLREGS rules any time in the near future. Meanwhile, how these rules apply to autonomous (and semi-autonomous) unmanned marine vehicles operating on and below the surface must be addressed, given current deployment trends. UMV platforms might ultimately be required to operate with certain specific behaviors in order to comply with COLREGS and with basic navigational constraints.

23.2 Sensing the World

In order to properly implement the COLREGS rules, UMV programmers and operators will first need to provide unmanned platforms with the capability to detect other vessels through adequate sensor systems, and react appropriately using robust behaviors.

The introduction of all mobile robots (on land, sea, and air) has required significant development in sensory systems capable of providing a *world view* to the autonomy system, producing the equivalent of a map of the environment surrounding the robot. This perceived knowledge of the world around the robot consists of data and meta-data collected by a suite of sensors integrated into a data fusion system, internally representing to the machine an awareness of the physical world in proximity to its operation. This perception is the basis of all that the machine *knows*. It is vital to understand that in order for a mobile robot to ultimately behave in

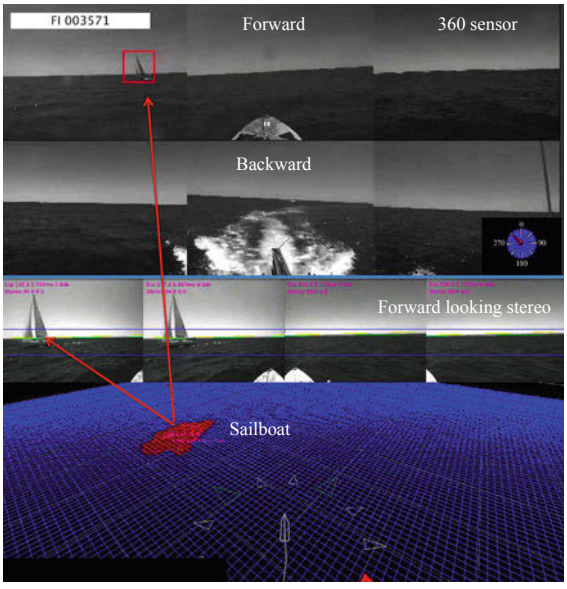

Fig. 23.1 Example of fusion of two sensor modalities (360° sensor, forward looking stereo) for a *proper look-out* of the environment surrounding the UMV. *Top*: the 360° sensor (in this case six cameras). *Bottom*: the forward looking stereo (in this case four cameras). The sailboat is detected in both sensor systems with the explicit range provided from the stereo system and relative bearing fused from both systems (courtesy of Jet Propulsion Laboratory, California Institute of Technology) ►

a *real-world* environment and to do so in a way that appears *human-like*, this perceived world must contain information that maps closely to that perceived by a human observer.

Sensors along with complex computer algorithms that fuse the raw sensor data are used to produce a representation of the surrounding environment much the same way the human eye and brain interact to create a picture of the surroundings. Relative to the evolution of the human eye, robot perception today is primitive. The perceived environment with all of its misperceptions and uncertainties is integrated into the robot's autonomy engine in order to facilitate safe mobilization. *Huntsberger* [23.2, 3] provides a good example of this process, as shown in Fig. 23.1, where a forward looking stereo system and a 360° sensor head are used to give full situational awareness around the UMV [23.2, 4].

Significant progress has been made within the past decade in the area of robot exteroception (perception of the world around the robot), including advances in the technology associated with improved sensors and evolution in the software associated with processing the information obtained by these sensors. Through an array of sensors, each sensitive to a limited spectral window (radar, laser, infrared, etc.), fused into a single *contact report*, the UMV assimilates information about its immediate environment. In general, the higher the fidelity of the fused data, the better the probability that the behavior algorithm will operate the robot with clearly defined (deliberate) movements. This will ultimately instill a high degree of trust of UMVs operating in crowded marine environments. It is not the focus of this paper to discuss the details of sensing the world around the UMV, but rather to discuss the impact that this capability has on advancing the functionality of the UMV and the potential for integration into the human/robot world in which these machines will operate.

As sensory capability and autonomy behaviors continue to evolve, marine robots will continue to become more and more capable of effectively discriminating between stationary and moving objects, sailing and motor driven vessels, channel markers, bridge pilings, and so on. Clutter rejection, false positives, lights on shorelines and other unwanted signal *noise* will be properly rejected, and complex artificial vision systems will produce reliable *contact reports* with a high degree of accuracy and confidence to the UMV *autonomy engine*. Eventually, humans operating in near proximity to these UMVs will have a difficult time distinguishing between human and machine operators.

23.3 Proper Behaviors Yield Compliance

Competent mobile marine vehicles generally operate with deliberate intentions (following a prescribed waypoint path) until a reactive behavior is necessary to avoid collision with a newly detected obstacle or vessel while underway. Various techniques for blending reactive and deliberate actions are practiced by many different groups engaged in programming mobile robots. For example, *Kuwata* et al. [23.5, 6] demonstrate *velocity obstacles* (VO) in conjunction with a *subsumption* approach [23.3] to meet COLREGS requirements with UMVs. *Benjamin* et al. [23.7] employ a mathematical methodology, termed *interval programming* (IvP) coupled with an open source *autonomy middleware* called MOOS [23.8] (mission oriented operating suite – developed at MIT and Oxford University), collectively termed *MOOS-IvP* [23.9]. Using MOOS-IvP, *Benjamin* et al. [23.10] use multi-objective optimization to generate an objective function weighing multiple objectives simultaneously and producing a globally optimized behavior solution. Conflicting objectives are weighed internally using interval programming (IvP) methodology, and a set of optimized vehicle heading and speed commands are issued to the UMV controller. By including COLREGS as one of the objective function sets, a balance is struck between near-term objectives (such as the desired goal to reach a waypoint) and safe operation (avoiding collision while satisfying COLREGS requirements), as shown in Fig. 23.2.

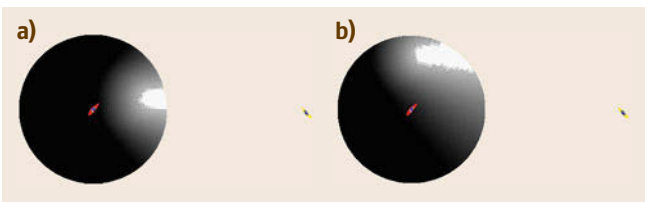

Fig. 23.2a,b Graphical depiction of an objective function as produced in this case by a collision avoidance behavior. The moving contact is shown with a motion vector indicating the contact's trajectory. Ownship has a fixed speed with the contact vehicle in **(a)** moving slightly below ownship speed and in **(b)** the contact is moving slightly faster than ownship. In both cases, *darker colors* represent more favorable trajectories and *white* indicates the closest point of approach between vehicles (courtesy of Massachusetts Institute of Technology, Laboratory for Autonomous Marine Sensing Systems) ►

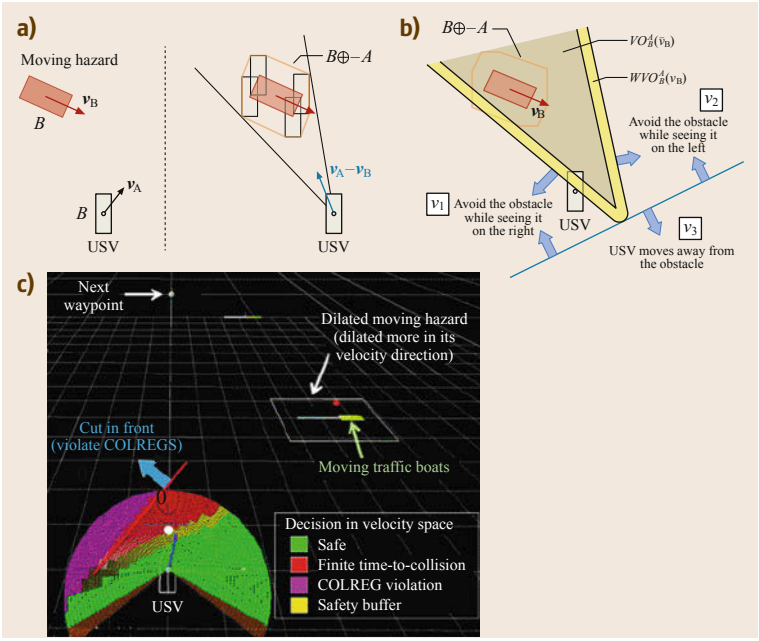

Fig. 23.3a–c A graphical representation of velocity obstacles **(a)** showing how the relative velocities of the unmanned surface vehicle (USV) and a moving hazard predict collision and define heading and speed combinations that allow safe passage. Combining the VO approach with COLREGS further constrains the problem, generating safe maneuvering projections that satisfy the COLREGS requirements **(b)**. Image **(c)** depicts a simulation run where the USV is encountering a potential collision and optimal COLREGS compliant trajectory is determined based on the VO and COLREGS restrictions (courtesy of Jet Propulsion Laboratory, California Institute of Technology)

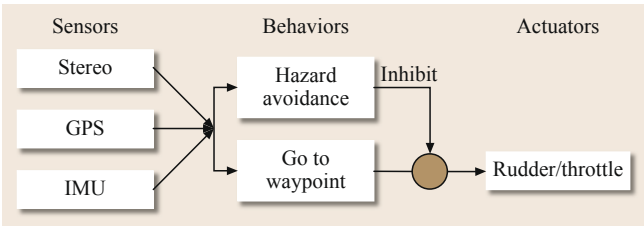

Fig. 23.4 An example of the *subsumption* approach as used in autonomous decision making, where certain behaviors are given higher priority

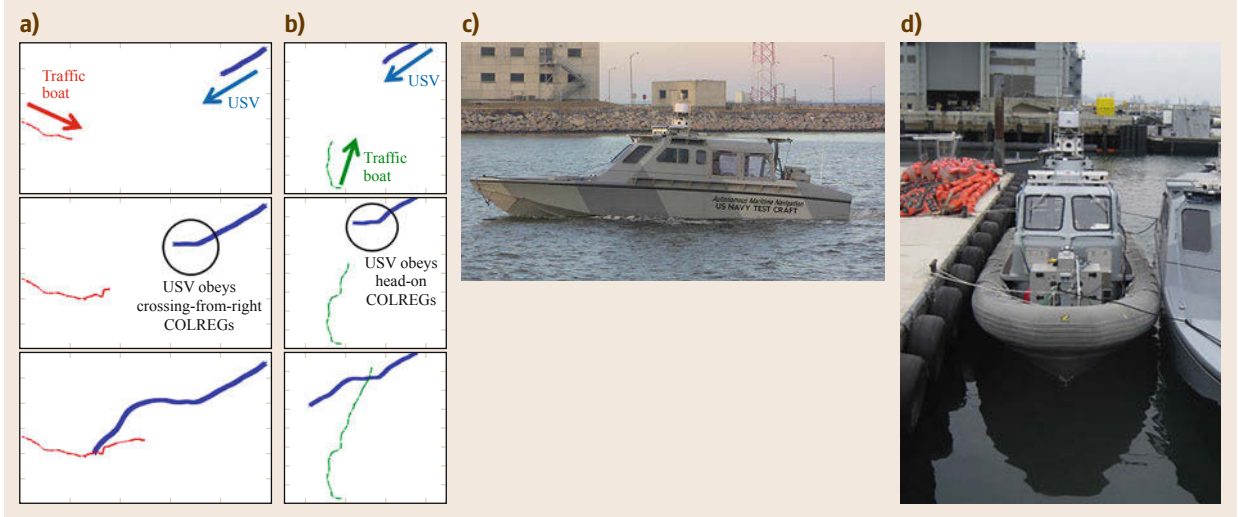

Fig. 23.5a–d Data showing a crossing from a right condition **(a)**, and a head-on situation **(b)** plotted from at-sea experiments using the two boats shown on the *right*. **(c)** The USV – power vent and **(d)** the 11 m RHIB (rigid hull inflatable boat) (courtesy of the Jet Propulsion Laboratory, California Institute of Technology)

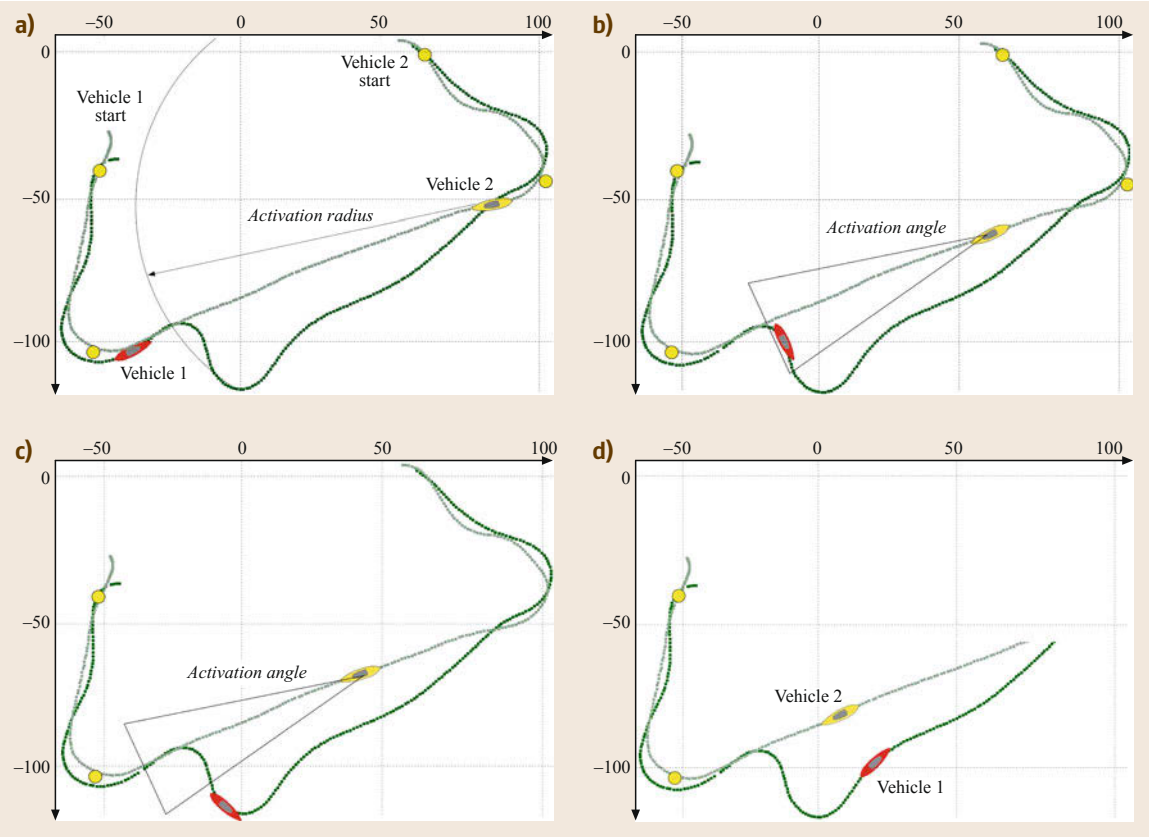

Fig. 23.6a–d In-water demonstration using two SCOUT vehicles in a *head-on* situation. Vehicle 1 is programmed to be COLREGS compliant with a waypoint objective active and vehicle 2 is simply transiting to the next waypoint with no regards to collision avoidance. When Vehicle 2 enters the 'activation radius' that necessitates collision avoidance behavior (from **(a)** to **(b)**), vehicle 1 makes a proper turn to starboard **(c)** to avoid collision and both vehicles continue towards next waypoint **(d)**. (courtesy of Massachusetts Institute of Technology, Laboratory for Autonomous Marine Sensing Systems)

Multi-objective optimization using IvP functions expressing utilities for all maneuvers (not just optimal maneuvers) is fundamental in allowing a common-sense balance between collision avoidance and mission objectives. This technique yields real-world behaviors that come strikingly close to being *human-like* in their implementation.

By comparison to the IvP approach, the velocity obstacle approach generates a cone-shaped area ahead of the UMV, mapped in a *velocity space* (defined as the area that the UMV would be capable of covering in some pre-determined time step, when considering the speed and maneuvering ability of the craft). Collision with other vehicles is prevented by assuring that the UMV's own velocity vector remains outside the region of the VO during transit. Fig. 23.3 graphically depicts the VO concept in conjunction with COLREGS compliant maneuvering restrictions. The subsumption approach to balancing conflicting behaviors uses a pre-established hierarchy in order to rank behavior authority, allowing certain behaviors to take precedence over other conflicting behaviors, as depicted in Fig. 23.4.

Some examples of in-water demonstrations of COLREGS compliant behaviors serve to illustrate the state-of-the-art. For example, as illustrated in Fig. 23.5, data taken from at-sea experiments demonstrate the robust nature of the NASA/JPL (National Aeronautics and Space Administration/Jet Propulsion Laboratory) system using COLREGS algorithms integrated into the JPL autonomy suite, CARACaS (control architecture for robotic agent command and sensing) [23.5]. In this example, it is evident that the USV altered course in proper compliance with COLREGS so as to avoid collision while continuing to pursue a waypoint objective. The NASA/JPL approach has been used successfully

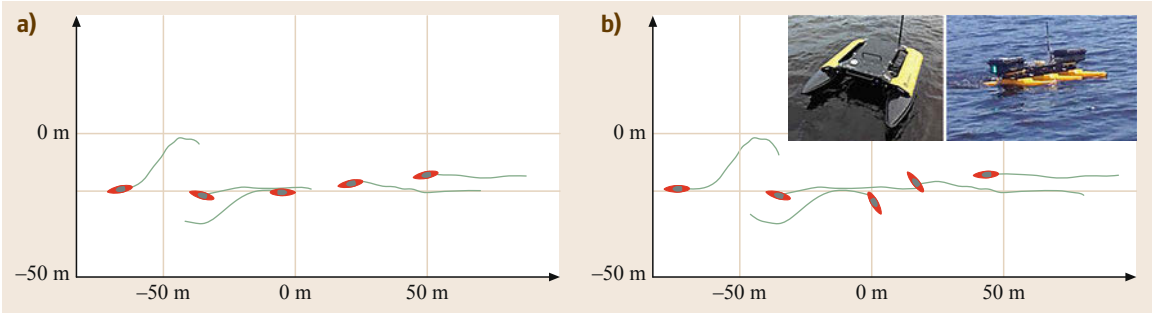

Fig. 23.7a,b Five UMVs demonstrating multiple collision conditions while executing COLREGS compliant MOOS-IvP behaviors (courtesy of Massachusetts Institute of Technology, Laboratory for Autonomous Marine Sensing Systems). Intentional head-on crossing conditions are set up by tasking four vehicles to transit along one trackline and one vehicle to transit in the exact opposite direction. A time series depiction of vessel motion **(a)** to **(b)** shows clearly executed avoidance maneuvers by two vehicles nearest the center of the image, both turning to starboard in accordance with COLREGS requirements

on several 11 meter USVs with on-board sensory capability, with operationally relevant speeds and conditions [23.11].

Benjamin et al. [23.12] have demonstrated the capability of the MOOS-IvP approach to satisfactorily achieve COLREGS compliant vehicle behavior while simultaneously reaching deliberate mission objectives. Using a small fleet of low cost SCOUT (surface craft for oceanographic and unmanned testing) [23.13] autonomous surface craft, *Benjamin* et al. [23.12] at MIT successfully demonstrated safe COLREGS compliant crossing of multiple UMVs in a controlled environment using only on-board sensors or knowledge of other vessels exclusively. A typical in-water demonstration (Fig. 23.6) depicts COLREGS compliant waypoint objective based activity between two vehicles demonstrating safe transit with collision avoidance. The focus of this research was directed at developing a suite of robust and efficient behaviors and as such, the physical hardware for detection of other vessels was substituted with active data sharing among vehicles. All of the SCOUT craft regularly broadcasted their GPS-derived trajectory information on a shared network. Eventually, detected vehicle contact reports would be generated by a fully integrated sensory suite using data fusion engines as developed and demonstrated by *Huntsberger* et al. [23.2–6, 6] and others. Multiple collision situations were generated, providing ample opportunity to focus on improving the robustness of the collision avoidance software.

COLREGS research at MIT has resumed in the last year to include field testing with up to five surface craft ([23.14], Fig. 23.7) with multiple simultaneous inter-vehicle interactions and COLREGS rule instantiations. Ongoing research also includes studying the effects of augmented AIS message structures conveying ownship state and intention, and an on-board acoustic sensing system for localizing other ships using a horn in low-visibility, fog situations. The effect of inter-vehicle voice communication is also being investigated including the automatic recognition of human intentions from manned vessels and the conveyance of intentions of UMVs using computer generated voice over standard radio channels.

As work continues to progress on this front, autonomy will move humans further out of the control loop, thereby requiring a higher degree of reliability in the autonomy system. Each vessel will need to detect all obstacles (moving and stationary) in its surroundings, be acutely aware of any restrictions to maneuvering imposed by physical constraints such as water depth restrictions, channels, obstructions, and so on, and behave in compliance with an established set of governing regulations.

For a glimpse into the likely future of UMV autonomy with superior sensory capability, one need only look at recent demonstrations of unmanned systems operating in real-world air (UAVs such as the Global Hawk and others operating in military theaters) and land (DARPA Grand Challenge and DARPA Urban Challenge) environments.

23.4 Integrating UMVs into Public Water Space

As we follow the evolution of UMV autonomy and the legal landscape associated with acceptance in public water space, observation of the process of the integration of unmanned aerial vehicles (UAV) into public airspace is instructive. The *see and avoid* paradigm in federal aviation regulations is analogous to underlying assumptions and procedures in marine COLREGS. Both are based on perception of the surrounding environment at a human competence level. Establishing autonomous control at acceptable competence levels in airspace will set precedents applicable to operations in waterways. UAV technology is currently more advanced than UMV technology because of the popularity of the R/C industry and because of the early adoption by military users. UAV platforms were able to prove their merit readily by providing operators with an *eye in the sky* and demonstrating the ability to deliver lethal payloads while protecting soldiers from harm. Due to the FAA Modernization and Reform Act [23.15], the FAA is currently working to integrate UAVs into the National Airspace System (NAS) and has developed a roadmap for achieving this objective [23.16]. In addition, the US Department of Defense (DoD) is preparing the Unmanned Systems Integrated Roadmap FY2011-2036 [23.17] so as to lay out a plan for integration of UAVs into the DoD Joint Force Structure and seamless integration of UAVs in the NAS along with other safety, interoperability, and reliability goals.

In the United States, public water space is governed at the local, state, and federal levels, depending on the specific water body and proximity to coastal boundaries. Both domestic and international maritime laws hold varying degrees of governing authority over vessels flagged to a specific country and to commerce carried out in international, territorial, and state waters. There is no single federal agency responsible for setting standards for accepting new types of *vessels* into public waters, as there would be in public air space through the FAA. The US Coast Guard is both an enforcing body and a regulatory agency within the US Department of Homeland Security. As such, certain legal responsibilities are likely to fall on the shoulders of the Coast Guard with regards to managing UMV activity in public waters. It is likely that UMV regulation will evolve in the United States through a comprehensive approach including self-regulation by owners, operators, and designers, along with constraints imposed by COLREGS regulations. Insurance costs and liability exposure will also likely be governing factors in defining legal standards and establishing best practices. No doubt a precedent-setting legal case will eventually be heard and settled, defining the legal liability associated with operating UMVs in public waterways, and the tort liability will most likely fall upon the shoulders of the owners, operators, and programmers of these vehicles.

Presently, there is an active dialog underway regarding the rules regarding operation of UMVs and, in particular, the possible evolution of COLREGS to accommodate unmanned platforms operating in public waters. This discussion involves the US Coast Guard, industry leaders, academia, the AUVSI (Association for Unmanned Vehicle Systems International), and US Navy representatives. All of the parties involved in these discussions are stakeholders to varying degrees, interested in reaching a consensus regarding the best approach to assuring safe and acceptable operation of UMVs in public waters. In particular, at the time of writing, ongoing discussions are being held in open forums with the goal of establishing a complete set of suggested changes to the rules governing UMVs operating in public water space. These changes are being reviewed, discussed, and compiled by the US Department of Homeland Security Navigation Safety Advisory Council (NAVSAC) and then passed on to the Coast Guard representative for final evaluation. From the Coast Guard, these proposed changes are passed on to a set of IMO (International Maritime Organization) member nations for translation, evaluation, and review before final acceptance and incorporation into COLREGS. This process is expected to take between 3 and 3.5 years to complete.

The process involved with revising COLREGS includes a fundamental discussion of the legal status of unmanned systems. In particular, the question of whether or not a UMV will be considered a *vessel* or not, as defined within COLREGS, may bear heavily on the resolution regarding their legal treatment. Most of the COLREGS regulations start out with a description of the term *vessel*, as this remains at the center of the discussion when ascertaining the need for compliance with the rules, as pointed out by *Bederman* [23.18]. A number of articles have been written on the subject of classifying an unmanned (and possibly autonomous) marine vehicle as a *vessel* under maritime law. The very definition of the term *vessel* varies as defined by International Maritime Law and COLREGS and goes undefined in UNCLOS (United Nations Convention on the Law of the Sea) [23.19]. The International Regulations for Avoiding Collisions at Sea (COLREGS) define a vessel as *every description of watercraft, including non-displacement craft and seaplanes, used or capable of being used as a means of transportation on water* [23.20]. Broadly speaking, these definitions do indeed encompass the modern autonomous marine ve-

hicle as a legal *vessel* subject to compliance with the rules of the road. This conclusion is important because it may be the determining factor in establishing admiralty [23.21] jurisdiction in settling any tort liability claims. In American jurisprudence literature [23.22], *vessel* interpretation includes: *For the purpose of determining admiralty jurisdiction, the term vessel has been interpreted liberally and broadly*. (It indicates) *any structure used or capable of being used for transportation on water* [23.23] *and predominantly characterized by movement, rather than fixity or permanence* [23.24]. These interpretations also portend that UMVs will be classified as vessels [23.25–27], demanding compliance to code and equal treatment by other vessels. The legal ramifications for the owners and operators associated with these UMVs will include full liability for damages to other persons and property, as though those same individuals were directly involved in the on-board operation of the UMV. However, allowance is made for vessels that are not fully capable. COLREGS rule 3(g) provides for a vessel which is *restricted in her ability to maneuver* defined as *a vessel which from the nature of her work is restricted in her ability to maneuver as required by these Rules and is therefore unable to keep out of the way of another vessel* [23.28].

Although the initial NAVSAC review held in 2011 reportedly demonstrated some doubt regarding classifying UMVs as *vessels* as defined by COLREGS rule 3(a), they did propose that the US Coast Guard sponsor an amendment to the RAM (restricted in her ability to maneuver) in rule 3(g) to add *a self-propelled vessel while unmanned and operating autonomously*. This proposal suggests that within the NAVSAC review panel there is some level of acceptance that UMVs will be classified as *vessels* within the COLREGS. By logical extension, if accepted as RAM vessels, UMVs will be afforded a *privileged* right over most manned vessels, due to their inherent limitations in keeping out of another vessels' way (in conditions where visibility is not restricted).

From the summary record of the NAVSAC Working Group Report of the May 2011 meeting, the following resolutions provide some insight to the present status of this evolving topic. NAVSAC advised the US Coast Guard to amend COLREGS so as to require vessel automatic identification system (AIS) transponders on all unmanned underwater vehicles, if practicable, suggesting that the overall vessel length be used as the defining characteristic, with 8 m in overall length and 1 m in overall diameter used as the delineation for meeting the AIS and lighting requirements. They also recommended an amendment to rule 23 (both inland and COLREGS), which would require all inconspicuous, partly submerged vessels or objects while unmanned and operating autonomously to exhibit the lights specified in rule 24(g), again suggesting the 8 m length and 1 m diameter minima. For underwater vessels, they recommended amending rule 24(g), both inland and COLREGS, to require that these same vessels exhibit the specified lights at night and by day. Similar suggestions were proposed that affected unmanned surface vessels requiring AIS where practicable, as well as specific lights and day shapes, where practicable. In addition, NAVSAC recommended that rule 3(g), both inland and COLREGS, be modified to include language addressing *self-propelled vessels while unmanned and operating autonomously*. Further, NAVSAC recommended that the lookout requirements in rule 5 be amended to include the term *manned*, thereby relieving unmanned vessels from lookout responsibility. NAVSAC clearly suggested that the US Coast Guard promulgate an interpretive rule under 33 CFR parts 82 and 90 to provide that a vessel being operated remotely is considered to be manned and must comply with the applicable navigation rules and annexes. At present, the NAVSAC Work Group recommendations are being evaluated by industry experts, academia, US Coast Guard representatives, and legal scholars. Should the proposed approach be adopted, a proposal will be carried by the US Coast Guard to IMO for further review and eventual adoption and inclusion into COLREGS. It should be pointed out that while UMV may be relieved of the lookout requirement if the NAVSAC recommendations are accepted by the US Coast Guard and eventually incorporated into the COLREGS, this will not relieve UMV from obligations under COLREGS rule 7 (risk of collision) and rule 2 (responsibility).

23.5 Developing Standards

In parallel to the evolving COLREGS rules as proposed by NAVSAC, the American Society for Testing and Materials (ASTM) established a technical committee (F41) that is responsible for developing standards for UMVS (unmanned maritime vehicle!system) in 2005. This committee includes subcommittees addressing autonomy and control (F41.01), maritime regulations (F41.05), and unmanned surface vehicles (F41.90.01), among others. Presently, the core (F41.01) autonomy and control section is the furthest developed of this set of standards. Through industry, academics, and user group input, the ASTM committees continue to push

the evolution of these guidelines with the objective of establishing common operational and interface standards. These are currently all in a state of ongoing development, but it is likely that the community will eventually come to recognize these as the accepted standards with regards to safe and compliant (COLREGS) operation of UMVs in public water space. The specific subcommittee responsible for the Maritime Regulations (F41.05) originally set out to establish self-regulating COLREGS compliance through these standards. Of late, this subcommittee is reaching out to the NAVSAC Working Group through the AUVSI community and participates in the ongoing dialog with the US Coast Guard, as described previously.

23.6 The Road Ahead

The rules of the road might evolve so as to include a provision for autonomous or unmanned operation in much the same way that there exists a provision for fishing vessels, vessels restricted in their ability to maneuver, draft restrictions, and so on. Provided with a legal designation as such, autonomous marine vehicles could then be afforded a safe operations entitlement, lifting the burden of full COLREGS compliance and designated via a unique AIS code, day shape, etc. This might be provided in the form of a proximity buffer (consider the high-occupancy vehicle (HOV) lane on highways, for example) to be observed by other vessels, or simply as an authorization to relax the vigilant lookout requirement. This would be a step in the direction of integrating UMVs into the world of human-operated vessels in public waterways.

Alternately, UMV developers might produce a *backseat driver* as an interim solution. This embedded autonomy device would employ all of the sensor fusion techniques previously mentioned and deliver driving guidance to a human operator, who would retain manual control of the helm and take full legal responsibility for the safe operation of the vessel. This backseat driver would provide a service to skilled marine operators, acting as a lookout and navigator, sounding alarms when collisions appear imminent and advising maneuvering decisions based on optimal travel paths in compliance with COLREGS. This scenario describes a glorified autopilot capability with enhanced perception capabilities and advanced behavior capability tuned for balancing multiple objectives.

No doubt scientists, engineers, and policy makers will continue to upgrade and refine the capabilities and the requirements placed upon unmanned vehicles that operate in public water space. Using advanced sensors and autonomous control, maritime robots may someday evolve into machines with super-human-like behavior that perform better than humans in noisy stressful environments where flawed perception and emotional irrationality erode the performance of mortals. When that happens, the rules of the road may need to be modified so as to designate manned vessels as those restricted in their ability to maneuver, requiring them to maintain a buffer zone for safe operation in the proximity of the more predictable and reliable unmanned vessels. The road ahead may indeed see the tables turned.

23.7 Conclusion

Improved system performance suggests that UMVs are here to stay and will be providing a wide array of valuable services in the marine environment for years to come. Along with the benefits afforded by these platforms, we should expect increasing interaction between manned and unmanned vessels and a need for clearly defined laws, policies, and procedures for safe and reliable operation of UMVs in public waterways.

In a semi-hybrid fashion, robotic autopilot *assistance* is creeping into how we operate aircraft, automobiles, and boats today. In cars, we now have braking assistance that prevents collision and steering assistance that maintains the vehicle track on the roadway and aids in parking. In aircraft and boats, we have autopilots that can follow prescribed waypoints to safely transit a craft over great distances. Autopilots coupled with obstacle avoidance need only an embedded autonomy engine with COLREGS compliant behaviors and a human helmsman will become a passive observer, albeit the legally responsible observer, but an observer and passenger, nonetheless. The rapid evolution of the technology and the legal framework associated with acceptance of unmanned cars and unmanned aerial vehicles provide precedents for the likely trajectory for unmanned marine vehicles.

It is conceivable that at some point in the near future, two unmanned marine vehicles will encounter one another in a potential collision situation. Or perhaps,

one manned vessel, operating under partial autonomy (autopilot) will encounter an unmanned vessel, both similarly programmed to avoid collision. One can imagine several outcomes to this encounter, including those involving a collision and eventual legal engagement. As with most technological evolutions, the rapidly changing technical and legal landscape will dictate the final regulatory environment that all vessels will operate within. In this world of convergence between manned and unmanned platforms, it is entirely possible that future vessel operators will become passive observers as robotic helms carefully maneuver all manner of water craft in safe and predictable fashion while obeying all of the established and accepted *rules of the road*.

24. Autonomy: Risk Assessment

Mario P. Brito, Gwyn Griffiths

Oceanography and ocean observation in general are ever trending toward both automated in situ observation and working in extreme environments. These goals can only be met by de-risking the technology and deployment practices to acceptable levels of risks. A number of industries have standardized risk management processes to support the design and development of their systems. The lack of formal risk assessment of autonomous ocean vehicles has hindered the potential for true autonomy, which is required for exploring unstructured and unexplored environments. When discussing risks, different stakeholders may have different consequences foremost in mind. For example, the vehicle owner may be interested in risk of loss, whereas the user is interested in risk of vehicle unavailability. Other risks, such as legal risks and risk of collision, affect all stakeholders. This chapter presents a risk management process using several methods tailored to autonomous ocean vehicles in which risk assessment is a key component.

24.1 **Risk Management Process for Autonomous Ocean Vehicles** 528
24.2 **Risk of Failure** 529
24.2.1 Reliability Estimation 529
24.2.2 Reliability Modelling 530
24.3 **Risk of Collision** 532

Our human curiosity to understand unexplored and hostile environments has led us to develop state of the art automated technology capable of meeting our measurement needs [24.1–3]. Despite having identified the requirements for greater autonomous ocean vehicles (AOV) intelligence and autonomy, to date, physics prohibits the deployment of the truly intelligent autonomous underwater vehicle (AUV) [24.4]. Over the years, for practical implementations, the community has addressed risk by making the vehicles as simple as possible, the missions as modest as possible, and the level of supervision as high as possible [24.4–6].

Nevertheless, over the years there have been a number of vehicle losses. Among the most high-profile losses are the loss of Autosub2 under the Fimbulisen ice-shelf, Antarctica on 16 February 2005, during mission 383 [24.7] and more recently the loss of the Autonomous Benthic Explorer (ABE), during dive 222, off the coast of Chile, on 5 March 2010. Both losses are thought to have been caused by technical failure. In the case of Autosub2, a formal independent inquiry concluded that an *abort command* or a *loss of power* were equally likely to have caused the vehicle loss. There was no formal independent inquiry into the loss of ABE; following the accident, the design and operation team concluded that ABE suffered a catastrophic implosion of a glass sphere used for providing buoyancy causing instant destruction of on-board systems [24.8]. Anecdotal evidence exists of losses of smaller vehicles such as of Remus 100s and undersea gliders but these have never been formally reported.

Prior to the work presented in this chapter, the risk of AOV loss may have been estimated by the principal engineer during design and deployment. From anecdotal evidence this was often pursued on an informal basis. Such an unstructured approach is rarely, if ever, found entirely satisfying to all parties. Neither is it likely to be immune to criticism, from one side or another. Estimating the likelihood of loss depends on a number of factors such as the vehicle's intrinsic reli-

ability, the effects of the operational environment, the quality of the maintenance program, and the experience and competence of the deployment team. Assessing this risk requires a formal process that, in addition to providing a quantitative assessment, is transparent and able to be followed and replicated by others.

In 2007, *Griffiths* and *Trembanis* [24.9] introduced a risk management process tailored to the operation of AUV. The approach was initially used for managing AUV risk of loss [24.10]. Different stakeholders have different interests in risk, for example, the AUVs owner is interested in the safe recovery of the vehicle, whereas a scientist is mostly interested in the recovery of data or in the vehicles' availability at a given time. The process for AUV risk management can be applied for managing other risks, not only the risk of loss. In this chapter, we present a risk management process tailored to AOVs. Different methods for assessing different risks are discussed in detail.

Most examples are given for propeller-based AUVs but these are equally applied to vehicles using buoyancy change engines, typically denoted as gliders. We also look at aspects of AUV design and deployment affecting risk.

24.1 Risk Management Process for Autonomous Ocean Vehicles

While aspects of reliability had featured within papers on the use of AOVs, reliability had been the topic of very few specific studies until the mid-2000. The provocative, anecdotal evidence in [24.11] gave rise to discussions within the community of users on how to improve reliability and reduce risk at a time when vehicle operations were just starting to be independent of deploying vessels. Spurred by these considerations, and especially by future requirements to operate under ice, *Griffiths* et al. showed that simple statistical methods could be applied to estimate risk of loss of autonomous vehicles operating in various environments [24.12]. Subsequently, *Podder* et al. extended this approach to look at reliability growth [24.13], which is the main desired outcome. However, these studies looked only at revealed reliability, documenting what problems were emerging; they were not set within a framework for risk management.

The loss of the Autosub2 vehicle under the Fimbulisen in 2005, and the recommendations of a subsequent board of inquiry led to the development of a holistic risk management process for AUVs (Fig. 24.1) [24.9]. By simple extension of differently described operating environments, it is applicable to the wider class of AOVs. This remains the only published structured procedure for risk management of these vehicles.

Taking the steps in sequence, first a responsible owner is identified and they state an acceptable probability of loss for the campaign under consideration. The owner may factor in the importance of the vehicle's mission, the value of the data it would return, the future program for the vehicle, and other considerations, into the acceptable probability of loss. Independently, the principal investigator, or user, sets out the requirements of the campaign in terms of number of missions, their duration, and the environment characteristics, such as surface or subsurface, coastal, open ocean, under ice, or in areas of high traffic. The next step is for the technical team to assess the probability of loss in light of the campaign just described. This is a difficult step, and much of the remainder of this chapter is given over to methods used to make this estimate.

Accepting for now that this estimate can be made, it is then compared with the responsible owner's acceptable risk. If the estimated risk of loss is less than the owner is willing to accept, there is a need to demonstrate that the estimated risk is realistic before the campaign can proceed. This demonstration could take the form of reliability trials, where the vehicle would be run in a benign environment over a duration or range commensurate with the planned missions and the outcomes evaluated. If the estimated risk of loss is greater than the owner's acceptable risk, several feedback paths are followed.

The first activity is to rank the risk factors identified by the analysis of fault history, or fault projections. Those that can be mitigated, without question, are dealt with. This demands that the causes of failure are fully understood and the corrective measures are known, able to be implemented, and tested, before the campaign. Belief in ability to mitigate faults, or assertion alone, is not sufficient.

In parallel, the user may reassess the missions required and the responsible owner may reassess the acceptable risk, following which the test for acceptable risk is repeated. Two or more iterations may be needed, or indeed, the decision may be to postpone or cancel the proposed campaign.

Primarily, this process has been used for campaigns with a significant risk of vehicle loss in the Polar Regions. *Brito* et al. described its use for a campaign of six Autosub3 missions under Pine Island Glacier, Antarctica [24.10]. Here, the initial estimated risk was sufficiently high that reliability-proving trials in a Nor-

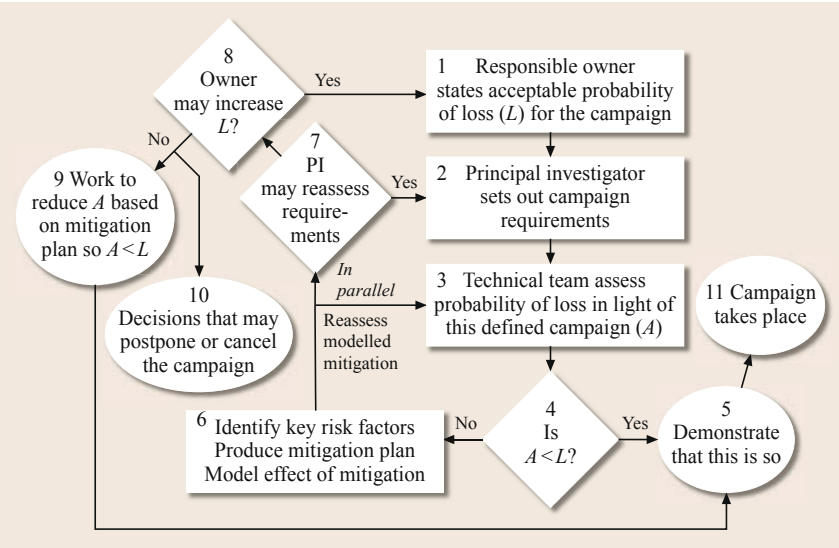

Fig. 24.1 A flowchart representing the risk management process proposed by *Griffiths* and *Trembanis* (after [24.9])

wegian Fiord were an essential precursor. While there were incidents on the Pine Island Glacier missions, the vehicle survived the campaign. More formal estimates of the likelihood of successful fault mitigation were made when the process was applied to an International Submarine Engineering (ISE) Explorer AUV for use in under sea ice missions in the Arctic [24.14]. The process has also been used in high-risk open water areas, such as for Autosub3 missions in the high traffic Bosporus Strait.

In practice, the methods used for quantifying the actual risk are directly linked with the acceptable level of risk. Risk is a measure of uncertainty. If the acceptable risk is high, for example, if the acceptable risk of AOV loss is 90%, there is little reward in applying formal methods for quantifying the actual risk. This is the case for platforms that are considered expandable, which may be deployed to study very rare events, such as a hurricane or the eruption of an underwater volcano. If the acceptable risk of AOV loss is low, then it becomes important to quantify the actual risk. This will give the user more confidence that the acceptable risk is met. This is the case where the platform is financed for long-term use.

24.2 Risk of Failure

The discipline of estimating a system's probability of failure or a system's reliability is well understood in many engineering fields. Reliability is defined as the probability that failure will not occur in the period of interest [24.15]. This probability figure can be estimated from system or component usage. However, in some applications it is not possible to obtain system or component failure history, particularly if the operating environment cannot be recreated in the laboratory or if a new system or component is being used. In such situations, reliability estimates can be obtained from expert subjective judgment – this is discussed in detail in Sect. 24.5.1.

Probabilistic modeling is key for the effective reliability estimation of a system composed of several components or subsystems. To facilitate the development of such models, graphical methods such as fault tree analysis can be applied. In this section, we present a summary of the techniques used for estimating AUV reliability. In Sect. 24.2.1, we present methods for estimating the reliability and reliability growth from operational data. In Sect. 24.2.2, we present how fault trees can be used for estimating the reliability of a complex system comprised of many other components.

24.2.1 Reliability Estimation

The number of failures that emerge during a vehicle, system, or component test can be used to estimate the mean time to failure for the vehicle. However, the mean time to failure alone is not sufficient to support decision-making with regard to AUV deployment. By fitting parametric models of reliability to AUV fault data it is possible to produce formulae that can be used to predict the probability of success of any mission in terms of its length. A number of distributions have been used for

modeling AUV failure distribution with time. The first study on AUV reliability estimation was conducted by *Griffiths* et al. [24.16]. Failures of Autosub1 AUV were collected from its first mission within Empress Dock, in Southampton in June 1996, to a science campaign on board the RV *Calanus* at Oban in November 1999. During this time, the vehicle conducted 216 missions covering 2125 km. Fifty failures were recorded, giving a probability of failure per mission of 0.231. Pareto analysis showed that human error, acoustic telemetry failure, and failure to dive were the top three failure modes in Autosub1's failure history. This report used statistical models for predicting the failure probability as function of mission length. The dataset used for this analysis consisted of the distance traveled for each mission and whether the mission ended due to a fault. Each entry was classed as censored or not censored. A censored observation is one where the mission was terminated not due to failure, whereas a noncensored data captures the distance at which a failure took place. Two types of functions were defined directly from the data [24.12]. The first function, the probability of failure $F(x)$, where x stands for an instantiation of distance X. In mathematical terms, this is captured by $F(x) = P(X < x)$, where $P(X < x)$ is obtained directly from the probability function that is fitted to the historic data and lower case x is an instantiation of X. The second function of interest is the reliability, otherwise known as survival function, is the probability of survival, $R(x)$. The reliability is the complement of the probability of failure, it is mathematically defined as $R(x) = 1 - F(x) = 1 - P(X < x)$. It stands for the probability of the system surviving without failure, the distance x.

Griffiths et al. fitted three well-known distributions to the historic data: *Weibull*, *log logistic*, and *log normal*. Results showed that the probability of a fault occurring in a 100 km mission was 0.352 using the *Weibull*, 0.334 for the *log logistic*, and 0.309 for the *log normal*. Software reliability was studied separately using two independent software reliability models: the Poisson model and the Littlewood model. Both models lead to the same reliability estimate for a 100 km mission of 0.93 for the software.

The dataset was later updated to include Autosub2 science missions on MV *Terschelling* at three sites on the west coast of Scotland in March and April 2000, equipment trials at Plymouth and a science campaign in the Strait of Sicily in June 2000. A total of 869 km were covered in 24 missions [24.12]. Here the authors fitted six different distributions to the data: extreme value, normal, logistic, and their logarithmic versions: Weibull, log normal, and log logistic. The logarithmic distributions provided a better fit to the data than their linear counterparts. The Weibull distribution showed the highest failure rate, and, to err on the conservative, was chosen as the preferred parametric model. Results were similar to those previously reported.

The first reported work on the effects of upgrades on the reliability growth for AUVs was presented in 2003 [24.17]. The dataset consisted of Autosub missions considered in [24.12] plus missions that were conducted in two engineering trials in June 2002 and September/October 2002. The purpose of these trials was to test new software that gave enhanced autonomy. The results of the analysis showed reliability growth prior to the missions carried out in June 2002. However, after the upgrades there was an increasing failure rate. These were worrying results because the vehicle was due for an under ice campaign in February–March 2003. The team used the reliability model to estimate the number of missions, with an acceptable number of faults, needed to ensure reliability growth. The analysis concluded that 10 missions were required with distances varying from 5 to 144 km in length, with only two high-impact faults allowed on the shorter missions.

A study in reliability growth was carried out for the Dorado AUV designed and operated by Monterey Bay Aquarium Research Institute (MBARI) in preparation for an Arctic campaign in the following summer [24.13]. The dataset consisted of mission data collected during operations in 2003 and 2004, where the vehicle had traveled approximately 1700 km in Monterey Bay, California. Several failures emerged; the analysis considered only failures that resulted in an abort – a total of 14. Basic trend analysis using the Laplace test yielded the conclusion that the AUV reliability exhibited an increasing trend. This was verified using two independent reliability growth models due to Duane and Crow. Both use graphical approaches to support reliability growth analysis. The estimation of the mean time between failures (MTBF) was conducted for different groups of failures; set according to their criticality. The estimated MTBF for the extremely critical faults was 167.8 h.

Reliability estimation based on revealed operational history helps those involved understand better the failure pattern of these autonomous vehicles, enabling the implementation of failure mitigation mechanisms during the operational lifetime of the AUV. However, for early lifetime, this failure history is not available. For the early lifetime of a vehicle, the reliability of a vehicle can be estimated using reliability modeling techniques. These are discussed in the next sections.

24.2.2 Reliability Modelling

Reliability modeling aims to estimate system's reliability based on its intended functionality, and design

architecture. The failure model end effect analysis (FMEA) is a well-established technique for identifying critical components or phases of the system design and operation [24.18]. However, this technique does not accommodate quantitative estimation of the system's reliability and therefore it will not be discussed in this chapter. Event trees and fault trees are two basic methods for system reliability quantification. Event trees use forward logic. They begin with an initiating event (an abnormal incident) and *propagate* this event through the system under study by considering all possible ways in which it can affect the behavior of the subsystems. Event trees are useful for accident sequence analysis in which the aim is to estimate the likelihood of a sequence of potential functioning or malfunctioning events. Thus event trees cannot be used for estimating the probability of failure of a system. This figure can be estimated with the support of fault trees. In a fault tree analysis, one attempts to develop a deterministic description of the occurrence of an event, the top event, in terms of the probability of occurrence of other (intermediate) events. Intermediate events are also described further until, at the finest level of detail, the basic events are reached. When the top event is failure of a system then the basic events are usually failures of components. A fault tree can be considered as an expression in a Boolean model, which implements predicate logic. A fault tree contains the same operators, for example, conjunctions and disjunctions. However, instead of operating with bits, where 0 corresponds to false and 1 corresponds to true, fault trees operates with probabilities – varying from 0 to 1 [24.20]. Figure 24.2 presents a fault tree devised by *Griffiths* and *Brito* for estimating the probability of failure during the deployment of an AUV through an ice hole [24.19]. Graphically a conjunction is represented using AND and a disjunction is represented using an OR gate. In Fig. 24.2, the operators named G_1, G_2, G_3, and G_4 are OR gates. The G_5 operator is an AND gate. A fault tree injects transparency into the fault analysis process. Failure modes are clearly presented and how they propagate in the system is visually displayed.

There is a unique probabilistic model associated with each fault tree, which enable us to calculate the probability of failure for the top event. The probability of failure to launch, $P10$, is calculated using the following expression:

$$\begin{aligned} P10 &= G_1 \\ &= 1-(1-G_2)\times(1-P3)\times(1-P4) \\ &\quad \times(1-G_3) \\ &= 1-((1-P1)\times(1-P2)) \\ &\quad \times(1-P3)\times(1-P4) \\ &\quad \times(1-(1-(1-G_4)\times(1-G_5)))\,. \end{aligned} \tag{24.1}$$

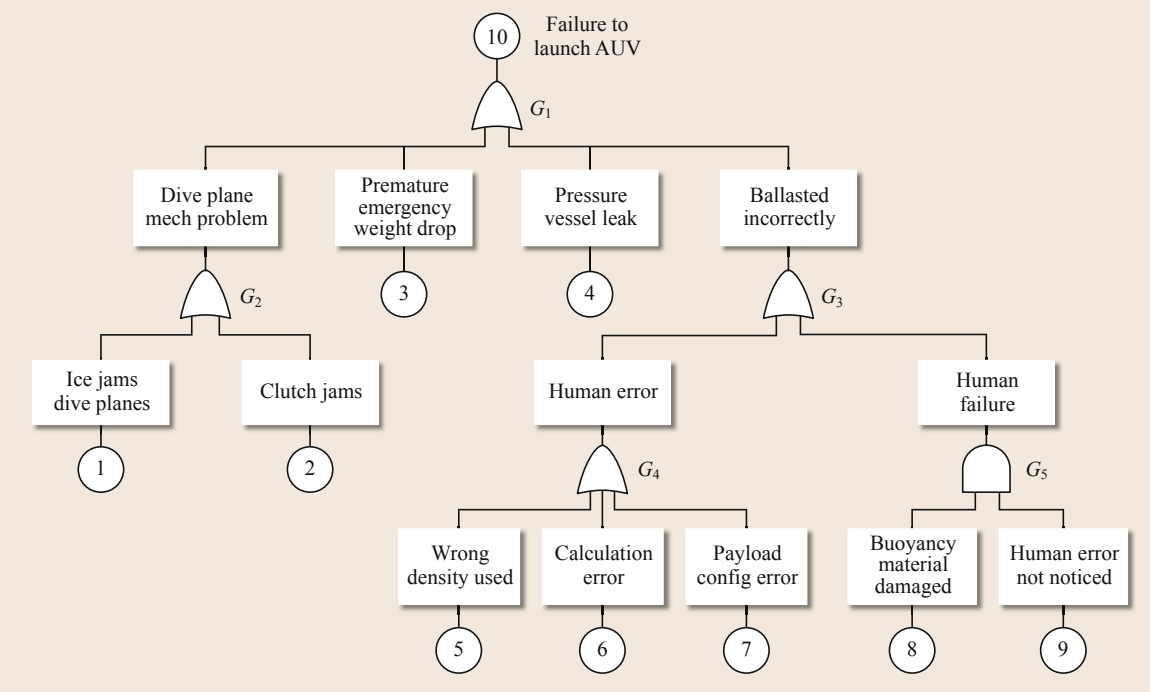

Fig. 24.2 Probability of failure during AUV deployment through an ice hole. Fault tree presented in [24.19]

and

$$G_4 = 1 - (1 - P5) \times (1 - P6) \times (1 - P7) \,, \quad (24.2)$$

$$G_5 = 1 - (1 - P8) \times (1 - P9) \,. \quad (24.3)$$

The probability of failure for each basic event can be estimated using statistical modeling discussed in the previous subsection in which a probability function is fitted to observed data. Alternatively, if operational data is nonexistent, the probability of failure for the base events can be estimated using expert subjective judgment. In Sect. 24.5, we provide more details on the formal methods that can be used to elicit expert judgment.

24.3 Risk of Collision

The risks of collision for AUVs are very real. However, as unregulated vehicles, no figures for the number of losses due to collisions can be given; there is no requirement to record losses for these unmanned vehicles. Through anecdote, the incidence of collision for underwater or surface vehicles is sufficiently high that any group operating several vehicles is likely to encounter this risk regularly. Sensitivity of many operators to the details of collisions also means that quantitative, or attributable, information is rare. The examples given here are based on our knowledge of real incidents.

24.3.1 Risks of Collision on or Near the Surface

For surface vehicles, and when underwater vehicles operate on or near the surface, the main collision risks are:

- *The shore, or water shallower than the minimum operating depth of the vehicle*: At least one autonomous vehicle has run ashore because parts of the chart from which waypoints were taken were surveyed in the 19th century, and the position error for the shoreline was substantial. Operating near a coast with very gentle beach gradients without full knowledge of, and accounting for, the tides can give rise to grounding.
- *Manned surface craft*: Collision with manned surface craft has probably been responsible for many autonomous vehicle losses. In some cases, the manned craft concerned has been the craft deploying the autonomous vehicle. Mistakes and miscommunication during launch and recovery, especially, can lead to collision with the support vessel. Collision with the sides of the vessel may inflict little damage, but collision with propellers has on more than one occasion led to damage to the pressure vessels of underwater vehicles and immediate loss.
  Where statistics of vessel traffic are available, probabilistic models may be used to assist in estimating the risk of collision. *Merckelbach* has developed such a model, specifically for undersea gliders [24.21]. In principle, his approach is applicable to other autonomous vehicles. The model considers the vessel and vehicle speeds, the vessel traffic density, the statistics of vessel length, draft and breadth, the water depth, the operating parameters of the vehicle, for example, time on surface and within the draft of vessels, and a bow-wave factor. This last factor accounts for the pushing aside that can happen as collision is imminent; in effect the effective breadth of the ship is reduced by this factor.
  Mission planning to take account of surface vessels can make use of the automatic identification system required on *internationally voyaging ships* of 300 tonnes or more, all passenger ships, and, from 2014, the entire European Union (EU) fishing fleet of vessels over 15 m in length. Websites with real-time maps enable planning ahead, and also near-real time collision avoidance.
  For very intensive shipping areas, for example, Bosporus Strait with typically six large ships per hour, autonomous vehicles should avoid the surface.
- *Large flotsam and jetsam, such as logs and baulks of timber, lost freight containers*: These hazards are less amenable to quantifiable modeling than ship traffic. Local knowledge is likely to be important, for example, on the known areas where felled trees from boreal forests may be prevalent.
- *Floating nets and fisheries-related hazards*: Despite being banned by international agreement since 1992 in international waters, drift nets with surface floats that are meant to catch pelagic fish are still in use within the exclusive economic zones of many countries, for example, the USA. Other nations stipulate maximum lengths (2.5 km for the EU). These nets are a hazard for AOVs on the surface. Local knowledge may suggest where such fishing happens. Avoidance using telepresence from the vehicle to the command center of video or radar imagery may assist in spotting the surface floats.
- *Offshore structures, for example, oil and gas installations, wind farms*: The positions of these surface

hazards are usually well known, and fixed. The onus is on the autonomous vehicle operator to plan missions with sufficient contingency and allowance for navigational error such that a vehicle does not infringe the exclusion zones around these structures.
- *Coastal structures such as breakwaters, or moles*: While there may be no exclusion zones around these hazards, their positions are fixed, and appropriate prior planning should be adequate to mitigate the risks.

24.3.2 Risks of Collision Underwater

Apart from the universal case of collision with the seabed, the other risks of collision when underwater depend on the environment of the missions. Near-shore missions may encounter obstacles such as piers and other fixed structures, vessels at anchor, and the submerged parts of vessels underway. In the open ocean, apart from with the seabed, collision when submerged is likely to be a rare event. Under ice, collision is likely with ice at the sea surface, with projecting keels of sea ice, and with icebergs. While grounded icebergs, ice shelves and glaciers and sea ice that is locked to the shore or a shoal may be stationary, other forms of ice should be considered as moving obstacles.

Collision, or obstacle, avoidance for AUVs is a well-studied topic, combining as it does the challenges of sensing, interpretation, and action. The effectiveness of obstacle avoidance is one indicator of the degree of autonomy of a vehicle. *Horner* et al. [24.22] summarized these challenges, and provided examples of how a forward-look sonar array can be integrated with an autopilot control algorithm that minimizes the cross-track error from the desired path. That is, the system provides for adequate, but minimum, deviation from the desired path to avoid the obstacle. The interpretation of the obstacle characteristics in this implementation uses image information from the sonar array, borrows techniques from computer vision, and can be made robust against false targets. This approach is relevant for avoiding the seabed, but is also sufficiently powerful to provide obstacle avoidance in more complex situations, such as near piers and other man-made structures.

There are situations where a simpler approach may give sufficient capability, for example, where the seabed is the only obstacle likely to be encountered. Using a single beam mechanically scanned sonar and a horizon-tracking algorithm, *McPhail* et al. [24.23] showed that effective seabed avoidance could be delivered when terrain following at altitudes down to 10 m on the flanks of a seamount, and down to 3 m on the flatter, but rocky, summit. Vehicle reactions included simple avoidance in the vertical plane, and turn-around and retry.

Under ice, information is needed on obstacles ahead, below, and above the vehicle. One approach, devised for the DEPTHX (deep phreatic thermal explorer) vehicle [24.24] proposed a suite of 24 narrow beam sonars and 30 imaging sonars. In the subsequent Endurance vehicle, 64 pencil beam sonars provided a 3.5 steradian view of the environment within ice-covered Lake Bonney in Antarctica. A far simpler approach is to use for obstacle avoidance purposes, sonar information from other instruments on the vehicle. *Pebody* has described how, for an under ice application, a forward-looking sonar may be augmented using range to reflector information from the four beams of an upward-looking and a downward-looking acoustic Doppler velocity log [24.25]. This system was tested using an air curtain behind a ship, to simulate an iceberg, and used under fast ice off Greenland, and under Fimbulisen and Pine Island Glacier in Antarctica to good effect.

As a backup to collision avoidance, some operators include rubber fenders or other protection on the nose and undersides of their vehicles. Incidents where collision avoidance has failed include repercussions of hardware failures and failures of the control systems to properly appreciate the form of the environment and hence failure to take proper action. Drawing on examples with Autosub AUVs, a sternplane fault led to the vehicle diving far too steeply, such that its bottom avoidance sonar was at the incorrect angle, the sonar could not see the seabed, the vehicle nose collided with the seabed but the vehicle continued to make slow forward progress until the nose became full of sediment. For an example of inappropriate response to an unexpected environment, when terrain following at low altitude up a steep cliff off Sicily, Autosub2 encountered an overhang. The appropriate response would have been to reverse out, but this behavior was not preprogrammed, and instead the vehicle dropped its abort weight and had to be retrieved using an remotely operated vehicle. These lessons also serve to show that not all collisions are fatal to a vehicle.

24.4 Risk of Unavailability

System availability is defined as the probability of the system being available given that the system is needed at a given time. System unavailability is the complement of this figure. The deployment of an AUV consists of several phases. A series of tasks are carried out in each phase of the deployment. These human- or machine-related tasks are not immune to error. Estimating the availability for the AUV being at a given phase is only possible if we take into account the sequence of phases that precede that phase. This problem can be mathematically modeled using a probability approach denoted as Markov theory.

For a brief description of Markov theory, consider a probability problem with a set of outcomes of interest $E_1, E_2, \ldots, E_k$. Given that there is a probability p_j associated with each event the joint probability for a given sequence is defined by the multiplicative property, thus $P(E_1, E_2, \ldots, E_k) = p_1 p_2 \ldots p_k$. The Markov chain theory introduces an assumption that simplifies this expression; it considers that the outcome of any trial depends on the outcome of the preceding trial and only on it [24.26]. Therefore, if event E_1 precedes event E_2 and event E_2 precedes event E_3 and so on for the remaining events, then instead of associating a probability to an event E_j, it uses a transition probability p_{jk} for every pair of events (E_j, E_k), where p_{jk} is the probability of E_k occurring given that E_{k-1} occurred in the previous trial. A Markov model may have more than one sequence of events; E_j may have two or more posterior states. Therefore j and k are not necessarily adjacent. In addition to p_{jk}, one must also define the probability of E_j occurring at the initial trial, a_{j0}. Therefore for the initial trial, $P(E_j, E_k) = a_{j0} \times p_{jk}$. For the general case, considering a sequence of several transitions, given that event E_{j0} precedes E_{j1} which precedes E_{j2} and so on for the remaining events, the joint probability distribution is computed using the expression in (24.4)

$$P_r(E_{j0}, E_{j1}, \ldots, E_{jn}) = a_{j0} p_{j0j1} p_{j1j2} \ldots p_{jn-2jn-1} P_{jn-1jn} \,. \tag{24.4}$$

It is not unusual to find problems where one state has more than one potential preceding state. When this is the case, the mathematical calculation cannot be performed using the simple equation presented above. Instead the calculation is performed using matrix operations. The transition probabilities are arranged in a matrix denoted as transition matrix or stochastic matrix. The transition probability together with the initial state vector completely defines the Markov chain. The availability after n transitions can be calculated by the product between the transition matrix to the power of n and the initial state vector.

Brito and *Griffiths* [24.27] used Markov chains for modeling and estimating the availability of Autosub3. The Autosub3 deployment sequence was modeled as a Markov chain in which each state corresponds to one phase of the vehicle deployment. A key assumption in the proposed model is that the Autosub is deployed from a stationary vessel. The model can be altered to capture the case where the AUV is deployed from an ice hole or from the coast. This would consist of adding a state for which the transition probabilities would depend on the failure modes that can emerge in the different type of deployment. *Griffiths* and *Brito* in [24.19] give an example of when the approach was adopted for deployments from ice holes.

Here we briefly describe the model proposed in [24.27] for estimating AUV availability based on surface vessel deployments. The Markov chain model for AUV availability consists of 11 phases, these states and the transitions are presented in Fig. 24.3. The first state captures the phase when the vehicle is on board of the vessel, switched on, ready for testing (*Dp*). A series of communication, actuation, and navigation checks are carried out during this phase. Having passed the onboard checks, the deployment moves to vehicle ready for deployment phase (*Dr*). Here the vehicle is waiting to be deployed overboard. While overboard there is the risk that the vehicle may run under the vessel causing severe damage, in which case the vehicle may need to be salvaged. This scenario is captured by the transition from phase overboard (*O*) to salvage (*S*). Once overboard and at a safe distance, communications checks are carried out before the vehicle starts diving. The vehicle is then set to stop diving when it reaches a predefined depth and enters a holding pattern (*Sh*). During this period, the vehicle is still within acoustic range, more checks are carried out before committing to the mission. Once underway (*U*), there are two possible outcomes: the vehicle can be recovered (*R*), or it can be lost (*L*). If historic operational data exist then the probability of AUV loss can be computed using reliability modeling techniques combined with expert judgment – this method is described in the Sect. 24.5. Alternatively, if there is no historic data of AUV operation then the probability of loss can be computed using fault tree modeling that takes into account expert judgment with regard to the consequence of each failure mode.

The AUV can be recovered while it is in the overboard phase, during diving, in holding pattern or underway. The vehicle can also be lost from any of these

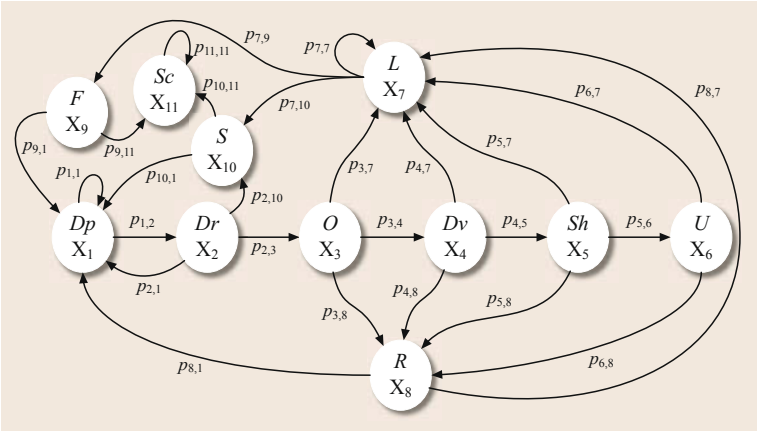

Fig. 24.3 Markov state-space model capturing the sequence of events undertaken during AUV deployment and operation. A directional arrow from state i to state j means that the process can move from state i to state j

Table 24.1 Aggregated expert judgments for the transition probabilities

Transition stimuli	Transition probability	Transition stimuli	Transition probability	Transition stimuli	Transition probability

phases. If a vehicle is lost, the deployment can be maintained in a permanent loss state (L), captured by the transition from $p_{7,7}$ or it can move to a state of Salvage (S) or Found (F). From these states, the AUV can be declared fit for re-deployment, this is captured with the transition from state (S) to (Dp) and (F) to (Dp), or declared scrapped (Sc). A deployment can reach a state of AUV scrapped from overboard (O), dive (Dv), holding pattern (Sh), underway (U), and recovery state (R).

For Autosub3 availability analysis, the transition probabilities were calculated based on expert judgments. Three experts with more than 60 years combined experience on AUVs have estimated the probability for each transition. The transition probabilities are a result of the un-weighted linear pool aggregation of the expert judgments. The transition probabilities for the availability of Autosub3 are in Table 24.1.

The Markov property states that the sum of the probabilities leaving any given state must be equal to unity. If the sum of all transitions leaving a state is constant c, where c is lower than 1, then the probability of the process remaining in the same state in the next transition is $1-c$. The Markov condition was applied to calculate transition probabilities $p_{1,1}$, $p_{6,7}$ and $p_{7,7}$.

The availability of Autosub3 from ready for test, while on deck, to underway was calculated to be 0.75. This estimate is similar to that obtained for unmanned aerial vehicles (UAVs). The United States Office of the Secretary of Defense published the availability figures for five UAVs: Predator RQ-1A (concept demonstrator) (0.40), Predator RQ-1B (early production) (0.93), Pioneer RQ-2A (1990–1991) (0.74), Pioneer RQ-2B (0.78), Hunter RQ-5 (reliability enhanced 1996–2001), (0.98), Average UAV (0.77).

24.5 Risk of Loss

The task of estimating AUV risk of loss is affected by many factors. Technical failure rate and the likelihood of a human error are two important factors in the assessment of AUV risk of loss but these factors alone are not sufficient. A failure has different impact depending on the AUV operational environment. For example, a failure leading to unexpected drop of the abort weight causing the vehicle to surface may have a low impact

in open-water operations; however, if the same failure takes place while the vehicle is under an ice shelf, sea ice, or busy coastal area it may lead to vehicle loss. The human element is also of great importance when it comes to failure mitigation, as highlighted by *Stokey* et al. [24.11], many technical failures in AUV operations can be mitigated by a more experienced team.

These factors are difficult if not impossible to capture deterministically, particularly if the number of previous deployments in the target operational environment is small or if the environment and operational conditions are impossible to predict. Autonomous ocean systems are not unique in this challenge, and many techniques have been developed and widely accepted, for risk quantification in areas such as nuclear, process, oil and gas, and aerospace safety. Common to these approaches is the formal use of expert judgment.

In this section, we present formal expert judgment elicitation methods focusing on their pragmatic characteristics for estimating AOV risk. When studying component or systems reliability, it is not sufficient to have the MTBF, designers and operators are often interested in knowing the component or system reliability as a function of time in operation or mission length. This is imperative for the implementation of corrective measures for risk reduction. Similarly, when operating AOVs the decision to go, or not go, for a mission is better informed by a risk profile that captures the probability of loss with mission time or length. The creation of a probability of loss profile is possible by integrating experts' subjective judgments with statistical survival techniques.

24.5.1 Expert Judgment Elicitation Processes

Governments and companies are increasingly relying on expert panels for providing risk assessments for high-risk or high-profile projects such as the safety assessment of a nuclear power station or the implementation of a major science program [24.28]. There are many dangers in eliciting expert judgments in an informal way. When providing assessments of events, people often follow one of a number of mental shortcuts, denoted as heuristics [24.29, 30]. Research has shown that when used incorrectly, these heuristics can lead to systematic and predictable bias [24.31]. In their work, *Tversky* and *Kahnemann* [24.29] have identified three predominant heuristics: representativeness, availability, and adjustment and anchoring. Representativeness is described as the tendency to judge the probability that A belongs to B by how representative A is to B. For example, if the description of Peter is highly representative of an engineer then people tend to judge the probability of Peter being an engineer as high regardless of the base rate, that is, the proportion of engineers in society. The base rate neglect is one type of bias that can be introduced by following the representativeness heuristics; other types of biases are, for example, insensitivity to sample size, insensitivity to predictability, and misconceptions of chance and regression [24.29]. Availability heuristics is the tendency to judge a particular event by the ease with which the instances and events can be brought to mind. For example, one may estimate the risk of heart attack among middle-aged men by remembering specific personal examples. Here bias can be introduced due to exposure to negative outcomes; they tend to be easier to remember than positive ones. Anchoring and adjustment is a tendency to anchor probability estimates at an initial estimate. Insufficient adjustment results in biases of underestimation or overestimation.

Formal judgment elicitation has been proposed as a solution to reduce biases and facilitate reproducibility of the results [24.32]. A formal expert judgment elicitation is a structured process that consists of a number of phases; a number have been proposed in the literature [24.33]. Below we describe the generic structure of a formal judgment elicitation process tailored to AOVs:

1. *Set out the issues*: In this phase, the issue that is to be addressed is described in general terms. This is a scope definition stage; it defines the nature and direction of the analysis, the choice of questions to be asked and issues to be considered. For example, the issue of interest is to estimate the probability of vehicle loss.
2. *Selecting the experts*: An expert is someone with specialist knowledge in the task in hand who is also capable of decomposing a complex problem into subsidiary problems. In vehicle risk assessment, an expert should be someone with experience in the type of fault scenarios and in AOV operations.
3. *Clearly define the issues*: The issue in hand is what is the probability of failure F leading to loss (L) in operational environment E? This is mathematically represented as $P(L \mid F, E)$.
4. *Training the experts and eliciting judgments*: This is the most important task in the elicitation process. Different formal judgment elicitation processes follow different approaches. For some, training is quite informal it consists of providing some examples of typical assessments and an explanation of basic principles of probability theory. Other judgment elicitation processes are stricter and encourage the facilitator to elicit expert assessments for a number of seed questions. These are questions for which the facilitator knows the answer but the expert is not familiar with the problem or question [24.32], and

where responses can be used to calibrate individual assessments.

5. *Analyzing and aggregating*: This is a critical phase of the assessment. Here the decision maker uses a strategy for combining the expert judgments into a single assessment that represents the group's view. This can be done mathematically or behaviorally. A mathematical aggregation uses analytical functions for combining the expert judgments. The analysis of expert judgments must be conducted prior to the aggregation to ensure that any misunderstandings and bias are removed from the assessments.
6. *Complete analysis and write-up*: The assessments provided by the experts are documented, and disagreements between experts are recorded. A report is submitted to the experts for review. Following this review, a report is submitted to the decision maker informing the results of the risk assessment exercise.

Mathematical Aggregation

The use of mathematical methods for consensus building has the benefit of facilitating the application of the elicitation process because experts are not asked to agree on the final judgment; in fact experts do not have to be in the same room during the elicitation. Supporters of mathematical methods have argued that behavioral methods, in addition to being time-consuming, can lead to systematic biases caused by group polarization [24.34].

The analytical function for combining individual judgments can take into account the level of expertise in the topic and the effectiveness of the calibration. These factors are captured in a weight w_i, where $i = 1, \ldots, n$ or in an a priori distribution judgment. Methods for mathematically aggregating expert judgments were developed based on a set of widely accepted axioms [24.35]. Perhaps the most appealing method for combining expert judgments is the *linear opinion pool* [24.36]. Here the expert judgments are aggregated by taking the weighted average of the assessments provided by the experts. The *linear opinion pool* complies with the property of *consistent marginalization* [24.37]. A different mathematical aggregation method, the *logarithmic opinion pool*, uses a multiplicative averaging of the expert assessments [24.36]. The *logarithmic opinion pool* does not comply with the marginalization principle but unlike the *linear opinion pool* it complies with the *principle of external Bayesianity*. This can be explained as follows: suppose that the decision maker or facilitator has reached an aggregated $p(\theta)$ but has subsequently learned new information relevant to θ. One way to update the judgment $p(\theta)$ in light of the new information is by updating the individual expert judgments $p_i(\theta)$ and then aggregate all judgments using an analytical function. A second way is to update the original $p(\theta)$ without updating the individual expert judgments, using Bayes theory. A mathematical aggregation method that complies with the *principle of Bayesianity* will produce the same result regardless of the process used for creating the final judgment.

Other mathematical aggregation methods are more complete from the axiomatic viewpoint. But this comes at a price of being more difficult to implement. *Bayesian aggregation methods* adopt a completely different prerogative to the *linear and logarithmic pools*. Here, the decision maker begins by defining his own prior distribution $f(\theta)$. The expert judgments are then incorporated, using Bayes' rule, to form the decision maker's *posterior* distribution $f(\theta \mid D)$, where $D = \{f_1(\theta), \ldots, f_n(\theta)\}$ is the set of experts' elicited distributions. In this context, according to Bayes theorem, the $f(\theta \mid D)$ is proportional to $f(\theta)$ multiplied by the likelihood term $f(D \mid \theta)$. The problem with Bayesian methods is that the decision maker must specify his own prior belief about the risk $f(\theta)$ and the knowledge and beliefs about the experts $f(D \mid \theta)$ [24.35].

In 2008, in preparation for the Autosub3 deployment under the Pine Island glacier, a risk model for Autosub3 was developed based on the assessments provided by eight independent experts. Experts were asked to assess the probability of AUV loss given that a fault X emerges during the deployment [24.10]. In addition to providing an estimated probability of loss, experts provided a weight, from 1–5, capturing their confidence in the assessment. A weight of 1 represented little confidence in the assessment, while a weight of 5 meant that the expert was very confident. The experts considered 63 faults, in four environments: open water, coastal water, under sea ice, and under ice shelf. A detailed description of each environment was provided prior to the assessment. The faults were collected during six Autosub3 campaigns from mid 2005 to mid 2008.

Figure 24.4a shows the relative frequency of the average of the weights used by the experts. The figure shows that on average, for 70% of the assessments, experts assigned a weight of 3 or higher, for open water, coastal waters, and ice shelf environments. Experts were least confident with the sea ice environment.

Figure 24.4b shows the un-weighted linear pool probability of loss, for the five most critical failures in the four different environments. This makes it clear that, in these experts' opinion, faults that would have a low probability of leading to loss in open or coastal water would have a high probability of loss under an ice shelf, but not through simple scaling.

Expert judgment has also been applied to estimating the risk of loss of commercial AUVs, including two Remus 100 vehicles in coastal areas and under

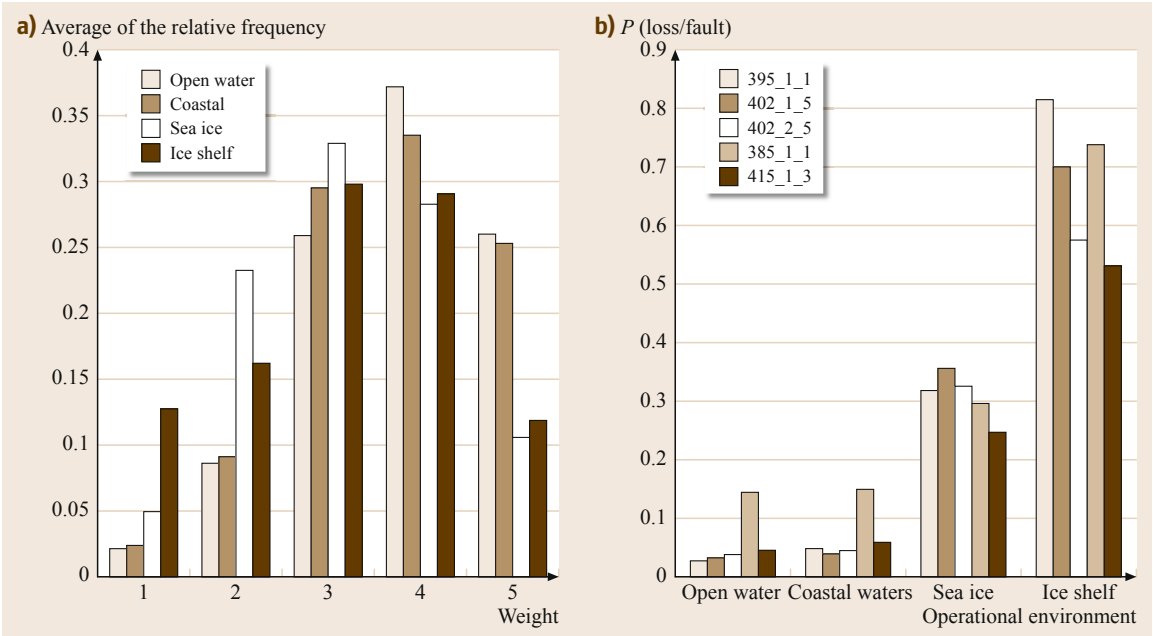

Fig. 24.4 **(a)** Relative frequency of the average weights used by experts Pareto plot of the faults collected for the expert judgment elicitation. **(b)** Un-weighted linear pool, probability of loss, for the five most critical failures

sea ice. These vehicles were operated by the Center for Coastal Marine Sciences at California Polytechnic State University (CalPoly). They were used for a range of missions to better characterize and improve understanding of coastal waters [24.38]. The operational data set contains faults and incidents recorded from 186 missions between July 2001 and February 2009.

For this elicitation experts were asked to specify an unimodal distribution for the probability of loss given a fault. A narrow distribution would show that the expert is confident about the assessment; a widely spread distribution would show that the expert was very uncertain about the assessment. Expert specified this distribution using five quantities:

1. The lower bound, L. The minimum value that P(loss) can take.
2. The upper bound, U. The maximum possible value of P(loss).
3. The median, M. The value for which there is 50% chance of P(loss) being above or below it.
4. The lower quartile, LQ. The value for which there is 25% chance that P(loss) is between L and LQ and 25% chance that it is between LQ and the median, M.
5. The upper quartile, UQ. The value for which the expert is 25% confidence that P(loss) is between the median and UQ and 25% confidence that it is between UQ and the upper bound.

The experts' judgments were aggregated using the un-weighted linear pool, but in two separate groups, the optimists and the pessimists; results are presented in [24.39]. A key conclusion was that these vehicles were being knowingly operated with very low probability of loss vulnerabilities, which, on a statistical basis could become important given the large number of missions undertaken.

The limitation with mathematical aggregation approaches is that experts do not have the opportunity to discuss different views and thus to remove bias from their assessment. The aggregation of expert judgments in two different groups helped solve this potential bias issue. However by doing so, the decision maker needs to decide whether he or she is going to be an optimist or pessimist. One way to mitigate the risk of bias is by having experts in the same room, allowing them to discuss their views before agreeing on a judgment. Such an elicitation method is denoted a behavioral elicitation method.

Behavioral Aggregation

The decision of whether to aggregate expert judgments mathematically or behaviorally ultimately rests with the decision maker. Research has shown that a group consensus will never outperform the assessment of the best expert in the group. The difficulty is in identifying the best expert [24.40]. Behavioral aggregation brings the experts together as a group, provides a structured

process so they can share their knowledge and allow persuasive arguments to change their views, and help them to generate a consensus distribution [24.41]. This approach is often more transparent and more immune to criticism than mathematical aggregation methods.

A behavioral expert judgment elicitation was conducted to build a risk model for two ISE Explorer AUVs, operated by Defence Research Development Canada (DRDC) [24.19]. As these vehicles were to be used on data gathering of national importance in the high Arctic [24.42], a transparent and justifiable process was needed for how the risk of vehicle loss was evaluated; hence a behavioral aggregation approach was taken. Analysis of the outcomes of the discussions central to behavioral aggregation showed that there were seven classes of fault assessments:

- Assessments where the panel reached unanimity that the fault would inevitably lead to loss under ice, which included five faults where experts set all parameters of the distribution to 1.
- Assessments where the panel reached unanimity that the fault would have no impact at all on survivability, such as failure of a component or subsystem that would not be present for the Arctic.
- Assessments for faults where the experts considered that the phase of the mission may affect the consequence. This class of faults, typified by a failure in the vehicle control computer, resulted in vigorous discussion by the experts on the probability of loss, as some experts considered the outcome to be strongly dependent on the phase of the mission during which the fault occurred.
- Assessments of faults where individual experts shared particular insights affecting the aggregated outcome.
- Assessments where there was an agreement that the fault leads to a wide range of probability of loss.
- Assessments of faults that provided insights into instances of where a fault implied a consequential vulnerability.
- Assessments where the panel reached an agreement to use heuristic shortcuts. The group agreed collectively that they would spend little time on those faults that had a very low, but nonzero, consequence for the risk of loss. For these, they agreed on a standard distribution with a lower limit of 0, a median of 6.2×10^{-8}, and an upper limit of 10^{-6}.

A novel aspect of this study was the quantification of the risk mitigation activities. For each fault, experts were asked to assess of the impact of the risk mitigation plan, setting P_M to 0 if they believed that the mitigation strategy would not mitigate the fault and to 1 if the mitigation plan would completely mitigate the fault, with intermediate values reflecting intermediate belief in mitigation effectiveness. When these judgements were plotted in a histogram, three distinct distributions were observed (Fig. 24.5).

One distribution, with a mode at zero, covered faults for which the experts agreed that the cause of the fault was unknown or unproven and thus experts were unconvinced that the proposed mitigation strategy would prove effective. The second distribution, with a sharp mode at 0.5, represented those faults the experts considered that, although the proposed solution was appropriate, the mitigation strategy had not been sufficiently tested or proven in field trials, or where a recurrence of a similar fault could not be ruled out. The third distribution had a mode at over 0.9, indicating a high to very high level of confidence by the experts that the causes of faults were well understood, the solutions known and tested.

The resulting probability of loss given the mitigation is calculated using the following expression $P(L \mid F, E, M) = P(L \mid F, E) \times (1 - P_M)$. Combining the assessments on $P(L \mid F, E)$ with P_M identifies those faults where $P(L \mid F, E)$ is high but P_M is low. These form an important subset of faults for the engineers to address. Most critical was a vehicle control computer configuration problem, where $P(L \mid F, E)$ was 1 and P_M was 0. All other faults where P_M was less than 0.1, $P(L \mid F, E)$ was less than 0.01, consequently, the need for effort into improving the understanding of the mitigation required was far less important. Of the 14 faults where $0.4 <$

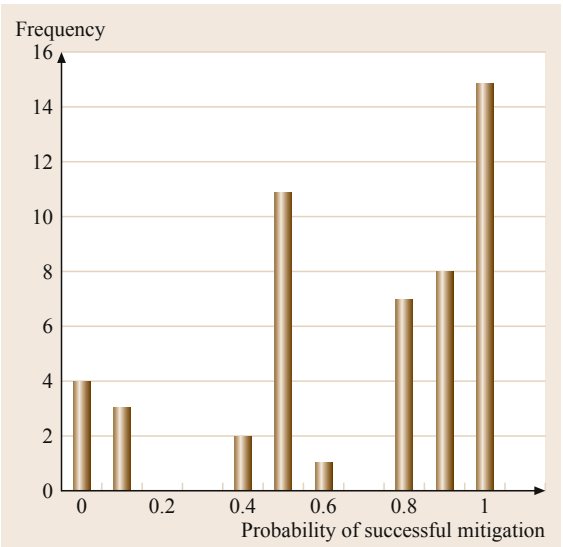

Fig. 24.5 Histogram of the assignments of probability of successful mitigation for the 51 faults, showing three distinct distributions

$P_M < 0.6$, 8 were assessed with $P(L \mid F, E) > 0.5$. This was the most important set of faults for further investigation and improvement in P_M.

24.5.2 Survival Prediction

The risk assessments discussed in the previous section can be used for directing engineers toward where to put more effort in fault mitigation. However, the AUV risk of loss will vary with mission time or length. The decision to deploy an AUV in an extreme environment is better informed by a risk profile that captures the variation of risk with mission distance or time. The creation of such risk profile is possible by integrating the expert judgments of probability of loss with statistical survival models.

Survival modeling is very popular in medical statistics, where the survival function $S(t)$ is defined as the ratio of the number of individuals with survival times $\geq t$ to the total numbers of individuals in the study. These methods have been adopted for modeling reliability of systems and components [24.43].

An adequate and representative dataset is central to the application of statistical survival techniques. Some entries will consist of recorded time of failures; however there may be missions with no failures. When this is the case an entry is denoted as right-censored data.

There are several mathematical models for representing censored data; these are divided into parametric and nonparametric models. Parametric models assume that the failure history follows a particular shape whereas nonparametric models make no assumption with respect to the shape of distribution. In [24.12] the authors used the Weibull parametric model and the Kaplan–Meier nonparametric estimator to model the probability of Autosub2 loss. For this analysis, faults were discriminated between low-impact faults and high-impact faults. Only high-impact faults were considered in the analysis as these were considered to lead to loss in the target operational environment. In their analysis the Kaplan–Meier estimator was used in its usual form [24.12, 44]

$$\hat{S}(r) = \prod_{r_i < r} \frac{n_i - d_i}{n_i} \,. \tag{24.5}$$

The survivor function $S(r)$ is defined as function of range r, where n_i is the number (of missions) at risk immediately prior to range r_i and d_i is the number of high-impact faults (or *deaths*) at range r_i. In the previous section, we have shown that the uncertainty over whether a fault can lead to loss should, and can, be captured through expert subjective judgments. Thus instead of having a number of *deaths* at time i, the statistical estimator must operate with the probability of loss given a fault in a given environment ($P(L \mid F_i, E)$). *Brito* et al. [24.10] derived an extended version of the Kaplan–Meier estimator to account for this uncertainty

$$\hat{S}(r) = \prod_{r_i < r} \left[1 - \frac{1}{n_i} P(L|F_i, E)\right] . \tag{24.6}$$

The expressions for the variance for this estimator were also derived

$$\hat{V}(r) = \frac{1}{\left[\log \hat{S}(r)\right]^2} \sum_{r_i < r} \frac{p_i}{n_i(n_i - p_i)} + \hat{V}_{EEJ_r} + 2\frac{1}{\left[\log \hat{S}(r)\right]^2} \sum_{r_i < r} \frac{p_i}{n_i(n_i - p_i)} \hat{V}_{EEJ_r} \,. \tag{24.7}$$

Where p_i is equal to $P(L \mid F_i, E)$, p_i is used above only to simplify the expression is the variance in the expert judgements.

This estimator was used for calculating the risk of losing Autosub3 under the Pine Island glacier in January–February 2009. Before the campaign, risk estimates based on prior history and the extended Kaplan–Meier approach helped devise a mitigation strategy based on a monitoring distance – reducing the risk to an acceptable level. In addition to a test mission prior to the start of the campaign, each mission beneath the glacier included an initial 5 h in open water where progress could be monitored [24.10]. The logic being that faults

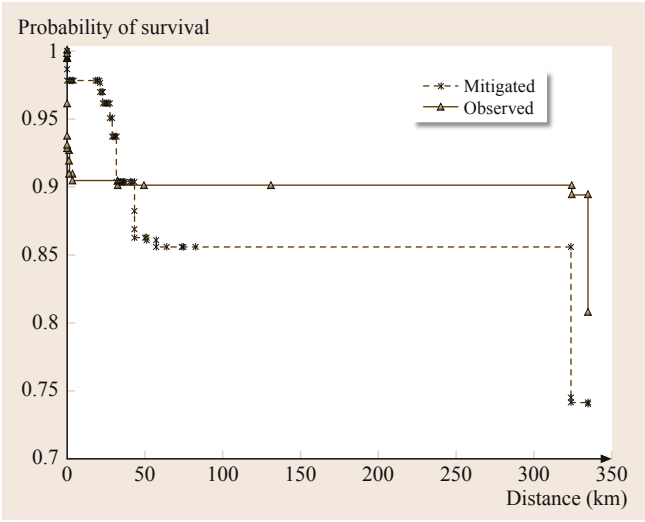

Fig. 24.6 Kaplan–Meier probability of survival against distance for the data set as considered by the experts with the pre-campaign assessment of individual fault mitigation included (*dashed* line). *Solid* line is the observed risk during an ISE Explorer Arctic campaign

emerging during this time could be discovered while the vehicle was in open water, and recovery effected. The appropriate monitoring period is determined from the initial reduction in probability of survival in the Kaplan–Meier plot (Fig. 24.6).

More recently, the same approach was used for estimating the probability of losing an ISE Explorer vehicle in the Arctic. The risk profile for the ISE Explorer under sea ice is presented in Fig. 24.6. Post-campaign a risk assessment exercise was carried out to calculate the observed risk. This profile is presented in full line in Fig. 24.6. Results show that following the mitigation, the maximum error between the predicted risk and the observed risk was 9% [24.14].

24.6 Legal Risks

The international rules for the law of the sea, as embedded in conventions such as the UN Convention on the Law of the Sea (UNCLOS) and the Convention on the International Regulations for Preventing Collisions at Sea (COLREGS) are clear with regard to the obligations of *ships* or *vessels*. These legal instruments were written and agreed before the use of AOVs became widespread in the academic, military and commercial arenas. It is not surprising therefore that it is not clear at all whether, in law, AOVs are indeed *ships* or *vessels*. The situation is further muddied by the possibility for a vehicle to be a *ship* for the purposes of one law, while not being a *ship* for another law. Consequently, the question, *Is an autonomous ocean vehicle a ship*? needs to be asked for each international Convention or national law. Only after the question has been answered each time can the legal issues, and the legal risks, within the scope of that Convention or law be fully understood. Unfortunately, as made clear in the exhaustive analysis in *Brown* and *Gaskell* [24.45] there is rarely a definitive answer to this question.

Given this situation, the vehicle owner or operator may face legal risks following incidents if their interpretation of laws or Conventions is found to be at variance with the opinions of courts. For example, if a court took a view that AOVs were vessels for the purposes of the Standards of Training, Certification and Watchkeeping (STCW) Convention 1995 their autonomous use on the surface would probably be proscribed [24.45]. It is not surprising therefore that action is being taken to prevent wholesale blocks on the use of unmanned systems in the ocean. These actions may be legal, procedural, or technical.

First, examining the legal context, *James Kraska*, a lawyer with the US Judge Advocate General's office, considers that the way forward is to recognize AOVs as *vessels* [24.46]. His opinion is that the *liberal legal architecture* of the key international conventions would allow for inclusion of autonomous systems. If he were proved correct then they would indeed gain benefit from being considered *vessels*. For example, the need to register an autonomous ocean vehicle as a vessel would provide for state protection. Rights in international law are given to *international persons*, such as states, and not to individual artifacts, such as an AOV. But a vehicle could benefit from those rights if it was clearly linked to a state, and hence the usual practice of registry under a particular state and flag. *Henderson* reinforced this point for unmanned underwater vehicles (UUV) [24.47]:

> *It is in the interest of the United States to establish the sovereignty of its UUVs to protect them from foreign seizure.*

Bork et al. [24.48] agree with Kraska that there is a need for action, and that a proper legal regime would give protection to autonomous (and free drifting) ocean vehicles, but they are not as sanguine that the existing framework of international maritime law can provide what is needed. They call for a new legal regime, but *it is not probable that one will soon come about* [24.48].

One aspect of international law that is being followed by many is that of seeking permits for use of AOVs in the exclusive economic zones of foreign nations, in accordance with UNCLOS Part XIII. *Showalter* gives an accessible summary of these issues [24.49]. Notable precedents are being set particularly relevant to the command and control of these vehicles. For example, the UK Foreign and Commonwealth Office has accepted that it is where the vehicle is piloted which determines which nation applies for diplomatic clearance from the foreign nation, not the nationality of the vessel making the deployment. Of course, had the vehicle the benefit of registration and a flag state in its own right, this question would be moot, but at least this acceptance is coherent with the outcome if indeed the vehicle did have a flag state.

Given strict interpretations of international maritime conventions, where autonomous vehicles would be considered as vessels, they would be hard to adhere to, consequently, many organizations and users are preferring self-regulation through collective codes of practice. An early attempt was the code of practice for AUVs produced by the AUV legal working group of the Society for Underwater Technology in 2000 [24.50]. With representation from military, indus-

try, and academic AUV users, the Code of Practice was a practical document that dealt with immediate issues of water-space management, environmental protection, operational considerations and training as well as vehicle marking and other matters. It was updated in 2008 with additional sections, among others, on deployment in congested waters, rules on salvage, protection of data, and damage to third parties, and broadened its coverage to AOVs [24.51]. A succinct code of practice specifically for commercial use of AUVs concentrating on safe operations, mission planning and launch and recovery has been produced by the International Marine Contractors Association [24.52]. Research supported by the European Defence Agency (EDA), through the Safety and Regulations for European Unmanned Maritime Systems (SARUMS) program, has led to an extensive draft best practice guide on handling, operations, design and regulations connected with unmanned maritime systems. Directed toward military use of these systems, the starting position in this paper is that these autonomous systems are vessels, and that *the main content of the COLREGS applies*. An earlier EDA study on maritime unmanned surface vehicles summarized *what additional rules and guidelines that should be developed*, which included adopting a classification scheme, sponsoring research into systems to enable the vehicles to comply with the COLREGS, and promoting cooperation with US agencies to examine whether these vehicles could become a specific class for the purposes of COLREGS.

There is active research into providing autonomous marine vehicles with both a rules-based approach to preventing collisions and with a common sense capability. *Benjamin* et al. examined a behavior-based control framework, and demonstrated the system in operation on an autonomous surface platform [24.53]. An alternative, path planning, approach has been investigated and demonstrated by *Naeem* et al. focusing on maneuvering and preventing head-on collisions [24.54].

There is a role for insurance in mitigating or limiting the financial consequences of legal risks, especially risks to third parties. The practical issues have been set out by *Edwards* [24.55], and *Griffiths* et al. provide case studies from scientific and industry users that have made insurance claims connected with AOVs [24.56].

Dr Robert G. Dean (1930–2015)

Dedication. Part C Coastal Design is dedicated to Dr Robert G. Dean (1930–2015), a world leader in coastal engineering – the practice of civil engineering at the coast – and Professor Emeritus at the University of Florida. During Dr Dean's long and distinguished career, he made important contributions in multiple facets of coastal engineering. These theoretical and practical contributions inform ongoing coastal engineering practices and appear throughout the chapters in Part C, as well as in some of the foundational chapters in Part A. Dr Dean's early work was in water wave mechanics, with an emphasis on the novel use of stream function theory to facilitate computational analysis of wave mechanics problems. Dean and others successfully applied stream function theory to a range of coastal engineering problems spanning from wave propagation on a shear current to wave damping by emergent vegetation. Dr Dean and colleagues also made important advances in our understanding of depth-limited wave breaking. His textbook with Dr Robert Dalrymple is one of the most widely used books on water wave mechanics.

Dr Dean may be most widely known for his work in coastal processes and beach nourishment design, with the latter being the subject of his Chap. 29 in Part C. Dr Dean pioneered the use of equilibrium profile concepts in understanding shoreline change and in the design of beach nourishment. After Dr Per Bruun first introduced equilibrium beach profiles in 1954, Dr Dean validated and popularized the use of the well-known two-thirds power law for equilibrium beach profiles for coastal engineering applications. Throughout his career, Dr Dean applied equilibrium profile concepts to advance current understanding of beach processes.

Since the 1970s, beach nourishment has gained popularity as an economical, aesthetically pleasing, and natural alternative to traditional hard-structure-based erosion control measures. Dr Dean played a major role in establishing beach nourishment design criteria over this period (Chap. 29). His work in this area spanned selecting beach fill sediments, estimating beach fill design volumes using equilibrium profile concepts, and assessing project performance.

The broad impact of Dr Dean's accomplishments and subsequent implementation in the field of coastal engineering are evidenced by the varied collaborations he engaged in over the last five years. Dr Dean and his colleagues reported new insight on storm surge dynamics, river diversions, benthic water flux induced by waves, and levee erosion by wave overtopping. His recent controversial work on sea-level rise with Dr James Houston raised awareness of the large uncertainty in projecting future sea-level change.

Part C Coastal Design is organized such that the first four chapters emphasize present-day knowledge and practices for quantifying the physical coastal environment, while the last four chapters discuss contemporary practices within four specific branches of coastal engineering design. Dr Dean's contributions appear in five of these eight chapters.

Chapter 25, Physical Characteristics of Coastal Hazards, describes the physical features of hurricane surge, tsunamis, and other severe coastal phenomena. Included are the impacts of climate change, sea-level rise, and anthropogenic effects on these hazards. The current understanding of these coastal phenomena is detailed. Straightforward methods for initial interpretation of these hazards are described. A historical perspective is also used, so the evolution of the understanding of these phenomena and the corresponding human response to them are evident.

Chapter 26, Statistical Characterization of Hazards and Risk in Coastal Areas, outlines the probabilistic nature of coastal hazards and details the implementation of this in coastal design. The impacts of combined forcing mechanisms, such as storm surge combined with rainfall, on the evaluation of the risk of flooding are discussed. As with the previous chapter, a historical perspective is given to the discussion of risk evaluation, which illuminates the transition from

early deterministic methods to more recent probabilistic approaches.

Chapter 27, Modeling of Coastal Waves and Hydrodynamics, covers the details of numerical models of wave propagation. Both phase-averaged (spectral) models and phase-resolved (Boussinesq time-domain, frequency-domain) models are covered, and an indication of the typical domains of applicability, and associated model computation times, are discussed. The appropriate modeling strategies for wind waves, swell, and long waves (tsunamis) are detailed. The use of Navier–Stokes type models for breaking waves and turbulence modeling is introduced, along with strategies to couple with time-domain wave models.

Chapter 28, Modeling of Coastal Morphological Processes, addresses the various types of models used to simulate the evolution of the shoreline and beach face due to waves and nearshore currents. Simple analytical and semi-empirical models are introduced first. The drawback of such models is the tendency toward an equilibrium solution that may not be realistic. Process-based models are then discussed, which eliminate any consideration of an equilibrium solution and allow the beach to evolve freely according to the forcing and resultant feedback. Details of these processed-based models are described, and their own development toward equilibrium states discussed. Case studies showing the application of these models are outlined.

Chapter 29, Beach Nourishment, describes the design, construction and analysis of beach fills, and shoreline stabilization. Design considerations for successful beach nourishment projects are discussed, with an emphasis on the quality of the sand and its effect on the success of the nourishment. The effects of coastal structures on beach nourishment are described. Analytical solutions for shoreline evolution are outlined as possible design tools for relatively quick analysis, with numerical models of shoreline evolution used for more detailed studies. Legacy beach nourishment projects are covered, and the reasons for their successful performance detailed.

Chapter 30, Storm Hazard Mitigation Structures, covers design issues regarding coastal structures and their implementation as part of a coastal system. Design conditions (waves, water levels) and their translation to forces on structures are described. Methods for quantifying wave runup and overtopping of structures are discussed. Vertical caisson structures and rubble mound structures are covered; the discussion of rubble mound structures also includes armor layer design, concrete armor unit design, and cross-section design. Life-cycle cost analysis and risk are also discussed. In addition, structures to enhance shoreline stabilization are addressed.

Chapter 31, Overview of Port and Harbor Design, describes the various components of port and harbor layout and their respective designs. There is an emphasis on the anticipated marine traffic and associated accommodation requirements in the design discussion. Types of port and harbor structures and their design criteria are described, including some aspects of their construction. Various kinds of piers and wharves, and the advantages and disadvantages of each, are outlined. Mooring and berthing operations are also described, including evaluation of the load on piers due to berthing and the associated fender design.

Chapter 32, Marine Outfalls, covers the design, analysis and environmental monitoring of outfalls used to discharge treated wastewater into the marine environment. Various drivers for marine outfall design are covered, including social, political, and health concerns. Treatment criteria for wastewater prior to discharge are outlined. Numerical modeling considerations for the outfall operation are discussed, and the impact of the results on the design outlined. The hydraulic characteristics of outfalls are addressed, including nozzle velocity, head losses, and anticipated mixing. Various configurations of outfalls are described and their impact on both treatment plant design and discharge performance addressed. Outfall construction and environmental monitoring techniques are also detailed.

25. Physical Characteristics of Coastal Hazards

Jennifer L. Irish, Robert Weiss, Donald T. Resio

Coastal hazards are among the world's most threatening hazards. With half of the world's population living near the coast, an immense threat is posed by these hazards to life and health, livelihood, and the economy. In this chapter, characteristics of coastal hazards are described, first by presenting a historical context, then by laying out our current understanding of the physical problems of interest for coastal design, and finally by presenting simple methods for initial interpretation of the hazard. A number of natural processes and anthropogenic activities adversely impact coastal communities, critical infrastructure, and port facilities along the coast. Natural coastal hazards may generally be classified into those that are episodic and those that occur over long periods of time. Episodic hazards include coastal storms and tsunamis while long-term hazards include, for example, sea-level rise. Many anthropogenic activities also result in long-term impacts at the coast. For example, inland dam construction produces long-term impacts on coastal sediment supply. In the following, we describe the most common coastal hazards and then discuss methods for evaluating their impacts at the coast.

25.1 **Types of Coastal Hazards** 549
25.1.1 Coastal Storms 549

25.1 Types of Coastal Hazards

25.1.1 Coastal Storms

Coastal storms are categorized either as tropical cyclones, for example, hurricanes, typhoons, or as extratropical cyclones, for example, Nor'easters in the United States. While both storm types generate high winds, surges, waves, and precipitation, there are several key differences between the two.

Tropical Cyclones

Tropical cyclones, which by definition form in the tropics, are generally well organized and compact. Thus, tropical cyclones are characterized by moderately strong to severe winds with the capacity to generate very large waves and surges. Because they are compact relative to other storms, the coastal region impacted by high winds and large surges, and to a lesser extent by large waves, is typically confined to a distance of the order of hundreds of kilometers. These storms also tend to pass fairly quickly across the continental shelf and coastal region, meaning that the period of high winds and large surges is generally of the order of hours, while large waves may persist for several days.

Historically, tropical cyclones have taken hundreds of thousands of lives and caused extensive destruction. The National Oceanic and Atmospheric Administration's (NOAA) local forecast official *Isaac Cline* (1900) commented on his firsthand experience during the Galveston Hurricane of 1900 [25.1]:

> *Sunday, September 9, 1900, revealed one of the most horrible sights that ever a civilized people looked upon. About three thousand homes, nearly half the residence portion of Galveston, had been completely swept out of existence, and probably more than six thousand persons had passed from life to death during that dreadful night. The correct number of those who perished will probably never be known, for many entire families are missing. Where* 20 000 *people lived on the 8th not a house*

remained on the 9th, and who occupied the houses may, in many instances, never be known.

The 1900 hurricane, which made landfall in Galveston, TX, USA, remains the most deadly natural disaster on record in the United States. Some of the largest death tolls associated with tropical cyclones have been those passing through the Bay of Bengal and impacting India and Bangladesh. The 1970 tropical cyclone, which made landfall near high tide, generated flood levels in excess of 6 m and claimed as many as a half million lives along the Bay of Bengal [25.2–4]. This area was impacted again in 1991, when another tropical cyclone with winds exceeding 130 km/h generated similar flood elevations, claiming over 100 000 lives and causing more than 1.5 billion US dollars in damages [25.4].

The United States also has a history of experiencing extensive damages as high winds, flooding, and large waves impact the coast during tropical cyclones. Over the last decade, the US has seen some of its highest storm surges on record as several significant hurricanes made landfall along the northern Gulf of Mexico coastline. Hurricane Katrina made landfall near New Orleans in 2005, generating flood elevations of more than 8 m along the Louisiana and Mississippi coasts [25.5], and became the most destructive hurricane in US history. Estimated economic damages from this event are in excess of 100 billion US Dollars [25.6]. The death toll caused by Hurricane Katrina was just under 2000, the third most deadly hurricane in US history [25.7]. Just three years later, Hurricane Ike made landfall in Galveston, TX, USA. While a moderate hurricane wind event, registering as a Category 2 hurricane at landfall [25.8], this very large storm generated flood elevations in excess of 4 m along much of the Texas and Louisiana coasts [25.9]. This storm became the second most costly storm in US history, with damages estimated to be around 30 billion US Dollars. Both of these events dramatically reshaped the natural and built landscape. Hurricane Katrina severely damaged the Chandeleur Islands and coastal wetlands of Louisiana (Fig. 25.1) while Hurricane Ike reshaped Texas's Bolivar Peninsula (Fig. 25.2). Most recently, Hurricane Sandy in 2012 wreaked havoc along the US eastern seaboard, causing widespread coastal flooding and damaging densely populated New York City and surrounding areas; while recovery is still ongoing, damages from this storm are currently expected to total 75 billion US dollars.

The significant surge and waves associated with this tropical cyclone resulted in significant changes to the islands. Photos courtesy of the US Geological Survey

Extratropical Cyclones

In contrast to tropical cyclones, extratropical cyclones are generally less well organized and usually span a large region. Because these storms tend to be much larger than tropical cyclones, the winds within them tend to be weaker overall, and associated surge magnitudes are generally smaller. Yet, since extratropical cyclones are large and oftentimes relatively move slower than tropical cyclones, the duration and extent of high winds and of large surges and waves are much greater. It is not uncommon for adverse conditions from a single extratropical cyclone to persist over several days to a week and for coastal shoreline distances of the order of thousands of kilometers to be impacted.

An example of a historic extratropical storm occurred in 1953, when a large extratropical depression moved across the North Sea. This storm caused widespread damages across The Netherlands and The United Kingdom, with hurricane-force winds and flood elevations exceeding 2 m above normal levels in many locations [25.10]. It is reported that nearly 1800 people died in the floods associated with overtopping and failure of many of the Dutch sea dikes, which protected communities below sea level [25.11].

Fig. 25.2a,b Aerial imagery of a portion of the Bolivar Peninsula, Texas, USA taken in 2008, shortly before **(a)** and shortly after **(b)** Hurricane Ike made landfall. The significant surge and waves associated with this tropical cyclone resulted in significant erosion across the peninsula. Photos courtesy of the US Geological Survey

In summary, coastal storms are among the most deadly and costly of coastal hazards. Understanding the conditions that lead to, as well as the likelihood of, high winds, flooding, and waves is essential for effective coastal design.

25.1.2 Tsunamis

Unlike storms, tsunamis occur unpredictably, and the response time to an event might be very short. Therefore, tsunami resilience strongly depends on the quick evaluation of the tsunami characteristics as soon as possible after the generation and on educating the population at risk to increase tsunami awareness and preparedness.

Earthquake-Generated Tsunamis

Earthquakes are the most common source of tsunami waves. The characteristics of earthquake-generated tsunami waves depend on the area and magnitude of the deformed seafloor, which is linked to the amount of energy released and depths of the focus underneath the seafloor. Because the magnitude of the vertical seafloor displacement is small compared to the water depth, and the area of displacement is large compared to the water depth, the generated tsunami waves are well described by linear wave theory while propagating in deep waters. This also means that the tsunami will not lose a significant amount of energy during the propagation in deep water and will bring its potentially destructive energy to coastlines hundreds of kilometers away. Tsunamis from very large earthquakes can even have a global reach as demonstrated by *Titov* et al. [25.12] for the 2004 Sumatra tsunami. The National Geographic (2005) reported on the 2004 tsunami [25.13]:

> *Giant forces that had been building up deep in the Earth for hundreds of years were released suddenly on December 26, shaking the ground violently and unleashing a series of killer waves that sped across the Indian Ocean at the speed of a jet airliner. By the end of the day more than* 150 000 *people were dead or missing and millions more were homeless in 11 countries, making it perhaps the most destructive tsunami in history.*

Throughout history, underwater earthquakes have caused widespread destruction not only by the tsunamis generated locally at the earthquake's epicenter, but also by causing landslides which in turn generate more localized tsunamis.

Landslide-Generated Tsunamis

Landslides can also generate tsunamis. Whether or not submarine and subaerial landslides generate tsunamis depends on the slope where the landslide occurs and the volume that is triggered to move. Subaerial landslides are linked to very steep slopes, such as in Alaska for Lituya Bay. The fjords in Norway are also very steep, and settlements and harbors are located along the shorelines [25.14–16]. Because the fjords generally become narrower going inland from the fjord mouth, waves will become larger and larger, posing a significant and increasing threat to low-lying communities (see [25.14] and references therein). For submarine landslides, slopes are usually much more gentle. Submarine landslides can occur on the continental shelf, but also at trenches of subduction zones. The initial waves from submarine landslides can be large, but the relatively short period causes the waves to dissipate while traveling toward the shoreline. Where the distance from the trigger area to the shoreline is short, tsunami waves can be very lethal. An example is the 1998 Papua New Guinea tsunami. An earthquake of about Mw 7 [25.17,

18] triggered a submarine landslide that then caused the death of 3000 people along a 30 km stretch of the Papua New Guinea coast.

The 1958 Lituya Bay, Alaska tsunami, a landslide-generated tsunami, produced a maximum runup of about 524 m, and is the largest tsunami runup ever measured. In the case of Lituya Bay, the rockslide started above the water column, accelerated, and hit the water surface with a velocity of about 110 m s^{-1} [25.19]. In a scaled model of the Lituya Bay rockslide and tsunami, *Fritz* et al. [25.19] demonstrated that Froude number scaling is applicable for the slide problem. The Froude number for this problem is defined as the ratio between the slide velocity at impact and $\sqrt{gh}$, where h is the average water depth in the vicinity of the impact location. The Lituya Bay rockslide exhibited a large Froude number. The impact of the slide body on the surface generates a cavity whose collapse generates a wave pulse that reached about 170 m in the experiments in *Fritz* et al. [25.19] and in simulations by *Weiss* et al. [25.20]. For slides featuring a small Froude number, the generated waves are much smaller with wave amplitudes of the order of the slide thickness.

Submarine slides generate very different waves. The wave characteristics of the generated tsunamis depend on the initial slide volume and its initial acceleration. In general, tsunami waves generated by landslides are steeper than those generated during earthquakes, but exhibit a smaller steepness than waves generated by high-Froude number subaerial landslides. The steeper the waves, the more effectively nonlinear processes work to dissipate and shift energy from longer to shorter frequencies. While early work on landslide-generated tsunamis suggested that a transoceanic propagation is possible [25.21], it is now believed that the extent of landslide-generated tsunamis are limited to locations near the source, and as such only have a regional effect. Furthermore, *Raichlen* and *Synolakis* [25.22] carried out experiments, which explored the influence of submergence (distance of the slide top to the water surface) and slide geometry on the tsunami runup. The slide body did not deform, but it could be shown that for slides triggered in shallower waters, the runup is more influenced by the shape of the slide than for slides that start in deeper water. Again these experiments were performed with a solid slide body. It can be expected that deformable landslides respond differently (for a preliminary discussion, see *Weiss* et al. [25.23]).

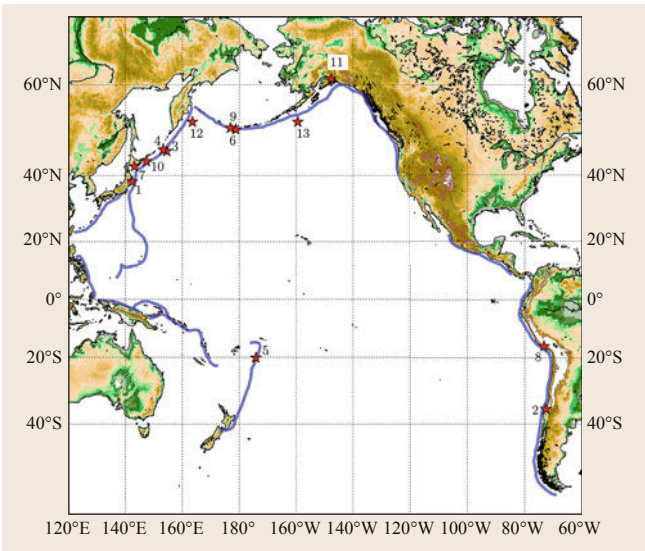

Fig. 25.3 Map of the Pacific Ocean. The *lines* represent the locations of subduction zones where large tsunamigenic earthquakes can occur. The *stars* represent the locations of earthquakes that generated significant tsunamis: 1 – Japan (2011), 2 – Chile (2010), 3 – Kuril Islands (2007), 4 – Central Kuril Island (2006), 5 – Tonga (2006), 6 – Rat Island (2003), 7 – Hokkaido (2003), 8 – Peru (2001), 9 – Anderanof (1996), 10 – Kuril Islands (1994), 11 – Alaska (1964), 12 – Kamchatka (1952), 13 – Unimak (1946)

Volcanic Eruptions and Meteorite Impacts

Tsunamis from volcanic eruptions and meteorite impacts are very rare; however, both events have the potential to generate very large initial waves. While generation of tsunamis from volcanic eruptions often reduces to a slide problem, other processes during eruptions, such as explosions and a caldera collapse are not very well understood. A larger body of knowledge exists for processes that lead to the generation of tsunamis during meteorite impacts into oceans. Understanding of impact-generated tsunamis requires numerical simulation techniques in order to provide the necessary flexibility for the multiphysics processes that govern meteorite impacts to be simulated adequately. For more details, see *Weiss* and *Wuennemann* [25.24] for wave generation and *Wuennemann* et al. [25.25] for wave attenuation as a function of meteorite size and water depth in the impact area.

Meteorite impacts in oceans can occur anywhere. Their hazard is large because they generate very large waves; therefore, any low-lying coastal area may face a significant threat. However, the likelihood of a meteorite impact to happen is very low. On the other hand, earthquakes, landslides, and explosive volcanic eruptions are more common and are linked to certain geographic areas. Strong earthquakes and explosive volcanic eruptions are directly linked to the subduction processes of the oceanic crust underneath the continental crust. The Pacific Ocean is surrounded by sub-

duction zones. Figure 25.3 depicts the locations of the earthquakes that generated significant tsunamis; also marked in Fig. 25.3 are the locations of island arcs that feature explosive volcanism.

The eruptions of Krakatau between 26th and 27th of August 1883 generated tsunamis in the Indian Ocean during different stages of the eruption (explosion, caldera collapse, etc. [25.26]). While the main explosion and caldera collapse are direct ways to generate tsunamis, oftentimes associated flank collapse either during an eruption or later, such as predicted for Cumbre Vieja Volcano (La Palma, Canary Islands, [25.27]), can be approached by considering the slide problem.

Tsunami Source Frequency

Earthquakes occur frequently and have been recorded for about 100 years. The distribution of earthquakes obeys a power-law distribution, indicating that smaller earthquakes occur more frequently than larger ones. A similar power-law distribution can be inferred from meteorite impact craters on the Moon and other planets [25.28, 29]. Like for earthquakes, the size distribution influences respective hazard assessment in that smaller impacts are more frequent than larger ones. Unfortunately, there is no direct measurement and specific distribution of submarine landslides. The main problem with defining appropriate frequency distributions originates from the fact that submarine landslides can be triggered not only by earthquakes, but also by sea-level rise, excess pore pressure, weak layers, and tectonic over-steepening of the local slope.

25.1.3 Climate Variability, Climate Change, and Sea-Level Rise

A changing climate impacts conditions at the coast via two main processes:

1. Changes in weather patterns, such as location and severity, and
2. Changes in the mean sea level.

Additionally, climate varies on multiple scales. We will only consider long-term changes; however, it should be noted that seasonal and decadal effects are important, for example, for determining annual periods of storm activity, high wave energy, etc. Consequently, even though our focus here is on secular trends, we will include some discussion of the impact of specific cycles.

Sea-Level Rise

Long-term changes in the climate are often associated with global trends. Recent literature supports a global warming trend [25.30], which in turn has implications on processes at the coast. Eustatic, or global sea-level rise (SLR), arises from the thermal expansion of the ocean and ice-sheet melting. Observations of eustatic SLR in response to global warming indicate an accelerating SLR trend [25.30–32]. Observations made in recent years indicate that eustatic SLR has accelerated at a rate of 3 mm/yr, with respect to an average rate of 1.7 mm/yr over the last century [25.30]. The Intergovernmental Panel on Climate Change (IPCC) [25.30], by considering a range of future climate scenarios, from low to high carbon emission rates resulting in a 1.1–6.4 °C sea-surface-temperature (SST) rise over the next century, estimated that eustatic SLR is likely to continue accelerating, reaching rates as high as 6.0 mm/yr when major ice-sheet melting is not considered. Literature published since the 2007 IPCC report, which considers major ice-sheet melting, largely supports a substantially larger upper limit on eustatic SLR projections, up to 20 mm/yr over the next century [25.33–36]. Currently, projections of eustatic SLR over the next century range from a low of 1.8 to a high of 20 mm/yr.

Regional influences also contribute to relative, or local, SLR at a particular location. These regional impacts are due to processes including subsidence and tectonic activity. The Permanent Service for Mean Sea Level reports relative sea-level trends for locations worldwide (Table 25.1), and shows that in many locations relative SLR rates exceed the eustatic rate. For example, the Virginia and Louisiana coasts of the United States exhibit 30-year relative SLR rates that are 30–300% larger than the eustatic rate; the Shanghai, China region exhibits a 30-year relative SLR rate that is also about 300% larger than the eustatic rate.

In addition to the obvious impact of raising the mean water level, SLR causes shoreline retreat and land-cover changes, allows for larger waves to propagate farther inland, alters tide levels and currents, alters storm surge magnitudes and as noted in the previous section induces landslide-generated tsunamis [25.37–41].

Storm Climate

Global warming trends have also been shown to impact coastal storm activity, with the potential to alter both storm intensity and frequency, leading to changes in wave climate and coastal flooding. In response to the SST rise, the coastal storm intensity and rate of occurrence is expected to change over the next century. A number of recent studies support an increase in tropical cyclone intensity with SST rise [25.43–47], where wind intensity is expected to increase by 2–11% over

Table 25.1 Observed sea-level rise rates at selected locations (adapted from [25.42])

Location	Time period	Sea-level rise rate [mm/yr]

the next century [25.48]. The impact of SST on future tropical cyclone rate-of-occurrence is not as well understood. Various analyses of the historical record reached conclusions ranging from no significant change [25.47] to an increase [25.49, 50] in tropical-cyclone activity with the SST rise. *Bender* et al. [25.51] summarized that for a mid-range carbon emissions scenario, climate models showed a decrease in Atlantic tropical cyclone activity, of −4 to −49%, by the 2100s, while most models showed an change for the most intense cyclones, between −53 and +110%.

A future increase in storm intensity means that, when storms do occur, storm wave and surge heights will likely be larger [25.41, 52–58]. Thus, we can expect future coastal storm impacts, including inundation elevation, and extent, wave and wind loading, erosion, and damages to be more severe [25.59–63].

25.1.4 Anthropogenic Activities

Coastal urbanization can lead to unintended, unmitigated increases in coastal hazard risk, exacerbating the need for improved coastal planning to mitigate such hazard impacts. Consider, for example, the low-lying and flood-prone New Orleans region in the United States. To stabilize the Mississippi River mouth, an important navigation waterway connecting the port of New Orleans with much of the United States, and to manage coastal flooding, a complex system of levees and polders was designed and constructed throughout the region over the last century. Recent studies show that under certain storm conditions, levees used to control the river may enhance and trap storm surge, thereby increasing flood-related damages [25.64]. As another example of unintended consequences in this area, the population of New Orleans grew more than 60% during the 20th century [25.65], with many residents now settling in areas behind levees, at elevations below the sea level. During Hurricane Katrina (2005), several levees breached, leading to widespread flooding of these populated, low-lying areas. While the devastating impacts of levee failure during Hurricane Katrina can be attributed to a combination of factors, including design load exceedance, this event made clear the need to better plan urban development to avoid urban growth in vulnerable locations.

Another example of the impact of development at the coast is the unintended consequences of construction of inland dams, mining of sediments from inland rivers and waterways, and urbanization that hardens the landscape. All of these processes impede the natural movement of sediments to the coast [25.66], resulting in a depletion of the natural sediment supply and contributing to widespread shoreline recession. Similarly, coastal erosion and navigation measures put in place without considering that the downdrift impacts often lead to unnecessary shoreline erosion. Recently, regional sediment management techniques have been used to manage coastal and inland sediment zones holistically [25.67].

There is also the danger of a major industrial accident, which leads to adverse environmental impacts at the coast. Recently, the Deepwater Horizon offshore platform explosion in 2010 released a 35−km-long plume of oil into the Gulf of Mexico [25.68]. Oil made its way to the coast, damaging the coastal ecosystem. This event directly impacted both tourism and commercial fishing in the region. The proliferation of oil refineries, nuclear power plants, chemical manufacturing plants, and other such major industrial developments in coastal areas must be carefully considered within this fragile and dynamic environment.

In summary, existing development and future anthropogenic activities may themselves aggravate coastal flooding and erosion. Combined with other natural threats, including sea-level rise, it is prudent consider long-term and regional impacts during all phases of coastal development, planning, and design.

25.2 Coastal Impacts

25.2.1 Winds

Winds associated with both tropical and extratropical cyclones must be considered during coastal development. High winds, which vary temporally and spatially, can damage residential and commercial infrastructure and can lead to route closures during evacuation. From a coastal engineering perspective, an understanding of storm winds is also relevant as they are the primary forcing mechanism for wave and surge generation. Field observations via satellite, point measurement, and real-time aircraft-based measurement transects have been used recently to successfully reconstruct cyclone wind fields [25.69, 70] and to provide real-time information on wind speeds. For cyclonic winds, the momentum balance yields the following equation for wind speed (U) in a moving reference frame relative to the cyclone's center

$$U = \frac{1}{\rho_a f}\frac{\partial p}{\partial r} + \frac{U^2}{f\hat{r}_c}\,, \tag{25.1}$$

where ρ_a is air density, f is the Coriolis parameter, p is the barometric pressure, r is the radial distance from the cyclone's center, and $\hat{r}_c$ is the radius of curvature of the isobars. The actual wind velocity relative to earth ($\boldsymbol{U}_a$) must include the storm's translational, or forward, velocity ($\boldsymbol{V}_f$). A simple approximation of the actual wind velocity is the vector sum: $\boldsymbol{U}_a = \boldsymbol{U} + \boldsymbol{V}_f$. Thus, the strongest winds in a cyclone are typically in the forward right (left) quadrant of the storm for storms in the Northern (Southern) hemisphere.

Because they tend to be less well organized, wind fields from extratropical cyclones are not as readily parameterized, and wind-field reconstructions for individual storms are typically developed from observations [25.71]. On the other hand, because tropical cyclones tend to be well organized, several vortex-based models exist [25.72–75] that may be used to estimate the cyclone's wind field for use in coastal hazard analysis and engineering design. The class of models known as planetary boundary layer (PBL) models generally assume that the tropical cyclone's barometric pressure field (p) is described as follows,

$$\frac{\partial p}{\partial r} = \frac{B(p_{far} - p_c)}{r}\left(\frac{R_{max}}{r}\right)^B \exp\left[-\left(\frac{R_{max}}{r}\right)^B\right], \tag{25.2}$$

where r is the radial distance from the cyclone's center, B is *Holland*'s [25.72] pressure profile shape parameter, p_{far} is the far-field barometric pressure, p_c is the cyclone's central pressure, and R_{max} is the radial distance from the cyclone's center to the location of the maximum wind speed. Equations (25.1) and (25.2) may be solved numerically to develop the tropical cyclone's wind field. In the centermost portion of the tropical cyclone, the second term in (25.1) approaches zero, allowing analytical estimation of the maximum relative wind speed parameter, U_{max}

$$U_{max} = \sqrt{\frac{B}{\rho_a e}(p_{far} - p_c)}\,, \tag{25.3}$$

where e is the base of the natural logarithm, 2.718. Figure 25.4 shows $U_{a\text{-}max} = U_{max} + V_f$ versus $p_{far} - p_c$ for three typical V_f values. It should be noted here that U_{max} is used in these models to represent winds that are in approximate balance with the slowing varying pressure gradients. They are not the characteristic of a particular maximum value over a fixed time interval similar to some wind statistics (such as the fastest 1-min wind speed in an hour typically given in tropical cyclone weather reports). As a rough approximation, this parameter varies suffi-

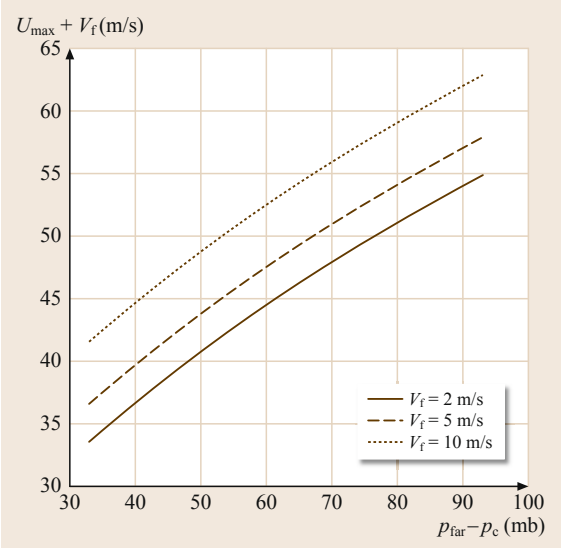

Fig. 25.4 Estimated maximum wind speed in a tropical cyclone using (25.3) and assuming Holland $B = 1$

ciently slowly to be considered constant over about 15–30 min.

In summary, storm winds in and of themselves pose a wind load threat to the built environment at the coast, for example critical infrastructure, such as roadways and utilities, as well as residential and commercial buildings. The above equations may be used to get a general sense of wind strength as it depends on storm meteorological parameters, but it is recommended that numerical simulation and assimilation techniques be employed for the rigorous assessment of winds and wind forcing. Lastly, these storm winds induce large storm waves and surges that are often the design condition of interest in coastal design, as discussed in the following sections.

Example 25.1

At landfall near the Louisiana-Mississippi border, US, Hurricane Katrina was observed to have a forward speed and central pressure of $V_f = 7\,\mathrm{m\,s^{-1}}$ [25.76] and $p_c = 920\,\mathrm{mb}$ [25.77]. Hurricane Katrina's maximum relative wind speed at landfall may be approximated using (25.3) or Fig. 25.4, where we assume $p_{far} = 1013\,\mathrm{mb}$ (standard atmospheric pressure), $B = 1.0$ (typical value), and $\rho_a = 1.23\,\mathrm{kg\,m^{-3}}$. The relative maximum wind speed is then $U_{max} = 53\,\mathrm{m\,s^{-1}}$. The actual maximum wind speed is estimated by summing the relative maximum speed and the tropical cyclone's forward speed, giving $U_{a\text{-}max} = 60\,\mathrm{m\,s^{-1}}$. Observed actual maximum 15-min wind speed for Hurricane Katrina at landfall was $U_{a\text{-}max} = 44\,\mathrm{m\,s^{-1}}$ [25.77]; thus, for this storm, (25.3) provides a maximum wind speed estimate that is about 35% larger than the observed value. This example illustrates the errors that can be introduced by using a simplified wind model close to the coastline, where the wind field is significantly altered by the storm's interaction with land.

25.2.2 Wind-Generated Waves

Large wind-generated waves often govern coastal engineering design. Understanding the magnitude and frequency of large waves is essential for quantifying impact loading on and overtopping of coastal structures and for quantifying storm erosion. These waves develop during far-field and near-field storm events. The reader is referred to Chap. 4 for a discussion of nearshore wave evolution and processes and Chap. 27 for a discussion of numerical modeling of coastal waves. While a thorough analysis of the design wave climate involves analysis of wave-field observations and computational modeling (Chap. 27), in this section we discuss simple methods for identifying general storm wave climate characteristics by considering tropical cyclone waves at the coast.

Wind-wave generation is governed by the strength, extent, and duration of the winds, as well as topographic conditions that limit energy transfer and growth by reducing fetch distance and depth, respectively. The empirical model developed by [25.78] from the interpretation of numerical simulations has been used extensively [25.79, 80] for approximating a tropical cyclone's maximum nonbreaking significant wave height ($H_{s\text{-}max}$)

$$\frac{gH_{s\text{-}max}}{U^2_{a\text{-}max}} = a\sqrt{\frac{gX}{U^2_{a\text{-}max}}}\,, \tag{25.4}$$

where $U_{a\text{-}max}$ is taken at a 10-m elevation, a is an empirical fit coefficient, and X is an equivalent fetch distance. The empirical coefficient is $a = 0.0016$, and is based on the earlier work of *Hasselmann* et al. [25.81] on fetch-limited spectral wave growth. *Taylor* [25.82] found that the formulation of *Alves* et al. [25.83] for X provides less scatter and bias for nearshore wave estimation, with respect to the original formulation of *Young* [25.78]. The *Alves* et al. [25.83] definition is

$$X = b\left[R_{max}\left(1 + d\frac{V_f}{c_{g\text{-}max}}\right)\right]^m\,, \tag{25.5}$$

where $c_{g\text{-}max}$ is the dominant wave's group speed at the location of interest (Part A, Chap. 4) and b, d, and m are empirical fit coefficients. *Alves* et al. [25.83] found $b = 1.11$, $d = 2.3$, and $m = 0.38$, based on numerical simulations with WAVEWATCH III, where R_{max} is in meters and V_f and $c_{g\text{-}max}$ are in $\mathrm{m\,s^{-1}}$. In shallower depths, depth-limited breaking should be considered and the wave-height prediction by (25.4) and (25.5) reduced accordingly. *Alves* et al. [25.83] suggested the following approximation for the peak wave period (T_p)

$$T_p = \frac{0.123U_{a\text{-}max}}{g}\,. \tag{25.6}$$

Representative calculations using (25.4) through (25.6) to estimate $H_{s\text{-}max}$ are presented in Fig. 25.5.

In summary, while it is recommended that computational simulations be used when possible to accurately quantify wave design conditions, the above empirical formulae provide a means for initially assessing extreme wave conditions at the coast.

Example 25.2

Continuing with the information provided in Example 25.1, where the 15-min maximum wind speed and the radius to maximum wind for Hurricane Katrina at

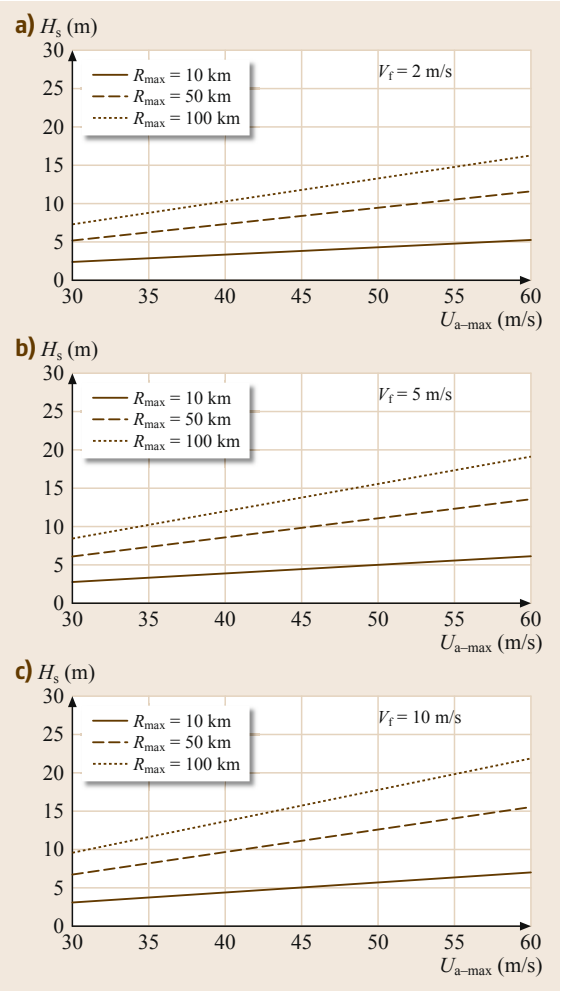

Fig. 25.5a–c Estimated maximum significant wave height for tropical cyclones by (25.4) through (25.6), when mean water depth is 25 m when $V_f = 2\,\mathrm{m/s}$ **(a)**, 5 m/s **(b)**, and 10 m/s **(c)**

landfall were estimated to be $U_{a\text{-}max} = 44\,\mathrm{m\,s^{-1}}$ and $R_{max} = 65\,\mathrm{km}$, respectively [25.77]. Using (25.4) and (25.5) or Fig. 25.5, and estimating $c_{g\text{-}max}$ using linear wave theory (Part A, Chap. 4), the maximum significant wave height at a 25-m depth may be estimated to be $H_{s\text{-}max} = 11\,\mathrm{m}$.

25.2.3 Flood Levels and Runup

Extreme water levels are oftentimes the critical design criteria in coastal engineering. At the coast, these extreme water levels are typically associated with coastal storms and tsunamis. In the following section, each of these phenomena is described.

Storm Surge

Storm surge is one of the most deadly and destructive components of coastal storms, often resulting in widespread inundation of roadways, homes, and critical infrastructure. The extent and magnitude of coastal flooding arise from the combination of the meteorological forcing that induces large waves and wave setup (ζ_{wave}), wind surge (ζ_{wind}), barometric surge (ζ_{baro}), and Ekman setup (ζ_{Ek}), and daily water-level conditions including astronomical tide levels (ζ_{tide}). To accurately estimate storm water levels and inundation along real coasts, high-resolution computational simulation of the shallow-water equations should be employed [25.84, 85] (Chap. 27). In this section, we will discuss the general behavior and characteristics of storm surges. While nonlinearities certainly arise during surge generation in areas with complex terrain and strong tidal signals, total storm flood elevation (ζ_{storm}) may be approximated as the linear sum

$$\zeta_{storm} = \zeta_{baro} + \zeta_{wind} + \zeta_{wave} + \zeta_{Ek} + \zeta_{tide}\,. \qquad (25.7)$$

Neglecting tidal effects, the shallow-water momentum equation for storm surge, in its linearized, depth-integrated form, is

$$-\frac{1}{g}\frac{\partial v_x}{\partial t}\frac{\partial \zeta_{storm}}{\partial x} = -\frac{1}{\rho g}\frac{\partial p}{\partial x} + \frac{\tau_{s\text{-}x}}{\rho g h} + \frac{\tau_{wave\text{-}x}}{\rho g h} + \frac{f v_y}{g} - \frac{\tau_{b\text{-}x}}{\rho g h}\,, \qquad (25.8a)$$

$$-\frac{1}{g}\frac{\partial v_x}{\partial t}\frac{\partial \zeta_{storm}}{\partial y} = -\frac{1}{\rho g}\frac{\partial p}{\partial y} + \frac{\tau_{s\text{-}y}}{\rho g h} + \frac{\tau_{wave\text{-}y}}{\rho g h} - \frac{f v_x}{g} - \frac{\tau_{b\text{-}y}}{\rho g h}\,, \qquad (25.8b)$$

where v is water velocity, τ_s is the surface wind stress, τ_{wave} is the wave radiation stress gradient, h is the total water depth, f is the Coriolis parameter, and τ_b is the bottom stress. The first four terms on the right-hand side of (25.8) respectively induce the barometric surge, the wind surge, wave setup, and Ekman setup.

The barometric surge arises from the storm's barometric pressure change, or gradient as seen in the first right-hand term in (25.8). The maximum contribution by barometric surge occurs at the location of the lowest pressure, at the storm's center, and may be approximated by assuming hydrostatic pressure

$$\zeta_{baro} = \frac{(p_{far} - p_c)}{\rho g}\,. \qquad (25.9)$$

Barometric surge tends to be of the order of 1 m or less; for example, an intense tropical cyclone central

pressure deficit of $(p_{far} - p_c) = 100\,\text{mb}$ yields a barometric surge of about 1 m at the storm's center.

The wind surge arises from the flux of atmospheric momentum into the water column. In the absence of any other forcing, (25.8) becomes for steady-state wind surge

$$\frac{\partial \zeta_{wind}}{\partial x} = \frac{\tau_s - \tau_b}{\rho g h} , \tag{25.10}$$

where x is in the wind direction and it is assumed that τ_s and τ_b are aligned.

Since nearshore wave conditions vary over a narrower range during storms, wave setup contributes of the order of 1 m to the total water level during most storms. The exact amount of wave setup will depend on incident wave and bathymetric conditions. In regions with steep topography, such as that characteristic of volcanic islands, wave setup is typically the dominant contributor to storm flood levels. See *Resio* and *Westerink* [25.86] for a discussion of wave setup during coastal storms.

Ekman setup is developed as a result of the Coriolis force acting on strong alongshore currents, driven by winds, waves, or tides. The result is a rise in water level at the coastline. In the absence of any other forcing, (25.8) becomes the steady-state Ekman setup

$$\frac{\partial \zeta_{Ek}}{\partial x} = \frac{f v_y}{g} , \tag{25.11}$$

where x is in the cross-shore direction and the water velocity v_y is in the longshore direction. While not always significant, the Ekman setup has been found to contribute up to several meters of surge under certain conditions. For example, *Kennedy* et al. [25.87] showed through observations and numerical simulation that as Hurricane Ike (2008) approached the Gulf of Mexico coastline, wind-generated alongshore currents yielded an Ekman setup of 3 m along the coasts of Texas and Louisiana (USA), well in advance of landfall.

Of the four meteorologically driven surge components, wind setup typically is the largest in shallow-sloping coastal areas. To aid in understanding the wind surge response for simple cases, (25.10) may be solved analytically by further assuming the still-water depth (h_o) is $h_o \gg \zeta_{wind}$, $\tau_b \ll \tau_a$, and a quadratic wind stress formulation

$$\tau_s = \rho_a c_d U^2 , \tag{25.12}$$

where c_d is the wind drag coefficient. The solution to (25.10) is then

$$\zeta_{wind} = \left(\frac{\rho_a}{\rho}\right) \frac{c_d U^2}{g} \int_o^{\tilde{x}} \frac{dx}{h_o} , \tag{25.13}$$

where $\tilde{x}$ is distance to the point of interest, measured in the wind direction. Equation (25.13) reveals that the wind surge gradient is proportional to the square of the wind speed, yet is inversely proportional to the depth. Thus, relatively larger surges are expected for relatively stronger wind conditions and for relatively longer distances over which the wind acts, and relatively smaller surges are expected in locations with relatively deeper depths.

For the case of wind surge generated by an onshore wind along the open coast, X is the cross-shore distance to the location of interest measured from a point deep enough for surge generation to be negligible ($x = 0$). The bathymetric profile of the continental shelf fronting many storm-prone coasts may be roughly approximated as an exponential function [25.88], such that (25.13) gives wind surge at the coast as

$$\zeta_{wind} = a \left(\frac{\rho_a}{\rho}\right) \frac{c_d U^2}{g} \left[\exp\left(b X_{shelf}\right) - 1\right] , \tag{25.14}$$

where a and b are the fit constants specific to the local continental shelf shape, and X_{shelf} is the local width of the continental shelf.

For the case of wind surge generation in an enclosed basin of uniform depth, analogous to a lake or coastal bay with restricted exchange with the ocean, the solution to (25.13) for the maximum wind surge is

$$\zeta_{wind} = \left(\frac{\rho_a}{\rho}\right) \frac{c_d U^2}{g} \frac{X_{basin}}{2 h_o} , \tag{25.15}$$

where X_{basin} is the width of the basin.

In real storms, the surge response is more complex. The wind forcing, for example, varies spatially and temporally with storm size and propagation speed. Likewise, the surge response varies from location to location based on local shoreline and bathymetry configuration. It was not until Hurricane Katrina made landfall near New Orleans, LA, USA in 2005 that the importance of the role of storm size on surge generation became widely recognized [25.89]. The Biloxi, Mississippi's Sun Herald [25.90] noted that following Hurricane Katrina:

> *an oft heard refrain ... is Hurricane Camille killed more people in 2005 than it did in 1969. Many officials and locals believed those ... who had survived what was then the strongest recorded hurricane were lulled into a false sense of security that kept them in harm's way.*

This sentiment reflects the disparity between storm intensity (central pressure, maximum wind speed) and surge generation from Hurricanes Camille and Katrina, both of which made landfall near New Orleans.

While Hurricane Camille was by far the more intense of the two, Hurricane Katrina's storm surge at 8.5 m was significantly larger than Camille's 6.9 m. The reason Hurricane Katrina generated such high surges was because of the large extent of hurricane-force winds, more than twice that for Hurricane Camille. It is now well accepted that tropical cyclone surge magnitude is primarily influenced by the regional bathymetric slope and the storm's intensity and size [25.89, 91–93], while the cyclone's forward speed and track orientation with respect to the coastline are generally less influential [25.85, 94, 95]. *Irish* and *Resio* [25.88] proposed a quasi-empirical model for estimating maximum tropical cyclone surge (excluding astronomical tide) on continuous coasts

$$\zeta_{\text{storm-max}} \cong n\frac{(p_{\text{far}}-p_{\text{c}})}{p_{\text{atm}}}X_{\text{shelf-30}}\psi\left(\frac{R_{33}}{X_{\text{shelf-30}}}\right)+q\,, \quad (25.16a)$$

$$\psi\left(\frac{R_{33}}{X_{\text{shelf-30}}}\right)= \begin{cases} \left(\dfrac{R_{33}}{X_{\text{shelf-30}}}\right) & \text{when } \left(\dfrac{R_{33}}{X_{\text{shelf-30}}}\right)\le 1\,, \\ 1 & \text{when } \left(\dfrac{R_{33}}{X_{\text{shelf-30}}}\right)>1\,, \end{cases} \quad (25.16b)$$

where n and q are empirical fit coefficients, p_{atm} is standard atmospheric pressure, R_{33} is the storm radius to $U_{\text{a}} = 33\,\text{m}\,\text{s}^{-1}$ (hurricane-force winds), and $X_{\text{shelf-30}}$ is cross-shore distance from the shoreline to the 30 m depth contour. Based on the observations from continental US hurricane strikes between 1941 and 2008, *Irish* and *Resio* [25.88] determined $n = 4.51\times10^{-4}$ and $q = 1.84\,\text{m}$. Figure 25.6 shows maximum surge estimates by (25.16) for selected storm parameters.

Example 25.3

Continuing with the information provided in Examples 25.1 and 25.2, we may use (25.16) or Fig. 25.6 to estimate the maximum storm surge from Hurricane Katrina, where the central pressure and radius to hurricane force winds at landfall were $p_{\text{c}} = 920\,\text{mb}$ and $R_{33} = 217\,\text{km}$, respectively [25.77]. At the landfall location, the cross-shore distance to the 30 m depth contour is $X_{\text{shelf-30}} = 140\,\text{km}$ [25.88]. Thus, (25.16) yields a maximum surge estimate of $\zeta_{\text{storm-max}} = 7.6\,\text{m}$. Maximum observed flood elevations [25.5] for Hurricane Katrina are between 7.5 and 8.5 m, indicating that (25.16) performs well for this storm.

In summary, storm surge is a complex process whose magnitude varies both as a function of topographic conditions and storm conditions. While it is recommended that computational simulations be used for detailed assessment of storm surge, the above simplified scenarios provide a means for understanding the general behavior of flood response during coastal storms.

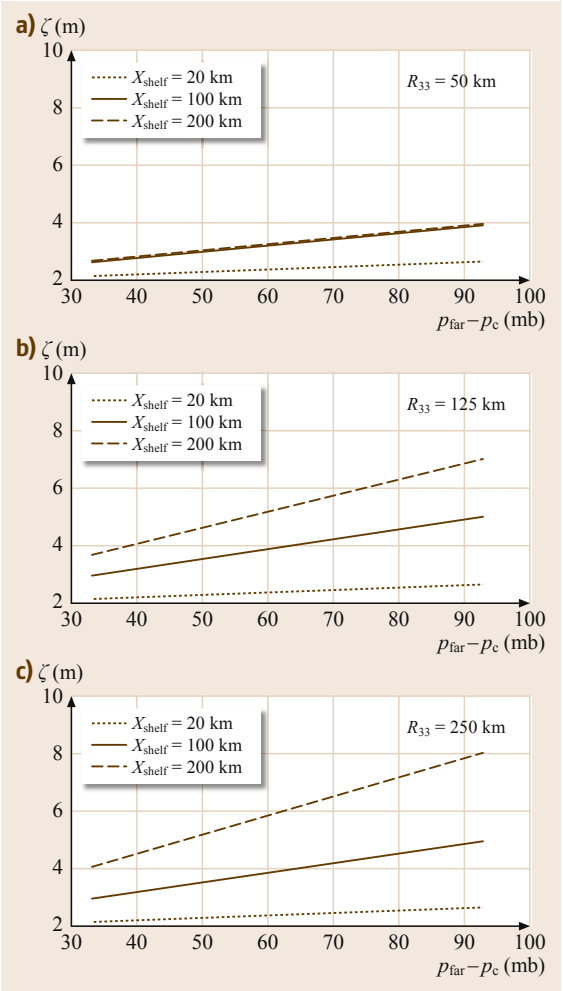

Fig. 25.6a–c Estimated maximum surge by (25.13) when $R_{33} = 50\,\text{km}$ **(a)**, 125 km **(b)** and 250 km **(c)**. In **(a)**, the result when $X_{\text{shelf}} = 200\,\text{km}$ matches the result when $X_{\text{shelf}} = 100\,\text{km}$

Tsunamis

It is a well-known fact that tsunami waves are capable of traveling very long distances to bring their destructive force to far-field coastlines. Depending on the tsunami source, the runup magnitude and the distribution of runup along the coastline can vary drastically. Tsunami events provide the important opportunity to study both runup magnitude and distribution. For example, the runup of the 2004 Sumatra tsunami was surveyed in Indonesia and Thailand, Sri Lanka and In-

dia, but also in Somalia, Madagascar, and Kenya [25.96, and references therein].

From a general point of view, there are very few simple rules that can be applied to quickly estimate the tsunami runup. The most successful rule is the Plafker rule of thumb, which states that the runup on a straight beach does not exceed twice the amount of slip on the fault. Numerical modeling is able to predict the runup magnitude and distribution during an event in a forecast framework [25.98] and is benchmarked with survey data in the aftermath of events. Commonly depth-integrated equations are solved numerically and provide a very flexible computational framework (Chap. 27). While theoretical analyses are restricted to the canonical problem for the long-wave runup, analytical treatment of the shallow-water equations provides not only crucial verification for numerical models, but also general information on the runup magnitude (R) as a function of the average nearshore and onshore topographic slope and wave characteristics. The canonical problem of long-wave runup is made up of constant-depth part and a sloping beach. Originally, solitary waves were employed as wave forcing. *Synolakis* [25.99, 100] found the long-sought analytical solution of the shallow water equations, which resulted in a runup law as a function of the slope ($\tan\beta$) and offshore wave amplitude (H, where the wave amplitude is normalized by the water depth in the constant depth portion, h). Synolakis' runup law is

$$\frac{R}{h} = 2.831\,(\tan\beta)^{-\frac{1}{2}}\left(\frac{H}{h}\right)^{\frac{5}{4}} . \qquad (25.17)$$

The canonical problem was extended by *Tadepalli* and *Synolakis* [25.97, 101] to consider N-shaped waves (hereafter N-waves), which are geophysically more realistic. The respective runup law for the N-wave is

$$\frac{R}{h} = \xi\,(\tan\beta)^{-\frac{1}{2}}\left(\frac{H}{h}\right)^{\frac{5}{4}} \qquad (25.18)$$

with the constant $\xi = 3.86$ for leading elevation and $\xi = 4.55$ for leading depression N-waves. Figure 25.7 shows the runup of N-waves compared to solitary waves. In general, the runup of N-waves is larger than that for solitary waves; therefore, runup estimated from (25.17) may underestimate the maximum runup. Furthermore, *Madsen* et al. [25.102] compared different types of tsunami problems and evaluated the performance of the solitary waves with the results that question the canonical nature of the solitary wave.

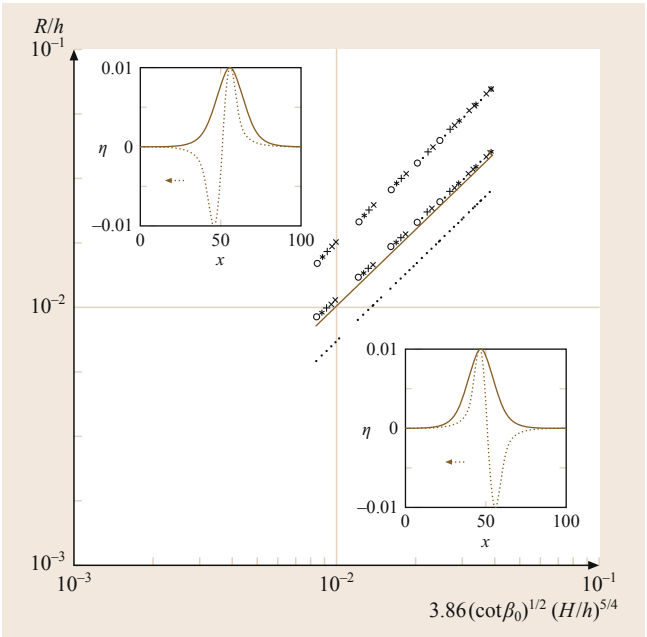

Fig. 25.7 The maximum runup of N-waves of both types: leading elevation and leading depression. The leading-depression N-waves produces larger runup than the leading-elevation N-waves. Both type of N-waves have a larger runup than solitary waves (*dotted line*) (adapted from [25.97])

With the help of numerical simulation, *Okal* and *Synolakis* [25.103] were able to confirm the Plafker rule of thumb with quantitative arguments, and they showed that tsunamis generated by earthquakes differ from those generated by landslides not only in runup magnitude but also in the runup distribution, which can be ascribed to the length scale of the different sources (Fig. 25.8). The runup distribution for landslide-generated tsunamis is narrow and may have a maximum in the runup distribution that can be four to five times larger that those from earthquake-generated tsunamis.

25.2.4 Environmental Impacts

Environmental impacts of natural hazards span from episodic and long-term changes to the natural landscape to episodic and long-term damage to critical infrastructure and industrial complexes, and the surrounding areas. In response to rising sea levels, extreme waves, and coastal flooding, the nearshore and onshore coastal zone is reworked, changing the topography and land cover. Long-term loss of intertidal habitat, for example wetlands and mangroves and the rich ecosystems they support, is anticipated as sea levels rise [25.104–107] and as coastal development continues. It is not yet clear what the broader environmental, social, and economic consequences will be of such changes to the coastal landscape.

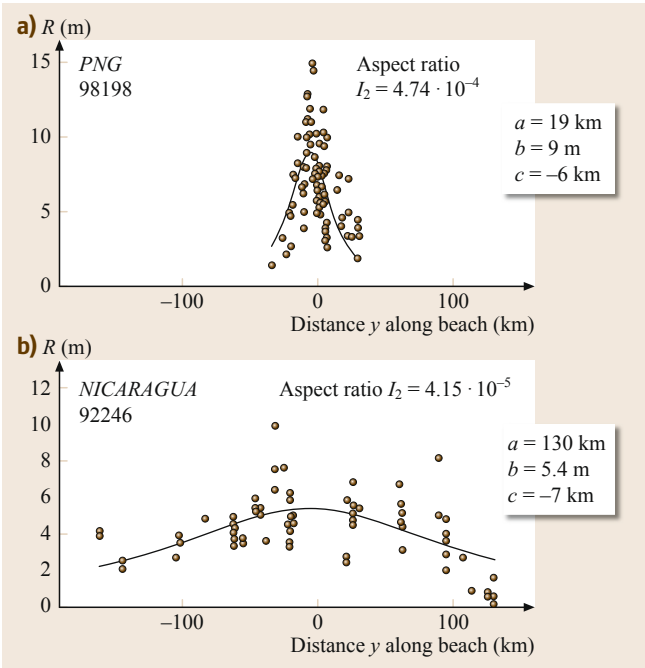

Fig. 25.8a,b Runup distributions along the shoreline for **(a)** the 1998 Papua New Guinea tsunami and **(b)** the 1992 Nicaragua tsunami. The narrow distribution in **(a)** indicates the runup of a landslide-generated tsunami, and the wide distribution in **(b)** is typical for earthquake-generated tsunamis (adapted from [25.103]) ►

Sea-level rise, episodic coastal flood events, and increasing drought events with global warming may also push salt water farther inland along rivers and estuaries, and in groundwater. Such processes will shift ecosystem habitats that are sensitive to salinity changes. In addition, there is the potential for direct human impact. The 2012 droughts in the United States, along with observed high rates of the relative sea-level rise in New Orleans, led to severe salt-water intrusion in the Mississippi River [25.108]. The salt-water intrusion was so severe that freshwater intakes for the region's drinking water supply were contaminated.

The impact of a major coastal inundation event on critical infrastructure can be catastrophic. In Japan, the March 2011 earthquake and tsunami lead to a meltdown at the Fukushima Daiichi nuclear power plant. The subsequent release of radioactivity resulted in the mandatory evacuation of more than 200 000 people, and long-term human health and environmental impacts are not yet known [25.109].

In summary, episodic and long-term hazards at the coast induce changes to the natural environment and can lead to human health threats. The feedback between the hazards and changes induced to the natural environment is currently not well understood. Yet, possible environmental consequences must be considered in all phases of coastal design.

25.3 Summary

In this chapter, we have outlined the various hazards threatening coastal communities and the surrounding environment, and we have presented a series of simple tools for assessing the general behavior of the physical hazard. The primary physical threats include flooding, wave impacts, erosion, loss of natural habitat, and environmental contamination and human health consequences. Coastal hazards are a complex problem, and coastal design often calls for an integrated, interdisciplinary team effort, in order to accurately assess the physical hazard and the threats it poses. Project teams often include a combination of engineers, physical scientists, ecosystem scientists, economists, and social scientists, and the hazard is quantified in terms of the risk it poses. In Chap. 26, hazard probability and risk concepts for coastal design are discussed.

25.4 Nomenclature

a, b, d, m, n, q	Coefficients
B	Holland's pressure profile shape parameter
c_d	Wind drag coefficient
$c_{g\text{-max}}$	Dominant wave's group speed
h	Water depth
h_o	Still-water depth
H	Offshore wave amplitude
$H_{s\text{-max}}$	Cyclone's maximum significant wave height
f	Coriolis parameter
p	Barometric pressure
p_{atm}	Standard atmospheric pressure
p_c	Cyclone central pressure

p_{far}	Far-field barometric pressure
r	Radial distance from cyclone center
$\hat{r}_c$	Radius of curvature of the isobars
R	Tsunami runup
R_{33}	Cyclone radius to $U_a = 33\,m\,s^{-1}$
R_{max}	Cyclone radius to maximum wind speed
SLR	Sea-level rise
T_p	Peak wave period
U	Wind velocity
U_a	Wind velocity relative to earth
$U_{a\text{-}max}$	Cyclone's maximum wind speed
U_{max}	Cyclone maximum wind speed, relative to the cyclone's center
v	Water velocity
V_f	Cyclone forward velocity
$\tilde{x}$	Distance to point of interest
X	Fetch distance
X_{basin}	Width of the basin
X_{shelf}	Local width of continental shelf
$X_{shelf\text{-}30}$	Cross-shore distance from shoreline to 30 m depth contour
$\cot\beta$	Bottom slope
ζ_{baro}	Barometric surge
ζ_{Ek}	Ekman setup
ζ_{storm}	Total storm flood elevation
ζ_{tide}	Astronomical tide level
ζ_{wind}	Wind surge
ζ_{wave}	Wave setup
ξ	Coefficient
ρ_a	Air density
τ_b	Bottom stress
τ_s	Surface wind stress
τ_{wave}	Wave radiation stress gradient

26. Statistical Characterization of Hazards and Risk in Coastal Areas

Donald T. Resio, Mark A. Tumeo, Jennifer L. Irish

We examine the foundation for hazard/risk assessment and its application to coastal problems. Historically, emphasis was on specifying expected values of wind waves and storm surges; however, as shown by the recent tsunamis in Southeast Asia in 2004 and in Japan in 2011, there are critical parts of the world where tsunamis represent the dominant threat to coastal communities. Recently, there has been an increased awareness of the combined effects of heavy rainfall and/or river discharge with surge levels and strong winds. This forcing combination played an important role in the flooding in southern Louisiana during Hurricane Isaac in 2012, where water levels exceeded the 500-year return interval levels. Such forcing combinations complicate both the modeling systems required for their simulation and the treatment of the multivariate probabilities that define the relative importance of their impacts.

We begin with a set of consistent hazards and risk definitions, along with comparative definitions from other fields. This should help readers who have focused primarily on traditional coastal hazards and risks understand the broader context of risk assessment and also allow readers with a broader perspective gain insight into the specific nature of coastal hazards and risk. Following this, we introduce the basic concepts used in estimating coastal hazards and risks. We then examine the historical perspective for the evolution of coastal risk assessment, beginning with early deterministic methods and culminating in a recent transition to probabilistic methods. The steady increase in the ability of probabilistic methods to deal with persistent problems such as the lack of data and uncertainty is documented as a part of this transition.

26.1 Overview of Risk and Uncertainty

Technically, *risk* is defined as the mathematical probability that a specific outcome will occur multiplied by the magnitude of the impact of that occurrence. However, there are many other definitions in use, and while a technical working definition such as the one presented is useful, it is more important that there is a contextual understanding of the concept.

While *risk* is now used in some manner across almost every discipline, the entire cultural framework upon which the concept is based is only a few hundred years old (and relatively young as a basis compared to other engineering and mathematical concepts). Most ancient cultures took the stance that the future was either fated (deterministic) or subject to the whims of

powers beyond our control or understanding. There is no concept of *risk* in such cultures beyond the fear of certain punishment should you anger the powers that be. The roots of our conception of risk arose in the Renaissance, as cultures in the west broke away from and challenged long-held beliefs. One of the critical turning points for the concept of risk as we know it was the development of the concept of *probability* – the idea that the future was not determined or unpredictable, but that there was the possibility to make predictions based on numbers, not oracles or soothsayers. The origin of this truly revolutionary concept is recounted by *Bernstein* as follows [26.1]:

> *In 1654, a time when the Renaissance was in full flower, the Chevailier de Mere, a French nobleman with a taste for both gambling and mathematics, challenged the famed French mathematician Blaise Pascal to solve a puzzle. The question was how to divide the stakes of an unfinished game of chance between two players when one of them is ahead. The puzzle had confounded mathematicians since it was posed some 200 years earlier by the monk Luca Paccioli ... Pascal turned for help to Pierre de Fermat, a lawyer who was also a brilliant mathematician. The outcome of their collaboration was intellectual dynamite. What might appear to have been a seventeenth-century version of the game of Trivial Pursuit led to the discovery of the theory of probability, the mathematical heart of the concept of risk.*

Hence, imbedded in the concept of risk is the inherent belief in predictability, at least in a probabilistic sense. This concept, however imbedded in our current culture, stands in stark contradiction to the well-known adage that one cannot accurately predict the future. In the modern world, this contradiction is resolved through the belief that if we knew enough, we could accurately predict the future. This belief in scientific determinism (the same concept from ancient times that was *overturned* by the concept of risk) was articulately stated by *Pierre-Simon Laplace* in his landmark 1812 treatise *Essai philosophique sur les probabilités* (*A Philosophical Essay on Probabilities* as translated by Truscott and Emory in 1902) [26.2]:

> *We may regard the present state of the universe as the effect of its past and the cause of its future. An intellect which at a certain moment would know all forces that set nature in motion, and all positions of all items of which nature is composed, if this intellect were also vast enough to submit these data to analysis, it would embrace in a single formula the movements of the greatest bodies of the universe and those of the tiniest atom; for such an intellect nothing would be uncertain and the future just like the past would be present before its eyes.*

We have therefore, in many ways, come full circle as a culture. Through the concept of risk we have moved away from the underpinning belief in determinism to accept that there is an unknown and unknowable future. Yet, through the application of mathematical probabilities, which gave rise to the concept of risk, we also have developed the idea of a scientific determinism, wherein if all lack of knowledge could be eliminated through scientific inquiry, we would once again have a certain and determined future.

The cultural concept of scientific determinism through the elimination of uncertainty and evaluation of undetermined but manageable future options are the heart of risk assessment. The purpose of the study of risk is to manage the future by using our best knowledge and current understanding to reduce uncertainty and quantify the remaining uncertainty through probabilistic prediction.

26.1.1 Definitions of Basic Terms

Because the concepts of risk and uncertainty are now so ingrained into our society, the use of terms associated with *risk and uncertainty*, including *hazard*, *probability*, *risk assessment*, *risk analysis*, and in fact the words *risk* and *uncertainty* themselves, are used frequently in differing and often confusing ways. When one adds to this situation the fact that risk and uncertainty inherently rely on other ill-defined and often misused concepts such as *error* and *variability*, it becomes apparent that before entering into a discussion of the application of hazard probability and risk assessment to coastal systems, it is necessary to ensure that there is a consistent and uniform understanding of terms. A full list of definitions for probability and risk related terms used in describing coastal hazards is given in the Sect. 26.A; however, several key definitions are retained here that are most pertinent to discussions within this chapter:

- *Probability*: In its most basic sense, probability is the chance or likelihood that something will happen. Qualitatively, the more likely an event is to happen, the more *probable* the event. Quantitatively, probability is a value between 0 and 1, with 1 representing absolute certainty of the event occurring. The probability of an event is typically measured as the ratio of the number of times an event occurred over the total number of times the event could have occurred. For example, if we consider the event to be the occurrence of precipitation on any given day,

we would collect information on whether it rained on any given day for a period of time (say 1 year). The probability of rain would then be

$$\text{probability of precipitation} = \frac{\text{number of days with precipitation}}{\text{Total number of days}} .$$

- *Probability distribution*: The basic definition of probability works for discrete events, but when the event or parameter being evaluated is continuous in nature (i. e., the maximum temperature on any given day, the stage of a river on any given day), then a single probability is not sufficient. Instead, possible values are grouped into discrete ranges and the number of occurrences in that range are counted, then divided by the total number of measurements.
- *Risk*: The potential for realization of unwanted, adverse consequences to human life, health, property, or the environment. The estimation of risk is usually quantified using the expected value of the conditional probability of the event occurring times the consequence of the event given that it has occurred. This definition is currently used by the Society of Risk Analysis. Mathematically, this is expressed as

$$R = P(A) * P(B|A) ,$$

where R – Risk (a probability from 0 to 1), $P(A)$ – probability of event (A) occurring, $P(B|A)$ – probability of a consequence (B) occurring given that event A occurred.
This technical definition is what will be used through this handbook. However, there are other definitions in other fields of which the knowledgeable practitioner should be aware (Sect. 26.A). Besides having multiple potential definitions, risk can also be differentiated by types. Different types of risk, even if they are of the same quantitative value, are often managed differently or even ignored. Some of the common risk types that greatly influence both how these risks are assessed, managed and communicated are defined below (Sect. 26.A for full list).
  - *Actual risk*: A scientifically verifiable risk. For example, it is well researched and documented that smoking places you at-risk for cancer [26.3–6]. Actual risk is sometimes referred to as *objective risk*, but whether risk is subjective or objective is related more to its ability to be measured than it is to its actual verifiability.
  - *Perceived risk*: Risk that is thought to exist by an individual or group that either is understated or is exaggerated. This often occurs in situations where the public is misinformed or in which media reports instill unnecessary panic. Food safety concerns often top the list of such events and lead to significant public policy debates, see, for example [26.7].
  - *Assumed risk*: Risk that is taken by choice. Assumed risk can be quantifiably large or small, and actual or perceived. For example, individuals who choose to partake in risky activities (skydiving, mountain climbing) choose to assume the relatively large risks associated with these activities, but choosing to drive a car, take medicines, or be involved in day-to-day activities all involve some assumed risk.
- *Imposed risk*: Risk that is forced upon an individual, either without the knowledge of the individual or if known, without consent. For example, second-hand smoke exposure is seen as an imposed risk [26.8–10]. Natural events such as earthquakes, tropical cyclones (e.g., hurricanes, typhoons), and extreme weather events are to a large extent *imposed* risks, but to some extent individuals assume that risk based on where they choose to live. For an interesting approach to this, see the work by [26.11].
- *Uncertainty*: Uncertainty arises from the fact that any model (including risk assessment models) cannot provide 100% *certainty* in its results. This uncertainty arises from two major sources.
  - *Epistemic uncertainty*: Epistemic uncertainty arises from the fact that there are things about the natural system we are analyzing that we do not know. This *lack of knowledge* can be because the knowledge is not yet scientifically available – and as such, it can be reduced (along with the resulting epistemic uncertainty) going forward through additional data, experimentation, theoretical development, and scientific inquiry. However, lack of knowledge also includes things that we do not even know that we do not know. This area of *lack of knowledge* is more difficult, because it is not easily identifiable and as such, becomes included in either variability, or is called *error* when comparing model results to reality.
  - *Alleatory uncertainty*: Variability is a range of potential values for a given parameter. Variability is an inherent characteristic of natural processes (also called natural variation). It is describable using probability distributions. The result of natural variation is sometimes called alleatory uncertainty. Variability in natural processes (and the resulting alleatory uncertainty) cannot be reduced, as it is an inherent property of the process itself.

26.2 Quantifying Coastal Hazards/Risks

A detailed treatment of all coastal hazards and risks is beyond the scope of the work presented here. Environmental/health hazards and risks such as those related to water quality, chemical spills, and salinity intrusions will not be treated here; however, it is hoped that the methods discussed in this section will be useful, at least in a general sense, to those working in these areas. Additionally, due to the fact that much of the recent research on coastal hazards/risks has been undertaken in response to Hurricane Katrina, much of the focus relating to recent developments will be on storm surges produced by tropical cyclones. Although extratropical storms play a very large role in many coastal areas, the lack of a recent catastrophic event, such as flooding the subway system in New York City before Hurricane Sandy (which was a hybrid mix of tropical cyclone and extratropical characteristics) has meant that methods used for evaluation of these hazards/risks have received far less attention than they probably deserve. A single section (Sect. 26.3.6) will be devoted here to specific issues related to extratropical storms, following our general treatment of extreme and related hazards/risks.

Before launching into our treatment of hazard probabilities, it should be recognized that both epistemic and alleatory uncertainties need to be considered within any thorough analysis of hazards and associated risks. Limitations in theoretical/numerical predictions come from many sources, including simplifications in our models to make nature fit our models, the lack of details in the information utilized by models, and shortcomings in our theoretical knowledge on which model are based. Similarly, the lack of sample size continues to be a serious problem in our estimations of extreme values. In some studies, many years of record are simulated and statements are made which might lead the reader to believe that a commensurate gain in information over the existing historical record has somehow been achieved. However, a detailed review of these studies reveals the obvious fact that alleatory uncertainty cannot be overcome by simply executing numerical models over many randomly posed simulations, since the information upon which the parent distribution is based remains the same.

Many available textbooks provide excellent formal reviews of statistics, derivations of distributions and applications specific to hazard/risk assessment [26.12–16]. Some recent examples of similar books which focus more on risk issues include [26.17, 18]. Here we will present only a summary of information which should allow a reader to gain sufficient familiarity with these basic statistical methods. As shown in Sect. 26.1, risk is associated with the probability of consequences. Since design thresholds are selected in a manner intended to limit consequences to an *acceptable* level, the study of natural hazards and associated risks tends to focus to either on extremely large or extremely small values in a distribution. Here we will focus on the upper end of the distribution, since these represent the major design consideration for most natural disasters in coastal areas.

We start here with the conventional definition of the probability density function (PDF) of a continuous variable x with the following properties

$$p(x) \geq 0 \,, \tag{26.1a}$$

$$\int_{-\infty}^{\infty} p(x)\,\mathrm{d}x = 1 \,, \tag{26.1b}$$

$$\int_{a}^{b} p(x)\,\mathrm{d}x = P(a < x < b) \,, \tag{26.1c}$$

where $p(x)$ is the probability density function for the variable x and $P(a < x < b)$ is the probability of x falling between the values of a and b. It is clear from the form of (26.1c) that the PDF is not a dimensionless function. Since $\mathrm{d}x$ has the same units as x, the dimensions of $p(x)$ must be x^{-1}. As an example if we allow the PDF to be given by

$$p(x) = k\mathrm{e}^{-qx} \,, \tag{26.2}$$

k and q must both have dimensions of x^{-1}; otherwise the integral would not produce results with the correct dimensions. A simple example with $q = 1$, $a = 1$ and $b = 3$ yields a value for (26.1c) equal to $\mathrm{e}^{-1} - \mathrm{e}^{-3} = 0.318$.

The cumulative distribution function (CDF) of x is equal to the probability that a value is less than or equal to a particular value of x,

$$F(x) = \int_{-\infty}^{x} p(x)\,\mathrm{d}x \,, \tag{26.3}$$

where $F(x)$ is the CDF of x. $F(x)$ is a dimensionless function since it is the product of two functions with dimensions x and x^{-1}; however, in engineering applications, it is very important to recognize that it becomes implicitly related to time when we convert to expected mean recurrence intervals. This is because, even though the time between samples does not appear explicitly in $F(x)$, it enters into the CDF implicitly via the time interval between samples. When we convert (26.3) into

a form for estimating the expected interval between exceedances of a particular value of x, we obtain a relationship of the form

$$T(x) = \frac{1}{\lambda(1-F(x))}\,, \tag{26.4}$$

where $T(x)$ is the mean return period (or interval), and λ is the sampling frequency. Even though (26.4) is often written without λ in the denominator, its omission can lead to a dimensional inconsistency. The units used to define λ (decade^{-1}, year^{-1}, month^{-1}, day^{-1}, etc.) provide the information which characterizes $T(x)$. In engineering, it is common practice to use years for $T(x)$, in which case the expected value annual probability of exceeding a particular value of x is given by $1/T(x)$. Thus, a 100-year mean return interval is associated with an event that has an annual exceedance probability (AEP) of 0.01.

Here we will use an example of some results taken from wave hindcasts (the reconstruction of wave conditions from simulations of past events) for a location in the southern Gulf of Mexico area to show the importance of considering the frequency term in our estimation of return periods. In this region, two different meteorological phenomena can generate large waves, tropical cyclones, and *Northers*. The latter type of wave generation occurs when a cold front crosses the Gulf of Mexico and produces very strong surface wind speeds behind it. For both hurricanes and Northers, the results are given for sites located in deep water and in nominal depths of 20 m. In Fig. 26.1, we plot $-\ln\{-\ln[F(x)]\}$ against x, using the 20 data points available in each specific sample. Points that plot along a straight line in such a graph are consistent with a Gumbel distribution.

From Fig. 26.1, it appears that Norther and hurricane hazards are roughly comparable in this region of the Gulf of Mexico; however, if we include the frequency parameter and estimate the mean return interval, we obtain Fig. 26.2. In this case, the hazards related to hurricanes are shown to be considerably larger than those related to the Northers.

Since the concept of a mean interval between occurrences (return period) is simpler for some people to grasp, it is often used instead of the AEP concept in applications; and for that reason we will use it in some of our figures and discussions. However, it is very important to recognize that a *100-year event* is not constrained to occur only once every 100 years. For example, we can define the probability of exceeding a given value of x_c as 1 minus the probability of that level not being exceeded in any year, in which case the probability of having no exceedances in n years is given by

$$\begin{aligned} &P(x < x_c|n \text{ years}) \\ &= 1 - P(x < x_c|\text{year } 1) \times P(x < x_c|\text{year } 2) \ldots \\ &\quad \times P(x < x_c|\text{year } n) \\ &= 1 - \prod_{i=1}^{n} P_i(x < x_c) = 1 - [1 - F(x_c)]^n\,, \end{aligned} \tag{26.5}$$

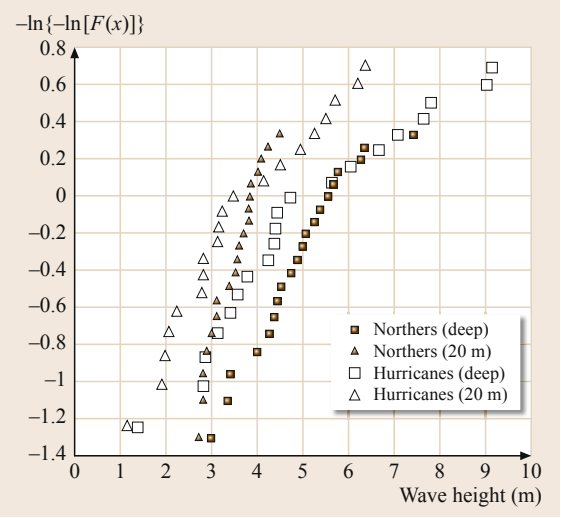

Fig. 26.1 Plot of the $-\ln\{-\ln[F(x)]\}$ versus x for waves generated at points in the southern Gulf of Mexico by hurricanes and *Northers* at sites in deep water and a depth of 20 m

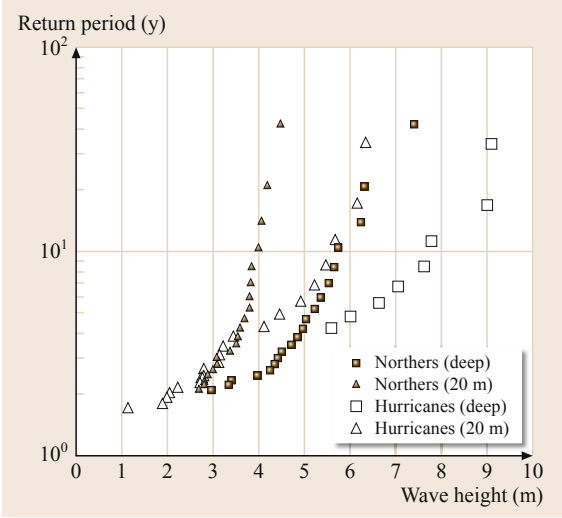

Fig. 26.2 Plot of the mean return period versus wave height for waves generated at points in the southern Gulf of Mexico by hurricanes and *Northers* at sites in deep water and a depth of 20 m

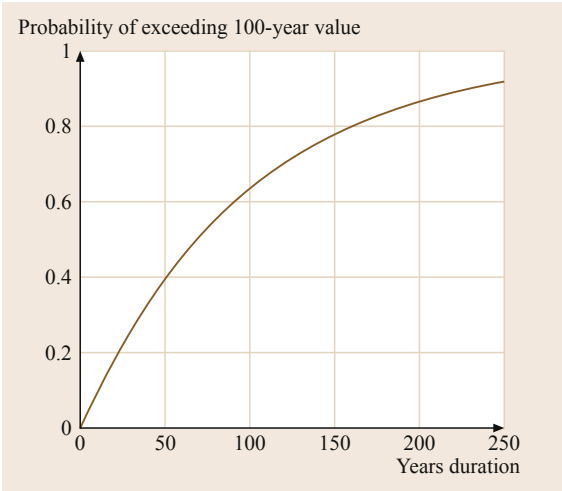

Fig. 26.3 Graph showing the probability of exceeding a value expected on the average only once every 100 years as a function of the number of years of duration

where n is the number of years and i is the year counter. Figure 26.3 gives the estimated encounter probability for an AEP of 0.01 as a function of the expected *design life*, the number of years being considered for the design. It can be seen that the actual exposure to hazards/risks is a clear function of the number of years considered for the design life. Over 30 years the probability of encountering a 100-year exceedance would be 0.2603; and over 50 years the probability of exceedance would be 0.3950.

Equation (26.5) is a bit tedious to use but is instructive regarding the reason why the probabilities become relatively large over a number of years. A second, perhaps simpler form for estimating the probability that a value, x_c, will not be exceeded in n years is to use a Poisson distribution with the integer value for occurrences equal to zero. In this case, if we define $\lambda =$ number of years over which the non-occurrence is being estimated divided by the mean recurrence interval for x_c, we can estimate the equivalent probability to (26.5) as $1-e^{-\lambda}$. For example, the equivalent value for the 30-year example above would be $\lambda = 0.3(= 30/100)$, or $1-e^{-0.3}$, which would equal 0.0259 and the equivalent value for the 50-year example would be $1-e^{-0.5}$, which would equal 0.3935. It should be noted that this would yield the same result for any combination of values of number of years over which the non-occurrence is being estimated and return value for x_c, such as 100 years of non-occurrence for a value with a 200-year recurrence interval for the latter example.

As an interesting side note to the above discussion, we can examine the common practice today of construction deterministic *flood zones* on maps for insurance purposes. If a property had an AEP for flooding of 0.009, it would lie outside of the primary flooding area covered under the program of the Federal Emergency Management Agency (FEMA) in the United States; yet the probability of flooding over 30 and 50 years would still be 0.2375 and 0.3637, respectively, which is only 8 to 9% different than for the property with the AEP of 0.01. Thus a definitive line on a flood map can be very misleading, with people on one side believing that their likelihood of flooding is much different than on the other side, which is certainly not the case.

Equation (26.5) shows that the accurate estimation of the CDF is fundamental to the estimation of hazards and risks. *Fuller* [26.19] credits George W. Rafter with initially pointing this out in 1896; however, the first published study directly linking hazards to a probability distribution in the United States (using the normal distribution) was that of [26.20]. Shortly afterward, *Hazen* [26.21] noted that logarithms of flood stages tended to provide more consistent estimates of CDF, essentially hypothesizing that floods followed a log-normal distribution. Since those early beginnings about a century ago, many studies have improved our understanding of the statistical behavior of extremes. Early studies typically attempted to fit specific distributions directly to empirically selected distributions. An excellent review of these early studies and the fitting methods used in them is contained in [26.22]. As shown there, many different distributions (for example, normal, lognormal, Poisson, generalized extreme value, and Pearson distributions) were developed, tested, and applied to a number of applications through the 1960s. The gist of the fitting methods was based on the concept that the CDF for each distribution could be related to the ranked data. For example, Table 26.1 shows the relationship between the estimated return period and the ranked order of the data, termed the plotting position, for a number of different distributions.

A detailed treatment of all of distributions used for estimating extremes is beyond the purpose of our discussion and Table 26.1 is only included to show how many different empirical approaches had been developed by the middle of the last century. For our purpose, it is sufficient to recognize that distributions can be classified into two general classes, parametric and nonparametric. Parametric distributions are characterized by assumed theoretical forms which include a small number of constants which must be determined by a statistical fitting technique; thus, such distributions constrain the number of degrees of freedom in the data. All of the distributions included in Table 26.1 are parametric. Nonparametric distributions are allowed to vary

Table 26.1 Plotting position formulae recommended by different investigators for the estimation of the return period

Name	Date	Formula[a] for T or $1/P(X \geq x)$
California	1923	$\frac{N}{m}$
Hazen	1930	$\frac{2N}{2m-1}$
Weibull/Gumbel	1939/1959	$\frac{N+1}{m}$
Beard[b]	1943	$\frac{1}{1-0.5^{1/N}}$
Chegodayev	1955	$\frac{N+0.4}{m-0.3}$
Blom	1958	$\frac{N+1/4}{m-3/8}$
Tukey	1962	$\frac{3N+1}{3m-1}$
Gringorten	1963	$\frac{N+0.12}{m-0.44}$

[a] N = total number of items; m = order number of the items arranged in descending magnitude, thus $m = 1$ for the largest item.
[b] This formula applies only to $m = 1$; other plotting positions are interpolated linearly between this and the value of 0.5 for the median event.

in a form consistent with the data elements; hence, they are not necessarily constrained to a small number of degrees of freedom.

Two different types of parametric distributions have been widely used in studies of natural phenomena, distributions which encompass the full range of data and distributions which focus only on the portion of the data with the largest observed values. Examples of coastal applications of the first type can be found in many studies of coastal waves in the 1960s through the 1980s, as discussed in [26.23, 24]. *Hogben* and *Lumb* [26.25] provide one of the earlier comprehensive collections of wave data around the world. Examples of subsequent studies using information covering the entire range of data measured can be found in [26.26–29]. However, here we will focus on the latter class of distributions, since extremes represent the primary variable range in most designs. This helps us avoid many of the issues with samples that have significant serial correlations, due to the shortness of the sampling interval. Most methods of the second type originally used a constant sampling interval (typically 1 year which implied a value of λ equal to one and the time units of years). However, as will be discussed in more detail in the historical perspective section, there are many cases where it is advantageous to allow the time interval between samples to vary. For example, if we are only interested in winds, waves and/or surges from tropical cyclones, the sampling time interval will vary and the λ in (26.4) would be equal to the mean frequency of tropical cyclone occurrence (or one over the mean interval between tropical cyclones). This parameter behaves analogously to the frequency term in the Poisson distribution and hence is often called the Poisson frequency, the average number of storms per year included in the analysis.

Before proceeding, it is important to note that wave extremes are usually posed in two different but related contexts: extremes related to the overall energy content in the local wave field (sometimes termed the sea state) and extremes related to individual waves. In the 1940s, it began to be recognized that the water surface was not well-described by simple unidirectional, monochromatic mathematical formulations. Instead, the wave field was better described as a random surface produced by the superposition of a continuous distribution of wave components in frequency and direction. The total energy within a unit area of water surface can be related to the variance of that surface around its mean position. The so-called *significant wave height* is approximately equal to the average of the one-third highest wave heights over an interval of time. More recently, it has been defined as $H_s = 4\sqrt{E_0}$, where H_s is the significant wave height and E_0 is the total variance of the water surface. The distribution of individual wave heights depends on the total energy and some additional factors which influence the degree of nonlinearity within the wave field, but these topics are beyond the main scope of what we will treat here. Significant wave heights tend to be used in applications dependent on time-averaged properties of waves (such as wave set-up, wave overtopping rates, beach erosion rates, etc.), while individual wave heights tend to be used in applications dependent on instantaneous forces (such as structural components in offshore facilities and some elements of ship design).

In nonparametric estimation of extremes, the probability of future events is obtained via methods that resample the available historical sample, under the assumption that future distributions will follow the same general form [26.30–34] This method is very powerful for application to extremes when the number of samples is large and the value range of interest falls within the range contained in the historical (initial) sample. In the context of coastal applications to extremes of waves, winds, and surges, probably the most widely used method of this kind is that of *Scheffner* et al. [26.35], which is termed the empirical simulation technique (EST). In this method, the CDF is estimated

in terms of the rank of the ordered values (m) and the total number of observations N,

$$F(x) = \frac{m}{N+1} , \tag{26.6}$$

which can be seen as an equivalent form to the Gumbel plotting position given in Table 26.1; the return period there is defined as the inverse of the nonexceedance probability. However, the manner in which such information is used in nonparametric methods is very different to its use in parametric methods.

To help demonstrate the basic premise of resampling, let us assume that our data includes 30 samples taken over 50 years. Thus, the range of the CDF covered would be $1/31(0.0323)$ to $30/31(0.9677)$, or more generally $1/(N+1)$ to $N/(N+1)$, where N is the number of samples. Based on (26.4), we would estimate that the return periods explicitly covered by this data cover the range 1.72–51.67 years, recalling that the value of λ would be $30/5$ for this example. If a specific design requirement fell into this range, the results from the EST could be used directly, without any extrapolation. However, two key points should be understood in applications of this methodology. First, outside of the CDF range covered by the data, it is necessary to extrapolate parametrically to obtain estimates of the CDF as a function of x; so in this example, for return periods larger than 51.67 years or less than 1.72 years, some fitting algorithm similar to that used in parametric methods must be utilized. Second, any sample drawn from nature cannot be regarded as the *parent* population constructed from of all possible samples.

Let us assume for simplicity that we have a fitting methodology, which extends the range of the CDF from 0 to 1. In this case, we can use a random number generator to construct a random sequence of values for both the number of storms in a particular year (based on a Poisson distribution) and the value of the variable of interest in all of the storms that occur. The latter of these is obtained by assuming that each random number is a CDF value and inverting this value (using the defined CDF-x relationship) to obtain an estimate of x. If we simulated 100 sets of 50 years using this method, we could obtain an estimate of the magnitude of the variability we might expect in a particular 50-year sample; however, it would still be assuming that the initial sample represented the population characteristics. In fact, the actual variability in a subsequent 50-year interval will include contributions from the potential deviation of the initial sample from the overall population sample plus the contribution of deviations due to sampling given an initial distribution.

26.3 Historical Perspective

It is important to recognize the role of thresholds in coastal hazards and their relevance to risk. For example, a flood over a particular value might overtop a levee, or a wave height greater than some limit might impact critical components of an offshore oil platform, and a toxin level over some threshold might endanger the environment. Any of these occurrences might have serious consequences on lives and property. Thus, the success or failure of engineering designs and decision making in general can be very sensitive to whether or not a particular threshold is exceeded. However, is it really this simple? Are we certain that any value lower than an exactly specified threshold (even by a minuscule amount) will not have serious consequences, while any value equal to or greater than the threshold will definitely have serious consequences? Given that we never have complete information about the processes and the probabilities of different combinations of environment conditions, it is intuitively obvious that such thresholds should be considered only as an approximation to a level at which consequences are initiated and our estimates of the probability of these thresholds being surpassed cannot be exact. Here we see that both alleatory and epistemic uncertainty affect our estimate of this threshold probability.

Traditionally, the role of conservatism is at least in part to compensate for uncertainties in our knowledge base, both alleatory and epistemic uncertainty, via some factor used to shift the design level in a manner that compensates for the lack of knowledge (i. e., an attempt to account for inaccuracies in our theories and models of nature and/or in our quantification of the probabilities of factors which influence these levels). In many engineering fields, it has been common practice to include the effects of such uncertainty through the application of a codified *safety factor* or some similar device; however, newer methods are beginning to evolve toward the consideration of risk in a more formal probabilistic sense.

Historically, two fundamentally different approaches have been used to estimate threshold values for the design of critical infrastructure: approaches based on the establishment of a deterministic estimate of an upper limit for a hazard level and approaches

based on the probabilistic estimation of a design level associated with a selected value for an acceptable hazard/risk level. Our review here will show that the field of engineering has been shifting through the years from the first approach to the second and that this trend is continuing.

Examples of the deterministic upper-limit approach can be found in early concepts used for designs of harbor protection, primarily based on somewhat subjective extrapolations of visual observations [26.36]. They have continued to play a dominant role in the development of design specifications throughout much of the twentieth century, including the estimation of environmental conditions for siting nuclear power plants in coastal areas, the formulation of design parameters for large dams, and the design of large coastal structures for protection from tsunamis. These methods tacitly assumed that there was no epistemic uncertainty in their estimated maximum values; hence, the estimated deterministic levels could be interpreted as absolute upper limits which could not be exceeded (i. e., the annual exceedance probability was zero or, conversely, the average return period was infinite). As will be discussed subsequently, applications of ultimate limits assuming no uncertainty can be under-conservative compared to probabilistic design levels; however, functioning structures based on this earlier approach still exist in many areas of the world.

Examples of the second approach include design specifications for most site-specific coastal structures around the world since the middle of the last century, when the combination of measurements and predictive tools attained sufficient skill to permit such estimates. Initially, these estimates were based predominantly on historical storms; but with time, there has been a slow transition from designs based only on events occurring in the historical record at a given site toward designs that consider all events that could occur at that site. Early during the development of the probabilistic approach, the accepted hazard level was taken to be associated with an annual exceedance probability of 0.01 (a mean interval between exceedances of 100 years). As shown earlier in (26.5) and the discussion following that equation, such a probability level does not represent a very low risk for many critical designs or applications, since there is a 1 in 3 chance that such a value will be exceeded in about 40 years.

26.3.1 The Development of Deterministic Methods

Before modern risk concepts, analytical tools, and computer codes existed, it was still necessary to estimate design parameters for various engineering applications. For example, in the 1950s, nuclear power began to be harnessed for commercial applications; and the issue of plant location quickly became extremely important to the overall scientific and engineering communities, as well as the public at large. Initially, a major consideration was given to issues related to national defense; and although the importance of this issue faded with time, it influenced the siting of many of the earliest nuclear power plants. In addition to economic and national defense issues, these plants were expected to be located in areas where natural hazards would not adversely affect performance and safe operation over their expected lifetime. The list of potential hazards considered was quite comprehensive and included the effects of earthquakes (both direct such as ground motions and indirect such as the loss of cooling water); atmospheric phenomena (lightning, tornadoes, tropical cyclones, etc.); flooding due to coastal storms, tsunamis and precipitation; and wave action superimposed on top flooding events.

A well-documented example of a deterministic design approach can be found in the methodology for siting of nuclear power plants in US coastal areas affected by hurricane storm surges. In 1959, the US Army Corps of Engineers (USACE) contracted the National Weather Service (NWS) to develop a hypothetical hurricane that could be used to design hurricane protection projects along the Gulf and Atlantic coasts of the United States. At that time the NWS, as part of its National Hurricane Research Project, set out to define *the most severe storm that is considered reasonably characteristic of a region*, defining a storm with such characteristics as the *Standard Project Hurricane* (SPH) [26.37]. Since their storm definition was related to nuclear power plants, the estimated maximum value possible was consistent with the concept of a very low allowable risk. *Graham* and *Nunn*'s report [26.37] contains a description of the derivation of the storm parameters for SPH along US Gulf and East coasts.

It is clear that all project designs do not require a level of acceptable risk as low as that used for nuclear power plants; so in 1979, the NWS Technical Report 23 [26.38] redefined the SPH in a fashion that would permit it to be more broadly applied. In this report, the SPH was defined as:

> *a steady state hurricane having a severe combination of values of meteorological parameters that will give high sustained wind speeds reasonably characteristic of a given region.*

This removed the idea that the SPH was related to the *most severe storm* expected in a particular area. Since many coastal projects are examined on an economic basis over a fixed interval of time, this re-definition of the SPH offered more general guidance on the relation

cost/benefits for a project. In fact, NWS goes on to say that this revised

> *concept of the SPH has been developed for Gulf and Atlantic coasts as a benchmark against which to judge the hazards for a particular community.*

Also in NWS 23 [26.37], the concept of a *probable maximum hurricane* (PMH) was introduced as:

> *a hypothetical steady-state hurricane having a combination of values of meteorological parameters that will give the highest sustained wind speed that can probably occur at a specified coastal location.*

It is clear from this definition that the PMH was intended to be an event that was much rarer than the SPH; but it is not clear that an objective definition can be gleaned from what is written in NWS 23. In its executive summary, NWS 23 states that the central pressure of the PMH *is simply the lowest sea-level pressure at the hurricane center*. Estimated central pressures for the PMH within the Gulf of Mexico had values ranging from about 887 mb at Port Isabel, Texas to about 891 in the vicinity of Apalachicola, Florida and then diminishing to about 885 at Fort Myers, Florida (Fig. 26.4). These are all values which are substantially lower than the lowest central pressure available in any observations within the Gulf of Mexico at that time and no methodology for their derivation is given. Thus, it is likely that a considerable amount of *expert judgment* was utilized in estimating these values. The treatments of the other parameters used to define the PMH (peripheral storm pressure p_0, radius to maximum winds R_{max}, forward speed of the storm V_f, storm heading θ_f) and the latitude of the eye of the storm φ_c) are all relatively straightforward; however, correlations among the parameters were not addressed.

Besides the apparent subjectivity in the SPH and PMH definitions, other problems with this deterministic approach have arisen. For example, the use of *sustained wind speed* as the fundamental parameter for specifying the combination of PMH characteristics implies that the highest sustained wind speed will always produce the highest storm surge and that other storm parameters are less significant to storm hazard levels and associated risk. However, *Irish* et al. [26.39, 40] have clearly shown that storm size can be equally important to the magnitude of the storm surges. Figure 26.5 from [26.39] shows that Hurricane Katrina, although a much weaker storm than Hurricane Camille at the time of landfall in Mississippi, produced much

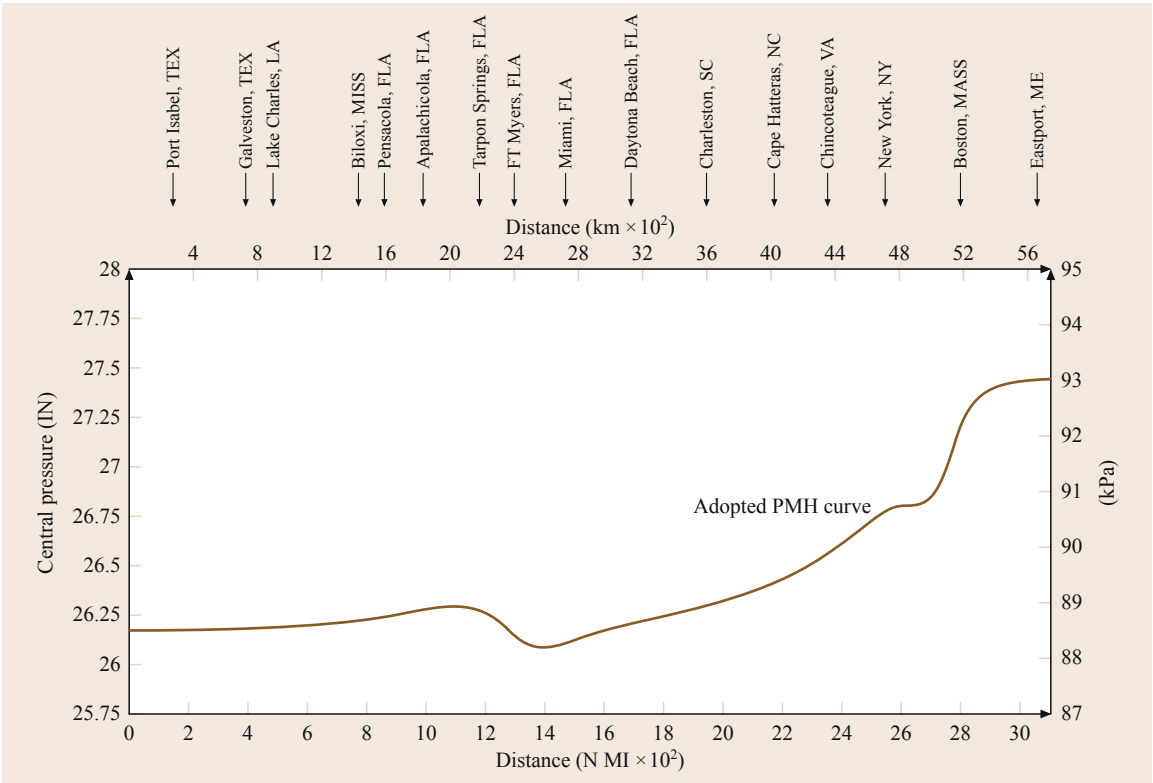

Fig. 26.4 Central pressure for PMH along US Gulf and East coasts (after [26.37])

higher surges there, consistent with results produced by idealized simulations. Additionally, storm approach direction can be important even along straight coastlines but can become exceptionally important on coasts with irregular shapes.

This particular example also affords a good opportunity to examine problems related to overly simplistic representations of the physics of processes in hazard/risk analyses. In the 1950s, the state of the art in surge prediction was quite crude and assumed that inland surges could be estimated via a two-step procedure, with the first step producing an estimate of the wind-driven surge levels at the coastline (neglecting the contributions of wave setup to these water levels) and the second step using hydrologic flow models to convey the water inland (neglecting both wind and wave contributions to inland surge levels). Subsequently, many studies demonstrated the need to estimate inundation in inland areas by including the effects of winds, topography, precipitation, and river discharge within an area [26.41–44]. Wind–wave contributions to coastal flooding have also been shown to be very significant in areas where the nearshore slope is high [26.41]. Based on all these studies, two primary results should be recognized. First, it is not possible to utilize a single factor to characterize waves and flooding in coastal and near-coast areas; and second, the older paradigm in which water levels were first estimated at the coast, using equations appropriate for surge prediction, and then allowed to propagate inland, using equations appropriate for hydrologic flow modeling, is inconsistent with today's state of the art.

There is an obvious analog between good computational models (Chap. 26) and good measurements in the estimation of extremes. No one would trust a design based on measurements known to have deficiencies leading to potentially large biases and random errors. In a similar vein, it is essential to obtain reliable, unbiased estimates from models of winds, waves, and surges for applications to hazard/risk assessment. Only after a modeling system is shown to be capable of generating accurate estimates is it worth expending the huge resources necessary to execute the number of computational simulations in such a system that would be required to provide reliable estimates of extremes.

26.3.2 The Development of Probabilistic Methods

During the latter half of the twentieth century two factors began to emerge which combined to allow significant progress in our capabilities for estimating coastal extremes: an improved theoretical foundation for the estimation of extremes and significantly increased quantities of data for analysis. The latter of these was associated with the development of automated measurement systems for waves and water levels in the 1960s and 1970s. For some purposes, such as daily operations at ports and coastal shipping routes, these direct measurements afforded an excellent source of quantitative information, since requirements for these purposes did not focus on extremes. For other applications, such as the design of breakwaters or the estimated recurrence of coastal flooding levels, the limited data collected from direct measurements proved to be insufficient, due to the short duration of available measurements.

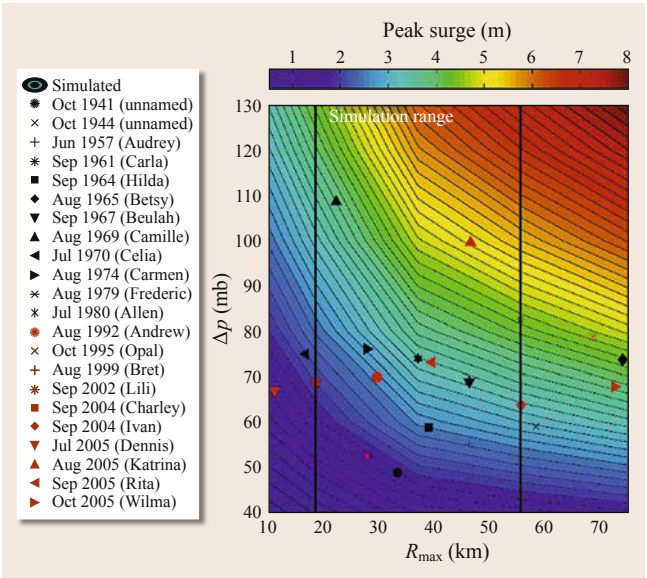

Fig. 26.5 Simulated peak surge as a function of hurricane size (R_{max}) and intensity (Δp) for a 1 : 10 000 bottom slope case. Historical R_{max} and Δp observations are superimposed on the numerical results to indicate peak surge potential of the historical storms (after [26.39], courtesy of American Meteorological Society)

An improved theoretical framework for extremes began to emerge when researchers started to question the application of empirical formulae to extremes based only on its *goodness-of-fit* to a given sample. Pioneers in this field such as Gumbel, Jenkinson, and Gringorten built upon earlier mathematical foundations of *Fisher* and *Tippett* [26.45], and *Gnedenko* [26.46] and began to develop improved methods for treating the behavior of the upper *tail* of the distribution of extremes. Following the work of these individuals, the concept of a generalized extreme value (GEV) distribution was formed. *Borgman* and *Resio* [26.47] offer an example of the application of GEV method to coastal hazards. More recent general reviews of the estimation of extremes from the sequences of random variables can be found in [26.16, 48].

The fundamental concept for the GEV is based on the analysis of asymptotic characteristics of probability functions. In this context, two CDFs are said to be of the same type if there exists constants $a > 0$ and b such that $F_1(ax + b) = F_2(x)$, where the subscripts denote the different CDFs. It was shown by *Fisher* and *Tippett* [26.45] that, excluding certain improper distributions characterized by discontinuities in the CDF, there are only three possible limiting distribution types which meet this constraint. *Jenkinson* [26.49] showed that all three of these asymptotic distributions could be written in a common form

$$F(x) = \exp - \left[1 + \varepsilon \left(\frac{(x-c)}{d}\right)^{\frac{-1}{\varepsilon}}\right] , \qquad (26.7)$$

where c, d, and ε are parameters of the distribution. For the case of $\varepsilon = 0$, this equation is defined over a range of x from $-\infty$ to $+\infty$ and reduces to the two-parameter Gumbel distribution, sometimes termed the Fisher–Tippett Type I distribution.

$$F(x) = \exp[-\exp(-y)], \quad \text{where } y = \frac{x-c}{d} . \qquad (26.8)$$

For $\varepsilon > 0$, the resulting distribution is a Frechet (or Fisher–Tippett Type II) distribution, which is bounded at the low end of the distribution but is unbounded for large x; and for $\varepsilon < 0$, the resulting distribution is a Weibull (or Fisher–Tippett Type III) distribution. The Weibull distribution has an explicit upper limit, but is unbounded in the negative direction.

Returning to Figs. 26.1 and 26.2, we see why a simple plot of x versus $-\ln\{-\ln[F(x)]\}$ will form a straight line if the sample follows a Gumbel distribution. If the points tend to curve upward on such a plot, the distribution is of the Fisher–Tippett Type III form; and if the points tend to curve downward, the distribution is of the Fisher–Tippet Type II form, which predicts larger values of x than the Gumbel distribution for a given value of the CDF.

Shortly after applications with GEV distributions began to become widespread, a second distribution with a somewhat different theoretical basis was introduced. This distribution, the generalized Pareto distribution (GPD), was first published by *Pickands* [26.50] and has been further developed by many subsequent researchers, with some of the more topical for our purposes being *Resnick* [26.14] and *Davison* and *Smith* [26.51]. Methods for fitting the GPD can be found in articles such as [26.52] and are now available in many statistical packages. The GPD can be written in the form

$$F(x|x_c) = 1 - \left(1 + \varepsilon' \frac{x_c}{\mu'}\right)^{\frac{-1}{\varepsilon'}} , \qquad (26.9)$$

which has three parameters (ε', μ', and x_c), similar to the GEV, and also similar to GEV; the GPD has three basic forms depending on ε. With $\varepsilon' = 0$, the GPD approaches an exponential form given by

$$F(x|x_c) = 1 - \exp\left(-\frac{x}{\mu'}\right) . \qquad (26.10)$$

Since the exponential and double exponential (Gumbel) distributions have been shown to converge for mean recurrence intervals greater than 7 years (based on annual data), significant deviations between the GPD and GEV for the case of $\varepsilon = \varepsilon' = 0$ tend toward zero for estimates of values with mean recurrence intervals greater than 7. When ε' is positive, the GPD will be similar to a Fisher–Tippett Type II and when ε' is negative, the GPD will be similar to a Fisher–Tippett Type III.

It is sometimes argued that the GPD is superior to the GEV, due to its formal incorporation of a threshold into its derivation; however, the essence of this distinction lies in the assumption that a sample of values from nature represents a *homogeneous population* in a statistical sense. As will be shown later in this chapter in Sect. 26.3.4, samples in nature often contain a mixture of populations. For example, large surges and waves can be generated along coasts by both extratropical and tropical storms. In smaller basins, squall lines and thunderstorms can become dominant wave and surge producers. Wherever possible it is advisable to try to avoid mixing populations from clearly different sources, but sometimes the ability to recognize more subtle variations can be obscured. A good example of this can be found in the work of *Resio* [26.53], who showed that what appeared to be a Fisher–Tippett II distribution for hindcast wave heights in the Cape Hatteras area was actually the sum of different types of storms definable in terms of how far off the coast they were when they passed Cape Hatteras. Estimated values within the record length are usually not affected by this mixed population problem however, it can become very significant when extrapolating to larger values.

Given the previous discussion, and hopefully without unduly disparaging the excellent theoretical work which has been accomplished in the field of extreme statistics, it should be recognized that given the nuances in the different theories upon which the GEV and GPD are based, it is difficult to argue definitively that one class of distribution is superior in applications to the other. Both distributions represent either a two-parameter distribution (for the limiting case $\varepsilon = \varepsilon' = 0$)

or a three-parameter distribution (for the case that either $\varepsilon \neq 0$ or $\varepsilon' \neq 0$). As noted here, samples of coastal winds, waves, and surges often contain very significant effects related to mixed populations, such as the obvious differences in statistical populations in surges generated by tropical cyclones making landfall some distance away from a site versus surges generated by a direct tropical-cyclone hits. These effects typically far outweigh any differences in theoretical justifications for using a GEV versus a GPD analysis. Because of this, it is probably better to develop a good level of familiarity with a tool of preference and use it appropriately (either the GEV or the GPD) rather than to be able to apply both distributions only marginally.

Returning to the problem of record lengths that are short relative to the mean recurrence interval of the design event, it is necessary to quantify the impact of randomness in the samples on the estimated values before we can assess the importance of this issue. As mentioned at the end of the last section, the quality of individual samples is an important factor in the estimation of extremes. Once routine measurements began to become available, there was an implicit expectation on the part of some that measurements would replace model estimates as the primary source of information used in the estimation of extremes. However, two sources of uncertainty can affect estimated extreme values: epistemic uncertainty in the sampled data (for example, theoretical unknowns and errors in model results) and alleatory uncertainty in the sampled data (natural randomness in the sample). Thus, there is a trade-off between using a short interval of very high quality measurements, removing most of the epistemic uncertainty, and using a long interval of lesser quality model results, which would reduce the alleatory uncertainty but would increase the epistemic uncertainty component.

Many studies in the 1960s and 1970s utilized a combination of theoretical formulations and computer simulations to establish guidelines for the standard deviations of estimates (sometimes referred to as confidence bands) around the value of x at a specific AEP. In most cases, the range of interest for design applications is beyond the range of observations. For example, the typical mean return interval was 100 years in most early design studies. However, in mapping flood zones for FEMA studies today, values up to the 500-year mean recurrence interval are required. For other applications, such as large offshore structures and coastal defenses in many areas of the world, the mean recurrence intervals of interest tend to be in the 1000s or even 10 000s of years, and probabilistic estimates for highly critical infrastructure such as nuclear power plants have been established to use mean recurrence intervals in the range of 1 000 000 to 10 000 000 years. Such estimates must consider the inherent uncertainties in extrapolations that are many times the length of the observational record. Estimates of standard deviations can be obtained by a number of methods based on the GEV or GPD forms [26.49, 54–56].

A useful form for the sampling uncertainty was given by *Gringorten* [26.57, 58]. Using a combination of theoretical characteristics and numerical testing, he showed that the expected root-mean-square (RMS) error of an estimated value as a function of mean recurrence interval in a Gumbel distribution could be estimated from the relationship

$$\sigma_T = \sigma \sqrt{\frac{1.1000y^2 + 1.1396y + 1}{N}} \,, \tag{26.11}$$

where σ is the distribution standard deviation; σ_T is the rms error at return period, T; N is the number of samples used to estimate the distribution parameters; and y is the reduced Gumbel variant given by $y = (x - \alpha)/\beta$; x is the value of the variable; and α and β are the parameters of the Gumbel distribution.

For a Gumbel distribution, the reduced variate and return period are related by

$$y = -\ln\left[\ln\left(\frac{T}{T-1}\right)\right] \,, \tag{26.12}$$

which for $T > 7$ years approaches an exponential form given by

$$\left(T - \frac{1}{2}\right) \to \mathrm{e}^y \,. \tag{26.13}$$

Equation (26.11) shows that the rms error at a fixed return period is related to the distribution standard deviation and the square root of a dimensionless factor involving the ratio of different powers of y (y^2, y^1, and y^0) to the number of samples used to define the parameters. In our previous description of the Gumbel distribution, we saw that the CDF for such a distribution has a double exponential form.

By the method of moments, the Gumbel parameters can be shown to be given by

$$\mu = c - \gamma d, \quad \sigma = \frac{\pi}{\sqrt{6}} d \,, \tag{26.14}$$

where γ is Euler's constant ($= 0.57721\ldots$), μ is the distribution mean, and σ is the distribution standard deviation.

Thus, the distribution standard deviation is related to the coefficient of variability for the distribution and

can be used for estimating the expected width of the confidence bands for a specified return period. The dependence of the confidence limits as a function of the mean recurrence interval and the presence of the square root of the sample number in the denominator show that these limits will become very large when one is extrapolating to several times the record length. Figure 26.6 gives an example for return periods greater than 100 years given a distribution standard deviation of only 0.25 m, which is somewhat smaller than found in many natural data sets. This figure shows the importance of record length to alleatory uncertainty (due to natural variation, see Sect. 26.A). The estimation of a 10% exceedance or 1% exceedance above the Gumbel value at a specific return period can be obtained by multiplying the estimated value of σ_T by 1.08 and 2.33, respectively, since the assumption of normality is inherent in this estimation method.

Although (26.11) through (26.14) were initially derived for applications to annual maxima, they can be adapted to any time interval for data sampling in a straightforward manner. For the case of tropical cyclones, the average interval between storms (the inverse of the Poisson frequency used in the compound Gumbel–Poisson distribution) can be used to transform (26.11) into the form

$$\sigma'_T = \sigma \sqrt{\frac{1.1000y'^2 + 1.1396y' + 1}{N'}} \,, \tag{26.15}$$

where σ is the distribution standard deviation; σ'_T is the rms error at return period, $T' = T/\hat{T}$, where $\hat{T}$ is the average years between hurricanes, and N' is the number of samples used to estimate the distribution parameters $(N/\hat{T})$.

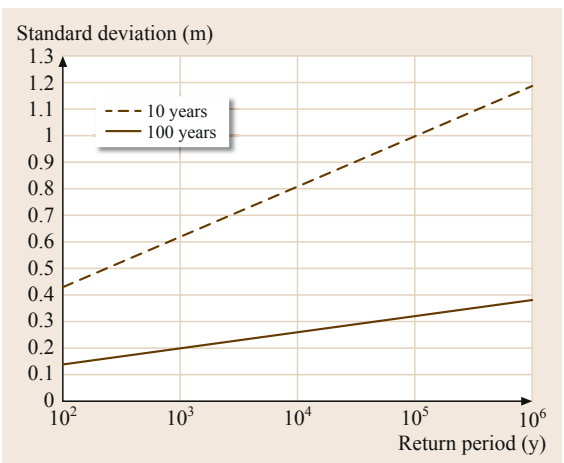

Fig. 26.6 Example standard deviation for confidence limits for a Gumbel distribution with a standard deviation of 0.25 m, shown here for sample lengths of 10 years and 100 years

Many decision-makers believe that the *best-fit* line for a distribution of extremes provides an unbiased estimate of the encounter probability of a value equal to or greater than a specific threshold; and this would be true if there were no alleatory or epistemic uncertainty in our sample. *Resio* et al. [26.44] have shown that uncertainty of both types can affect the expected encounter probabilities. In particular, their study shows that the estimated standard deviation provides a good means of quantifying the spread of the probabilities around the deterministic estimate; in this context, the probability of encountering a given surge value can be written in terms of an integral in two dimensions with a delta function to reduce it back to a single dimension

$$p(\eta) = \int_0^\infty \int_{-\infty}^\infty p[\hat{\eta}(T) + \varepsilon_\eta | \hat{x}] p(\hat{\eta}) p(\varepsilon_\eta) \times \delta(\hat{\eta} + \varepsilon_\eta - \eta)\, \mathrm{d}\varepsilon_\eta\, \mathrm{d}\hat{\eta}(T) \,, \tag{26.16}$$

where $\hat{\eta}(T_r)$ denotes the deterministic estimate of η for a given return period and ε_η denotes the deviation from the deterministic surge estimate.

In (26.6), the estimate for $p(\varepsilon_\eta)$ is taken as a Gaussian distribution with the mean value at $\hat{\eta}$ and the standard deviation taken from the equation for estimating confidence bands, which will have the form

$$p(\varepsilon_\eta | \hat{\eta}) = \frac{1}{\sigma_T \sqrt{2\pi}} \mathrm{e}^{-\frac{1}{2}\left(\frac{\varepsilon_\eta}{\sigma_T}\right)} \,, \tag{26.17}$$

where σ_T is the standard deviation of the estimate at a given value of $\hat{\eta}$.

Equation (26.16) can be integrated directly to convert to a return period representation using estimates of population parameters and standard deviation as shown by *Resio* et al. [26.44]

$$T(\eta) = \frac{1}{1 - F(\eta)} \,, \tag{26.18}$$

with

$$F(\eta) = \int_0^\infty \int_{-\infty}^\infty p[\hat{\eta}(T) + \varepsilon_\eta | \hat{\eta}] p(\hat{\eta}) p(\varepsilon_\eta) \times H(\hat{\eta} + \varepsilon_\eta - \eta)\, \mathrm{d}\varepsilon_\eta\, \mathrm{d}\hat{\eta}(T) \,, \tag{26.19}$$

where $H(g)$ is the heaviside function, equal to 1 if $(g) \geq 0$ and equal to 0 if $(g) < 0$.

To give an example of the impact of extrapolating many times the record length of the sample on the expected encounter probabilities, the *Resio* et al. [26.44]

study analyzed central pressures from a 70-year interval for the west coast of Florida. Since surges are related more to tropical cyclones which make a landfall than to exiting tropical cyclones, they stratified their storm sample to include only storms with a general west to east motion in a latitude-longitude box with boundaries at 81°W and 85°W longitude and 25°N and 30°N latitude. Additionally, to eliminate very weak storms which might behave differently to well-organized storms, they further limited the storms included within their sample to those with central pressures less than 990 mb within the selected geographic area. Using the most recent reanalysis data available from NCDC (National Climate Data Center), it was determined that most storms before about 1940 did not report central pressures; consequently, the analysis was limited to the interval 1940–2009.

Figure 26.7 shows the results of this integration for three Florida cases compared to the original deterministic estimate from [26.44]. Case 1 is the deterministic solution for the return period based on the best-fit Gumbel distribution. Case 2 is a test of the numerical algorithm generated by representing the probability of the deviations as a delta function (i. e., all of the probability exactly on the deterministic line), which was computed as a test case for the integration algorithm. As expected, this case exhibited no significant deviations from case 1, so the case 1 and case 2 lines are identical. Case 3 shows the results using standard deviations equal to the estimated distribution standard deviations divided by 2, simply to provide an indication of how nonlinear the dependence is on the standard deviation in the confidence band when compared to case 4; case 4 shows the results for the estimated standard deviation. These results indicate that in this region of the Gulf of Mexico, the encounter probabilities of central pressure (a surrogate for tropical cyclone intensity) are markedly affected by sample uncertainty.

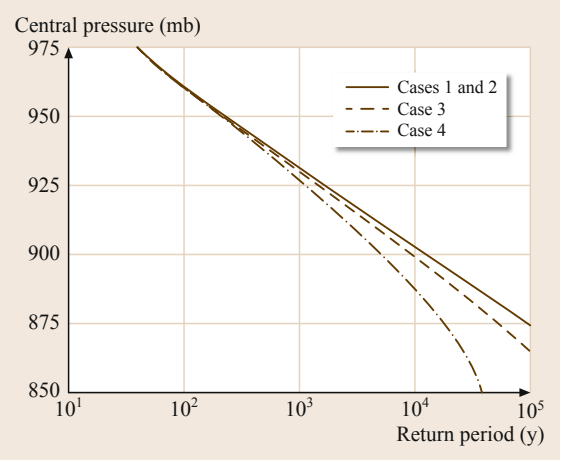

Fig. 26.7 Comparison of expected return periods for central pressures without uncertainty considered (cases 1 and 2) and with uncertainty considered (cases 3 and 4) for the West Florida region using data from 1940–2009

A curious aspect of these results is the increasing deviation between the lines as the return period increases. Whereas the 10 000-year value for the distribution which includes the full uncertainty (case 4) is slightly higher than the maximum possible intensity (MPI) value of 880 mb assumed here, the 40 000-year value has a much lower value (850 mb). This suggests that the role of uncertainty in very low probabilities is to act as a sort of filter for how long of a time period one can extrapolate before the uncertainty begins to become a dominant contributor to the distribution. Even at the 10 000-year value for the central pressure, the pressure differential has already been increased by about 20% over its value with uncertainty neglected. Since values for maximum possible surges in many areas along the west Florida coast are around 10 m, the impact of including this uncertainty would add about 2 m to the design surge levels over the deterministically estimated values.

26.3.3 The Development of the Historical Storm Method for Estimating Coastal Extremes

By the 1980s, it was widely recognized that record length was a significant factor in the confidence that could be placed on estimates of extremes. This led to a quandary of sorts. How could estimates of 100-year values be meaningfully estimated when observational data from measurements covered only relatively short time spans? In addition to the lack of long record lengths for waves and surges, careful review of the available measurements showed that data from large storms were often missing, further compromising the ability of measurements alone to provide a suitable base for the estimation of design values. The answer came via the development of improved physics-based models for predicting waves and surges from available meteorological information. Since meteorological information extended much farther back in time, it was hypothesized that reconstructions of winds and pressures for past events could be used to drive wave and surge models to obtain a surrogate for measurements during these storms. As noted previously, however, it is critical that the computational models used for this purpose are sufficiently accurate to provide accurate unbiased estimates of the extreme values.

This focus on storm hindcasts (the estimation waves and/or surges during past intervals of time) soon be-

came the primary method used in many offshore designs [26.60] as well as in many coastal designs [26.61–64]. Over time, it began to be evident that the selection of storms for hindcasts of waves and surges often exhibited different CDF characteristics in different magnitude ranges. This led to the development of the points over threshold (POT) method for estimating extremes. In this method, only the sample values above some threshold would be included within the sample to be fit by the selected parametric form.

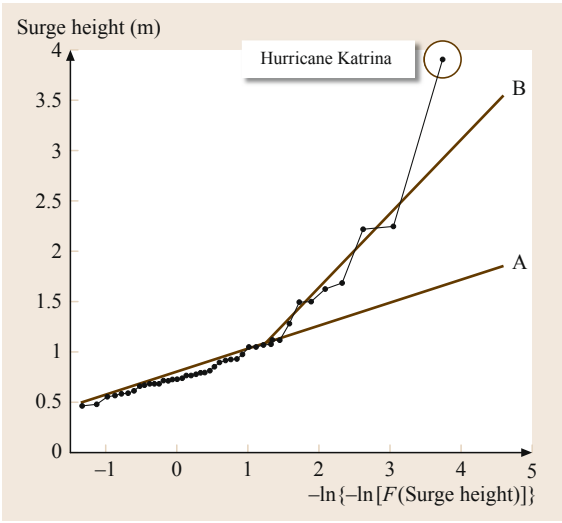

Fig. 26.8 Graph of a sample of hindcast surge heights as a function the double-negative logarithm of the CDF. The *line labeled A* represents storms which made landfall a significant distance away from the site, while the *line labeled B* represents hurricanes which made a landfall in the immediate vicinity of the site. The *single circled point* represents the surge at this site from Hurricane Katrina

Figure 26.8 is a good example of the situation faced by many planners and engineers when dealing with real-world data and helps to demonstrate the need for the POT approach in many situations. In this example, the data is actually more recent than the data that was used initially to justify the POT in earlier studies; however, the point is the same. The data shown here are simulated hindcast storm surges for a site in Lake Pontchartrain, Louisiana. A simplistic concept would be to use a three-parameter GEV (or GPD) distribution to fit the overall distribution. This would imply that Hurricane Katrina was only about a 65-year event in terms of the surges that it generated at this site; however, based on several independent analyses, it appeared that such a surge level would be expected considerably less frequently than this.

In Fig. 26.8, we have added two lines labeled A and B, representing a stratification of the surges at this site based on the proximity of landfall to the site. As can be readily seen and as expected from the physics of surge generation, there is a substantial difference between these two groups of events. This finding is consistent with the findings of researchers who had for years been advocating for the necessity of stratifying the sample before fitting the sample data to some parametric distribution. An interesting additional issue arises in Fig. 26.9. This relates to the issue of *outliers*. An outlier is an event that is believed to represent something

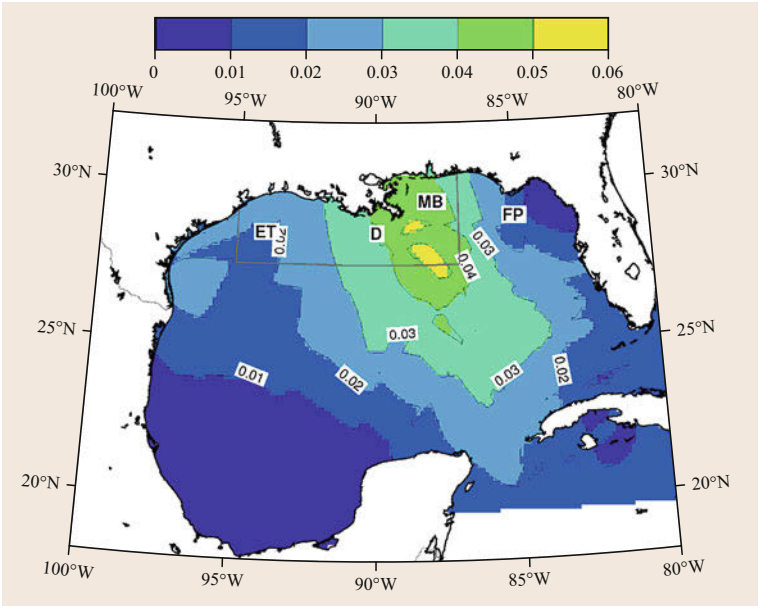

Fig. 26.9 Analysis of hurricane frequency within the Gulf of Mexico based on an analysis using an optimized spatial kernel (after [26.59]

that would only happen much less often than the time span of the sample record. It is intuitive that even the 1 000 000-year event must happen in some 10-year sample, so the historical treatment for these points was to consider them as not representative of the record length within which they were sampled. Such points were typically simply omitted from the distribution fitting process; however, it seems obvious that this omission for all points in a region neglects a potentially valuable piece of information from all of the analyses in an area.

26.3.4 The Development of Alternative Methods

The tragedy of Hurricane Katrina emphasized the point that reliable estimates of coastal hazards and risks should include the effects of all storms that can occur in an area and not just the events that occurred within a particular historical sample. However, as early as the 1970s, this had been recognized, and alternative methods started to be developed which afforded improved estimates of coastal hazards and risks. Probably the two most widely used of these methods have been the joint probability method (JPM), along with a derivative of the JPM termed the JPM-OS (joint probability method optimal sampling), and a second approach which, in this handbook, we will term the empirical track method (ETM). Material from a US Army Corps of Engineers White Paper [26.65] and a reduced version of the White Paper [26.66] will form a substantial portion of our discussions of these developments, and a considerable amount of details on the specifics can be found there.

The Development of the Joint Probability Method (JPM)

The JPM was developed for application to coastal surges in the 1970s [26.67, 68] and subsequently extended by a number of investigators [26.38, 69] in an attempt to circumvent problems related to limited historical records. In this approach, information characterizing a small set of storm parameters was analyzed from a relatively broad geographic area. In applications of this method in the 1970s and 1980s, the JPM assumed that storm characteristics were constant along the entire section of coast from which the sample was drawn. This assumption is inconsistent with more recent studies (Fig. 26.9) which show that storm frequencies vary substantially in this area.

The JPM used a set of parameters, including central pressure, radius of maximum wind speed, storm forward speed, storm landfall location, and the angle of the storm track relative to the coast, to generate parametric wind fields. Furthermore, initial applications of the JPM assumed that the values of these five parameters varied only slowly in storms approaching the coast; therefore, the values of these parameters at landfall could be used to estimate the surge at the coast, and these values could be treated as a constant during the approach of a storm to the coast. Recent data shows that this is not a good assumption [26.70, 71]; specifically, these studies suggest that tropical cyclones decay as they approach land. *Kimball* [26.72] has shown that such decay is consistent with the intrusion of dry air into a tropical cyclone during its approach to land, although other hypotheses for this consistent decay in intensity, such as the lack of energy production from parts of the tropical cyclone over land and increased drag in these areas have also been advanced. In any event, the evidence appears rather convincing that major tropical cyclones begin to decay substantially before they make landfall, rather than only after landfall as previously assumed.

The initial formulation of the JPM used computer simulations of straight-line tracks with constant parametric wind fields to define the maximum surge value for selected combinations of the basic five storm parameters. Each of these maximum values was associated with a probability

$$p(c_\mathrm{p}, R_\mathrm{max}, v_\mathrm{f}, \theta_\mathrm{l}, x)\,, \tag{26.20}$$

where c_p is the central pressure, R_max is the radius of maximum wind speed, v_f is the forward velocity of the storm, θ_l is the angle of the track relative to the coast at landfall, and x is the distance between the point of interest and the landfall location.

These probabilities were treated as discrete increments and the CDF was defined as

$$F(x) = \sum p_{ijklm} | x_{ijklm} < x\,, \tag{26.21}$$

where the subscripts denote the indices of the five parameters used to characterize the tropical cyclones.

The JPM represents a straightforward application of the *response surface* method for estimating extremes. In this method, the response of a particular variable (such as waves and surges) is derived as a function of several parameters, such as the set $(c_\mathrm{p}, R_\mathrm{max}, v_\mathrm{f}, \theta_\mathrm{l}, x)$ used in the above example. Given that the multivariate probability of the five-parameter space is known and a method for defining the response from this set of variables is known, the equation for the CDF for the response can be written for this example as

$$\begin{aligned} F(\eta) = \int\int\int\int\int & p(c_\mathrm{p}, R_\mathrm{max}, v_\mathrm{f}, \theta_\mathrm{l}, x) \\ & \times H[\eta - \Lambda(c_\mathrm{p}, R_\mathrm{max}, v_\mathrm{f}, \theta_\mathrm{l}, x)] \\ & \times \mathrm{d}c_\mathrm{p}\mathrm{d}R_\mathrm{max}\mathrm{d}v_\mathrm{f}\mathrm{d}\theta_\mathrm{l}\mathrm{d}x\,, \end{aligned} \tag{26.22}$$

where Λ represents the model used to convert the parameters to an estimate of maximum surge for each event as a function of $(c_p, R_{max}, v_f, \theta_l, x)$; however, it is easy to see that this approach can be generalized to any set of n parameters for which a response surface can be defined, along with the multivariate probability distribution. Variations on the methodology for evaluating the parameter probabilities and the storm set to be simulated have been presented by *Toro* et al. [26.59], *Niedoroda* et al. [26.73], *Resio* et al. [26.70], and *Irish* et al. [26.74]. Each has its advantages and disadvantages, and as long as the multivariate probability function is sufficiently resolved in the integration process, the results should be in reasonable agreement with each other.

Similar to the EST, this method is nonparametric with respect to the form of the CDF; however, the type of extrapolation used to extend the JPM result beyond the record length is very different to that used by the historical storm method. As shown by *Irish* et al. [26.75], the former of these is based on probability estimates which are much more smoothly varying than the local surge response inherent in the historical data, which means that when applied the JPM provides a significant decrease in sampling uncertainty, when compared to the historical storm method.

A potential advantage of the JPM over methods which depend heavily on historical storms is that the JPM attempts to consider all storms that might happen in an area; whereas, the EST considered only storms that did happen in that area. For example, the 100-year return period storm set to contain a full suite of $(c_p, R_{max}, v_f, \theta_l, x)$; whereas, the historical storm method will have just one or two storms available in this parameter space. Assuming that, for the purpose of surge generation, storm characteristics can be represented adequately by the set of parameters used, it is possible to construct a Katrina-like storm (high intensity combined with large size) even if one has not happened previously. Likewise, it is possible to interpolate between re-curved storms such as Hurricanes Opal and Wilma to understand probabilities of possible hurricane impacts in the Tampa, Florida area, even though neither of these storms produced significant surges in the Tampa area.

Perhaps the biggest controversy in JPM applications during the 1970s and 1980s centered on the sufficiency of this five-dimension set of parameters used in the joint-probability function to produce accurate wind fields. In addition to this concern, the lack of data on historical storms prior to 1950 made it very difficult to derive representative distributions, even for extended sections of coast. For example, information on storm size (R_{max}) was lacking for most historical storms; consequently, a statistical estimate of R_{max} (as a function of latitude and central pressure) was frequently substituted for actual values in the probability distribution. One wind field factor not considered in early JPM applications was the variable peakedness of tropical cyclone wind fields. This term is represented in terms of the Holland B parameter [26.76] in recent tropical cyclone wind models.

It is clear that the number of primary dimensions within the JPM must be capable of representing wind fields to sufficient accuracy so that they provide reasonable, relatively unbiased skill when used to drive coastal wave and surge models. For the case of extratropical storms, there is no known simple set of parameters that meets this criterion, and some extension of the EST or POT method may be the suitable choice for such applications, at least for recurrence intervals which are not too long (less than 100 years or so). For the case of tropical cyclones, dynamic models of tropical cyclone wind fields [26.77, 78] have been shown to capture a substantial portion of the wind field structure, when driven with the parameters listed above plus the Holland B parameter.

An argument against using the parametric wind fields in the JPM is that each historical tropical cyclone will tend to exhibit some degree of deviation from the theoretical parametric (planetary boundary layer) estimates. At any fixed time, such deviations could be produced by strong storm asymmetries, variations in R_{max} around the storm, enhanced spiral bands, etc. Hence, a *best-estimate* wind field crafted by experts to assimilate all the observations in a given tropical cyclone will typically represent the details of that particular storm much more faithfully than is possible via a parameterized theoretical model. Such wind fields today are produced primarily by groups like the National Oceanic and Atmospheric Administration (NOAA) Hurricane Research Division [26.79]. These wind fields are absolutely essential for advancing our understanding of tropical cyclone winds relative to wave and surge forcing in offshore and coastal areas. An excellent discussion of the reconstruction of historical wind fields and the impact of different approaches on model accuracies can be found in [26.80].

It is obvious that *best-estimate* wind fields contain an extremely large number of degrees of freedom in their formulation. Given the relatively small number of historical tropical cyclones, it is unlikely that we can understand/quantify the probabilistic nature of all the interrelated detailed factors that create these deviations. If these details were absolutely critical to coastal wave and surge estimation, we would be able to represent a past tropical cyclone very accurately but would know little about the probability of future tropical cyclones unless we retained the same number of degrees of free-

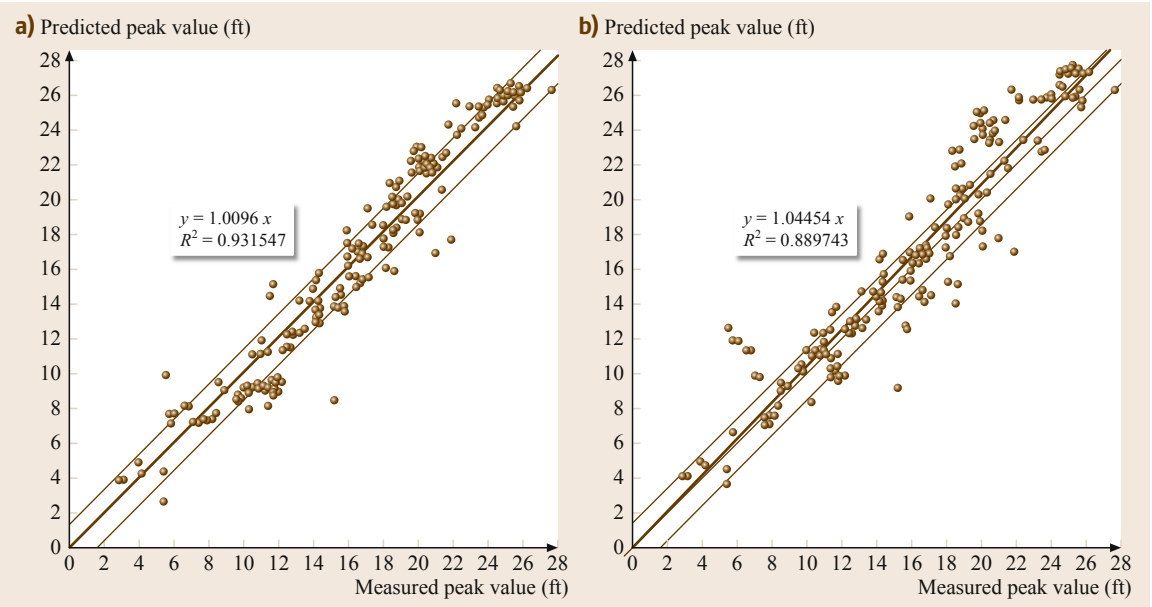

Fig. 26.10 **(a)** Comparison of observed high water marks (HWM, [26.81] for Hurricane Katrina and the computational simulation using *best-wind* wind fields. Points are the values at the recorded HWMs. Lines display a 1 : 1 correlation as well as 1.5 ft standard deviation on each side. **(b)** Comparison of observed HWM for Hurricane Katrina and the computational simulation using the best hand-analyzed post-event wind fields. *Points* are the values at the recorded HWMs. Lines display a 1 : 1 correlation as well as 1.5 ft standard deviation on each side

dom, including their expected variability in estimates of future storm surge and wave estimates. However, Figs. 26.10a and 26.10b show comparisons of hindcast storm surges using *best-estimate* wind and parametric wind fields in a hindcast of Hurricane Katrina. As can be seen in these figures, the differences in the surge model results are relatively small for this case.

Following Hurricane Katrina, improvements to the JPM were made to include additional physical factors affecting the storm and to improve the efficiency of the method [26.40, 66, 70, 74]. These newer methods have played a large role in the estimates of design levels for the new Hurricane Risk Reduction System for New Orleans. A more detailed discussion of these improvements can be found in [26.65].

Empirical Track Method (ETM)

Vickery et al. [26.78] presents a method for modeling hurricane risk in the United States. This method has been adopted for the development of design wind speed maps within the US (American National Standards Institute (ANSI), [26.82, 83]). The ETM uses a Monte Carlo approach to sample from empirically derived probability and joint probability distributions. The central pressure is modeled stochastically as a function of sea surface temperature along with storm heading, storm size, storm speed, and the Holland B parameter. This method has been validated for several regions along US coastlines and provides a rational means for examining hurricane wind risks associated with geographically distributed systems such as transmission lines and insurance portfolios.

A key requirement for the application of the ETM within its Monte Carlo framework is the ability to execute storms over many, many years (20 000 years in the application by *Vickery* et al. [26.78]). As such, a basin-scale study area with an average of three tropical cyclones occurring per year occur would require the simulation of 60 000 storms. Whereas this is not too demanding for the estimation of wind probabilities using an efficiently written planetary boundary layer (PBL) wind model, it is well beyond the range of current computer capacity for existing large, high-resolution ocean and coastal response models (wave models and surge models). For this reason, the ETM is typically not used for applications in which the computational burden for individual events is very high.

In its present form, the ETM is based on an autoregressive approach in which storm parameters at a subsequent time step are determined numerically from the same set of parameters at the current time step, utilizing a set of relationships derived from statistical and theoretical considerations. Although it is recognized that such predictions would contain very large statis-

tical errors for a specific storm, particularly in terms of predictions of storm intensity and size, the predictions appear to approximate certain statistical characteristics of the storm population reasonably well, such as the mean number of storms in an area. What is not so clear is whether they capture the complex multivariate structure that is inherent in interrelationships among storm characteristics, such as the interaction of rates of change of these characteristics and the effect of land proximity. The effect of the omission of these higher order interactions on the statistics of predicted extremes remains a topic for future research.

26.3.5 Probabilistic Analyses of Extratropical Storms

As noted earlier, extratropical storms tend to be more frequent and affect larger coast regions than tropical cyclones due to the relatively large size of these storms. Based on these two considerations, it has been assumed that, for most coastal areas, the use of the historical storm method is adequate for quantifying hazards/risks. However, there are four reasons why this may not be a justifiable assumption given the geometric complexity of many coastal areas, particularly inland areas such as major bays and lakes:

- In some areas, the use of in situ observations to characterize the extremes may contain mixed populations, with a few observations from storms in which strong winds blow along the optimal surge/wave generating direction mixed with many other observations with winds from other directions. In such situations, the former events often have the appearance of outliers. Since a record length of 30–40 years may only contain a single interval of intense storms in which winds line up with the optimal generation direction, this creates a difficult situation for the analysis of extremes and a difficult situation for planners and engineers to assess.
- Although the GPD is specifically derived to fit a distribution above a particular threshold, it is still subject to the statistical constraint that all the samples are drawn from a homogeneous population. Like the GEV, the GPD is still only a three-parameter distribution, and if too many small events are mixed into the analysis, the upper tail of the distribution is very likely to be misestimated. Thus, in applications where researchers choose the lower limit to be given by an arbitrary (pre-selected) number of events, this can lead to a very poor estimation of the actual hazards/risks.
- Earlier, we noted that storm characteristics and frequencies seem to be significantly influenced by multidecadal variations in atmospheric circulation patterns. In these situations, it is exceptionally difficult to quantify the effects of the climatic variability and relatively short-term sample durations may not be adequate for accurately quantifying expected extremes. This is an especially important point relating to the difference between storm events that can occur and storm events that have occurred.
- Due to all of the issues raised in items 1–3 and inherent effects of uncertainty on encounter probabilities, the use of historical storm methods for very low probabilities, as is needed for certain critical infrastructure vulnerability assessment and design, is very difficult to justify without the inclusion of some means to add substantial conservatism into the analysis. Additional research developing a variation of the JPM to fit extratropical storms would be very valuable in meeting this need.

26.3.6 Future Directions and Final Comments

Irish and *Resio* [26.40] show that the effects of storm size, storm forward speed, landfall location, and storm track angle at the coast on storm surges all have asymptotic upper limits in tropical cyclones. Although these upper limits are site dependent, the forms of these limiters can be written in terms of some relatively simple functions. This information can help simplify the estimation of very low probability extremes; since in this very extreme range of surges, it reduces the surge probabilities back to a univariate distribution, in this case a function of a single parameter, storm central pressure. However, as emphasized previously, sampling uncertainty must still be considered in the estimation process. It is likely that, in many areas, the inclusion of sampling uncertainty within relatively small sample sizes will potentially make the estimates of central pressure for AEP values of 10^{-6} unrealistically low. In such situations, it will likely be necessary to combine probabilistic estimates with theoretically derived upper limits to be able to estimate coastal surges. Presently, this theoretical upper limit, the MPI, is still developed via relatively simplistic theoretical formulations combined with empirical envelopes of lowest observed central pressures around the world [26.84–86]. In their present form, this limit is estimated primarily as a function of sea surface temperature; however, more theoretical work will likely show the importance of additional terms to the estimation of the MPI. It should certainly be recognized that any estimate of an MPI will directly contain epistemic errors and indirectly contain alleatory errors due to the sampling distribution used to derive and calibrate theories.

26.4 Summary

On the one hand, we can see that considerable progress has been made in the estimation of hazards and associated risks in coastal areas over the last 100 years. Like all decision-making processes which become codified, it is difficult to change a methodology used for such estimates very quickly; hence engineering practice has often significantly lagged the recognized state of the art of our understanding of coastal hazards and risks, tending to wait until the occurrence of a natural disaster, such as Hurricane Katrina and the tsunami affecting Fukushima, Japan, to foster a willingness to change. Prudent design concepts in areas with critical infrastructure and communities that can be affected by hazards/risks must continue to consider the effects of both alleatory and epistemic uncertainty.

While the discussion herein focuses primarily on the coastal storm problem, the key concepts translate to the wide array of hazards impacting the coast. While each of these hazards will have its own unique set of physical characteristics and statistical challenges, the general concepts discussed here are appropriate for evaluating their probability and risk, as well as for understanding the factors contributing to uncertainty in these extreme estimates.

26.5 Nomenclature

a	specified limit or coefficient
b	specified limit or coefficient
c	coefficient
c_p	storm central pressure
d	coefficient
k	coefficient
n, m	indices
$p(x)$	probability density function
q	coefficient
v_f	storm forward speed
x	variable
x_c	coefficient
AEP	annual exceedance probability
CDF	cumulative distribution function
EST	empirical simulation technique
ETM	empirical track method
$F(x)$	cumulative distribution function
GEV	generalized extreme value distribution
GPD	generalized Pareto distribution
JPM	joint probability method
MPI	maximum possible intensity
N	total number of items
P	probability of exceedance
PDF	probability density function
PMH	probable maximum hurricane
POT	peaks over threshold
$Pr(A)$	probability of event A occurring
$Pr(B\|A)$	probability of a consequence (B) occurring given that event A occurred
R	risk
R_max	storm radius to maximum winds
SPH	standard project hurricane
T	return period (or return interval)
T'	dimensionless return period (or return interval)
ε	coefficient
ε'	coefficient
ε_η	deviation from deterministic surge estimate
η	surge value
θ_l	storm track angle relative to coast at landfall
λ	sampling frequency
μ	coefficient
y	reduced Gumbel variate
σ	distribution standard deviation
σ_T	rms error at return period T
σ'_T	dimensionless root-mean-square error at dimensionless return period T'

26.A Appendix: Glossary of Probability and Risk Terms

- *Confidence intervals*: A confidence interval is a statistical representation of how certain one is that a given variable will lie within a given range. A confidence interval includes two components – the *interval* (the value will be between x and y) and the level of *certainty* (a 90% confidence interval indicates one can say that there is a 90% probability the value *will* fall between the cited interval. As the interval gets smaller, the certainty that the values will fall within the interval goes down. Confidence intervals are related to uncertainty in that they are a statistical method of measuring uncertainty of

a predicted value based on past data that provides the probability distribution and variance of the specific parameter of interest.

- *Error*: Error itself has multiple meanings. In the modeling/predictive sense, the concept of error requires that there be a *correct answer* against which to compare a predicted answer (modeling context) or sample result (statistical context). Error is then defined as the difference between the actual and predicted answer or measured sample. Therefore, in the sense of predictive risk assessment (looking forward in time), error is not a useful concept, as there is not yet any *actual* or *true* value against which to measure or compare. Error should not be confused with *mistake*, which is the result of an incorrect assumption, calculation or model formulation. The hallmark of a mistake is that it is avoidable.
- *Error* (*Types I and II*): Type I error and Type II error are technical terms used in statistics to describe particular types of erroneous results in a testing process. The terms relate to the acceptance or rejection of the hypothesis being tested (the null hypothesis). If the null hypothesis was rejected (found to be false) when it actually is true, then a Type I error occurred. Conversely, if the null hypothesis is not rejected (found to be true) when it actually is not true, a Type II error has occurred. These definitions correlate to the concepts of false positives (Type 1 error) and false negatives (Type II error) in testing. For a good technical tutorial on Type I and Type II errors [26.87].
- *Exposure*: The process of the receptor coming into contact with the hazard.
- *Exposure pathway*: The route by which the receptor is exposed. For animals, this is either by ingestion, inhalation, or dermal absorption.
- *Exposure assessment*: Quantitative analysis of how much (concentration, duration) of the hazard reaches the receptor.
- *Hazard/stressor*: An event (storm, accident), agent (chemical, radiation), situation or action with a potential for an undesirable consequence, such as harm to property, the environment, and human health or life. This term is often used synonymously with threat.
- *Probability*: In its most basic sense, probability is the chance or likelihood that something will happen. Qualitatively, the more likely an event is to happen, the more *probable* the event is. Quantitatively, probability is a value between 0 and 1, with 1 representing absolute certainty of the event occurring. The probability of an event is typically measured as the ratio of the number of times an event occurred over the total number of times the event could have occurred. For example, if we consider the event to be the occurrence of precipitation on any given day, we would collect information on whether it rained on a given day for a period of time (say 1 year). The probability of rain would then be

$$\text{probability of precipitation} = \frac{\text{number of days with precipitation}}{\text{total number of days}} .$$

- *Probability distribution*: The basic definition of probability works for discrete events, but when the event or parameter being evaluated is continuous in nature (the maximum temperature on any given day, the stage of a river on any given day), then a single probability is not sufficient. Instead, possible values are grouped into discrete ranges, and the number of occurrences in that range are counted then divided by the total number of measurements.
- *Receptor*: A receptor is the specific thing or entity being affected by the hazard/stressor. In a human health risk assessment – the receptor is a person.
- *Risk*: The potential for realization of unwanted, adverse consequences to human life, health, property, or the environment. The estimation of risk is usually quantified using the expected value of the conditional probability of the event occurring times the consequence of the event given that it has occurred. This definition is currently used by the Society of Risk Analysis. Mathematically, this is expressed as

$$R = P(A) * P(B|A) , \tag{26.23}$$

where R = risk (a probability from 0 to 1), $P(A)$ = probability of event (A) occurring, and $P(B|A)$ = probability of a consequence (B) occurring given that event A occurred.

This technical definition is what will be used through this handbook. However, there are other definitions in other fields of which the knowledgeable practitioner should be aware. Table 26.2 presents a summary of other definitions used in various fields and a list of citations to which one may refer for more information. In each case, the same mathematical representation can be used, but there are assumptions made that result in the definition being slightly different. This is also presented in Table 26.2.

Besides having multiple potential definitions, risk can also be differentiated by *types*. Different types of risk, even if they are of the same quantitative value, are often managed differently or even ig-

Table 26.2 Risk definitions in different applications

Source	Risk definition	Mathematical representation	References
Occupational Safety and Health Administration (OSHA)	The probability that an adverse effect will occur	In this approach, the event is assumed to happen as the hazard is the item being regulated. For example, the absence of the railing in a factory catwalk would be the hazard. For OSHA purposes, if the hazard exists, then the probability of the accident becomes the risk. Mathematically, the probability of the even $[P(A)]$ is assumed to be 1.0. Therefore, the risk equation becomes: $R = 1 * P(B\|A) = P(B)$	[26.88]
Ecological and Human Health Risk – US Environmental Protection Agency (EPA)	Risk is the overall the probability of injury, disease, or death to humans or damage to the environment resulting from exposure to a chemical, stressor, or occurrence of a hazard. Risk has three components: a hazard, a receptor, and a method for the hazard to reach the receptor (involves both transport and exposure pathway)	The modification in this formulation is that the risk of the effect is not only dependent on the occurrence of A, but on the ability of the hazard to reach the receptor to cause the consequence. Hence, if the occurrence is a release of a toxic chemical, and the outcome of the release on a person is cancer (B), there will be no risk if there is no pathway (P) to the receptor. Mathematically, this means that the probability of the event becomes a conditional probability on the occurrence of the pathway. Therefore, the risk equation becomes: $R = P(A\|P) * P(B\|A)$	[26.89–95]
Medicine, psychology, health and social services	The potential for realization of unwanted adverse consequences or events	This approach, much like the OSHA approach assumes the hazard to be a reality (in this instance, an illness or negative condition such as poverty or exposure to domestic violence). Therefore, there is no probability of a conditional event – the illness/condition *is* the adverse outcome (i. e., $P(A) = 1$). This is also referred to as being *at risk* for some illness or negative outcome. Therefore, the risk equation becomes: $R = 1 * P(B\|A) = P(B)$	[26.96–103]
Nuclear Regulatory Commission [26.104]	Risk is the combined answer to three questions that consider (1) what can go wrong, (2) how likely it is, and (3) what its consequences might be	While posed as three questions, the first two are the definition of the probability of a hazard (e.g., what could go wrong is a pump failure (A), and the probability of that failure is by definition $P(A)$. The third question is the conditional probability of the negative consequence given the occurrence of A. Therefore, mathematically: $R = P(A) * P(B\|A)$	NRC Glossary (Web) [26.105]

Financial Professions	Risk is the chance of loss with respect to person, liability, or the property of the insured or the possibility that the actual return on an investment will be different from its expected return. This includes such things as the danger or probability of loss to an insurer, the amount that an insurance company stands to lose, the variability of returns from an investment, and the chance of non-payment of a debt. Also often defined as the standard deviation of the return on total investment or the degree of uncertainty of return on an asset	In this formulation, the B (outcome) is defined as the deviation from an expectation. Note – this can be either positive or negative (return can exceed expectation), but the scenarios examined typically are only those which will produce a negative impact. If we assume the expected return of an investment to be x, the actual return realized to be x_a, and the difference to be defined as $D = (x_a, -x)$, then the risk financially if some event A occurs is: $R = P(A) * P(D\|A)$	[26.106–113]
United Nations	Risk is defined as the uncertainty that surrounds future events and outcomes. It is an expression of the likelihood and impact of an event with the potential to influence the achievement of the organization's objectives and goals. Risks in the United Nations context are normally referred to as programmatic and operational areas that have the greatest exposure to inefficiencies, ineffectiveness, fraud, waste, abuse, and mismanagement	In this formulation, the only difference is that the specific *hazard* is pre-defined as inefficiencies, ineffectiveness, fraud, waste, abuse, and mismanagement. Therefore, the mathematical formulation remains the same: $R = P(A) * P(B\|A)$	[26.114]
The ISO 31000 (2009)/ ISO Guide 73:2002	Risk is the effect of uncertainty on objectives. In this definition, uncertainties include events (which may or may not happen) and uncertainties caused by ambiguity or a lack of information. It also includes both negative and positive impacts on objectives. This definition was developed by an international committee representing over 30 countries and is based on the input of several thousand subject matter experts	This approach is closest to the financial professions in that risk is measured with respect to a desired objective (an expected outcome in financial terms). Using the same approach as financial risk, define the expected outcome as $\bar{o}$; the actual as o_a and the difference $D = (o_a - \bar{o})$, then the risk if some event A occurs is: $R = P(A) * P(D\|A)$ The only difference between this and financial risk is that the event A being analyzed explicitly may cause o_a to increase (a positive result)	ISO31000:2009 Risk Management Standard [26.115]

nored. Some of the common risk types that greatly influence both how these risks are assessed, managed and communicated are defined below.

- *Actual risk*: A scientifically verifiable risk. For example, it is well researched and documented that smoking places you at-risk for cancer [26.3–6]. Actual risk is sometimes referred to as *objective risk*, but whether risk is subjective or objective is related more to its ability to be measured than it is to its actual verifiability.
- *Perceived risk*: Risk that is thought to exist by an individual or group that is non-existent or exaggerated. This often occurs in situations where the public is misinformed or in which media reports instill unnecessary panic. Food safety concerns often top the list of such events and lead to the significant public policy debates, see, for example, [26.7].
- *Assumed risk*: Risk that is taken by choice. Assumed risk can be quantifiably large or small, and actual or perceived. For example, individuals who choose to partake in risky activities (skydiving, mountain climbing) choose to assume the relatively large risks associated with these activities, but choosing to drive a car, take medicines or be involved in day-to-day activities all involve some assumed risk.
- *Comparative risk*: Risk placed in context through comparison with another, perhaps better known risk. For example, stating that one is more likely to be hit by a meteor than to be injured in a plane crash compares a risk that people perceive as low (being hit by a meteor) with one they *perceive* as high but which actually is not. This helps place the risk in a conceptual framework.
- *Imposed risk*: Risk that is forced upon an individual, either without the knowledge of the individual or if known, without consent. For example, second-hand smoke exposure is seen as an imposed risk [26.8–10]. Natural events such as earthquakes, hurricanes. and extreme weather events are, to a large extent, *imposed* risks, but to some extent individuals assume that risk based on where they choose to live. For an interesting approach to this, the reader is referred to the work of *Parsad* [26.11].
- *Relative risk*: Risk of a particular outcome compared between two different groups or conditions. The relative risk is calculated as

$$\text{relative risk} = \frac{\text{risk under condition 1}}{\text{risk under condition 2}} .$$

Thus relative risk proved a value of the risk for Condition 1 as a multiple of the risk for Condition 2. For example: suppose property bordering a coastline (Condition 1) has a 30% probability of being inundated during a storm surge, while properties over 100 m away from the coastline (Condition 2) have a 25% probability of inundation. The relative risk of inundation is, therefore, 1.2 times higher along the coastline (Condition 1).

It is imperative that the underlying information about the actual baseline risk be given (i. e., 30% and 25% probability of inundation). Relative risk statistics where no baseline information is given can be very misleading. For example, if there is a 1 in 1 000 000 (10^{-6}) chance of an event at location A, and a 1 in 10 000 000 chance of the same event at location B, saying that location A has a 10 times greater risk than B belies the fact that the risk is still exceedingly small at location A.

- *Percent increased risk*: Risk of a particular outcome compared between two different groups or conditions measured as a relative difference of the two risks related to a base risk. Percent increases risk is calculated as

$$\text{percent increased risk} = \frac{\text{risk under Condition 1} - \text{risk under Condition 2}}{\text{risk under Condition 2}} \times 100 .$$

Using our example from conditional risk, the percent risk increase for inundation by living on the coast would be

$$\text{percent increased risk} = \frac{30-25}{25} \times 100 = 20\% \text{ increase} .$$

Just as with relative risk, it is imperative that the underlying information about the actual baseline risk be given (i. e., 30% and 25% probability of inundation). Percentage increased risk can be even more misleading than relative risk, especially where small risks are involved. For example, if there is a 1 in 1 000 000 (10^{-6}) chance of an event at location A, and a 1 in 10 000 000 chance of the same event at location B, the percent increased risk at location A would be 900%, which clearly presents a very different picture than saying that location A has a *one in a million* chance of the event.

- *Risk analysis*: The overall name given to the application of risk concepts to decision making. It

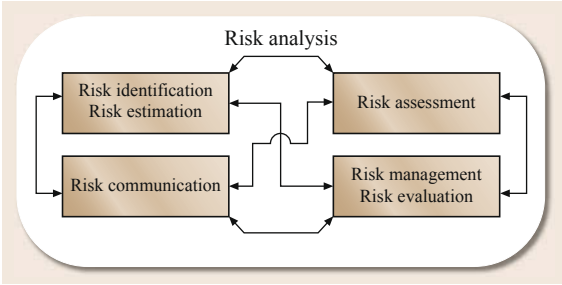

Fig. 26.11 Graphical representation of relationship of the elements of risk analysis

involves detailed examinations performed to understand the nature of unwanted, negative consequences to human life, health, property, or the environment. The process includes identification of potential events (scenarios), quantitative and/or qualitative assessment of risk, analysis of risk management alternatives, and communication of that risk to the necessary stakeholders; an analytical process to provide information regarding undesirable events; and the process of quantification of the probabilities and expected consequences for identified risks. Figure 26.11 gives a graphical representation of the iterative and highly interactive relationship of the various aspects of risk analysis.

- *Risk assessment*: The use of scientifically supported relationships to evaluate the magnitude and probability of adverse impacts on selected endpoints of specific actions, events or hazards/stressors. The assessment may be either qualitative or quantitative. An example of a qualitative risk assessment is the prediction of cancer based on decreased ozone in the atmosphere conducted by the World Meteorological Organization. The risk assessment predicted that if conditions did not change, there would be 50 million additional skin cancer cases due to sunburn by the year 2000 [26.116]. An example of a qualitative risk assessment concerning the same topic (cancer from sunburn) is that a person's risk for melanoma – the most serious form of skin cancer–doubles if he or she has had five or more sunburns [26.117].
- *Risk estimation*: The scientific determination of the characteristics of hazards/threats, usually in as quantitative a way as possible. This includes the magnitude, spatial scale, duration, and intensity of adverse consequences and their associated probabilities, as well as a description of the cause and effect links.
- *Risk evaluation*: A component of risk assessment in which judgments are made about the significance and acceptability of risk.
- *Risk identification*: Recognizing that a hazard exists and trying to define its characteristics. Often risks exist and are even measured for some time before their adverse consequences are recognized. In other cases, risk identification is a deliberate procedure to review, and it is hoped, to anticipate possible hazards.
- *Stochastic*: The property of having inherent random variation. The variation in a stochastic process, while random, is describable through probability theory (see *uncertainty* and *variability* below).
- *Threat*: See *hazard/stressor* above.
- *Uncertainty*: Uncertainty is a widely used term that is unfortunately often misused as a *catchall* term. In some instances, it is erroneously applied to the concept of confidence interval, which is actually a method of quantifying uncertainty. For the purpose of risk assessment, modeling, and/or prediction, uncertainty arises from three main components: error, variation, and lack of knowledge (see definitions herein and in the chapter text).
- *Variability* (*alleatory uncertainty*): Variability is a range of potential values for a given parameter. Variability is a natural characteristic of natural processes (also called *natural variation*). It is describable using probability distributions. The result of natural variation is sometimes called *alleatory uncertainty*. Variability in natural processes (and the resulting alleatory uncertainty) cannot be reduced, as it is an inherent property of the process itself.
- *Lack of knowledge* (*epistemic uncertainty*): The result of a lack of knowledge in risk assessments is also sometimes called epistemic uncertainty. A lack of knowledge can arise because the knowledge is not yet scientifically available – and as such, it can be reduced (along with the resulting epistemic uncertainty) going forward through additional data, experimentation, theoretical development, and scientific inquiry. However, lack of knowledge also includes things that we do not even know we do not know. This area of *lack of knowledge* is more difficult, because it is not easily identifiable and as such, becomes included in variability, or is called *error* when comparing model results to reality.

27. Modeling of Coastal Waves and Hydrodynamics

Patrick J. Lynett, James M. Kaihatu

This chapter presents an overview of the available methods for modeling coastal waves. First, an overview of the relevant coastal processes, from shoaling to turbulent mixing, is provided to establish a basis to compare the various modeling approaches. The bulk of the discussion centers on modeling wind waves and includes a brief overview of the linear and analytical theory available to quantify coastal transformation, and then follows with a summary of spectral and phase-resolving approaches. Modeling long waves is discussed next, with a focus on tsunami simulation. Finally, the chapter summarizes techniques to couple the various models and reviews recent advances in the topic.

As an ocean surface wave enters the coastal zone, broadly defined here as the water landward of the continental shelf or some other depth transition, interaction with the seafloor and currents causes significant transformation. Waves will first start to feel the bottom when the depth (h) to wavelength (L) ratio is less than $1/2$, and waves are considered to be in shallow water, where the effects of the bottom are strong, when this ratio dips below approximately $1/25$. Two-dimensional (2-D) variations in the seafloor can lead to wave focusing due to the effects of refraction. Wave shoaling causes the wave amplitude to grow and the wavelength to shorten, steepening the wave front until the wave breaks.

Depending on the properties of the incoming wave, nonlinearities in the wave behavior are important for some distance before breaking and through the surf zone. Shallow water nonlinearity is governed by the wave height to water depth ratio; as the ratio gets larger, it is expected that nonlinearity becomes increasingly important. From this definition, it is clear that nonlinearity must be important near breaking, as this is the point when the wave height is similar to the depth. Nonlinearity in the coastal zone can change the speed at which a wave travels, where it breaks, and how it interacts with currents.

Nonlinear waves in the coastal zone also induce a net mass transport in the direction of the wave. This net mass transport is due to wave radiation stress, which is name given to the net positive momentum flux in the direction of wave propagation, and leads to wave-induced currents. Currents moving parallel to the shoreline are termed alongshore currents and are primarily responsible for alongshore sediment movement. These currents can generate instabilities, often driven by alongshore bathymetry variation, which can manifest as strong rip currents and shallow turbulent coherent structures. Such features induce high horizontal shear on the flow, and lead to significant horizontal and vertical mixing.

When designing coastal structures, engineers are often most concerned with extreme event loads. Here, extreme events may be storm surges and the accompanying storm waves or tsunamis, for example. It is a present challenge for coastal engineers to determine these extreme event loads, as there is currently no accepted design code for extreme wave loads. Furthermore, the sea level rise associated with climate change

has the potential to increase peak water levels during storms [27.1], also implying that wave energy may penetrate further inshore. The engineer is left with many different options to quantify the wave properties in the coastal zone, from overly simple methods to impractically complex numerical tools.

Relative to many engineering disciplines, the use of numerical coastal wave models for design is new. Many analyses still rely on the simple linear wave methods described in the following section. The usage of large-scale spectral wave models has become commonplace, as these models are efficient and well tested. Currently, it is less common to go to detailed phase-resolving models in engineering practice. These models provide a wave-by-wave resolution of the coastal dynamics, and can provide insight on a small spatial scale. Such insight is important when trying to, for example, accurately estimate wave overtopping of a coastal levee or wave impact loads on a structure. The following sections of this paper will outline the various approaches, providing a brief literature review and theoretical background.

27.1 Wind Wave Modeling

There is a wide range of useful techniques for estimating wind wave properties in the nearshore; the choice of which technique to use depends on limiting factors such as the resources available, the precision required in the result, and the physical properties of the waves themselves. The types of approaches discussed in this section have both highly variable physical approximation as well as computational demand; these two factors often have an inverse behavior. It is the purpose of the following presentation to outline the main types of coastal modeling options, providing theoretical background, numerical modeling schemes, and typical applications.

27.1.1 Linear, Analytical and Semi-Empirical Approaches

The simplest methods for estimating coastal wave properties utilize linear potential wave theory. While this theory is covered comprehensively in many textbooks [27.2], the most relevant equations are given here. Additionally, this presentation will serve to establish the basic variable quantities used in coastal hydrodynamic modeling. The free surface elevation η for a single frequency component is given by

$$\eta = \frac{H}{2}\cos\theta \,,$$

where H is the wave height equal to twice the wave amplitude a. For one horizontal dimension and constant depth, θ is the wave phase function given by

$$\theta = kx - \omega t \,,$$

where k is the wave number, x is a horizontal coordinate, ω is the angular frequency, and t is time. In general terms, k and x can be vector quantities when directional waves are considered. Wavenumber and angular frequency are related to other important physical quantities

$$k = 2\pi/L, \quad \omega = 2\pi/T, \quad f = 1/T \,,$$

where L is the wavelength, or horizontal distance between two successive crests or troughs, T is the wave period, and f is the wave frequency. The linear dispersion relation provides the connection between wave frequency and wavelength

$$\omega^2 = \mathrm{g}k\tanh(kh) \,,$$

where g is gravity, h is the local water depth, and the fluid is assumed inviscid. Expressions for fluid velocity and pressure under the wave can be found in textbooks, and will not be repeated here. Linear wave theory predicts closed, elliptical orbits of fluid particles under waves, and, therefore, no net mass transport.

In the limited case of very shallow water, where the ratio of water depth to wavelength approaches zero, simplifications can be made to the full linear potential theory discussed above. The dispersion relation reduces to

$$\omega^2 = \mathrm{g}hk^2 \,,$$

which yields a wave speed c of

$$c = \frac{\omega}{k} = \frac{L}{T} = \sqrt{\mathrm{g}h}$$

and a horizontal fluid velocity u of

$$u = \frac{H}{2}\sqrt{\mathrm{g}/h}\cos\theta \,.$$

These expressions should be applied only in the case of a very long wave, such as for tides, tsunamis, and swell

waves in very shallow water. However, even outside these cases, quick wave property calculations based on the above will still provide a useful preliminary reference point for shallow water wind waves.

Linear wave transformation in shallow water includes the effects of shoaling, refraction and diffraction, and can be expressed in the general form

$$\frac{H}{H_o} = K_S K_R K_D \,,$$

where H represents the wave height at some coastal location, H_o the height at some offshore location, K_S is the shoaling factor, K_R is the refraction factor, and K_D is the diffraction factor. Assuming no dissipation of energy during propagation, the conservation of wave power between any two locations in the propagation path gives the shoaling coefficient

$$K_s = \sqrt{\frac{n_o L_o}{nL}} \,,$$

where

$$n = \frac{1}{2}\left[1 + \frac{2kh}{\sinh(2kh)}\right] .$$

This n value varies from 0.5 for a deep water wave to 1.0 for a shallow water wave. It is remarked that the basic linear theory presented here does not include bottom reflection or bottom dissipation, and can thus be applied between any two points regardless of the bathymetry between these two points. However, the theory implicitly assumes inviscid propagation and a mildly sloping bottom, and this must be satisfied at a minimum for the shoaling estimation above to be physically appropriate.

Wave refraction is the process of wave crests bending due to propagation-normal variations in bathymetry. Wave crests will bend *into* shallow water regions as the propagation speed slows in such regions, with the refraction coefficient

$$K_R = \sqrt{\frac{\cos\alpha_o}{\cos\alpha}} \,,$$

where α is the angle of incidence relative to the shoreline or some prescribed depth contour, and can be found using Snell's Law

$$\sin\alpha = \frac{c}{c_o}\sin\alpha_o \,.$$

This relation may only be used in simple bathymetries with shore-parallel bottom contours. In more complex regions, modified forms of Snell's law can be used to create wave rays, which were commonly used in the twentieth century to show wave paths and outline possible areas of wave focusing and de-focusing. These techniques have been displaced by numerical methods, some of which are discussed in later sections of this chapter. There is no general equation for the diffraction coefficient. The engineer should reference the numerous diffraction diagrams that can be found in the Coastal Engineering Manual CEM) [27.3], which plot K_D surfaces for various combinations of breakwater configurations and incident wave directions.

Once the wave reaches the break point, the coastal transformation equation given above can no longer be used, and some other approach must be used to cap the wave height. A common engineering approach is the introduction of the breaker index, which is the ratio of the breaking wave height to the local water depth. For a given wave period and bathymetry slope, a breaker index can be estimated. Once the shoaling and refraction analysis estimates a wave height to depth ratio that exceeds the breaker index, it is assumed the wave starts to break; this is the break point. Breaking is then usually assumed to be *depth limited*, meaning that the breaker index remains constant as the water depth decreases onshore. The difficulty in this approach is determining a reliable estimation of the breaker index. There are numerous different equations for this index; the most common are found in the CEM. For waves shoaling over a very steep slope, the breaker index can be greater than 1.0, while for waves breaking over an essentially flat bottom, the breaker index may be lower than 0.4 [27.4]. A commonly assumed value for the breaker index found in engineering studies is 0.78; this is derived from the maximum theoretical solitary wave height, and its physical relevance to random coastal wind wave breaking is questionable.

For studies that seek to use straightforward analysis methods but also provide an estimate of the wave height envelope across a cross-shore beach profile, the energy flux method [27.5] is a useful tool. Here, it is assumed that the spatial rate of change of wave energy flux F is due to some dissipation function φ

$$\frac{\mathrm{d}F}{\mathrm{d}x} = -\varphi(x) \,.$$

The dissipation function is driven by breaking and is proportional to the difference between the local wave energy flux and some *stable* energy flux for the local depth. Determination of a stable energy flux is, similarly to the determination of a breaker index, difficult for a wide range of conditions. Commonly used models for the dissipation function include [27.6] and [27.7], which are both established for random wave break-

ing. Note that outside the breaker zone, where the left-hand side of the above equation is zero, the energy flux method will reduce to a linear shoaling model. This wave transformation model has been adopted by a number of large-scale morphology change simulators, which require a good estimate of the breaker location and resulting longshore currents for large horizontal areas. However, this approach has been largely displaced by more recent numerical tools, which can better include directionality, dissipation, and nonlinear effects. Some of these tools are discussed in the following sections.

27.1.2 Spectral Modeling: Phase-Averaged and Phase-Resolving Approaches

In the open ocean, wind wave generation and propagation are typically described using phase-averaged spectral models. These spectral models determine spatial and temporal changes in the wave spectrum, or the wave energy as a function of frequency and direction. A spectral energy balance is derived, accounting for wave growth, propagation, and dissipation based on wind energy input, whitecapping, and bottom friction. Examples of such models are WISWAVE (wave information study wave model) [27.8], WAVEWATCH III [27.9], and WAM (wave model) [27.10]. These models are highly developed for open ocean waves, but do not account properly for coastal effects such as shallow water wave–wave interactions and depth-induced breaking [27.11]. They output a directional spectrum, which can then be employed as boundary conditions in a coastal zone model to simulate nearshore propagation. For example, WAM could be coupled with SWAN (simulating waves nearshore) [27.12], a coastal spectral model, to estimate the spectral evolution from deep to shallow water [27.11]. However, even coastal spectral models only crudely approximate dynamic nearshore phenomena, due to the inherent approximations such as phase-averaging, weak nonlinear effects, and no diffraction.

In its most general form, the spectral wave action density balance equation is given by

$$\frac{D_w(N)}{Dt} = \frac{S}{\omega} ,$$

where N is the time-dependent wave action density, or energy density divided by frequency, defined for an individual frequency; the total derivative $D_w(N)/Dt$ is taken in the direction of wave motion, and S represents any external source or sink acting on the conservation volume for which the total derivative is taken. S by definition includes forcings such as those of wind and viscous dissipation, such as whitecapping, wave breaking, and bottom friction. If the nonlinear advection terms are neglected from the total derivative, then S must also include nonlinear energy transfers among the various frequencies. Expanding the above balance equation, and including the terms of coastal importance, we have

$$\begin{aligned}\frac{\partial N}{\partial t} &+ (\text{linear energy transfers}) \\ &= \frac{S_{\text{bottom friction}}}{\omega} + \frac{S_{\text{breaking}}}{\omega} + \frac{S_{\text{whitecap}}}{\omega} \\ &\quad - \frac{S_{\text{wind input}}}{\omega} - (\text{nonlinear energy transfers}) ,\end{aligned}$$

where the mechanism of each source/sink S term is given in its subscript, and the nonlinear energy transfer term represents energy transfer from one frequency to a different frequency. For example, the bottom friction sink is most commonly expressed in the Joint North Sea Wave Project (JONSWAP) form [27.13]

$$S_{\text{bottom friction}} = -C_b G(f) E ,$$

where C_b is a bottom friction coefficient dependent on local wave and bottom conditions, G is the *functional form* of the sink and is dependent on the frequency, and E is the local energy density. G has the physically reasonable form of being large at low frequencies (high dissipation in shallow water) and approaches zero (no dissipation) in the deep water region. The breaking dissipation source function is restricted by breaker-index uncertainties similarly as discussed with the linear modeling in the previous section. However, due to the ability of these coastal spectral models to include nonlinearity and approximate dissipation, they have been shown to be excellent predictors of wave height transformation for a wide range of physical configurations. It is reasonably stated that, if the user is not interested in detailed wave-by-wave breaking estimation, runup, infragravity waves, three-dimensional (3-D) flow profiles, and turbulent dynamics such as rip currents and coastal eddies, then coastal spectral models are the most efficient and accurate option available. For a further discussion and a nice review of state-of-the-art spectral modeling methods, the reader is directed to [27.14]. Figure 27.1 shows a result from the SWAN model [27.12], with an improved numerical scheme for the geographical propagation terms [27.15], applied to the area surrounding Santa Rosa and San Miguel Islands in the Southern California Bight. The extreme refraction around the islands served as a stringent test of the model; the single-peaked incident wave spectrum (Fig. 27.1c) has split into two discrete spectra at the location of the measurement station between the two islands.

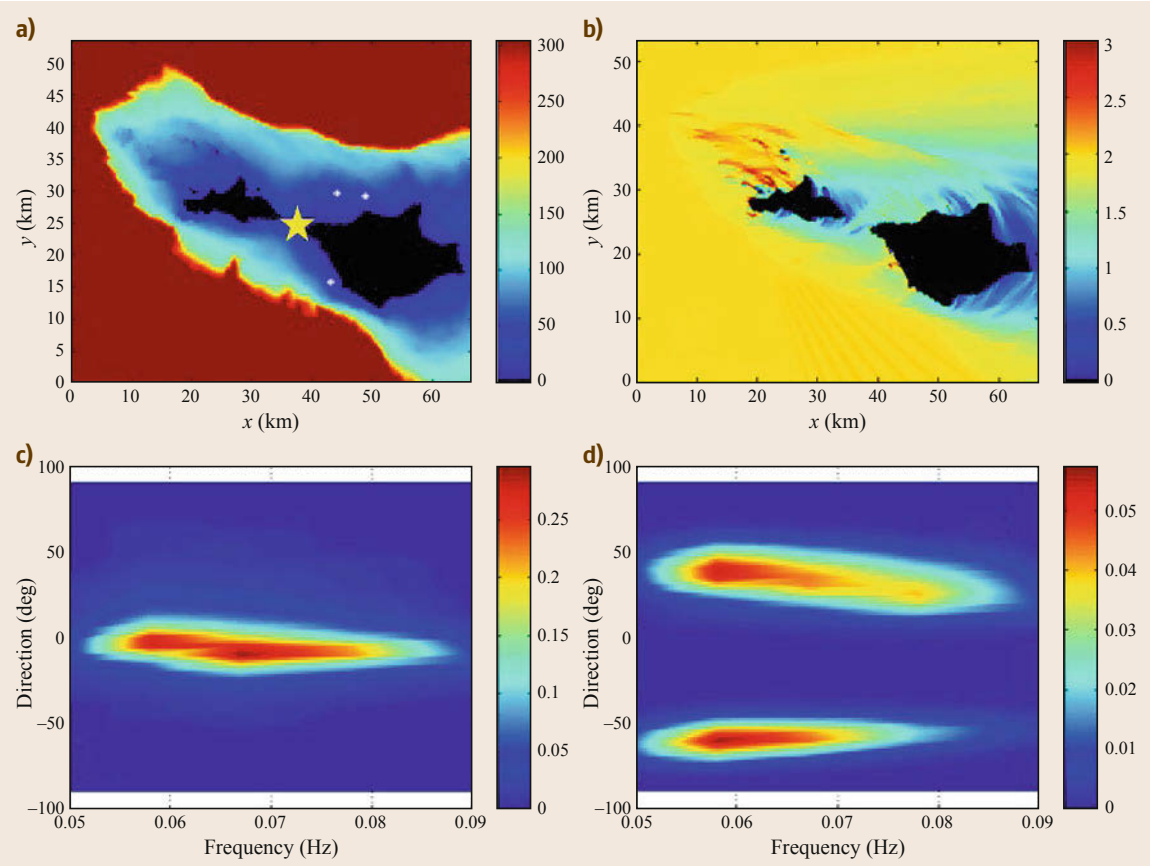

Fig. 27.1a–d SWAN simulation of wave refraction around San Miguel and Santa Rosa Islands in the Southern California Bight. **(a)** Bathymetry (in m) and pressure gage locations (*white dots*) near San Miguel (*left*) and Santa Rosa (*right*) Islands; location of pressure gage #10 denoted with a *star*. **(b)** Significant wave height (in m) on January 14, 1992 at 2300 Pacific Standard Time. **(c)** Incident swell wave spectrum measured offshore of Southern California Bight (January 14, 1992 at 2300 PST) and applied to the left and upper boundaries of local model domain shown in **(a)**; zero degrees denotes waves approaching from due west, while +90 degrees denotes waves approaching from due north. **(d)** Swell wave spectrum output at location of pressure gage #10

Modelers looking to perform phase-resolving simulations of waves from intermediate depths to the shoreline have few options. Well-established models such as SWAN and STWAVE (steady state spectral wave model) [27.16] are phase-averaged models and do not directly provide time histories of free surface and velocity fluctuations due to waves. Mild-slope equation models, such as REF/DIF (refraction/diffraction model) [27.17], are phase-resolving models and are computationally practical to run in most cases. However, these models have restrictions that limit their use, such as weak diffraction effects, a lack of wave reflection, and the limitation to narrow banded spectrums, and higher-order nonlinearity is generally not captured [27.18].

An alternative approach to spectral phase-averaged modeling, which retains both shallow water nonlinearity and the periodic nature of waves, is nonlinear frequency-domain wave modeling [27.19–22]. In essence, these models are nonlinear extensions of phase-resolving nearshore linear refraction-diffraction models such as REF/DIF [27.17]; a relatively comprehensive account of these models is given in [27.23]. These models retain second-order nonlinearity via near resonant interactions (both subharmonic and superharmonic interactions) between triads of frequencies. The strength of the interactions is dictated by both the interaction coefficients and the phase mismatches between the complex amplitudes of the spectral components. These models have been improved to include wide-

angle parabolic propagation [27.24] and interaction effects among triads of longshore wavenumbers [27.22, 25]. Several models also contain a dissipation mechanism representing spectral wave breaking, consisting of a lumped parameter breaking description [27.7] coupled with an adjustable distribution of dissipation over the frequency range. The distribution is an adjustable balance between a frequency-independent weighting of dissipation and one that is weighted as frequency squared. The latter distribution was shown by *Kaihatu* et al. [27.26] to be an inner surf zone asymptote of the dissipation dependence on frequency. Smoothed versions of these phase-resolving models that treat triad interactions in terms of averaged bispectral quantities [27.22, 25, 27] have also been developed; these models are closer akin to the phase-averaged spectral models discussed previously.

27.1.3 Depth-Integrated and Boussinesq-Type Approaches

While frequency domain models are advantageous due to their relatively small computational demand, a significant effort in the nearshore wave model community towards developing phase-resolving, time domain Boussinesq models has occurred in the past decade. Assuming that both nonlinearity and frequency dispersion are weak and are of the same order of magnitude, *Peregrine* [27.28] derived the *standard* Boussinesq equations for variable depth in terms of depth-averaged velocity and free surface displacement. Numerical results based on the standard Boussinesq equations or the equivalent formulations have been shown to give predictions that compared quite well with field data [27.29] and laboratory data [27.30, 31].

As mentioned above, the standard Boussinesq equations are derived based on an assumption between the nonlinearity of the wave, $\varepsilon = a/h$, and the frequency dispersion of the wave, $\mu = kh$. The precise relation of these parameters comes from a nondimensionalization of the full potential flow equations using a shallow water scaling and is given by

$$O(\epsilon) = O\left(\mu^2\right) \ll 1 \,,$$

which is the *true* Boussinesq assumption as related to nonlinear long surface waves. With this assumption, nonlinear two-dimensional-vertical potential flow can be reduced to the one-dimensional 1-D-horizontal equation set for a wave over constant water depth as

$$\text{continuity:} \quad \eta_t + (\eta u)_x + h u_x = 0 \,,$$

$$\text{momentum:} \quad u_t + g\eta_x + u u_x - \frac{1}{3} h u_{xxt} = 0 \,,$$

where the subscripts represent partial derivatives and u is the depth-averaged horizontal velocity. The nondispersive, shallow-water wave equations are easily extracted from this equation set by neglecting the last term ($\frac{1}{3} h u_{xxt}$) on the left-hand side of the momentum equation; it is this single term that adds dispersion to the shallow water base.

The mathematical effect of the additional dispersive term can be quantified by examining the linear form of the standard Boussinesq equations given above and substituting in the linear wave solution form

$$\eta = \eta_o e^{i\theta} \,, \quad u = u_o e^{i\theta} \,, \quad \theta = kx - \omega t \,.$$

After some algebra, the dispersion relation of this approximate equation set can be expressed as

$$\omega^2 = \frac{g h k^2}{1 + \frac{1}{3}(kh)^2} \,,$$

which is also the $[0, 2]$ Pade approximation of the full linear dispersion relation given in the Linear Wave Approaches above (Sect. 27.1.1). In the practical sense, this single additional term in the momentum equation allows for accurate linear propagation of waves up to $kh \approx 0.5$, which is approximately a fivefold increase in applicability compared to the shallow water model, using the same accuracy thresholds in phase and group velocity [27.32].

As it is required that both frequency dispersion and nonlinear effects are weak and of the same order, the standard Boussinesq equations are not applicable to very shallow water depth, where the nonlinearity becomes more important than the frequency dispersion, nor to the deep water depth, where the frequency dispersion is of order 1. The standard Boussinesq equations break down when the depth is greater than $\approx 1/10$ of the wavelength. For many engineering applications, where the incident wave energy spectrum consists of many frequency components, a lesser depth restriction is desirable. To extend the applications to shorter waves (or deeper water depth) many modified forms of Boussinesq-type equations have been introduced [27.22, 33, 34]. Although the methods of derivation are different, the resulting dispersion relations of the linear components of these modified Boussinesq equations are similar, and may be viewed as a slight modification of the $(2, 2)$ Pade approximation of the full dispersion relation for linear water waves [27.35]. It has been demonstrated that the *modified* Boussinesq equations are able to simulate wave propagation from intermediate water depth (the water depth to wavelength ratio is about 0.5) to shallow water including the wave–current interaction [27.36].

Despite the success of the modified Boussinesq equations in intermediate water depth, these equations are still restricted to weak nonlinearity. As waves approach the shore, the wave height increases due to shoaling, until they eventually break. The wave height to water depth ratios associated with this physical process violates the weakly nonlinear assumption. This restriction can be readily removed by eliminating the weak nonlinearity assumption [27.37, 38]. Numerical implementations of the highly-nonlinear, Boussinesq-type equations include FUNWAVE (fully nonlinear Boussinesq wave model) [27.38] and COULWAVE (Cornell University long and intermediate wave model) [27.39]. These models have been applied to a wide variety of topics, including rip and longshore currents [27.40, 41], wave runup [27.42], wave–current interaction [27.43], and wave generation by underwater landslides [27.42], among many others. Boussinesq models are steadily becoming a practical engineering tool. Directional, random spectra can readily be generated by the models, which capture nearshore evolution processes, such as shoaling, diffraction, refraction, and wave–wave interactions, with very high accuracy. The applicability of the Boussinesq models is limited by the fact that the models are fundamentally inviscid. The dissipation processes, such as breaking and bottom friction, must be parameterized in traditional Boussinesq models.

Recently, a number of *non-traditional* Boussinesq approaches have been developed, with the goal of including horizontal vorticity explicitly in the flow field. An attempt to include these dynamics under a breaking wave is found in [27.44], with further advances given in [27.45]. Integrated within a Boussinesq-type derivation, the stream function equation is used to determine the vertical variation of the velocity. This allows the inclusion of the vorticity generated by breaking. The breaking terms that appear as corrections to the momentum balance are a function of the amount of vorticity generated during the breaking process. This vorticity is obtained from the solution to the vorticity transport equation and has been shown to capture the flow field dynamics under a spilling breaker.

A similar attempt was made by *Kim* et al. [27.46] who included the viscous effects of a bottom shear, and the associated rotationality, directly in a Boussinesq-type derivation. While this leads to a far more complex equation model, it includes the physics necessary to simulate boundary shear and the complete coupling of these effects with a nonlinear, dispersive wave field. This model can predict the friction-induced changes to the vertical profile of velocity under weakly unsteady flow and can thereby provide good estimates of internal kinematics. It is also able to translate the bottom-created horizontal vorticity into a vertical vorticity field.

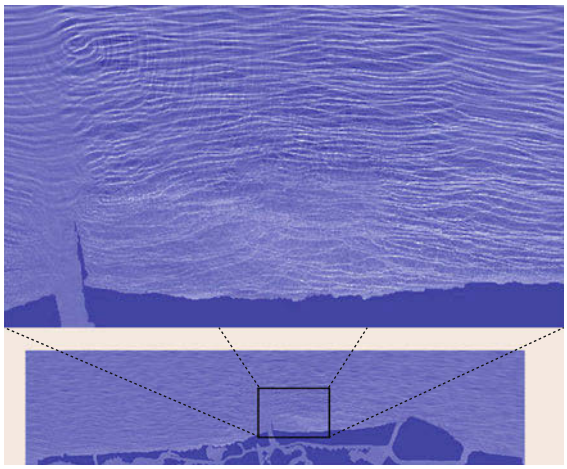

Fig. 27.2 Boussinesq simulation of waves near Freeport, TX. Resolution of the model is 5 m and the total spatial extent is $\approx 100\,\mathrm{km}^2$

Such a model is able to couple the dissipative and nonlinear effects of a bottom shear with a dispersive and nonlinear wave field. While this and similar recent advances allow the depth-integrated equations to model a wider range of physical processes, the computational cost for this inclusion is high [27.47]. In addition to the many individual calculations needed to quantify the various terms in these equations, since the model includes first to third-order spatial derivatives, it becomes necessary to resolve the leading order terms to fourth-order numerical accuracy. This leads to the requirement of a fourth-order spatial differencing and temporal integration scheme. Compared to an efficient shallow water solver, the highly nonlinear Boussinesq-type model can require 50−100 times more computational time for the same numerical grid and time step configuration. While this cost is relatively high, large domains can be tackled with parallel computing [27.48]. For an example of the possible scale of these simulations, see Fig. 27.2.

27.1.4 Navier–Stokes Equation-Based Approaches

Phase and depth-resolving surf zone hydrodynamic models, such as those that use the Reynolds-averaged Navier–Stokes(RANS) equations along with a turbulence closure and a robust free surface-tracking scheme, are an ideal alternative for simulation of complicated nearshore processes that involve breaking waves. In general, RANS-based models are capable of calculating turbulence energy and energy dissipation due to wave breaking and bottom friction. For example, in one of the RANS-based models, COBRAS (Cornell breaking wave and structure) [27.49–51], the two-

dimensional RANS equations are coupled with the k-ε turbulence closure and the volume of fluid (VOF) method for tracking free-surface position. This and similar models can adequately resolve the wave breaking process and its interactions with the seabed. An example of the types of output that this model provides is given in Fig. 27.3. RANS-based models have not yet been widely accepted into coastal science and engineering practice, as their computational cost is relatively high and the high-resolution physical output provided is often beyond what is needed by engineering standards of practice for design. Where these models are applied, it is usually for two dimensional vertical (2DV) transect studies, where, for example, details of wave breaking [27.52, 53], wave interaction with complex and/or porous structures [27.54], and fluid stresses and pressure distributions [27.55] are studied.

This general class of model is still not practically applicable, even in the academic sense, for simulating waves in 3-D coastal regions. 3-D solvers, using various turbulent closure schemes, are, however, becoming a common basis for large-basin numerical wave tanks. One of the more promising programs is OpenFOAM [27.56], which is an open-source and freely available computational fluid dynamics package. The flexibility in this package, and the ability to build off a significant body of previous computational fluid dynamics (CFD) work, makes it possible to apply the codes towards a variety of coastal modeling problems [27.57]. In the coming decade, it is anticipated that wind wave modeling will continually move towards the utilization of very high resolution, large eddy simulation (LES) tools, as this class of model is the main option for predicting vertical and turbulent structures which drive mixing and transport.

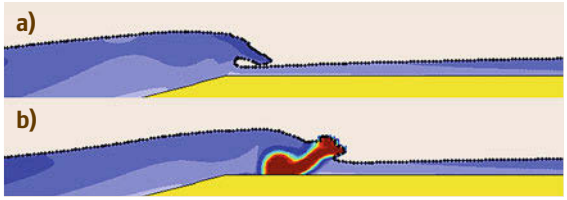

Fig. 27.3a,b Two snapshots from a RANS simulation of wind waves breaking on a shallow shelf. The *colors* indicate the intensity of turbulent kinetic energy. **(a)** shows the free surface and turbulent kinetic energy at moment of jet impingement on the free surface, and **(b)** shows the breaking wave a short time later.

27.2 Modeling Long Waves

A long wave is defined as having a wavelength much larger than the local water depth. Waves that commonly meet this requirement include tides, storm surges, and tsunamis. When the wave disturbance is considered to be *long*, it is reasonable to use the non-dispersive nonlinear shallow water (NSW) wave equations. The NSW equations can be derived in a number of different ways, but fundamentally all arise from an integration of the Euler or Navier–Stokes equations with an assumption of vertically-invariant horizontal velocity and hydrostatic pressure. Due to the simple and well-studied nature of the NSW equations, a wide variety of numerical schemes have been used to solve them.

Models that are used to examine tides and storm surges are often similar, if not the same model. Examples of this class of model include ADCIRC [27.58] and DELFT3D-FLOW [27.59], both of which have received widespread acceptance in the engineering community. These models need to include proper tidal forcing, wind stress for surge, and bottom friction in nearshore areas. Recently, circulation models have been coupled with nearshore short-wave spectral models, which provide a wave-induced water level and current forcing through radiation stress that is ingested by the circulation model [27.60]. This allows for a more complete nearshore simulation, as wave-induced currents become important near the surf zone. Of particular importance for accurate surge prediction is high resolution and accurate coastal bathymetry and topography, often down to 10 m or less. Therefore, as is a common challenge for simulation of long wave generation and evolution, a very wide range of scales must be simulated. Numerical approaches that can accommodate this issue, such as finite element meshing or grid nesting, must be adopted.

With the large number of deadly tsunamis in the past decade, tsunami simulation capabilities have increased relatively rapidly. Several tsunami computational models are currently used in the National Tsunami Hazard Mitigation Program, sponsored by the National Oceanic and Atmospheric Administration, to produce tsunami inundation and evacuation maps for the states of Alaska, California, Hawaii, Oregon, and Washington. The computational models include MOST (method of splitting tsunami), developed originally by researchers at the University of Southern California [27.61]; COMCOT (Cornell multi-grid coupled tsunami model), developed at Cornell University [27.62]; and TUNAMI-N2, developed at Tohoko University in Japan [27.63]. All three models solve the same depth-integrated and 2-D horizontal (2DH)

nonlinear shallow water equations with different finite-difference algorithms.

Successful simulation of tsunami propagation and accurate prediction of the arrival time and wave height at different locations rely on a correct estimate of the earthquake fault plane mechanism. Interplate faults in subduction zones are responsible for most of the large tsunamis in history. For interplate fault ruptures, the resulting seafloor displacement can be estimated approximately using linear elastic dislocation theory [27.64, 65]. For more sophisticated fault models, non-uniform stress-strength fields (faults with various kinds of barriers, etc.; [27.66]) are expected, so the actual seafloor displacement may be very irregular. Once the seafloor displacement has been determined, the initial ocean free surface profile is assumed to take the same configuration, based on the assumptions that the upward seafloor movement is impulsive and seawater is incompressible.

For a given source region condition specified by either the initial free surface elevations or a time history of sea floor displacement, existing models can accurately simulate propagation of a tsunami over a long distance, provided that bathymetry data exists. Figure 27.4 shows a snapshot of free surface elevation from a COMCOT simulation at 10 h and 44 min after the March 11, 2011 Japan tsunami. The shallow-water equation models by definition lack the capability of simulating dispersive waves, which could well be the dominating features in landslide-generated tsunamis [27.39] and for tsunamis traveling a long distance [27.67]. To address this issue of dispersivity, a different set of governing equations must be employed, or some manipulation of the numerical truncation error must be made.

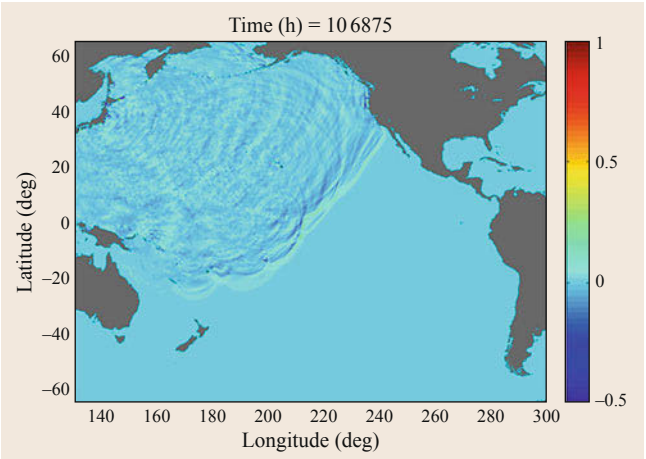

Fig. 27.4 Snapshot from tsunami simulation of the March 11, 2011 Japan tsunami

As a tsunami propagates into the nearshore region, the wave front undergoes a nonlinear transformation while it steepens through shoaling. If the tsunami is large enough, it can break at some offshore depth and approach land as a bore. Wave breaking in traditional NSW tsunami models has not been handled in a physically satisfactory manner. Numerical dissipation is commonly used to mimic breaking, and thus results become grid dependent. In Boussinesq models, this breaking is still handled in an approximate manner due to the fact that depth-integrated derivation does not allow for an overturning wave; however these breaking schemes have been validated for a wide range of nearshore conditions [27.68].

27.3 Coupled and Nested Techniques

As mentioned above, there have been recent successful attempts at coupling spectral wave models with circulation models, which allows for robust simulation of nearshore currents and the resulting transport. If one is interested in basin-scale simulation of wind waves with high coastal resolution, a natural coupling technique would be to use spectral wave information taken from a large-scale model, such as SWAN or STWAVE, to drive a detailed near-coast model, such as the Boussinesq model. Since these two models function in different dimensional space, the coupling between the two models is likely to be one way; meaning that information is given by the spectral model, but no information is received by the spectral model. The implementation of this coupling is straightforward, as it is with most one-way coupling methods, and has been used in a number of studies.

If examining transient wave phenomena or wave hydrodynamics on a fine scale, spectral models are of limited use. Of the two typical phase-resolving, depth-integrated models used in wave studies, the Boussinesq model can be considered a more physically complete (or at least a higher-order) approximation compared to the NSW. In coastal regions, where the water depth is very shallow and thus amplitude is large and wavelength becomes short, nonlinear and bathymetric interactions across a wide range of frequencies occur. These interactions can locally generate various shorter-crested, or dispersive wave components, even if the offshore forcing is considered a long wave. A well-known example is the transformation of a tsunami front into an undular bore. Thus, the nearshore is expected to be nonlinear and (possibly) dispersive, and a Boussinesq model is appropriate. However, the additional physics

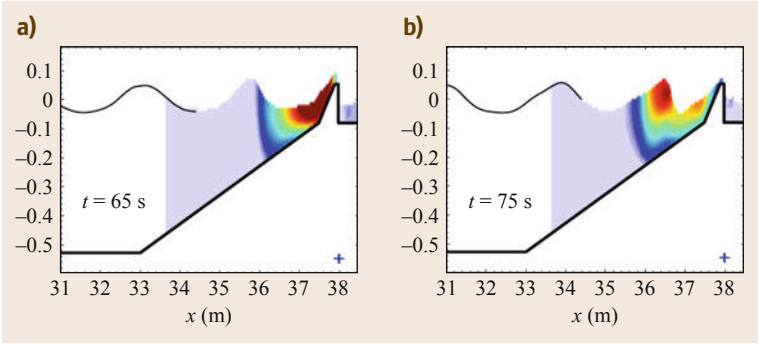

Fig. 27.5a,b Example hybrid Boussinesq-RANS setup; the Boussinesq domain stretches from $x = 0-34$ m and the RANS exists from $x = 34-39$ m. **(a)** shows an overtopping wave at the time of maximum speed on the front of the seawall, while **(b)** depicts the wave and turbulent kinetic energy during the downrush of water along the seawall

included in the Boussinesq approximation come with substantial computational cost, often making the model impractical for ocean basin scale simulations. If one wants to use the physical advantages of the Boussinesq model for a local region in the nearshore zone, it becomes necessary to couple that Boussinesq model with some other source of wave information for its boundary conditions. The obvious coupling choice would be the NSW, proven for both efficient and accurate basin scale tsunami prediction.

There are numerous challenges with this coupling, most notably that fact that the two approximations (NSW and Boussinesq) are different, and so there can be a physical mismatch across the coupling interface. Also, the NSW will typically have a low-order numerical solution approach (hence its computational efficiency), while high-order partial derivations in the Boussinesq model require a high-order scheme; matching these two schemes can also create numerical stability issues. Details regarding a coupling NSW-Boussinesq approach can be found in [27.69].

While Boussinesq models can provide a detailed description of the flow due to a tsunami, it can be necessary to use a model with even less restrictive physical approximations, and the ability to resolve very small-scale (sub meter) turbulent features, such as a 3-D Navier–Stokes model. A similar coupling argument as provided above for the Boussinesq can be made here for the fully 3-D model. Due to their high computational costs, full 3-D models would best be used in conjunction with a depth-integrated two-dimensional-horizontal model (2DH) (i. e., depth-integrated NSW or Boussinesq). While the 2DH model provides incident wave information, the 3-D model computes local wave–structure interactions. The results from 3-D models could also provide a better parameterization of small-scale features (3-D), which could then be embedded in a large-scale 2DH model. One-way coupling (using a NSW-generated time series to drive a 3-D model, but not permitting feedback from the 3-D model back into the NSW) is fairly straightforward to construct [27.70]. Two-way coupling, however, is difficult and requires consistent matching of physics and numerical schemes across model interfaces.

Sittanggang and *Lynett* [27.71] presented work on coupling of a Boussinesq model and 2-D Navier–Stokes model. The two models are two-way coupled, and so act as if they are a single model working on a continuous domain. In the coupling implementation, the Boussinesq model is applied in the non-breaking zone and the RANS model in the breaking/high-turbulence zone. The two models share a common domain interface for exchanging data, used as boundary conditions in the models. By coupling the two models, accurate large-scale wave simulation using a coarse grid and *simple* physics in the deep-to-intermediate water and fine grid and detailed physics in the nearshore area is computationally feasible. Figure 27.5 gives an example of this hybrid simulation approach for nonlinear wind waves overtopping a coastal structure. The wind waves propagate from offshore with the Boussinesq model. Approximately one wavelength offshore of the break point, the Boussinesq and RANS models are two-way coupled, giving the ability for high resolution of the wave overtopping and a relatively large domain.

27.4 Summary of Model Properties

Table 27.1 provides a descriptive listing of the various models described in this chapter. Included in the table are typical spatial and temporal extents used in simulations along with resolutions, the number of derivatives operators found in the governing equations, and common applications and outputs. The information in the derivative operators column, which also includes the highest order of differentiation, is

Table 27.1 Summary of model types, with basic information for comparison purposes

Theory	Typical spatial domain sizes and spatial resolution	Typical simulation time coverage and time step	Number of derivative operators on unknowns in governing equations and highest derivative order	Typical applications and output types
Spectral wave energy balance equations	From planet-wide domains at ≈ 30 arcmin resolution to $O(100)$ km^2 at $O(100)$m resolution	Hours of simulation time with time steps of $O(5)$min	Four derivatives per frequency, with ≈ 250 frequencies. All derivatives are first order	Global scale operational wave prediction, coastal wave prediction, and wave drivers for nearshore circulation models. Models provide frequency-directional spectra
Phase-resolving nonlinear frequency domain equations	$O(1)$km^2 domains at $O(1)$m resolution	Hours, though dependent on number of frequencies retained. Time periodic models – no time step	Two derivatives per frequency, with 150–300 frequencies. Highest derivative order is 2	Nearshore and surf zone wave prediction, wave drivers for nearshore circulation models and models of instantaneous sediment transport. Models provide complex (phase-dependent) amplitudes of free surface elevation
Nonlinear shallow water (NSW) equations	From planet-wide domains at ≈ 2 arcmin resolution to $O(100)$km^2 domains at $O(10)$m resolution	Hours to multiple days of simulation time with time steps of $O(1)$ s	Approximately 10 in the 2DH formulation, depending on the specific formulation. All derivatives are first order	Coastal circulation modeling, tides, river and overland flows, tsunamis. Model provides water surface elevation and depth-averaged velocity components
Boussinesq-type equations	$O(1)$km^2 domains at $O(1)$m resolution	Tens of minutes to a few hours, with time steps of $O(0.1)$ s	Approximately 15 in the 2DH weakly nonlinear, standard formulations, with highest derivative order of 3. In the highly nonlinear 2DH versions, approximately 50, with highest derivative order of 3	Coastal wave prediction, breaking waves, setup, runup, overtopping, and coastal flooding due to waves. Model provides water surface elevation and velocity components at some z-level, which can be post-processed to construct the vertical profile of velocity
Navier–Stokes (NS) equations	Coastal applications currently focus on transect (2DV) studies, covering $O(1)$km of horizontal length, with depths less than 10 m. Horizontal resolutions are $O(1)$m and vertical resolutions are $O(0.1)$m	Tens of minutes to a few hours, with time steps of $O(0.01)$ s	Approximately 40 in the 2DV RANS equations with standard k-e turbulence closure model. Highest derivative order is 2	Detailed coastal wave prediction, breaking wave dynamics, turbulence, pressure distributions, wave loads on structures, wave transmission through porous structures. Model provides velocity components and turbulence information throughout the water column

meant to provide a basis to compare the computational cost of the various models; this is a measure of the effort required to determine a solution at every model grid node at every time step. It is remarked that this table provides information relative to *typical* model usage, here meaning applications that might arise in engineering practice or on an operational level. Research-level applications push the domain sizes, resolutions, and applications well beyond the types given below.

27.5 Conclusions

In this chapter, we have provided a cursory overview of coastal wave modeling theory and methods. The information contained here provides a useful starting point for understanding the differences in the wide variety of approaches. Ultimately, the choice of model will be governed by the resources available for the study and the primary piece of physical information that requires estimation. If resources are light and a precise estimate of the wave conditions is not yet needed, as might be the case for a preliminary scoping analysis, linear wave theory may be an acceptable approach for coastal transformation. If accurate and relatively large-scale wave height and period information is the goal, spectral models will most likely be the best option, with the included level of nonlinearity and resolution controlled by the resources of the project. For studies requiring detailed, small-scale, and wave-resolved information, such as might be needed for critical infrastructure, a Boussinesq or Navier–Stokes approach is reasonable. It is reiterated that the background given here, in terms of the individual models discussed, does not represent the wealth of numerical modeling tools available to the international engineering community.

27.6 Nomenclature

η free surface elevation
H wave height
a wave amplitude
θ wave phase function
k wave number
ω angular frequency
L wavelength
T wave period
f wave frequency
g gravity
h water depth
c wave speed
u horizontal fluid particle velocity
H_o offshore wave height
K_S shoaling coefficient
K_R refraction coefficient
K_D diffraction coefficient
α wave angle of incidence
F wave energy flux
N time-dependent wave action density
S external wave forcing, source/sink term in spectral wave equations
C_b bottom friction coefficient
G functional form of wave energy sink
E local wave energy density
ε wave amplitude divided by water depth $= a/h$
μ wave number times water depth $= kh$

28. Modeling of Coastal Morphological Processes

J.A. Dano Roelvink, Dirk-Jan R. Walstra, Mick van der Wegen, Roshanka Ranasinghe

Morphology is the study of forms, whether of animals, plants or words; coastal morphology is the study of coastal forms. Some of these forms are hard (like rock) and do not move much. Others, such as beaches, dunes, channels, sandbars, shoals, are made of mud, sand, or even gravel and move all the time. Understanding and predicting these motions are what coastal morphologists try to do.

The approach we take depends on the scale of the problem or process we are interested in. This scale ranges from small-scale ripples to entire tidal inlets or coast lines. The larger the length scale, the larger the timescale; the upper beach profile can adapt to a storm in hours; the coastline around a port can take decades to adapt, and the effects of closing a tidal inlet can be felt for many centuries.

In coastal engineering, morphology is a core discipline. It is needed to assess damage to beaches, dunes, and barrier islands during extreme events; it is needed to understand and mitigate coastal erosion; it is important in the design of ports, to assess impact on the coast and estimate dredging requirements for the navigation channel and basins; it is needed in the design and impact studies of land reclamations and finally, it provides scenarios to use in coastal zone management.

In this chapter, we will first discuss different types of coastal morphology models. We will then zoom in and focus on process-based modeling in more detail. First, the fundamentals of process-based modeling are described, which is followed by short descriptions of the commonly used types of process-based models. Subsequently, a number of modeling approaches considering different scales, from storm-event modeling to long-term modeling of estuaries are presented. We conclude by discussing some future directions.

28.1 Types of Coastal Models

28.1.1 Physical Scale Models

We generally approach these problems with models, of which we have a variety at our disposal or under development. To start with, there are the physical scale models, which appear to be starting a new life, after a period in which all the focus was on numerical models. The Dutch design rules for dune erosion

are almost entirely based on large-scale flume tests and just recently have been adapted for changed design wave conditions based on such tests [28.1]. Scour around structures is another example where physical models are still much in use, in this case because of the complexity of the three-dimensional (3-D) currents and turbulence around them. However, in many cases such a direct application of physical modeling to a problem is difficult, and such models are then used to look into the details of processes and to validate numerical models that can be used at larger scales.

Large-scale physical models of tidal systems, rivers, and estuaries have become too expensive in developed countries to compete with ever-improving numerical models, but are still widely used in countries like China, where labor cost is relatively cheap and there is considerable expertise in dealing with inevitable scale effects. Combining such models with numerical modeling can lead to interesting results, and is probably a direction worth exploring further.

When waves are important and we have to look at large systems at the same time, physical modeling is no longer an option. The modeled waves would be too small to be represented properly, so we will have to look at other methods.

28.1.2 Analytical Models

First, we turn to analytical models. They can be simple and elegant and provide almost instant insight. The coastline theory of *Pelnard-Considère* [28.2] has shaped our thinking about large-scale coastal evolution, and analytical and numerical successors of the theory are still abundantly used [28.3]. Other, more complex, analytical models explain point bars in rivers and estuaries [28.4], sand waves and tidal sandbanks [28.5], and though they use strong approximations of the physics, they tell us which processes are responsible for certain phenomena we see, so we can make sure that more complex numerical models reproduce these processes, which in theory they should, but in practice often fail to do.

28.1.3 (Semi-)Empirical Models

The next type of models is heavily based on data and therefore called *empirical models*. The equilibrium profile model for dune erosion, which has made it into Dutch law, is a good example [28.1, 6]. Based on the observation that beach profiles always have the same shape after a storm, the method consists of shifting that profile back and forth until the eroded area equals the accreted area. A more advanced approach for beach evolution and dune erosion is used in SBEACH [28.7]. SBEACH is a one-dimensional (1-D) (profile) beach erosion model for storm where net sediment transport occurs when the local wave dissipation rate is different from the equilibrium rate. For tidal inlets and estuaries, there is a host of equilibrium equations [28.8], relating the tidal volume to channel cross-section, to total channel volume, to ebb delta volume, etcetera. If you divide a tidal inlet or estuary up into a number of units (ebb delta, channels, tidal flats) you can define equilibrium situations for each of them. However, that does not tell you how they get to their equilibrium. To solve this, *semiempirical* models were developed, where the units all try to get to their equilibrium but sediment has to be transported between them. The rate of sediment exchange depends on how far each unit is from equilibrium. *Stive* and *Wang* use this concept to model long-term, large-scale effects of sea-level rise and gas extraction, inlet closure, dredging, and other scenarios [28.9].

Such models have shown a lot of value for specific situations, where there is a lot of historical data and nice test cases from the recent past (closure of inlets, channel deepening for navigation) to calibrate the coefficients in such models. In many places around the world this is not the case; also, more complex situations or more detailed questions need to be addressed than can be represented by the semiempirical models we just discussed. In such cases, we turn to process-based morphodynamic modeling.

28.1.4 Process-Based Models

In process-based models, we start from a detailed description of processes and let sediment transports, bottom changes, and the evolving bathymetry follow from that. It is a bottom-up approach, where we do not specify any equilibrium situation beforehand but let the model evolve freely to wherever it wants to go. Obviously, this raises the question of whether such an approach can ever lead to sensible solutions in the longer term. As we will see in the following sections, there is ample scope for reasonable behavior using this approach and in the rest of this chapter we will focus on the process-based approach.

28.2 Principles of Process-Based Morphodynamic Modeling

The term *morphodynamic model* is short for *dynamic morphological model*, where *morphological* means the study of shapes, in this case of the sea bed, and *dynamic* indicates that we consider how sea bed changes as a result of processes acting on it. The basic flowchart given in Fig. 28.1 is valid for most types of morphodynamic models. We call it process-based modeling since we take a detailed description of the physical processes leading to sediment transport and bottom changes as a starting point.

28.2.1 What Is a Process-Based Morphodynamic Model?

We start from a bathymetry, given in two dimensions (in the case of area models) or one dimension (in the case of coastline or coastal profile models). Given boundary conditions for waves and currents, we predict the wave and current fields, which usually interact; together, these processes determine the sediment transport. As we will discuss next, the sediment transport gradients lead to bottom changes which then feed back into the bathymetry, the currents and waves and the sediment transports, and so on. Different models may differ greatly in the way they compute currents, waves, and transports and in the way the bottom changes are computed and fed back into the bathymetry. In the following, we will first discuss the sediment balance and the importance of the feedback between the bed evolution and the evolution of the sediment transport.

28.2.2 Mass Balance Equation

The dominant process acting to change the bottom is the sediment transport, and for coasts as in rivers, the most fundamental equation describing erosion and sedimentation is the mass balance equation or the Exner equation

$$(1-\varepsilon)\,\frac{\partial z_\mathrm{b}}{\partial t}+\frac{\partial q_x}{\partial x}+\frac{\partial q_y}{\partial y}=0\,. \tag{28.1}$$

Here ε is the porosity of the bed, z_b is the vertical position of the bottom (positive upwards) and q_x and q_y the components of sediment transport in x and y direction, respectively, expressed as volume transport per second crossing a unit width ($\mathrm{m}^3/\mathrm{m}/\mathrm{s}$).

The first thing we learn from this equation is that the rate of bed-level change depends on the sediment transport *gradients* rather than on the transport rate itself; an increasing transport (positive gradient) leads to a decrease in bed level (erosion), since more sediment leaves a control volume than enters it; likewise, accretion (sedimentation) occurs when the sediment transport decreases (negative gradient).

If the transport rates would not change with time, the erosion and sedimentation rates would be constant and the bed would move up or down with a constant speed. However, usually the sediment transport changes when the bottom changes, and this interaction creates a dynamic behavior where bed forms move around.

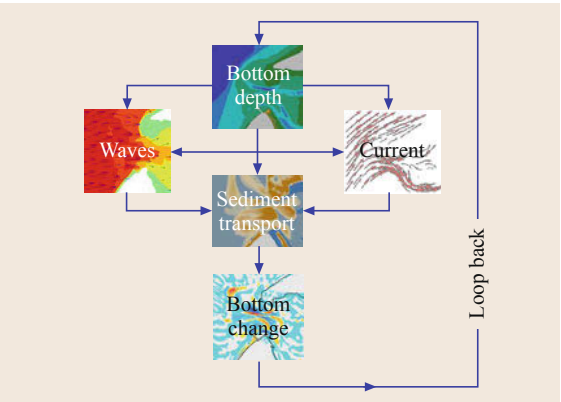

Fig. 28.1 Basic flow chart of a morphodynamic model

28.2.3 Bed Celerity

For one-dimensional, stationary flow through a channel, under the assumptions that transport is a function of velocity to a certain power b and that the current velocity is given by a constant discharge divided by depth h, it follows (see [28.10] for a derivation) that the bed evolution is described by the *simple wave* equation

$$\frac{\partial z_\mathrm{b}}{\partial t}+c_\mathrm{bed}\frac{\partial z_\mathrm{b}}{\partial x}=0\,. \tag{28.2}$$

Here

$$c_\mathrm{bed}=\frac{bq_x}{(1-\varepsilon)\,h}\,. \tag{28.3}$$

These simple equations explain how a hump on the bottom propagates at a speed proportional to the transport rate and to the power b in the transport relation, but inversely proportional to the depth; in other words, in shallow water bed forms move faster. It also explains why humps turn into shock-like dunes (because the top moves faster than the bottom) and for trenches the upstream side steepens, while the downstream side tends

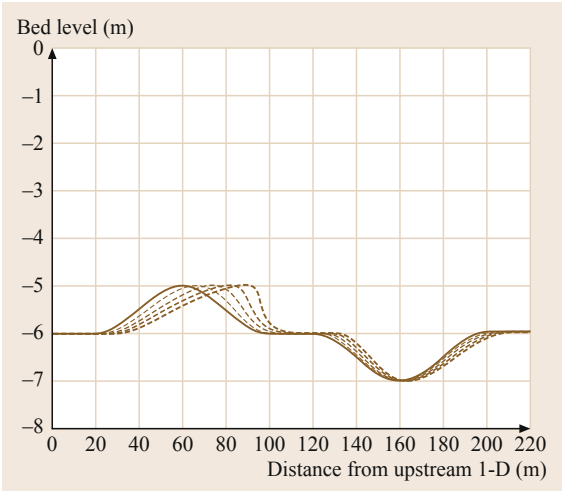

Fig. 28.2 Behavior of a hump and a trench in a channel

to smooth out. This behavior is illustrated in Fig. 28.2 for a 1 m high hump and 1 m deep trench across a channel with uniform depth of 6 m. In coastal areas, the development of such fronts is often seen, for instance, in the development of ebb shoals; likewise the behavior of a dredged channel perpendicular to a longshore current is often similar to what we see in the figure: a downstream migration and steepening of the upstream slope.

The so-called bed celerity c_{bed} also plays an important role in determining the time step of morphological updating in a numerical model, as we will see further on.

Through the simple example of the moving hump, we see that the shape of the transport relation is important in determining the morphological response. If the power b in the sediment transport relation changes, so does the bed celerity. Likewise, adding complexity to the sediment transport relation will lead to a more complex morphological response.

28.2.4 Development Toward Equilibrium

Another important feature of the mass balance equation is that when the divergence of the transport field goes to zero, the bottom change rate also goes to zero and an equilibrium or near-equilibrium is possible even though sediment transport circulations are present. Typical examples are a straight coastline where longshore transport is constant and therefore gradients are zero, or even a tidal inlet bypassing longshore sediment transport in a complex pattern, while experiencing little change. To illustrate this process, let us look at the bed evolution around a newly constructed, 300 m long groyne in an otherwise uniform, 1 km wide channel. The initial water depth is 5 m and the undisturbed current speed is around 1 m/s. Figure 28.3b shows the sediment transport magnitude just before we start updating the bed; the initial rate of erosion and sedimentation (Fig. 28.3a) for this example is of the order of 1.5 m/day. If the same transport pattern would persist, we would have around 500 m of erosion per year; however, since a scour hole develops the sediment transport is reduced by some orders of magnitude, and after 3 years the scour hole is *just* around 10 m deep. Upstream and downstream of the groyne shallow shoals develop; the overall morphological pattern leads to a much smoothed out and reduced sediment transport pattern, which is very close to equilibrium, as we can see from the time series of transport through a number of cross-sections (Fig. 28.3d), which all converge to the same value, almost two orders of magnitude smaller than the initial transport rates.

From these simple examples, we can see that the essence of morphodynamic modeling is the interaction between the sediment transport and the evolving bottom, which leads to moving bed features during transient states and under certain conditions will lead to equilibrium.

The way the sediment transport is a function of the evolving bottom is governed by the currents and waves acting on it and on the sediment properties both in the bed and in suspension. The level of detail at which these processes are described depends on the type of model; modeling approaches that are commonly adopted at present can be broadly divided into coastline models, coastal profile models, and coastal area models. These different approaches are described below.

28.2.5 Types of Process-Based Models

Coastline Models

The oldest type of morphodynamic model was first developed by *Pelnard-Considère* [28.2], who developed an analytical solution for the horizontal movement of the coastline, assuming that the cross-shore profile is constant in shape and that the part between the dune crest and the so-called depth of closure moves seaward or landward depending on the longshore transport gradient

$$h\frac{\partial y}{\partial t}+\frac{\partial S}{\partial x}=0\,. \tag{28.4}$$

Here, h is the active profile height, y is the cross-shore position of the coastline, x is the longshore position along the coastline, and S is the total longshore transport. When, for small deviations of the coast angle, we assume that transport varies linearly with the coast an-

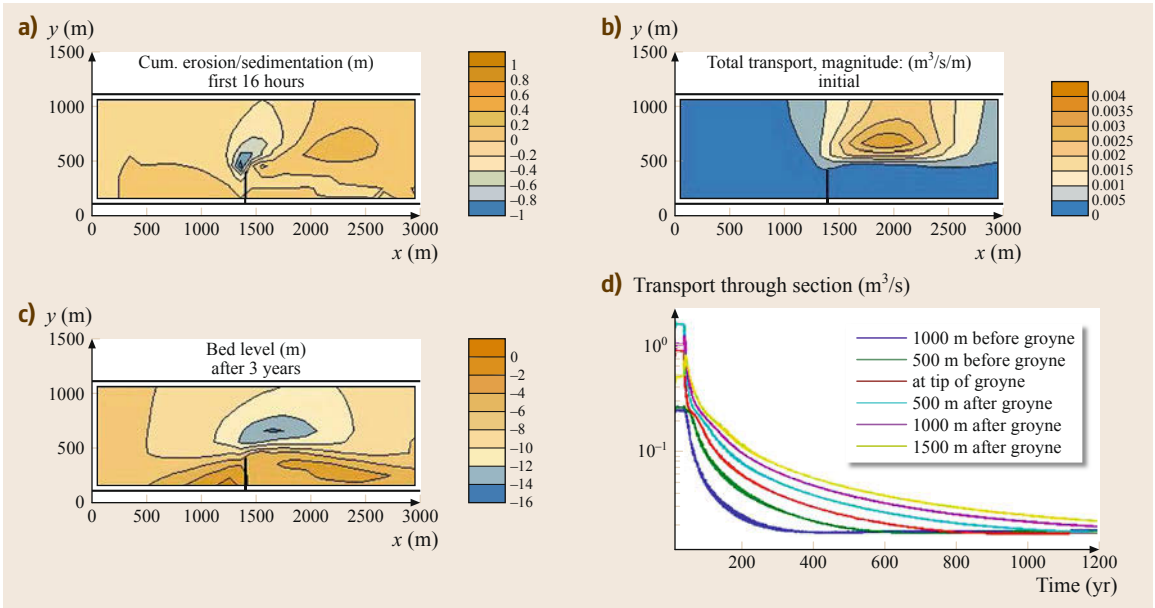

Fig. 28.3a–d Initial transport **(b)** and sedimentation/erosion **(a)**, final bathymetry **(c)** and time series of transport through selected cross-sections **(d)**, for the development of a scour hole near a groyne; sample simulation using Delft3D in 2-D horizontal (2DH) mode

gle and therefore with $\partial y/\partial x$, the coastline evolution is given by a diffusion equation as given by Pelnard-Considère

$$\frac{\partial y}{\partial t} - \frac{s}{h}\frac{\partial^2 y}{\partial x^2} = 0\,. \qquad (28.5)$$

Here s is a coastal constant depending mostly on the wave climate. Analytical solutions exist for this equation, describing for instance the accretion due to a groyne or the longshore dispersion of a nourishment. However, for more practical situations and a wider range of angles and processes the transport and resulting coastline evolution can be numerically evaluated using a bulk formula such as the CERC or Kamphuis formulas, in which case it is mostly a function of the incident wave energy flux and angle, or it may be evaluated using a coastal profile model. Coastline models such as GENESIS, UNIBEST LT/CL, BEACHPLAN, and LITCROSS (for a summary see for instance [28.10]) are widely used in engineering studies, but a word of caution is in order.

Coastline models assume gradually varying flow conditions and approximately parallel depth contours. Under such circumstances, the longshore transport can locally be treated as if it is fully adapted to the local incident wave conditions relative to the coast orientation. Since it typically takes hundreds of meters for the longshore current to spin up, coastline models should in principle be applied for large-scale applications, over alongshore distances of many kilometers. Good examples are the accretion of beaches updrift of a harbor [28.11], the large-scale evolution of river deltas, longshore spreading of large beach nourishments [28.12], evolution of headland embayments, and realignment of coastlines due to changes in wave climate [28.13].

However, with the help of various additional techniques coastline models are also frequently applied at relatively small scales, such as behind emerged offshore breakwaters, around T-groynes and near tidal inlets. This is achieved by combining a coastline model with a two-dimensional (2-D) wave model to predict nearshore wave climates, by extra terms in the longshore transport equations to account for set up differences, and sometimes by schematizing the coast into two interconnected coastlines. Such applications meet with increasing criticism, since a lot of the processes acting on such small scales are not represented in this approach.

Sometimes small-scale structures are somehow represented in a coastline model that is aimed at predicting large-scale trends. This in our opinion is fine, as long as one realizes that the details of the evolution in the vicinity of the structures cannot be trusted.

As explained above, the behavior of coastline models is mostly diffusive. However, when dominant waves approach the coast at an angle of more than approx-

imately 45°, the coastline evolution may become unstable: the maximum longshore transport rate occurs at an angle of around 45°, so if the angle at a given point is higher than that of its upstream neighbor, sand will accumulate there until the maximum transport is reached again. *Ashton* and *Murray* [28.14] elegantly show through coastline modeling that this can explain spectacular coastal shapes such as sand waves, flying spits, and capes.

It is shown in [28.10] that the behavior of coastline models can also turn from diffusive to propagating if the sediment supply is limited, for instance because of the presence of sea walls or groynes. As an example, if the coastline behind a groyne cannot retreat, the erosion shadow propagates alongshore in the downdrift direction. The mechanism for this is that the longshore transport does not only depend on the coast orientation, but also on the absolute coastline position. In Fig. 28.4, we show an example for a nourishment on a sandy versus a sand-starved coast. It must be noted that the latter situation often occurs as population encroaches on the sea and rivers cease to supply sand to the coast.

Coastal Profile Models

In profile models, the main assumption is that the coast is almost uniform in the longshore direction and therefore profile changes are dominated by cross-shore processes. A review of some possible approaches was given in [28.15]; an extensive discussion of physical processes relevant to cross-shore behavior can be found in [28.10]. Profile models typically consist of:

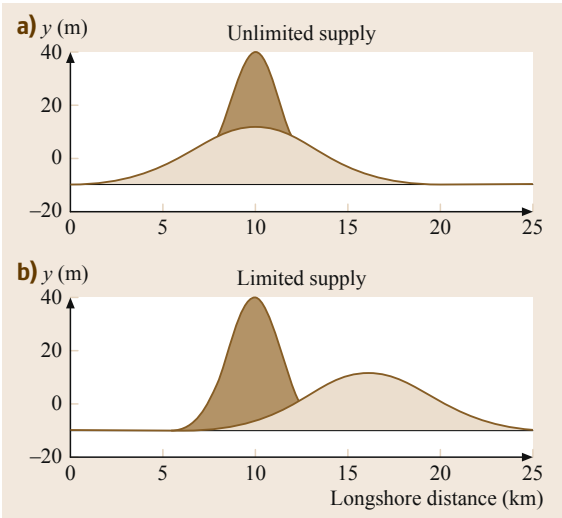

Fig. 28.4a,b Behavior of nourishment on **(a)** sandy coast versus **(b)** sand-starved coast; initial distribution (*dark brown*) and distribution after some time with obliquely incident waves (*light brown*)

- A wave model based on some form of the wave energy balance; this provides local wave conditions at each point along the profile.
- A 1DV (vertical profile) or 2DV model for the undertow and other near-bottom flow processes.
- A sediment transport model, which includes contributions due to undertow, wave skewness, and asymmetry, bed slope, etc.
- A sediment balance equation from which bottom changes are computed.

Since such models are not too computationally heavy, they can be run using realistic variations of wave, wind, and tide boundary conditions (brute force simulation), over periods of up to many years (Sect. 28.3.2).

Coastal profile models are typically applied to address two kinds of problems: evaluation of storm impacts on a coastal profile, with or without hard structures, and evaluation of longer-term behavior of sandbars and nourishment schemes, both on the beach and on the shoreface. The first type is the oldest, and in a way the simplest, since we try to model a situation with a very dominant seaward-directed transport, where the main difficulties lie in predicting the right magnitude and speed of erosion and in achieving the correct profile shape after the storm. Most of the profile changes take place in a few hundreds of meters seaward of the dune front or sea wall, and the duration of such events is at most a few of days. The second type involves the whole active profile, typically of the order of a kilometer cross-shore, down to a depth of some 6–15 m depending on the wave climate and on the simulation duration. Changes in the pattern of bars and troughs take place over years, where in some systems a single bar moves back and forth, and in others bars are created near the shoreline, move seaward initially while growing, and then damping out, allowing a new cycle to begin. This process may take from a couple of years to more than a decade. Such behavior is the result of a subtle balance between various counteracting processes, none of which are modeled very accurately. *Roelvink* et al. [28.16] obtained somewhat realistic, almost periodic bar behavior on a timescale of approx. a decade; *Ruessink* et al. [28.17] after rigorous model sensitivity study and extensive calibration reproduced bar behavior on a timescale of months for three different sites. Systems like this are affected by beach or foreshore nourishments that are of similar scale and clearly interact with the bar pattern. This makes modeling the behavior and longevity of nourishments very difficult: only when the natural bar behavior is modeled somewhat realistically can we have some confidence in the model's capability to predict the relative impact of the nourishment. Similar arguments are valid for hard

structures, which also interact with the profile on the same scale as the longshore bars.

Coastal Area Models

Coastal area models are applied where a separation between longshore and cross-shore scales is not possible, for instance in the vicinity of a tidal inlet, with a complex bathymetry with channels and shoals at varying angles with respect to the undisturbed coast orientation.

The typical composition of an area model is as follows (see also Fig. 28.1):

- A 2-D wave propagation model; by far the most used are spectral wave models, e.g., SWAN [28.18, 19] or Mike21SW; such models solve for wave shoaling and refraction, wind growth, whitecapping, and wave breaking and provide spatially varying field of wave properties and radiation stresses used in the flow and sediment transport models.
- A 2DH, Q3D or 3-D flow model, usually based on the shallow water equations, solving the nonstationary flow fields and water level variations due to tide, wind, waves, and density gradients.
- A sediment transport model, usually combining bed load transport with suspended load transport based on the 2DH or 3-D advection–diffusion equation or on an energetics approach, with specifically for coastal areas important effects of wave stirring included.
- A sediment balance and bottom composition bookkeeping system, which updates the bathymetry and composition of the bottom (in case of multiple sediment fractions).

Area models are applicable at a range of scales, from small-scale coastal engineering problems to macro-scale evolution of tidal basins.

At the smallest scales, we are talking about the details of the waves and wave-driven flow patterns and resulting morphology changes around small structures such as groynes and detached breakwaters, or the erosion of dunes where the coast is not alongshore uniform. The small grid cell sizes required to resolve the main processes and associated small time steps make such problems computationally intensive, especially when predictions over longer time than some storms are required. An important choice is whether to treat the problem as two-dimensional, where the focus is on the effect of the horizontal circulation patterns, or as (quasi-) three-dimensional, where vertical circulations (undertow) are accounted for as well as additional wave-related effects providing an onshore component [28.20, 21]. In the first case, beach profiles may evolve that are far from an equilibrium shape; in the second case, there will be a tendency toward restoring a certain profile shape, but much care must be given to tuning the cross-shore processes in such a way that reasonable profiles develop or are maintained. At these scales, sandbars may also be resolved, but as we discussed under profile models, obtaining the right bar behavior is a tight balancing act. An especially difficult challenge is to model the natural evolution of complex three-dimensional beach topography, where it is a key to get the transitions between different beach states right [28.22–24].

At a larger scale, for instance, in studies of harbor extension, inlet stabilization or large-scale nourishments or land reclamations, details of processes within the surfzone usually cannot be resolved, but the surfzone must be resolved at least enough to generate a decent longshore current and transport; this means a minimum of 5−10 grid cells across the surfzone. As these studies are often aimed at predicting the evolution over months to years, it is important that some cross-shore transport processes are accounted for, so cross-shore profiles stay in a reasonable shape even though bars cannot be represented and must perhaps even be prevented from occurring. Part of the evolution of coastal profiles depends on the interaction with the dunes, in terms of dune erosion and regeneration by wind-blown transport. Such processes are typically ill-represented and some heuristic approaches to exchange sand between the wet model domain and the dry beach and dunes are called for.

In larger scale, longer term situations, for example the long-term evolution of tidal basins, simulations over time spans of centuries are now possible with the help of new acceleration techniques, allowing us to study the equilibrium behavior of tidal basins and the potential impacts of the sea-level rise on such basins [28.25–29]. Surprisingly, realistic results are obtained using relatively simple physics, though a general tendency in such simulations is to generate too deep and narrow channels. Recent research, however, shows that much better channel profiles are obtained when taking into account the spatial variation in grain sizes and especially the tendency of sediment to coarsen with increasing mean shear stress. When the adjacent coasts and ebb deltas are to be properly represented wave effects must also be included. This poses severe restrictions on the nearshore grid resolution and drastically increases the computational cost, typically, by at least an order of magnitude. The applications and scales discussed in the previous paragraphs are summarized in Table 28.1.

28.2.6 Upscaling Techniques

Morphodynamic model components each have their typical timescales and numerical time steps. For flow

Table 28.1 Overview of model applications and scales (after [28.10])

Time scale	Space scales		
	1 m–1 km	10 m–10 km	100 m–100 km

Scales of application of [a] profile models, [b] coastline models, [c] area models

models that resolve tide and wind-related variations (hours–days) typical time steps are from seconds to minutes; wave models used are often stationary or slowly-varying with 5−10 min time steps; transport models usually have time steps similar to the flow model. A straightforward way to update bathymetry in a morphodynamic model is to update the bathymetry every flow time step, and to have the morphological time step equal to the flow time step. However, since morphological timescales are often several orders larger than hydrodynamic timescales (compare bed celerity with wave celerity), this is very inefficient, except during extreme conditions when morphology changes rapidly.

To overcome this gap in timescales, several methods have been proposed, see [28.30, 31] or [28.32]. The most common methods used today are:

- Tide-averaging approach: Here, sediment transports are computed through a tidal cycle, while keeping the bottom constant; the transports are then averaged and from the averaged transports the bottom change rate is computed; bottom changes are computed using a morphological time step that may be larger than the tidal period. Often this method is combined with simplified updating of the transports using so-called *continuity correction* or *rapid assessment of morphology* (*RAM*) techniques, to avoid having to re-evaluate the full hydrodynamics too often. Drawbacks of the method are that morphological time steps are limited by bed celerity Courant number and in dynamic systems can become less than the tidal period, which makes the method inefficient; the continuity correction or RAM steps reduce the accuracy, especially in wave-dominated cases.
- *Online* or *morfac* approach: Here the bottom is updated every flow time step but bottom changes are multiplied by a morphological factor or *morfac*. This way, after 1 tidal cycle one obtains the morphological changes of *morfac* tidal cycles. The results within the tidal cycle cannot be trusted because the amplitude of bed changes is exaggerated *morfac* times, but since these intratidal changes are typically very small, the end result is surprisingly accurate. Since updating takes place so often, the method is numerically very smooth; the implementation is also very straightforward, so nowadays in most long-term simulations the *morfac* approach is used. Typical *morfac* values range from 10 for very dynamic, small-scale problems to 200 or more for large-scale tidal basin simulations. With some caution, it is possible to use a time-varying *morfac*, for instance when simulating a series of wave or river discharge conditions, where short energetic conditions are simulated with a lower *morfac* than long moderate conditions. In [28.33], based on the results of a numerical modeling exercise using the morphodynamic model Delft3D, the main dependencies and sensitivities of the MORFAC approach were investigated. A criterion (based on the Courant–Friedrichs–Lévy (CFL) condition for bed form migration) for the a priori determination of the critical MORFAC was also proposed, but further work is needed to extend this criterion to tidal situations.
- *Parallel online* approach, where in the case of a rapidly varying wind and wave climate the chronology of different conditions is not important, simulations for different conditions are carried out in parallel, while the bottom changes due to all conditions are exchanged, averaged, and passed back after every time step. This has the advantage that the simulations for different conditions can be carried out on different processors, and since the averaged result is rather smooth, a relatively high *morfac*

can be used. A drawback of the method is that it is technically somewhat involved, but once implemented correctly it makes long-term simulations in complex areas including wave effects feasible; *Dastgheib* [28.34] used it to make a very detailed 50-year hindcast of the development of the Marsdiep inlet in the Netherlands after closure of the Zuiderzee.

An important aspect of the upscaling approach is the necessary input reduction in the forcing; in order to simulate with high *morfac* or using the tide-averaging approach, the wind, discharge, and wave climate must be schematized to a smaller number of representative conditions. A number of approaches have been developed to do this; for extensive discussions, see [28.10, 35, 36].

28.3 Modeling Approaches

In the following sections, we will discuss a sampling of process-based coastal morphodynamic modeling approaches for cases where there has been much recent development.

In the first approach, we discuss modeling of storm or swell events impacting complex coasts, where longshore uniformity cannot be assumed, impacts may go from collision to full inundation regimes [28.37], and where wave-group-related long waves can be dominant.

In the second study, we describe recent developments and insights into modeling the mechanisms of cross-shore breaker bar cycles, the understanding of which is necessary to design local engineering works or nourishments, which often interact with the bar behavior and are studied on timescales of months to years. In the discussion, we stick to alongshore uniform conditions but the model concepts are readily extendable to coastal area models.

The last case describes the long-term modeling of estuaries, using a schematized 2DH process-based modeling approach. This type of modeling has important implications for understanding the response of tidal systems to sea-level rise, but can also support geological research as it can actually generate realistic morphologies, not just predict bottom changes.

28.3.1 Storm Event Modeling

Background

In this approach, we describe the modeling of fast and complex processes during extreme events, where high temporal and spatial resolution are required. We do this based on a recent model development which has allowed a paradigm shift from simple, quasi-stationary, largely empirical approaches to a physics-based approach where the lessons learned from decades of model development have led to a robust modeling tool where the important processes during such events are resolved. In the following section, we will focus on storm events rather than tsunamis, since the vast majority of modeling studies related to tsunamis, their impact and design consequences deal with hydrodynamics only, as the morphology changes during a tsunami do not affect the flow speeds and runup heights much. However, morphological studies are increasingly carried out in order to interpret tsunami deposits, which will be discussed in Sect. 28.4.6.

The devastating effects of hurricanes on low-lying sandy coasts, especially during the 2004 and 2005 seasons in the USA (Fig. 28.5), have pointed toward an urgent need not only to be able to assess the vulnerability of coastal areas and (re-)design coastal protection for future events, but also to evaluate the performance of existing coastal protection projects compared to *do-nothing* scenarios. Existing dune erosion models such as DUROS [28.38], DUROSTA [28.39], and SBEACH [28.7] had proven their usefulness but could not cope with longshore varying topography, overwashing and inundation, hard structures, and other complexities.

The XBeach model [28.40] was developed to overcome these limitations. It can not only be used as a stand-alone model for small-scale (project-scale) coastal applications, but can also be used within the operational model systems, where it is driven by boundary

Fig. 28.5 Post-Katrina aerial photograph of Dauphin Island, Alabama (USA). Source: USGS/NASA

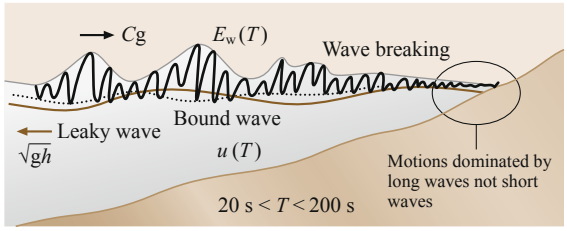

Fig. 28.6 Principle sketch physics of wave groups and surf beat

conditions provided by the wind, wave, and surge models and its main output to be transferred back will be the time-varying bathymetry and possibly discharges over breached barrier island sections.

Physical Processes Included in XBeach

The model solves coupled 2-D horizontal equations for wave propagation, flow, sediment transport, and bottom changes, for varying (spectral) wave and flow boundary conditions.

Because the model takes into account the variation in wave height in time (long known to surfers) it resolves the long wave (infragravity) motions created by this variation. This so-called *surf beat* is responsible for most of the swash waves that actually hit the dune front or overtop it. Because of this innovation, the XBeach model is better able to model the development of the dune erosion profile and to predict when a dune or barrier island will start overwashing and breaching. The physics behind the surf beat formulations in XBeach is illustrated in Fig. 28.6. The individual waves travel in groups and their envelope slowly varies in time and space. The short-wave energy and its modulation propagate at the group speed Cg; associated with these variations are bound long waves; as they propagate into the surf zone, the short-waves break but the bound waves are released and are reflected in offshore direction as *leaky waves*. In total, the result is that the short wave energy at the shoreline is small and the motions there are dominated by the infragravity motions. In XBeach, the individual wave motions are not resolved but the wave energy variation on the wave group scale is, as well as the resulting long-wave motions.

Furthermore, in contrast to most existing dune erosion models, XBeach is a fully two-dimensional (area) model and can thereby take into account longshore variations in topography, effects of the longshore current and gradients in longshore transport.

1-D Validation Tests

The model has already been validated against extensive large-scale flume data sets including short- and long-wave distributions, return flow, orbital velocities, concentrations, and profile change during dune erosion events. An essential part is an avalanching mechanism which allows a surprisingly accurate description of the evolution of the upper profile and dune face. Figure 28.7 shows a comparison between measured and computed dune profile development for large-scale tests carried out at Delft Hydraulics' Delta Flume in 1993 [28.41]. In the lower panels, the importance of both the

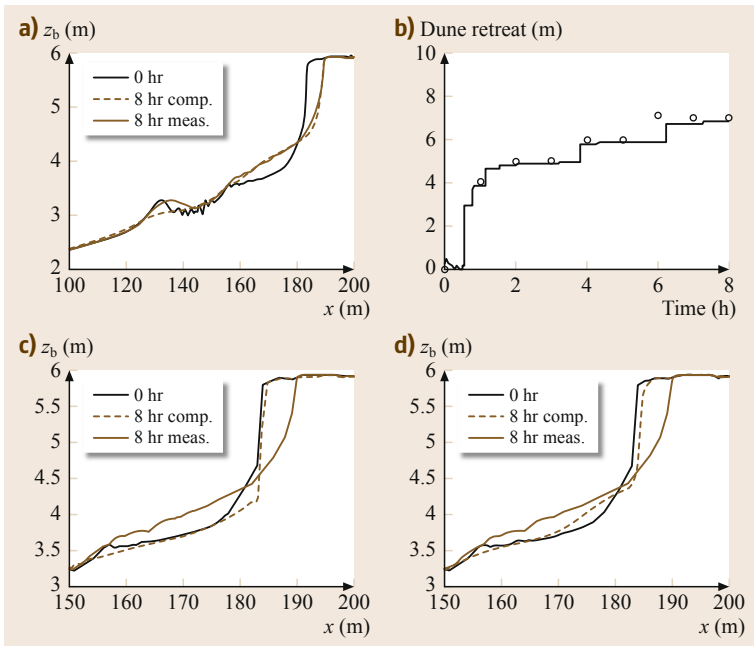

Fig. 28.7a–d Measured and simulated profile development for Deltaflume test (after [28.41]), test 2E; **(a)** all processes; **(b)** retreat of dune front in time, measured (*circles*) versus computed (*drawn line*); **(c)** profile evolution without avalanching; **(d)** without wave groups (after [28.40])

long-wave motions and the avalanching mechanism is illustrated.

In [28.40], extensive validation is shown for hydrodynamics, sediment transport, and profile evolution for a number of test cases. This number has since been extended to practically all large-scale tests used in the past to develop empirical dune erosion models, and results can be found in the regularly updated skillbed report on www.xbeach.org.

2DH Validation Tests

In [28.42], the first 2DH field validation test was carried out, in a hindcast of the impact of hurricane Ivan on Santa Rosa Island, Fl, in the Gulf of Mexico. This simulation has shown that XBeach can simulate complex runup and inundation overwash over longshore varying terrain. The level of detail of these simulations is illustrated in Fig. 28.8, which shows a snapshot of an animation during the onset of overwashing. The model is capable of producing morphological features common to overwash, such as foredune erosion, back barrier deposition, and washover fans. The uncalibrated result showed an overestimation of the erosion during the inundation phase and accompanying extreme current speeds, as the Soulsby–van Rijn transport model used at the time was not developed for such conditions, but after a shear stress limiter was included the behavior was much improved.

In Fig. 28.9, the erosion and sedimentation pattern as simulated and observed from LIDAR (light radar) data is shown; there is a striking agreement both in the erosion zone and in the deposition areas. The quantitative skill of the calibrated model was reasonably good.

Erosion of Curved Coastlines

The original implementation of XBeach uses a rectilinear, nonequidistant finite-difference grid, which is adequate for applications with a relatively short longshore extent or with a rather straight coast, such as the Santa Rosa Island case. However, for longer stretches of a curved coast (typical applications where you would want to use it) it becomes cumbersome to maintain the required fine resolution to resolve dune erosion processes. A curvilinear approach can overcome this problem and allow including the effects of longshore gradients on coastal evolution in a smooth manner.

This first field test case for the curvilinear version of XBeach, described in [28.43], concerns the response of the sandy sea defense of the new Rotterdam port extension Maasvlakte-2 during an early construction phase when it had a banana-like shape (Fig. 28.10). During a storm event on September 3–5 2009 considerable scarping of the steep profiles took place, where

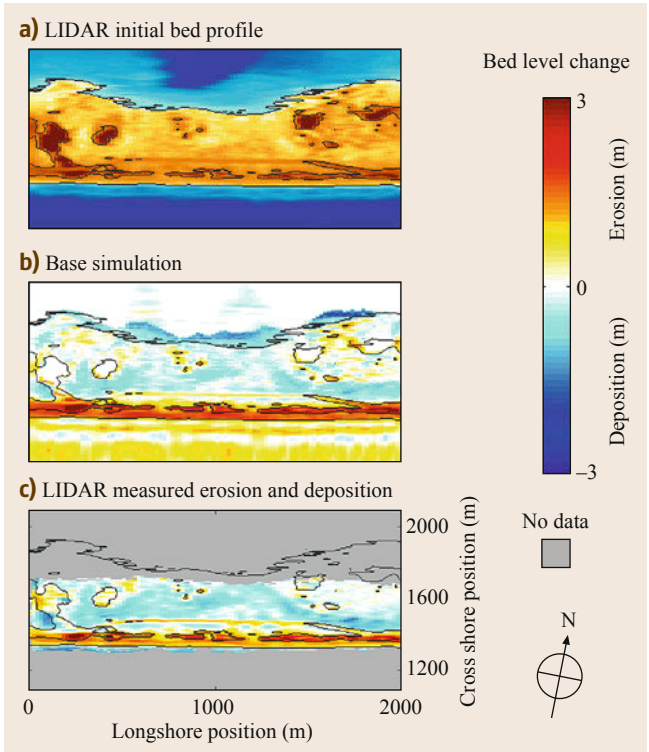

Fig. 28.9 **(a)** Measured LIDAR topography, **(b)** simulated and **(c)** observed sedimentation and erosion, Santa Rosa Island

the eroded sediment was not just deposited seaward but to a large extent was moved alongshore, as can be seen in the third panel. A curvilinear grid was set up with the resolution of 6–20 m in cross-shore and 17–50 m in the longshore direction. Observed time

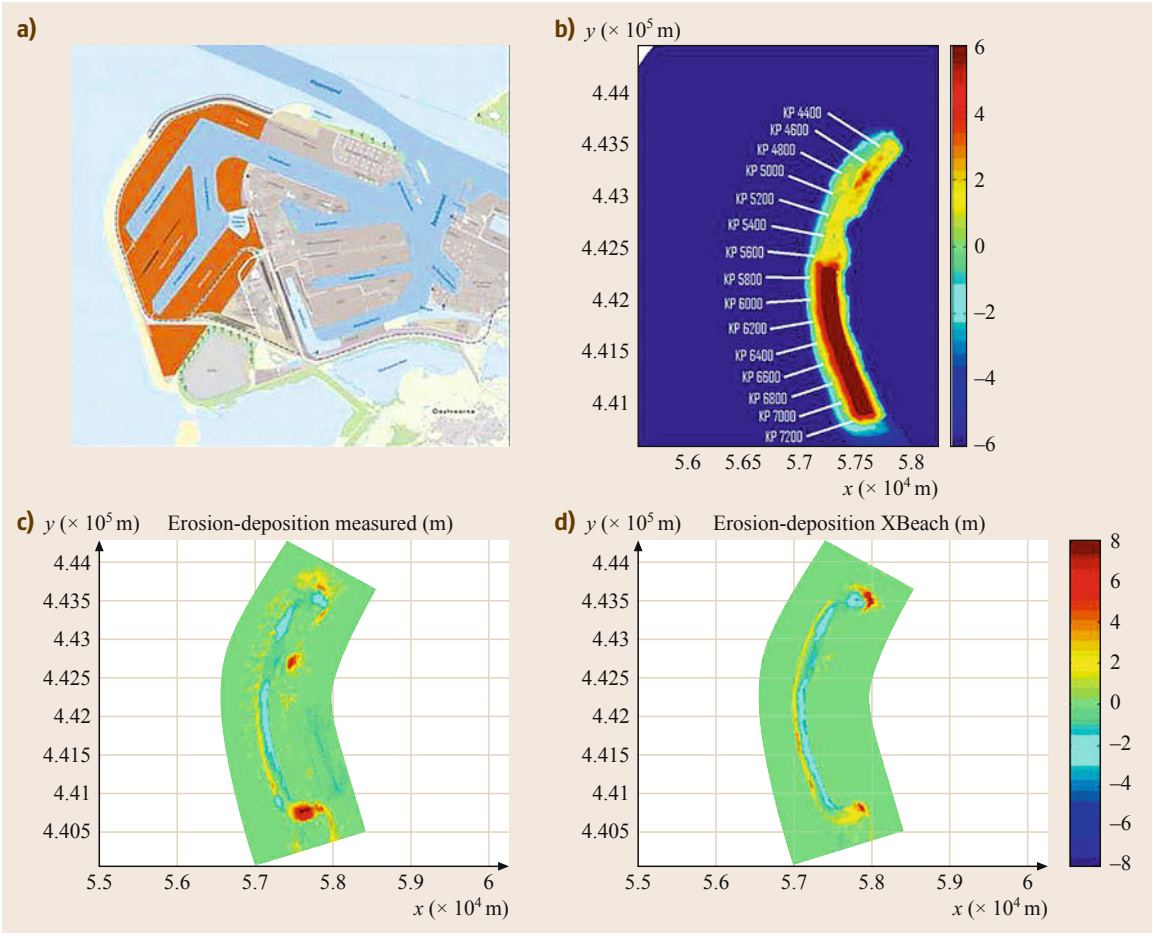

Fig. 28.10 **(a)** Layout of new port extension; **(b)** topography during building phase; **(c)** measured and **(d)** computed sedimentation/erosion

series of water levels and wave conditions were imposed and a simulation was carried out over a period of three days, using default sediment transport settings. Figure 28.10b,d shows the computed erosion and sedimentation. Both in observations and simulation, considerable scarping took place with only a small part being deposited offshore and a larger part moved alongshore and deposited at the ends. This is illustrated further in a cross-sectional view of KP4800 in Fig. 28.11, where the observed profile change is compared against 2DH and 1-D simulations.

This case clearly shows the importance of including the longshore dimension in the modeling of storm erosion.

The model was tested for nine field sites in the framework of the EU-MICORE project (Fig. 28.12). Each field site had a unique bathymetry/topography and/or wave/tidal climate and contributed to testing the

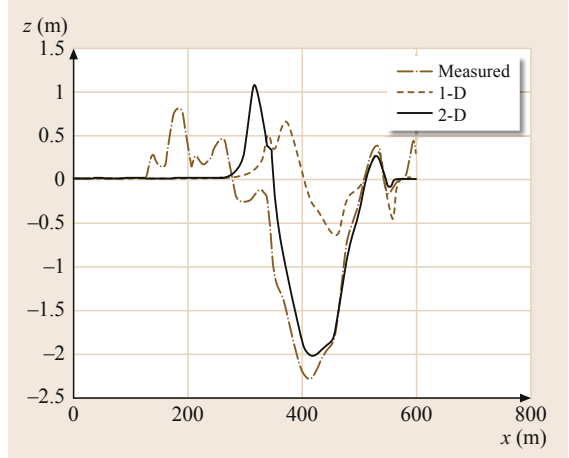

Fig. 28.11 Comparison of profile change between observed, 1-D and 2-D simulations

modeled physics under a wide range of environmental conditions. The full results are presented in [28.44].

In the previous section, we have shown that modeling dune erosion and overwash processes do no longer have to rely on empirical or semiempirical approaches, but that a process-based approach is feasible. The big advantage of such an approach is that it is much more generic and the same model concepts may be applied, after thorough validation, in widely varying environments, from the sandy North Sea coasts to open-ocean coral reef environments.

28.3.2 Modeling Cross-Shore Breaker Bar Cycles

Most sandy coasts have sand-bar features [28.45, 46], which exhibit a range of behavior, on timescales of days to decades. Such features are at similar length and timescales as engineering measures such as groynes, offshore breakwaters, and nourishments, and their state at any given time affects the safety of dikes and dunes behind them. It is therefore very important to unravel the dynamics behind their generation, migration, and fading out. In a recent paper [28.47], important steps were taken to do just that; a summary is given below.

Multiple bar systems often show a cyclic net offshore directed migration with return periods of the order of years. Typically, a bar is generated near the shoreline, grows in height and width, while migrating offshore before finally decaying at the seaward limit of the surf zone [28.48–51]. The observed bar behavior reflects cross-shore oriented bar variability and is not the result of alongshore propagating shore oblique bars [28.52]. This implies cross-shore hydrodynamic and sand transport processes are dominant over longshore processes. Cycle periods vary worldwide between approximately 1 and 15 years [28.49]. The net offshore bar migration is the result of gradual onshore movement during calm periods and episodic strong offshore movement during storms. However, the longshore coherence does not imply that bars along the coast are in the same phase of the cycle. At certain locations, distinct shifts can be observed in which for example the outer is attached to an inner bar, this is often referred to as bar switching. Furthermore, small alongshore variations in bar position and crest height may result in a different morphological response during parts of the cycle period.

Walstra and *Ruessink* [28.53] explored the suitability of a process-based cross-shore profile model (Unibest-TC, [28.17]) to hindcast one cycle at Noordwijk, the Netherlands from 1984 to 1987 using the standardized calibration approach of [28.17]. The multiple bar system at Noordwijk in the Netherlands was selected because it has a relative short bar cycle of about 3–4 years.

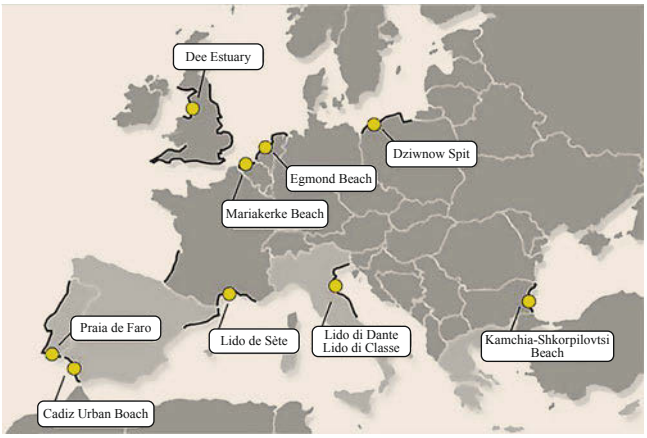

Fig. 28.12 MICORE field test sites

Quantitative descriptions of cyclic large-scale morphological developments have been provided, but the physical reasons underlying the intersite difference in the bar cycle period are not well understood. Among others [28.49] and [28.52] have found various correlations between bar response and environmental parameters. However, these correlations only provide a phenomenological explanation for observed intersite differences. In the following, we summarize [28.47] which investigated the bar amplitude growth and decay within the bar cycle using the [28.17] wave-averaged cross-shore process model to identify the dominant mechanisms driving this transient bar amplitude response.

Mechanisms Underlying Bar Amplitude Change

A detailed analysis, in which the Noordwijk hindcast is combined with a range of schematic cases, is undertaken with the aim of determining the dependency of bar amplitude growth and decay on the offshore wave conditions (height, period, and angle) and cross-shore bar location. Finally, the identified dominant processes that govern bar amplitude change are related to the observations to explain the transient bar amplitude change during the interannual net offshore bar migration.

As a first step to determine when bars grow and decay, dA_b/dt, extracted from the 3.4 year simulation (Fig. 28.13), was correlated with offshore and local (i. e., at the bar crest) wave parameters. Figure 28.14 demonstrates the correlation coefficients significant but lower than 0.5. The offshore wave height and the wave height at the bar crest result in similar correlations. Interestingly, the sign of the correlation changes from bar 1 (most landward) toward bar 4 (most seaward). This indicates the opposite response to similar wave conditions, also observed in Fig. 28.13. Especially the large

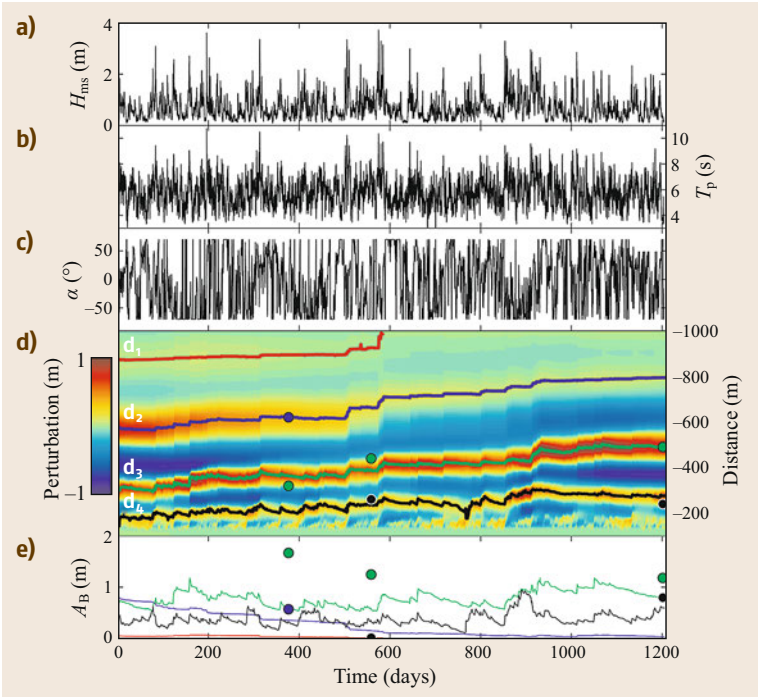

Fig. 28.13a–e Time series of **(a)** offshore root-mean-square wave height $H_{\widehat{rms}}$, **(b)** offshore peak wave period $T_{\hat{p}}$, **(c)** offshore incident wave angle α, **(d)** time stack of predicted profile perturbation and indication of bar crests (after [28.1–4]), and **(e)** predicted bar amplitudes $A_{\hat{b}}$

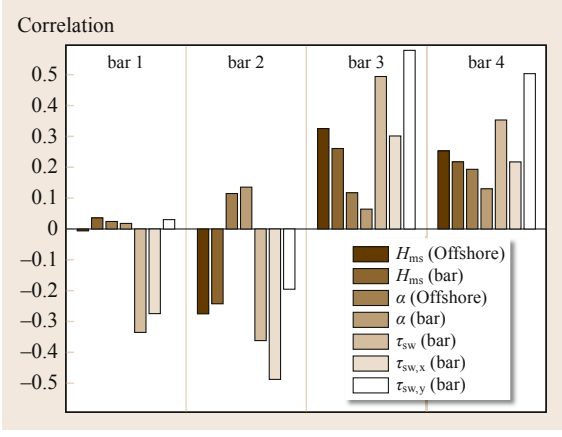

Fig. 28.14 Correlation coefficients between wave parameters and dA_b/dt

correlation with the longshore surface stress $\tau_{sw,y}$ for bars 3 and 4 indicates that longshore forcing may play a significant role in the bar growth in the inner surf zone.

Application of a range of conditions systematically varying H_{rms}, T_p, α, and η revealed that bars only grow for specific wave conditions and that the angle of wave incidence controls whether a specific (H_{rms}, T_p, η) condition results in bar growth or decay (the same wave height and period can result in either bar decay or growth depending on the wave angle). However, the growth rates ($dA_b/dt > 0$) are more frequent and significantly higher for the more shoreward inner bars. This also explains the transient bar response in the hindcast simulation (net decay of bars 1 and 2 and net growth of bars 3 and 4).

Detailed evaluation of model results showed that obliquely incident waves induce longshore wave-driven currents which influence the magnitude of bed shear stresses and subsequently the cross-shore distribution of the sediment transport via enhanced sediment stirring. As waves break, they do not instantaneously dissipate energy, it is first transferred to the surface rollers in which the energy is dissipated: this results in a landward shift of τ_{sw}. However, the local distribution of the cross-shore currents over the bar is particularly sensitive to variations in the local water depth due to the wave-induced undertow which causes the location of the maximum cross-shore currents to coincide with the bar crest location. In contrast, the wave-driven longshore current originates directly from $\tau_{sw,y}$, and consequently has a very similar distribution resulting in a concomitant landward shift of the longshore current [28.54, 55]. Since the longshore current is typically much larger than the cross-shore current for oblique incident waves it dominates the cross-shore distribution of the sediment concentration. If the longshore current is strong enough, the offshore transport peak is shifted landward of the bar crest promoting bar amplitude growth when bars migrate offshore. During onshore bar migration the

presence of longshore current results in enhanced offshore transports in the trough and on the landward bar slope. Thus, for onshore bar migration also, the incident wave angle and the associated longshore currents are very important as sand is eroded from the troughs and deposited on the bar enhancing bar growth and onshore migration.

The implications for the bar response are further illustrated using schematic profiles with bars at various cross-shore positions, thus varying the water depth at the bar crest h_{Xb} (Fig. 28.15). The initial bar amplitude (dA_b/dt) and migration (dX_b/dt) responses were analyzed using a single wave condition ($H_{rms} = 1.7\,m, T_p = 8\,s$) combined with a range of wave angles ($\alpha = 0°–70°$, $\Delta\alpha = 2.5°$). By combining the transitions from growth ($dA_b/dt > 0$) to decay ($dA_b/dt < 0$) (indicated by gray line in Fig. 28.16) with the transition from landward ($dX_b/dt > 0$) to seaward ($dX_b/dt < 0$) (black line Fig. 28.16) it is clear that landward or seaward migration is uncorrelated with amplitude change as all combinations of bar response: landward, seaward migration (denoted as L, S) with bar growth and decay (denoted as: D, G; Fig. 28.16) can occur for the same wave condition. It is noteworthy that in deeper water ($h_{Xb} > 6\,m$) bars decay but do not migrate anymore. Furthermore, onshore migration rates are usually lower than offshore migration rates and are associated with lower growth rates. The largest bar amplitude change (growth and decay) takes place during offshore migration.

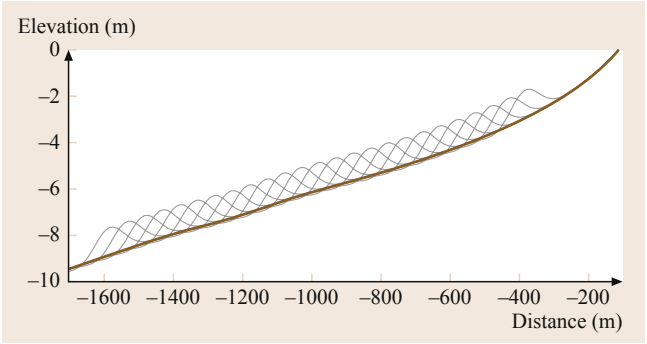

Fig. 28.15 Averaged profile (*black*) and bottom profiles with the schematic bars (*gray*)

Cyclic Bar Behavior Explained

The water depth at the bar crest h_{Xb} and the angle of wave incidence α control the generation of the longshore current. For bars in shallow water, the bar amplitude response and α are strongly related, due to the relatively strong longshore current that waves breaking under an angle generate. The absence of breaking waves and the associated longshore current at bars in deeper water result in the dominance of cross-shore currents on sediment transport. This results in transport peaks that coincide with the bar crest location forcing the bar amplitude decay at larger water depths. The strong dependency on the longshore current also explains the observed transient bar amplitude response during the net interannual offshore migration. For bars in relatively shallow water wave breaking is more frequent, promoting net bar amplitude growth in case of oblique wave incidence, whereas in deeper water wave breaking on the bars is limited, leading to net bar amplitude decay. The latter usually is the onset of a generation of a new bar being generated near the shoreline perpetuating the cycle.

The studies described here indicate that even assuming longshore uniformity, much of the cross-shore behavior of sandbars can be described with relatively simple physics, where undertow, wave asymmetry and skewness, longshore current, and bed slope effects are the dominant mechanisms. Since these processes can be readily implemented in 2DH or 3-D models, there is a reason for optimism that with the tuning provided in this study, such models will be able to describe the full rich behavior in the case of nonlongshore uniform morphologies. However, this still remains to be proven in practice.

28.3.3 Long-Term Modeling of Estuaries

The morphodynamic modeling of estuaries is an area where much progress has been made in recent years, in physical modeling, analytical, semiempirical, or aggregated methods and in process-based numerical modeling. In the following section, we aim to present an overview of recent advances and case studies of estuarine morphodynamic modeling efforts with process-based models. We distinguish studies with a *fundamental* approach from studies with a more *realistic* approach. The fundamental approach is more schematized and aims to develop understanding on the long-term evolution or equilibrium conditions of morphodynamic systems. The *realistic* approach aims at morphodynamic predictions in a realistic environment on an engineering timescale up to decades.

System Understanding – Schematized Approach

Process-based numerical models can be used to explore equilibrium conditions of the longitudinal estuarine bed profile by tidal forcing under idealized 1-D forcing conditions [28.27, 56–60]. Idealized 2-D models including the evolution of channel-shoal patterns [28.4, 26, 27, 61–64] show that stable channel-shoal patterns develop within decades by starting from a flat sandy bed in a rectangular basin and applying highly schematized tidal forcing. The development of the longitudinal bathymetric profile is subject to a second, much longer timescale and is caused by tide-residual sediment transports resulting from tidal asymetry along the basin. In a similar modeling exercise [28.65, 66] show that morphodynamic evolution leads to less morphodynamic activity due to continuously smaller spatial shear stress gradients. The model results compare well the empirical relationship between the cross-sectional area (A) and tidal prism (P) [28.67] (Fig. 28.17).

The importance of a flow-confining estuarine geometry becomes clear once a realistic plan form is applied within the schematized modeling approach. 2-D process-based models are able to reproduce realistic morphological patterns observed in real estuaries [28.28, 29, 68, 69]. Van der Wegen et al. [28.70] show that modeled channel-shoal patterns significantly resemble the measured bathymetry by just imposing the Western Scheldt geometry and major tidal forcing. A systematic sensitivity analysis shows that including external overtides, varying grain size, different sediment transport formulations, and dredging and dumping activities only have a secondary effect on the evolving channel-shoal patterns. This suggests that the estuarine plan form is a governing factor in the estuaries' morphology and morphodynamic development.

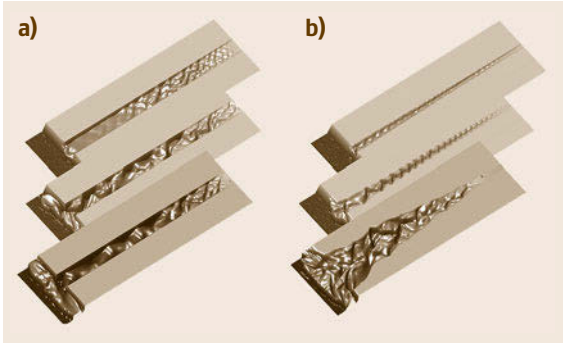

Fig. 28.17a,b Impression of bathymetry after 25, 400, and 3200 years **(a)** with fixed banks (2.5 km wide and 80 km long) and **(b)** with erodible banks (initially 0.5 km wide and 80 km long). Scales are distorted (after [28.67])

Given that a highly schematized model is able to reproduce a realistic bathymetry, long-term varying forcing conditions may be adapted. An example is the study by the authors of [28.71, 72] who explore the impact of the sea-level rise on the morphology previously generated by the same model under constant forcing conditions. They show that intertidal area slowly disappears when realistic sea-level rise scenarios are imposed on a stable channel-shoal pattern earlier generated by the model itself. The advantage of this methodology is that model parameter settings are kept constant. In such a case, the model results will not suffer from morphological adaptations by poor model parameter settings or limited process description, which would probably occur when the sea-level rise is imposed on a measured bathymetry in a more realistic setting.

Realistic Conditions – Dealing with Complexity and Uncertainty

In contrast to highly schematized model settings, more *realistic* models take an existing and often complex environment as a starting point. Policy makers, decision makers and engineers have an interest in short-term high-resolution predictions, since there is an urge to anticipate on likely morphodynamic evolution to mitigate unwanted developments, or else, take action. The morphodynamic effect of man-made works in an estuary may be relatively large within a relatively short (decadal) period compared to system adaptations due to slowly varying forcing conditions such as sea-level rise. As an example, *Apostos* et al. [28.73] and *Van der Wegen* and *Jaffe* [28.74] describe process-based modeling efforts to reproduce morphodynamic developments in San Pablo Bay, a subembayment of San Francisco Estuary. A unique data set describes a 150-year period measured on a 30-year interval. It covers

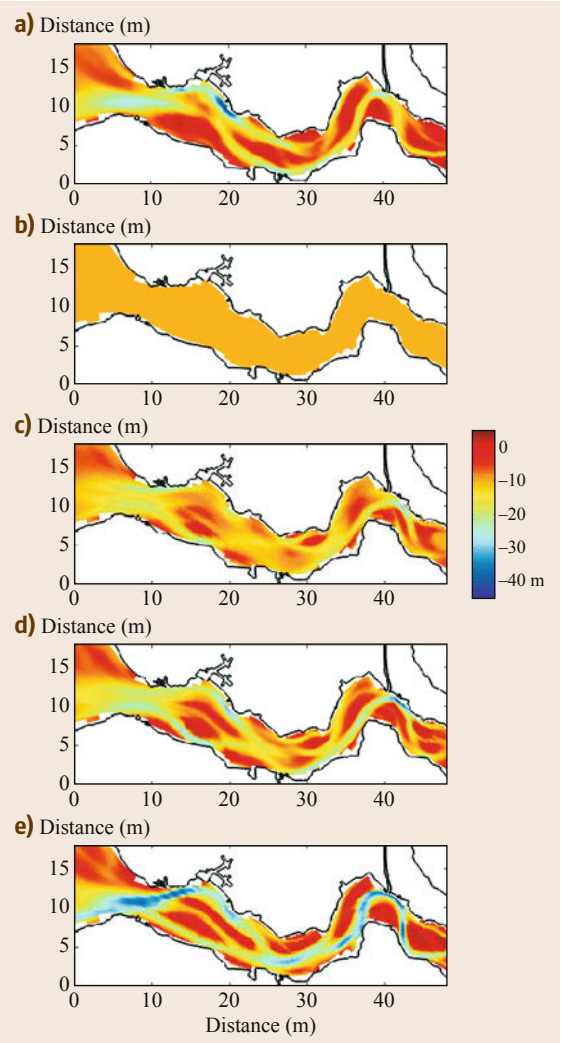

Fig. 28.18 **(a)** Measured 1998 bathymetry; bed development as the result of a 3-D hydrodynamic model with the Engelund–Hansen sediment transport formulation, **(b)** starting from an initially flat, **(c)** the bathymetry after 15 years, **(d)** the bathymetry after 30 years, **(e)** the bathymetry after 200 years (after [28.70], courtesy of Elsevier)

periods of net deposition and erosion as the result of the excessive sediment supply by upstream hydraulic mining (between 1849 and 1884) and the subsequent period of decaying sediment supply also due to the construction of reservoirs in the catchment. The environment required 3-D modeling of salt and fresh water interactions, sand, and mud sediment fractions, wind waves and varying boundary conditions by river flow leading to a highly complex model setup. Despite the large amount of processes and forcing conditions, Fig. 28.19 shows that the model results resemble measured morphodynamic development remarkably well. Furthermore, varying the model input parameters (i. e., uncertain sediment characteristics and forcing condition) within reasonable limits showed only limited and quantitative impact on the model results. The San Pablo Bay plan form and bathymetry seem to determine the evolving erosion and deposition patterns to a high degree.

Process-based models have evolved into powerful models that approach the complexity of reality. The models generate detailed and high-resolution output that allows for a close analysis of processes and forcing mechanisms. However, two critical remarks are made:

- The large number of processes included also requires high-quality model input, which cannot always be guaranteed by measurements. Collecting detailed knowledge on bed composition and SSC (suspended sediment concentration) boundary conditions, for example, is costly, especially when the whole model domain is involved. Other model input such as the diffusion coefficient (varying in space and time) is almost impossible to measure. *Van der Wegen* and *Roelvink* [28.70] present a promising message by showing that model results do not change fundamentally when sediment characteristics are varied within a reasonable range.
- Uncertain model input leads to uncertain model outcomes. Process-based models may describe reality well enough to justify a certain level of forcing schematization or best-guess model input. Still, model results should be presented in terms of probable developments and not as the single outcome of an optimized model. *Pinto* et al. [28.75] present examples on the uncertainty associated with different sediment transport formulations. *Fortunato* et al. [28.76] and *Van der Wegen* and *Jaffe* [28.74] are among the first to explore the possibilities of evaluating ensemble-averaged morphodynamic predictions in an estuarine environment.
- Starting from a measured bathymetry, model result may initially show developments due to limited model definition rather than reproducing realistic developments. Only after decades the bathymetry may have adjusted to the model parameter settings enough to lead to reliable forecasts. It is a major task to discriminate between actual developments and the effect of a period of such a *morphodynamic spin-up*. *Van der Wegen* et al. [28.77] describe a methodology to limit *morphodynamic spin-up*. They let the model itself generate a distribution of sediment classes over the model domain before

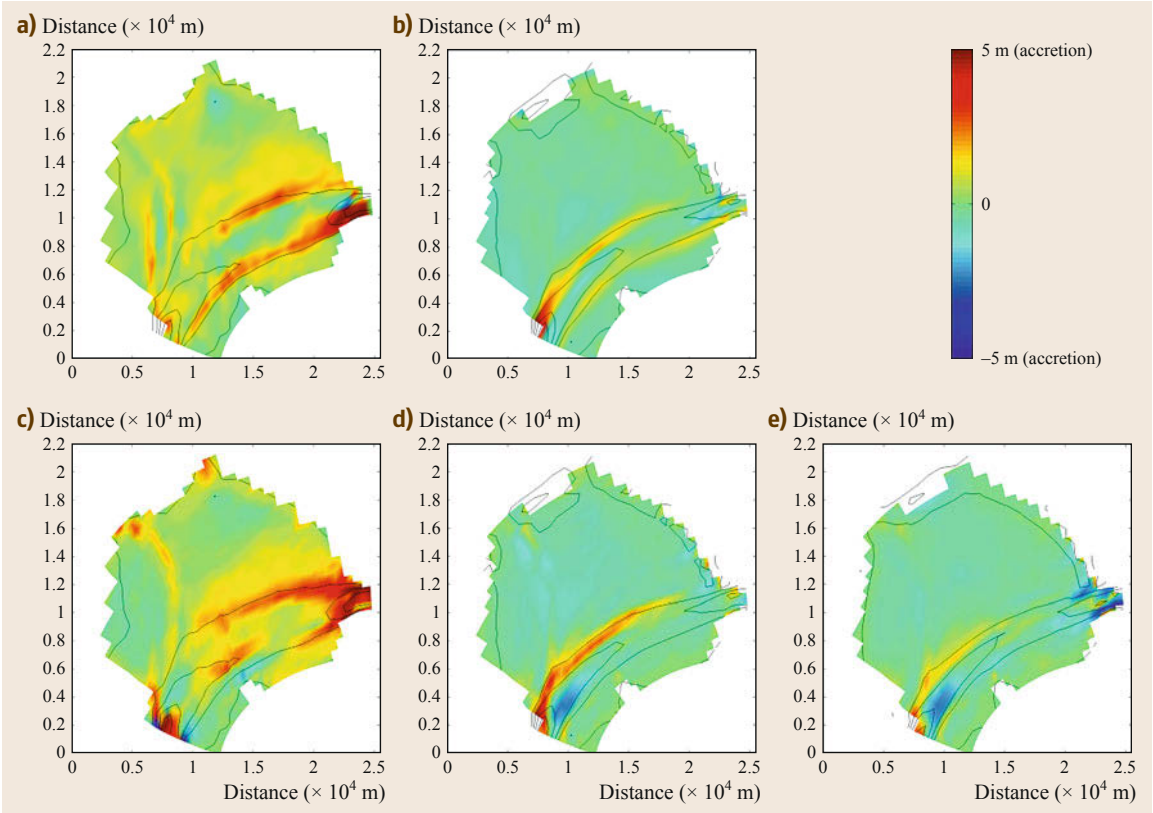

Fig. 28.19a–e Erosion and sedimentation patterns (in meter) measured **(a,b)** and modeled **(c,d,e)** for the 1856–1887 net depositional period **(a,c)** the 1951–1983 net erosional period **(b,d)** and the 1983–2013 forecast period **(e)**. The difference in modeled patterns between the depositional and erosional periods is mainly from a decreasing sediment supply at the landward boundary (after [28.74], courtesy of Elsevier)

allowing for bed level updates. In this way, they prevent an unrealistic peak in morphodynamic development as the result of an ill-defined initial distribution of sediment classes over the model domain.

From the preceding section, we may conclude that process-based morphodynamic modeling has grown up in the sense that stable, long-term simulations can be carried out that tend toward sensible near-equilibrium states; that the models are robust enough to create morphologies out of flat-bed initial conditions and that external forcing and geological or man-made constraints define the morphology to a large extent.

The classical assumption that morphodynamic models get derailed after a certain time and are useless in the long term has been proven wrong in many cases. On the contrary, recent studies have shown that the estuaries' outline determines the morphodynamics to a high degree and that morphodynamic modeling results are sensitive to model input parameter settings only to a limited extent.

Although it is formally difficult to prove and scientific discussion continues, experience suggests that process-based models will perform better once:

- The estuarine geometry confines morphodynamic development (the geometry is of similar length scale as the morphological features of interest [28.70]).
- A perturbation dominates other secondary processes (the scour hole as the result of breakwater construction, a large supply of sediments [28.78, 79] or the presence of major tidal forcing compared to river flow [28.70]).
- Longer timescales (> decades) are considered [28.78, 80, 81]; however, this requires further research; *Fortunato* et al. [28.76] suggest that uncertainty increases with time for a wave-dominated system, whereas *Ruessink* and *Kuriyama* [28.82] conclude that in a wave-dominated environment storms dominate the predictability.

Typically, estuarine morphodynamic development is slower than beach morphodynamics described in

the previous sections. The major reasons may be that wave forcing is relatively limited due to short fetch length and a shallow and wind-sheltered environment. Also, estuarine channel-shoal patterns develop by tide-residual sediment transports that are about an order of magnitude smaller than the maximum ebb, flood, or river-induced sediment transports. As a result, data sets for calibration and validation of these models should cover decades and (preferably) longer time spans. This makes case studies rare and often limited to estuaries with considerable human impact such as environments of ports.

28.4 Future Directions

28.4.1 Ensemble Modeling

Morphodynamic forecasts are never the result of a single run. Modeling practice shows the need for considerable testing of model parameter settings and model behavior until the results can be presented with confidence. The testing is sometimes caused by model shortcomings or bugs, but another important reason is that model input parameters are unknown beforehand.

When we take process-based modeling as an example, uncertainty exists with respect to:

1. Process definitions in the model itself: Are sediment transport formulae described adequately? Is there a need for including more processes? Can we apply a morphological factor?
2. Input parameter values: What should be the values for the viscosity/diffusivity coefficient, and sediment characteristics such as the critical bed shear stress or fall velocity? How many sediment classes should be defined?
3. Initial conditions: What is the initial sediment composition in the bed? What should be the initial SSC or salinity field in the water column?
4. Forcing conditions: Is it possible to schematize the wind climate? Can we apply a morphological tide? What is the impact of extreme events? What are expected rates in the sea-level rise?
5. The modeled system itself: Does the modeled system itself reflect (deterministic) chaos or is it insensitive to slightly different model input?

Until now, the literature shows only limited attention for a systematic analysis on morphodynamic model uncertainties. *Baart* et al. [28.83] point to confidence intervals around morphological forecasts as the result of the propagation of uncertainty through a chain of models from weather (wind and pressure) to hydrodynamic (waves and tides) and finally morphodynamic predictions. *Vreugdenhil* [28.84] and *Pinto* et al. [28.75] present examples on the uncertainty associated with different sediment transport formulations, whereas *Fortunato* et al. [28.76] and *Ruessink* and *Kuriyama* [28.82] explore the development of uncertainty over time. Further, *Ruessink* and *Kuriyama* [28.82] and *Van der Wegen* et al. [28.79] show that ensemble runs in morphodynamic predictions can be used to discriminate dominant forcing from secondary processes.

There lies a challenge in future research to further explore the conditions in which morphodynamic models function well, what the quality of model input parameters should be to come to trustworthy forecasts and what the quality of model output is in the light of uncertain model input parameters. Ensemble runs that include a systematic variation of (unknown) input parameters as well as model output presented in terms of a probability range may be a promising way to explore the value of models under uncertain conditions.

28.4.2 Biogeomorphology

In the last two decades, recognition has grown on the importance of the interaction between geomorphological and biological processes, and a new field of biogeomorphology has sprung up. In the coastal context, important areas where such interactions are dominant are mudflats, salt marshes, mangroves, coral reefs, and floodplains. Erosion and sedimentation of the estuarine bed may be subject to biological processes. Bed developments are influenced by benthic flora and fauna and can be a function of biological processes like the development of bio-films or the presence of bio-engineers [28.85–87]. Salt marshes eventually may be the most dramatic example where vegetation cover governs flow patterns and sedimentation trapping rates. *D'Alpaos* et al. [28.88] and *Temmerman* et al. [28.89] present process-based modeling efforts including the feedback process of vegetation on morphodynamics. In this way, salt marsh dynamics and its feedback on channel shoal morphodynamics can be included in the modeling effort.

Bed stabilization may occur due to bio-films or vegetation roots, whereas surface deposit feeders destabilize the upper bed layer during feeding activities. All these processes may be a function of time so that they change considerably over months, seasons, or even over decades.

Models such as Delft3D and SWAN nowadays have many algorithms describing effects of vegetation on wave dissipation, flow resistance, and trapping of sediments by vegetation and recently [28.90], generic vegetation succession formulations were implemented, which provides a toolbox to explore these complex interactions.

28.4.3 Dune Modeling

Aeolian transport models can be a valuable addition to hydrodynamic models to describe the long-term interaction between land and water. In a recent paper [28.91] present the application of an aeolian transport model [28.92, 93] as a tool for the evolution of coastal nourishments and dunes. The model was originally developed to describe important features and dynamics of typical desert dunes and was modified to apply to sandy beaches and coastal nourishments. This is expected to be the start of an important line of research as with the increase of large-scale nourishments natural dune-growth processes are being restored and need to be considered when trying to predict the long-term evolution of such nourishments.

28.4.4 Coral Reefs

A subject receiving increasing attention is the role coral reefs play in protecting and building up coastal environments. Coral reefs are different from other hard-protection structures in that they are incredibly rough and thereby dissipate wave energy very effectively; they also generate sediment and thereby, in a healthy situation, can keep up with sea-level rise. Modeling of the hydrodynamics of coral reef systems has got increasing attention in the last decade; a thorough review and new insights into the importance and modeling of infragravity waves on such systems are provided in [28.94]. The important problem on how island and low-lying coastal communities protected by reefs can adapt to climate change and sea-level rise will need much attention in years to come; see for instance [28.95].

28.4.5 Modeling Stratigraphy

Morphodynamic models are able to reproduce realistic morphological patterns. By including different classes of sediment and adding a model for bed composition administration, they are also able to reproduce stratification in the bed. Depositional layers of fine sediments can alternate with coarse sediment layers depending on hydrodynamic conditions in the water column and variations in sediment supply. Long-term ($\approx$ centuries to millennia) simulations may thus reproduce stratification characteristics, for instance in a reservoir or river delta [28.96, 97].

This information is of particular interest to geologists. Morphodynamic models offer a tool to explain what processes could have caused certain observed stratification features. Stratification models could also be used the other way round. Once it is known what prevailing hydrodynamic conditions in a certain domain were, the stratification model may reproduce stratification characteristics and permeability parameters. These data are of particular interest to investigating groundwater flows or to determining in a better way the placing of wells or bore holes for the oil industry.

28.4.6 Morphological Modeling of Tsunami Deposits

There is a wide body of research related to the analysis of historical tsunami deposits in order to obtain information on the frequency and strength of tsunamis. In [28.98], a simple model is proposed to link the tsunami flow speed to tsunami deposits; *Goto* and *Imamura* [28.99] consider the requirements of numerical models capable of modeling transport of sediment and large boulders during tsunamis; in [28.100], detailed morphodynamic modeling of the 2004 Indian Ocean Tsunami is carried out and the damping effect of vegetation is considered, using the Delft3D model; the same system is used in an extensive 2DV analysis of flow patterns, turbulence, sediment concentration, and erosion/deposition for different cross-shore profiles [28.73]. In an extensive hindcast of the tsunami at Bandar Aceh, *Li* et al. [28.101] apply a two-way coupled system of nested models to simulate both the generation of the tsunami waves and the propagation toward the area of interest; for the finest grid where morphology changes are important they apply the XBeach model incorporated into their COMCOT–SED system. They found that the model presented in the paper was capable of simulating extreme tsunami events (tsunami wave height in the order of 30 m) over a large domain, that the thickness of tsunami deposits could be quantitatively simulated and that therefore forward models of tsunami sediment transport can be a promising tool to help tsunami geologists understand tsunami deposits.

28.5 Nomenclature

α	wave angle [rad]
b	power in transport relation [–]
c_{bed}	bed celerity [m/s]
$\mathrm{d}A_{\mathrm{b}}/\mathrm{d}t$	initial bar amplitude [m/s]
$\mathrm{d}Xb/\mathrm{d}t$	bar migration [m/s]
ϵ	porosity of seabed [–]
h	depth [m]
$h_{\mathrm{X}b}$	water depth at bar crest [m]
q_x, q_y	horizontal components of sediment transport [$\mathrm{m}^3/\mathrm{m/s}$]
S	total longshore transport [m^3/s]
s	longshore transport coefficient [$\mathrm{m}^3/\mathrm{s/rad}$]
z_{b}	vertical position of seabottom [m]

29. Beach Nourishment

Robert G. Dean, Thomas J. Campbell

Although beach nourishment is a relatively young technology, some major projects have been in place for 80 years and monitored sufficiently to provide a basis for design and performance prediction with a reasonable degree of confidence. Of the various methods available for shoreline stabilization, beach nourishment is unique in addressing the sand deficit and with the capability to restore the recreational, storm protection, and ecological functions of a natural beach. The quality and quantity of sand placed in beach nourishment are shown to be essential to effective performance. Design and performance prediction methods are reviewed including the analytical method of Pelnard Considère, which provides interrelationships between various design parameters and is an excellent pedagogical tool for both understanding these relationships and guiding the more detailed methods which are evolving toward greater and greater complexity. Legacy projects are defined as those that were nourished many years ago, require very little maintenance, have been documented to the degree that their performance is well established and are generally not recognized as constructed beaches by the typical beach user. Two of these legacy projects are reviewed in some detail as well as several other projects for which the performance is well established. The challenges facing beach nourishment in the future include: rising energy costs, environmental issues, public perception and limited sand resources.

Beach nourishment, the placement of large volumes of good quality sand along the shoreline to advance it seaward, is a comparatively young technology. Apart from some early *projects of opportunity* with sand available from construction projects, the first large-scale designed nourishment projects in the United States commenced in the mid-1970s. The earliest projects were placed with comparatively little design background, regulations, or concerns for environmental effects. Yet, some of these projects continue to function

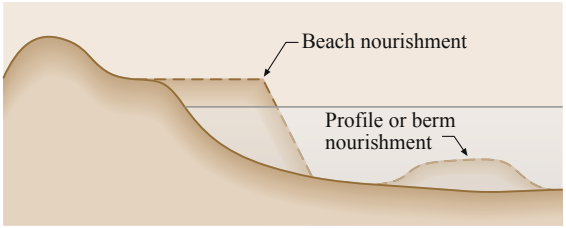

Fig. 29.1 Beach and profile nourishments

today with relatively little maintenance and generally without recognition of their nourishment history by the beach-user community. Two of these so-called *legacy* projects will be described in some detail later in this chapter.

Beach nourishment may be placed directly on the beach or as an underwater berm with the intention that this subaqueous feature will move ashore and widen the dry beach. An alternate design objective is that this feature will damp waves and stabilize the beach (Fig. 29.1).

Alternatives to beach nourishment generally involve hard structures including groins, seawalls, and detached breakwaters. Planting and stabilization of dune vegetation is effective against wind-induced erosion and in trapping wind-blown sand, but is less so against water-induced erosion. Although structural approaches can be effective in shoreline stabilization, and can accumulate sand, this is usually at the expense of the adjacent beach. In some cases, structures can be used in combination with beach nourishment projects, thereby improving project longevity. A number of lower cost so-called *innovative methods* have been proposed and some have been installed and monitored on an experimental basis; however, in our experience, none has been proven successful. These include artificial seaweed, beach drains, nets placed perpendicular to the shoreline, etc. These will not be discussed further in this chapter.

For information beyond that presented in this limited length chapter, the reader is referred to the *US Army Corps of Engineers Coastal Engineering Manual* and various journals and proceedings including those of the *International Conference on Coastal Engineering* series.

29.1 Advantages of Beach Nourishment Over Other Approaches

Nourishment is an attractive alternative for shoreline stabilization for a number of reasons. With the placement of good quality sand, after a relatively short period of adjustment, the beach appears and functions as the natural beach including the restoration of the natural recreational and environmental functions. Finally, the wider beach serves as an effective buffer against storm surge and waves and usually results in a substantial increase in upland property values.

Beach nourishment is usually conducted to restore an eroded beach to an earlier state. The causes of an eroding beach can be either natural or artificial or a combination. The most prevalent and persistent natural cause is rising sea level, which according to the *Bruun* Rule [29.1] causes the shoreline to retreat at a rate which is 50–100 times the rate of sea level rise. With the average 20th century rate of global sea level rise of 1.7 mm/year, this would translate into a beach retreat of 8.5 cm to 17 cm/year, not a large amount that certainly could be offset economically by beach nourishment in many areas. Often, areas in need of nourishment have experienced much larger erosion rates, frequently due to human activity affecting the nearshore system, in particular interference with the longshore sediment transport. Examples are provided later.

The general characteristics of an eroded beach that are well suited for beach nourishment include a relatively small erosion rate, valuable upland property, and large quantities of suitable sand located offshore in proximity to the candidate nourishment project. Small erosion rates ensure that the system can be restored to a previous desired state with a reasonable amount of sand and funding.

29.2 Methods of Delivery of Sand for Beach Nourishment

The delivery of sand to the beach is usually done by dredge; however, a comparatively small number of reasonably large projects (on the order of hundreds of thousands of cubic meters) have been conducted by truck haul. Factors favoring dredge placement include minimal interference with normal traffic and beach activities. Due to the large volumes of sand required for some projects, the truck haul approach can disrupt normal traffic activities and degrade road surfaces. Considering a beach nourishment project of 1 million

cubic meters, large dump trucks delivering approximately 20 m^3 per trip would require 50 000 trips. With favorable weather conditions, a large dredge can deliver up to 40 000 m^3 per day resulting in a project duration of 1–2 months or so allowing for maintenance, weather down time, etc. The area of the seafloor from which sand is removed by a dredge is termed a *borrow area* and must be investigated thoroughly for sand size suitability and other potential environmental effects.

Dredges usually employed for beach nourishment include pipeline dredges and hopper dredges. Pipeline dredges remove the sand from the seafloor with an intake pipe and convey the sand through a pipeline directly to the nourishment area on the dry beach. The diameter of the pipeline can vary from 0.5 to 1 m. Hopper dredges operate in more of a *batch mode* process. The dredges contain a large storage area in their hull and have *dragarms* that trail over the sides of the dredge through which sand is extracted from the sea floor and deposited in the hull while the dredge is underway at a speed of a few knots. In contrast to a pipeline dredge which operates best while excavating at least a meter *cut* depth, a hopper dredge skims a relatively thin layer on the order of 30 cm from the surface of the sea floor. Hopper dredges are classified by the volumes of sediment that they hold which can range up to several thousand cubic meters. Once full, the dredge moves to the nourishment area where various means are used to place the sand as beach nourishment. Direct pump out capacity from the dredge to the beach is becoming more common although the sand can be dropped to the sea floor and a pipeline dredge used to transport the sand to the beach while the hopper dredge returns to the borrow site for another load.

29.2.1 Characteristics and Considerations in Design of Beach Nourishment Projects

Beach nourishment projects are usually constructed with profiles steeper than equilibrium, in part, to facilitate quantification of sand volumes placed and also to minimize the immediate introduction of silts and clays into the nearshore waters during nourishment. Additionally, the project represents a *planform* which is out-of-equilibrium. Immediately after placement, wave action tends to cause the profile and planform to evolve toward equilibrium (Fig. 29.2). For most projects, the time scales for profile and planform equilibration are quite disparate with the profile equilibration occurring on a considerable shorter time scale than that for planform evolution. The profile adjusts such that approximately one-half the placed beach width is lost in the equilibration process and this adjustment is about

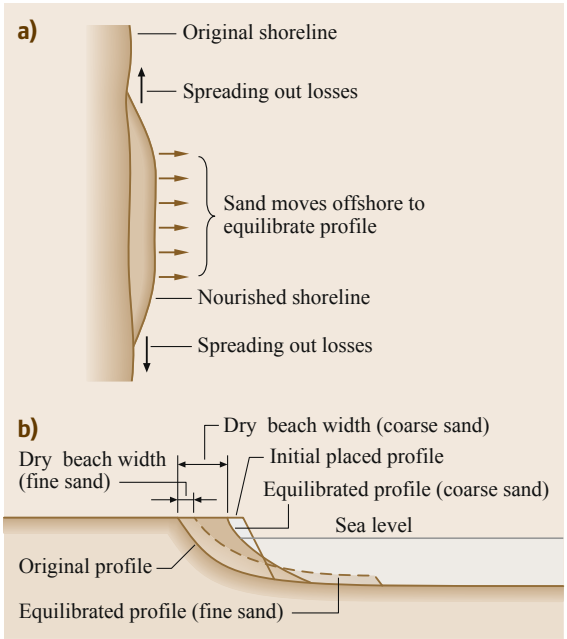

Fig. 29.2a,b The two modes of design consideration. The planform **(a)** evolves on a considerably longer time scale than the profile **(b)**

one-half complete in several years in moderate wave climates [29.2]. As a result of the difference in profile and planform equilibration time scales, design and prediction of the performance of beach nourishment projects usually consider the profile equilibration to occur instantaneously, leaving only the requirement for considerations of planform evolution which is a measure of project performance.

For compatible nourishment sediment, the volume density placed per unit length of beach v is translated to equilibrated additional dry beach width, Δy, by the relationship

$$\Delta y = \frac{v}{(h_* + B)} , \tag{29.1}$$

in which h_* is the so-called *depth of closure* considered to be the seaward limit of nourishment sand distribution and B is the berm height (Fig. 29.3). For example, with a value of $h_* + B = 10$ m, a volume density of 200 m^3/m will result in an equilibrated beach width of 20 m. We will discuss sand that is finer or coarser than the native sand later. The quantity, v is the volume per unit length of beach, is referred to as the *volume density* and is a useful parameter in comparing beach nourishment projects. Along Florida's east coast, an effective volume density has been found to be on the order of 250 m^3/m.

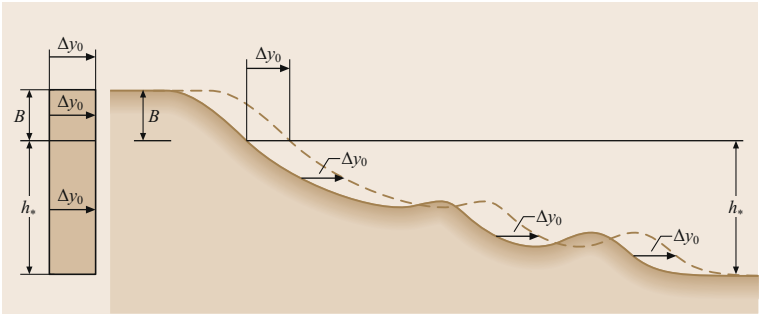

Fig. 29.3 Seaward profile advancement due to beach nourishment

29.2.2 Significance of Good Quality Sand

Understanding the significance of nourishing with good quality sand is essential to design and prediction of a beach nourishment project. *Good quality* infers that the nourishment sand hydraulic characteristics are similar to the native, a feature usually referred to as *compatibility*. In most cases, sand hydraulic characteristics equate to sand size characteristics; however, in those cases where the sand particle shape differs, such as for shell fragments, the fall velocity is a better indicator of sediment (and hydraulic) compatibility. Thus, our main concern here in the performance of nourishment projects is with the physical and hydraulic properties of the sediment although color may be of significant interest in some projects.

The main issue with sediment compatibility is that finer sands will equilibrate to a milder slope than for compatible sand. Thus for a given nourishment volume density, the additional dry beach width, an important parameter for the beach user and funding agencies, will be less for the finer sediment than for compatible sediments. A second effect is that the planform centroids of projects constructed of finer sand will migrate in the direction of net longshore sediment transport whereas those constructed with compatible sand will be stationary (discussed later). The planforms of projects constructed with finer sands will also evolve faster. Nourishment sand which is coarser than the native will yield a wider beach than with compatible sand although normally sand from offshore tends to be finer than the native; however, there are exceptions. Figure 29.4 shows calculated relationships between volume density and equilibrated shoreline advancement for various sediment size characteristics [29.2]. The term σ represents the so-called *sorting* or range of sediment sizes and a value of 0.5 is more representative than the more idealized $\sigma = 0.0$ (all of a single size). (Note that the line shown as $d_F = 0.2$ mm applies for $\sigma = 0.0$ and $\sigma = 0.5$. See *Dean* [29.2] for details). In this plot, $h_* + B = 7.8$ m. Considering only those cases with $\sigma = 0.5$, for a volume density, $v = 250\,\mathrm{m^3/m}$, it is seen that for a native sediment size of 0.2 mm, nourished (fill, subscript F) sediment sizes of 0.14, 0.2, and 0.275 mm yield equilibrated dry beach widths of 14, 32 and 48 m, respectively. Thus, the benefits of compatible sediment and sediment coarser than the native sand are substantial.

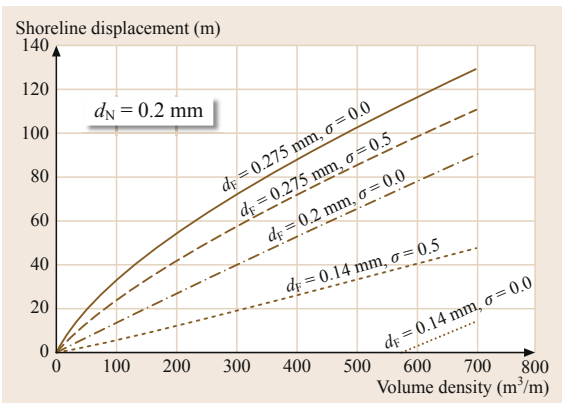

Fig. 29.4 Calculated variation of shoreline displacement vs volume density added and sediment characteristics (after [29.2])

29.2.3 Various Settings for Beach Nourishment

The geomorphic settings under which beach nourishment projects are constructed include:

1. Long beaches uninterrupted by artificial or natural barriers
2. Downdrift of a jettied or unjettied inlet
3. Pocket beach.

The first two of these settings are discussed briefly below.

Long Uninterrupted Beach

From design and prediction considerations, this is one of the simplest settings. As discussed later, for nourishment with compatible sediment, the project evolution is

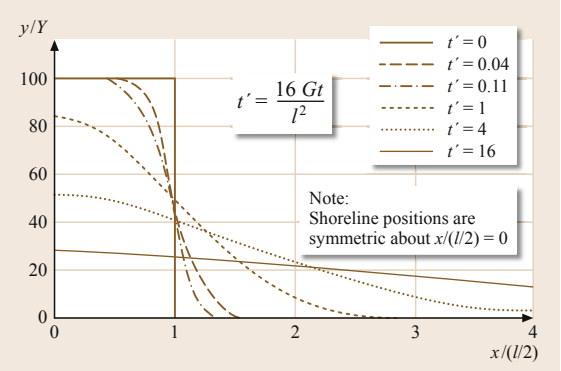

Fig. 29.5 Nondimensional planform evolution of an initially rectangular beach nourishment project of length ℓ and width Y. Note that only one-half of the project is shown and the evolution is symmetric about $x/(\ell/2) = 0$

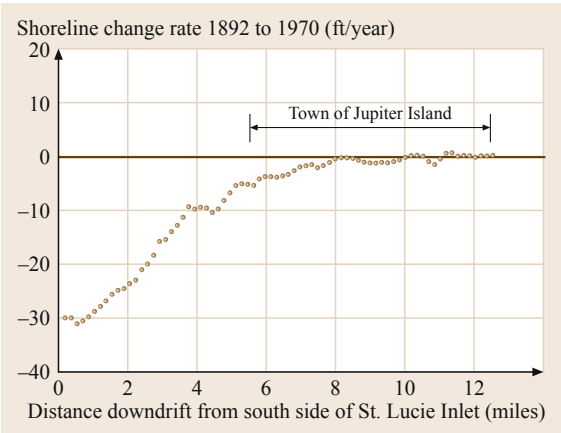

Fig. 29.6 Shoreline change rates downdrift of St. Lucie Inlet along the Southeast Florida coast

essentially independent of wave direction. Thus these projects act as *feeder beaches*. That is, as they evolve, they benefit both updrift and downdrift beaches. Figure 29.5 presents the calculated evolution of an initially rectangular planform for the case in which there is no background erosion. In the more usual case, background erosion (discussed later) must be taken into account in the design and prediction phases. It is seen that initially, the planform adjusts rapidly followed by a slower evolution as the planform becomes smoother. This effect will be quantified later.

Downdrift of a Littoral Barrier

Littoral barriers such as jetties and groins can cause substantial downdrift erosion which must be considered during the design and prediction phases. Two approaches can be applied to account for this background erosion and are discussed later. The most realistic approach of the two requires specification of the *effective* wave direction. Figure 29.6 presents the downdrift recession rate from 1883 to 1970 due to the cutting in 1892 of St. Lucie Inlet located along the southeast coast of Florida. The shoreline recession rate immediately downdrift (south) of the inlet was approximately 9 m/year, certainly among the highest in the State of Florida. With increasing time, the erosion within the Town of Jupiter Island increased and was addressed by a large-scale beach nourishment program. To date, the general area has been nourished with more than 12 million m^3 of sand.

29.3 Role of Structures in Beach Nourishment

Coastal structures can be used to slow or stop erosion of a specific section of beach by slowing littoral sediment transport. The main concern regarding coastal structures is that they can have unintended consequences such that by reducing beach erosion in one area, they may transfer the erosion to adjacent beaches. This is illustrated by the example of many groins constructed prior to understanding the interaction with adjacent beaches. In recognition of the possible adverse effects of coastal structures, they are essentially not permittable in some US coastal states. We regard this stance as unfortunate because, applied carefully, coastal structures can have a beneficial effect on the entire system. For example, using structures to reduce erosion of erosional hot spots (Sect. 29.5.1) within a nourishment project can reduce sand needs and long term costs. *Campbell* et al. [29.3] demonstrated that on an open coastline structural fields need to extend beyond the hot spot erosion areas to manage down-drift effects.

29.3.1 Terminal Structures

The term *terminal structures* indicates that the structures are placed at the end of a project or at the end of a littoral system. Although, as noted, structures are not considered favorably in many regulatory climates, terminal structures can provide a substantial benefit to beach stability. This is especially the case adjacent to inlets that have been dredged for navigation purposes. The deepened inlet can act as a *sink* on both the updrift and downdrift beaches causing sand to flow into the inlet. Thus, a short structure on the updrift or downdrift

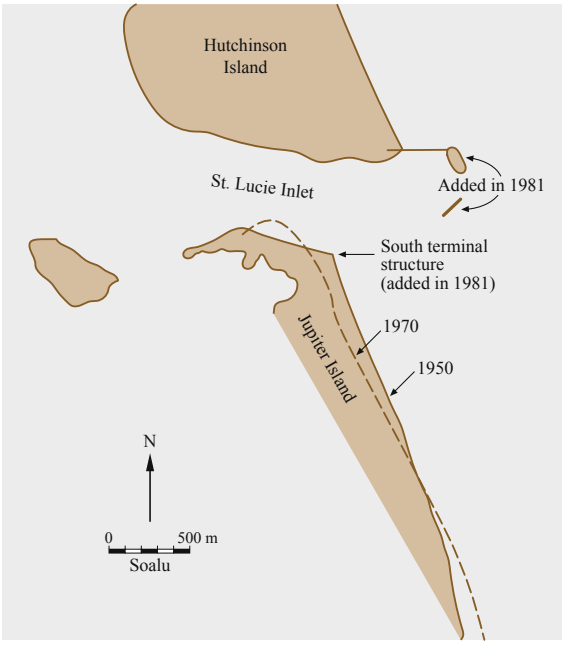

Fig. 29.7 Beneficial effect of downdrift jetty in reducing sand drawn into St. Lucie Inlet from Jupiter Island (after [29.4])

side of the inlet has been shown to provide a substantial stabilizing influence on the adjacent beach [29.4]. This can even be the case on a coastline with a substantial net longshore sediment transport.

Figure 29.7 shows the beneficial effect of a short south (downdrift) jetty constructed at St. Lucie Inlet. Prior to the construction of this jetty, sand was mobilized and drawn northward from Jupiter Island into the inlet, primarily on flood tidal currents at a rate estimated to be 170 000 m^3/year which is almost equal to the net southerly net transport of 180 000 m^3/year.

29.3.2 Groins

Groins have been discussed briefly above. They are best designed as a *template structure* which governs the profile of the affected beach. In designing a single groin or a field of groins, the potential effect on adjacent beaches should be examined carefully and understood along with a monitoring and contingency plan if the groins cause adverse effects. Adjustable groins have been applied with some success and provide a means of *fine-tuning* the structures in response to the monitoring results.

29.3.3 Detached Breakwaters

Detached breakwaters can be emergent or submerged and act to reduce wave energy in their lee and thus reduce longshore sediment transport in the case of oblique waves and cause sand to flow behind and be sequestered in the lee of the breakwater in the case of normally incident or oblique waves. Detached breakwaters have the same potential to interact with the nearshore sediment transport processes as groins and the same cautions apply for these structures especially if considered in areas with substantial net longshore sediment transport. An advantage of groins over detached breakwaters is their direct control on the beach profile. Additionally during elevated water levels which usually accompany storms, the effectiveness of detached breakwaters is reduced if the crest elevation is exceeded.

Submerged breakwaters have been proposed and implemented as an approach that is less visually intrusive than emergent detached breakwaters. However, it has been found that for effective performance, the combination of the breakwater crest width and elevation must be such that considerable energy dissipation occurs. The effect of elevated water levels during storms as discussed above is even more of a factor for submerged breakwaters in reducing their wave energy dissipation effectiveness. Also, with submerged breakwaters, there is the possibility that water transported over the breakwater by the waves will *pond* and flow along the coast removing sand from the area intended for stabilization, see *Dean* et al. [29.5] for monitoring results of a full scale submerged breakwater where this occurred.

29.4 Design and Prediction Approaches and Methods

The brevity of this chapter precludes a detailed presentation of design and prediction methodologies. For additional information, the reader is referred to *Dean* [29.2] and other references in this chapter. The sections below describe some of the key considerations in design and performance prediction of beach nourishment projects. The stakeholders, those funding the project, will be vitally interested in the future performance of the project especially when and how much future renourishment will be required. It is therefore incumbent on the engineer to be able to provide as accurate an assessment of future performance as possible along with a quantification of the uncertainties. It is our position that the *evolution of*

shorelines can only be predicted with some success if the initial shorelines are significantly out of equilibrium such as due to a nourishment project or a feature (such as a groin) is present that interrupts the longshore sediment transport. In the usual case in which shoreline erosion was occurring prior to the nourishment, this must be accounted for in the performance predictions.

Prior to designing a beach nourishment project, it is very helpful to try to understand the cause and magnitude of the erosion leading to the need. The cause may or may not be apparent. In most cases, nourishment will not correct the cause, so best estimates are that the project will continue to erode at a more-or-less predictable rate equal to the sum of the project-related evolution rate and the historic rate.

There are several levels of methodologies or *models* that can be applied to performance prediction. These range from an analytical model to one-line numerical models to advanced three-dimensional models. One-line models track only one contour of the profile, usually mean sea level, or some other contour representing the shoreline. Each of these model types can play a useful role in design and prediction.

29.4.1 Pelnard Considère Methodology

The simplest approach, that of Pelnard Considère (P-C) [29.6], is analytical and is useful for developing a basic understanding of the interrelationships between the design variables including project length, wave height, and sand transportability. Relatively simple one-line numerical models provide flexibility not available in the analytical models. The more advanced models provide greater detail than the other two levels. Due to the simplicity of the P-C approach, it is suggested that, if applicable, it be applied in conjunction with one of the other two more advanced level models. All models include a transport equation and a conservation of sediment equation.

A brief discussion of the P-C model and some results obtained will illustrate its utility. This one-line model combines a linearized version of the longshore sediment transport equation with the sediment conservation equation to yield the classic heat conduction equation

$$\frac{\partial y}{\partial t} = G\frac{\partial^2 y}{\partial x^2}\,, \tag{29.2}$$

in which y is the shoreline displacement, t is time, x is the longshore coordinate (the sign convention is positive to the right of an observer looking seaward), and G is the so-called *longshore diffusivity*, defined in terms of breaking wave conditions as

$$G = \frac{KH_b^{5/2}\sqrt{g/\kappa}}{8(S-1)(1-p)(h_* + B)}\,. \tag{29.3}$$

The quantity K is a sediment transport coefficient (of order 1) related to sediment size, H_b is the *effective* breaking wave height (similar to the root-mean-square wave height), g is gravity, κ is the ratio of breaking wave height to breaking depth (on the order of unity), S is the ratio of the sand specific weight to that of the water in which it is immersed (usually 2.57), p is the in-place porosity (0.35–0.4), h_* is the so-called depth of closure, and B is the beach berm height. The latter two variables are defined in Fig. 29.3.

There are several significant advantages to the P-C methodology. The governing equation is a classic linear equation with a number of known solutions that are relevant to beach erosion and beach nourishment. Due to its linearity, it is possible to superpose solutions, for example, the shoreline recession due to spreading out of a nourishment project and the historic background erosion rate. Finally, although the equation is linearized, it provides surprisingly valid results for many cases [29.7]. In our view, perhaps the greatest value provided by this methodology is the insight into the interrelationships between the various design and project variables, several of which are discussed below.

The P-C Solution for Nourishment of an Initially Rectangular Planform on a Long Straight Beach

The most valuable results apply for nourishment with compatible sediment on a long straight beach and, unless noted otherwise in this subsection, the following results apply to this case. The evolution of a beach nourishment project of an initially rectangular planform in the absence of background erosion (Fig. 29.5) is given by

$$y(x,t) = \frac{Y}{2}\left\{\operatorname{erf}\left[\frac{\ell}{4\sqrt{Gt}}\left(\frac{2(x-x_o)}{\ell}+1\right)\right] - \operatorname{erf}\left[\frac{\ell}{4\sqrt{Gt}}\left(\frac{2(x-x_o)}{\ell}-1\right)\right]\right\}\,, \tag{29.4}$$

where erf is the so-called error function, x_0 is the longshore location of the project center, ℓ is the project length, and Y is the project width.

A surprising result from the P-C methodology is that for nourishment with compatible sand, the centroid of a nourishment project remains fixed and is independent of wave direction (note that wave direction does not appear in the above equation). This is a valuable

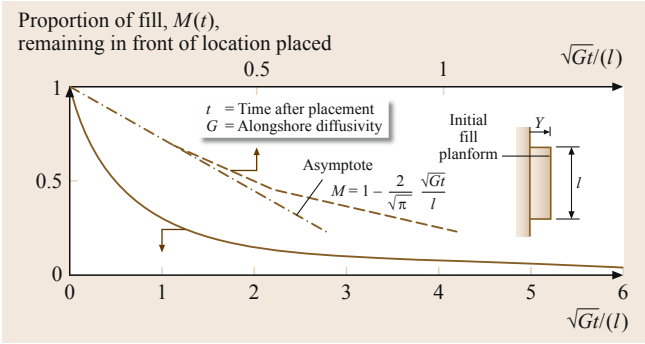

Fig. 29.8 $M(t)$ for case of beach nourishment of initially rectangular planform and no background erosion

result in design because usually the uncertainties of estimated wave heights and periods for design are much less than wave directions. Additionally, in the absence of background erosion, the longevity of a project is proportional to the square of the project length and inversely proportional to the effective breaking wave height raised to the 2.5 power, thus explaining why projects constructed in areas of reasonably mild wave climates are much more long lasting than those in more energetic wave environments and why longer projects last longer than shorter projects. In all settings, the evolution of a project depends only on the cumulative wave energy flux affecting the project. Thus, the evolution at a particular time is independent of the sequence of prior wave conditions that have resulted in the project evolution and depends only on the cumulative wave *loading*. The presence of a background erosion adds nuances to the above solution, but these can be incorporated by fairly direct approaches for simple background erosion distributions in the longshore direction.

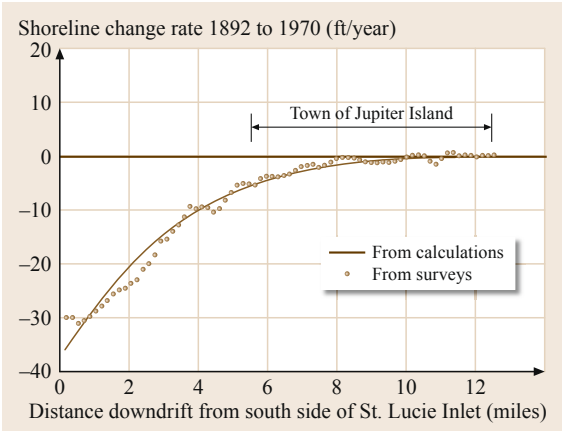

Fig. 29.9 Comparison of P-C theory with survey data south of St. Lucie Inlet, FL. Survey data: 1883 to 1970. For the theory, $G = 0.0111\,\mathrm{m}^2/\mathrm{s}$, $\theta - \alpha = 8.65°$

An example of the evolution of a nourishment project of initial rectangular planform as a function of time and distance has been presented earlier as Fig. 29.5. The evolution shown is symmetric about the centerline and the project center in this example is taken as $x = 0$. It is seen that the project first evolves rapidly, then at a slower rate. It is possible to integrate (29.4) to determine the proportion of sediment remaining at any time within the project limits, here defined as $M(t)$. The result is

$$M(t) = \frac{2\sqrt{Gt}}{\ell\sqrt{\pi}}\left(e^{-(\ell/2\sqrt{Gt})^2} - 1\right) + \mathrm{erf}\left(\frac{\ell}{2\sqrt{Gt}}\right), \qquad (29.5)$$

which is graphically shown in Fig. 29.8 where it is seen that initially the rate of loss is more rapid than after the project planform has become longer and with less abrupt changes (also, Fig. 29.5).

The P-C Solution for Shoreline Change Updrift or Downdrift of a Littoral Barrier

A second solution for shoreline change is that for downdrift (or updrift) of a littoral barrier

$$y(x,t) = \pm\left[\sqrt{\frac{4Gt}{\pi}}e^{-x^2/4Gt} - x\mathrm{erfc}\left(\frac{x}{\sqrt{4Gt}}\right)\right] \times \tan(\theta - \alpha_0), \qquad (29.6)$$

where the plus and minus signs apply for updrift and downdrift, respectively, of the barrier, θ and α_b are the azimuth of the outward normal from the unaffected shoreline and the azimuth of the direction from which the breaking wave originates, respectively and $\mathrm{erf}c = 1 - \mathrm{erf}$. The above solution applies to the case before bypassing commences around the barrier, after which a different solution applies (see *Dean* and *Dalrymple* [29.8] for additional information). To apply (29.6), an estimate of breaking wave direction relative to the shoreline, α_b, is required. An alternative if shoreline

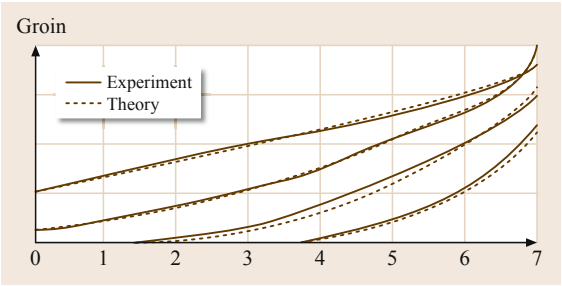

Fig. 29.10 Comparison of P-C theory with laboratory data updrift of a groin (after [29.9])

change data are available is to determine the wave direction corresponding to the best fit of the solution to the measured data. Figure 29.9 presents the *best fit* of the P-C methodology to the data presented earlier in Fig. 29.6. In this case, the associated value of the longshore diffusivity G, and angle $\theta - \alpha$ are $0.0111\,m^2/s$ and 8.65°, respectively.

Figure 29.10 presents results from a laboratory experiment in which measurements on the updrift side of a groin compare favorably with the P-C theory.

29.4.2 One-Line Numerical Models

One-line numerical models have a considerable advantage over the P-C method in terms of the flexibility they offer allowing groins or other coastal features such as inlets with or without bypassing to be introduced into the design. Many such models have been developed, some to an advanced level of detail. The US Army Corps of Engineers has developed the GENESIS model to a level that allows application to a variety of useful design conditions including groins and detached breakwaters [29.7, 10, 11].

29.4.3 N-Line and more Detailed Models

More complex models allow the third (vertical) dimension to be represented and thus, in principle, provide much more valuable information than the less complex models. Some of these models are in the research rather than the application arena. Application of all models requires some calibration with the more complex models usually requiring the greatest amount of calibration to achieve the level of detail desired.

Delft3D is a comprehensive, publicly available, process-based modeling suite that simulates two-dimensional (2-D) and three-dimensional (3-D) flows, sediment transport and morphology, waves, water quality and ecology and is capable of representing the interactions between these processes. The suite is designed for use by experts and nonexperts, which may range from consultants and engineers or contractors, to regulators and government officials, all of whom are active in one or more of the stages of the design, implementation, and management process. Delft3D is suitable for simulating erosion and deposition over storm-length (7–14 day) or project-length (5–10 year) time scales and handles a variety of coastal structures. Morphology type models like Delft3D offer distinct advantages over N-Line models because they are capable of updating three-dimensional bathymetric features at each time-step, thus providing feedback to the wave and flow models for a more complete simulation of the coastal environment. Delft3D requires an extensive amount of data and time to set up and run, and therefore may not be the best option for many applications.

29.5 Additional Design Considerations

29.5.1 Erosional Hot Spots

In beach nourishment projects, erosional hot spots (EHSs) are defined as areas that erode more rapidly than the adjacent areas or possibly areas that erode more rapidly than anticipated in the design. EHSs occur in nearly all beach nourishment projects and may or may not be predictable. In a celebrated case at Grand Isle, LA, USA [29.12], the nourished beach advanced significantly landward of the two seaward borrow areas. These borrow areas which may reported to have filled with very fine sediment and caused significant damping of the waves (personal communication, A. J. Combe). These borrow pits acted as detached breakwaters in reducing the shoreward wave heights causing shoreline advancement landward of the dredge pits and erosional hot spots adjacent to these advancement areas. *Benedet* and *List* [29.13] applying Delft3D, have correlated EHSs on the Delray Beach, FL, nourishment project with the seaward borrow areas.

The EHSs experienced at Grand Isle, LA, are exceptional; however, EHSs that occur in typical nourishment projects are not inconsequential. Figures 29.11 and 29.12 present the performance of the 1992 Anna Maria Key, FL, beach nourishment project. This project was 6.7 km in length with a nourishment volume of 1.78 million m^3. The initial additional beach width varied from 55 to 107 m and the nourishment volume density varied from 200 to $350\,m^3/m$. The most recent survey (February 1999) in these figures is for 6 years after nourishment and as of that time, the change in immediate postnourishment volumes ranged between a loss of 320 to a gain of $160\,m^3/m$. The corresponding shoreline width reductions ranged from 37 to 69 m. The borrow area for this project was located between monuments 25–34 and was fairly close to shore. Thus, some of the postnourishment changes in these figures could be due to the proximity of the borrow pit; however, some changes for other areas within this project are significant and generally cannot be predicted by any numerical models. The shoreline recession includes both volume loss and profile adjustment toward equilibrium.

Shoreline irregularities also exist along natural beaches. Often this occurs during mild wave conditions

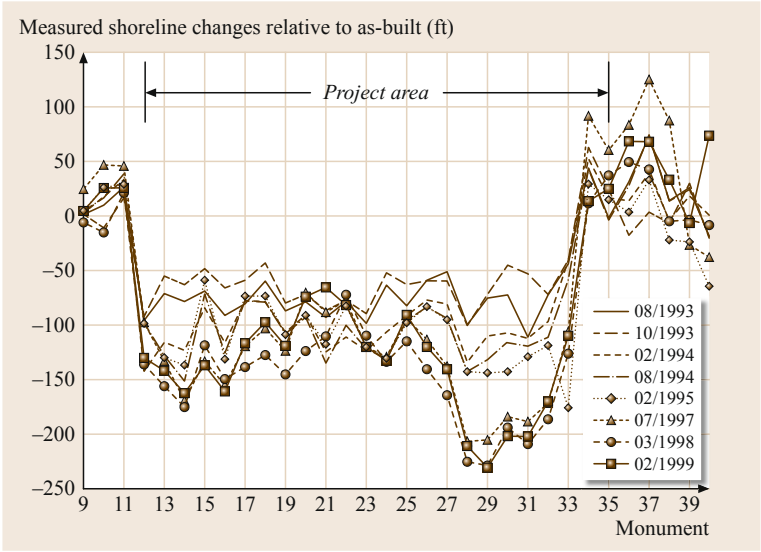

Fig. 29.11 Postnourishment shoreline changes in Anna Maria Key beach nourishment project. Borrow area is quite close to shore and between monuments 25 and 34. Monuments are spaced at approximately 300 m

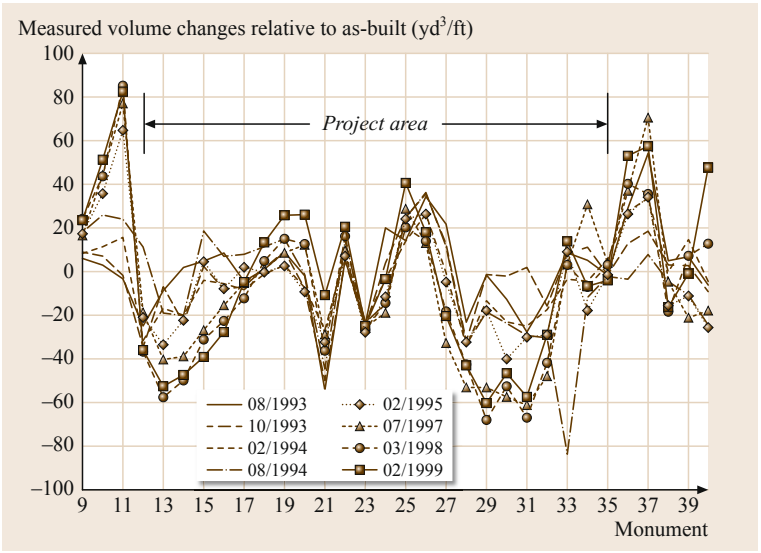

Fig. 29.12 Postnourishment volume density changes in Anna Maria Key beach nourishment project. Borrow area is quite close to shore and between monuments 25 and 34. Monuments are spaced at approximately 300 m

after an erosional event that has deposited a more or less linear offshore bar. The milder wave conditions tend to result in portions of the bar moving shoreward and landward of these portions, the shoreline tends to advance. This stage of recovery is often associated with the presence of rip currents.

29.5.2 Nearshore Placement

Figure 29.1 showed the case of sediment placed in the nearshore with the expectation that either the sand would move landward and widen the beach or dampen the incident waves thus sheltering and stabilizing the beach. The following discussion only addresses the conditions under which the nearshore placement would move landward. However, it is noted that during storms with elevated water levels, the effectiveness of the nearshore mound in wave damping would be reduced.

A number of studies have been conducted to address conditions under which nearshore deposits would be stable or move landward or seaward. Some field observations are inconclusive partly due to the lack of detailed wave measurements and surveys of the deposit. An analytical model has been developed by *Douglass* [29.14, 15] and *Hands* and *Allison* [29.16] have developed criteria based on the wave-induced bottom water particle velocities in the vicinity of the placement. *Otay* [29.17] has developed an extensive summary of

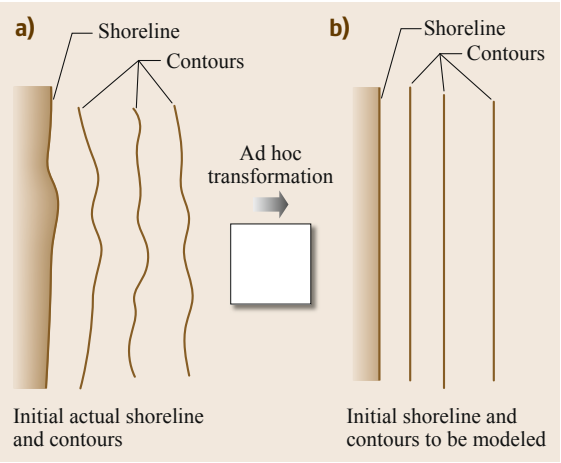

Fig. 29.13 Recommended ad hoc transformation for modeling systems in which a large perturbation (nourishment and/or a littoral barrier) is to be introduced (after [29.20]) (courtesy of the American Society of Civil Engineers)

the field tests of nearshore deposits and information regarding their movement.

Andrassy [29.18] described a fairly small (113 500 m^3, 365 m long) nearshore placement off southern California. The deposit was placed in a water depth of approximately 7 m with the crest in 4 m depth. It was found that the deposit moved landward over a period of approximately 2 year. The sediment size was not stated and the wave heights and periods encountered were up to 1.5 m and 15 s, respectively.

The best instrumented field test in the United States has been described by *Browder* and *Dean* [29.19] in which 3 million m^3 was placed in water depths of 6 m over a 7 −km length with the deposit crest 4.5 m below water level. This deposit was monitored for approximately 9 years during which four hurricanes passed over the site. Directional wave gages were deployed for 4.5 year and measured significant wave heights up to 2.7 m with a period of 13 s during Hurricane Andrew in 1992. These conditions certainly would have caused onshore transport of the placement based on the Douglass or Hands and Allison predictive methodologies. During the 9 year monitoring period, it was found that the centroid of the deposit moved landward a distance of approximately 20 m compared to the centroid location some 700 m seaward of the shoreline.

In summary of this issue, it is concluded that sediment size, while not included in most predictive methods, may be important. Second, to be sure that the placement will move landward within a reasonable time frame, it is recommended that beach profiles be examined to determine the seasonal limit of the offshore bar and place the sand landward of this limit.

29.5.3 Ad-Hoc Transformation for Modeling

Most shorelines are somewhat irregular. The question arises as to the best approach to represent these shorelines for numerical modeling, It has been noted that shoreline evolution can only be effectively modeled if the system is significantly out of equilibrium. Also, generally prenourishment shoreline change rates must be included in postnourishment shoreline change predictions. Our recommendation, sketched in Fig. 29.13, is that an ad-hoc transformation be applied in which the modeled shoreline and offshore contours are straight and parallel and the prenourishment shoreline change rates be applied empirically. In this way, the system perturbation (nourishment) is modeled in a geometry which is most appropriate for that purpose and the subtleties of the offshore contours that cause the background erosion are applied directly through application of the prenourishment shoreline changes. The question arises of whether the prenourishment conditions should be applied directly as shoreline changes or as gradients in sediment transport. The best approach requires judgment by the modeler of the cause of the changes. If they are due to cross-shore transport, then obviously, they should be applied directly. If no coastal structures such as groins are present, the results will not be affected by the choice of the application method.

29.6 Legacy Beach Nourishment Projects

Legacy projects as defined here are those that have been nourished and in place for many years, have performed well, have reasonable documentation, and in many cases, the average beach user is unaware of their nourishment history. Although there are undoubtedly many such projects that qualify, we illustrate two US projects in some detail and provide references for several other legacy projects.

29.6.1 Examples and Discussions of Legacy Projects

Santa Monica Bay Beach Nourishment

Santa Monica Bay in southern California is approximately 64 km in length. The central and southern portions of this bay have been nourished primarily with *sand of opportunity* generated through construction un-

Fig. 29.14 Santa Monica Bay. General Area of Interest (after [29.21])

related to a primary need for beach nourishment. The nourishment commenced in 1939 with the two main nourishments occurring in 1947 (13 million m^3, construction of the Hyperion Sewage Treatment Facility) and in 1963 (7.7 million m^3, construction of Marina del Ray Harbor). These two projects accounted for 93% of the total of 22.2 million m^3 placed between 1939 and 1989. Of the total sand volume placed, less than 4% was for shoreline stabilization purposes. Several structures consisting of groins and detached breakwaters, two harbors and a submarine canyon are located within the 35 km segment of the central and southern portions of Santa Monica Bay. There are no known large natural sources of sediment input to this system and the submarine canyon is believed to represent a substantial sediment sink. Some losses into the submarine canyon have been controlled through groin construction. This overall project qualifies as a Legacy Project due to its longevity, monitoring data, and general lack of recognition as a nourished beach by the average beach visitor. Most of the description of this project presented herein is from *Leidersdorf* et al. [29.21] and the reader is referred to that source for a more complete description.

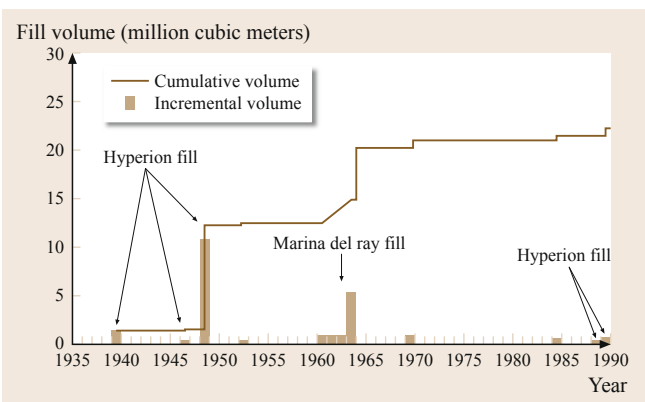

Fig. 29.15 History of nourishment along Santa Monica Bay (after [29.21])

The beaches remain substantially advanced relative to their pre-1939 positions. On average, it is estimated that the beaches are approximately 100 m wider than their pre-1939 conditions. Figure 29.14 shows the general area of interest and Fig. 29.15 presents the history of beach nourishment. Figure 29.16 shows the shoreline changes at two locations from 1935 to 1990, a period of 55 years.

In summary, the beaches of Santa Monica Bay have performed extremely well, have had a profound impact on the economy and recreational activities of the area, are recognized internationally, and are rich in documented results thereby providing learning opportunities for students of coastal engineering.

Delray Beach, FL

The first City of Delray Beach nourishment project was constructed in July of 1973 along 4.3 km of shoreline. The immediate postconstruction surveys showed an average mean high water beach widening of 80 m but the beach equilibrated to about half that width within the first few years. The 1973 project placed approximately 1 250 000 m^3 of material, of which 380 000 m^3 had eroded by 1977. In 1974, dune vegetation was planted to augment the beach restoration project and assist in reducing the losses due to wind blowing sand across the coastal road and covering the adjacent lawns.

Fig. 29.16a,b Variation with time of two profiles in Santa Monica Bay (after [29.21]) ►

As of 2012, a total of over 4.78 million m^3 of sand has been placed on Delray Beach over a period of 39 years as a result of four beach nourishments (1978, 1984, 1992, 2002). A storm damage repair was also constructed in 2005 with 190 000 m^3 following a series of hurricanes that impacted Florida during the 2004/5 hurricane seasons. The Delray Beach Fifth Periodic Beach Renourishment Project has been designed and permitted for construction in 2012. That project will place approximately 920 000 m^3 of fill on the beach along a distance of about 3.1 km.

The time between nourishment events has increased from 5 to 10 year (except for the hurricane repair in 2005). Additionally, as is evident in Fig. 29.17, the additional sand volume within the project area has increased from 1.25 million m^3 in 1973 to 2.9 million m^3 in 2009. The increase in the nourishment interval with increasing time can be attributed to reduced spreading losses as the earlier projects perform as longer projects and thus lose sand at slower rates.

Figure 29.17 also presents a comparison of the measured and calculated volume changes remaining within the project area. The calculations are based on the Pelnard Considère method (29.4) and present results for two G values, $G = 0.3\,ft^2/s$ ($0.0028\,m^2/s$) and $G = 0.6\,ft^2/s$ ($0.0056\,m^2/s$). Of interest in this comparison is that a factor of 2 in the G values has a relative small effect on the calculated performance; however, of course, this effect increases with time. Second, referring to the calculated performance for the smaller G value, it is seen that at some times the calculated volumes are greater than the measurements and at other times less. This is due to the calculations based on a single *representative* wave height whereas in nature, some years are more *stormy* than others (the G values vary with time as shown the dependency on wave height in (29.3)). Comparisons such as this provide an effective basis for calculating performance of future projects.

Other Legacy Projects

Here we list three other legacy projects with a very brief description and some references.

Additional Southern California Beaches. *Herron* [29.22] has summarized the early placement of large quantities of sand as beach nourishment on several beaches including Santa Monica Bay. This sand was usually derived as a by-product of coastal projects rather than for beach nourishment. He states:

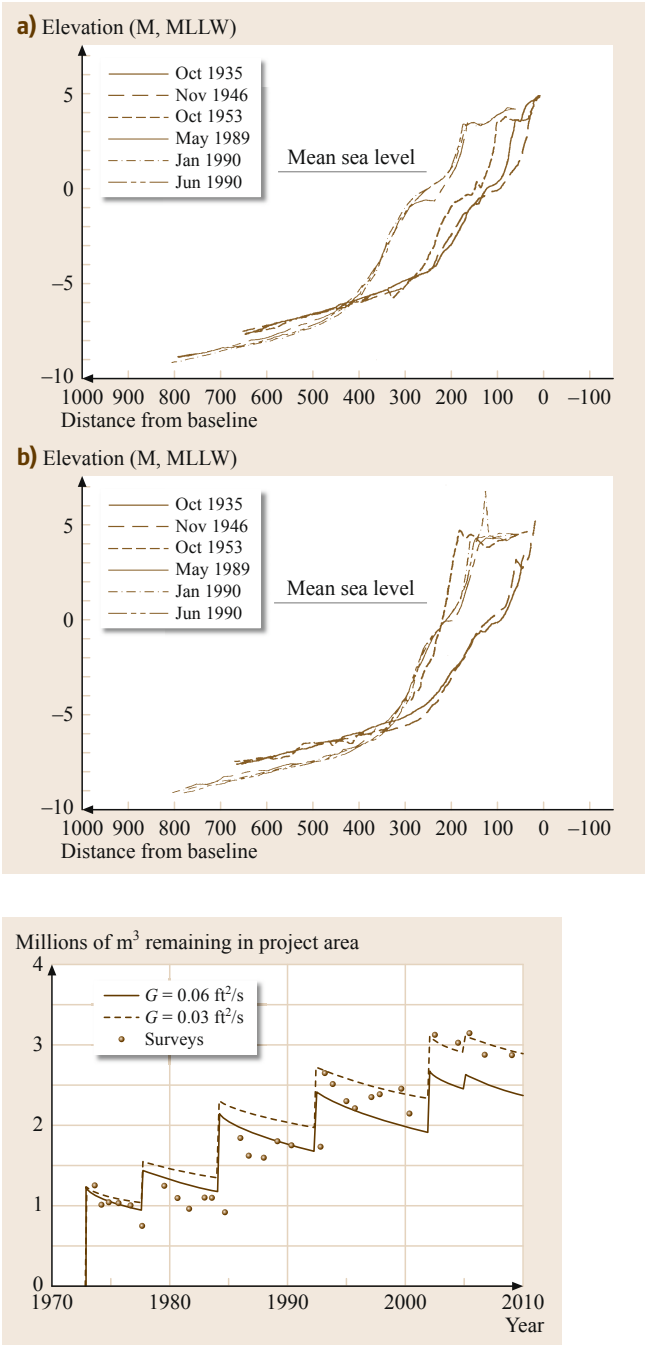

Fig. 29.17 Comparison of measured and calculated volume remaining within the project area, Delray Beach Nourishment Project. Two values of longshore diffusivity G. No background erosion considered

Between 1919 and 1978 about 60 *coastal projects have supplied* 83 million m^3 *of sand to improve the*

beaches of southern California. Three projects were solely beach replenishment projects. All of the others were coastal oriented projects in which the deposition of sand on the public beaches was simply a by-product or secondary benefit of the total consideration.

Of this 83 million m^3, Herron only lists 21 million m^3 placed in the Santa Monica Bay cell leaving 62 million m^3 placed on beaches other than those in Santa Monica Bay. Based on personal observation, many of these beaches continue to perform well with only minor maintenance required.

Miami Beach, FL. This project, also known as the Dade County Beach Nourishment Project, is approximately 16 km long and was constructed over the period 1976 to 1981 with approximately 7.7 million m^3 of sand from offshore borrow areas. Prior to the nourishment, in many places the beach was located along the seawalls making it risky to walk along the shoreline at high tide and energetic wave conditions. An excellent review of this project is provided by *Wiegel* [29.23]. The effects of this project in revitalizing the economy of the area are quite substantial and are presented in *Houston* [29.24, 25].

Atlantic Beach and Jacksonville Beach, FL. The St. Johns River Entrance north (updrift) of Atlantic Beach and Jacksonville Beach has been stabilized by long jetties and deepened for navigational purposes. This entrance has essentially severed the substantial net southerly sediment transport estimated at approximately 420 000 m^3/year resulting in severe erosion of the beaches of Atlantic Beach and Jacksonville Beaches in the early 1960s. The major northeaster of 1962 and Hurricane Dora in 1964 devastated these beaches destroying seawalls and other structures located along the shore. Following these events, nourishment projects were constructed with sand obtained from the entrance channel shoal material and ebb tidal shoal of St. Johns River. This combination of projects has successfully maintained the beaches in this area since the 1970s, best illustrated in the beach performance during the 2004 severe hurricane and Nor'easter season, where the buildings and properties adjacent to nourished beaches were relatively undamaged.

Since 1963, a total of 10.3 million m^3 of sand has been placed south of the St. Johns River Entrance. Ten projects were constructed with sand dredged for navigation (4.05 million m^3), seven were Federal shore protection projects (5.2 million m^3) and two were joint navigation and shore protection projects.

Although a thorough documentation of this project is warranted, none has been conducted. However, an excellent Powerpoint presentation by *Howard* et al. [29.26] is available.

29.7 Other Beach Nourishment Projects

The nourishment projects discussed in this section are examples of projects of different scales and settings and are generally considered to be performing quite effectively.

29.7.1 Seabright to Manasquan Inlet, NJ

This beach has one of the longest histories as a recreational beach destination in the United States, which led to the early development of the coastline. The shoreline was protected early and often with a wide variety of coastal protective structures, including substantial seawalls, groins, and revetments, all considered the latest methods at the time.

Initial project construction occurred between January 1994 and June 2000 and the first and second renourishments were completed in November 2002 and early 2012. Initial construction placed 17.0 million m^3 of sand along most of the 34 km ocean shoreline of Monmouth County. The beach has performed well and exceeded the expected nourishment performance despite some predictions to the contrary.

29.7.2 Captiva Island, FL

Captiva Island is a 8 km long island on the southwest coast of Florida bordered by two coastal inlets; Redfish Pass to the north and Blind Pass to the south. Since Redfish Pass was opened by a hurricane in 1923 the island has been starved of the net southerly sediment transport and has eroded significantly. In 1981 beach nourishment took place along the northern 3.2 km of the island placing 500 000 m^3 of sand from the ebb shoal of Redfish Pass. Island-wide nourishment followed in 1989 which placed 1.2 million m^3 of sand was also taken from Redfish Pass ebb shoal. There have been two subsequent renourishments of the island using offshore sands in 1996 and 2005 which placed an additional 1.4 million m^3. The southern limit of the project has been extended to

the adjacent Sanibel Island. Captiva Island has two terminal groins to help reduce losses from the island.

29.7.3 Treasure Island, FL

Treasure Island is a 5.3 –km barrier island bordered by Johns Pass to the north and Blind Pass (a different Blind Pass than adjacent to Captiva Island) to the south. Treasure Island grew to its present size after a tidal inlet at the north end of the island closed and the southern migration of Blind Pass caused the island to lengthen. Development of resorts on the island began in the 1920s followed by a surge in development in the 1950s. By the 1960s, the island was facing serious erosion problems. In response, the city of Treasure Island constructed 56 concrete (originally timber) groins and a rubble mound jetty on the north side of Blind Pass. At the time, the average erosion rate was determined to be 52 000 m^3/year [29.27].

The first nourishment project on the west coast of Florida was on Treasure Island in 1969. After the initial construction and repair following Hurricane Gladys in 1968, Treasure Island was renourished every 2–3 years. The material used for the nourishments was sourced from Blind Pass, Johns Pass, and an offshore sand pit parallel to the island. Sunshine and Sunset beaches required frequent nourishment.

Sunshine Beach, at the north end of Treasure Island, is historically erosional as a result of inlet effects. The only times that Sunshine Beach has been accretional was after a nourishment in the 1970s when dredge material deposited in shallow offshore waters migrated onshore. In 1989, an angled structure was constructed to protect development to the south [29.28]. No evidence was found on why or when it was removed. A terminal groin was constructed on the south side of Johns Pass in 2000 to limit the end losses from Sunshine Beach to the inlet. Prior to its construction, the shape and beach width at Sunshine Beach fluctuated significantly. After the groin construction, the beach was fixed and straight, limited by the effective length of the groin.

29.8 Summary and Conclusions

Large-scale designed beach nourishment projects are the result of a relatively young technology and thus issues expected to be dominant in the next century or so are still evolving. However, the major emerging issues are discussed below.

Energy Costs

Dredging is a process requiring fairly large amounts of energy. High velocities must be maintained in the pipeline delivering the sand–water mixture to prevent sand from settling and blocking the pipe. Some projects are located at substantial distances from the borrow areas and may require a booster pump which increases the energy costs. Currently (2012), in the United States, energy costs are approximately one-third of the total. Although future innovations in dredging technology may reduce energy costs per volume of sand delivered a specific distance, these improvements are not expected to reduce energy requirements by more than 25%.

Environmental Issues

Beach nourishment has been shown to both temporarily impact and to be a long-term benefit to the beach environment. Certainly a nourished sandy beach provides more benefits to the biota than an armored beach which could be either a seawall or a revetment. In the State of Florida where many sea turtles nest, it has been found that, compared to prenourishment nesting density, usually a reduction in nesting density will occur for several years after which the turtles will return to their prenourishment nesting activities. Beach nourishment and society would benefit by a more balanced environmental assessment of the beneficial and adverse impacts of beach nourishment including the adverse impacts of a *do-nothing* approach.

Limited Sand Resources

The availability of offshore sand resources varies widely with location depending on its geologic history. The relatively large deposits of sand in ebb tidal shoals have been utilized for nourishment in some projects. In some areas, the volumes of good quality offshore sand resources are quite abundant whereas at others, quantities are quite limited. In southeast Florida, limited sand resources tend to be located between offshore reefs that are generally approximately parallel to the shoreline. Along some counties in this area, the offshore sources of large quantities of readily available, good quality sand have been nearly depleted. In some areas, sand from previous nourishments has evolved to uneven distributions along the project area, resulting in programs to redistribute the sand along the project rather than provide additional sand. In other areas, additional sand has been provided by truck haul from inland sources as discussed earlier. The limitations of truck haul and damage to roads have been discussed. One possibility would be to deliver sand from inland quarries to the shore by dedicated pipelines and then transport this sand by dredge

along the shoreline to areas of need. Sand delivered in this manner could also act as long-term *feeder beaches* to the adjacent shorelines.

Public Perception

The public often perceives beach nourishment as benefitting only those adjacent to the beaches although the benefits may extend well inland and accrue to both state and federal coffers (see the excellent articles by *Houston* [29.24, 25]). However, most, if not all, projects that receive partial public funding require public access and parking, restroom facilities, and must meet other public benefit criteria. Often, the projects play a substantial role in protecting emergency evacuation routes and provide storm protection to valuable real estate that generates significant tax revenue.

29.9 Nomenclature

α_b Azimuth of the direction from which the breaking waves originate.
B Berm height
d Sediment grain diameter
G Longshore diffusivity
g Gravitational acceleration
h_* Depth of closure, seaward limit of nourishment sand distribution
H_b Breaking wave height (root-mean-square)
K Sediment transport coefficient
κ Breaker index, or ratio between breaking wave height and breaking depth
ℓ Project length
$M(t)$ Proportion of beach nourishment sediment remaining at time t
p Porosity
σ Sorting, or range, of sediment sizes
S Specific gravity
t Time after placement
θ Azimuth of the outward normal from the unaffected shoreline
v Sediment volume density placed per unit length of beach
x Longshore distance
x_o Alongshore location of beach nourishment project center
Δy Equilibrated additional dry beach width
y Cross-shore distance
Y Beach nourishment project width

30. Storm Hazard Mitigation Structures

David R. Basco

Hard structures have long been the method of shore protection from coastal storms. In this chapter, we first introduce the design criteria, design philosophy, and design constraints. Both armored shorelines (seawalls, dikes, revetments, etc.) and stabilized shorelines (headland breakwaters, near-shore breakwaters, groins, etc.), are possible alternatives. However, stabilized shorelines coupled with beach nourishment (Chap. 29) have become the preferred choice for many reasons at many locations. Rubble-mound (rock) structures and monolithic (concrete) structures are the most common types. Their functional design (wave run-up, overtopping, plan form layout, etc.) and structural stability (armor layer, sliding, overturning, etc.) are the focus of this chapter summarizing the latest and most trusted probabilistic design methods employed in the United States, Europe, and Japan. There exists a very large literature on these topics. Design practice details are quite extensive; we include website links to major reference sites, and a responsible engineer must consult these references for all the details.

In the future, the potential for the accelerated, relative sea level rise (including local subsidence) will increase the risk for more damage and reduce the resilience of existing shore protection systems. The design of hard structures for shore protection continues to evolve over time. As sea levels rise more quickly, the need for more basic research and more knowledgeable coastal engineers will also increase.

Armoring the shoreline with a hard structure has long been a traditional way of coastal shore protection from the excessive forces of the sea. Since about 1950, coastal population increases, tourism, and concerns for the environment have caused a shift away from the traditional armoring solution. Shoreline stabilization structures and the addition of natural sediments (Chap. 29) have often become the preferred choice for shore protection. In this chapter, *hard structures* refers to both (1) coastal *armoring structures* (seawalls, dikes, revetments, etc.) and (2) shoreline *stabilization structures* (head lands, breakwaters, groins, reefs, sills, etc.). These structural alternatives are changes to the natural, physical system for shore protection. Nonstructural alternatives (flood proofing, zoning, retreat, etc.) are changes to the built environment by adaptation and accommodation. There are many alternatives for shore protection as illustrated in Fig. 30.1. The correct choice depends on the design constraints for the particular site and is the responsibility of the design coastal engineer.

The excessive forces are the result of:

1. Coastal storms that produce elevated water levels, high waves, and strong currents over the storm duration, and

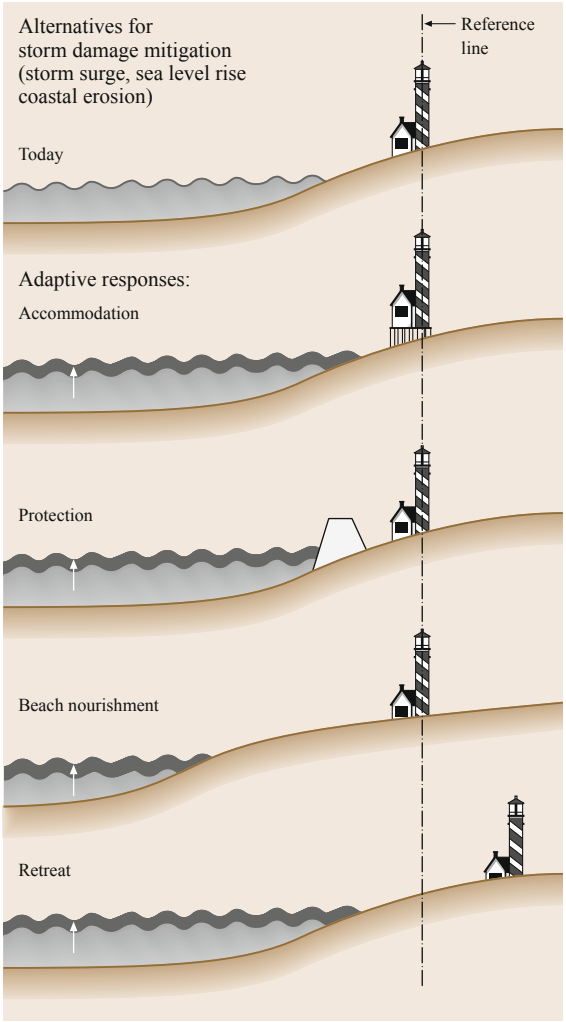

Fig. 30.1 Alternatives for shore protection (after [30.1, Fig. V-3-2])

2. Coastal tsunami events. These excessive hydrodynamic forces may also cause
3. Coastal erosion.

In this chapter, the term *shore protection* refers to the mitigation of the damage hazard consequences to people, property, infrastructure, and transportation systems from these types of excessive hydrodynamic forces and resulting coastal erosion. These forces are much different for open coasts than for limited fetch, bays, and estuaries so that the shore protection alternative selected for design is always site specific.

A discussion of the needed design criteria is presented in Sect. 30.1. Design practice has evolved from deterministic to probabilistic so that water wave spectra and statistics are now required in design. A coastal engineer is a member of an interdisciplinary team and always limited by the five major design constraints (science/technology, economics, the environment, institutional-political-social, and aesthetics). The key to a long term, sustainable solution is to first clearly define the problem and the purpose of the design solution for the general public (or client) responsible for paying the life-cycle costs for initial construction and long-term maintenance. Practice of the coastal engineering profession is much more than modeling and applying the design formulas in the next sections of this chapter.

In Sect. 30.2, the types, functional design, and structural design of coastal armoring structures are briefly summarized. Then, Sect. 30.3 addresses the types, functional and structural design of shoreline stabilization structures. There exists a vast amount of literature on these topics. The main references used herein are the US Army, Corps of Engineers, Coastal Engineering Manual [30.1], the Wave Overtopping Manual [30.2] funded by the UK, Germany, and the Netherlands, the Rock Manual [30.3] funded by CIRIA (Construction Industry Research and Information Association)/CUR, the textbook by *Goda* [30.4] that summarizes the Japanese literature, the results of the PROVERBS project for vertical breakwater design [30.5], and results of PIANC Working Groups [30.6, 7]. We can only present a very limited overview and summary of the literature. Section 30.4.1 lists the latest website links to some references at the time of publication of this book. Design practice details are quite extensive so that the responsible engineer must consult these references for the details. Space did not permit the discussion of dikes (levees), flood walls, and moving gate structures in tidal estuaries. The information presented on wave run-up, overtopping, and wave forces on vertical walls is applicable for these structures.

In the future, the potential for the accelerated, relative sea level rise (RSLR) rates (including local rates of subsidence) will increase the risk for more damage and reduce the resilience of existing shore protection systems. Section 30.4.2 concludes with some suggestions for the *best* alternatives for man's sustainable living at the coast. The design of hard structures for shore protection continues to evolve over time. As sea levels rise more quickly in the future, the need for more basic research and more knowledgeable coastal engineers will also increase.

30.1 Design Criteria, Philosophy, and Constraints

30.1.1 Water Levels

Water depth is arguably the most important independent variable in coastal structure design. By definition, the structure is at or near the land–water interface (the coast) where shallow water depths limit the wave height due to wave breaking. Low pressure storms and hurricanes with strong winds create storm surge that can significantly increase the local water depths during the storm event. Larger storm waves result before breaking depths are again attained and result in higher loads on the structure. Figure 30.2 displays the water elevations (above the National Geodetic Vertical Datum, 1929) versus the recurrence interval, T_r and the exceedance probability, $P_>$ for that elevation within the Chesapeake Bay (data from the National Oceanic and Atmospheric Administration (NOAA)/National Ocean Service (NOS) Tide Gauge at Sewells Point, Norfolk, VA). The elevation of Hurricane Isabel (Sep 18, 2003) was 2.38 m (7.82 ft) and the second highest water level recorded since records began in 1927. The mean tidal range is 0.82 m (2.7 ft) at this location. Clearly, the water depths at the structure used in design must consider the probabilistic variation of the water elevations.

Storm surge is the major difference between the measured and predicted, gravitational tide. If Hurricane Isabel (Sep 18, 2003) had occurred 10 days later during spring tide conditions, the water surface elevation measured at the Sewells Point (Norfolk, VA) tide gauge would have been 0.26 m (0.85 ft) higher and the highest ever recorded since 1927. There are several methods that have been historically applied for a flood frequency analysis. They are:

1. Estimates based only on historical storm data
2. The empirical simulation technique (EST)
3. The joint probability method (JPM), and
4. The Monte Carlo simulation method.

The length of record (years) for the historical storm data is generally short for many tide gages stations in the world but the total number of surge events can be extended. The storm events may be caused by both tropical and extra-tropical storms. See *Coles* [30.8] for a practical reference on statistical modeling of extreme flood events.

The EST has been developed *Scheffner* et al. [30.9] to generate a synthetic sequence of storms. The historical storm record is extended by assuming that each storm could have occurred at various combinations of the tidal phase and tidal range as in the example above for Hurricane Isabel. See *Scheffner* et al. [30.10] for complete details. The EST method can be applied for both tropical and extra-tropical storms.

The JPM is primarily for tropical storms (hurricane) since the joint, wind variable probabilities within the hurricane are reasonably well know that produce the storm surge along the coast. A modified JPM-OS method has been developed [30.12]. It has also been applied for extra-tropical storm events.

The Monte Carlo method [30.13] is similar to the JPM and relies on estimates of the probability distributions established for the parameters needed to characterize a storm. But a random number generator is employed to select values for each parameter. Each storm selected by this Monte Carlo procedure is equivalent to simulating a long period of history and many thousands of storms can be generated with high speed computers to improve the extrapolations to extreme storm events.

For hurricanes, [30.14, 15] and [30.12] recommend the JPM method.

Coastal sediment transport processes are discussed in Chap. 29 (erosion and accretion) and may also alter the bathymetry to modify the water depths and wave conditions near the coast and at the structure. Numerical modeling of bathymetric change near coastal structures is now possible for consideration in design.

Some level of the recurrence interval is often still selected in the deterministic design method. The risk-based approach employs the entire exceedance proba-

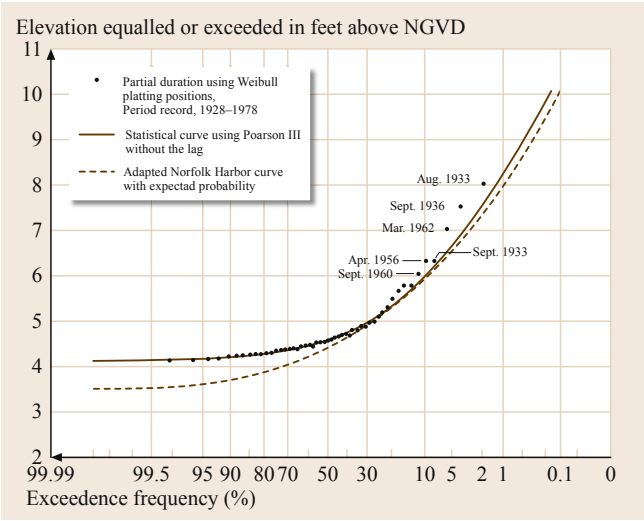

Fig. 30.2 Exceedance probability curve for water levels, Norfolk, Virginia, Tide Gauge at Sewells Point for 61 years data set (after [30.11])

bility curve and is the modern approach as discussed below.

Finally, the wave conditions at the structure can produce wave setup, $\bar{\eta}$ which is the time averaged increase in water level due to the presence of waves at the coast. Local beach slope is important. *Dean* [30.16] suggests using $\bar{\eta}/H_s = 0.191 \pm 0.100$ as a useful guide for the maximum setup at the coast. See *Dean* [30.16] for a detailed review of the wave setup. However, the state-of-practice is to use a cross-shore wave transformation model to calculate setup because the water level in the surf zone is a complex nonlinear process that depends on the details of the near-shore morphology and wave breaking. Empirical relations are not as accurate.

30.1.2 Wave Conditions

The mechanics of ocean waves and the modeling of coastal waves and hydrodynamics (wave-induced currents and tidal currents) are discussed in Chaps. 4 and 27, respectively. The real ocean surface variation is irregular in space and time so that some statistical, characteristic wave height and wave period must be employed for design. The most common choice is the significant wave height, H_s, which is the average of the highest one-third of the wave heights in a 17–20 min record of water surface variation as determined by the zero down-crossing analysis method in the time domain. The down-crossing method correctly captures the true wave height (vertical distance taken from trough in front and tail in rear) and should be used in the zero-crossing analysis method. The mean time period, T_m, is then used for the representative wave period.

An alternative, common choice is the result of a spectral analysis of the water surface record in the frequency domain to determine the spectral, significant wave height, H_{mo}, and the spectral peak wave period, T_p (see Chap. 4 for the definition of H_{mo}). A third wave period definition, the spectral wave period (or negative, first-moment wave period), $T_{m-1.0}$ ($= m_{-1}/m_o$) has been found useful because it gives more weight to the longer periods in the spectrum and is independent of the type of spectrum. It is commonly employed for wave run-up and overtopping calculations on coastal structures and is discussed in full detail below. The wave spectrum may contain two peaks indicating waves from different wave directions that produce both sea and swell conditions needed in structural design. The wave direction and storm duration are additional variables required for both functional and structural design.

The risk-based design approach also requires the analysis of many years of wave data or wave information. Figure 30.3 displays the Weibull distribution,

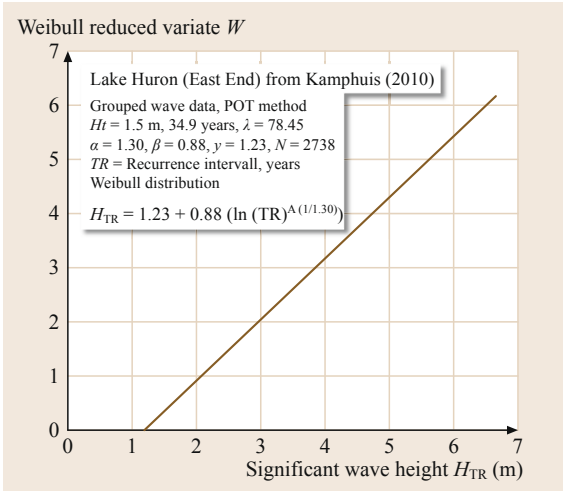

Fig. 30.3 Weibull distribution for extreme, significant wave heights for Lake Huron, Eastern Shore for 34.9 years (wind information after [30.17, Chap. 4])

reduced variate, W curve for extreme, significant wave heights, H_s as determined by the peak-over-threshold (POT) method for one site at the far eastern end of Lake Huron, Canada. The POT method separates related wave heights into independent *storm* events and the *reduced variate* is simply a coordinate transformation of the exceedance probability of storms to produce a straight line for extrapolation to extreme, wave heights ([30.17, Chap. 4], for a thorough explanation of how to apply the POT method with worked examples). The extreme wave heights for the very high recurrence interval conditions may never be reached if the water depths limit the wave heights due to wave breaking. The symbol $\hat{H}_S^T$ (hat for central estimate, subscript s, and super script T) will be employed for the central estimate of the significant wave height, H_s which on average is exceeded every T years [30.1, 2011, Part VI, Sep. 28, 2011].

Finally, the full wave climate (heights, periods, and directions) as experienced over the average, annual, seasonal cycle is needed for the functional design of shoreline stabilization structures (near-shore breakwaters, groin fields, etc.). In the United States, the US Army Corps of Engineers, Wave Information Studies (WIS) provide the full wave climate for the Atlantic, Pacific, Gulf of Mexico, and Great Lakes coasts.

30.1.3 Surf Conditions on the Structure

Different types of wave breaking (spilling, collapsing, plunging, and surging) occurs on structure slopes, $\tan\alpha$. The wave steepness is the ratio of the wave height, H to wavelength, L, and is usually defined for the deepwater

wavelength, $L_o = (g/2\pi)T^2$ so that clearly the definition of wave steepness depends on what irregular wave characteristics are employed for H and T.

The surf similarity parameter, ξ, is the ratio of the structure slope to the square root of the wave steepness and employed in many of the empirically developed design formulas for the functional and structural design of coastal structures because the different types of wave breaking produces different results as explained further below.

30.1.4 Probabilistic Design

Three levels of probabilistic design can be considered. We herein apply the level I (lowest) method which simply employs partial safety factors related to a characteristic load, γ_H, and characteristic resistance, γ_Z for the stability equations utilized in design. The designer selects the appropriate probability of the failure level, P_f and the degree of uncertainty as determined by the coefficient of variation, σ' is defined as the standard deviation, σ divided by the mean. Commonly employed partial safety factors for implementing reliability in design are discussed in detail below. Complete details are found in the CEM [30.1, VI, Sect. 6].

30.1.5 Coastal Risk

Fragility curves are functions that describe the probability of failure that is dependent on the *load* (force) over the full range of the *loads* to which the coastal system might be exposed [30.18]. These authors discuss four methods (judgemental, empirical, analytical (models) and hybrid combinations) to develop fragility curves. How to define the *load* for coastal systems is not discussed. Herein, we define the *load* as the coastal storm.

The probability of failure is the convolution of the probability of exceedance for the hazard (coastal storm) and the probability of coastal system damage from the hazard [30.17]. Coastal risk is then simply the summation of the probability of failure times all the consequences (economic, structural, functional, loss of life, environmental, etc.), over the full range of coastal storms.

Resilience is the ability of a system to maintain and recover its structural and functional performance following a disturbance [30.19]. The *disturbance* is the short-term excess of forces (the load or coastal storm) acting on the coastal system components and processes that may impair the system function. These authors discuss three types of resilience (ecological, engineering, community) for coastal systems, focus on engineering resilience, and cite the Saffir–Simpson wind speed scale for hurricanes as an example of a coastal storm disturbance scale. If the level of disturbance (coastal storm) exceeds a critical level, both the level of performance impairment and the duration of performance impairment may exceed management objectives for the resilience of the coastal system.

Fragility curves are needed to quantify risk and hence resilience in coastal systems design. The intensity of the *load* or *disturbance*, the severity of the coastal storm must be quantified to develop fragility curves. Excess water levels (storm surge), wave conditions (height, period, direction), and storm duration all contribute to the intensity of a coastal storm. How to combine these three factors has long been a concern for coastal scientists and engineers.

30.1.6 A Coastal Storm Severity Index

The definition of a coastal storm may depend on wave height, or water level (site specific), and sometimes depends on the consequences of the storm event. For example, the Corps of Engineers, Field Research Facility (FRF) at Duck, NC, on the mid-Atlantic, east coast of the US uses the mean, significant wave height plus two standard deviations of the mean (as measured at an offshore, deepwater buoy) to define the start of a coastal storm (*Birkemier* [30.20], personal communication). However, flood levels in the Piazza San Marco in Venice, Italy, result from meteorological conditions in the Adriatic Sea that trigger a coastal *storm* event for the Italian government. The consequences are property damage, interruptions of tourism, etc. Therefore, a storm is defined in Venice by the *flood level*. There presently exists no known, universally accepted, hydrodynamic definition of a coastal storm. One potential method that combines waves, water levels, currents, and storm duration into one number is the coastal storm impulse (COSI) parameter [30.21].

30.1.7 Design Constraints

One good definition of engineering is *design under constraint*. Coastal engineering design is constrained by our scientific and engineering understanding of nature; by economics (costs); by concerns of environmental impact; by social, political, and institutional issues; and possibly by aesthetics. See the CEM [30.1, Part V, Chap. 3, Sect. 1c] for a detailed discussion of design constraints. This chapter only considers our scientific and engineering understanding of armoring and stabilization structures for coastal protection design.

30.2 Coastal Armoring Structures

30.2.1 Types and Purpose

There are many different types of seawalls and dikes, bulkheads, and revetments as illustrated in Fig. 30.4. Their functional purposes are different. The seawall mitigates damage to what lies behind from flooding and wave forces; the bulkhead prevents the soil behind from sliding into the sea; and the revetment protects the bank from erosion. They all have, however, the following in common:

1. They are located at the land/water interface.
2. They harden (armor) the shoreline to fix its location, and
3. They have some configuration and crest elevation that determines the height of the wave run up and the amount of wave overtopping for the range of water levels and wave conditions at their location on the coast.

30.2.2 Functional Design

The functional design of coastal armoring structures involves calculations of wave run-up, wave overtopping, wave transmission, and reflection. These technical factors together with economic, environmental, and other constraints all combine to determine the crest elevation of the structure. We only consider run-up and overtopping due to space limitations.

Wave Run-Up

The wave run-up, R_u is defined as the vertical distance above the still water level that can be reached by the waves as illustrated in Fig. 30.5. Common practice is to consider the irregular wave heights following the Rayleigh distribution and define a run up level exceeded by i % of the waves as $R_{ui\%}$. One popular, dimensionless, formulation [30.23] is

$$\frac{R_{ui\%}}{(H_s)_{toe}} = (A\xi + C)\gamma_r\gamma_b\gamma_h\gamma_\beta \,, \tag{30.1}$$

where:

- H_s = the significant wave height at the toe of the structure
- ξ = the surf similarity parameter
- A, C = empirical coefficients from laboratory and field data depending on the value of i, and
- γ = reduction factors (subscripts) for roughness (r), fronting berm (b), shallow water depths (h), and wave approach angle (β).

The key independent variable is the surf similarity parameter, ξ, and three definitions have been employed in the literature depending on which irregular wave period, T is specified to define the deep water wavelength L_o and the wave steepness $S_o = H_s/L_o$. The mean wave period T_m, the spectral peak wave period T_p; and the spectral wave period $T_{m-1.0}$ all have been employed by various researchers. And, since the structure slope and wave steepness trigger different types of breaking waves (spilling, plunging, collapsing, and surging, see *Battjes* [30.23]), the coefficients A and C vary with ξ for a given structure. *Hunt* [30.24] was the first to introduce (30.1).

For the design of crest elevations with nonovertopping wave conditions, the 2% value for run-up has long been the choice. See the EurOtop Manual [30.2] for the history of this choice for design dating back to 1932 in the Netherlands.

Impermeable embankments (dikes and levees) with smooth, rough, and rock cover were studied by *de Waal* and *van der Meer* [30.25]. Using the peak wave period T_p to define ξ_{op}, the run-up at the $i = 2\%$ exceedance level, $R_{u2\%}$ depended on the breaker type. For $\xi_{op} \le 2$, $A = 1.5$ and $C = 0$. When $2 < \xi_{op} < 3$–4, $A = 0$ and $C = 3.0$. The coefficient of variation $\sigma' = 0.085$. When the impermeable surface is roughened, γ_r was in the 0.5–0.6 range. See Table VI-5-3 in the CEM [30.1] for other reduction factors in (30.1).

Rock-armored slopes with impermeable and permeable cores (rubble-mound breakwaters) were studied in great detail by *van der Meer* [30.26]. The permeable structure resulted in a slightly more complicated form for the dimensionless, wave run-up formulation

$$\frac{R_{ui\%}}{(H_s)_{toe}} = A\xi + B\xi^C + D \,. \tag{30.2}$$

And, the mean wave period T_m was employed to calculate the surf similarity parameter ξ_{om} for use in correlating the experimental data. For the impermeable core, the permeability parameter $P = 0.1$ and the permeable structure $P = 0.5$ (see Fig. 30.12 in the next section for a graphical depiction of P).

At the 2% exceedance level for the impermeable core case $A = 0.96$, and $B = D = 0$, when $\xi_{om} \le 1.5$; and $A = 0$, $B = 1.17$, with $C = 0.46$ and $D = 0$ when $1.5 < \xi_{om} \le 3.1$. For the permeable core, these coefficients for A, B, and C are the same except now $D = 1.97$ for all $\xi_{om} \ge 3.1$. The CEM [30.1] also presents coefficients for A, B, C, and D for other values of the exceedance level i for use in (30.2). See Table VI-5-5 in the CEM [30.1].

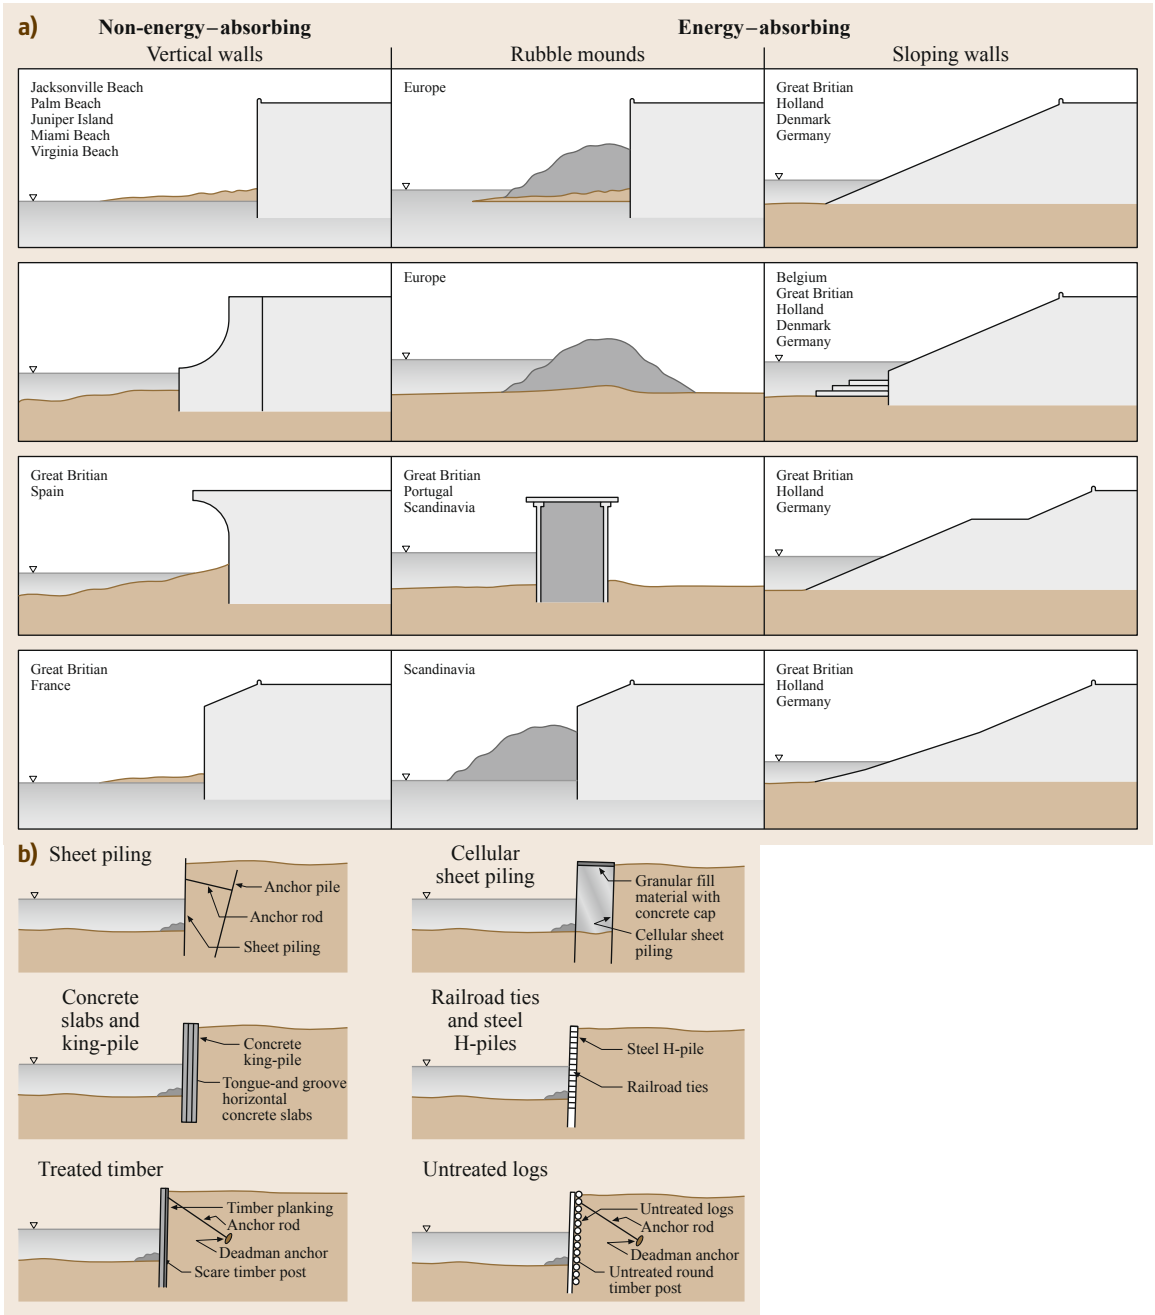

Fig. 30.4 (a) Typical seawall types (after [30.22]); (b) typical cantilever and tie-back bulkheads; (c) typical embankments with revetment armor

But all the above is for some level of the significant wave height H_s at the toe of the structure. A full probabilistic treatment for wave run-up on rock-armored slopes with impermeable and permeable cores using $\hat{H}_S^T$, the mean significant wave height at some recurrence interval can now be determined for a range of partial safety factors and levels of probability of failure P_f. See Table VI-6-17 as developed from the work of *de Waal* and *van der Meer* [30.25] in the CEM [30.1] for complete details.

Many other formulations are available. See the EurOtop Manual [30.2] for the calculation of wave run-

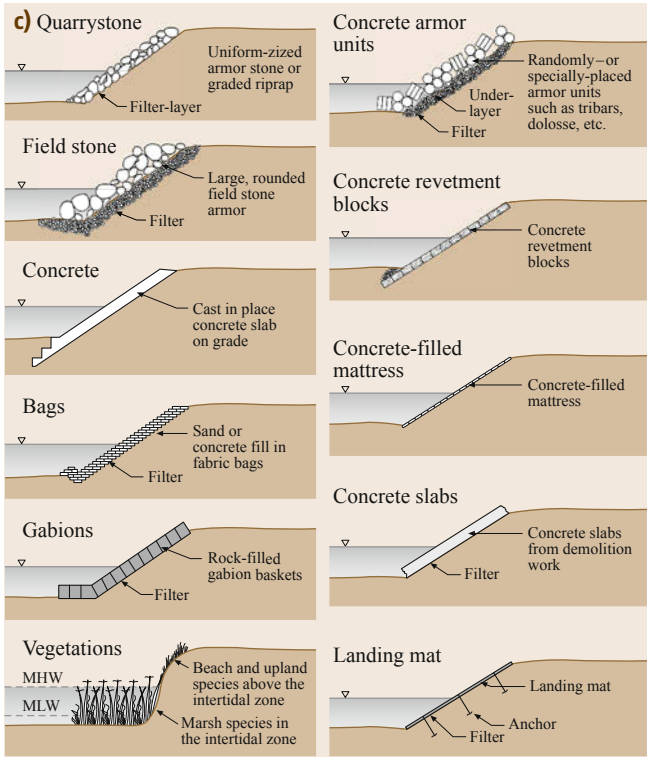

Fig. 30.4 (continued)

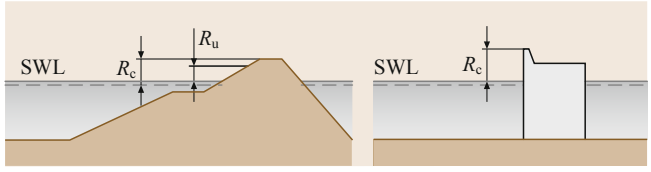

Fig. 30.5 Wave run-up R_u and wave freeboard R_c definitions

up heights under the range of experimental conditions employed to develop EurOtop. These authors have employed the spectral wave period $T_{m-1.0}$ to define $\xi_{m-1.0}$ in all their work to better incorporate the longer period waves in the empirical, wave run-up formulations, and coefficients.

The US Army, Corps of Engineers, has developed a hydrodynamic, numerical model to predict wave run up for coastal structures and beaches called CSHORE. The Federal Emergency Management Agency (FEMA) in the US sponsored a study [30.27], which concluded that EurOtop *is likely to have better skill than CSHORE* for structures that were within the range of experimental conditions (bathymetry and wave-water level). However, for complex near-shore bathymetry and complex structures with waves and water levels outside the range of EurOtop, the *CSHORE is likely to show better skill*. CSHORE also predicts cross-shore beach morphology change during storm events that can significantly impact wave run up.

Wave overtopping is related to wave run up and the crest elevation of the structure.

Wave Overtopping

Wave overtopping occurs when the highest wave run-up R_u exceeds the crest freeboard R_c as defined in Fig. 30.5. For almost all coastal structures illustrated in Fig. 30.4, the crest elevation will be overtopped by some waves during extreme storm events. The functional purpose of the structure and the design constraints discussed above will dictate the design crest elevation such that some wave overtopping will occur over the life of the structure. Individual waves overtopping a structure vary considerably in space and time, so that the average discharge rate may only be a small fraction of the peak value from a single wave. However, the *average*, allowable wave overtopping discharge rate q (m^3/s per meter length of structure) in most cases determines the design crest elevation of the structure.

Field studies of critical, tolerable overtopping limits have been performed by many investigators over the years. Figure 30.6 is a composite of US, Dutch, Italian, and Japanese researchers as complied in the CEM [30.1, Table VI-5-6]. The designer must first start with a target goal for the allowable value of q which may come from Fig. 30.6 or institutional criteria, local experience, or an educated guess of the client. For example, the US Government, Federal Emergency Management Agency (FEMA) publishes *Suggestions for Interpretation of Mean Wave Overtopping Rates* [30.28, Table D.2.8-6], for flood insurance risk zones behind coastal structures. For Zone AO (1 m depth) the order of acceptable q is 9.3–93 l/s per meter. Figure 30.6 can then be consulted for safety of structures, vehicles, and pedestrians. If unacceptable, the crest elevation of the structure can be increased to reduce the average overtopping rate by applying a suitable formula for calculation.

A review of the structural profiles in Fig. 30.4 reveals four basic types of geometrical patterns: straight slope, bermed slope, slope with crown wall, and vertical wall (with and without recurved top). As a result, many different wave overtopping formulations have appeared in the literature (see the CEM [30.1], Table VI-5-7 for eight popular formulae dating from *Owen* [30.29, 30] to *Pedersen* [30.31]). Space limitations permit only the case for straight and bermed impermeable slopes [30.32] to be presented here. Their formulation, however, includes the influence of surface roughness, shallow water, oblique, and short-crested waves so that it is quite useful. The surf similarity parameter ξ_{op} is employed.

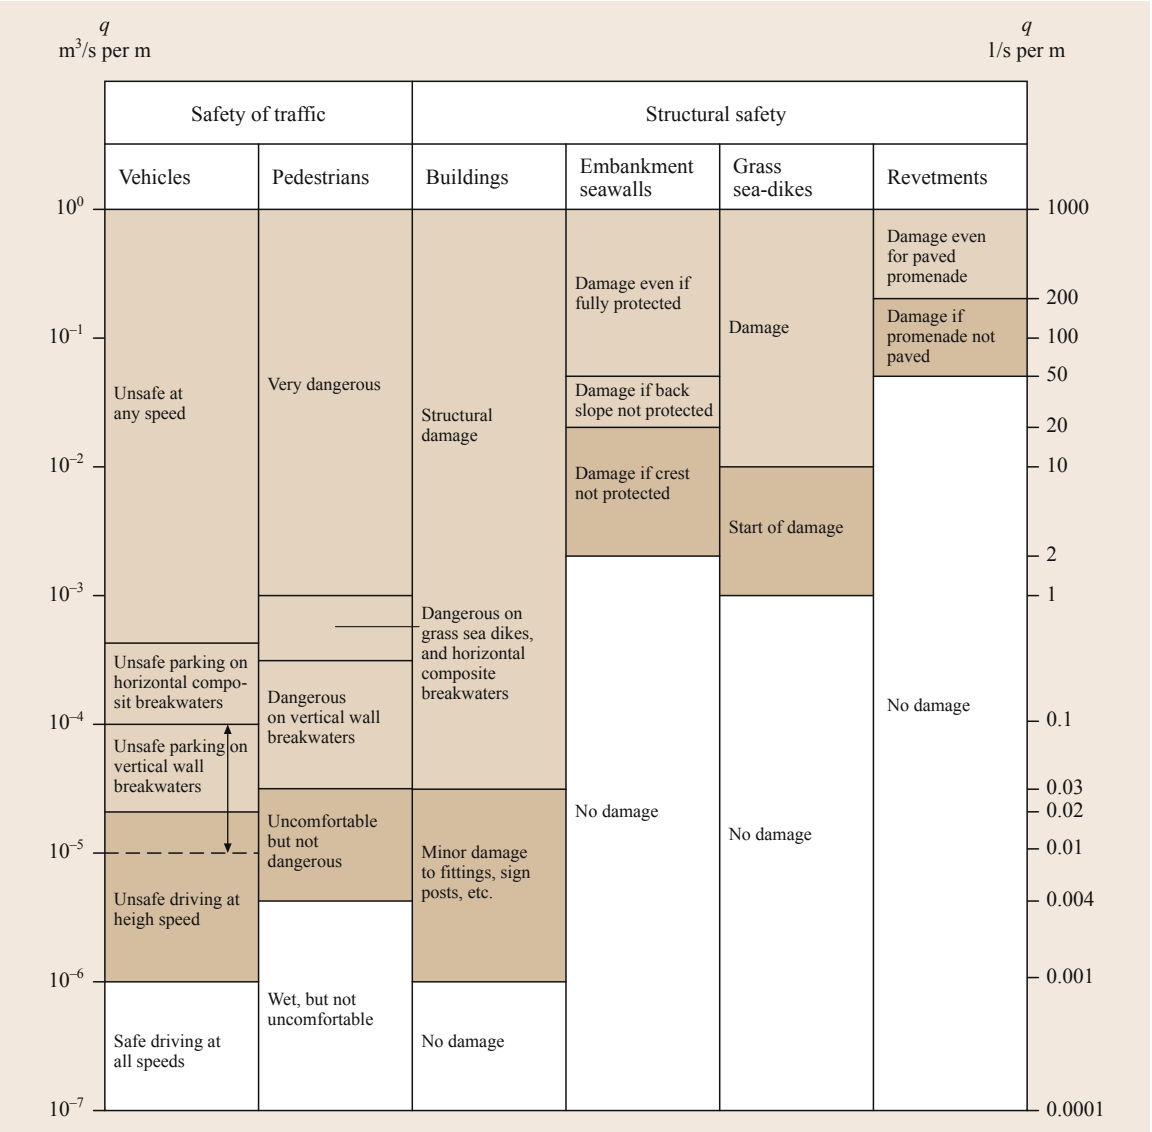

Fig. 30.6 Critical values of average wave overtopping discharge rates (after [30.1])

When $\xi_{op} < 2$

$$\frac{q}{\sqrt{gH_s^3}}\sqrt{\frac{s_{op}}{\tan\alpha}} = 0.06\exp\left(-5.2\frac{R_c}{H_s}\sqrt{\frac{s_{op}}{\tan\alpha}}\frac{1}{\gamma_r\gamma_b\gamma_h\gamma_\beta}\right) . \tag{30.3}$$

The application range is

$$0.3 < \frac{R_c}{H_s}\sqrt{\frac{s_{op}}{\tan\alpha}}\frac{1}{\gamma_r\gamma_b\gamma_h\gamma_\beta} < 2 . \tag{30.4}$$

The uncertainty $\sigma' = 0.55$ on the factor 5.2.

When $\xi_{op} \geq 2$

$$\frac{q}{\sqrt{gH_s^3}} = 0.2\exp\left(-2.6\frac{R_c}{H_s}\frac{1}{\gamma_r\gamma_b\gamma_h\gamma_\beta}\right) . \tag{30.5}$$

The uncertainty σ' equals 0.35 on the factor 2.6.

All the symbol definitions are the same as that for wave run-up as are the reduction factors for roughness, water depth, and wave obliqueness. See Table VI-5-11 in the CEM [30.1] for adjustments for short- and long-crested waves. The minimum value of any combination of γ-factors is 0.5. Wave overtopping formulas for ver-

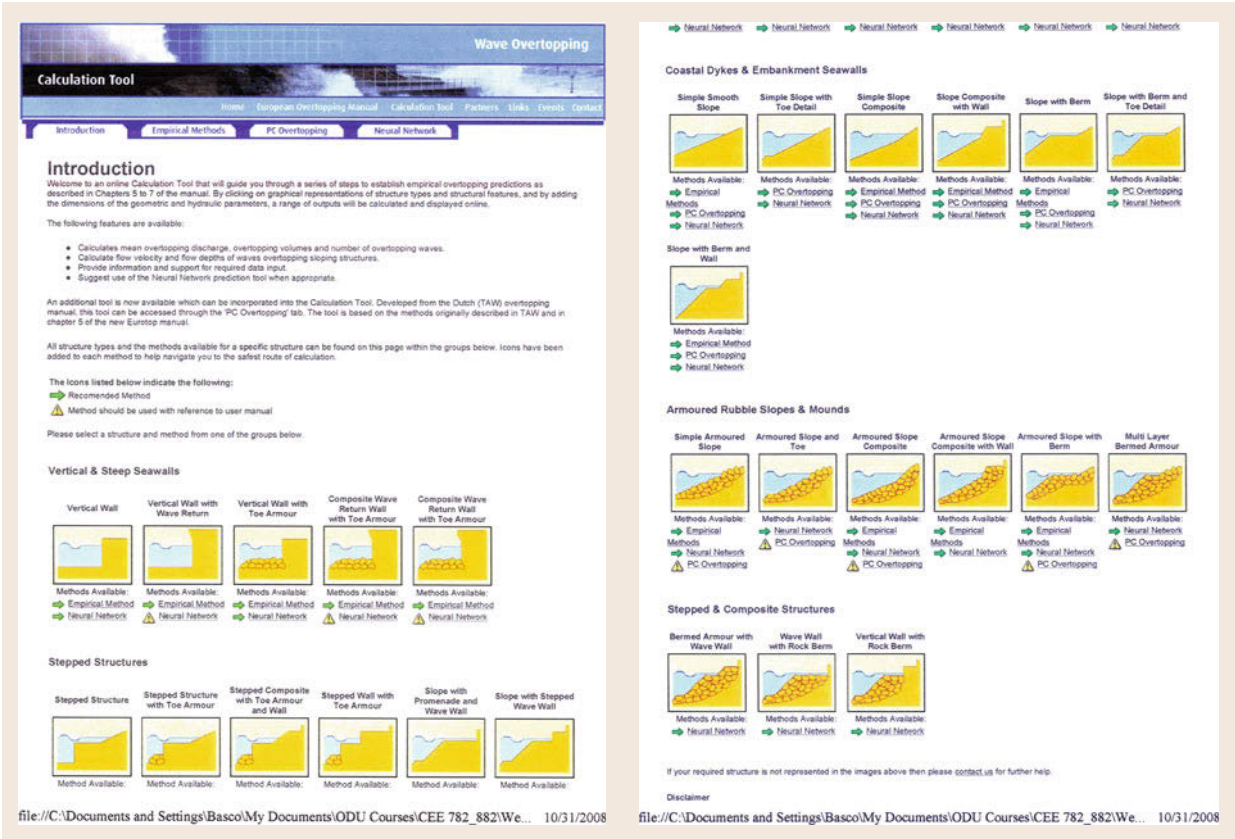

Fig. 30.7 Structure types as treated in the online, EurOtop calculation tool (after [30.2])

tical walls are not well covered in the CEM [30.1] and recent research efforts in northern Europe have provided a more extensive treatment of wave overtopping in the EurOtop Manual.

In August 2007, a research team from the United Kingdom, Germany, and the Netherlands, published the *Wave Overtopping of Sea Defences and Related Structures: Assessment Manual* commonly referred to as the EurOtop Manual. The publication is No. 73 in the Archive for Research and Technology on the North Sea and Baltic Coast [30.2]. It replaces previous manuals in these three countries and provides significant new information obtained from many European Union (EU) and national projects (OPTICREST, PROVERBS, SHADOW, VOWS, BIG-VOWS, ComCoast, etc.) and continues in the CLASH project. The acronym *CLASH* stands for

> *crest level assessment of coastal structures by full scale monitoring, neural network prediction and hazard analysis on permissible wave overtopping*

and is a fifth framework program in the European Community. The key final product of this major international effort is the *EurOtop calculation tool* which is an extremely useful, online, and freely available tool for use by the world's coastal engineering community [30.33].

The structure types analyzed are: vertical and steep seawalls; stepped structures; coastal dikes and embankment revetments; armored rubble slopes and mounds; and stepped and composite structures as displayed in Fig. 30.7. Three calculation methods are available (empirical, overtopping formulas, and neural networks) but not all for each structure type.

One advantage of the *EurOtop calculation tool* is the ease of application for a large range of structure types and knowledge that the latest international, field research efforts have been incorporated for the results. One disadvantage is that each water level and wave condition of interest must be entered manually. Documentation of the formulas employed in the calculation tool is discussed in the assessment manual available at www.overtopping-manual.com. Some formulas are the same as in the CEM [30.1] such as those by *van der Meer* and *Janssen* [30.32] for impermeable slopes (30.3).

30.2.3 Structural Design

The structural design of coastal armoring structures involves the water levels and wave forces (and possibly ice loads) that may produce movements (sliding, rotation, overturning, etc.) of complete sections of the structure or loss of stability for individual units of rock (rubble)- and concrete-armor layers of the structure. Structural stability is the goal under design storm events. Damage is probable under more extreme storm conditions for the given design constraints (economic, environmental, etc.) so that maintenance costs for repair must always be considered in the initial design phase of the project. We herein consider, monolithic, caisson-type, vertical-walled structures and rock (rubble) revetments. Water level and wave loads on vertical *seawalls* are similar as considered herein for caissons. The stability of rubble-mound (rock) breakwaters is also included here with further discussion in Sect. 30.3. The origin of the use of the word *rubble* for rock structures is unknown.

The choice between use of a vertical-walled, caisson-type structure or a rubble-mound breakwater depends on many factors with water depth being one of the most important. In deep water, the cross-sectional area (hence cost) of the caisson-type is lowest where as in shallow water the material cost often favors the rubble-mound type. No general design rules apply so that both types should be considered in the feasibility study.

Oumeraci et al. [30.5] cite the following reasons for research on monolithic, caisson-type structures: catastrophic failures in Europe, need for breakwaters at greater depths, need for environmentally friendly structures, need for multipurpose structures, and the potential for application in sea-wall designs. The result was the PROVERBS project as discussed below.

Vertical-Walled, Caisson-Type Structures

With no waves present, the water pressure distribution on a vertical wall is hydrostatic being zero at the surface and $-\rho z$ at any distance z below the surface ($+z$ is positive above the surface). The mass density of the fluid is ρ. The horizontal, water force per unit width f_h on the vertical wall is then $\frac{1}{2}\rho g h^2$, where h is the fluid water depth at the wall. Storms increase the water depth and bring waves that are both reflected by and break on the wall to greatly increase the horizontal forces on the wall. A long history of research efforts throughout the world has produced many formulas over the years for the calculation of wave pressures and forces on vertical walls.

Pioneering efforts of Japanese coastal engineers have led the way to develop practical formulas for the wave pressures and forces on caisson-type structures under both nonbreaking and breaking wave conditions. We focus on these herein.

Figure 30.8 (from the CEM [30.1]) presents the key pressure distribution and other variables for irregular waves as formulated by *Goda* [30.34] and *Tanimoto* [30.35] and herein called the *Goda* formula

$$\eta^* = 0.75(1+\cos\beta)\lambda_1 H_{\text{design}} \,, \tag{30.6}$$

$$p_1 = 0.5(1+\cos\beta)(\lambda_1\alpha_1 + \lambda_2\alpha_* \cos^2\beta) \times \rho_w g H_{\text{design}} \,, \tag{30.7}$$

$$p_2 = \begin{cases} \left(1-\dfrac{h_c}{\eta^*}\right) p_1 & \text{for } \eta^* > h_c \\ 0 & \text{for } \eta^* \le h_c \end{cases} \,, \tag{30.8}$$

$$p_3 = \alpha_3 p_1 \,, \tag{30.9}$$

$$p_u = 0.5(1+\cos\beta)\lambda_3\alpha_1\alpha_3\rho_w g H_{\text{design}} \,, \tag{30.10}$$

where

$$\beta = \text{angle of incidence of waves} \,,$$

$$\alpha_* = \alpha_2 \,,$$

$$\alpha_1 = 0.6 + 0.5\left[\frac{4\pi h_s/L}{\sinh(4\pi h_s/L)}\right]^2 \,, \tag{30.11}$$

$$\alpha_2 = \text{the smallest of } \frac{h_b - d}{3h_b} \times \left(\frac{H_{\text{design}}}{d}\right)^2 \text{ and } \frac{2d}{H_{\text{design}}} \,, \tag{30.12}$$

$$\alpha_3 = 1 - \frac{h_w - h_c}{h_s}\left[1 - \frac{1}{\cosh(2\pi h_s/L)}\right] \,, \tag{30.13}$$

- L = wavelength at water depth h_b corresponding to that of the significant wave $T_s \simeq 1.1T_m$, where T_m is the average period.

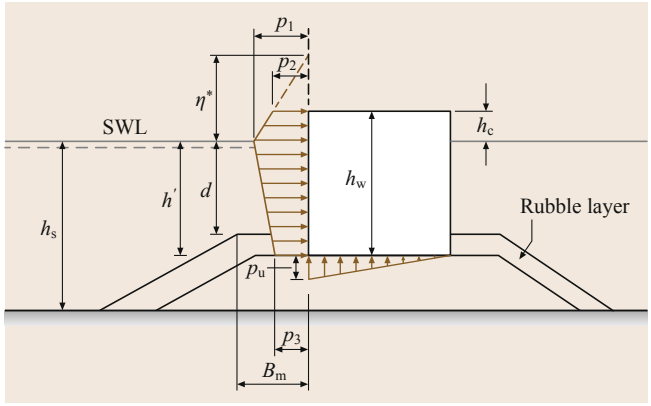

Fig. 30.8 Definitions of terms in Goda formula for irregular waves (after [30.1])

- h_b = water depth at a distance of 5 H_s seaward of the breakwater front wall.
- λ_1, λ_2, and λ_3 are the modification factors depending on the structure type. For conventional vertical wall structures, $\lambda_1 = \lambda_2 = \lambda_3 = 1$. Values for other structure types are given in related tables.

The key pressure is p_1 at the design still wave level (SWL) and its calculation depends on many factors in the formulation listed above including the design wave height H_{design}. What to use for the design wave height in the Goda formula to calculate p_1 is subject to debate as discussed further below. The water level on the leeward side of the structure is the same so that the hydrostatic forces on the structure are balanced out and not shown.

The wave pressure and uplift pressure distributions produce forces and moments per unit length of structure that are readily calculated by the following formulas (from the CEM [30.1, Table VI-5-55]). The gravity force F_G is simply the difference between the caisson weight in air W and the buoyant force B

$$F_H = U_{FH}\left[\frac{1}{2}(p_1+p_2)h_c + \frac{1}{2}(p_1+p_3)h'\right], \tag{30.14}$$

$$F_U = U_{FU}\frac{1}{2}p_u B, \tag{30.15}$$

$$F_G = \rho_c g B h_w - \rho_w g B h', \tag{30.16}$$

where:

- ρ_c = mass density of the structure
- ρ_w = mass density of the water
- U_{FH} = stochastic variable signifying the bias and the uncertainty related to the horizontal force in the Goda formula

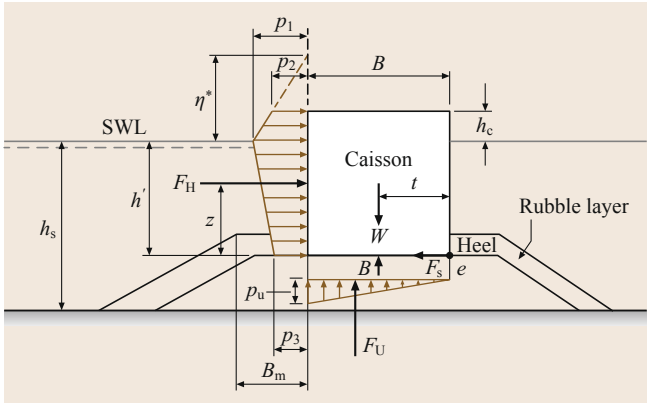

Fig. 30.9 Forces on the Caisson structure that cause sliding, overturning and bearing pressures

Table 30.1 Correction factors for moments in Goda formulae

Stochastic variable X_i	Mean value μ_{X_i}
U_{FH}	0.90
U_{FU}	0.77
U_{MH}	0.81
U_{MU}	0.72

- U_{FU} = stochastic variable signifying the bias and the uncertainty related to the uplift force in the Goda formula
- h' = submerged height of the wall from the toe to the still water level
- B = structure width.

The corresponding moments at the heel of the structure are

$$M_H = U_{MH}\left[\frac{1}{6}(2p_1+p_3)h'^2 + \frac{1}{2}(p_1+p_2)h'h_c + \frac{1}{6}(p_1+2p_2)h_c^2\right], \tag{30.17}$$

$$M_U = U_{MU}\frac{1}{3}p_u B^2, \tag{30.18}$$

$$M_G = \frac{1}{2}B^2 g(\rho_c h_w - \rho_w h'). \tag{30.19}$$

Uncertainty and bias in the Goda formulae were reanalyzed by *van der Meer* et al. [30.36] and resulted in correction factors U for the horizontal and uplift forces and moments (per unit length of structure) in these equations. These correction factors are all less than unity and are related to the H_{design} value employed to calculate p_1.

The correction factors for moments are defined as follows and their values are indicated in Table 30.1:

- U_{MH}: Stochastic variable signifying the bias and the uncertainty related to the horizontal moment in the Goda formula.
- U_{MU}: Stochastic variable signifying the bias and the uncertainty related to the uplift moment in the Goda formula.

See the CEM [30.1, Table VI-5-55] for standard deviations of the mean and the coefficients of variation for the uncertainty factors U listed above in the Goda formula.

Three stability tests are normally conducted (sliding, overturning, and heel bearing pressure) to determine the design caisson width B as illustrated in Fig. 30.9. The gravity force F_G is simply the difference between the caisson weight in air W and the buoyant force B and when multiplied by a sliding friction coeffi-

cient μ produces the sliding friction resistance force F_S that opposes the horizontal wave force F_H. The wider the caisson width B the greater the sliding friction resistance force to produce a stable structure against sliding failure.

The uplift force F_U is the result of an assumed triangular uplift pressure distribution with p_u maximum on the front edge. Note that p_u is not equivalent to p_3. The uplift moment arm is $2/3B$ and the horizontal wave force moment arm is the distance z for clockwise moments about the heel of the caisson at location e. The gravity force $(W-B)$ times its moment arm, t produces the counter-clockwise moment about the heel location e to prevent overturning of the caisson. Here again, the wider the caisson width B, the greater the resistance to the overturning moments to produce a stable structure against overturning failure.

The third *failure* test normally considered is the soil-bearing pressure at the heel of the caisson structure. Space limitations do not permit a discussion here. See the CEM [30.1].

Global safety factors can be applied for the sliding, overturning, and bearing pressure formulations but they are not recommended because they are not related to the probability of failure of the structure. Modern, probabilistic design methods now employ partial safety factors. For sliding failure, conditions for deep and shallow water, and design with and without model tests are presented for both the load partial safety factor γ_H for wave height and the resistance partial safety factor γ_Z for the friction coefficient. See Table VI-6-24 in the CEM [30.1]. Note that two levels of knowledge of the wave height coefficient of variability ρ' (0.05 for good knowledge and 0.2 for relatively poor knowledge) are also presented for use to estimate the appropriate five levels (0.01, 0.05, 0.10, 0.20, 0.40) of probability of failure P_f. Similar summary tables of partial safety factors for overturning (Table VI-6-25) and for bearing pressure foundation failure for both sand subsoil (Table VI-6-22) and clay subsoil (Table VI-6-23) are found in [30.1].

In all the tables of partial safety factors in [30.1], the design wave height, H_{design}, is taken as the mean (carrot symbol) of the long term, statistical probability distribution for the significant wave height (subscript s) at the recurrence interval of choice (superscript T) noted as $\hat{H}_S^T$. *Goda* [30.4] recommends using H_{design} as 1.8 H_s if seaward of the surf zone and *the highest of the breaking waves* when within the surf zone. The use of the 1.8 factor corresponds to 0.15% exceedance value in the Rayleigh distribution included in 1/250 total number of waves. Use of $H_{design} = 1.8H_s$ in the specification of the design wave height is equivalent to using a higher recurrence interval wave height. For example, in Fig. 30.3, if the design wave height was 4 m ($T = 50$ yrs), then 1.8 H_s is about 7 m at a recurrence interval, T of 5000 yr. Tables of partial safety factors [30.1, Tables VI-6-22, 23, 24, 25], all specify using $\hat{H}_S^T$.

The original Goda method is normally for design of relatively long structures where the structure length in effect spreads the wave loads along the length of the structure. This horizontal spreading of the wave loads calculated per unit length of structure is an added factor of safety in applying the original Goda formulations for the pressure p_1 at the water surface as shown in Fig. 30.8 for both nonbreaking and breaking waves [30.37]

However, under some wave-breaking conditions, very high wave impact (aka, impulsive, slamming, hammering) loads of short duration occur that produce greater wave loads than estimated by the original [30.34] formula. *Takahashi* [30.38] has modified the pressure p_1 at the still water level (SWL) to take this slamming force into account. [30.1] advises that these relatively small-scale model results do not correctly include air pockets trapped between the wall and the slamming wave. The use of the Minikin method as found in [30.39] is recommended [30.1, p. VI-5-162] even though it is well know that the Minikin method gives very high results.

The need for improved knowledge for the wave impact loads, geotechnical aspects, and structural analysis aspects of vertical breakwater design resulted in the PRObabilistic Design Tools for VErtical BreakwaterS (PROVERBS) project in the European Union (1994–1998) as summarized below.

The results of the PROVERBS project are summarized by *Oumeraci* et al. [30.5]. Only the wave impacts are presented here. The interested reader should consult this reference for geotechnical aspects, structural aspects, and probabilistic design tools that are applicable for vertical, monolithic structure design.

Three major advances have resulted from the PROVERBS project, namely:

1. A parametric decision map has been developed (Fig. 30.10) to provide a calculation procedure to identify the breaker-type in front of the vertical structure.
2. The breaker-type depends on the structure (four structure types are identified and studied) as well as the wave parameters approaching the structure.
3. A 12-step design procedure has been developed that includes new formulas to calculate the wave impact

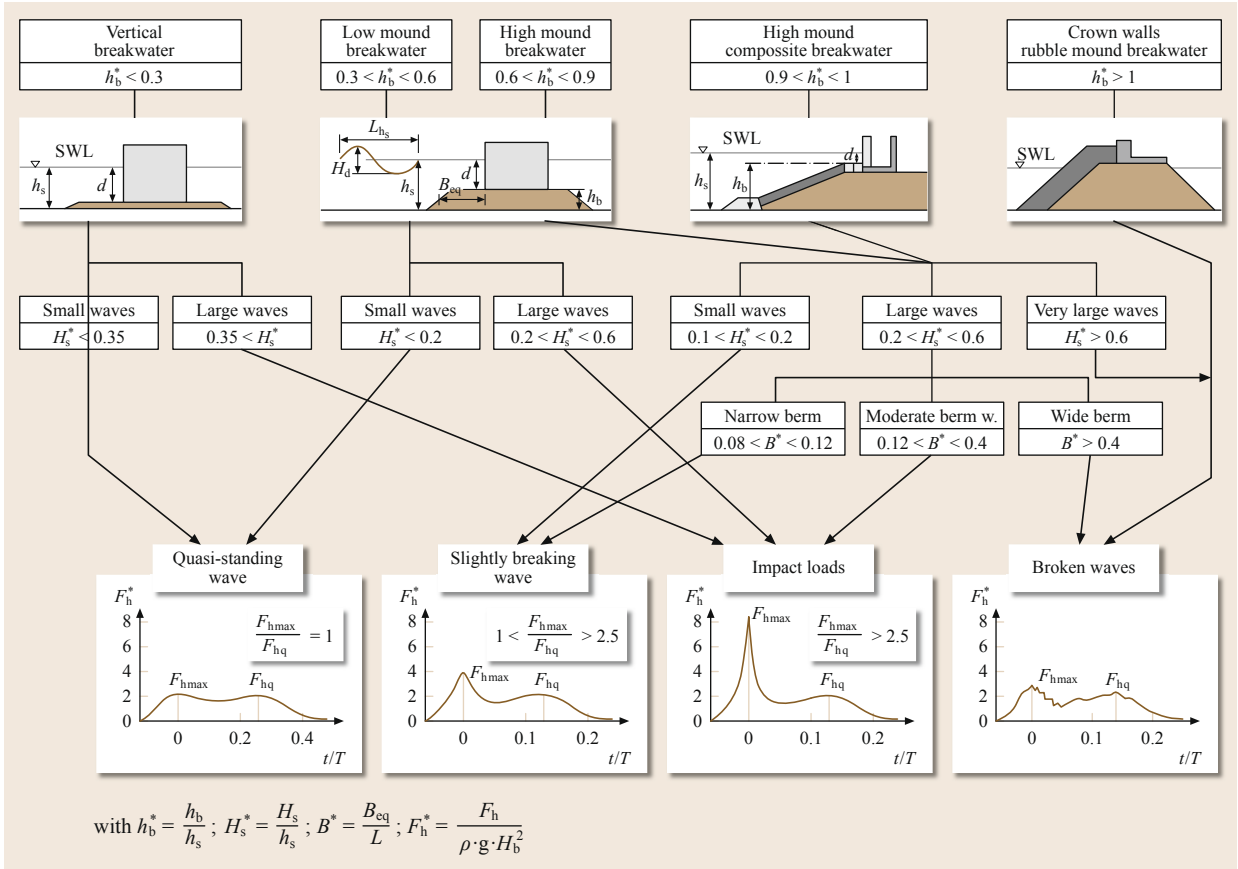

Fig. 30.10 The parametric decision map for four structure-types and four classes of irregular wave types that result in different wave loadings on the structures (after [30.40])

forces on the four types of vertical-walled structures considered.

As shown in Fig. 30.10, the four structure types are: a *vertical* breakwater, a low- or high-mound breakwater (Fig. 30.9), a composite breakwater, and a rubble-mound breakwater with crown wall. They are identified by the relative berm height, h_b^*, and the relative berm width, B^*, which can trigger various kinds of wave breakings on the structure. The key wave parameter is the relative (depth-limited), significant wave height H_s^* and results in four different breaker types: quasi-standing waves, slightly breaking waves, impacting waves, and broken waves. Small, large, and very large waves can produce all four breaking wave types.

The bottom of Fig. 30.10 shows the relative, horizontal force F_h^* (t/T) that is produced by the four kinds of wave breaking over the wave period (t/T). Clearly, the wave impact case produces the largest maximum force on the structure.

The 12 steps in the recommended design procedure are as follows:

- *Step 1*: Identify the main geometric and wave parameters. Various possible water levels should be considered since they produce different values of the relative berm height h_b^* and relative wave height H_s^*.
- *Steps 2–4*: Estimate wave force and pressure distributions. Use *Goda* [30.34], outlined above to provide the first estimate of structure size. Use $H_{max} = 1.8\, H_s$.
- *Step 5*: Identify the loading case using the parameter map (Fig. 30.10). The key decision parameters are h_b^*, H_s^*, and B^*. For example, if there is a low-mound breakwater $(0.3 < h_b^* < 0,6)$ with large waves $(0.2 < H_s^* < 0.6)$ then the impact load formulas must be applied to check the design dimensions.
- *Step 6*: Initial calculation of impact force. If the results from step 5 indicate a *slightly breaking* or *im-*

pact load, then estimate the horizontal force, $F_h = 15\rho w g d^2 (H_s/d)^{3.134}$ [30.41]. This can be used as a reference value.

- *Step 7*: Estimate the percentage of breaking waves ($P_{i\%}$) that produce impacts. Use results to decide and confirm the loading case type from the following levels of Pi%:
  - Pi% < 2%: Little breaking. Wave loads are primarily nonbreaking.
  - 2% < Pi% < 10%: Breaking waves give impacts.
  - Pi% > 10%: Heavy breaking may give impacts or broken wave forces.

  Unfortunately, space does not permit the procedure and formulas needed to compute Pi% and the reader must see *Oumeraci* et al. [30.5, pp. 78–82].
- *Step 8*: Estimate impact force. This is a key result within the PROVERBS project that gives a new procedure based on the statistical distribution of forces [30.42]. The relative wave force F_h^* is found from

$$F_h^* = \frac{\alpha}{\gamma}\{1 - [-\ln P(F_h^*)]^{\gamma}\} + \beta \,. \qquad (30.20)$$

  The wave force on the structure F_h divided by $\rho g H_b^2$ gives the relative wave force F_h^*. And H_b is the *individual or maximum wave height at breaking* [30.5, p. 99] calculated taking into account local refraction, shoaling, and reflections from the structure that modify a version of the *Miche* breaking formula [30.43] adapted for irregular, significant wave heights by *Vrijling* and *Bruinsma* [30.44]. The calculation of H_b is first used in Step 7 to find Pi%. Again space does not permit us to explain all the details.

  This expression for F_h^* is a generalized extreme value (GEV) distribution [30.8] and dependent on three statistical parameters α, β, and γ with the key variable $P(F_h^*)$, the probability of non exceedance for the impact force. The values for α, β and γ depend on the bed slope and number of tests conducted to measure the wave force F_h. The summary PROVERBS report [30.5] recommends using $\alpha = 3.97$, $\beta = 7.86$, and $\gamma = -0.32$ as determined from large-scale model tests closest to prototype conditions.
- *Step 9*: Impact rise time and duration. The spike in the impact load (force) over the wave period (Fig. 30.10, bottom) can be estimated by formulas representing a triangular force distribution in time with (F_h) maximum taken at the 90% non exceedance level.
- *Step 10*: Estimate uplift forces under impacts. Uplift force, uplift pressure distribution, and uplift moment arm location formulas are presented to calculate the structure stability.
- *Step 11*: Scale corrections. When conditions in steps 6 and 7 warrant impact loads, the PROVERBS includes some scaling corrections in the force calculation.
- *Step 12*: Pressure distributions. Formulas are presented to estimate the pressure distribution over the vertical face of the wall and used to find the location for the moment arm of the horizontal force. Again, when the Steps 6 and 7 reveal that the impact loads are important, these formulas should be employed.

Finally, space does not permit us to provide the details needed to follow steps 9–12 herein and the reader must refer to *Oumeraci* et al. [30.5] to implement the parameter map (Fig. 30.10) and apply the results for vertical, monolithic structure design. A section is included for the case of broken waves hitting the vertical wall.

When the vertical breakwater is made up of relatively short, individual sections, the sudden, direct impact of a plunging, breaking wave may be along the length of one, short, caisson section. Then clearly, the impact load formulas from the PROVERBS project should be used to check the design.

The development of spreadsheets greatly facilitates the design process. The key design variable is the caisson width B which dictates cost. The crest elevation can also be varied (for the same width) so that the minimum, caisson cross-sectional area can be determined.

Oumeraci et al. [30.5] also included a section on what are labeled *alternative, low-reflection structures*, namely perforated vertical walls.

In summary, for many designs, use of Fig. 30.10 to determine the loading case will reveal that the *Goda* [30.34] method is adequate. And when it is not, following Steps 6–12 for the impact loading case will provide a safe design.

Seawalls and Bulkheads

As illustrated in Fig. 30.4, (a) seawalls and (b) bulkheads are backed by soils which provide substantial resistance to water level forces and wave forces. The geotechnical loadings of the soils on the wall or bulkhead often governs the design. and are beyond the scope of discussion in this chapter. Proper seawall design requires the combined efforts of coastal engineers (wave and water level forces on the vertical wall, toe scour at the base of the wall to locate the lowest beach elevation, potential down drift impacts, etc.); geotechnical engineers (soil properties behind the wall, active and passive soil pressures on the wall, active and passive

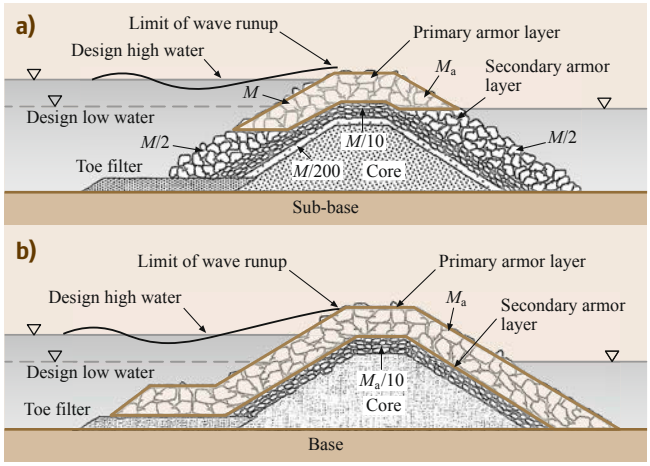

Fig. 30.11 (a) Cross-section of breakwater in deep water (b) Shallow-water depth

soil forces and moments on the wall, etc.) and structural engineers (loads, stresses, strength of materials, etc.) for concrete, steel, and wood (bulkhead) structures. The design of the Virginia Beach seawall by the Norfolk, District Office of the US Army, Corps of Engineers is an example [30.45]. The design of seawalls and bulkheads would require a complete, separate chapter in this Handbook.

Rock Structures

Natural rock of sufficient size (weight or mass) is the common material to provide protection for shorelines around the world. The rock is employed as the outer, *armor layer* (revetment) for sloping embankments and dikes composed of earth materials (Fig. 30.4c, and for breakwaters, groins and jetties where the entire cross-section may be constructed of rock (Fig. 30.11). Determining the stable size (weight or mass) of the *armor layer* under the design wave conditions is the responsibility of coastal engineers.

There are many variables that control the required size and hence stable weight (or mass) of the armor layer for a stable rock structure. Table 30.2 provides a list as found in [30.47]. This initial discussion is for structures with crest elevations of sufficient height to prevent little of no wave overtopping.

In the early 1980s, the Delft Hydraulics Laboratory in the Netherlands conducted an extensive series of laboratory experiments using irregular wave spectrums with the following *variables*:

1. Spectral shapes
2. Core permeability
3. Structure slopes
4. Rock grading, and
5. Relative mass density of the rock structures at the test section.

The results were published as *Design Formulae-(for) Stability of Breakwater Armour Layers* by *van der Meer* [30.47], which has become a standard reference work [30.3]. It was learned that the type of wave breaking as quantified by the surf similarity parameter ξ_m (using T_m, the average wave period) was critical to separate the data set into that for plunging-type wave breaking and that for surging-type waves on the structure. In other words, for irregular, head-on waves impacting the rock test section, two separate dimensionless formulations were employed [30.26, 47], namely:

1. Plunging waves: $\xi_m < \xi_{mc}$

$$\frac{H_s}{\Delta D_{n50}} = 6.2 S^{0.2} P^{0.18} N_z^{-0.1} \xi_m^{-0.5} , \qquad (30.21)$$

and

2. Surging waves: $\xi_m < \xi_{mc}$,

$$\frac{H_s}{\Delta D_{n50}} = 1.0 S^{0.2} P^{-0.13} N_z^{-0.1} (\cot\alpha)^{0.5} \xi_m^P , \qquad (30.22)$$

where the critical, dividing surf similarity parameter ξ_{mc} is

$$\xi_{mc} = [6.2 P^{0.31} (\tan\alpha)^{0.5}]^{1/(P+0.5)} , \qquad (30.23)$$

and:

- H_s: significant wave height in front of breakwater
- D_{n50}: equivalent cube length of median rock
- ρ_s: mass density of rock
- ρ_w: mass density of water

Table 30.2 Primary variables affecting armor stability (after [30.47])

Primary variables affecting armor stability		
Variable	**Symbol**	**Dimension**
Nominal diameter	D_{n50}	m
Relative mass density	Δ	–
Significant wave height	H_s	m
Average wave period	T_z	s
Slope angle	α	degr.
Damage level	S	–
Number of waves	N	–
Armour grading	D_{85}/D_{15}	–
Spectrum shape	$\epsilon_{5\%}$, Q_p^*	
Groupiness of waves	GF, j_1, j_2^*	–
Permeability of core	P	–
Gravity	g	m/s^2

* Described in detail by [30.46]

- Δ: relative mass density $(\rho_s/\rho_w) - 1$
- S: relative eroded area
- P: permeability parameter
- N_z: number of waves
- α: structure slope angle
- s_m: wave steepness, $s_m = H_s/L_{om}$
- L_{om}: deepwater wavelength corresponding to mean wave period, T_m.

These two formulae can be converted into design equations with partial safety factors γ_H and γ_Z; where the hat symbol indicates mean values of the variable, and each equation has its own table of partial safety factors for the full range of failure probability P_f and wave height uncertainty σ'. The partial safety factors are from [30.6] and [30.48]:

- Plunging waves

$$G = \frac{1}{\gamma_Z} 6.2 \hat{S}^{0.2} \hat{P}^{0.18} \hat{\Delta} \hat{D}_n \hat{f} (c\hat{o}t\,\propto)^{0.5} (\hat{s}_{om})^{0.25} \hat{N}_Z^{-0.1} - \gamma_H \hat{H}_S^T \,, \tag{30.24}$$

with partial safety factors as displayed in Table 30.3.

- Surging waves

$$G = \frac{1}{\gamma_Z} \hat{S}^{0.2} \hat{P}^{0.13} \hat{\Delta} \hat{D}_n \hat{f} (c\hat{o}t\,\propto)^{0.5-p} (\hat{s}_{om})^{-0.5P} \hat{N}_Z^{-0.1} - \gamma_H \hat{H}_S^T \,, \tag{30.25}$$

with partial safety factors as displayed in Table 30.4.

In these formulations for design use, the reduction factor $\hat{f}$ models the effect of low crested, overtopped breakwaters [30.49] and is given by the expression

$$\hat{f} = \left(1.25 - 4.8 \frac{R_c}{H_s} \sqrt{\frac{s_{op}}{2\pi}}\right)^{-1} , \tag{30.26}$$

$$0 < \frac{R_c}{H_s} \sqrt{\frac{s_{op}}{2\pi}} < 0.052 \,. \tag{30.27}$$

Note that when the freeboard R_c is zero, $\hat{f}$ reduces to a minimum of 0.8 and when the argument $\frac{R_c}{H_s}\sqrt{\frac{s_{op}}{2\pi}}$ reaches 0.052, there is no reduction in the stone size since $\hat{f} = 1.0$.

See also *van der Meer* [30.49] for the formulation when the rock breakwater is completely submerged. The overtopped and submerged cases do not always give a smaller, lighter rock size for the armor layer. *Burchardt* et al. [30.48] give an alternate method to estimate the static stability of a detached, low-crested breakwater.

For the G = Resistance – Load to be zero, the primary variables in these design equations are ($\hat{H}_S^T$, $\hat{P}$, $\hat{S}$, N, T_{om}, and $c\hat{o}t\,\propto$) for a given, stable rock size $\hat{D}_n$. The rock mass is then simply $\rho\,(\hat{D}_n)^3$. In what follows, the mean value (hat symbol) is assumed and the hat symbol is omitted.

The permeability parameter, P, as defined by *van der Meer* [30.47] is shown in Fig. 30.12. At one extreme are impermeable structures ($P = 0.1$) such as revetments on dikes and natural earth slopes. Rubble-mound, breakwater structures as depicted in Fig. 30.11 with a core use $P = 0.4$ or 0.5. The most permeable structure is made up of all one size rocks with no core and has a permeability parameter, $P = 0.6$, in the *van*

Table 30.3 Partial safety factors (after [30.1, Table VI-6-5])

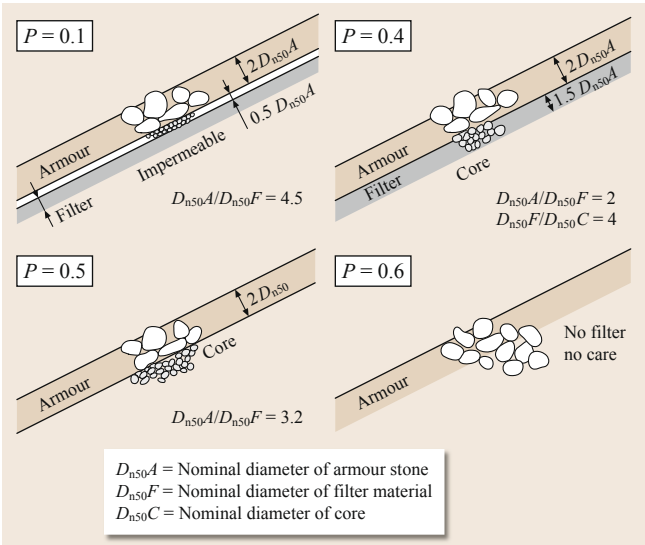

Fig. 30.12 Permeability parameter P as defined in [30.47]

der Meer [30.47] formulation. The structure configuration for $P = 0.4$ was assumed and never tested by *van der Meer* [30.26].

The acceptable level of damage is parameterized by the dimensionless damage factor S which is the ratio of the area eroded to the square of the nominal rock diameter, that is, $S = A_e/(D_n^2)$. The zero damage level is $S = 2$ (for cot $\alpha = 1.5$, 2, and 3) and $S = 3$ (for cot $\alpha = 4$, 5, and 6). Failure levels (for a $2D_{n50}$ armor-layer thickness) are when the secondary layer is exposed beneath the armor layer. These failure levels are $S = 8$ (cot $\alpha = 1.5$, 2), $S = 12$ (cot $\alpha = 3$) and $S = 17$ (cot $\alpha = 4$, 5 and 6). The *van der Meer* [30.47] equations can be used to develop damage (fragility) curves for a given design, stable rock size D_n by calculating S as the wave heights increase above the design wave height. See [30.3] for *intermediate* damage levels S.

The surf similarity parameter ξ_m brings the mean wave period T_m into the formulation. For normal, single peaked spectrums, $T_m \approx 0.82\ T_p$, where T_p is the spectral peak wave period.

Finally, the number of waves N_z is a variable in the *van der Meer* [30.47] formulation. For short storms lasting 4–7 h, $N_z = 2500$ is recommended for mean wave periods from 5 to 10 s. The maximum N_z is 7500 giving 15–30 h storms for waves in the 5–15 mean period range.

The development of spreadsheets with the structure slope angle α as the key design variable greatly facilitates the application of these equations and tables for design of the stable size, or weight (mass) of the armor layer.

There are many variables, coefficients, and exponents in the original [30.26, 47] formulations as seen in (30.21)–(30.23). Graduate students at the Delft Technical University and engineers at Delft Hydraulics (now Deltares) have been conducting research investigation over the past 15–20 years to further understand and improve the original vdM formulas. The following summarizes some past and recent developments as found in the literature with more (probably) to follow.

The publication by *van der Meer* [30.26] was his Ph.D. dissertation at the Technical University of Delft. In it, *van der Meer* [30.26] acknowledges the earlier work of *Thompson* and *Shuttler* [30.50] as the starting point for this basic research using irregular, random waves in the laboratory. He recognized that the coefficient 6.2 (defined as coefficient C_{pl} for the plunging breaker (30.21)) and coefficient 1.0 (defined as coefficient C_s for the surging breaker (30.22)) were stochastic, mean values with standard deviations of mean of 0.4 and 0.08, respectively. Hence, the coefficient in the transition (30.23) separating both formulas was $C_{pl}/C_s = 6.2$. *van der Meer* [30.26] also recognized that waves moving into shallow water would be depth-limited in height and suggested using the Rayleigh distribution ratio of $H_{2\%}/H_s = 1.4$ to adjust the C_{pl} and C_s coefficients and to use $H_{2\%}$ in the formulas. Finally, *van der Meer* [30.26] called for more research to understand the permeability parameter P and stone shape (roundness) on static stability.

It has been recognized that most of the over 300 tests conducted by *van der Meer* [30.26] were with relatively deep water at the toe of the structure. Additional tests (over 200) of rock stability with shallow foreshores have been conducted at Delft Hydraulics [30.51], *Smith* et al. [30.52] as reported by *van Gent* et al. [30.53]. These additional tests demonstrated that:

1. Less scatter was evident if the mean wave period T_m was replaced by $T_{m-1.0}$, the spectral wave period to find the surf similarity parameter $\xi_{m-1.0}$.
2. Less scatter was evident if the ratio of $H_{2\%}/H_s$ is employed because of depth-limited wave breaking.
3. The additional data reduced the standard deviations of the mean values of the modified C_{pl} coefficient in the original formulations of *van der Meer* [30.26].

For *shallow water* wave conditions, *van Gent* et al. [30.53] recommended using $C_{pl} = 8.4\ (H_s/H_{2\%})$ and $C_s = 1.3\ (H_s/H_{2\%})$. These values are also given in the Rock Manual [30.3] and require/allow the user to specify the appropriate $(H_s/H_{2\%})$ ratio. Note that these modified values for C_{pl} and C_s for shallow water will result in smaller (lighter) rock for stability than the original, deep water [30.26] values since the $(H_{2\%}/H_s)$ ratio will be less than 1.4. This is in keeping with shallow water wave breaking and truncation of the wave spectrum from that of the deep water, Rayleigh distribution. The Rock Manual [30.3] defines *shallow water* when the water depth h is less than 3 H_s at the toe of the structure. *Van Gent* and *Pozueta* [30.54] suggested using $H_{s_{toe}} = 0.7H_{so}$ (deep water wave) as the *shallow water* condition. No partial safety factors have yet been published for the shallow water, van der Meer formulations.

More recent research efforts have focused on the permeability parameter P. The values originally assigned by *van der Meer* [30.26] have no physical definition except the general trend that as P increases, the structure has more pore space volume to absorb wave energy. *Verhagen* et al. [30.55] used a numerical model (volume of fluid, VOF) method to calculate wave run-up on permeable and impermeable cores and correlated P as a function of run-up ratios and the surf similarity parameter. *Kik* et al. [30.56] showed with new laboratory experiments that the $P = 0.4$ configuration in Fig. 30.12 is correct in the *van der Meer* [30.26] formulas. Note that P is an important variable in (30.23)

separating plunging, and surging wave breaking and identifying which formulation to employ in the static stability analysis.

The Corps of Engineers has a long history of research on the static stability of rubble-mound breakwaters. The *Hudson* [30.57] formulation was the standard for many years and is still applied for artificial, concrete armor-layer units as discussed below.

Melby and *Kobayashi* [30.58] proposed new, static stability formulations for plunging and surging waves on sloping, armor stone structures that depart from the traditional approach where the primary load variable is the significant wave height H_s at the toe of the structure. In their approach, the maximum, nonlinear wave momentum flux $(MF)_{max}$ as defined by *Hughes* [30.59] is employed as the key load variable in the static stability formulations. The results in *Melby* and *Kobayashi* [30.58] expanded and improved the earlier work in *Melby* and *Hughes* [30.60]; utilized the small-scale physical data from *van der Meer* [30.26], and employed the same definitions for S, N_z, and P as originally proposed by *van der Meer* [30.26]. Two new coefficients were needed and defined. One coefficient, a_m appears in the final equation, but has two separate formulations, one for plunging and one for surging waves. The second new coefficient, K_s, is added for an analysis of damage progression and will be further discussed below. The new, dividing equation separating the plunging and surging formulations was formulated to only depend on the structure slope and does not include the permeability parameter P as found in *van der Meer* [30.26] and (30.23). The analysis and formulas presented by *Melby* and *Kobayashi* [30.58] are relatively new and are not included herein.

We now have over 25 years of experience applying the *deep water*, *van der Meer* [30.26] formulations for the static stability of rock structures. And, slight adjustments have been added for the *shallow water*, van der Meer versions as summarized in Table 30.5.

Equation (30.23) for finding the critical, dividing line surf similarity parameter ξ_{mc} is still valid but uses the C_{pl}/C_s values in Table 30.5 for shallow water applications.

The Rock Manual [30.3] presents further design details surrounding the van der Meer static stability formulas including: the influence of rock gradations, the influence of rock shapes, the influences of packing and rock placement, and the influence of steep approach slopes. All these variables along with a sensitivity analysis using the standard deviations σ in Table 30.5 should be considered for design.

Artificial, Concrete Armor-Layer Units

When it is not possible to use natural rock for the armor layer (quarry size limitations, transport distance, etc.) then some manufactured, artificially shaped, concrete unit must be employed. Figure 30.13 displays a sample of the some shapes that have been employed (from *Kamphuis* [30.17]). The most common are tetrapods, dolos, Accropode, Core-Loc and cube.

The US Army, Corps of Engineers, has developed the CORE-LOC unit (not shown) [30.61], which is similar in shape to the Accropod. Many of these shapes have superior interlocking ability so that smaller, lighter weight units are more stable than natural rock. But

Table 30.5 Key coefficients in the van der Meer formulas

Breaker type	Deep water mean value μ	Deep water standard deviation σ	Shallow water mean value μ	Shallow water standard deviation σ	Equation
Plunging C_{pl}	6.2	0.4	$8.4(H_s/H_{2\%})$	0.109	(30.21)
Surging C_s	1.0	0.08	$1.3(H_s/H_{2\%})$	0.109	(30.22)
Surf parameter ξ	ξ_m		$\xi_{m-1.0}$		
Wave period T	T_m		$T_{m-1.0}$		

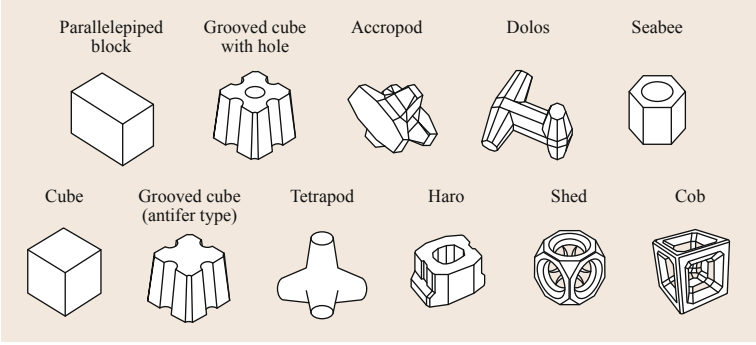

Fig. 30.13 Sample of some concrete armor units (after [30.17])

their cost is generally more due to special forms, concrete mixtures, curing times, etc., for their manufacture. Some contain steel reinforcement but most are completely made of concrete.

The Hudson formula [30.57] is often applied to determine the stable size (mass, or weight) for design

$$\frac{H}{\Delta D_{n50}} = (K_D \cot\alpha)^{1/3} \quad \text{or}$$

$$M_{50} = \frac{\rho_s H^3}{K_D \left(\frac{\rho_s}{\rho_w} - 1\right)^3 \cot\alpha}\,, \tag{30.28}$$

where

- H: characteristics wave height (H_s or $H_{1/10}$)
- D_{n50}: equivalent cube length armor unit
- M_{50}: medium mass of armor unit, $M_{50} = \rho_s D_{n50}^3$
- ρ_s: mass of density of armor units
- ρ_w: mass of density of water
- Δ: $(\rho_s/\rho_w) - 1$
- α: slope angle
- K_D: Hudson stability coefficient.

The only new variable is the Hudson stability coefficient K_D. The Hudson formula is popular for the design of concrete armor units because the K_D values are available for many of the common shapes as illustrated in Table 30.6. Unfortunately, however, the Hudson formula does not include the influence of the wave period T, the structure permeability P, the level of damage S, and the number of waves N_z. And, unfortunately, it is not clear which wave height to apply for design (H_s or $H_{1/10}$) and different K_D values appear in the literature for breaking and nonbreaking waves. The K_D values in Table 30.6 come from many sources including CEM [30.1], and *Reeve* et al. [30.62]. Note that all the concrete units have K_D values greater than natural rock. Some are licensed and have trademarks for application.

Table 30.6 Hudson stability coefficients for nonbreaking waves on concrete units, zero damage, nonovertopping, structure trunk

Armor unit	Hudson stability coefficient K_D
Natural rock	4 (nonbreaking waves)
Natural rock	2 (breaking waves)
Tetrapod	8
Dolos	32 (8)
Accropod	9.5–15
CORE-LOC	13–16
Antifer (grooved)	6.0
Cube, modified	7.5
Cube	6.5
Tribar	10
XBloc	13–16
Stabit	10

A *top-down* design is followed for the standard, cross-sectional breakwater shapes illustrated in Fig. 30.11. Ten *rules* for design have been developed over the years by experience and model testing in the laboratory. These rules cover the following topics:

1. Mass (weight) of the lower layer relative to upper layer ($W_{lower} \approx 1/10 W_{upper}$ as shown in Fig. 30.11)
2. Extent of armor layer below the water surface in deep water
3. Armor-layer thickness
4. Number of concrete units per unit structure length (if applicable)
5. Crest width
6. Crest elevation
7. Need for filter cloth and bedding stone at the bottom
8. Toe protection
9. Design of the head relative to the structure trunk, and
10. Materials and construction methods.

Space does not permit a full discussion and the designer must consult the CEM [30.1] or the Rock Manual [30.3] for complete details.

All the above is for the seaside, static stability of the breakwater shape under the design conditions. Consideration must also be given to the stability of the armor stones on the crest and rear-side of the structure as shown in Fig. 30.11. The maximum velocity on the rear side of the crest during a wave overtopping event (exceeded by 1% of the waves) was given by *van Gent* [30.63] and is used in the stability equation for the required, stable stone size, D_{n50} as found in [30.54]. Complete details can be found in the Rock Manual [30.3, Sect. 5.2.2.11]. No partial safety factors are presented.

When the quarry cannot produce the size of armor stones needed and the cost of manufacturing concrete armor units is prohibitive, then a dynamically stable (*berm* or *reshaping* or *unconventional*) breakwater cross-section may be employed as illustrated in Fig. 30.14 (from *Baird* and *Hall* [30.64]). The upper cross-section is the conventional design and the other cross-sections show a typical berm breakwater design using smaller rocks and a larger volume of armor for subsequent dynamic profile development (reshaping) during storm events. A model for the dynamic shape can be found in *Pilarczyk* [30.22] as proposed by *van der Meer* [30.13] (in *Pilarczyk* [30.22, p. 157]). A state-of-the art report on designing and constructing berm breakwaters has been compiled in [30.7]. Many other recent references can be found in *Torum* et al. [30.65, 66].

Life-Cycle Cost Analysis and Balanced Design

All breakwaters will receive some *damage* (i. e., rock movements that are greater than that in the original design and resulting shape changes that may expose the vulnerable under-layers) when the wave heights are greater than the design wave height. Repairs can be made immediately or after the storm season ends when favorably wave conditions return to the site. These repairs are the *maintenance* costs to keep the breakwater shape functional. These maintenance costs are probabilistic in that they are the product of the exceedance probability curve for the wave heights at the site (Fig. 30.3) and the damage (fragility) curve as found from the van der Meer formulation as discussed above or actual model tests. These annual repair costs must then be multiplied by the present worth factor (pwf) to determine the total, present worth maintenance costs for the design life of the project. (See any standard engineering economic text for the formula to calculate the pwf for the design interest rate i and estimated design-life T) The total life-cycle costs for the given design are then simply the sum of the initial costs and the expected maintenance costs over the design life of the project.

The above procedure should be repeated for a range of design wave heights to determine the optimum or *balanced-design*. Lower design wave heights will produce lower initial costs but higher, long-term maintenance costs. Very high design waves will increase the initial construction costs and lower the maintenance costs. Ideally, a classical, U-shaped, total cost curve will result with the *balanced-design* being the lowest total cost for the structure. This will be different than the deterministic design as dictated by a selected recurrence interval (e.g., the 1% chance wave height) for the design.

In many cases, annual repairs of damaged breakwaters are not carried out for a variety of reasons. *Melby* and *Kobayashi* [30.67–70] have developed formulas to estimate the progression of damage in time from varying wave and water-level conditions for use in the life-cycle analysis process. Their recent work [30.58] extends these earlier efforts to include the nonlinear wave momentum flux [30.43] as the forcing function in the time-varying, $S(t)$, equation for damage progression. The second new variable, K_s, discussed above is needed to handle the initial adjustment of stones places in unstable patterns. Other formulations for damage progression are possible, for example, *van der Meer* ([30.71], who made the direct use of his static stability formulations (30.21) and (30.22)). Space does not permit more details on this relatively new and interesting topic.

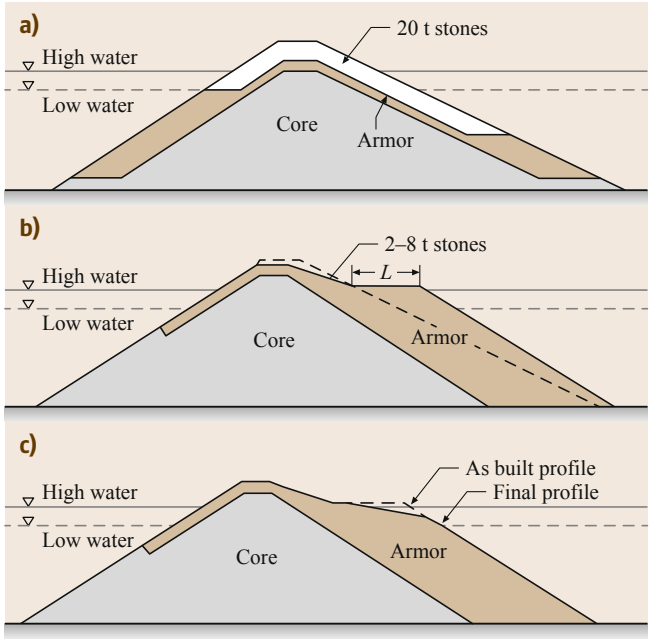

Fig. 30.14 **(a)** Conventional breakwater shape and **(b,c)** berm breakwater with reshaping armor-layer profile (after [30.64])

Functional Costs and Risk

Added to the maintenance costs for structure repair are the functional costs for the economic loss (if any) due to the inability to perform the functional needs of the breakwater. For example, if fuel, oil, or other materials cannot be safely unloaded from a docking facility behind the breakwater, then these potential economic losses (costs) must also be considered in the evaluation of the *risk* for the selected breakwater design.

The basic risk equation for coastal engineering design is

$$R = \Sigma P_E P_F C_i \,. \tag{30.29}$$

where:

- R: The risk
- P_E: The exceedance probability curve for the wave heights
- P_F: The damage (fragility) curve for the structure, and
- C_i: The consequences (i. e., the costs) with $i = 1, 2, 3$, etc. for all the consequences.

In the simple example above, C_1 were the maintenance repair costs and C_2 were the functional (loss) costs for not being able to unload materials. Many other consequences can be considered including environmen-

tal, loss of life, etc. when using the risk equation in coastal engineering design. The final choice for the selected design should consider all the possible consequences of damage and the potential failure of the selected design. The one with the lowest risk should be selected for construction.

30.3 Shoreline Stabilization Structures

Coasts with marine deposits (barrier islands and sandy beaches) are one of the most widely found geomorphic forms in the world. Figure 30.15a displays an example of a dynamically stable shoreline shape between two rocky headlands (from [30.72]) and Fig. 30.15b the concept of a minimum dry beach width, Y_{min}, in the profile cross-section. The dry beach width is much narrower behind the headland than that receiving direct wave attack during storms. This volume of sediment protects the uplands (cliffs, dunes, vegetation, infrastructure, or structures) from damage under normal storm conditions. In 1960, *Silvester* wrote [30.73, p. 469]:

> *... to allow for storm-cycles and the short term reversals of drift, a sufficient width of beach should be allowed as working capital on which the sea can operate. Once the coast has been stabilized by preventing the net movement of sediment, no long-term erosion need be anticipated and the* active *beach width can be minimized.*

However, many shorelines are eroding due to both natural causes (e.g., sea level rise) and for anthropogenic reasons (e.g., down drift of jetties that block the natural sand movements past tidal inlets). Shoreline stabilization structures can provide upland protection beyond the reference baseline for storm events and hence can mitigate the impacts of coastal erosion. At a minimum, these structures should be designed to provide the minimum, dry beach width, Y_{min}, for shore protection.

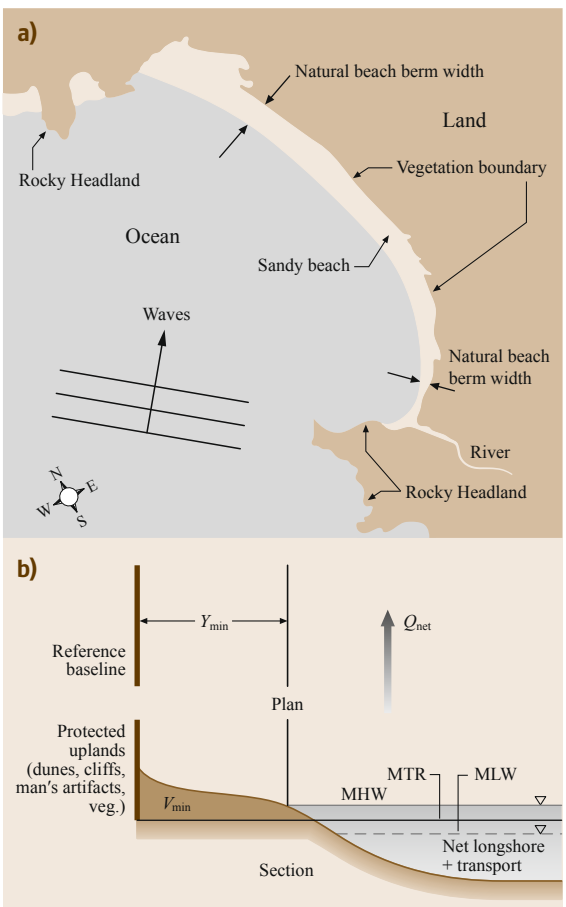

Fig. 30.15 **(a)** Plan form of naturally stable shoreline (after [30.72]) with the *natural beach width* distance from mean sea level (MSL) to upland vegetation; and **(b)** concept of minimum dry beach width, Y_{min} (after [30.1, V-3-3])

30.3.1 Types and Purposes

Figure 30.16c–e displays the three most common types of beach erosion mitigation structures, namely headland breakwaters, near-shore breakwaters, and a groin field. Their primary purpose is to retain sand on the beach during storm events. Present design practice is to always combine their construction with beach renourishment (Chap. 29) to minimize their down drift impact. Clearly, headland and near-shore breakwaters work best when cross-shore sediment transport processes are dominant and a groin field where long-shore sediment transport processes are most important.

As illustrated in Fig. 30.16, the response of the shoreline behind the structure due to waves, currents and resulting sediment transport can be either a tombolo (Fig. 30.16c, shoreline attached to structure) or a salient (Fig. 30.16d, no shoreline attachment). Field data published by *Pope* and *Dean* [30.74] are presented in Fig. 30.17 and reveal that the key variables are:

- L_s: The length of the structure
- L_g: The length of the gap between the structures
- Y: The structure distance offshore from the design, renourished beach shoreline, and

- d_s: The mean water depth offshore at the toe of the structure.

When the L_s/L_g ratio is large (long structure/small gap) so that less wave energy reaches the shoreline and/or when the Y/d_s ratio is small (structure close to shore in shallow water) tombolos form behind the structures which are called *headland* breakwaters. When the opposite is true with these key ratios, more wave energy reaches the shoreline to maintain long-shore sediment transport processes and only salients are present behind what are called *near-shore* breakwaters. Clearly, as illustrated in Fig. 30.17, when short structures with large gaps are located far offshore in relatively deep water, they may have little or no influence on the shoreline (no sinuosity) and offer little shore protection.

30.3.2 Functional Design

Headland Breakwaters

The shoreline configuration between headland-type breakwaters is modeled after the equilibrium plan form shape of natural beaches between natural, rocky outcropping called *headlands* along the coast. As illustrated in Fig. 30.18, wave rays (solid lines 1,2,3, etc.) shoal, refract and diffract in the shallow water contours (dashed lines) and strike the shoreline. If the wave rays break at right angles to the shoreline, no long-shore sediment transport can take place. This is the equilibrium shoreline position for the given offshore wave direction. When the shoreline is in nonequilibrium as shown in Fig. 30.19 (dotted lines) it will continue to evolve (erode or fill) until again reaching equilibrium. The furthest nonequilibrium position is after a coastal storm when the design Y_{min} is reached. Major storm events may produce breaching.

For design, the ratio of $L_S/Y = 1.8$ is recommended for a headland breakwater system [30.75]. Over 40 headland breakwater systems have been built around the Chesapeake Bay [30.76] in Virginia, USA. They recommend using $L_s/L_g = 1$, and setting $Y_g/L_g = 0.6$, where Y_g is the gap distance from a line connecting the structures and the re nourished beach shoreline. These shore parallel structures have been combined with a beach fill at the time of construction and the berm elevation set so that the subaerial beach is visible (tombolo) at high tide.

An empirical approach developed from shoreline data taken from bays known to be in static plan form equilibrium and physical hydraulic models has been developed by *Hsu* et al. [30.77] and is called the *parabolic* model. Figure 30.20 illustrates the two, key independent variables (1) R_o, the distance of a control line from the upland coast headland (tip) to the down coast headland (tip) and (2) the approach wave angle β, between the wave crest and the control line, R_o ($\beta = 24°$ in Fig. 30.20). These variables are site specific and part of the headland breakwater design. The two dependent variables are (R, θ), where R is the radius and θ the angle as defined in Fig. 30.20. Using 10–12 (R, θ) pairs defines a parabola given by the formula [30.77]

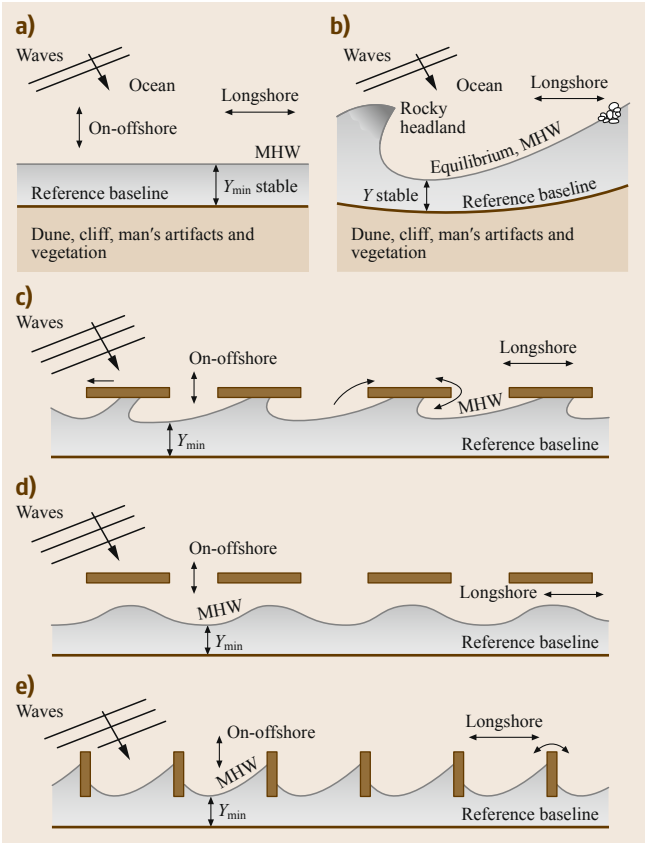

Fig. 30.16a–e Natural **(a–b)** and artificial stable shorelines with minimum dry beach width, Y_{min} for **(c)** headland breakwaters, **(d)** nearshore breakwaters and **(e)** groin field

$$\frac{R}{R_o} = C_o + C_1\left(\frac{\beta}{\theta}\right) + C_2\left(\frac{\beta}{\theta}\right)^2 . \qquad (30.30)$$

The coefficients C_o, C_1, and C_2 in the parabolic model are shown in Fig. 30.21 as a function of the approach wave angle, β, developed empirically by *Hsu* et al. [30.77]. Simple, second-order polynomials have been applied to curve-fit these coefficients as a function of the approach wave angle, β and give

$$C_o = -0.0002\beta^2 + 0.0079\beta - 0.0209 , \qquad (30.31a)$$

$$C_1 = 0.0002\beta^2 + 0.0004\beta + 0.9437 , \qquad (30.31b)$$

$$C_2 = -0.00005\beta^2 - 0.0093\beta + 0.0879 . \qquad (30.31c)$$

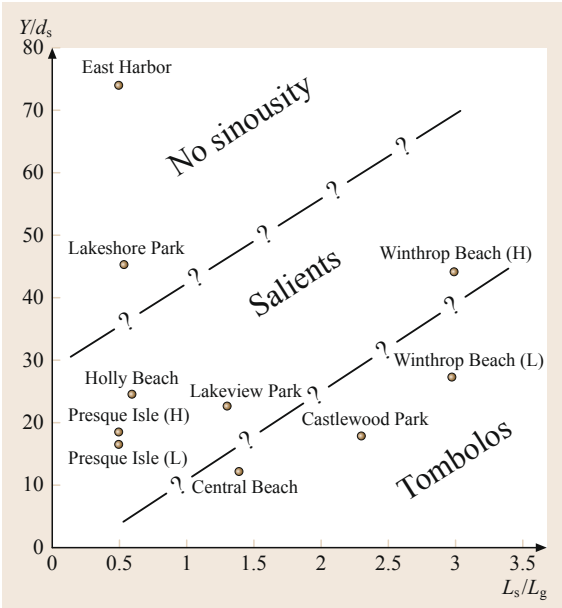

Fig. 30.17 Field data from the Corps of Engineers studies of breakwaters constructed around the United States (after [30.74])

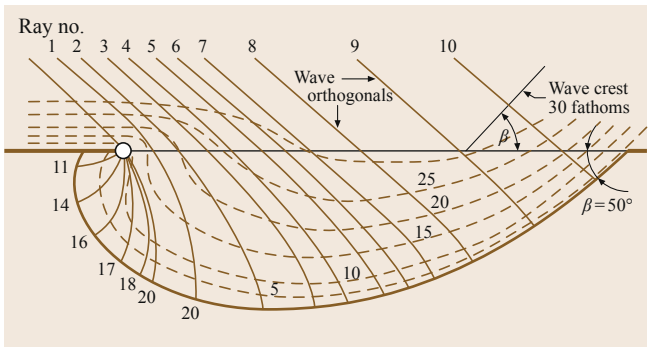

Fig. 30.18 Wave rays shoaling, refracting and diffracting to break at right angles so that no long-shore sediment transport results on the equilibrium plan form shape

The accuracy of the C_2 expression can be improved using a higher order polynomial. To improve the efficiency of application and facilitate the design process, a software package MEPBAY has been developed from computation to graphic display of the results [30.78]. The accuracy of (30.30) to model equilibrium-shaped bays of natural and man-made beaches in Spain has been confirmed by *Gonzalez* and *Medina* [30.79].

Most sites have dominant waves approaching from more than one direction as schematically illustrated in Fig. 30.22 showing wave roses from the Northeast (blue) and the Southwest (green) directions. The parabolic model can then be applied twice and the

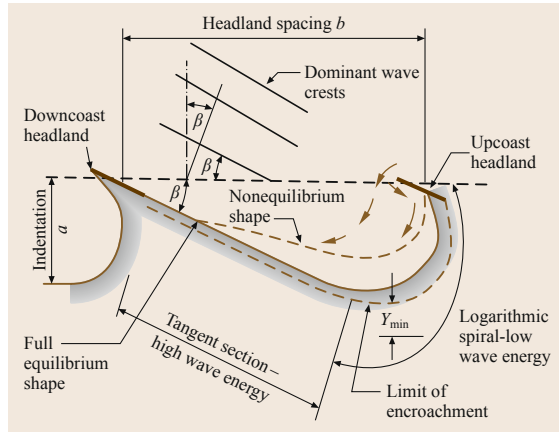

Fig. 30.19 Schematic of headland breakwaters and beach plan forms that are in equilibrium (*solid line*) and nonequilibrium (*dotted lines*) shape

resultant, stable plan form shape (red) be estimated (weighted average position) as the result. In Italy, *D'Alessandro* and *Frega* [30.80] proved that (30.30) modeled the shoreline behind a series of nearshore breakwaters along the Tyrrhenian sea coast. And, they also showed that the formula to calculate the surface area in the tombolo created by the breakwater could be modeled by the method (space herein not available) given by *Ming* and *Chiew* [30.81].

When placed further offshore, the system of nearshore breakwaters will create salients as discussed in the next section.

Near-Shore Breakwaters

Near-shore breakwaters are found mainly in the US, Japan and in the Mediterranean Sea. These locations are primarily along coasts with small (micro-tidal, 0–2 m) daily variations in the tidal range. The empirically derived relationships for the primary variables shown in Fig. 30.17 and listed below are for micro-tidal coasts and from the US experience as reported in the CEM [30.1].

Near-shore breakwater systems are generally shore-parallel and detached structures that are located and spaced such that only salients form behind the structure. Figure 30.23 presents the key variables in the plan form and profile views. Their purpose is the same as that for headland breakwater systems, namely to:

1. Increase the fill life (longevity) of the beach nourishment project behind the breakwaters
2. Provide upland protection from storm damage
3. Provide a wide recreational beach, and in some cases
4. Create or stabilize an upland wetland area.

The key geometric variables are the structure length L_s and the distance offshore Y from the renourished beach at the design beach width. *Dally* and *Pope* [30.75] recommend $L_s/Y = 0.5$ to 0.67 for the shore system and even further offshore (i. e., $L_s/Y = 0.125$) for very long systems of near-shore breakwaters as for example constructed at Presque Isle, Pennsylvania, USA.

A detached, near-shore breakwater system with salient formation is the preferred, breakwater shoreline stabilization system recommended by the US Army Corps of Engineers as stated in [30.1]. This design permits long-shore sediment transport to continue to move through and past the project area to down drift shorelines and minimize down drift impacts. Wave action and long-shore currents are strong enough to keep the salient from connecting to the structure. An extensive literature review of both near-shore and headland- breakwater systems can be found in *Chasten* et al. [30.82] as applied on micro-tidal beaches.

Note in Fig. 30.23 that the salient distances from the design beach width shoreline position, W, are not symmetrical ($Y_s \neq Y_g$) and that the storm erosion distance, e in the gap must be included to predict Y_{min} for the design storm. The plan form configuration of the salient-shaped beach, and the storm erosion distance, e have been studied extensively over the years, but no general analytical procedure exists. See *Chasten* et al. [30.82] for some examples. The breakwater crest elevation and crest width, the structure permeability, the structure slope, and other factors also influence the functional performance of near-shore breakwater systems. For these reasons, numerical models of waves, wave-induced currents, sediment transport, and bathymetric change have been employed to study the shoreline modifications created by near-shore breakwater systems.

On coasts with tides in the range of 2–4 m (meso-tidal) or greater than 4 m (macro-tidal), design guidance is limited. Because over 75% of the UK coastline is classified as meso- or macro-tidal, *Rodgers* et al. [30.83] concluded that the UK needed to study and develop guidelines for breakwater performance on sandy, macro-tidal coasts. Two morphological, numerical models were employed (PISCES and MIKE 21-CAMS) in the effort with conflicting results as reported in Environmental Agency [30.84]. This is not surprising since the numerical models require four coupled, submodules (waves, currents, sediment transport, and bathymetric change) and use different empirical formulations for sediment transport. In fact, the design guidelines cited above for micro-tidal coasts have been used to confirm numerical model results [30.85].

However, results of the numerical modeling study did reveal some important differences that have been summarized in Environmental Agency [30.86]. Diurnal and semidiurnal types, and tide range; the effect of oblique wave incidence; and the effect of breakwater crest elevation were all found to be important.

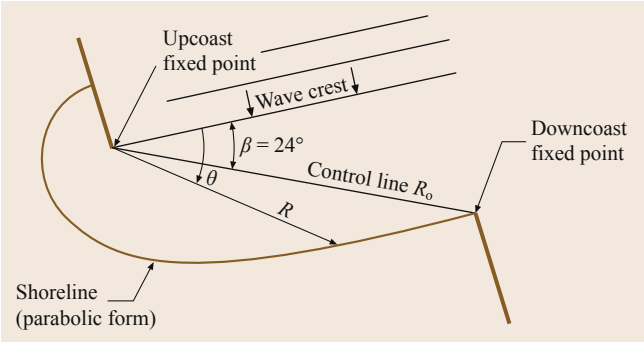

Fig. 30.20 Schematic of parabolic shoreline form defined by four variables R_o, β, R, and θ

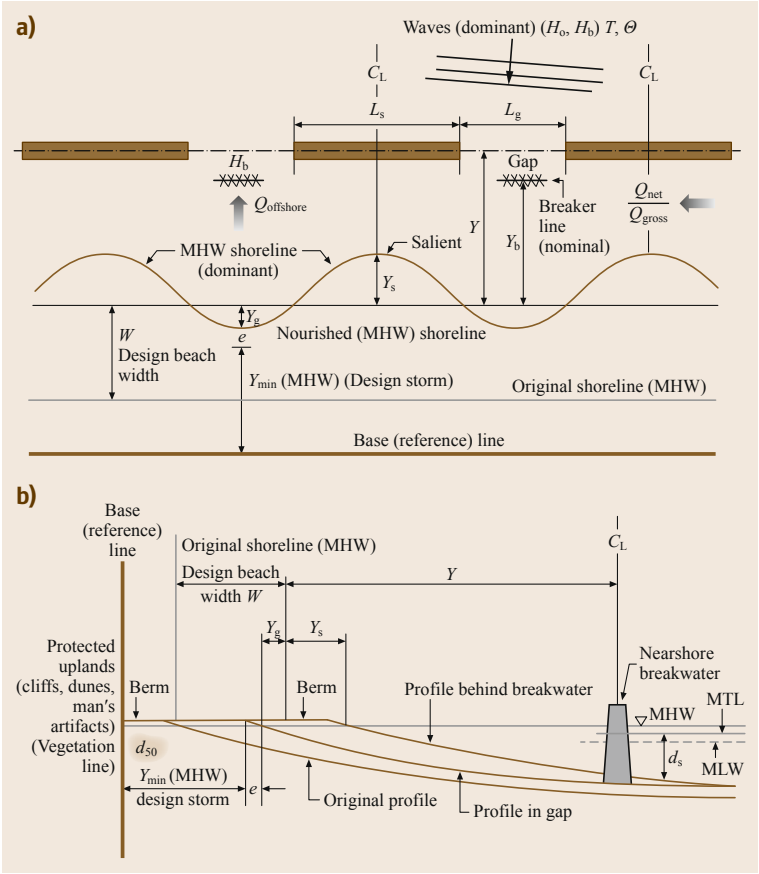

Fig. 30.23a,b Near-shore breakwater. **(a)** Plan view, **(b)** profile view (after [30.1])

As a result the existing design guidance (*Fleming* and *Hamer* [30.87] and similar to that above) was replaced with a new design procedure for macro-tidal coasts. Unfortunately, space does not permit all the details to be presented herein.

At some shoreline locations with large long-shore sediment transport rates in one dominant direction, an initially constructed, detached, near-shore breakwater system will become filled with sediment and be transformed to a headland system with tombolos. This is what took place at Fort Story, Virginia, on the Atlantic Ocean near Virginia Beach, Virginia, as shown in Fig. 30.24. Sediments moving to the North (bottom left to upper right) have filled in behind the breakwaters and trapped a large volume of sediment that was not transported to downdrift beaches and is producing down drift impacts. The designer must always be aware of the potential for sand retention behind a system of detached, near-shore breakwaters that could cause down drift erosion.

Fig. 30.24 The system of nineteen near-shore breakwaters at Fort Story, Virginia that have been transformed into headland breakwaters

Groin Fields

Groins are the oldest, the most commonly applied, and arguably the most misused and improperly designed of all coastal structures. They are normally shore-perpendicular structures of relatively short lengths (when compared with navigational jetties at tidal inlets) as illustrated in Fig. 30.16e. A groin interrupts the

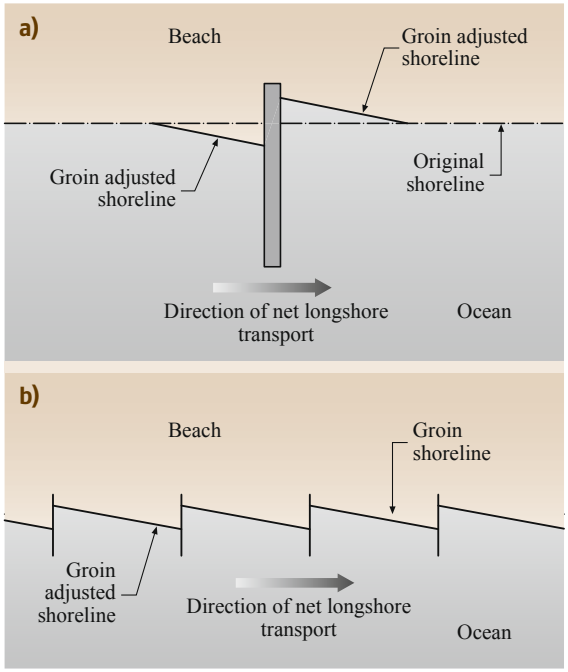

Fig. 30.25a,b Schematic of (a) single groin and (b) groin field displaying down drift impacts ◄

long-shore transport such that sand is deposited on the up-drift side and consequently absent on the down-drift side as illustrated in Fig. 30.25.

The net long-shore transport direction is revealed (sand accumulates on the side of the groin from the up-drift direction). How to maintain a minimum width of beach at the down-drift side has always been of concern in coastal engineering design. As illustrated in Fig. 30.26, the present-day philosophy of groin design is to combine the structure with a beach nourishment project to:

1. Minimize down-drift impacts
2. Maintain some basic level of coastal hazard mitigation as defined by Y_{min} after storm erosion e, and
3. Allow some sand bypassing around the end.

The basic rule of thumb for the ratio of groin spacing X_g to the groin length Y_g is $X_g/Y_g = 2-3$ as found from many years of experience to satisfy the three design goals listed above [30.88]. Note that the groin

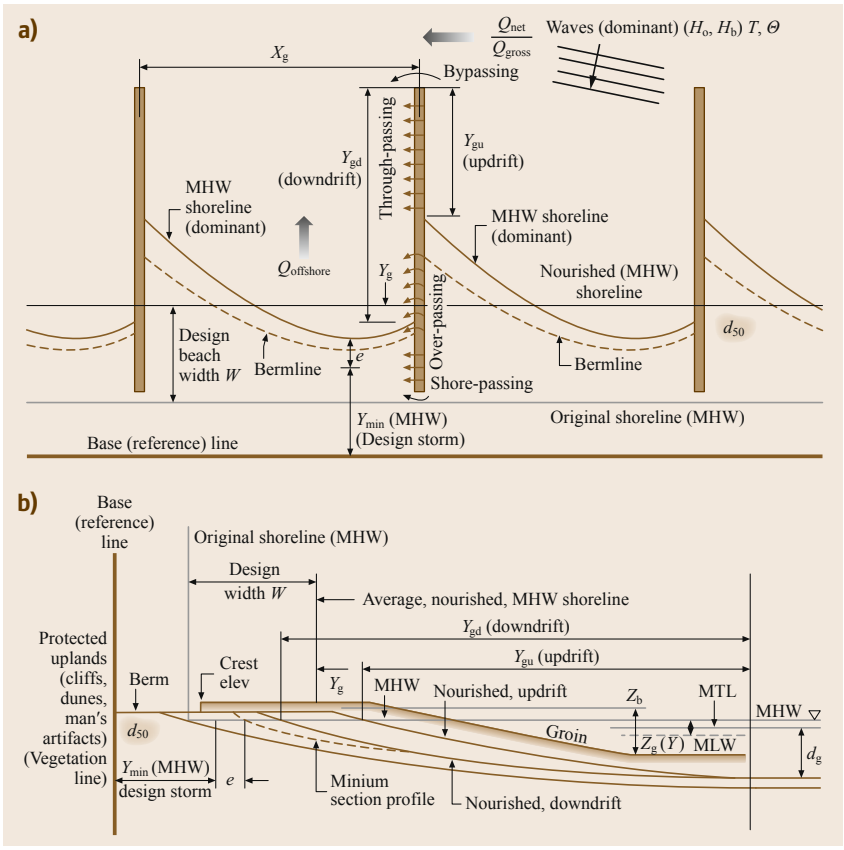

Fig. 30.26a,b Definitions of variables in groin field design

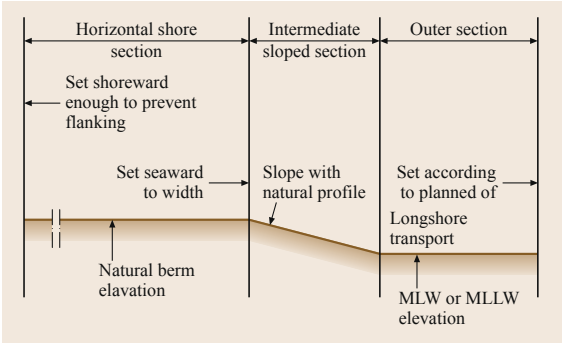

Fig. 30.27 Recommended groin profile with sloping section to permit sand bypassing both over the groin and around the outer end to mitigate down-drift impacts

length, Y_g is measured from the nourished (mean high water, MHW) shoreline position to the end of the groin. The up-drift, Y_{gu}, and down-drift, Y_{gd}, distances shown in Fig. 30.26 are after shoreline adjustment within the groin compartment.

The cross-shore profile of the top of the groin should mimic the local, normal beach profile as illustrated in Fig. 30.27.

There are ten basic *rules* commonly recommended for the functional design of groins [30.88]:

- *Rule 1*: Conservation of mass for the transport of sediment alongshore and cross-shore means groins neither create nor destroy sediment.
- *Rule 2*: To mitigate the erosion of adjacent beaches, always include a beach fill in the design.
- *Rule 3*: Agree on the minimum, dry beach width Y_{min} for upland protection during storm events as a measure to judge success.
- *Rule 4*: Begin with $X_g/Y_g = 2–3$ at time of construction.
- *Rule 5*: Use a numerical, one-line model to estimate shoreline change around single groins and groin fields (e.g., the GENESIS model of *Hanson* and *Kraus* [30.89]).
- *Rule 6*: Use a cross-shore, profile-change model to estimate the minimum, dry beach width Y_{min} during storm events (e.g., the SBEACH model of *Hanson* and *Kraus* [30.89]).

  In the near future, Rules 5 and 6 may be combined by using a numerical, beach evolution model that combines both long- and cross-shore transport processes in one model. For example, GenCade [30.90].
- *Rule 7*: Bypassing, structure permeability, and the balance between net and gross long-shore transport rates are the three key factors in the functional design. Use model simulation to iterate a final design to meet the Y_{min} criterion.
- *Rule 8*: Consider tapered ends, alternate plan forms, and cross-sections to minimize impacts on adjacent beaches. For example, consider T-groins, permeable groins, notched groins, submerged groins, and other shapes [30.88]
- *Rule 9*: Establish a field-monitoring effort to determine if the project is successful and to identify adjacent beach impacts.
- *Rule 10*: Establish a *trigger* mechanism for decisions to provide modification (or removal) if adjacent beach impacts found not acceptable.

A Rule 0 could be added to emphasize the fact that groins are only useful where long-shore sediment transport processes are dominant. If cross-shore transport processes control, then near shore or headland breakwaters should be considered first.

Reference [30.91] focused on the functioning and design of coastal groins. It included papers on the background and literature review, management, design, case studies, and numerical and physical modeling of groin fields. It contains a wealth of information and should be consulted for both functional and structural design.

Summary

From the above, it is clear that our understanding of the functional, plan form layout of coastal structures is relatively primitive. We only have some design guidance and rules of thumb that have been obtained from field experience and physical model experiments in the laboratory. The use of numerical models will signifi-

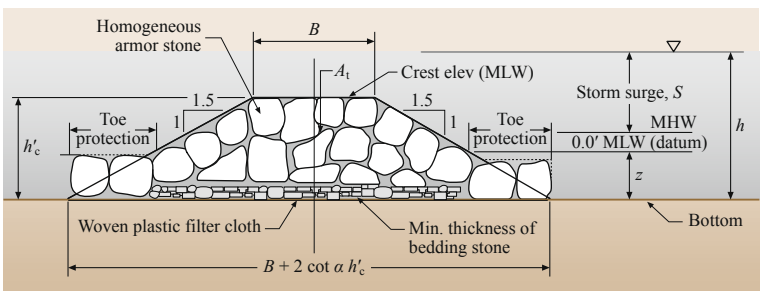

Fig. 30.28 Typical cross-section of a low-crested rock structure constructed with one stable-sized armor stone as determined by *van der Meer* (after [30.47])

cantly increase our understanding of the physics in the future.

30.3.3 Structural Design

The predominant material of construction for shoreline stabilization structures is rock. Timber, steel, and concrete materials have been employed for groins but are not considered here.

The structural design of rock structures is discussed above (Sect. 30.2.3) for coastal armoring structures. However, in many cases where headland breakwaters, near-shore breakwaters, and groins are built in shallow water, only one rock size is employed as illustrated in Fig. 30.28. The crest elevation is above the mean high water (MHW) tidal elevation but the structure is overtopped and often completely submerged during storm surge events. The van der Meer formulations for overtopped and completely submerged conditions should be employed. These structures are highly permeable so that the permeability parameter, $P = 0.6$.

30.4.2 Sea Level Rise Trends

Global climate change is real. The potential for accelerated, RSLR rates at most coastal locations poses a threat to existing shore protection hard structures around the world. Severe storms (low-pressure events and hurricanes) may occur more often to increase the frequency of storm surges and shift the exceedance frequency curves for high water elevations (Fig. 30.2). More severe storms may produce higher offshore wave heights. Consequently, breaking waves near shore will be larger due to deeper water depths closer to shore. These consequences of climate change and sea level rise on water elevations and wave heights will produce larger stresses on coastal structures. The exceedance probability for the loads (water levels and wave heights) will increase the probability of failure and resulting risk. In addition, wave run-up and overtopping will increase to reduce the functionality of the structures and add to the flooding damage.

A review of the typical shore protection structures shown in Fig. 30.4 and shoreline stabilization structures presented in Fig. 30.16 reveals that rock structures are most often the *best* alternative (lowest life-cycle costs) for shore protection with hard structures. Rock structures can be more readily raised in crest elevation and repaired when damaged than all the other types. Rock structure crests can be elevated to keep up with potentially accelerating sea level rise rates to maintain functionality for wave run-up and overtopping. And, rock structure damage can be repaired to keep up with larger waves producing more damage more often. The resilience of the coastal shore protection effort can be maintained with rock structures and hybrid structure combinations (rubble mounds with frontal berms) will be important in the future.

However, complete failure of the hard, shore protection system must always be considered in modern, contemporary, coastal engineering design. See *Kamphuis* [30.17, Chapter 17] for a discussion of resilient systems design that must also consider the social, political, and institutional constraints in the complete process of resilient systems design.

References 709

A harbor is defined as a haven, and in the context of this handbook, it is a body of water that provides shelter to vessels. A harbor can be natural or artificial, situated along the shore with water deep enough for anchoring a ship in an area that provides protection from wind, waves and currents. When Henry Hudson arrived in the new world in 1609, he discovered what would become New York, and the success of New York can be traced to its excellent natural harbor. Many of today great seaports are located at natural harbors that have been developed into world-class port facilities. This handbook will deal exclusively with artificial harbors and the port facilities they protect.

Ports can be defined as a city, town, or place where ships are moored, loaded, or unloaded. They typically reside within a harbor and are made up of one or more individual terminals that handle a particular cargo including passengers, bulk cargo, or containerized cargo. This chapter in the handbook will define the various types of marine terminals and the structures that can be found in a port.

This chapter provides the coastal and ocean engineer an understanding of the types of port and harbor facilities that they may be involved in, including the individual structures that make up these facilities and the loads imposed on them. It is intended to provide an overview of these structures, so that the coastal and ocean engineers can better provide the design support to the marine structural engineers in the planning and designing of such facilities.

31.1 Port and Harbor Layout and Design

In the design of ports and harbors, the design team must be aware of the site-specific environmental conditions (such as tide and storm surge, current, waves, sediment transport), the type of marine terminal that is being constructed, and the various vessel types that may call on the terminal. Ports can be offshore terminals or within naturally or artificially protected harbors, bays, estuarine bodies, or rivers. Offshore terminals may be on either reclaimed or natural islands joined to the land by trestles or pipelines or using buoys and pipelines to shore. The function and capacity of the terminal have an effect on the types of vessels that will call on the terminal and in turn dictate factors in the design of the navigation channel, berth depth and length, environmental conditions that impact berthing and mooring, and the overall layout of the facility. This section will

discuss the geometric layout of various harbor facilities as well as the vessels that call on them. These factors will dictate the design effort that coastal and ocean engineers will have to put in during the overall design of such facilities and harbors. Figure 31.1 illustrates typical features found within a harbor and includes the design of the following elements:

- Navigation channel – A channel deep enough and wide enough to allow for vessels to access the port and pass if two-way traffic is required or demanded.
- Turning basin – An area at the end of the navigation channel that allows for the vessels to turn around and maneuver into and out of the harbor. Typically, the basin is at a preferred minimum, twice the length of the largest vessels calling on the terminal.
- Berthing basin – A dredged area adjacent to the wharf structure that allows for the berthing and mooring of vessels.
- Berth – A dock structure with sufficient length and lateral capacity to support berthing and mooring loads. Principal types include:
  - Wharf, quay, pier, or jetty structure: Wharves or quays are typically oriented parallel to shore while piers or jetties project out from shores and include decks for loading and unloading commodities. Terminology varies with locale. These types of berthing structures typically handle container (Fig. 31.2), break bulk, or general cargo, that is, noncontainerized cargo shipped in bags, barrels, drums, palletized, loose, etc., and handled by stevedores, or roll-on/roll-off cargo, pushed, pulled, or driven directly off the ship requiring laydown space for loading and unloading until moved off the dock. Mooring dolphins at ends of the berth, described below, are often provided to tie up bow and stern lines obviating the need to extend the deck beyond the limits required for loading and unloading.
  - Dolphin-type docks include multiple freestanding structures (breasting and mooring dolphins), including pile clusters, multiple piles supporting a cap equipped with mooring hardware, and fenders or solid-filled structures, such as circular cofferdams. An unloading platform and a shore access trestle are typically provided to support pipes and equipment for transferring product handled to shore. Narrow walkways or *catwalks* are usually provided between access platforms and the dolphins to facilitate mooring line handling. These types of facilities typically handle liquid (Fig. 31.3) and dry-bulk materials (Fig. 31.4) that are transported using pipelines or conveyors.

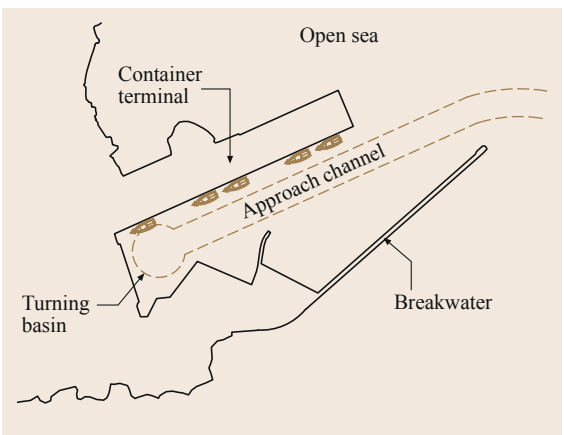

Fig. 31.1 Typical port features

Fig. 31.2 Container terminal – Antwerp (courtesy of AECOM)

Fig. 31.3 LNG terminal cove point Chesapeake Bay (courtesy of AECOM)

Fig. 31.4 Dry bulk berth (courtesy of AECOM)

- Fender systems – Elements that allow for the absorption of berthing loads to prevent damage to the wharf structure and the vessel hull.
- Mooring hardware – Elements, such as bollards, bitts and cleats to safely tie up vessels during various environmental conditions. It also includes motorized capstans to assist longshoremen or stevedores with line handling.
- Upland facilities – Depending on the type of facility, the area required to perform loading and offloading operations as well as to provide temporary storage of goods or product. It also provides connection to intermodal transportation of goods.

31.1.1 Types of Marine Terminals

Throughout history, waterborne transportation has been an integral part of the movement of goods and people. Today, waterborne transportation accounts for the largest volume of goods transportation in the world. With the advent of containerization in the mid-to-late 1950s the cost of moving large quantities of goods around the world has allowed for the continued economical shipment of goods. Additionally, the shipment of bulk materials, such as oil, natural gas, coal, grain, and minerals has continued to grow. Although air travel has taken over from vessel travel for passengers, there continues to be significant passenger trips by vessel in pleasure cruises and in ferry movements. Ports can be dedicated to a single commodity or handle multiple cargo types. Ports range in size from small single-berth facilities to large ports containing dozens of berths. Typical port facilities can be classified into the following categories.

Container Terminals

These ports handle cargo that is shipped in specialized containers. To unload these vessels, the port must have specialized cranes designed to lift the containers from the vessels to the wharf.

Most container terminals use ship-to-shore cranes (Fig. 31.2) that are fixed on rails and that can gantry on the rails along the length of the wharf to unload the vessels. This, however, can also be accomplished with mobile harbor cranes traveling on wheels or tracks and lifting with outriggers that can be fitted with a spreader to handle containers or other equipment to unload the noncontainerized cargo. Mobile harbor cranes are typically more common on smaller or multipurpose terminals. One of the critical factors in the design of these facilities is the wave condition at the berth, as the vessel must remain stable during the loading and unloading of containers. Once unloaded, imported containers are transferred from dockside using straddle carriers or onto trailers/bombcarts and then into the yard. Straddle carriers, rubber tire gantries (RTGs), rail-mounted gantries (RMGs), or reach stackers, stack the containers for short-term storage in the container yard until shipped to final destination either by rail, truck, or smaller vessels (sometimes call short sea shipping). Exports work in reverse.

Liquid Bulk Terminals

These port facilities handle the loading and unloading of liquid materials, such as oil, gas, and liquefied natural gas (LNG) (Fig. 31.3). To facilitate the transfer of liquid material from the vessel, these facilities typically have loading arms installed on the dock structure that maneuver flexible hoses to the ship deck. These hoses are connected to pipelines that allow for the transfer of material to and from storage tanks located upland of the dock. Wave conditions that these facilities can operate under are typically greater than that of container facilities due to the flexibility of the transfer hoses. With certain products, such as LNG, additional space is required in the navigation channel and turning basins for ship maneuvering due to safety concerns. The product may be shipped into or from the terminal either by pipeline, truck, or rail.

Dry Bulk Terminal

These port facilities handle the loading and unloading of dry bulk material, such as coal, iron ore, minerals, grain, and sugar (Fig. 31.4). Its basic and original form, a derrick or crane with a clamshell or other bucket is used for loading and unloading assisted by bobcats or front-end loaders to pile material. To facilitate and automate the transfer of material to and from the vessel, these facilities are typically equipped with specialized bulk-handling equipment, such as conveyor belts, screw conveyors, stackers, reclaimers, shiploaders, hoppers,

and dumpers. The upland facilities typically consist of storage facilities, such as stockyards, storage silos, or stockpiles. The operational conditions tolerable at these facilities are dependent upon the type of material handling equipment used, as some operations can allow vessel movement, while others require a very stable environment. Bulk materials are distributed via trucks or rail to their ultimate destination.

Military Terminals

These port facilities support military operations and are typically used to homeport naval vessels. The sizes of vessels calling on these ports can vary greatly from small craft to destroyers and submarines to the largest aircraft carries. As such, the navigation channel must be adequate to allow for the largest vessels to access the dock facilities. The design of the harbor must also take into account security measures. Typically, the wharf facilities are outfitted with lifting equipment to load materials and supplies to and from the vessels and to support minor repairs. Additionally, the wharf structures are equipped to supply power, communications, water, and sewage utilities to the vessels while they are in port. Special care is required for berthing of submarines and aircraft carriers typically involving the use of camels to hold the vessels off the face of the dock, in the case of aircraft carriers due to the overhanging decks and in the case of submarines which lay up against the dock below waterline. Some specialized facilities include double-deck piers that allow servicing the ship on a lower deck and loading/unloading operations on an upper deck.

Ship Repair Facilities (Drydocks)

These port facilities are designed to support the building and repair of vessels of various sizes. Typically, these facilities have wharf structures that facilitate working on the vessels in the dry. This can be accomplished in a variety of ways, including graving docks (dry docks), floating dry docks, ship lifts, and marine rail facilities. As these facilities may require ships to remain at berth during heavy weather conditions, consideration must be made for heavy weather mooring in their design.

Cruise Ship Terminals

These port facilities provided for the loading and unloading of passengers embarking on pleasure cruises. As this industry has grown in the recent past, the size of the vessels in the cruise fleet has continued to grow and the facility designs have had to accommodate these changes. The wharf facilities typically are outfitted with movable gangways to allow for the safe boarding of passengers as well as security zones for customs and immigration processing. In some harbors where adequate berthing facilities are not available, offshore

Fig. 31.5 Whitehall ferry terminal (courtesy of AECOM)

mooring locations are used and passengers are shuttled to and from the vessel via ship tenders.

Ferry Terminals and Transfer Bridges

These port facilities (Fig. 31.5) can either accommodate just passengers, or passengers and vehicles. To accommodate vehicles, the wharf facility must include a platform or ramp that can support a ramp from the vessel, or provide a movable ramp for the vehicles to travel over. The end of the ramp is suspended and supported from a gallows tower or a pontoon. Similar transfer bridges (Fig. 31.6) serve similar function allowing rail cars to be transported across a harbor or river. Fendering and mooring elements are designed to accommodate the unique characteristics of the ferries that call on the facility.

Fishing Ports and General Cargo Terminals

These port facilities are typically deigned to support a wide variety of vessels and the design of berthing, and mooring structures must accommodate these requirements. Fishing wharves typically do not have heavy lifting equipment but the upland facilities must support

Fig. 31.6 Rail transfer bridge (courtesy of AECOM)

a wide variety of processing and logistics operations. General cargo wharfs may or may not provide lifting equipment, and if they do, it is usually mobile harbor cranes that require heavy live load capacity to handle the variety of material that the port services. Cargo arrives and is typically transported from these terminals either by rail or truck.

Small Craft Harbors and Marinas

These port facilities are typically smaller in nature than the previously described facilities but have their unique design considerations. These port facilities typically include floating docks that are fixed in place by anchors or guide piles. For their design, the tidal range, currents, and wave conditions are critical.

31.1.2 Vessel Overview

When designing for and dealing with ports, it is important to first have an understanding of the vessels that utilize them. The world shipping fleet contains hundreds of types of ships of many different sizes and measurements, with many different distinct uses and functions. Despite the variance in ship type, there are measurements and size classifications common to all shipping vessels.

Some of the most common cargo ships today include general cargo, container, tanker, bulk, car carrier, and cruise ships. Each of these types of ship varies in the cargo it transports. *General cargo vessels* have been plying the seas for thousands of years and can handle a multitude of goods and products. In order to speed and facilitate vessel loading and unloading, dedicated purpose vessel were developed in the 20th century. *Container ships* transport goods in stacked containers. Tankers carry petroleum products in tanks. *Bulk carriers* transport bulk items such as ores and raw materials that are held in bays on board. *Tankers*, *ATBs*/*ITBs* (articulated and integrated tug barges, a barge with a notch at the stern that a tug noses into an articulated connection or is rigidity connected (ITB)) carry oil and chemicals in tanks. Liquefied natural gas (*LNG*) and liquefied petroleum gas (*LPG*) vessels transport fuel in bulk, liquified, and under pressure. *Car carriers* or *RO-RO vessels* transport vehicles that are unloaded by driving across ramps incorporated into the vessel, hence the name, Roll-on, Roll-off. *Cruise ships* transport people. In river and estuarine bodies, smaller versions of these vessels may operate or cargo may be transported in or on *barges* either self-propelled or towed or pushed by *tugs* singly or lashed together in groups. Barges include *deck barges* that cargo is placed on the deck, *scows* where principally dry bulk commodities are placed compartments or bays (a smaller version of a bulk carrier) or *carfloats* which is a barge with tracks on deck for transporting railroad cars. Figure 31.7 illustrates some of these different types of vessels.

Additionally, the world's fleet of vessels includes military and coast guard vessels, pleasure craft, fishing and exploration vessels, ice breakers, construction equipment, and service craft. Military vessels include aircraft carriers, battleships, destroyers, submarines, cruisers, and support/supply vessels often similar to commercial fleet vessels. Service craft include pilot boats to guide a large vessel from the open sea to port, tug boats to assist vessels maneuvering in confined waterways and during docking, barges to fuel and offload waste and bilge water from ships, as well as floating

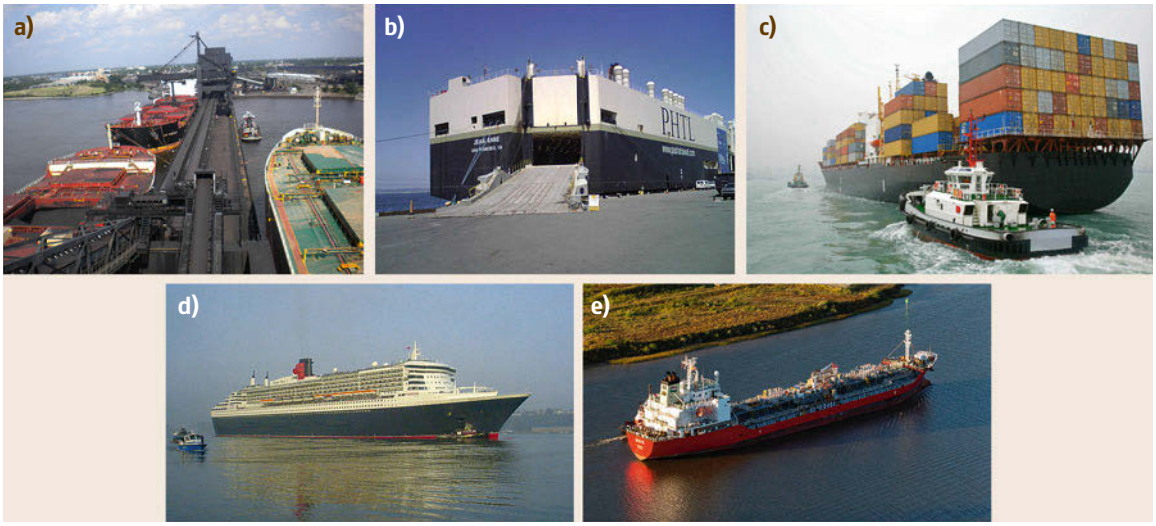

Fig. 31.7 Vessel types (courtesy of AECOM)

drydocks and other repair-type vessels. Construction equipment includes derricks, barges, tugs, dredges, and various specialty craft.

While designed for different purposes and each having unique characteristics, there are common dimensions and measurements between all vessel types of which engineers and designers should be aware.

The most commonly used measurements for ships assess both the physical dimensions of ships and the amount of cargo that they can carry. For harbor or port design, the principal dimensions of a ship include length overall (LOA), length between perpendiculars (LBP) beam (width), averaged draft, freeboard, molded depth, longitudinal (broadside) wind area, and transverse (head-on) wind area. The beam is the measure of the breadth of a ship at its widest point. LOA is the measure of a distance from the bow of a ship to the stern. The draft of a vessel is the vertical distance between the waterline and the deepest part of the ship at any point along the length of the vessel. Other measurements of vessel which are important to the harbor/port design include *displacement* (the displacement is the weight of the water of the displaced volume of the ship), *DWT* (deadweight tonnage, the total carrying capacity of the vessel including cargo, crew, water, fuel, etc. DWT is typically the measurement used to place ships into different classes but is not needed for design rather used only for classification), center of gravity, center of buoyancy, metacenter, and center of flotation. Important coefficients of form of vessel include block coefficient (the ratio of the immersed hull volume at a particular draft to that of a rectangular prism of the same length, breadth, and draft as the ship), midship section coefficient (the ratio of the area of the immersed midship section at a particular draft to that of a rectangle of the same draft and breadth as the ship), the waterplane coefficient (the ratio of the area of the waterplane to that of a rectangle of the same length and breadth as the ship), and longitudinal prismatic coefficient (the ratio of the immersed volume to the volume of a prism with length equal to the ship's and cross-section area identical to the midship section). For container ships, vessels may also be classified by TEU (twenty-foot equivalent unit) capacity. A TEU refers to the container used to ship goods at sea which typical measure 20 ft long by 8 ft high by 8 ft wide (1 TEU) or 40 ft long by 8 ft high by 8 ft wide (2 TEUs). For mooring analysis, the layout of onboard mooring equipment will be important. For berthing analysis, in addition to ship's mass and principal dimensions, hull radius is needed which is sometimes difficult to obtain. For ship navigation studies, the vessel parameters (or key components) that affect the vessel maneuverability will be required; these parameters or components include vessel wind coefficients, current coefficients, wave hydrodynamic coefficients, engine type and power, rudder type specifications, bow/stern propellers, etc.

By using many of the measurements above, ships can be placed into different classes. Classes vary by the type of a ship, but most are broken up into DWT ranges. Handi or Handymax vessels are traditionally the backbone of the dry bulk vessels. Some classes are also derived from trade route restrictions that limit where certain sized ships can travel in the world. Canals, such as the Panama and Suez, offer ships a more direct route to destinations, but the lock systems used in these canals limit the maximum size of vessels that can pass through. The *Panamax* class is an example of a class that was created due to size restrictions in the Panama Canal. The name Panamax refers to the maximum size ship that can fit through the locks in the Panama Canal. *Capesize* vessels are too large for the Suez or Panama canals and must travel around the capes of South Africa or South America when making long voyages. Malacamax refers to the largest that can pass the Strait of Malacca between Malaysia and Indonesia. While different types of cargo ships may share class names, the ranges and limits of the defining measurements may vary. Table 31.1 gives example ranges of some of the different classes.

The world's fleet of ships has changed greatly over the past decades and will continue to do so in the future. In 2011, the world cargo carrying fleet was comprised of over 60 500 ships with a total gross tonnage of a trillion tons. It is predicted that as ships continue to get bigger, a larger percentage of total fleet DWT will come from a fewer number of ships. Ports worldwide are looking at ways to accommodate larger ships, as the size of new vessels keeps increasing. The Panama Canal hopes to have its third set of locks operational by 2016, which would allow post-Panamax ships to make use of the canal. Figure 31.8 illustrates the increase in vessel size that the Panama Canal expansion will allow it to handle.

With a basic understanding of ship types and sizes, it is easier to understand what must be considered when working on a port-type project. Different types of cargo ships have different characteristics and measurements that must be taken into account to design the most effective marine environment.

31.1.3 Harbor Operational Limits

Operational limits can be divided into different levels, from cargo handling limit based on maximum allowable vessel movements at berth to the upper limit that a vessel can stay at berth, but with cargo handing ceased, then to the ultimate limit that a vessel can stay at berth

Table 31.1 Example of vessel class

Vessel class	DWT [t]	Other capacity measurement	Beam [m]	Length [m]	Draft [m]
Handymax	30 000–50 000	–	27–	150–200	10–
LNG[a]	60 000–160 000+	75 000–175 000 m^3	35–48	260–300	10–12
Panamax	65 000–80 000	5000 TEU	32.3	294.1	12
Post-Panamax	–	12 000 TEU	49	366	15
Suezmax	150 000	10 000 TEU	48	274	16
Capesize	150 000+	–	> 32	–	> 20
VLCC (very large crude carriers)	200 000–300 000	–	58	330	22
ULCC (ultra large crude carriers)	300 000–55 000	–	68	380	–
Malaccamax	–	–	60	470	24
ULCS (ultra large container ship)	200 000+	18 000 TEU	57	–	16.4

[a] Representing approximately 80% of world's fleet in 2009

	Panamax	post-Panamax
Capacity:		
Containers (TEUs)	4500	12 000
Dimensions:		
Beam	32 m (106′)	49 m (160′)
Length	294 m (965′)	366 m (1200′)
Draft	12 m (39.5′)	15 m (50′)

Fig. 31.8 Panamax vs. post-Panamax

during an extreme storm event before departing to the open sea. There are also environmental limitations for vessel navigation safety (including limiting wave conditions for tugs) and vessel berthing. For some old terminal facilities, the structural capacity of the pier or wharf may limit conditions when the moored vessel may stay at berth. In general, the harbor operational limits will depend on the type and size of vessel, the mooring facilities on board and at the terminal, and the cargo handling equipment. The most commonly used criteria is [31.1] and when published the updated criteria from PIANC MarCom 52: Criteria for the (un) Loading of Container Ships. Some countries also develop their own criteria for harbor operational limits, such as BS 6349 Part 1 [31.2].

31.1.4 Harbor Navigation

For harbor navigation design, the fundamental elements to be considered include design vessels and their maneuverability, layout of navigation components (navigation channel, harbor entrance, stopping area, turning basin, berthing basin, and anchorage area), aids to navigation, requirement/availability of tugs (Fig. 31.9) and pilots, and limiting environmental limit conditions in which maneuvers can be performed. The approach channel and harbor basins are sized for the design vessel. In most cases, due to the variation of types and sizes of vessels calling on the terminal, several design vessels will be needed to ensure that all other vessel using the channel and basin can safely navigate. The navigational design usually includes channel alignment, cross section, and depth. During the detailed design phase, fast-time ship simulations and real-time ship simulations are typically employed to reduce the uncertainty and improve the design. The assessment of marine risk and safety of operation are very important issue in the modern harbor navigation design and usually include traffic simulation for the estimation of marine risk, to employ aid to navigation and ves-

Fig. 31.9 Tanker berthing under tug assist with concrete dolosse breakwater in foreground (courtesy of AECOM)

sel traffic service, and establishment of harbor safety criteria. For navigation channel design, [31.1], [31.3] and [31.4] may be used. For aids to navigation design, the International Association of Lighthouse Authorities (IALA) Aids to Navigation Manual [31.5] can be referenced.

31.1.5 Sediment Transport Considerations

In general, the evaluation of maintenance dredging is an important consideration in the planning and design of a harbor. The methodology for the evaluation of maintenance dredging is significantly different for mud transport and sand transport. In most situations, the reasonable evaluation of maintenance dredging is much more complicated than most people realize. Typically, a numerical model is employed and, in some special cases, a physical model may be needed. Regardless of the modeling technique employed, the wave–current climate and sediment source must be studied first. It should be realized that though extreme storm events could in some cases dominate sediment transport, moderate waves and current could also have a large contribution to the long-term sediment transport because these events occur very frequently. Maintenance dredging of navigation channels and harbor facilities restrict or complicate ship movement operations, and dredging costs are a burden for most operators of harbors. These burdens have become worse due to stricter environmental restrictions on dredged material disposal. To cope with this increasing challenge, the most important step is to perform a study of key coastal processes (tide, current, wave, and sediment transport) and to have a sound understating of the siltation mechanism before any attempt is made to develop mitigation strategies. Typical mitigation strategies include basic structural approaches to promoting the passage of suspended sediments through facilities to limiting the entrance of water with suspended sediment from entering the harbor area including measures such as training walls, jet array systems, and moveable curtains, etc.

31.2 Structure Types

In the design of ports and harbors, there are various types of structures that need to be considered. The configuration of these structures responds differently to the wave, wind, current, and tides that coastal and ocean engineers evaluate. This section describes the various types of structures as well as the loads on structures due to vessel mooring and berthing as and due to ocean environmental conditions.

31.2.1 Breakwaters and Wave Attenuation

A breakwater is a coastal defense structure employed to reflect and dissipate the wave energy and thus prevent or reduce wave action within the harbor. Breakwaters can also sometimes serve to guide the current and improve navigation. In other cases, a breakwater can reduce the amount of dredging required in harbor entrance by blocking the longshore sediment transport. In some harbors, breakwaters serve dual functions for wave protection and quay facilities. There are three main types of breakwaters, namely, rubble mound breakwater, vertical breakwater, and composite breakwater (Figs. 31.9 and 31.10). For the majority of cases, the primary func-

Fig. 31.10 Concrete block breakwater at port of Haina – Dominican Republic (courtesy of AECOM)

tion of a breakwater is wave protection. The degree of protection required (or allowable wave conditions within the harbor) will depend on the vessel characteristics, harbor operational and downtime requirements. In practice, a numerical wave model with diffraction capability needs to be employed to investigate the optimum layout of breakwater and wave climate within the harbor. For breakwater design, bathymetry and geotechnical considerations are very important because it will determine the applicability of various types of breakwaters, the volume of material needed to build the breakwater, and scour requirements. Wave height and their frequency of occurrence (both during normal conditions and extreme storm events) are the most important inputs for the optimum design of a breakwater. Wave run-up and overtopping analysis also need to be conducted to determine the elevation of the breakwater. Guidance for the design of breakwaters may be found in [31.6, Chap. 5]. For navigation safety, aids to navigation are typically needed at the head and along the trunk of breakwater. During design, the availability and cost of construction materials and equipment need to be considered. Revetments often found adjacent to or beneath in the case of pile supported marginal wharfs. Design principles for revetments are similar to breakwaters and in addition to [31.6] guidance may be found in [31.7].

31.2.2 Open Pile Platforms

Open pile platforms allow water to flow underneath and are supported on steel, concrete, timber, or composite piles or drilled shafts. Typically, a solid deck is provided, except for liquid and dry bulk facilities, which use pipelines, conveyors, or other methods to transfer bulk products, where only a frame may be provided. Deck types can include either concrete two-way flat plate slabs or concrete pile caps with one-way deck slabs with the pile caps typically oriented normal to the pier's or wharf's length to take advantage of the pile cap's greater strength to resist lateral loads due to berthing or mooring. One-way deck systems may be cast in place but more commonly use precast planks (solid or voided) or less frequently beams (box, tee, etc.) since such deck components can be more easily precast and erected rapidly. Two-way deck systems with or without pile caps in one or both directions are also common; these usually employ longitudinal beams/girders to accommodate heavy wheel loads, such as container and other travelling cranes, often on rails. Two-way slabs without beams are less common since a cast-in-place deck is usually necessitated requiring a high-cost formwork over the water; drop panels over piles if used further increase costs. A deck cast on ground and then soil below removed is also possible, but there is a challenge in removing the soil below. Two main types of open pile platforms include high- and low-level platforms. In addition to berthing and mooring loads discussed hereafter, the design of open pile platforms must consider current and wave loads on substructure elements. Guidance may be found in [31.6, Chap. 5].

Low-Level or Relieving Platforms

Relieving platforms (Fig. 31.11) are structures where fill is placed atop a structural deck set several feet below the paved surface, often just above mean low water. Historically, these types of platforms were usually constructed on timber piles whose butts were set just above mean-low water to minimize rot and replacement of the pile in the tidal zone area and areas subject to wetting and drying, highly rot susceptible. As waterways became highly polluted at the end of the 19th century, resulting in the demise of marine borers, their popularity increased in coastal waterways since timber piers no longer were subject to this type of attack and a long-life achievable with rot concern eliminated by virtue of their continual submergence. When clean water regulations were developed and the waterways became cleaner, borers returned making timber less desirable in coastal waterways; however, with the advent of modern higher capacity materials including steel and concrete piles, low-level platforms remained viable and economical allowing the use of fewer higher capacity piles that are out of the highly corrosive splash zone by virtue of a low deck. Relieving platforms are highly effective in distributing heavy concentrated loads through the soil to the deck resulting in a more uniform load that can be more economically constructed. They are also useful as platforms over highly compressible soils, *relieving* superimposed material storage loads which

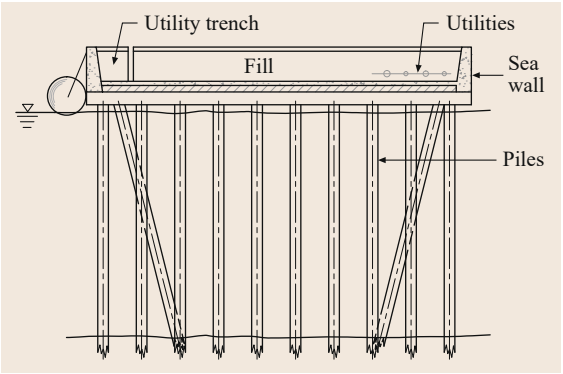

Fig. 31.11 Low-level relieving platform

would otherwise result in an unacceptable settlement of the facility. Finally, low-level platforms offer the advantage of a no cost space for utilities within the fill atop structural deck, especially useful for military, service, and outfitting piers. Their main disadvantage is their intrinsically higher cost since they support higher dead loads and their construction is limited to periods of lower water.

High-Level Platforms

High-level platforms (Fig. 31.12), where the deck is the finish pavement, are the most common type of open-pile platforms. They are usually less costly than low-level platforms since construction can proceed uninterrupted by tide cycles and, with the possible exception of heavy moving concentrated loads, the deck structure need not be as robust as a low-level platform. Hence, they can usually be constructed at lower cost than a comparable low-level structure. The height of the pier deck of high-level platforms allows easier access and more space below deck; hence, they are easier to maintain. However, the piles in the tidal and splash zone are more susceptible to deterioration and either requires special and more costly design consideration and protection or increased maintenance.

Hybrid Platforms

These include both high- and low-level platforms, most frequently as existing structures supported on timber piles. Usually, this type of platform will include piers with high-level aprons whose piles have long exposed lengths and an inner core on a low-level platform with piles of short exposed length. Typically, the mudline is mounded toward the center for this type of structure to take advantage of the higher capacity of short piles. Another variation of a hybrid platform is where piles are near or at the water level and concrete walls or truncated pyramid pedestals are constructed up to a high-level deck.

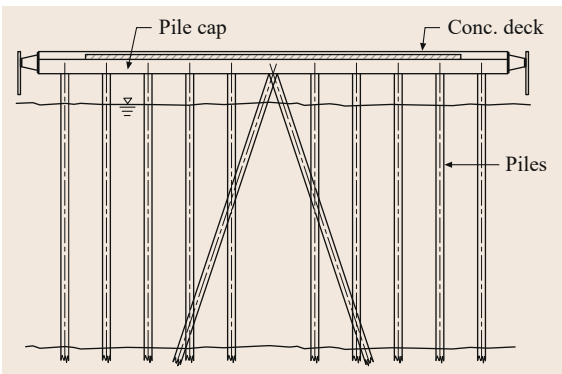

Fig. 31.12 High-level platform

31.2.3 Solid Structures

Solid structures use a wall to retain fill that supports the working structure. Solid structures do not allow water to flow beneath and interrupt or disrupt water circulation patterns. Solid structures additionally provide a berthing cushion which temporarily traps water between the vessel and the berth. If bulbous bow ships will use the facility, the bulkhead is typically set back from the berthing line. Lateral forces due to wave loading on solid structures can be found in [31.6, Chap. 5].

Sheet Pile Bulkheads

Sheet pile bulkheads include cantilever bulkheads, anchored bulkheads, and cellular cofferdams. Sheet piling consists of rolled steel, Z- or U-shape sheets or flat sheets both with interlocks.

Cofferdams

Cofferdams (Fig. 31.13) have been around for thousands of years and the Roman Architect Marcus Vitruvius Pollio wrote of them in *De Architectura* in 15 BCE. In modern day cofferdams, flat sheets are used in cellular cofferdams, either circular with connecting arcs or diaphragm type with connecting straight cross walls. Cloverleaf types are also used. Cofferdams attain their strength as gravity structures relying on hoop tension in the cell or diaphragm to contain the earth fill and lateral mooring loads.

Cantilever Bulkheads

These rely solely on embedment in the earth for their support. Since embedment is typically in the range of one to two times exposed wall height and stresses increase rapidly, cantilever walls are generally economical for shorter heights, most typically used on rivers and small craft facilities. Cantilever bulkheads are also used in locations where anchoring the bulkhead is not feasible.

Anchored Bulkheads

Anchored walls use either deadmen and tiebacks or soil anchors to hold back the top of the wall, thereby significantly reducing the embedded depth of the bulkhead with the most common embedment of 40–60% of the exposed height. This makes anchored bulkheads practical and economical generally up to about 45–50 ft exposed height using Z sheeting. However, modern terminals can typically exceed these heights and *combi-* or *king pile* bulkheads (Fig. 31.14) have been developed for these facilities that use large diameter pipe- or H-pile sections, by themselves or in combination with Z sheets, allowing bulkhead heights to accommodate

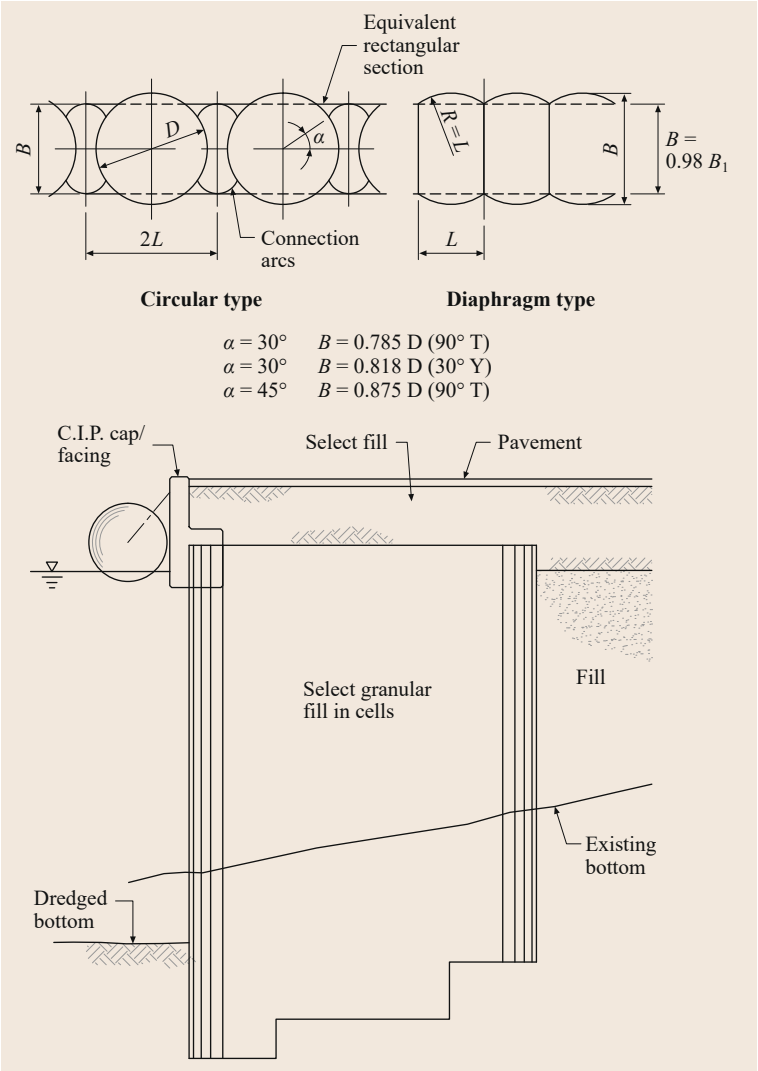

Fig. 31.13 Cellular cofferdam

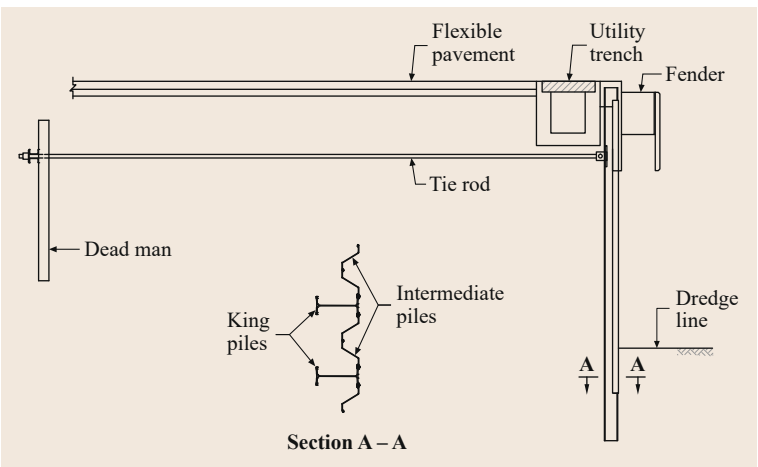

Fig. 31.14 Anchored king pile bulkhead

deepest draft vessels. Sheet pile structures are usually built in the waterway (in the wet); however, they can and have been constructed upland and the berth excavated afterward. For the lowest structural demand on the wall, the anchor should be as low as possible but above water for practicality of installation. Typically, tie rods are set around the mean tide level allowing installation for most of a usual 8 h work day, roughly half a diurnal tide cycle.

All sheet pile bulkheads in salt water ports have the ubiquitous problem of corrosion, especially in the tidal zone. Even the latest coating systems cannot be expected to last more than 20–30 years and therefore should have provision for cathodic protection (CP) as coatings degrade or a corrosion allowance. Since CP systems are only partially effective in the tidal zone, and ineffective above in the splash zone, alternative future provisions, such as concrete facings should be considered. Aluminum, fiberglass, vinyl and other composite plastics are also available; however, they are used for smaller marine bulkhead structures.

In addition to earth pressure, the principal forces acting on bulkheads include wave forces, tidal lag, ice thrust, mooring and berthing loads, scour and propeller swash. Guidelines for the design of sheet pile bulkheads are found in [31.8] for cofferdams [31.9] and the commonly referred to [31.10].

Gravity Wall Structures

Gravity-retaining structures typically constructed of concrete rely on their weight to resist lateral loads of the soil and mooring forces. The most common types of gravity wall structures include block walls, retaining walls, caissons, and crib structures.

Block and Retaining Walls

Block walls (Fig. 31.15) consist of massive concrete blocks stacked into place either in the wet or in an excavated dry basin. Similarly, massive retaining walls are possible but uncommon. The concrete blocks are often un-reinforced and are not subject to typical corrosion found in reinforced concrete structures.

Caisson Walls

Caissons (Fig. 31.16) are box- or egg-like concrete structures with a bottom; typically, they are floated into position, filled with rock or earth, and then sunk into place. Block wall and caisson structures are extremely durable but uncommon in the United States due to their high initial capital cost, especially massive material quantities. They are common in Europe, Middle, and Far East, where long-term viability and sustainability are desirable, and especially in countries with emerging economies where the cost of labor and materials can be significantly less.

Cribs are similar to caissons but constructed of timber or concrete *Lincoln log style*. Cribs are used on smaller marine structures, more commonly in the past than present. Concrete cribs are typically erected in place without a bottom, whereas timber cribs often had a bottom and were floated into place and filled with rock.

Secant Pile, Diaphragm, or Concrete Slurry Wall

These structures are basically modern adaptations anchored sheet pile bulkheads using reinforced concrete instead of steel sheets, developed in Europe and used there and elsewhere since the 1940s. These types of walls typically avoid the corrosion issues of steel bulk-

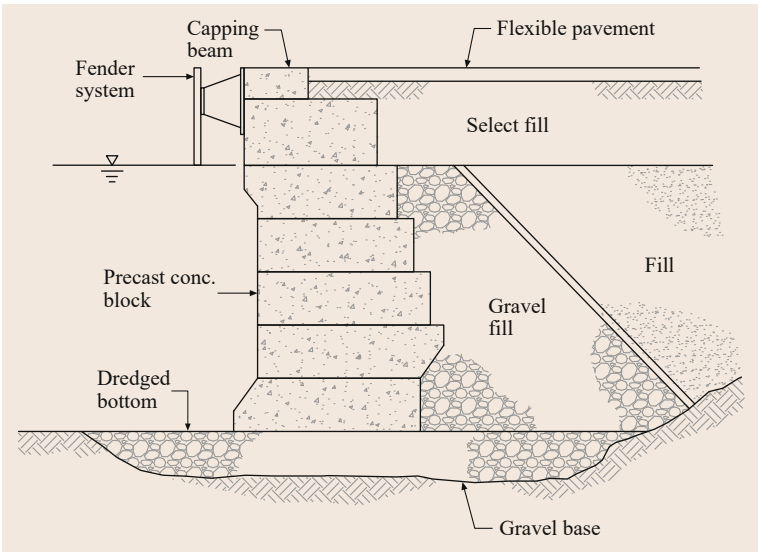

Fig. 31.15 Concrete block wall

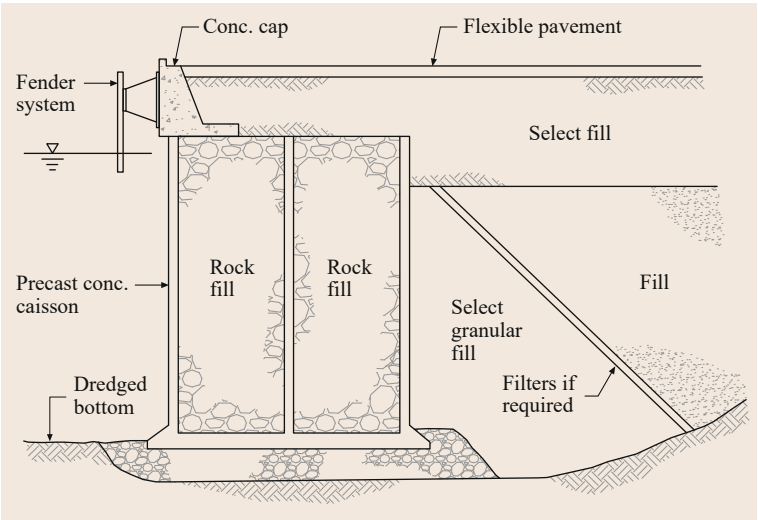

Fig. 31.16 Concrete caisson wall

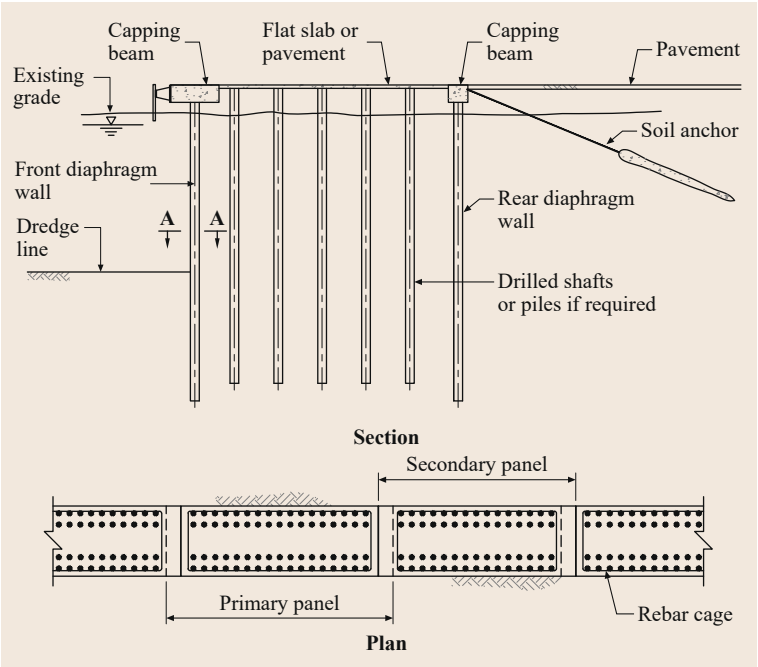

Fig. 31.17 Concrete diaphragm wall

heads, although concrete design mixes, cover, and rebar protection must be carefully considered. They are typically used in *dig-out* ports where the bulkheads are constructed in the upland and the berth excavated later. Secant walls consist of overlapping cast-in-place circular piles or drilled shafts, whereas diaphragm walls (Fig. 31.17) consist of overlapping rectangular piles or panels. Drilled shafts are sometimes referred to as caissons in foundation engineering. This terminology should be avoided in marine and coastal engineering to avoid confusion with caissons described above. These walls are typically drilled in, with a casing if conditions warrant, which is then filled with a bentonite slurry; a reinforcing cage is then lowered into the slurry and the hole concreted by displacing the slurry and the casing if provided is withdrawn. They are typically installed in a skip-step pattern filing in and overlapping the skipped piles or secondary panels on a second pass. A continuous slurry wall can also be used.

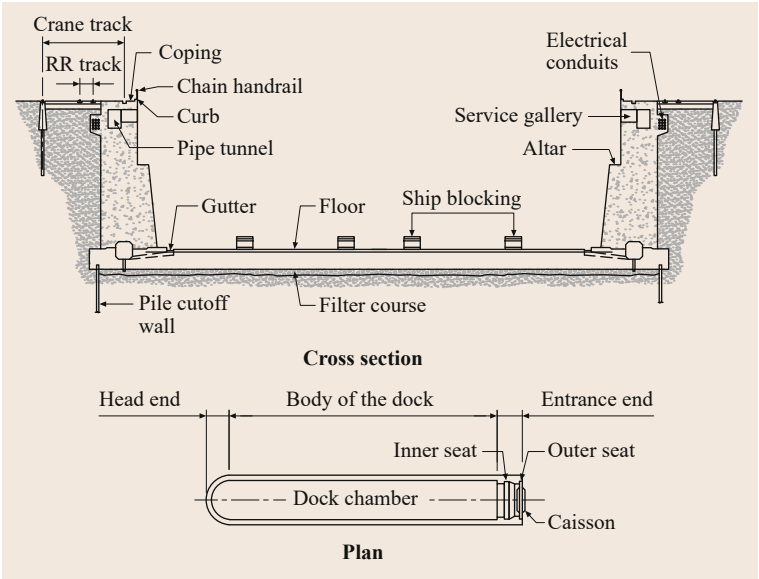

Fig. 31.18 Graving dock

Summary

While some type of structures may be more common in a particular locale, region, or area, there is no one-size-fits-all choice for the selection of structure type. Table 31.2 presents some of the considerations in the selection of structure types. Local practices, regulations, contractor familiarity, design life, and costs can heavily influence structure selection.

31.2.4 Drydock Facilities

Dry docks [31.11, 12] are used for the repair, overhaul, and painting of ships above and below the waterline. Principal types include graving docks, floating drydocks, and marine railways.

Graving Docks

Graving docks (Fig. 31.18) are large, fixed basins including a floor, sidewalls, head wall, and a gate. Altars or steps are often incorporated into the side walls for structural stability. Since they are at water's edge and below groundwater, graving drydocks must either be massive heavy structures or employ dewatering systems to reduce hydrostatic pressure. The choice is usually economic one, balancing the high operational cost of a relieved drydock vs. the higher initial capital cost of nonrelieved docks. The principal critical loads acting on drydocks include:

- Dock under construction
- Dock empty; maximum hydrostatic uplift
- Maximum ship load; minimum hydrostatic uplift
- Dock full of water

The drydock is separated from the waterway by a gate which resists the water pressure when the dock is dewatered. There are four principal types of gates, each with their own advantages, disadvantages, and design considerations. They include *miter gates* that consist of a pair of gate leaves hinged at the dock walls that swing open horizontally, sides and bottom fit against seats in the drydock walls and floor when closed. *Set-in-place gates* are available in various forms and may be built in one piece or multiple sections of beam and plate construction. These gates are extensively used for small docks. Their placement and removal must be done by weight-handling equipment and large gates render them impractical. The *floating caisson gate* is of the most common type, consisting of a watertight box with flooding and dewatering chambers and systems. After the drydock is flooded, the caisson is dewatered to raise it up off its seat. It can then be towed clear of the dock entrance. *Sliding or rolling caissons* consist of builtup box sections with a sliding or rolling surface at the base. The gate slides or rolls into a notch built into the side of the dock. Flap gates consist of a rigid one-piece gate hinged at the bottom that swings downward and upward. Both miter and sliding gates are similar in design and operation to canal lack gates. In addition to potential wave loads, an important consideration in the design of a caisson gate and graving dock entrance is the siltation potential at the entrance. Table 31.3 provides some guidance on merits of each type of gate.

Floating Drydocks

Floating drydocks (Fig. 31.19) consist of two main parts – pontoon and wingwalls. Pontoons are the main

Table 31.2 Merits of open platforms and solid structures

Factor	Open pile platform	Solid structures	Advantage
Environmental impacts	Minimizes filling of waterway; maintains fish habitat	Reduces habitat significantly	Open pile
Deep depth to competent bearing strata, moderately compressible material above	Long piles costly; splicing is time consuming and cuts productivity	Soil improvements techniques can be used	Solid
Moderate depth of very soft to soft soil strata	Easily penetrated by piles to competent materials below	Requires time consuming soil improvements or costly dredging out and replacement	Open pile
Wide structure or marginal wharf type	High per square foot cost	Pavement and fill relatively inexpensive if fill readily available but costly bulkhead or wall construction	Solid – wide to very wide open pile – narrow to moderate
Maintenance	High long term labor intensive maintenance required/replacement	Steel bulkhead types can be faced with concrete or cathodically protected; block or caisson type virtually forever. Diaphragm and secant type walls fall between	Solid

Table 31.3 Advantages and disadvantages of drydock gate types

Gate type	Advantages	Disadvantages
Miter gates	• Fast operations	• Creates heavy loads on wall supports. Although loads can be relieved by roller and track arrangements, these are not satisfactory for operational and maintenance reasons. The same objections apply to relief of loads by controlled buoyancy in the gates. • Operating mechanism is costly, susceptible to breakdown and requires costly maintenance • Major repairs require removal of gate • Recesses must be built into dock walls to maintain ship clearances with open gates adding to drydock length and complexity
Set in place gates	• Low capital costs	• Heavy and impractical for larger docks • Time consuming to install and require weight handling equipment
Floating caisson gate	• Low cost • Can be towed to other sites or drydocks • May be used in more than one dock • Reversible, exposed side can be repaired in place	• Slow operating • Needs shore power to operate (electric and sometimes air); it is not operative too far from the caisson seat
Sliding or rolling caissons	• Fast operations	• Cleaning and maintenance of rollers or slide paths is difficult • Operating mechanism is expensive • Major repairs require removal of gate • Recesses must be built into Walls
Flap gates	• Fast operations	• Creates heavy loads on wall • Operating mechanism is costly & requires costly maintenance • Major repairs require removal of gate • Recesses must be built into walls to maintain clearances

supporting bodies that displace the weight of the vessel and drydock in order to lift the vessel using buoyancy. The pontoon must distribute the concentrated load of the ship along the dock's centerline to the uniform buoyant support of the water pressure by its transverse strength. The wing walls provide stability when the pontoon is submerged and the longitudinal strength to distribute the irregular ship weight to the uniform

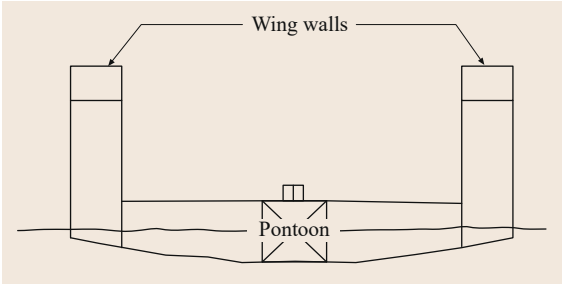

Fig. 31.19 Floating drydock

buoyant support. Some floating drydocks have portal cranes on tracks on the wingwalls and some floating drydocks use cranes from the pier side. The dredge depth at these facilities must accommodate the floating drydock when submerged. Floating dry docks have capacities from a few hundred tons to over 100 000 t. In general, the most economical range for floating docks is about 1000–100 000 t. Advantages of a floating drydock are:

- Does not require valuable waterfront real estate.
- Can be built at the yard of low bidder and towed to the site keeping construction costs low by increasing competition.
- Can be sold on the world market keeping resale values high and making obtaining financing easier.
- Vessels can be transferred to and from shore relatively easily.
- Can be operated with a list or trim when docking vessels with a list or trim. This can reduce block loading and reduce or eliminate vessel stability problems when landing.
- Permits docking of vessels longer than the dry dock by overhanging the bow and/or stern.
- Can be moved for dredging.
- Minimal landslide construction works with potentially easier permitting.
- Can be moved to deeper water for docking and undocking operations, reducing or eliminating need for dredging.
- The dock can be lengthened relatively easily.

Disadvantages of a floating drydock are:

- High maintenance is required on pumps, valves, and steel structure.
- Routing of men and material is restricted to gangplank and/or crane service.
- Large tidal variations can complicate gangways, mooring, etc.

Floating drydocks are normally moored using two or more vertical spuds or mooring arms, sometimes called Crandall arms after the Crandall Drydock Company that pioneered their development, which hold the dock in position throughout its full range of vertical movement from fully submerged to fully dewatered and during normal tidal changes. The pier/wharf structure must be designed to accommodate spud or mooring arm placement and loading.

Marine Railway

A marine railway [31.13] (Fig. 31.20) is a mechanical means of hoisting a ship out of the water along an inclined plane. It consists of an inclined track on a foundation, a cradle, or bogies that move on rollers or wheels to support the vessel and ride up and down the track, and a hauling mechanism to pull and control release the cradle. Two types include endhaul and sidehaul. Endhaul type is easier, safer, and less complicated to pull up and occupy less valuable waterfront frontage than sidehaul or broadside type. A sidehaul marine railway may be the only type that can be used safely on a nontidal river bank if there is no slack water period to permit docking a vessel normal to the current, width, and location, and the traffic up and down the river may preclude the use of an endhaul docking. The sidehaul type is particularly adapted to hauling out vessels with flat bottoms and a shallow draft, such as barges and other river craft. Operationally, the cradle is lowered into the water along the inclined track. The ship is floated over the cradle and tied to the uprights, the cradle is hauled up the track, and the vessel grounds onto the blocks. After complete grounding on the keel blocks, the side blocks are brought to bear and the hauling continues until the cradle is full up. Some facilities employ a lateral transfer system once upland to accommodate multiple vessels using a single railway. Ideally, the slope of the track would be selected to fit the natural slope of the particular site to minimize dredging and yet provides the required drafts over the blocks for docking the vessel; however, tradeoffs usually have to be made between the length and slope. Lift capacities range from 100 to 6000 t, or theoretically, even larger but the floating drydock usually becomes a more economical alternative. Advantages of a marine railway over drydocks are as follows:

- Low initial construction cost
- Fast operating
- The track slope can fit the natural slope of the shore in many cases. This eliminates or reduces dredging or bulk-heading requirements.

Disadvantages of a marine railway are as follows:

- It is a mechanical system that requires the periodic replacement of some moving parts (hauling chains, rollers, etc.).

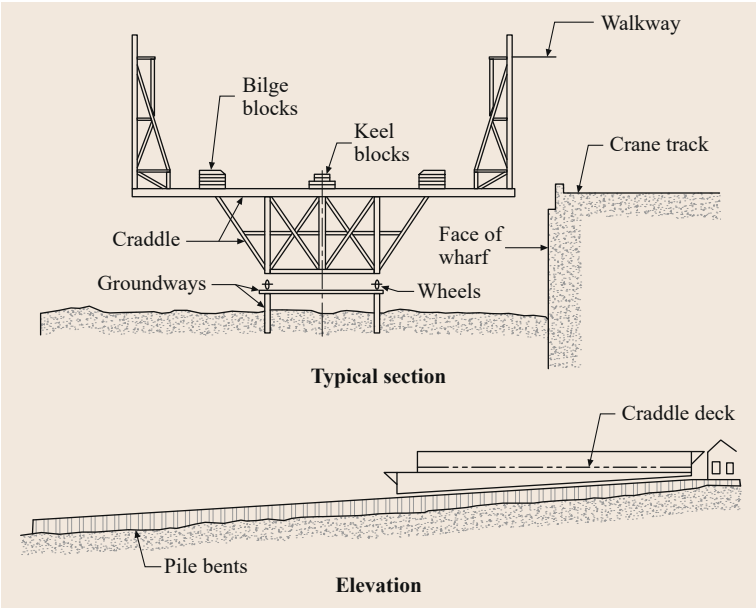

Fig. 31.20 Marine railway

- Handling and transition from tugs to cradle can make handling difficult.
- Underwater maintenance is required.
- The vessels can damage the track.
- Ice can form on the tracks, rollers, and chains, potentially delaying or endangering the docking. Ice can build up at the graving dock entrance, but removal is easy.

31.2.5 Floating Structures

Floating structures use a pontoon structure anchored to the seabed through spud piles or mooring lines and connected to the shore by bridges or ramps. Floating piers are most commonly found in small-craft marinas and include foam-filled concrete floats, steel pontoons, or plastic encased foam-filled pontoons joined and connected with a steel, aluminum, or timber frame and deck. Modular steel pontoon systems are also used for marine construction including shore landings. The Third Lake Washington Floating Bridge in Seattle is a 105 ft wide 1 mile bridge that includes a series of pontoons. The US Navy has developed concepts [31.14] for large concrete floating pier; however, a prototype has not yet been built. Some of the largest floating structures are concrete breakwaters including the world's largest at La Condaime Port in Monaco 352 m long by 28 m wide.

A variation, semibuoyant structure, utilizes a pontoon or an underwater chamber for the partial support of the pier. Similar to floating structures, caissons are floated into place then sunk onto a pile or other foundation. They are useful where firm-bearing material is at great depth and buoyancy provided by caisson offsets the pile loads, reducing the number of piles required. An example includes Pier 57 in New York City.

31.2.6 Swinging Moorings

Swinging moorings, referred to as fleet moorings in Navy parlance, include moorings where the ship is not berthed against a structure; rather, it is allowed to swing freely on a mooring in a basin, river, harbor, or sea. In its simplest form, a ship-dropping anchor is a temporary mooring under benign conditions. A large area or a ship-swing watch area is required (Fig. 31.21). Two or

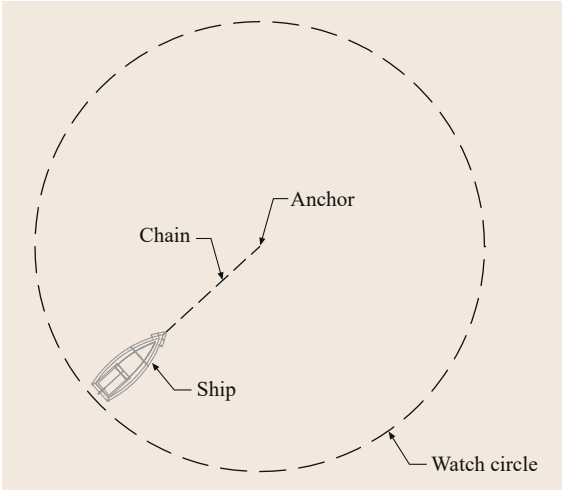

Fig. 31.21 Single-point mooring watch circle

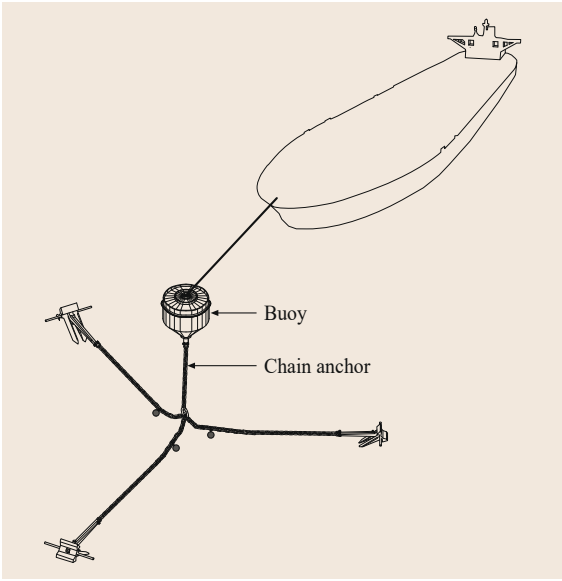

Fig. 31.22 Single-point mooring

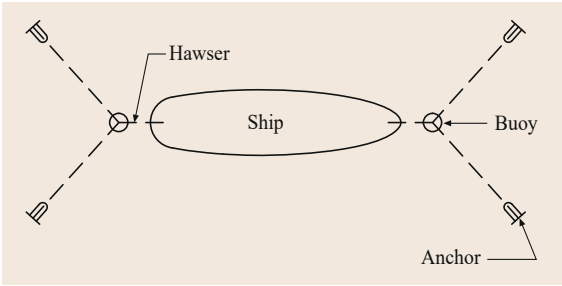

Fig. 31.23 Bow-stern mooring

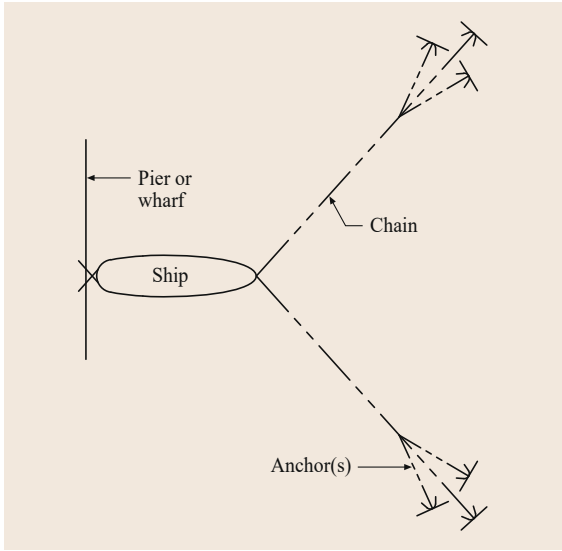

Fig. 31.24 Mediterranean mooring

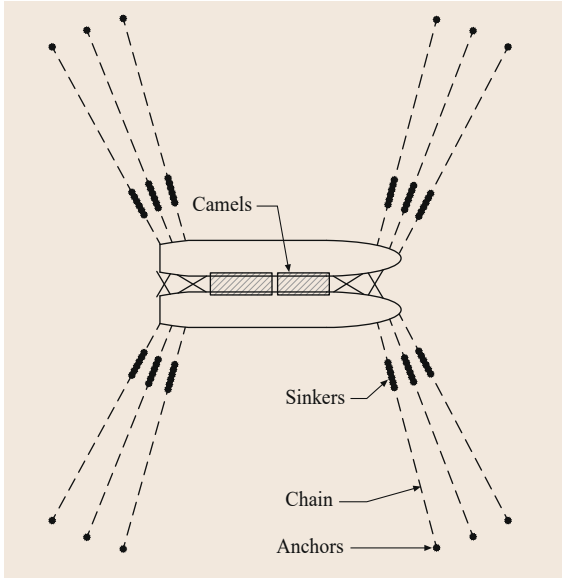

Fig. 31.25 Spread mooring

more anchors may be used to decrease the watch area or deal with shifting wind, crowded anchorages, twisted ropes, etc., including Bahamian mooring, dual anchor mooring, fore and aft mooring, hammerlock mooring, dual tandem mooring, star, and modified star but are usually not the subject of marine engineering, and the readers should, if interested, do their own research on subject. The other type of swing moorings is structural elements to which a vessel is moored including anchors, ground legs, a riser chain, a buoy, and other mooring hardware. These include single-point mooring (SPM), bow-stern mooring, Mediterranean mooring, and spread mooring.

Single-Point Mooring (SPM)

An SPM consists of a buoy anchored to a base on the seabed (Fig. 31.22). There are literally dozens of types of SPMs depending on the method of anchoring the buoy to the seabed, which can include chains acting as catenaries, pretensioned chains, or underwater towers structures. SPMs include riser type where a single chain anchors the buoy and whose bottom is secured with one or more chains. Telephone-type moorings include buoys secured with multiple chains to the seabed. A ship moors to the buoy using an anchor chain or hawser and weathervanes about the buoy depending on the wind and current direction and speed. In its simplest form, SPMs consist of an anchor, catenary chain, and buoy that are used to moor small craft boats on rivers and bays. The largest SPMs are used to moor VLCCs and ULCCs and transfer liquid petroleum prod-

Fig. 31.26 North river ice breakers (courtesy of J. Carel)

uct from the mooring to shore. The design of SPMs is a specialized area of marine engineering. Two references include [31.15] and [31.16].

Bow–Stern Moorings

Bow-Stern Moorings aka double- or twin-buoy moorings (Fig. 31.23) are similar to SPMs except buoys are provided and the ship is secured to buoys at both ends of the vessel. This system has a much smaller watch circle than a vessel at a single mooring buoy. Also, two moorings share the load. However, the mooring tension can be much higher if the winds, currents, or waves have a large broadside component to the ship.

Mediterranean Mooring

Med mooring or Tahitian mooring (Fig. 31.24) the vessel bow is secured to two mooring buoys and the stern is moored to the end of a quay, pier, or wharf. This type is the most common for tenders or where the harbor space is limited.

Spread Moorings

Spread moorings (Fig. 31.25) use multiple mooring legs to secure a vessel. Spread moorings are especially useful for securing permanently or semi-permanently moored vessels, such as floating drydocks and inactive vessels. With spread moorings, the ships are usually oriented parallel to the current. Marine and Coastal Engineers involvement typically involves developing oceanographic and environmental loads (wind, waves, current, and ice) on the vessel.

31.2.7 Ice Breakers

Ice breakers (Fig. 31.26) are commonly provided to break up large ice floes during spring thaw and protect structures along riverbanks. Their design is governed by current speed and ice sheet size flowing downriver. They may be constructed of any material but typically utilize steel rails or beams to actually break up ice by both lifting and separating the ice sheets.

31.3 Loads on Structures due to Vessel Mooring and Berthing

31.3.1 Vessel Berthing Loads

Berthing loads are imparted onto a structure as a vessel docks at a berth due to its kinetic energy which reduces to zero as it comes to rest at a berth. This kinetic energy $KE = \frac{1}{2}MV_b^2$ of the moving vessel is a function of the mass of the vessel M and its berthing velocity V_b normal to the berth where:

- M = the vessel's displacement tonnage divided by gravity g plus an added mass of water moving along with the vessel. Displacement tonnage may not be the vessel's maximum tonnage and will depend on the type of facility (import, export, both) and its order of call (is the vessel lighter due to unloading at other port of call). Do not confuse ship's displacement tonnage with dead weight tonnage (DWT), the ship's carrying capacity or other terms, such as gross or net tonnage.
- V = the Vessel's approaching speed which is perpendicular to the berth.

The ship's velocity is a function of vessel size, method of berthing (tug assist or self), exposure of the dock, ease of navigation, and physical exposure conditions, including wind, waves, and currents. This kinetic energy on berthing must be resisted by the work done by the pier or wharf during impact. The ship's kinetic energy is transferred and absorbed by the fender in the form of work done as the fender is compressed. For detailed descriptions of the phenomena involved, see *Costa* [31.17].

A fender is usually provided to resist vessel berthing energy and distribute resulting loads to the pier or wharf structure. Such systems have evolved from simple timber piles with wales and chocks to various rubber and synthetic rubber compound shapes and forms with and without fender piles. Some of the most common types currently used include cell fenders (Fig. 31.27) and foam-filled fenders and low-budget ubiquitous old truck tires (Fig. 31.28). Table 5 of [31.2] and Section 5.3 of [31.12] provide illustrations of various fender types.

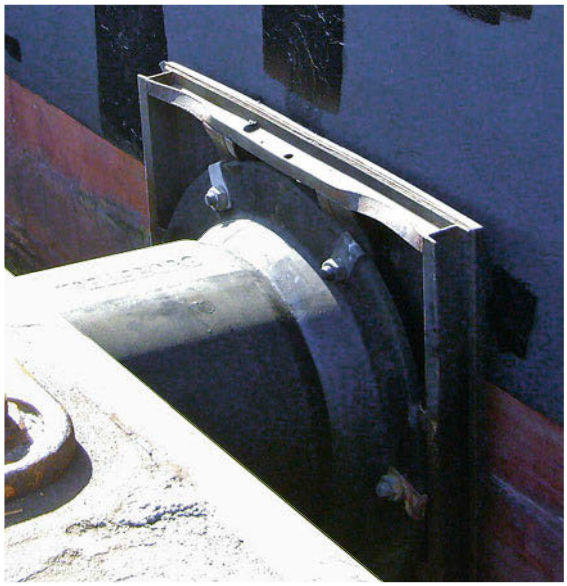

Fig. 31.27 Cell type fender (courtesy of AECOM)

Fig. 31.28 Used tire fendering (courtesy of AECOM)

The required design energy for a fender could be calculated by the following equation,

$$KE_{\text{design}} = \frac{1}{2} M V_{\text{b}}^2 C_{\text{m}} C_{\text{e}} C_{\text{s}} C_{\text{c}} \,,$$

in which:

- C_{m} = added mass factor of vessel
- C_{e} = eccentricity factor added mass factor of vessel (depending on the vessel characteristics, berthing, contact point, and berthing angle)
- C_{s} = softness factor (depending on the ratio between the elasticity for the fender system and that of the vessel's hull)
- C_{c} = berth configuration factor (depending on the pier structure type, keel clearance, berthing pattern, and vessel's hull, and fender's thickness).

It should be noted that abnormal impact should be considered in most fender designs. The abnormal factor applied to the design will depend on the size (the smaller the vessel, the larger the abnormal factor should apply); type of the design vessel, and the site-specific conditions; it is usually in the range from 1.25 to 2.0.

Fender device design is based on the above vessel energies, and the method of berthing. The area of the fender is dependent on the number of fenders, the vessel hull radius, the vessel's angle of approach, etc. Detailed guidance on calculating vessel berthing loads and required fender energy absorption can be found in [31.18], and [31.2] provides detailed guidance on this subject as does [31.12, Chap. 5]. Most major fender manufacturers also provide guidance based on these standards. These standards also provide guidance for vessel sizes based on the class of vessel. Guidance on confidence levels for ship dimensions can be found in [31.19]. Abnormal higher than usual impacts resulting from mishandling or accidents should also be considered. Another source for obtaining vessels characteristics is [31.20].

In most scenarios, the vessel berthing load on the structure is a complicated process. However, for practical design purpose, this load can be approximately estimated from the reaction–deflection curve of the design fender (rated–reaction).

31.3.2 Mooring Loads

Mooring loads are important for the lateral capacity design of pier and wharf structures. In port and harbor projects, vessel mooring loads are usually caused by external environmental conditions acting on the ship, such as wind, current, waves/swell, tidal variations, and passing vessel.

For most protected docks, if the effect of waves is minor and the tidal range is not significant, it may be sufficient to design the mooring system to withstand wind and current forces only. In this situation, the mooring loads can be estimated either by hand/spreadsheet calculation (see related OCIMF references) or a static mooring analysis program. The basic governing equations for static mooring analyses are as follows

$$\left(\sum \frac{\partial F_x}{\partial x}\right)\Delta x + \left(\sum \frac{\partial F_x}{\partial y}\right)\Delta y + \left(\sum \frac{\partial F_x}{\partial \theta}\right)\Delta \theta = -F_{x\text{a}} - \sum F_x \,,$$

$$\left(\sum \frac{\partial F_y}{\partial x}\right)\Delta x + \left(\sum \frac{\partial F_y}{\partial y}\right)\Delta y + \left(\sum \frac{\partial F_y}{\partial \theta}\right)\Delta\theta = -F_{ya} - \sum F_y \,,$$

$$\left(\sum \frac{\partial M_{xy}}{\partial x}\right)\Delta x + \left(\sum \frac{\partial M_{xy}}{\partial y}\right)\Delta y + \left(\sum \frac{\partial M_{xy}}{\partial \theta}\right)\Delta\theta = -M_{xa} - \sum M_{xy} \,,$$

where:

- F_x and F_y = x-direction and y-direction components of forces exerted on vessel by mooring lines
- M_{xy} = yaw moment on vessel due to load in mooring lines
- F_{xa} and F_{ya} = x-direction and y-direction components of total applied load on vessel due to wind and current
- M_{xya} = yaw moment on vessel due to applied wind and current loads
- Δx, Δy, and $\Delta\theta$ = finite vessel motion increment.

The above set of vessel equations can be solved by the iteration method to obtain a method for Δx, Δy, and $\Delta\theta$. The vessel is moved to $x + \Delta x$, $y + \Delta y$, and $\theta + \Delta\theta$, and the process is repeated until the computed total force components are all within the specified tolerance. Once the final displacement of vessel (Δx, Δy, and $\Delta\theta$) is determined, the corresponding mooring loads on mooring lines could be estimated based on the load-elongation/excursion curve of mooring lines/chains.

At offshore, nearshore, or unprotected berths, sites where waves are considerable or significant tidal variations or berths along the narrow channel where vessels pass closely, the effects of waves, tides, and passing vessel must be included in the analysis. As a commonly accepted practice in the marine engineering community, under this situation, a dynamic mooring analysis has to be conducted, which is much more complicated than the static mooring analysis.

In general, there are two categories of numerical models for dynamic mooring analysis: frequency-domain analysis model and time-domain analysis model.

The motions of a moored vessel in three-dimensional space can be described by six degrees of freedom (surge, sway, heave, roll, pitch, and yaw) in a right-handed coordinate system (x, y, z). Initially, the vessel is at rest with its center of gravity (COG) in the origin of the space-fixed coordinate system. The motion of a moored vessel can be represented by displacements in the x-, y-, and z-directions (surge, sway, and heave, respectively), and rotations about the x-, y-, and z-axes (roll, pitch, and yaw, respectively).

The motion of the moored vessel in the frequency domain can be represented by the following set of equations,

$$\sum_{j=1}^{6}\{(M_{kj} + A_{kj})\ddot{x}_j + B_{kj}\dot{x}_j + C_{kj}x_j\} = F_k^{\text{wave}} + F_k^{\text{other}}, \quad k = 1, 2, \ldots, 6 \,,$$

where

Vessel mass and inertia M_{kj} :

$$= \begin{bmatrix} m & 0 & 0 & 0 & 0 & 0 \\ 0 & m & 0 & 0 & 0 & 0 \\ 0 & 0 & m & 0 & 0 & 0 \\ 0 & 0 & 0 & I_{44} & 0 & -I_{46} \\ 0 & 0 & 0 & 0 & I_{55} & 0 \\ 0 & 0 & 0 & -I_{46} & 0 & I_{66} \end{bmatrix}.$$

- A_{kj} = vessel frequency-dependent added mass coefficient matrix
- B_{kj} = vessel frequency-dependent damping coefficient matrix
- C_{kj} = hydrodynamic restoring force matrix
- x_j = vessel displacement or rotation in surge, sway, heave, roll, pitch, and yaw
- F_k^{wave} = wave-induced excitations (force or moment)
- F_k^{other} = all other external forces (such as wind and current) and mooring constraints (such as mooring lines and fenders).

It must be realized that a major assumption made for a frequency-domain approach is that all the right-side items in the above-mentioned equation (wave-induced excitations, all other external forces and mooring constraints) vary sinusoidally at a single frequency and the coefficients on the left-hand side of the equation are constant (or nearly constant) for that frequency. However, in most cases, this assumption is invalid because of the nonlinear behavior of the mooring system.

The shortcomings of a frequency-domain model can be overcome by using a time-domain model at the expense of added complexity and computational effort.

The vessel motion in the time domain could be described by a set of equations as follows

$$\sum_{j=1}^{6}\left\{(M_{kj} + m_{kj})\ddot{x}_j + \int_{-\infty}^{t} R_{kj}(t-\tau)\dot{x}_j + C_{kj}x_j\right\} = F_k^{\text{wave}} + F_k^{\text{other}} \,, \quad k = 1, 2, \ldots 6 \,,$$

in which, the retardation function

$$R_{kj}(t) = \frac{2}{\pi} \int_0^\infty B_{kj}(\omega) \cos(\omega t)\, \mathrm{d}\omega \,,$$

where:

- ω = the wave frequency (rad/sec)
- m_{kj} = vessel-frequency-independent added mass coefficient matrix and can be obtained from the following equation
- $m_{kj} = A_{kj}(\omega') + \frac{1}{\omega'} \int_0^\infty R_{kj}(t) \sin(\omega' t)\, \mathrm{d}t$
- ω' = an arbitrarily chosen value of ω. The result for m_{kj} is independent of the value of $\omega' A_{kj}(\omega')$ and is the frequency-dependent added mass of vessel.

The set of vessel motion equations in time domain can be solved for x_j for each time step, and the corresponding mooring loads can be obtained from the known load-elongation curve for the mooring line or the load-excursion curve for the chain and anchor, or the reaction-deflection curve for the fender (if applicable). The wave forces (first order of wave load, the mean drift wave force, and oscillating drift wave force) can be computed though utilizing the corresponding vessel hydrodynamic database.

Commercially available programs have been developed for mooring analysis both by static and dynamic methods. These include [31.21] for static analysis, [31.22] for a time-domain dynamic method, and [31.23] for both frequency and time-domain dynamic models.

Depending on site-specific conditions (metocean, type, and size of vessel, and mooring layout) and the project phase (feasibility study, conceptual design, preliminary design, or final design), and available budget, the complexity of this analysis varies from very simple hand calculations to complicated dynamic computer-aided mooring models. For a vessel moored at a pier or wharf, typical input data for a dynamic mooring analysis model include the vessel characteristics (length overall, length between perpendiculars, beam, loading condition, draft, vessel displacement, windage areas, fairlead coordinates, mooring line properties, winches/bollard capacity), basin water depth, metocean conditions at berth, fender or dolphin locations and properties, and safe working capacity of on-shore mooring fittings. The output of analysis includes mooring loads and, if applicable to vessel unloading requirements, vessel responses in surge, sway, heave, roll, pitch, and yaw. References [31.2], [31.16], [31.24] and [31.25] can be used as references.

Vessel collisions with marine structures are rare and infrequent but have occurred in the past. There are no definitive standards or requirements for design for such events, typically an errant barge, but occasionally for a ship that has lost power. Coastal engineers may occasionally be required to recommend design requirements that can typically be based on actual vessel traffic which in the US is available through the US Coast Guard. The authors of [31.26, Sect. 3.14] provides some guidance for bridge structures, which can serve as guidelines for marine structures.

31.3.3 Loads on Structures due to Ocean Environmental Conditions

The load sources in the ocean environment include wind, wave, current, tide and storm surge, ice, tsunamis caused by earthquakes, and vessel propeller wash. Among these load sources, for the majority of situation, the wave load is the most complicated and the most important load that needs to be analyzed for the port and harbor structure design.

Wind

Wind load could be critical in some cases. Strong winds can be generated by hurricanes, typhoons, tropical storms, and locally generated storms. For port and harbor design, long-term wind records are usually required to derive the extreme wind for different return periods. When such records are not available, numerical wind models are often employed. It needs to be realized that it is difficult to predict the wind with sufficient accuracy with numerical models. Due to its dynamic nature, the accurate calculation of wind load on marine structures is difficult. In most situations, appropriate approaches are employed. Depending on the input of wind to the formula or model, there are two methods commonly used for wind load calculation. The first method for wind load calculation is to use constant speed. The second method for it is to use constant wind speed plus gusting wind. The commonly used wind spectrums for wind gusting include API, Ochi-Shin, and Harris-DNV. When performing the wind load calculations, it is important to apply the concept of wind duration. For rigid marine structures, it is reasonable to use the 3 s gust, as is used by most building codes. However, for the vessel, a much longer wind duration needs to be used for the wind load calculation. Depending on the size of the vessel and corresponding anchor or mooring system, it could be of the range from 15 to 60 s. Many references are available for wind load calculation, these include [31.27–29], etc.

Waves

For port or harbor design, the wave prediction and wave loads are a primary concerns for the designer. For many

sheltered ports or harbors, wave diffraction analysis is required to derive the appropriate design wave parameters for wave-loading calculation. In general, the accurate prediction of the wave load is extremely difficult due to the dynamic and nonlinear nature of waves and the fluid–structure interaction. The magnitude of wave loads depends not only on the wave height and wave period, but also on the ratio of wavelength to the dimension of the structure. If the structure is relatively slender compared to the wavelength, the drag and inertia forces dominate and the Morison equation can be used to calculate the wave load. If the structure's dimension is larger than the wavelength, the wave reflection will become important and the effect of wave reflection should be considered in the wave load calculation. If the structure's dimension is between these two cases, the effects of wave diffraction will become important, and the wave-loading calculation will become more complicated. For wave loadings on floating structures, in additional wave height, wave period, and structure's dimension, the wave load will also depend on the anchor system and the natural frequency of the floating structure. It needs to be realized that the wave load and corresponding calculation are different for breaking and nonbreaking waves. The impact force on structures caused by wave breaking is significant larger than the quasi-static wave force used in the most wave load formulas. For more detailed wave-loading analysis, the major references include USACE (United States Army Corps of Engineers) Coastal Engineering Manual (CEM) [31.6] and British Standard 6325 [31.28]. National codes and guidelines, and related ocean and coastal engineering design books can provide further guidance.

Current

In the marine environment, the magnitude and direction of a current at a site vary not only with time, but also with the vertical water-depth profile. The current could be tidal current, river discharge currents (within the estuary), wind-generated surface currents, wave-induced currents, and currents caused by vessel propeller wash. The current load acting on a structure usually consists of a static component and an oscillatory component. However, for port or harbor design, in majority cases, the maximum depth-averaged current under the design storm condition is employed in the current force formula. For more detail on the current-loading calculations, the reader may refer to [31.6, 28].

31.3.4 Tide and Storm Surge

The water-level change by tide and storm surge will have effects on structure loads. These effects include hydrostatic pressure change, soil surcharge change, change on the mooring line loads and fender load, change in the wave overtopping rate and corresponding impact force, and change in the wave uplift force on the pier deck due to the change of the air gap. For port or harbor structure design, the effects of tide and storm surge on the load calculation should be considered in the design.

31.3.5 Ice

In some ports or harbors, the load caused by the sea ice on the marine structures includes the impact (or thrust) load from floating drift ice, increased weight and area (for current load), uplift due to the decrease of the air gap for pier deck, etc. The above effects need to be considered when performing the port or harbor structure design.

31.3.6 Tsunamis

Tsunamis are actually one type of long waves. They are mainly caused by earthquakes. Though heights of these waves are small in deep water, they can be amplified significantly when these long waves propagate close to the shore if the sea bottom slope is steep. Tsunamis could be disasters for port or harbor facilities and moored vessels. For more details on the mitigation of tsunami disasters in port planning and design, readers can refer to PIANC [31.30].

31.4 Suggested Reading

This chapter is not intended to be a comprehensive manual on the planning and design of ports and harbors. For more detailed information on the civil and structural design of ports and harbors, it is suggested to refer to more detailed international design standards and publications, such as the following:

- Department of Defense, United States of America, UFC 4-152 *Design Piers and Wharves*, 2012: This Unified Facilities Criteria (UFC) document contains descriptions and design criteria for pier and wharf construction, including subsidiary, contiguous, and auxiliary structures. Loading details, regulations,

furnishings, appurtenances, and other information are discussed when applicable. This UFC provides minimum facility planning and design criteria for efficient homeporting facilities of Naval vessels. Existing ports, facilities, and berths may not meet all criteria and may, therefore, perform less efficiently, but they do not necessarily require to be upgraded. This UFC focuses on the entire homeport operation. UFC documents are available through Whole Building Design Guide, National Institute of Building Sciences (NIBS), 1090 Vermont Avenue NW, Suite 700, Washington, DC 20005 can be only be downloaded for free at their web site: http://www.wbdg.org

- Overseas Coastal Area Development Institute of Japan (OCDI), *Technical Standards and Commentaries for Port and Harbor Facilities in Japan*, 3-2-4 Kasumigaseki, Chiyoda-ka, Tokyo. This manual covers a wide variety of port and harbor facilities and structure types. It provides the detailed design guidance on foundations, navigation channels and basins, protective structures, and mooring facilities available at http://www.ocdi.or.jp/en/public.html.
- Oil Companies International Marine Forum (OCIMF): The OCIMF, 9 Queen Anne's Gate, London SW1H 9BU, England provides a series of publications related to the design of marine oil terminals and moorings. These include: Guidelines for the Design, Operation and Maintenance of Multi-Buoy Moorings (MBM); Jetty Maintenance and Inspection Guide; Mooring Equipment Guidelines (MEG3); and the Single Point Mooring Maintenance and Operations Guide. OCIMF documents, published by Witherby and Co, London can be ordered from their web site: www.ocimf.com/Library/Books.
- Permanent International Association of Navigation Congresses (PIANC) is a global organization providing guidance for sustainable waterborne transport infrastructure for ports and waterways. It is a forum where professionals around the world join forces to provide expert advice on cost-effective, reliable, and sustainable infrastructure to facilitate the growth of waterborne transport. Established in 1885, PIANC continues to be a leading partner for the government and private sector in the design, development, and maintenance of ports, waterways, and coastal areas. As a nonpolitical and nonprofit organization, PIANC brings together international experts on technical, economic, and environmental issues pertaining to waterborne transport infrastructure. Members include national governments and public authorities, corporations, and interested individuals. With expert guidance and technical advice, PIANC provides guidance to public and private partners through high-quality technical reports. Their international working groups develop regular technical updates on pressing global issues to benefit members on shared best practices. PIANC is headquartered at Bâtiment Graaf de Ferraris – 11ième étage, Blvd. du Roi Albert II, 20 – Boîte 3 B-1000 Bruxelles (la Belgique) and Technical Reports can be ordered on their website: www.pianc.org.
- British Standards Institution (BSI), 389 Chiswick High Road, London, W4 4AL, England, provides guidance on the criteria relevant to the planning, design, construction, and maintenance of structures in a maritime environment and located at or close to the shore and covers environmental factors, operational requirements, sea state, loadings, geotechnics, materials, and protective measures. The various standards under BS 6349 Maritime Structures include BS 6349-1 Code of Practice for General Criteria; BS 6349-2, Design of Quay Walls, Jetties, and Dolphins; BS 6349-3 Design of Dry Docks, Locks, Slipways and Shipbuilding Berths, Shiplifts and Dock and Lock Gates; BS 6349-4 Code of Practice for Design of Fendering and Mooring Systems; BS 6349-5: Code of Practice for Dredging and Land Reclamation; BS 6349-6: Design of inshore moorings and floating structures; BS 6349-7: Guide to the Design and Construction of Breakwaters; BS 6349-8: Code of Practice for the Design of Ro-Ro Ramps, Linkspans and Walkways. These standards can be ordered from the BSI website: http://shop.bsigroup.com/en/.

Reference books covering the full range of planning and design of marine structures include [31.31–38], as well as the following titles:

- Task Committee on Marinas 2020 of the Ports and Harbors Committee of the Coasts, Oceans, Ports, and Rivers Institute (COPRI) of the American Society of Civil Engineers (ASCE) *Planning and Design Guidelines for Small Craft Harbors*, ASCE Manuals and Reports on Engineering Practice No. 50, American Society of Civil Engineers, Reston, Virginia, 2012.
- Drydock Asset Management Task Committee of the Ports and Harbor Committee of the COPRI of the ASCE, *Safe Operation and Maintenance of Dry Dock Facilities*, ASCE Manuals and Reports on Engineering Practices No. 121, American Society of Civil Engineers, Reston Virginia, 2010.

31.5 Notation

A_{kj} vessel frequency-dependent added mass coefficient matrix
B_{kj} vessel frequency-dependent damping coefficient matrix
C_c berth configuration factor
C_e eccentricity factor during berthing
C_{kj} hydrodynamic restoring force matrix
C_m added mass factor of vessel
C_s softness factor during berthing
DWT deadweight tonnage of a ship, total carrying capacity
F_{ax} x-direction component of total applied load on vessel due to wind and current
F_{ay} y-direction component of total applied load on vessel due to wind and current
F_x x-direction component of forces exerted on vessel by mooring lines
F_y y-direction component of forces exerted on vessel by mooring lines
LBP length between the perpendicular sides of a vessel
LOA length overall of a ship
M vessel mass
m_{kj} vessel-frequency-independent added mass coefficient matrix and can be obtained from equation below
M_{xy} yaw moment on vessel due to load in mooring lines
M_{xya} yaw moment on vessel due to applied wind and current loads
SPM single point mooring
TEU twenty foot equivalent unit container
V vessel approach velocity
x_j vessel displacement or rotation in surge, sway, heave, roll, pitch, and yaw
ω wave frequency [rad/s]
F_k^{other} all other external forces and mooring constraints.
F_k^{wave} wave-induced excitations (force or moment)

32. Marine Outfalls

Peter M. Tate, Salvatore Scaturro, Bruce Cathers

Marine outfalls are used to discharge treated liquid waste to the environment. Not all contaminants in liquid waste can be removed by treatment. A properly designed, constructed, and operated marine outfall effectively dilutes the discharged waste which then substantially reduces the concentration of contaminants in the wastewater. In turn, this reduces the risk to biota and human users of the marine environment. An introduction to some of the main aspects of marine outfalls is provided.

Five areas are covered, commencing with the main influences associated with the decision to build a marine outfall. Included is an overview of the wastewater treatment process. Near-field numerical modeling is described and it is demonstrated how this tool can be used to assist with the design of a marine outfall. Outfall hydraulics is discussed, detailing a range of features including head losses, manifolds (or diffusers), seawater intrusion, and air entrainment. A very brief summary of the construction of a marine outfall is provided. The final area covered describes environmental monitoring that should be undertaken to confirm the putative impacts associated with a marine outfall.

32.6.3 Long-Term Monitoring 738
32.6.4 Summary 739

References 739

Work presented in this chapter concentrates on the discharge of wastewater to the environment through marine outfalls. Marine structures are required for intakes for drinking water (e.g., extraction of some types of minerals, cooling of thermoelectric power equipment, desalination plants) and water for industrial or commercial use (e.g., flushing of toilets). The focus here is on marine outfalls; marine intakes are not considered further.

The primary objective of this chapter is to provide practitioners with an overview of the fundamentals of marine outfalls and to outline some initial considerations to help those new to the subject area. Understandably, the present chapter does not cover all areas in detail; the focus is on the design and monitoring aspects of marine outfalls. Information on some of the problems drawn from experience with marine outfalls is provided and reference material with additional detail is identified.

32.1 Terminology

The following terminology is used throughout this chapter. Sewage is the raw input to a municipal wastewater treatment plant, the product of which is effluent. Seawater is the raw input to a desalination plant, the product of which is brine. Wastewater refers to either effluent or brine. An outfall refers to the disposal system from the treatment plant to the discharge outlets. The manifold is that part of the outfall from which there is a series of offtakes, termed risers. A diffuser comprises that section of the outfall which includes the manifold and the risers.

Two generalized marine outfalls are shown in Fig. 32.1. Figure 32.1a shows the discharge of positively buoyant effluent from a wastewater treatment plant and Fig. 32.1b shows the discharge of negatively buoyant brine from a desalination plant. Both schematics show an inclined tunnel from the wastewater treatment plant, the outfall tunnel, a diffuser comprising several risers, and the wastewater plume emanating from outlet nozzles on the top of each riser. The outfall tunnel is inclined upward to ensure any air trapped in the declined tunnel exits though the outlet nozzles (or ports) and does not remain in the tunnel. The number of risers, separation distance between risers, length of each riser and number of outlet nozzles on each riser will depend on the specific needs for each outfall.

Some points to note are provided later:

- It is advantageous to locate the diffuser in fast flowing ambient waters. This will enhance dilution of the wastewater and rapidly transport the wastewater away from the diffuser.
- For effluent discharge, the outlet nozzles are usually horizontal. Effluent is less dense than the ambient marine waters and will rise to the sea surface or, if the stratification is sufficiently strong, become trapped below the surface. In contrast, outlet nozzles associated with a brine discharge are angled toward the surface (often, an angle of 60° to the horizontal is used). The density of brine is greater than that of seawater and it will fall toward the sea bed. Angling the outlet nozzles toward the surface and discharging the brine with high velocity will maximize its dilution.
- A pipeline may replace the tunnel as shown in Fig. 32.1. The pipeline is anchored to the sea bed and discharge is through outlet nozzles fixed to the pipeline. Risers are not used in these con-

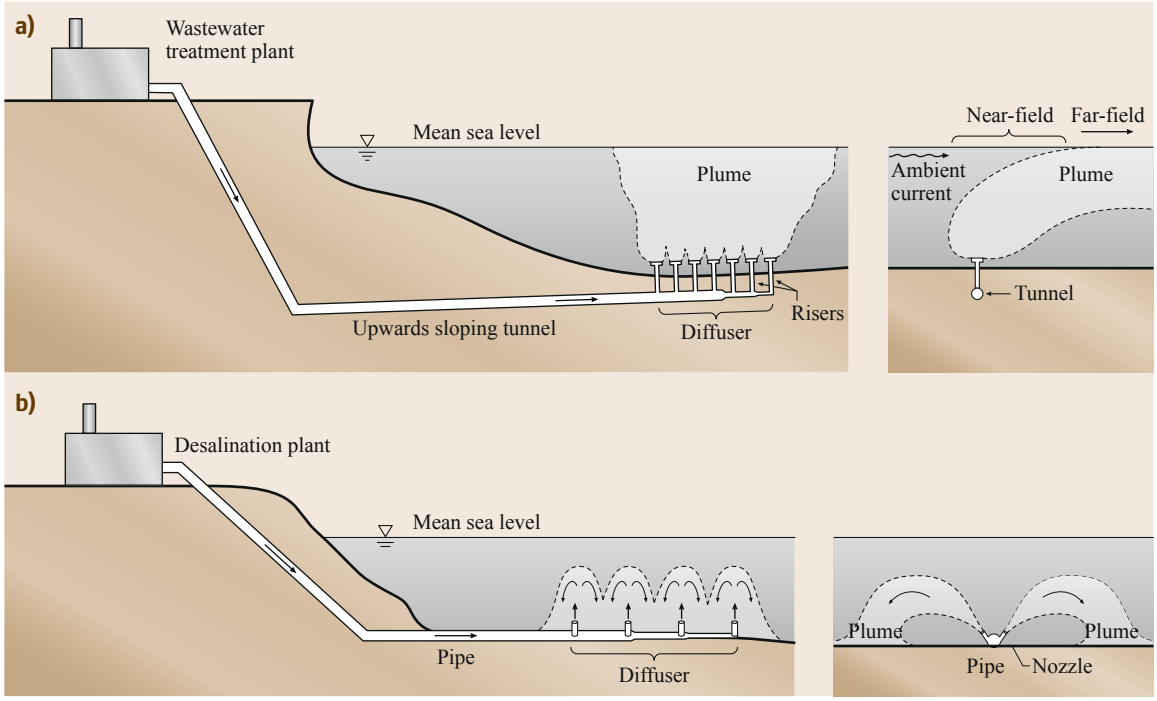

Fig. 32.1a,b Schematics of **(a)** a wastewater treatment plant outfall, and **(b)** a desalination plant outfall, showing side views and end views

figurations. (Risers are vertical structures used to transfer the wastewater from an outfall tunnel to the outlet nozzles. They may be tens of metres in length).
- The number of outlet nozzles attached to each riser is usually restricted to eight or less. If more than eight outlet nozzles are used, the plumes from adjacent nozzles interfere with each other and reduce the effective dilution of the wastewater.
- The outfall pipeline and diffuser may be tapered to ensure the velocity of the wastewater remains sufficiently high to prevent sediments from settling in the pipeline.
- Outlet nozzles may be fitted with nonreturn check valves (also called duckbill valves). These valves are closed when the wastewater flow is zero and prevent the ingress of seawater into the pipeline. One advantage of check valves is that they enhance dilution, compared with a round nozzle of the same cross-sectional area [32.1]. However, they may be fouled by biota or fishing nets, rendering them permanently open or closed.

32.2 Governance

There are many factors affecting the decision to build a marine outfall.

Municipal wastewater collects at the bottom of the catchment. For a coastal city, this is at the edge of the marine environment. There are large costs associated with the movement of wastewater to the top of a catchment for potable reuse, including construction of a pipe network, pumps, and energy required to operate the pumps. Furthermore, there may be high costs associated with the conversion of wastewater to potable water. The disposal of wastewater through a marine outfall may be the best overall use of resources. Despite this, the decision to proceed with a marine outfall should first examine other options and maximize the beneficial uses of recycled wastewater.

32.2.1 Drivers for a Marine Outfall

SPHERE is an acronym we use to describe the main factors overlying the need for government sponsored development (social, public health, environmental, regulation, economic). The first three elements of SPHERE represent the main aspects in which a marine outfall has an impact (i. e., the community values). The last two elements of SPHERE represent the constraints on the marine outfall – *regulation* tending toward high treatment and consequential high cost and *economic* tending toward low cost and consequential low treatment. Below, some of the considerations of SPHERE are described in the context of a marine outfall.

Most countries have environmental guidelines that need to be met during the design of a marine outfall. These guidelines are unique to each country and all cannot be detailed here. Suffice to say that they include meeting concentrations of contaminants which may include pathogens, nutrients, metals, and organics. These guidelines usually apply at the boundary of a mixing zone, which needs to be clearly defined prior to construction of the marine outfall.

Social

What does the community expect from a marine outfall? What are the values that are important to the community? This will vary among and within different geographical regions and cultural groups. Some communities will comprise a large number of beach users. To them, the concept of a marine outfall may not be palatable unless it can be clearly demonstrated that the marine outfall poses minimal risk to their use of the marine environment.

Public Health

Is it safe to swim in the marine waters? What are the types and concentrations of substances that will be discharged to the marine environment? Will they be of harm to us? Much information is available to inform us about of the potential harm of substances that may be discharged through a marine outfall. Most countries synthesize this information into a set of guidelines applicable to their marine environment. There is a tacit assumption that, provided the concentrations of the substances are kept below the guideline levels, the health of the users of the marine environment will be maintained. This does require knowledge of the types, concentrations, and variability of the substances in the wastewater. It should be noted here that all the substances are potentially toxic given sufficiently high concentrations and the environment into which they are discharged.

Environmental

Will the discharge of substances through the marine outfall cause harm to marine organisms? Will the marine environment be degraded into the future? Will the beaches and marine waters be free from visible pol-

lution – oil, grease, rags, etc.? As noted under *Public Health*, most countries have environmental guidelines. Provided these guidelines are met, it is assumed that the marine environment will be protected. The guidelines are usually in the form of concentrations of substances (e.g., metals, nutrients, and bacteria) that should be met at a specific distance from the outfall (this distance defines a mixing zone). This implies that there will be a region inside the mixing zone in which the guidelines may not be met. The consequences are that the biological diversity inside the mixing zone may not be the same as that in reference areas.

Regulation

What are the regulations that govern the discharge of any substance to the marine environment? Regulations are often in the form of licence conditions restricting the types, concentrations, and/or loads of substances that can be discharged to the marine environment. As noted above, there is a tacit assumption that keeping within these restrictions will ensure the safety of humans, and the protection of flora and fauna in the marine environment.

Economic

Governments will invest a large amount of money for the construction of a marine outfall. Ultimately, this money is raised through taxes and governments are accountable for the wise use of the taxes they collect. Outfall dollars will be competing with funding areas as diverse as education, security, and care for the aged. What does the community value? What is the community willing to pay to protect both humans and the environment? The marine outfall is just one of many options that should be considered. Ultimately there is a balance between the level of protection offered and the cost incurred by each option. It is the responsibility of the engineer and scientist to evaluate each option and provide the government with the most effective solution.

32.2.2 Wastewater Treatment

Our main focus in this section is on municipal outfalls. Critical to a marine outfall is knowledge of what is being discharged, particularly the types, concentrations, and variability of contaminants in the wastewater. Discharge of contaminants from other sources including private outfalls, rivers and estuaries, atmospheric inputs, discharges from vessels, and illegal dumping are not considered. The reader is referred to *Tchobanoglous* et al. [32.2], which provides considerable detail on wastewater treatment.

Wastewater discharges from domestic, commercial, and industrial sources. Often, the wastewater systems are not isolated from the environment and infiltration of water during storms may also occur. The composition of wastewater depends on the relative contribution of these three main sources and on the type and size of industry and/or commercial activity. Each wastewater system is unique and treatment plants are designed to deal with the quantity and quality of wastewater produced by a specific system.

Wastewater comprises particulate matter, pathogens, nutrients, organic, and inorganic material. Severe environmental damage can result if wastewater is discharged undiluted or without treatment. Therefore the main objective of sewage treatment is the elimination or reduction in concentration of these materials.

Different concentrations of substances will invoke different responses in different species. Metals may be adsorbed onto particulates that may be ingested by fish and shellfish. Organics are often adsorbed by the fatty tissues in aquatic animals. Reducing the concentrations of suspended solids, oil, and grease during the wastewater treatment process, reduces the quantity of metals and organics that may affect marine organisms.

Wastewater treatment can be broadly divided into three levels: primary, secondary and tertiary (or advanced). The levels are modular, subsequent treatments being *bolted* onto lower levels of treatment. Within each level of treatment there are multiple options that produce wastewater of similar quality. The distinction among the treatment levels themselves is blurred and will depend on how individual levels are operated and maintained. Usually, concentrations of suspended solids, biochemical oxygen demand (BOD), and indicator bacteria in the effluent are used to distinguish the levels of treatment. The type of wastewater treatment plant adopted is often based on the collective experience of the engineers and process workers within an organization.

Primary Treatment

Primary treatment removes debris that could damage the wastewater treatment system. This is done by passing the sewage through trash racks and screens. Sewage then flows through sedimentation tanks at low velocities ensuring residence times of 2–3 h or more [32.2]. This allows sufficient time for negatively buoyant solids to settle at the bottom of the tank and positively buoyant oils and greases to rise to the surface of the tank. Chemicals can be added to the sewage to accelerate the settling process. Both the solids and oil and grease can then be easily removed. Primary treatment also helps regulate the flow of sewage to subsequent levels of treatment. Primary treatment may be used in isolation, but this usually depends on the environment into which the wastewater is discharged.

Table 32.1 Median concentrations of substances in sewage and after various levels of treatment. The numbers are indicative only and may vary in time and between sewage treatment plants

Substance	Units	Raw sewage	Primary	Secondary	Tertiary
Faecal coliforms	cfu/100 ml	10^7	10^6	10^4	10
Suspended solids	mg/l	250	100	10	< 5
BOD	mg/l	200	100	10	< 5
Oil and grease	mg/l	50	20	< 5	< 5
Total nitrogen	mg/l	50	40	20	10
Total phosphorus	mg/l	10	7	5	3

Secondary Treatment

Secondary treatment covers a wide range of biological processes including: activated sludge, trickling filters, rotating biological contactors, aerated lagoons, oxidizing beds, and membrane bioreactors. The basic objective of all of these processes is the removal of organic material and suspended solids. Secondary treatment may also include disinfection to reduce the concentrations of bacteria in the wastewater. A common form of secondary treatment is activated sludge in which microorganisms are mixed with the wastewater under aerobic conditions for about 4–8 h. The microorganisms metabolize the organic matter in the wastewater, ultimately producing inorganic materials.

Tertiary Treatment

Tertiary treatment often involves the further removal of suspended materials using sand filters. High levels of nitrogen and phosphorus may remain in the wastewater after secondary treatment, which can contribute to excessive primary production and eutrophication. The basic premise for nitrogen removal is to convert nitrate to nitrogen gas, which is then discharged to the atmosphere. Biological processes and chemical precipitation are two methods used to remove phosphorus from the wastewater. Once removed, phosphate can be used as a fertilizer.

Microfiltration and reverse osmosis are specific forms of advanced wastewater treatment. The wastewater is forced through a fine membrane. The size of the membrane mesh is sufficient to allow the passage of water, but larger materials are captured and removed from the wastewater. Increasingly, micro- or milli-filtration are added to primary or secondary treatment processes. When combined with an effective outfall diffuser, the diluted wastewater may achieve licence requirements.

An indication of the median effluent concentrations of selected substances after treatment is given in Table 32.1. It is stressed that these are general values that will differ for specific wastewater treatment plants and are highly variable.

A desalination plant discharges brine in which the primary contaminant is salt. Median concentrations of brine are about 60 psu, although it may vary between 40 and 80 psu. The median salt content in seawater is about 35 psu. Marine organisms can tolerate salt concentrations to about 39 psu [32.3], although this value varies with different organisms. Therefore, the configuration of an outfall discharging brine to the marine environment should ensure a rapid reduction in salinity to less than 39 psu.

32.2.3 Data Collection for Outfall Design

While the preliminary design of a marine outfall can be undertaken using minimum data, the detailed design usually requires considerable data. The main aim for these data collection programs is identification of the site (or sites) for the marine outfall. That is, for the lowest cost, identifying the level of treatment and site that best meets the environmental (and other) guidelines.

The type and volume of data required depends on the marine outfall being considered. Broadly, data include: volume and flow rates of effluent to be discharged, water quality (both in the treated effluent and in the marine waters), ocean currents, and stratification. A critical aspect of monitoring, often overlooked, is the variability of these data. Our favored approach is to use the data variability in a Monte Carlo approach, running the models for many different combinations of input values. This results in a statistical distribution of the concentrations of contaminants in the marine waters, which can be synthesized in, for example, a probability of exceedance plot.

Historical data or data collected from different projects can be used. The difference between the data needs and the historical data defines a gap that a data collection program needs to fill. Much of the data collected as part of these studies can also be used in Sect. 32.6. Some of the main data collection programs are outlined below.

The volume of effluent flow can be estimated from human population projections. This information allows assessment of when environmental guidelines are likely to be exceeded; hence when upgrades of the treatment plant are likely to be needed.

Water quality in the treated effluent will be a function of the level of treatment. Estimates can be obtained from other, similar treatment plants or from the indicative values provided in Table 32.1. Ongoing monitoring of the effluent quality after construction will help ensure maintenance of environmental standards.

Measuring water quality in the marine waters (into which the wastewater is discharged) provides background concentrations of contaminants. The background concentrations must be added to the modeled concentrations to estimate the total concentration of contaminants in the marine waters. Background concentrations may already exceed environmental guidelines, in which case, they may need to be relaxed or another outfall location sought. To obtain a representative picture of marine water quality, sampling should take place over large spatial and temporal scales and should include replication. Instruments that can be moored in the field for long periods of time are increasingly being used to obtain water quality measurements, although the accuracy of such results is less than can be achieved in the laboratory.

Current speed and direction are important for plume dilution. Moored current meters can provide detailed temporal information at a point in space (or a profile throughout the water column). However, they are expensive to deploy, maintain and retrieve, and careful consideration needs to be made in regard to the number and location of such moorings. Spatial information can be obtained by profiling currents from a vessel underway, drifters drogued at specific depths and remotely sensed data (e.g., via satellites or airborne scanners). The number and duration of moored current meters will depend on the size of the outfall under consideration. For a moderately sized outfall, a single profiling current meter moored for 12 months and serviced monthly, provides the minimum data requirements. A roving current meter (deployed at different locations for one month at a time) may provide a compromise between the number of instruments and spatial coverage.

Density stratification of the water column largely governs the height of rise of the wastewater. (The effect is much reduced for brine discharges). In coastal marine waters, density is a function of both temperature and salinity, both of which should be measured. For shallow outfalls (outfalls in water depths less than about 10 m), stratification has little effect. However, for outfalls in deep waters, relatively small stratification may produce a submerged plume resulting in lower dilutions and a nonvisible plume (at least to a surface observer). Moored temperature/salinity strings provide a profile of density throughout the water column, although marine fouling will reduce the quality of data from salinity sensors. Such data can also be collected during the servicing of moored instruments, which may be monthly over a period of 12 months.

Other data such as surface waves and tides may also be important, particularly for shallow outfalls where the changes in water depth resulting from such processes may represent a significant proportion of the water column.

32.3 Predicting Near-Field Dilutions

The design of a marine outfall centers on the dilution required to meet the relevant guidelines. Occasionally, guidelines may be met after an appropriate level of sewage treatment. However, many substances will rely on the dilution with marine waters to meet these guidelines. Dilution depends on:

- Wastewater flowrate
- Depth of water into which the wastewater is discharged
- Length of the diffuser
- Outlet diameter (and whether a single or multiple outlets will be used)
- Configuration of the diffuser (e.g., whether T-section outlets or gas-burner type rosettes are used, whether nonreturn check valves are used)
- Ocean conditions (e.g., currents, stratification of the water column, tides, and ocean turbulence).

Together with cost, the above factors are used to optimize the location and configuration of the marine outfall. This is further discussed in Sect. 32.3.7

After discharge from the marine outfall, effluent rises (whereas brine descends) due to buoyancy (Fig. 32.1). The wastewater (effluent or brine) then mixes with the ambient currents and is diluted. Two types of models are used to quantify this process: near-field and far-field. This separation is made because the time and space scales of the processes in each model are substantially different.

In the near-field, the motion of the wastewater is dominated by its initial momentum and buoyancy; the velocities and rates of dilution are high. Up to 90% of wastewater dilution takes place within the near-field at the end of which most regulations apply. The engineer can configure the outfall design to maximize dilution in the near-field.

In the far-field, the wastewater is passively transported by the ambient currents and the rates of dilution are much lower than in the near-field. Far-field mixing is dominated by natural processes, over which the design engineer has little control.

While the use of both near-field and far-field models may be necessary for the detailed design of a marine outfall, we argue that near-field modeling alone may be adequate for the initial design and emphasis in the following sections is placed on near-field modeling.

This section provides a broad introduction to near-field modeling. *Wood* et al. [32.4] provide considerable detail on near-field modeling and many of the problems that may be encountered in the design of a marine outfall.

32.3.1 Physical Models

While the focus of this section is on near-field numerical modeling, it is recognized that physical modeling can also play an important role in the design of a marine outfall. Scaled physical models of prototype marine outfalls are sometimes constructed in the laboratory and used to examine the behavior of jets and plumes in the near-field. They provide good visualization of the plumes, particularly interactions between multiple plumes and include effects that are not found in most numerical models.

The fluids used in the model are typically fresh and saline water. The scales for such models are expressed as a ratio of a prototype quantity to a model quantity. Model design requires the selection of (i) the fluids which yield the reduced gravity ratio (g' defined below), (ii) the length scale to ensure that the model Reynolds numbers are sufficiently high to guarantee turbulent model flows and (iii) a scaling criterion which, in this case, is the densimetric Froude number (FR), i. e., there is a point-to-point correspondence of FR in prototype and model. This scaling criterion, together with the length scale, yields the velocity scale. Other scales for time, pressure and buoyancy force can then be determined. Although the inclusion of ambient currents in physical models is possible, it places greater demands on laboratory facilities and data acquisition systems.

Results from physical models may include information on dilutions, trajectories, the velocity field, and interactions between neighboring plumes.

32.3.2 Positively Buoyant Jets and Plumes

Two basic approaches to near-field numerical modeling are available: Eulerian and Lagrangian. A Lagrangian approach is followed in both *Lee* and *Cheung* [32.5] and *Tate* and *Middleton* [32.1, 6]. Central to either approach are the conservation equations for mass, momentum, and buoyancy. In a Lagrangian framework, they are:

- Mass conservation
$$\frac{\partial(\rho V)}{\partial t} = \rho_a f_{ent} U_{ent} A$$
- Momentum conservation
$$\frac{\partial(\rho V u_i)}{\partial t} = U_i \frac{\partial(\rho V)}{\partial t} + \rho g' V$$
- Buoyancy conservation
$$\frac{\partial(g' V)}{\partial t} = -N^2 u_i V ,$$

where ρ is the density of the jet/plume, ρ_a is the density of the ambient fluid, f_{ent} is an entrainment function, U_{ent} is the entrainment velocity, V is the volume of a buoyant fluid element, A is the cross-sectional area through which ambient water is entrained, u_i is the velocity of the buoyant fluid, U_i is the velocity of the ambient fluid, g' is the buoyancy modified gravity $(= (\Delta\rho g)/\rho_{ref}$, where ρ_{ref} is a reference density), and N is the Brunt–Väisälä frequency

$$N = \sqrt{-\left(\frac{g}{\rho_{ref}}\right)\frac{\partial \rho_a}{\partial z}} .$$

These governing equations are also applicable to negatively buoyant jets and plumes.

If the buoyant jet/plume (a) lies well away from its source (i. e., beyond the influence of the initial momentum), (b) is moving with the ambient fluid, and (c) the Boussinesq approximation is applied, then the above equations can be solved analytically to give what is known as the asymptotic results. These equations (Table 32.2) are equivalent to the *advected thermal* equations in *Wood* et al. [32.4] and the corresponding flow classifications are detailed in *Jirka* and *Akar* [32.7] and *Jirka* and *Doneker* [32.8].

Solutions to the asymptotic governing equations for positively buoyant plumes emerging from round (i. e., axisymmetric) outlet ports and from a slot (i. e., line source), in a flowing ambient fluid, with both linearly stratified or nonstratified marine waters, are presented in Table 32.2. It should be noted that these asymptotic solutions below should only be used at the conceptual stage of outfall design. For preliminary and detailed design, the full set of conservations equations above should be used and solved numerically.

The entrainment function has evolved from the constants used in *Morton* et al. [32.9] to a complex function of the densimetric Froude number, plume geometry, the velocity of the fluid inside the plume, and the velocity of the ambient current [32.5]. *Wood* et al. [32.4] use

Table 32.2 Solutions to the governing asymptotic equations for positively buoyant plumes when the ambient current speed is nonzero and the marine water density is linearly stratified (after [32.6]). Solutions to the asymptotic equations are applicable only at the end of the near field and do not include the outlet port diameter, angle of discharge, or the exit velocity

Axisymmetric source	Line source
$z(x) = \frac{0.98}{f_{ent}^{2/3}} \left(\frac{B_S[1-\cos(\frac{Nx}{U})]}{UN^2} \right)^{1/3}$	$z(x) = \frac{1.00}{f_{ent}^{1/2}} \left(\frac{B_S[1-\cos(\frac{Nx}{U})]}{UN^2} \right)^{1/2}$
$2b(z) = 2.00 f_{ent} z$	$2b(z) = 2.00 f_{ent} z$
$(z) = \frac{C_S}{C(z)} = 3.14 f_{ent}^2 U z^2 \frac{n_{ports}}{Q}$	$S(z) = \frac{C_S}{C(z)} = 2.00 f_{ent} U z \frac{L_D}{Q}$
$z_{max} = \frac{1.24}{f_{ent}^{2/3}} \left(\frac{B_S}{UN^2} \right)^{1/3}$	$z_{max} = \frac{1.41}{f_{ent}^{1/2}} \left(\frac{B_S}{UN^2} \right)^{1/2}$
$2b(z_{max}) = 2.48 f_{ent}^{1/3} \left(\frac{B_S}{UN^2} \right)^{1/3}$	$2b(z_{max}) = 2.82 f_{ent}^{1/2} \left(\frac{B_S}{UN^2} \right)^{1/2}$
$S(z_{max}) = \frac{C_S}{C(z_{max})} = 4.84 f_{ent}^{2/3} \left(\frac{UB_S^2}{N^4} \right)^{1/3} \frac{n_{ports}}{Q}$	$S(z_{max}) = \frac{C_S}{C(z_{max})} = 2.83 f_{ent}^{1/2} \left(\frac{UB_S}{N^2} \right)^{1/2} \frac{L_D}{Q}$

z is the elevation of the plume above the outlet [m], z_{max} is the maximum elevation (i. e., height of rise) of the plume [m], $S(z) = \frac{C_S}{C(z)}$ is the average dilution at elevation z, C_S is the concentration at the source [kg/m^3], $C(z)$ is average concentration at elevation z [kg/m^3], x is distance downstream from the outfall [m], f_{ent} is the dimensionless entrainment function, U is ambient current velocity [m/s], N is the Brunt–Väisälä frequency [1/s], where $N^2 = \frac{-g}{\overline{\rho_a}} \frac{d\rho_a}{dz}$, and $\overline{\rho_a}$ denotes a representative seawater density, $2b(z)$ is the diameter (or thickness) of the plume [m], Q is the flow through the outfall [m^3/s], L_D is the length of the diffuser [m], n_{ports} is the total number of outlet ports on the diffuser and, B_S is the buoyancy flux at the source, $B_S = g \frac{\rho_a - \rho_S}{\rho_S} \frac{Q}{n_{ports}}$ for an axisymmetric source and $B_S = g \frac{\rho_a - \rho_S}{\rho_S} \frac{Q}{L_D}$ for a line source, where ρ_S is the density of the wastewater at the source.

a spreading function to model the entrainment of ambient fluid into the plume.

32.3.3 Negatively Buoyant Jets

Research conducted on negatively buoyant jets over the past several decades has sought to quantify jet behavior using a variety of analytical and experimental techniques. Results from these studies have led to the development of proportionality coefficients which relate the jet densimetric Froude number and nozzle diameter to trajectory and dilution. The particular points of interest along the jet trajectory are the centerline peak (z_m) and return point (x_r) which are both defined in Fig. 32.2. A range of experimentally derived values for each of the proportionality coefficients compiled from various experimental studies are presented in Table 32.3, as reported in *Lai* and *Lee* [32.10]. Note that these coefficients are only valid for single jets discharging into quiescent ambient conditions from a nozzle orientated at 45° to the seabed. Coefficients for other discharge angles can be found throughout the research literature [32.11–17]. Current research on negatively buoyant jets focuses on multiport diffusers and discharge into receiving waters with ambient currents.

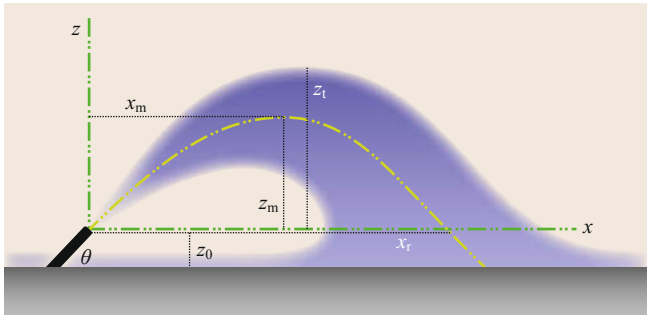

Fig. 32.2 Trajectory of a negatively buoyant jet

32.3.4 Model Validation

The information presented in Table 32.2 and Fig. 32.3 are based on asymptotic models i. e., results only at the end of the near-field and should only be used at the conceptual stage of outfall design. Full numerical models detail the movement of the wastewater from the outlet nozzle to the end of the near-field and include the nozzle size, the initial momentum of the wastewater and its trajectory. A limited set of results from the laboratory experiments of *Fan* [32.18] for a single outlet, discharging positively buoyant water into a flowing, unstratified ambient fluid are compared with several near-field models that have been used by the authors. The models are: IMPULSE [32.19], JETLAG [32.5], CORMIX [32.7, 8], OSPLM [32.4], and PLOOM [32.1, 6]. Fan's data set is used here because it is independent of the laboratory

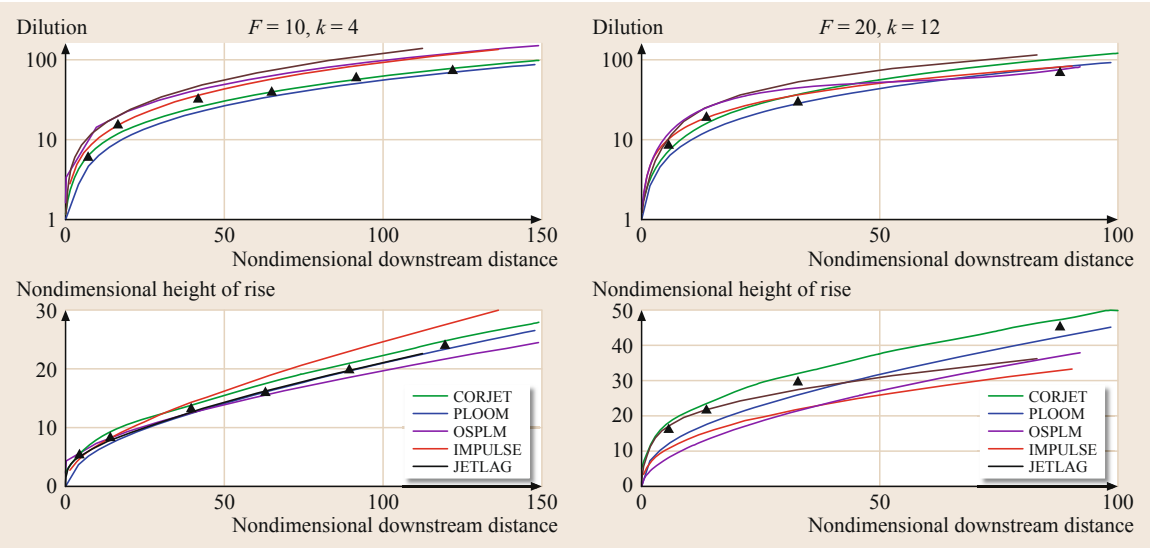

Fig. 32.3 Near-field model results for plume dilution and trajectory compared with laboratory data from *Fan* [32.18]

Table 32.3 Experimentally derived coefficients for a single negatively buoyant jet discharging into quiescent ambient conditions at an angle of 45° to the seabed (after *Lai* and *Lee* [32.10])

Description	Equation	Experimentally derived coefficients
Jet terminal rise height	$z_t = \frac{C_1}{D\mathrm{Fr}}$	$1.43 \le C_1 \le 1.61$
Horizontal location of return point	$x_r = \frac{C_2}{D\mathrm{Fr}}$	$2.82 \le C_2 \le 3.34$
Dilution at return point	$S_r = \frac{C_3}{\mathrm{Fr}}$	$1.09 \le C_3 \le 1.55$
Vertical location at jet trajectory centerline peak	$z_m = \frac{C_4}{D\mathrm{Fr}}$	$1.07 \le C_4 \le 1.19$
Horizontal location at jet trajectory centerline peak	$x_m = \frac{C_5}{D\mathrm{Fr}}$	$1.69 \le C_5 \le 2.09$

data collected by any of the above authors. The unique identifiers for Fan's experiments are FR, the densimetric Froude number

$$\mathrm{Fr} = \frac{u_{\mathrm{port}}}{\sqrt{g' d_{\mathrm{port}}}} ,$$

where u_{port} is the velocity through the outlet port, d_{port} is the diameter of the outlet port and

$$k = \frac{u_{\mathrm{port}}}{U}$$

and

$$g' = g\left(\frac{\rho_a - \rho_S}{\rho_S}\right) .$$

Compared with the laboratory data of *Fan* [32.18], these models all produce similar results (Fig. 32.3) providing confidence in the models themselves. However, it is recognized that different models may behave differently for different regimes and model selection needs to be appropriate to the problem under investigation. For example, a particular model may provide good estimates of dilution for outfalls comprising a single point discharge but poor estimates of dilution for outfalls comprising a long diffuser with multiple risers and outlet nozzles. It is stressed that there are other near-field models available [32.20–22] that would likely provide similar results.

While laboratory studies are often used to calibrate parameters within a model, field experiments are used to validate the model predictions for a specific marine outfall. This is undertaken using outfall dilution studies. Obviously, such validation studies can only be carried out after the marine outfall has been constructed. Outfall dilution studies involve the continuous injection of a tracer into the wastewater and the measurement of its concentration downstream from the discharge point. The tracer is injected at a known rate and concentration, and the flow of wastewater is also known. Therefore, by measuring the concentration of the tracer in the marine waters, the concentration of the wastewater can be determined.

Many tracers are available, for example: rhodamine water tracing (WT), fluorescein and the isotopes gold-198, technetium-99m, and tritium. Natural tracers such as salinity have also been used, but the variability in the data is usually too large to produce meaningful results. Preference is given to use a tracer that has little or no background signal; hence contact with the tracer will result in unambiguous readings. The tracer sensing device (such as a fluorometer or scintillation counter) may be towed behind a vessel and/or profiled through the water column to build a three-dimensional picture of the location and size of the plume. A critical element of the work is accurate position fixing, now usually done with differential GPS (global positioning system).

Simultaneously, the wastewater flow, ambient current speed and direction, and the density of the water column are measured. These data are used as input to the model. A direct comparison between the observations and model results can then be made. However, models are only approximations to the real world and there will be uncertainty associated with the results. Based on the results from many such experiments, predicted dilutions within a factor of two of actual dilutions are generally acceptable.

An example of the results obtained from a tracer experiment is shown in Fig. 32.4. The transect lines run parallel to the diffuser, 100 (lower panel) and 1000 m (upper panel) downstream from the outfall. Multiple transect lines are shown in each panel. In the lower panel, plumes from each of the nine risers comprising this outfall can be clearly identified. At a distance of 1000 m downstream from the outfall, plumes from the individual risers have merged, the overall width of the plume has increased and the concentration of the tracer (or plume) has markedly reduced.

Problems with Tracer Studies

Some problems encountered by the authors in conducting tracer studies are outlined below.

Some marine outfalls may have intermittent flow, particularly early in the life of the outfall when the design flow capacity is not yet reached. With intermittent flow, the time history of the patch of wastewater is unclear. However, it may be possible to temporarily store the wastewater, to enable a continuous and steady flow over the duration of the field experiment.

Locating the plume in the field may be difficult. The tracer may not be visible when the ambient waters are stratified and the plume is trapped below the water surface. A conductivity-temperature-depth probe can be used to identify stratification in the water column and hence the likely depth at which the effluent will reside.

Isotope tracers decay with time. The half-life of technetium-99m is 6 h which is comparable with the duration of many tracer experiments. If technetium-99m is used as a tracer, the initial signal will change significantly over time and needs to be accounted for in the data analysis. Tritium, with a half-life of about 12 yr, can be used for long duration tracer experiments or when there is considerable transport time between the nuclear facility that produces the isotope and the experiment site.

When a positive contact is made with the labeled plume, it is not possible to know where this contact oc-

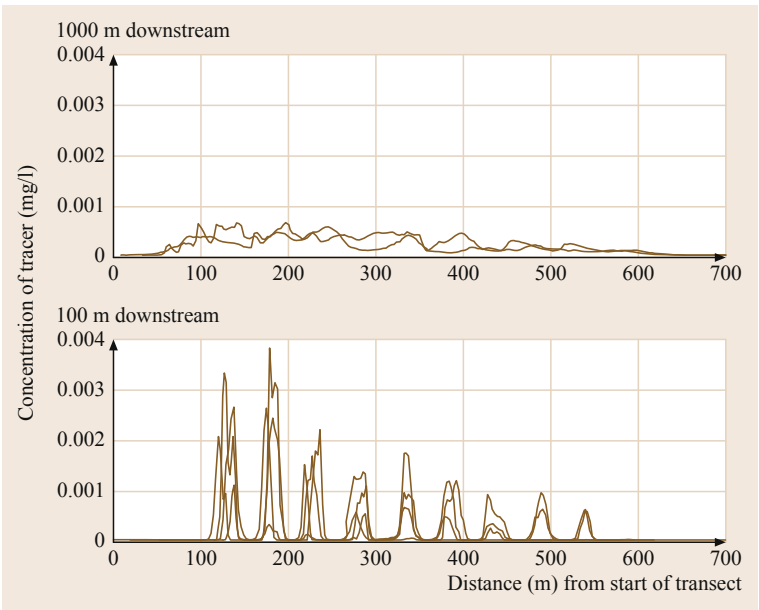

Fig. 32.4 Example of tracer concentrations obtained from field studies. Concentration data were collected from 1 m below the surface, at distances of 100 and 1000 m downstream from the outfall. Note the uneven distribution of concentration along the diffuser indicating an uneven distribution of flow

curs in the wastewater plume. One solution is to take many tracer readings closely separated in space and time to identify the plume boundaries and the region of highest tracer concentration.

The fluorescence of rhodamine WT is highly temperature dependent. It loses about 3% of its fluorescence for every one degree Celsius drop in water temperature. In very cold environments, it may not be possible to detect a signal at all – as happened to the authors when first using rhodamine WT in Antarctica.

32.3.5 Far-Field Numerical Modeling

The emphasis in this chapter is on near-field modeling rather than far-field modeling. The reason for this is because most of the dilution of the discharged wastewater occurs in the near-field, and environmental guidelines and licence conditions are usually applied at the end of the near-field. However, far-field modeling is important when assessing discharges into relatively shallow waters when mixing in the near-field is incomplete or when examining potential impacts at sites remote from the outfall, e.g., beach bathing waters or sensitive marine habitats or communities.

Far-field modeling usually includes hydrodynamic and water quality components. The hydrodynamic models are based on the principles of mass and momentum conservation of the marine waters; water quality models are based on mass considerations of the contaminant(s) or tracer(s) being discharged. Hydrodynamic models are usually based on a fixed mesh in space (i. e., an Eulerian formulation) and produce the depth and velocity fields as output. The water quality models require the velocity field as input; their formulation may be based on the same mesh as the hydrodynamic model. In another formulation (i. e., the Lagrangian formulation), many parcels of contaminant or tracer may be tracked as the velocity field transports and disperses them. The results from an Eulerian formulation yields the contaminant concentrations on the fixed mesh, while the Lagrangian formulation yields the number of contaminant parcels contained in each volume of fluid bounded by mesh points or nodes; these numbers can then be converted into contaminant concentrations.

The most common types of Eulerian models used are finite difference (i. e., point-wise approximations of the variables), finite element (piecewise approximations of the variables), or finite volume (based on fluxes of mass or momentum within each mesh cell). The meshes can be regular (i. e., structured) or irregular (i. e., nonstructured); they can be 2-D (2-dimensional; i. e., depth averaged) or 3-D (three-dimensional).

In a 2-D, hydrodynamic model the mesh is in the horizontal plane. At each mesh point or node, the unknowns consist of two velocity components and a depth. In a 3-D model, the mesh includes the 2-D horizontal plane and the mesh points or nodes in the vertical dimension. The unknowns at each 3-D mesh point or node, typically consist of two horizontal velocity components and pressure.

Usually, 2-D models require substantially less computational time and less data for calibration and running than 3-D models. In water depths exceeding about 20 m, the velocity vector at a single location in plan, may vary in magnitude and direction throughout the water column. If resolution of this variability is considered significant from the point of view of pollutant movement, a 3-D model may be preferred to a 2-D model. The horizontal spacing between mesh points or nodes will depend on the bathymetry and the presence of islands, headlands, and submarine canyons. The near-field model results need to be incorporated into the far-field model. To achieve this effectively, it may be desirable to refine the far-field mesh in the vicinity of the near-field.

Far-field models run under various flow scenarios can be used in the early stages of an investigation to guide data collection programs before, during, or after commissioning of an outfall. Such model studies may be conducted using a coarse mesh for quick turnaround of results.

32.3.6 Data for Running the Models

A range of information is required to run the numerical models. This includes: the outfall configuration, wastewater flow, and oceanographic data (currents and stratification of the water column). Over the long term, the model results can be used to examine changes in outfall performance. Below is a summary of the information required to run the models and how that information may be obtained.

Outfall Configuration

The concept outlined in the following section can provide a starting point for the outfall design. In the design phase, the outfall configuration can be changed and refined until the relevant environmental guidelines are met and engineering feasibility assessed. Once the outfall has been constructed, its configuration is essentially fixed. However, some flexibility may be enabled. For example, twin pipelines may be built and only one pipeline used for present wastewater flows (the second pipeline being saved for use when wastewater flow increases with future growth in population). Similarly, a multiport diffuser may have one or more outlet ports blanked, again in anticipation of future growth.

Information needed for the outfall configuration includes:

- Water depth in which the diffuser section is located.
- Length of the diffuser section.
- Configuration of the diffuser (e.g., a single or multiport outlet).
- Diameter of each outlet port.
- Whether the outlet ports are fitted with nonreturn check valves.

Wastewater Flow

Wastewater flow is usually measured in the outlet pipe at the end of the treatment processes. A range of flow measuring devices are available including flows based on electromagnetic, pressure, ultrasonic, or capacitance sensors. Also important is the density of the wastewater in relation to the density of the marine waters into which the wastewater is discharged. Usually it is safe to assume that the density of the wastewater is close to that of fresh water [32.2], although large amounts of particulate material in the wastewater may alter the density of the wastewater.

For numerical modeling purposes, wastewater flow is usually assumed to be uniform throughout each outlet port. This may not be necessarily the case. Energy loss may be significant over long diffuser sections, resulting in reduced flows through outlets lying further offshore. Low flows may result in the intrusion of seawater into the diffuser and a reduction in its performance. To help establish uniform flow, diffuser sections may be tapered (Fig. 32.1) and to help prevent the intrusion of seawater, outlet ports may be fitted with nonreturn check valves.

Currents

Currents determine the movement and dilution of the wastewater. Often a moored Doppler profiler is used to measure the current speed and direction throughout the water column. Doppler profilers can also be ship mounted, which allows a spatial picture of the currents to be obtained. Remote sensing and shore-based radar systems can provide detailed spatial coverage of the surface currents. However, it is subsurface current data which is critical for running the near-field models.

The choice of mooring location should be as close as possible to the diffuser. However, a compromise is often made, balancing the proximity of the diffuser to the mooring, with the health of workers who service the mooring (in waters that may be contaminated with diluted wastewater) and the security of the mooring itself.

Stratification

Stratification is a rapid vertical change in the density of the marine waters. In coastal waters, changes in the density are dominated by changes in temperature and salinity. The height to which a wastewater plume rises in the water column is largely governed by the strength of the stratification.

Measurements of temperature and salinity are often made using a conductivity, temperature, depth (CTD) probe. (Salinity is calculated from conductivity and temperature). The CTD probe can be lowered from a boat providing a continuous profile through the water column. CTD probes can also be moored, thereby providing a time series of density data at a fixed point. Historically, conductivity data from moored CTDs drift with time due to the gradual build-up of biofilm on the sensors. While there have been substantial improvements in the reliability of moored conductivity sensors in recent years, the quality of the data may still be highly variable. Temperature sensors (unless heavily fouled with marine growth) do not suffer the same problem. Hence changes in stratification using data from long-term moored systems are usually estimated from temperature sensors alone.

32.3.7 Conceptual Design for Positively Buoyant Discharges

Wilkinson [32.23] described a method by which the minimum length of a *simple outfall* could be determined. In his concluding remarks, *Wilkinson* [32.23] was careful to point out that this provides a preliminary estimate only, and he provided some suggestions on ways in which the outfall configuration could be further refined. This analysis is only intended as a starting point for outfall design. Detailed analyses are site specific and must be undertaken for final design. Some site specific factors include: the bathymetry, environmental guidelines, level of wastewater treatment, and the likelihood of plumes reaching the surface or sensitive ecological areas. *Wilkinson*'s [32.23] approach is modified here, by using the single set of equations (Table 32.2) and introducing construction cost as criteria for outfall design.

The following analysis is applicable to nonzero ambient currents, which is usually applicable to marine waters (e.g., currents near the Sydney, Australia deep water ocean outfalls exceed 0.05 m/s more than 90% of the time).

The total cost (T_c) of a marine outfall can be expressed as

$$T_c = lL_p + mL_D + nn_{ports} \quad (32.1)$$

where l is cost per meter of the outfall pipeline or tunnel [$/m], L_p = length of the outfall pipeline or tunnel [m], m is the cost per meter of the diffuser [$/m], L_D

is the length of the diffuser [m], n is the cost per outlet port [$], and n_{ports} is the number of outlet ports.

The basic premise used in *Wilkinson* [32.23] is that the profile of the water depths as a function of distance offshore (i. e., the length of the marine outfall, L_p) can be expressed as the power curve, $L_p = rz^s$, where r and s are constants that express the least-squares, best-fit shape of the across shelf bathymetry that may be obtained from navigational charts and z is the water depth.

Expressions for the length of the diffuser and the number of outlet ports can be obtained from Table 32.2 and the total cost can then be rewritten as

$$T_c = l(rz^s) + m\left(\frac{SQ}{2f_{ent}U}z^{-1}\right) + n\left(\frac{SQ}{3.14f_{ent}^2U}z^{-2}\right), \tag{32.2}$$

where S is the dilution required to comply with licence conditions or environmental guidelines.

To minimize the total cost, the above expression is differentiated with respect to the water depth (z), equated to zero and solved. The result gives the depth at which the minimum cost for the marine outfall is achieved. Substituting this value for depth into the equations in Table 32.2, gives the length of the diffuser and the number of outlet ports that comprise the marine outfall.

Actual costs do not need to be known. If the relative costs among l, m, and n are known, then the total cost of the marine outfall can be expressed in terms of a normalized cost, T_c/l. Again, it is stressed that this analysis is preliminary and is only intended as a starting point for outfall design.

32.4 Hydraulic Analysis and Design

It is often necessary to define the physical extent of a brine or wastewater outfall system for project planning and design purposes. While the ambient sea in the vicinity of an outfall structure typically defines the downstream boundary of an outfall system, defining the upstream boundary may not necessarily be as straightforward. For the purposes of this chapter, the upstream boundary is assumed to be a free surface which exists somewhere upstream of the outfall conduit entrance. Typical locations for this boundary could be the effluent level in outfall shafts, deaeration chambers, sedimentation basins, or pumping wet wells. For configurations without any free surfaces between the treatment process and outfall conduit, the upstream boundary may be taken at some hydraulically arbitrary point. Regardless of its physical location, this boundary represents a key design interface that must be properly integrated with the treatment plant as a whole. Determining the piezometric head at the upstream boundary of an outfall system is therefore a critical hydraulic design objective.

32.4.1 Governing Hydraulics

Consider the gravity-driven outfall system shown in Fig. 32.5 which includes an upstream shaft to capture plant effluents, as well as rosette style outfall structures installed on the seabed. (A rosette structure typically has multiple nozzles that are arranged around its perimeter.) The piezometric head at the outfall shaft, defined by point 0 on the fluid surface, can be obtained by applying the energy equation between this point and point 1 which is located precisely at the tip of the nozzle. It does not matter which outfall structure or nozzle is used to define point 1 because this multiple riser configuration is an example of parallel flow. For parallel flow, the total head loss must be equal through each parallel flow path.

The energy equation applied between (0) and (1) is written in terms of total head (i. e., energy per unit weight of effluent),

$$\frac{V_0^2}{2g} + \frac{p_0}{\rho_e g} + z_0 = \frac{V_1^2}{2g} + \frac{p_1}{\rho_e g} + z_1 + \sum H_{L(0\to1)}, \tag{32.3}$$

where V is the velocity [m/s], p is the pressure [Pa], z is the elevation above an arbitrary datum [m], z_{SL} is the elevation of sea level above datum [m], $\sum \Delta H_{L(0\to1)}$ is the total head loss between locations (0) and (1) [m], ρ_e is the density of effluent [kg/m^3], ρ_a is the density of ambient seawater [kg/m^3].

Working with gauge pressures and assuming negligible effluent velocity in the outfall shaft, the first two terms on the left-hand side of (32.3) are reduced to zero. Using the assumption that the pressure at (32.1) is hydrostatic based on the density of seawater, or $p_1 = (z_{SL} - z_1)\,\rho_a g$, this relationship is substituted into (32.3) to yield an expression for effluent level in the outfall shaft, z_0.

$$z_0 = \left(\frac{V_1^2}{2g}\right) + \left[\frac{\rho_a}{\rho_e}(z_{SL} - z_1) + z_1\right] + \sum \Delta H_{L(0\to1)} \tag{32.4}$$

Equation (32.4) demonstrates that the effluent level in the outfall shaft is a combination of (i) the head required to drive effluent out of the nozzle at the specified velocity, V_1, (ii) elevation to the center of the exit port (z_1)

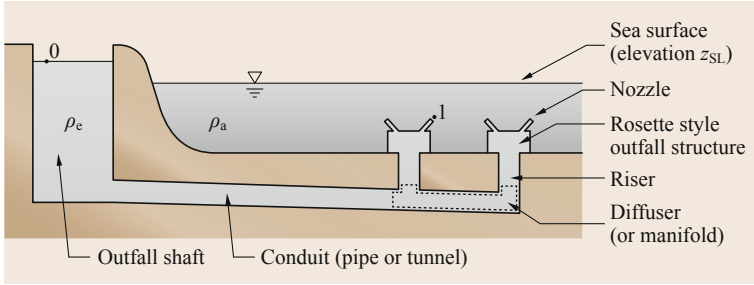

Fig. 32.5 Typical outfall system with rosette style outfall structures

plus discharge depth below sea level ($z_{SL} - z_1$) scaled by the ratio of fluid densities, and (iii) a summation of head losses through the system. Each of these components is briefly described in the following sections.

Nozzle Exit Velocity

The overall diffuser configuration including total number of ports or nozzles, and nozzle diameter (or exit velocity) is typically provided as an input to the hydraulic design based on the results of near-field modeling. The nozzle configuration affects the efficiency with which effluent is diluted in the near-field region and is generally selected based on the maximum outfall flow rate. In some outfall systems, such as those at desalination plants, maximum nozzle exit velocities of the order of 10 m/s may be required to ensure the brine is adequately diluted. The corresponding velocity head would likely be the largest component of the outfall shaft water level for exit velocities of this magnitude, especially for a relatively short outfall conduit with low conduit friction loss.

Sea Level

If seawater is discharged through the outfall system ($\rho_e = \rho_a$) the second term of (32.4) simplifies to z_{SL} and the outfall shaft fluid level is equal to sea level for the no-flow case. For sewage outfalls in which $\rho_e < \rho_a$, the effect of the density difference is to increase the outlet shaft effluent level. Conversely, the level in the outfall shaft is decreased when brine ($\rho_e > \rho_a$) is discharged. Density differences tend to be of the order of $(|\rho_e - \rho_a| / \rho_a) \times 100 \approx 3\%$ for most sewage and desalination applications. Although this difference corresponds to a relatively small change to outfall shaft level when discharging into shallow waters, (32.4) shows that the density ratio effect is amplified for deeper outfall discharges.

In addition to changes in plant operating conditions which could increase or decrease outlet flows, changes in sea level will also cause the outfall shaft effluent level to vary. The outfall system design should therefore consider the entire range of sea levels that could occur over the project design life, accounting for tidal fluctuations as well as storm surge. Statistical methods can be applied to sea level time series at the project location in order to determine exceedance probabilities and recurrence intervals. Using sound engineering judgment in conjunction with project requirements and/or local design standards for infrastructure design life, the results of the statistical analysis can be used to select design values for minimum and maximum sea level. To capture any seasonal trends which could include wind and barometric effects, sea level data used in the statistical analysis should include field measurements taken regularly throughout the year. It is imperative that data specific to the project location is used because sea level characteristics can vary greatly from one locale to another, regardless of the distance between them.

An allowance for sea level rise due to the effects of climate change should also be included because it could have a significant impact on maximum outfall shaft fluid level. Some statistical models estimate that the sea level will rise more than 1 m by the year 2100 (*Seneviratne* et al. [32.24]).

Head Losses

The total system head loss represented by the third term of (32.4) consists of the sum of conduit friction losses and the sum of local head losses through all fittings, system components (e.g., bends and contractions), and dividing flows in the manifold/diffuser. These losses can be expressed as

$$\sum \Delta H_L = \sum \frac{V_c^2}{2g}\left(f_c \frac{L_c}{D_c}\right) + \sum \frac{V_L^2}{2g}(K_L), \quad (32.5)$$

in which the first term on the right-hand side of the equation is the Darcy–Weisbach equation for conduit friction loss and f_c = conduit Darcy friction factor [–], D_c = conduit diameter [m], L_c = conduit length [m], V_c = velocity through the conduit [m/s], K_L = local head loss coefficient at fitting or component [–], and V_L = velocity through fitting or component [m/s].

In (32.5), the term *conduit* refers to the tunnel or pipe which delivers flow to the manifold and risers. The Darcy friction factor can either be determined from manufacturers' charts for particular wall roughnesses,

computed iteratively using the implicit Colebrook–White formula given in (32.6), or approximated using the explicit Swamee–Jain equation given in (32.7). The Swamee–Jain approximation is accurate to within a few percent of the value computed using the Colebrook–White equation over the typical ranges of roughness values and fully turbulent Reynolds numbers

$$\frac{1}{\sqrt{f_c}} = -2\log\left(\frac{k_S}{3.7D_c} + \frac{2.51}{\mathrm{Re}_c f_c^{1/2}}\right) \tag{32.6}$$

$$f_c \approx \frac{0.25}{\left[\log\left(\frac{k_S}{3.7D_c} + \frac{5.74}{\mathrm{Re}_c^{0.9}}\right)\right]^2} \tag{32.7}$$

where: k_S is the Nikuradse equivalent sand grain roughness of the conduit wall [m], Re_c is the conduit Reynolds number [−] $= \frac{V_c D_c}{\nu}$, ν is the effluent kinematic viscosity [m^2/s].

The kinematic viscosity of water for various temperatures and salinities can be obtained using the relationships provided in *Sharqawy* et al. [32.25]. Wall roughness values for common pipe materials can be found in any hydraulics data handbook, while roughness values for segmentally lined tunnels are presented in *Pitt* and *Ackers* [32.26]. It is customary to make an allowance for increased wall roughness over the conduit design life to account for aging and degradation.

Local head losses arise from flow through bends, tee or wye junctions, flow or pressure control devices (e.g., valves), and expansions or contractions in cross-sectional flow area. Local head losses will also occur at conduit entrances, at submerged discharges, and any location in the system where flow separation occurs. As shown in the second term of (32.5), local head loss is expressed as a multiple of the velocity head at the particular component of interest. The local loss coefficient, K_L, depends on the component geometry and is determined experimentally. Loss coefficients for common system components can be found in any hydraulics data handbook. Several references such as *Miller* [32.27] and *Idelchik* [32.28] are devoted entirely to local head loss coefficients and include many components present in marine outfall systems.

As local head loss coefficients are always based on some reference velocity, it is important to ensure consistency between a given K_L and the velocity, V_L, in the associated velocity head term ($V_L^2/2g$). For components with constant cross-sectional area such as certain bends, K_L is normally based on the average velocity through the bend. However, there is no standard reference velocity for components like nozzles or sudden expansions or contractions which have multiple cross-sectional areas; some sources may use the upstream velocity for reference, while others may use the downstream velocity. Using an incorrect reference velocity could result in significantly higher or lower head losses.

For complex hydraulic systems, it is important to note that the total local head loss may not simply be the sum of individual local loss components as (32.5) suggests. Rather, head loss coefficients are typically subject to certain limitations. For example, the coefficient for a single tee-junction can only be applied to a series of tee junctions (such as in a dividing manifold) if the separation distance between successive junctions is, say, 5 to 10 times the manifold diameter. Correctly applying local head loss coefficients will help to minimize under- or over-prediction of total local head loss. For cases in which the loss coefficient limitations are not clearly defined or the system configuration cannot easily be broken down into *standard* components (such as through a rosette-style outfall structure), physical and numerical modeling can be used to confirm head losses.

32.4.2 Diffusers – Hydraulic Design

Outfall systems usually consist of a manifold (also referred to as a diffuser) whereby a common pipe or tunnel supplies flow to multiple risers, ports, or branches. Although a manifold is an example of parallel flow in which the head loss between the outfall shaft and each exit port is the same, it is critical to note that the flow rate out of each port will not necessarily be the same. The variation in flow rate can be attributed to (i) decreasing flow and total head along the length of the manifold, (ii) changing depth along the manifold, and (iii) head loss coefficients for tee junctions which are a function of (a) the ratio of conduit diameter to branch diameter, and (b) the ratio of local flow through the conduit to flow through the branch. Head loss curves for a range of tee-junction configurations can be found in *Miller* [32.27].

Given that effluent dilution is directly related to port exit velocity, the overall design objective should be to achieve equal exit velocities (or as close to equal as possible) at each port to ensure consistent dilution levels over the length of the manifold. Traditional analytical methods of solving for the hydraulic performance of manifolds involve making an initial guess about the flow conditions at the most downstream port, then using an iterative approach to progressively work upstream, port by port, until a final solution is reached. An alternative approach using simultaneous equations is presented in this section. The resulting set of equations can be quickly solved using a spreadsheet application with built-in equation solver. The spreadsheet can be set up to optimize port velocities by varying known quantities such as the port and manifold diameters and/or port

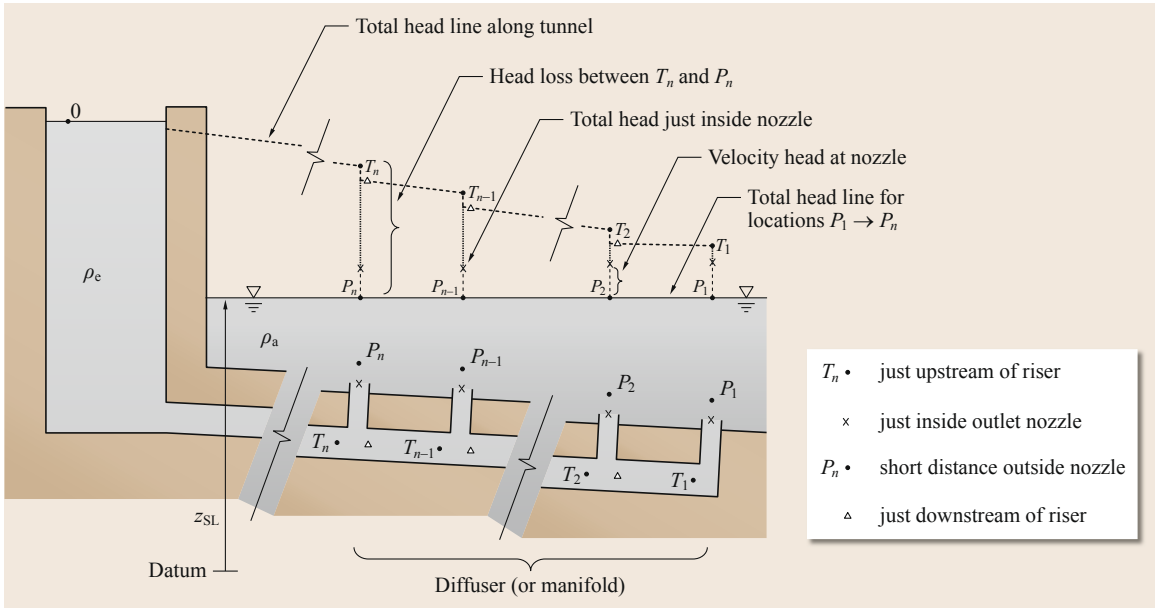

Fig. 32.6 Schematic for a manifold or diffuser flow calculation

spacing. Once the final manifold configuration is selected, the same spreadsheet model can also be used to determine the resulting port velocities and outfall shaft fluid levels over a range of flow rates and/or effluent densities.

Consider the diffuser with n ports arranged along a tunnel manifold as shown in Fig. 32.6. Points P_1 through P_n correspond to locations downstream of the individual port openings, while points T_1 through T_n are located along the tunnel centerline, just upstream of the port with the same subscript i. Flow conditions through this system – or any similar system – can be solved using the set of simultaneous equations provided in Table 32.4. Note that the values in brackets in the 3rd and 5th columns indicate that there is an equal number of equations and unknown variables ($8n + 1$). The parameters in the 6th column labeled *inputs* are assumed to be known values. The governing principles reflected in this set of equations are:

- *Continuity* – the sum of individual port flow rates (ΣQ_{P_i}) must equal the total outfall flow rate (Q_T). (Table 32.4, (8a))
- *Energy equation* – the total head at point P_n must be equal to the total head at point 0, less the total head loss between these two points $\left(\sum \Delta H_{L(0\rightarrow P_n)}\right)$. (Table 32.4, (8j))
- *Parallel flow* – the total head loss between points T_{i+1} and

$$P_i \left(\sum \Delta H_{L(T_{i+1}\rightarrow P_i)}\right)$$

must be equal to the total head loss between points T_{i+1} and

$$P_{i+1} \left(\sum \Delta H_{L(T_{i+1}\rightarrow P_{i+1})}\right)$$

(Table 32.4, (8k)). Note that exit loss should be included in the expression for the head loss between T_i and P_i (Table 32.4, (8f)) because the velocity head has been fully dissipated by the time the discharge has reached any point P_i. The total head at all points P_i are equal.

Subscript P_i denotes individual ports, subscript T_i denotes individual tunnel manifold sections, subscript P_n denotes the most upstream port, and subscript T_n denotes the tunnel section between the outfall shaft and port P_n (Fig. 32.6).

In cases where loss coefficients $K_{L_{T_i\rightarrow P_i}}$ in (8f) are functions of a flow ratio between the manifold and individual ports, the set of simultaneous equations in Table 32.4 may need several iterations in which adjustments are made to the loss coefficients after each iteration until the change in solution between successive iterations is negligible.

Note that the head loss coefficients in (8f) of Table 32.4 are presented in terms of the port exit velocity (i. e., the velocity at which the effluent is discharged into the sea). For cases in which the port geometry is more complex with varying diameters and multiple head losses, all loss coefficients used in (8f) of Table 32.4 must be converted such that they are based on the port exit velocity. To convert a head loss coefficient

Table 32.4 Set of simultaneous equations for manifold flow calculations

Description	Equations	No. of equations	Unknowns	No. of unknowns	Inputs	Equation
Continuity: total flow rate is equal to sum of individual port flow rates	$Q_T = \sum_{i=1}^{n} Q_{P_i}$	1	Q_{P_i}	n	Q_T	(8a)
Port exit velocity	$V_{P_i} = \frac{Q_{P_i}}{\frac{\pi}{4} D_{P_i}^2}$	n	V_{P_i}	n	D_{P_i}	(8b)
Velocity in manifold section between adjacent ports	$V_{T_i} = \frac{\sum_{1}^{i} Q_{P_i}}{\frac{\pi}{4} D_{T_i}^2}$	n	V_{T_i}	n	D_{T_i}	(8c)
Reynolds number in manifold section between adjacent ports	$\mathrm{Re}_{T_i} = \frac{V_{T_i} D_{T_i}}{\nu}$	n	Re_{T_i}	n	ν	(8d)
Darcy friction factor in manifold section between adjacent ports	$f_{T_i} = \frac{0.25}{\left[\log\left(\frac{k_{s_i}}{3.7 D_{T_i}} + \frac{5.74}{\mathrm{Re}_{T_i}^{0.9}}\right)\right]^2}$	n	f_{T_i}	n	k_{s_i}	(8e)
Head loss between manifold station i and just downstream of port i	$\sum \Delta H_{\mathrm{L}(T_i \to P_i)} = \frac{V_{P_i}^2}{2g}\left(\sum K_{\mathrm{L}_{T_i \to P_i}}\right)$	n	$\sum \Delta H_{\mathrm{L}(T_i \to P_i)}$	n	$\sum K_{\mathrm{L}_{T_i \to P_i}}$	(8f)
Head loss between outfall shaft and just downstream of the n-th port	$\sum \Delta H_{\mathrm{L}(0 \to P_n)} = \frac{V_{T_n}^2}{2g}\left(f_{T_n}\frac{l_{T_n}}{D_{T_n}} + \sum K_{\mathrm{L}(0 \to T_n)}\right) + \sum \Delta H_{\mathrm{L}(T_n \to P_n)}$	1	$\sum \Delta H_{\mathrm{L}(0 \to P_n)}$	1	l_{T_n} D_{T_n} $\sum K_{\mathrm{L}(0 \to T_n)}$	(8g)
Head loss between manifold station $(i+1)$ and just downstream of port i	$\sum \Delta H_{\mathrm{L}(T_{i+1} \to P_i)} = \frac{V_{T_i}^2}{2g}\left(f_{T_i}\frac{l_{T_i}}{D_{T_i}} + \sum K_{\mathrm{L}(T_{i+1} \to T_i)}\right) + \sum \Delta H_{\mathrm{L}(T_i \to P_i)}$	$n-1$	$\sum \Delta H_{\mathrm{L}(T_{i+1} \to P_i)}$	$n-1$	l_{T_i} $\sum K_{\mathrm{L}(T_{i+1} \to T_i)}$	(8h)
Pressure just downstream of port i, expressed in terms of the ambient seawater density	$p_{P_i} = \left(z_{\mathrm{SL}} - z_{P_i}\right)\rho_{\mathrm{a}} g$	n	p_{P_i}	n	z_{SL} z_{P_i} ρ_{a}	(8i)
Energy equation applied between point 0 and the most upstream port (n)	$\frac{V_0^2}{2g} + \frac{p_0}{\rho_{\mathrm{e}} g} + z_0 = \frac{V_{P_n}^2}{2g} + \frac{p_{P_n}}{\rho_{\mathrm{e}} g} + z_{P_n} + \sum \Delta H_{\mathrm{L}(0 \to P_n)}$	1	z_0	1	V_0 p_0, ρ_{e} z_{P_n}	(8j)
Parallel flow: head loss is the same between manifold station $i+1$ and just downstream of either port i or port $i+1$	$\sum \Delta H_{\mathrm{L}(T_{i+1} \to P_i)} = \sum \Delta H_{\mathrm{L}(T_{i+1} \to P_{i+1})}$	$n-1$	-	-	-	(8k)
Total:		$8n+1$		$8n+1$		

based on some velocity into an effective loss coefficient based on another velocity, the following equation can be used,

$$\frac{V_1^2}{2g} K_{\mathrm{L}_1} = \frac{V_2^2}{2g} K_{\mathrm{L}_1'} \Rightarrow K_{\mathrm{L}_1'} = \frac{V_1^2}{V_2^2} K_{\mathrm{L}_1} \,. \tag{32.8}$$

Manifold Section Diameters

The equations in Table 32.4 are kept general so that geometric parameters can be varied along the length of the manifold. In some cases, it may be necessary to progressively reduce the manifold diameter in order to maintain velocities that prevent settlement of solids

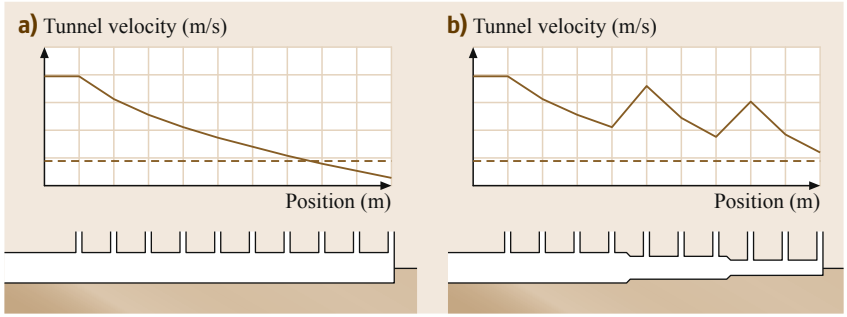

Fig. 32.7a,b Tunnel velocity variation along manifold – **(a)** constant diameter and **(b)** stepped diameter . The *dotted line* indicates a minimum self-cleansing velocity; refer to Sect. 32.3.7 for details

along the invert. (Due to the potential for excessively high head losses, it may not be possible to maintain sufficient self-cleansing velocities over the entire length of a conduit with a constant diameter.) Velocities through a typical diffuser are shown for two cases in Fig. 32.7 – constant diameter and stepped diameter. The dotted line represents a nominal minimum velocity required to prevent solids from accumulating. It should be noted that reducing the manifold section diameters is usually only feasible for applications involving piped outfalls. For tunneled solutions in which sedimentation can occur, an allowance for sedimentation build-up or a provision for periodic removal of accumulated sediments should be included in the design of the system. Refer to Sect. 32.3.7 for a discussion on sedimentation.

Port Diameters

The number of ports as well as the port exit velocity required to ensure adequate dilution are typically determined from the results of near-field modeling. These constraints effectively set the port diameter which, in turn, establishes hydraulic performance of the system. After the port diameter has been selected, the system should be checked for excessively high head losses, unbalanced flow distribution, and seawater intrusion (for sewage outfalls only) to minimize the potential for adverse operating conditions. In practice, an iterative design process is usually required in order to strike an appropriate balance between dilution performance and favorable hydraulic conditions.

Achieving a consistent discharge velocity at all ports along a line diffuser is not necessarily a simple task due to the varying head loss coefficients along the length of the manifold. An analysis of head loss coefficients for dividing flows shows that they are a function of both the flow ratio and the area ratio, between individual ports and the corresponding conduit section [32.27]. In general, loss coefficients are greater for larger flow ratios and smaller area ratios. Assuming constant conduit and port diameters, upstream ports will therefore have relatively low loss coefficients while downstream ports will have relatively high loss coefficients. In order to satisfy the principle of parallel flow such that head loss between the outfall shaft and each port is the same, the flow rate through each port will be different.

The flow variation among ports is not necessarily a problem from a hydraulic perspective. However, the near-field effluent dilution may become unbalanced if the flow differential among ports becomes too great. This condition may prevent near-field dilution targets from being met which could lead to adverse environmental consequences. In the case of sewage outfalls in which the effluent density is less than that of seawater, the variation in port discharges can create another undesirable condition – seawater intrusion. One way to prevent seawater intrusion from occurring is to use smaller port diameters to ensure adequate port discharge velocities. Modeling a less dense fluid flowing through an orifice into a more dense fluid shows that seawater intrusion can be prevented when the port densimetric Froude number is greater than approximately 1.6 [32.29],

$$\mathrm{Fr} = \frac{V_{P_i}}{\sqrt{g\left(\frac{\rho_a - \rho_e}{\rho_e}\right) D_{P_i}}} > 1.6\,. \tag{32.9}$$

In practice however, port densimetric Froude numbers are typically kept well above this threshold value. For example, the port densimetric Froude number at the Sydney deep water ocean outfalls is of the order of 20–30.

A sensitivity analysis of port diameters using the set of simultaneous equations in Table 32.4 shows that port flow rates along the manifold do not vary significantly after port diameters are reduced below some critical value. Moreover, reducing the port diameter will increase the overall system head loss and lead to higher outfall shaft effluent levels. In some cases, the maximum possible head that can be accommodated at the outfall shaft may dictate the smallest allowable port diameters. If these diameters still do not lead to sufficiently high velocities, an alternative configuration may be required.

One option is to use variable-orifice nozzles such as the duckbill valves described in Sect. 32.4.3.

Another option is to use rosette style outfall structures. A similar analysis of flow conditions through a manifold configured with rosettes shows that port discharges can be more evenly distributed. This better flow balance occurs because head loss coefficients along the manifold are nearly uniform along its length, provided the friction losses and local losses between the conduit and risers are kept low. In this case, flow rates into each rosette will be nearly equal. Furthermore, the flow rate through each port on a given rosette structure will be the same for axisymmetric rosette designs because the total head loss coefficient will be the same regardless of which port the effluent flows through. Rosettes can have any number of nozzles, however, there tends to be an upper limit beyond which the additional nozzles will impede individual jet mixing processes. This behavior occurs because neighboring jets tend to coalesce due to reduced pressures caused by entrainment of the ambient water between them. The result is to reduce overall dilution performance. Near-field modeling can be used to determine the maximum number of nozzles for a specific rosette structure configuration.

32.4.3 Flow Variability

The wide range of flows that may be experienced at treatment plants is one of the greatest challenges in designing an outfall system. The preceding discussion assumes that the nozzle diameters have been sized to provide the required dilution for the maximum design flow rate, while at the same time maintaining sufficient velocity to prevent salt water intrusion at the ports and avoiding problems arising from sedimentation. In reality, treatment plants operate over a wide range of flows, and it is quite possible that the design flow might not be achieved until many years after the plant is initially constructed. In addition, plant start-up and ramp-down operations as well as any major changes to process flow requirements could create situations in which the plant will operate well below the design flow rate. The frequency and duration of any such events that result in low dilutions should be considered. If low flow scenarios are likely to result in sustained periods of insufficient dilution, the following mitigation schemes for managing low-flow scenarios can be used. Each of these options has advantages and disadvantages, and a hybrid solution may turn out to be the most suitable approach.

Supplemental Flows

For desalination plants, a connection between the intake and outfall systems can be incorporated in the plant design to provide a way for seawater to be bypassed directly into the outfall system during periods of low outlet flow. The bypassed seawater effectively increases the outlet flow rate and nozzle exit velocity, thereby providing additional momentum for dilution by mixing. The bypassed seawater also acts as an initial diluting agent before effluent is discharged into the sea; as such, adequate levels of dilution may be obtained with lower nozzle exit velocities for a given brine flow. The amount of bypassed seawater required for any particular combination of outlet flow rate and salinity can be determined using results of the near-field modeling and basic conservation principles.

Although this option provides a near instantaneous level of control for managing the outfall system (when the appropriate flow control devices are included in the design), the addition of bypassed seawater will lead to increased energy use and operating costs due to additional pumping of seawater. These costs should be considered when deciding whether this option is an appropriate strategy for managing low flows. Depending on the frequency and amount of bypassing required, this solution may, in fact, be found to be the most practical or cost effective when compared with other alternatives. The incorporation of a seawater bypass system also provides a way to commission both the marine intake and outfall systems independently from the rest of the plant.

Staged Construction of Marine Works

Many treatment plants are designed to be initially operated at a low flow rate, then periodically upgraded until the maximum design capacity is attained. To manage the low flows associated with early stage plant operation, the marine construction works can be staged such that only some of the nozzles or rosette structures required for the ultimate flow case are initially installed. Additional nozzles, diffuser structures, or sections of a line diffuser can be installed each time the plant is upgraded; near-field modeling will inform the number of nozzles to be installed at each stage.

The main disadvantage with this solution is that additional marine construction works are required whenever the plant is upgraded. Moreover, it assumes that once the plant is upgraded to ultimate capacity, it will not operate at the lower early stage flows. This assumption may not be valid if demand can fall below the plant's maximum capacity after it is upgraded (for example, lower demand from a desalination plant due to a temporary period of increased rainfall). This solution also does not address periods of low flow that will occur even for ultimate capacity when the plant ramps up or shuts down due to operations or maintenance requirements. These periods of low flows may not be an issue if they occur infrequently and for short durations, and if environmental licences allow for temporary periods of

lower dilution. As such, plant processes and the feasibility of periodic marine construction works need to be considered should this option be pursued.

Nozzle Sizes and Blanks

If it is not feasible to stage the installation of marine outlet structures or sections of a line diffuser, another option for managing low flows is to install blanking plates at the nozzle openings. This solution provides greater flexibility than staged construction because each nozzle can be brought online or taken offline individually to suit the flow requirements. In addition, it allows the total flow rate to be evenly distributed since nozzles on multiple structures or at any location along a line diffuser can be blanked off. Near-field modeling is needed to confirm the number and location of nozzles to be blanked off for each long-term operating flow rate. Input from the plant operators should be sought when considering this option, as making adjustments to nozzle blanks more than two or three times per year may render this option infeasible.

A similar option is to install smaller diameter nozzles for the initial stages, then remove and replace with larger diameter nozzles each time the plant is upgraded. To minimize installation activities, each set of nozzles should be designed to have the same entrance diameter such that modification to the manifold or rosette structures is avoided. This option provides the same degree of flexibility as nozzle blanking if demand or process requirements lead to an extended period of low flow; the smaller nozzles can be re-installed at any time.

Although these options will also require marine works each time the plant is upgraded, the scope and duration of such works is likely to be considerably less than for staged installation of marine structures or the addition of more diffuser length. These options also carry some operational risk due to the fact that the plant could still be operated at any given flow rate, even with an incorrect number or size of nozzles. A nozzle configuration that is not aligned with the target operating flow could lead either to insufficient dilution (for lower flow), or excessively high head losses through the system (for higher flow). The operating procedures for these two options must ensure that plant capacity is linked to the installed nozzle configuration at any given time.

Variable-Orifice Nozzles

Variable-orifice nozzles, also known as *duckbill valves*, can be used instead of fixed diameter nozzles. These valves are made from a variety of flexible materials such as rubber or neoprene and are designed to close during periods of no flow. Due to stiffness of the valve material, the valves gradually open in an elliptical shape as the flow rate increases resulting in higher velocities at lower flow rates as compared to fixed-diameter nozzles. This eliminates or reduces the need for blanking nozzles or introducing bypassed seawater into the outlet flows is reduced or eliminated. The check valve feature of duckbill valves also prevents backflow from the sea into the outfall system during periods of zero or low flow. Seawater intrusion into wastewater outfalls can therefore be prevented with this option.

As material stiffness dictates the degree to which the valves will open for any given flow rate, these valves are usually custom designed for each particular application. Hydraulic testing of the valves is recommended prior to selection and incorporation into the final design, given the specificity of duckbill valves to each outfall design. Hysteresis of the material should also be investigated to ensure that the valve will perform consistently over time. This consideration is particularly important if flows are expected to be highly variable and/or prevail for extended periods (i. e., months or longer). The local conditions in which the valves will be installed is another important aspect that should be taken into account when deciding whether duckbill valves are an appropriate solution. If high levels of marine growth are expected, the valves may not close properly if organisms attach themselves to the area near the valve opening.

32.4.4 Hydraulic Integration

Following a hydraulic assessment, the range of piezometric heads at the upstream boundary of an outfall system must be considered with respect to the hydraulics through the entire treatment plant. Failure to properly integrate the outfall system with other plant systems could result in adverse operating conditions such as decreased plant capacity, spillage and flooding, and inefficiencies for pumped systems. The choice between gravity-driven or pumped outfalls depends on several factors including site topography and plant elevation, management of low flow scenarios and long-term operating or maintenance costs.

Gravity Systems

Gravity-driven outfall systems are often preferred because they are relatively simple to operate (few electrical and mechanical components) and have virtually no long-term operating costs. Apart from periodic inspection and maintenance, the passive nature of a gravity-driven system ensures continuous reliability and minimal operator intervention. The free surface that exists at an outfall shaft is convenient when outflows from different parts of the treatment plant must be collected and combined into a single outfall stream. In addition,

a hydraulic break is usually required for certain process schemes such as removal of entrained air or settlement of suspended particles; refer to Sects. 32.4.5 and 32.4.6 for a discussion of these issues.

The range of piezometric heads in the outfall shaft should first be considered in relation to the vertical alignment of the outfall conduit and ground surface level at the shaft location. Given the complexity associated with installing an outfall conduit, the key factors in selecting its vertical alignment typically include suitability of ground conditions, constructability, cost, and construction scheduling. For example, a trenched solution which follows site topography and bathymetry is often desired as it can be the cheapest and easiest to build. However, this alignment may cause adverse hydraulic conditions such as hydraulic jumps and accumulation of air at localized high points. The potential for such conditions should be assessed before finalizing the outfall conduit alignment.

In general, the entrance to the outfall conduit should be fully submerged for all flow rates and sea levels in order to prevent operational instabilities. Otherwise, hydraulic jumps would be likely to occur at the downstream end of unpressurized steep sections or where free surface flow conditions develop along an alignment that follows a ground profile containing intermediate peaks and valleys, as illustrated in Fig. 32.8. Hydraulic jumps would likely be dynamic, unstable, and unpredictable, and could lead to air entrainment (Sect. 32.4.5 discusses the effects of air entrainment in greater detail).

Regardless of whether the outfall shaft can be designed and constructed to accommodate the range of operating levels, these levels must also be compatible with the upstream treatment plant systems. Ideally, the plant is configured in such a way that shaft fluid levels do not influence the upstream hydraulics. At the very least, any backwater effect caused by the outfall shaft levels should not adversely impact the treatment plant processes or reduce the plant operating capacity.

Vertical Drops

For cases in which the treatment plant is located at a significantly higher elevation than the outfall shaft fluid levels, a means of transferring the outflows down a large vertical distance may be required. Allowing outlet flows to simply drop over a weir into the outfall shaft causes a great deal of air entrainment and results in rapid dissipation of energy which can cause operational instabilities and structural damage if not properly managed. A vortex, drop shaft system can be incorporated into the design using methods such as those outlined in *Hager* [32.30] in order to gradually dissipate energy and minimize impact on the structure, and reduce the potential for air entrainment.

As an alternative, a mini-hydroelectric scheme can be installed to recover the energy that would otherwise be *lost* by the vertical drop between the plant and the outfall shaft. Whether the recovered energy is used to power other parts of the plant or sold back to the power grid, a substantial portion of the costs associated with pumping of intake flows (e.g., at a desalination plant) may be recoverable. The potential cost savings associated with any such mini-hydro scheme should be compared with the initial cost of all necessary mechanical and electrical components, as well as their ongoing maintenance and replacement costs. The frequency and duration of flow/head combinations should also be considered when determining viability of a mini-hydro scheme. While a large amount of energy might be available for recovery during peak flow conditions, lower operating flow rates over the long term might render this option uneconomical. If a mini-hydro scheme is included, a passive system such as the vortex drop shaft may also be required as an emergency bypass or back-up in case the turbines need to be taken offline.

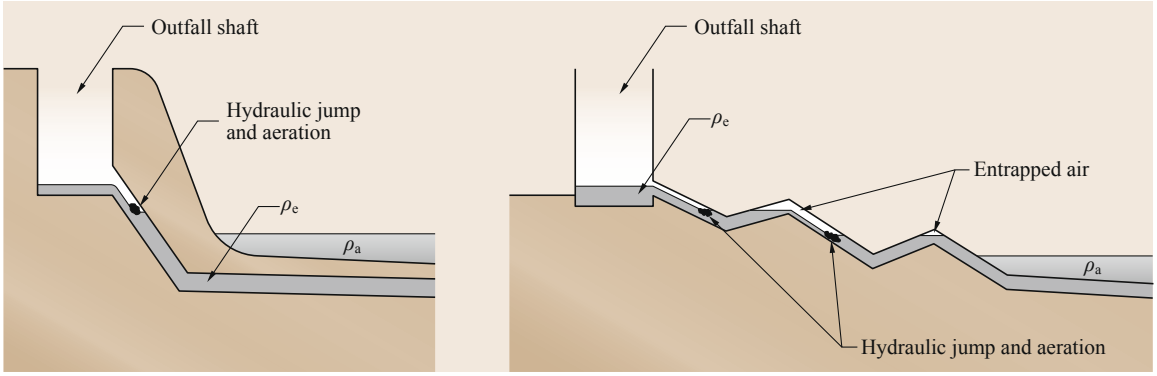

Fig. 32.8 Examples of configurations that could entrain or entrap air and cause hydraulic jumps

Pumped Systems

If specific site conditions render a gravity-driven system unfeasible, a pumped solution will be needed to provide the driving head required for maintaining the required nozzle exit velocities. The hydraulic analysis for a pumped system is the same as for a gravity-driven system because the pumps will need to deliver flow at a head equal to the fluid level in a hypothetical outfall shaft placed at the pumping station location. Pump selection should be based not only on the required piezometric head on the discharge side of the pump (which is a function of both flow rate and sea level), but also on any flow- or time-based fluctuations of the upstream water level or pressure. Selecting a single type and size of pump to efficiently cover the entire flow and head range may not be possible. However, using a single type and size of pump is generally desired from an operations and maintenance perspective because it adds flexibility and redundancy to the system.

Pumping can also be used as a way to manage low flow scenarios or ensure constant nozzle exit velocity over the entire flow range. This option provides near instantaneous control for managing nozzle exit velocities, but the associated operating costs will also be relatively high. Nonetheless, a pumped outfall system may be required to manage low flows at a desalination plant outfall when bypassing seawater is not possible.

32.4.5 Air Entrainment

Managing air that becomes entrained in the treatment plant effluent stream is an important consideration for outfall system design. If air bubbles are not captured and released before effluent enters the outfall conduit, the bubbles could eventually agglomerate and form air pockets. Depending on the particular conduit configuration, air pockets can become trapped at localized high points along the outfall conduit and alter the hydraulic performance of the system. Localized head losses can be induced at these locations due to the associated flow contractions and expansions. This condition could lead to reduced system capacity and the potential for excessively high outfall shaft water levels (in a gravity system) or inefficient pump operation (in a pumped solution). As it is typically not feasible to include air release mechanisms along an outfall conduit, trapped air pockets can remain in the system for extended periods of time.

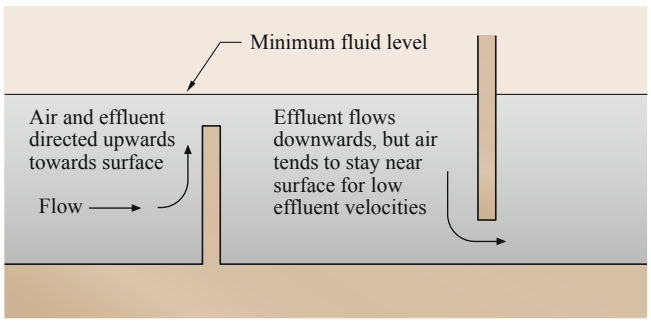

Fig. 32.9 Indicative deaeration system using baffles

Air pocket accumulation can also be problematic even if there are no high points along the alignment. In the case of a conduit with constant slope (including zero slope), entrained air will tend to come out of solution and accumulate along the conduit soffit. Depending on the conduit slope and diameter, and the effluent flow rate, the air pocket may move upstream or downstream. Regardless of direction, the air pocket may not start moving until it reaches some critical volume or pressure, at which point it may move suddenly and violently. This sudden release of air at either end of the conduit results in a condition called *blow-back* or *blow-out* which can cause strong vibrations and even structural damage in extreme cases. Operational instabilities in the outfall system and farther upstream may be experienced, especially in cases where the gradual accumulation of air followed by a sudden release (i. e., gulping), becomes repetitive.

It is important to recognize the processes by which air becomes entrained so that the system can be designed to minimize the adverse conditions described above:

- Flow conditions at the upstream end of the outfall conduit can be a major contributor to entrained air if the effluent is conveyed vertically through a drop shaft, over a weir, or by way of any other hydraulic structure which causes a jet to plunge through air.
- Hydraulic jumps can occur in open channels at locations where the cross-sectional flow area or depth changes abruptly. It is even possible to have hydraulic jumps occur within the outfall conduit if the upstream end is not fully submerged.
- For wastewater outfalls, gases can be generated over the entire conduit length due to biological processes in the effluent.

The two main approaches to removing entrained air are: (i) remove it upstream of the entrance to the outfall conduit, and (ii) configure the outfall conduit such that air bubbles either move upstream or downstream without forming large air pockets. A deaeration chamber or channel can be included immediately upstream of the outfall conduit entrance to capture and release air from the effluent in a controlled manner. The general idea behind these schemes is to provide a flow path

of sufficient length such that air bubbles have enough time to rise to the surface before entering the conduit. Indicative air bubble terminal rise velocities are provided in *Falvey* [32.31] and *Lauchlan* et al. [32.32]. To minimize the deaeration chamber or channel flow path length, effluent velocities can be reduced by increasing the cross-sectional flow area. Properly configured baffle walls can also be used to direct flow upward and facilitate air removal through the fluid–air interface, or to permit only the effluent at the bottom of a chamber or channel to continue downstream toward the outfall conduit; effluent near the invert is likely to have less entrained air than that near the surface for low effluent velocities. Refer to Fig. 32.9 that shows an indicative deaeration system using a baffled configuration.

In other cases where site constraints limit the amount of space available for upstream deaeration schemes, or where a majority of entrained air is the result of biological activity occurring in the outfall conduit, an alternative approach can be taken. The conduit can be designed to allow air bubbles to travel to either the upstream or downstream ends of the system. *Falvey* [32.31] presents a series of curves which summarize a range of conditions for air bubble and air pocket movement in a closed and fully flowing conduit; refer to Fig. 32.10 in which Q is the conduit flow rate, D is the conduit diameter, and θ is the angle of the conduit to the horizontal.

32.4.6 Sedimentation

Sediment management tends to be a more relevant issue at wastewater treatment plants than at desalination plants; desalination inflow (i. e., seawater) generally has fewer solids than sewage, and its pretreatment processes generally remove a wider spectrum of material. Indeed, the filtration membranes in reverse osmosis plants are very sensitive to fouling and require the removal of solids as well as organic compounds. Nonetheless, the solid matter removed in the desalination pretreatment processes may end up being added to the brine effluent downstream of the reverse osmosis filters if not disposed of by other means. The design of an outfall conduit for a desalination plant must therefore consider all plant processes that discharge an effluent stream into the outfall system.

The build-up of granular sediments, organic matter, and other solids along the invert of an outfall conduit will eventually lead to increased head losses and decreased hydraulic capacity. In extreme cases, the conduit section can become clogged and the function of the discharge nozzles impeded. There are two general approaches to reduce the risk of sediment build-up, each of which is described below. For some applications, a combination of these options may prove to be the most effective solution.

Minimize the Amount of Solids that Enter the Conduit

By providing a way for solids to settle out of the effluent stream upstream of the conduit entrance, deposition and removal becomes a matter that can be managed locally at the plant site, rather than along the entire length of the conduit. This approach using sedimentation basins or settling tanks may be the preferred solution for cases in which the outfall conduit is long and/or inaccessible for periodic inspections and cleaning. It may also be used if it is not possible to design the conduit to achieve self-cleaning velocities. The general design principle behind this approach is that the sedimentation basins/tanks reduce the effluent stream velocity to a point where the time it takes for suspended particles to settle is less than the residence time of the fluid in the basin or tank. Because particle settling time increases as the target particle size decreases, a potential drawback of this option is that a large basin or tank footprint may be re-

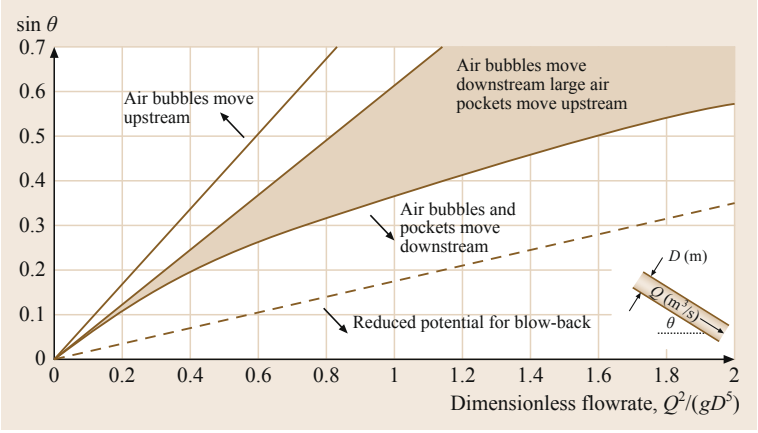

Fig. 32.10 Air movement in pressurized conduits (after *Falvey* [32.31, Fig. 29])

quired. As such, this option may only be feasible for removing larger solids. To decrease the basin/tank footprint and increase its efficiency, internal baffle walls can be installed to lengthen the flow path. However, the resulting effluent velocity should remain sufficiently low to allow sediments to settle out.

Design for Self-Cleansing Velocities

If upstream sedimentation control is not feasible, the outfall conduit diameter can be selected to yield velocities that are high enough to prevent deposition of solid materials. Given the wide flow variability associated with many types of treatment plants, the outfall conduit diameter should be based on the lowest-flow scenario. If, however, the chosen diameter leads to excessively high velocities and head losses during peak flow, it may not be possible to achieve self-cleaning velocities for all flow conditions. In this case, the design objective should aim for self-cleaning velocities on a frequent basis (i. e., at least once per day) and for sustained periods of time (i. e., hours) in order to prevent build-up of sediments and organic matter over time. The research literature contains a great deal of information on the velocities and shear stresses required to move solids through the conduit and to re-suspend solids that may have already settled. Velocities to keep solids in suspension range from approximately 0.5–2.0 m/s depending on conduit diameter, particle size and specific gravity, and particle concentration [32.33].

32.5 Outfall Construction

An effective design is not possible without input from those engaged to construct the outfall. The design must be detailed in conjunction with how the marine outfall will be built. *Grace* [32.34, 35] and *Wood* et al. [32.4] provide good information on outfall construction approaches and techniques.

There are two fundamental types of wastewater delivery: via tunnels or pipes (either on trestles or in trenches). They can be used in combination, a tunnel for the bulk of the outfall length and a pipeline on the sea bed comprising the outlet ports. The decision is often governed by the geography of the region – tunnels may be preferred in areas with rocky coastlines or where beach access is difficult, while pipelines may be preferred in areas with easy access such as a sandy shoreline.

32.5.1 Construction Materials

The materials used for outfall construction include steel, reinforced concrete, and high density polyethylene. The marine environment is corrosive and steel structures must be protected by coating the steel to prevent direct contact with sea water (often concrete is used) and/or using sacrificial anodes. Ongoing inspections are required to monitor the integrity of the protective coating or the anodes and replace them as necessary.

Steel reinforcement in concrete is susceptible to corrosion by chloride salts in marine waters. To help in preventing such corrosion, low permeability concrete is used, often in conjunction with additives that inhibit corrosion. Hydrogen sulphide in wastewater is corrosive to concrete and concrete pipes are lined (usually with plastic) for protection. Regular inspections are undertaken to ensure the lining has not peeled away from the concrete. The density of concrete is about one-third that of steel (although still about double that of seawater) and the concrete pipeline may need to be anchored to the sea floor.

High-density polyethylene is relatively light, with a density slightly less than that of seawater. Its big advantage is that it is flexible and can be relatively easy to deploy. Long sections are welded together on shore, the pipeline then towed into position and anchored to the sea floor. Purging of air from the pipe is critical to prevent the pipe from floating back to the surface.

32.5.2 Construction Methods

Pipelines are often manufactured in sections and assembled at an access point close to the proposed line of the outfall. When in the water, each section is buoyed to facilitate easy movement. Offshore, a vessel is anchored and pulls a section of the pipe into a trench along the line of the outfall. The next section is welded on and the pull continues. This is a popular technique for steel pipelines, which are very strong in tension. Concrete blocks or ballast rock may be used to anchor the pipe to the sea floor.

The trench is then backfilled either mechanically or by natural means. Techniques have been devised whereby trenching, pipe-laying and backfilling are all done in a single operation. The end of the pipeline terminates in a diffuser and the wastewater is discharged through outlet nozzles.

The active wave climate of the surf zone makes it the most critical region. Often, a temporary trestle and sheet piling is used to protect the pipeline through this region. Sometimes, wave action can damage the trestle and sheet piling (Fig. 32.11).

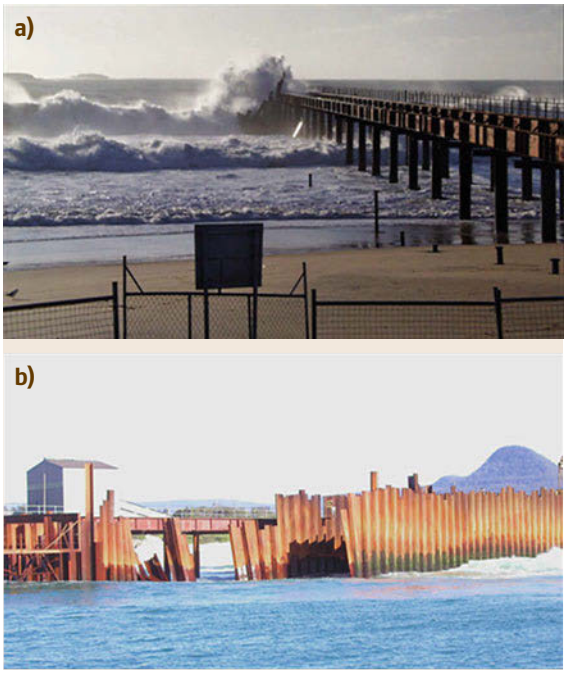

Fig. 32.11a,b Photographs from the same site, during **(a)** and after **(b)** a storm that caused extensive damage to sheet piling. The sheet piling was placed to protect the outfall pipeline (located in a trench) as it passes through the surf zone (photographs by P. Tate)

Tunnels are expensive to construct but their big advantage over pipelines is that they avoid the surf zone where damage to a pipeline is more likely to occur. This is particularly important along high wave energy coastlines.

One of the two tunnel construction techniques is usually adopted: full face tunnel boring or drill and blast. The latter technique is more commonly used on shorter outfalls where the cost of a tunnel boring machine cannot be justified. The drill and blast technique can be dangerous, releasing gases into the tunnel or weakening the tunnel structure.

Long risers (tens of metres or more in length) are drilled from the sea floor down to the tunnel. The risers are capped with high velocity nozzles through which the wastewater is discharged. On the three Sydney deep water outfalls, between four and eight outlet nozzles are fitted in a rosette configuration to each riser.

32.5.3 Some Considerations

Environmental Impacts of Construction

During the construction of a marine outfall there will inevitably be environmental damage caused by trenching and drilling activities. Habitats may be removed, infauna displaced and particulate material placed into suspension. Apart from the obvious physical destruction of habitats, suspended matter may reduce light in the water column (affecting photosynthesis), clog the gills of fish and, on resettling, may smother marine plants and infauna.

Route Selection

The shortest distance may not be the optimal route for the outfall. Other influencing factors include: the presence of rocky outcrops, wave and current climate, maritime activity, fishing zones, and ecological considerations. The route of the Wollongong outfall (Australia), constructed in 2005/2006, was changed in its early design phase to avoid the habitats of the weedy seadragon (*Phyllopteryx taeniolatus*) – a local protected species.

Wave and Current Climate

Waves can induce drag and lift forces on pipelines. Breaking waves are most prevalent in the surf zone. They can produce very large forces on a pipeline, although their duration is short lived. Abnormally large waves can be generated from storm surges, rogue waves and tsunamis. Currents over a pipeline exert a drag force. The weight of the pipeline needs to be sufficient to prevent such forces from moving the pipeline. *Grace* [32.34] provides some simple calculations that estimate the force exerted on a pipeline by waves and currents. In part, this problem can be largely overcome by burying the pipeline in a trench, which is then backfilled.

Sediment Movement

The current and wave climate may resuspend sediments. Once in suspension, their movement and distribution can be widespread. Of particular importance is the potential for sediments to erode from beneath the pipeline, potentially placing considerable stress on the pipeline itself. Conversely, an accretion of sediments may smother the pipeline inhibiting or preventing the discharge of wastewater from the outlet ports. This may also cause sediments to enter the outfall pipeline, reducing the efficiency of the outfall.

Head Loss Monitoring

The hydraulic grade line for an outfall can be determined as a function of the discharge. At each discharge, upper and lower limits for the hydraulic grade line can be established and by maintaining the discharge between these limits, we can optimize the hydraulic performance of the outfall. Below the lower limit, seawater intrusion into the outfall is likely to occur and operators can increase the wastewater flow accordingly (although

increasing the flow may not always be possible). The addition of salinity sensors on individual risers can confirm whether seawater intrusion has occurred.

Seawater Intrusion and Purging

A rule-of-thumb for preventing seawater from entering the outfall is to keep the port densimetric Froude number (32.9) well above unity (e.g., on Sydney's deepwater ocean outfalls, the port densimetric Froude number is of the order of 20–30). Occasionally, the port densimetric Froude number may become small and seawater may enter the outfall. One method to help prevent such an intrusion of seawater is to use nonreturn check valves. However, not all outfalls are so equipped and it may be necessary to periodically purge the seawater from the outfall. This is done by backing up the wastewater in the treatment plant and releasing the wastewater at high velocity. This also has the advantage of clearing the outfall of sediments.

Outfall Maintenance

Regular inspections of the marine outfall should be carried out as part of a regular maintenance program to ensure there is (a) no physical damage to any components and (b) no blockage of any outlet nozzles. This can be carried out by divers although this is accompanied by substantial health and safety concerns (e.g., diving in contaminated waters, wave action, and decompression requirements for deep diving). Our preference is to carry out inspections using remotely operated vehicles. The frequency of maintenance inspections will depend on a range of factors such as environmental conditions and construction materials. Often, annual inspections are adopted.

32.6 Environmental Monitoring

The fundamental objective of environmental monitoring is to quantify impacts that may arise as a result of the discharge of wastewater to the marine environment. Some of the questions that an environmental monitoring program should address include:

- Is it safe to swim?
- Is it safe to eat the seafood?
- Will the marine communities be protected into the future?
- Will the beaches be free from contamination?

Two distinct environmental monitoring programs are often implemented. The first is a pre- and post-construction monitoring program. This is usually an intense program of short duration (perhaps five years) aimed to quantify the initial impacts of the discharges from the marine outfall. The second is a long-term (ongoing) monitoring program, which usually takes a subset of the information obtained from the pre- and post-construction monitoring program, and uses it to define acceptable limits of change in the environmental indicators. Long-term monitoring is designed to determine whether a subsequent change lies outside these limits.

There is an assumption, often tacit, that the engineering aspects of a sewage treatment system and marine outfall are operating as designed. If there is a treatment bypass, breakdown or blockage of some of the outlet ports, the quality of the effluent (or its delivery to the marine environment) will be less than expected. Monitoring the operational performance is an important element of environmental monitoring.

32.6.1 Change Versus Impact

The marine environment is in a state of continual flux. The challenge of a monitoring program is to separate change that occurs via natural processes from change that is a direct result of the discharge from the marine outfall (i. e., impact). It is critical to define what constitutes an impact prior to the execution of the post-commissioning monitoring program. This places clear bounds on the interpretation of change that may be observed in the marine communities.

32.6.2 Pre- and Post-construction Monitoring

Broadly, the pre- and post-construction monitoring program compares conditions before and after the marine outfall is commissioned. It is critical that sufficient time is allowed to carry out the *before* monitoring. An *after* monitoring program can be conducted at any time after commissioning of the marine outfall. However, we only get one chance at the *before* phase of the monitoring program.

A monitoring program may be of several years' duration. Consequently, the cost of an environmental monitoring program may be large – perhaps 5% of the construction costs may be needed to properly address the main environmental issues.

Monitoring Philosophy

Some of the characteristics that constitute a good monitoring program are outlined below. These characteris-

tics combine to define our philosophy for environmental monitoring.

Environmental monitoring programs should be designed to establish cause-and-effect between the discharge and the environmental response. The approach we favor uses *weight-of-evidence*. This simply means applying different techniques and approaches to the same problem. If the answers that they provide are consistent with what might be expected from such discharges, then we have greater confidence in the overall result. Our weight-of-evidence is a three-pronged attack, which is detailed in the following section.

Most countries have guidelines (or licence conditions) that reflect the values that need to be protected. These values include social, public health and environmental aspects. While some values may be subjective, many can be quantified in terms of *safe* levels of contaminants that can be discharged. There is a tacit assumption, that by adhering to these concentration limits, there will be no irreversible damage done to the marine environment.

The most critical task in undertaking a monitoring program to quantify environmental impacts of a marine outfall is to ask the right questions. This requires an understanding of what is being discharged, what effects these discharges are likely to have on the marine environment and the level of change that we are willing to accept. An answer to the wrong question, no matter how accurate is that answer, will not allow impacts to be quantified.

Environmental monitoring programs must be scientifically robust and defensible. We must test a hypothesis and gather empirical evidence to support (or disprove) the hypothesis. The experiment must be repeatable, cover a range of conditions and, in theory, repeated experiments should arrive at the same conclusion. Marine outfalls may be contentious and the monitoring program may need to be defended. One way in which this can be done is via peer review of the work and publication of the results in a reputable journal.

Conditions of approval for a marine outfall are often reliant on predictions. The objectives of an environmental monitoring program should include the verification (or otherwise) of those predictions and whether the environmental values have been maintained. Further, the program should include a mechanism by which problems identified in the monitoring program can be rectified or mitigated.

The Three-Pronged Attack

An approach to collecting weight-of-evidence for impact assessment includes three components. These are detailed below.

Sources of Contaminants. There are many potential sources of contaminants discharged to marine waters, including rivers, sediments (as both a source and sink), private and industrial outfalls, illegal dumping, and coastal wastewater treatment plants. An important consideration to environmental monitoring is separating the relative contribution of an outfall from contributions from the other sources. It may be possible to characterize (and isolate) the different sources via the types, concentrations, and variability of contaminants being discharged from each source.

Marine organisms may be impacted if exposed to wastewater. Toxicity testing is a technique used to determine the concentration of substance which is likely to harm to marine organisms. Whole effluent toxicity (WET) testing examines whether a toxic response is identified when an organism is subjected to the complex wastewater matrix.

If toxicity testing is carried out using a single test organism, it is then inferred that all marine organisms will exhibit the same toxic response. This is not necessarily the case and multiple organisms are recommended for toxicity testing: different organisms display different responses to different substances at different stages in their life cycle. Ideally, a range of fish, invertebrates, and algae at different stages in their life cycle should be considered for toxicity testing. Toxicity tests can be either acute or chronic and both types of tests should be included. The former determine the concentration of wastewater that is lethal to the test organism. Chronic testing examines the reduced capability (e.g., impaired development or reproductive ability) of the test organism.

Movement of Wastewater. Once we know what is being discharged, we determine the path that the wastewater will take after discharge and how dilute it becomes. *Emery* and *Thompson* [32.36] describe many techniques to measure and/or monitor the physical properties of the marine environment.

Instrumented moorings provide excellent temporal coverage although the horizontal spatial coverage is limited by the number of such systems that the monitoring program can afford to deploy. Remote sensing provides good spatial coverage of the region, although in general, the temporal scales are much longer than those associated with the movement of wastewater plumes.

Numerical modeling enables us to predict how the wastewater will react to different marine conditions and to changes in the volume or method of discharge. It is critical to calibrate and validate any numerical model to ensure confidence in the results under existing conditions and for future scenarios. Coupled with this is

a need for confidence limits to be placed on model results. Too often model results are provided without a real appreciation for the confidence that can be placed on those results.

Quantifying Change. There are a number of approaches to quantifying change in response to a marine outfall. One favored by the authors is the *beyond BACI* (or multiple) approach [32.37]. BACI is an acronym for *b*efore, *a*fter, *c*ontrol, *i*mpact. Sites close to, and remote from, the outfall are monitored on several occasions both before and after commissioning of the marine outfall. Perhaps the main reason that this is a favored approach is its emphasis on statistical power and statistical error.

Statistical Errors. A Type I statistical error occurs when the results of our analysis incorrectly predicts that a change has occurred. We can protect against making such a mistake by specifying the level of significance. Usually this is set at 5% (equivalent to 95% confidence limits), i. e., there is a 5% chance that our analysis makes a Type I statistical error.

A Type II statistical error occurs when the results of the analysis incorrectly predicts that a change has not occurred. From an environmental point of view, this is more insidious than a Type I error because it incorrectly leads us to believe that there is no environmental problem. It is difficult to protect against a Type II error as this requires a priori knowledge of the variability in the system being measured. Such knowledge is acquired only after the monitoring is complete. Therefore, we need to use experience to estimate the system variability and design experiments accordingly. To protect against making a Type II statistical error, we usually design our experiments to target statistical power above 80%. However, if statistical power is too high, very small changes become statistically significant and we question whether such small changes are meaningful. It is critical to check the statistical power after the experiments have been completed.

Type III statistical errors occur when we arrive at the correct answer but have asked the wrong question.

Some of the marine components measured to detect change as a result of a new marine outfall include water quality, sediment quality and community studies (such as intertidal, plankton, pelagic, benthic, and sessile communities). Marine community studies should be tailored for specific outfalls and might include:

- Intertidal community studies for shoreline or short outfalls.
- Subtidal settlement panel studies for marine outfall in waters less than about 20 m depth (much deeper than this and the light attenuation starts to inhibit the growth of organisms on the settlement panels).
- Fish, shellfish, and planktonic communities move in, and with, marine waters. The variability among control sites may be as much as the variability between putatively impacted sites and control sites. Therefore, it may be difficult to isolate the marine outfall as the cause of change in such communities.
- Sediments have been used to assess the accumulation of contaminants and to examine infauna community variations. Our experience is that such studies have limited success. Unless the contaminant signal is very strong, it is unlikely to register in a sediment sample.
- Bioaccumulation studies are sometimes recommended as impact assessment indicators. However, caution is needed when interpreting the results of such studies because:
  - Fish move, and it is not always possible to know the region from where contaminants were accumulated. This necessitates fish home range studies, which can be expensive and, perhaps, inconclusive.
  - Species that are caught at one particular time and location may not be caught at other times or locations and pooling into higher biological levels may be required. Different species may accumulate different substances at different rates and the pooling process may mask potential impacts.
  - Moored systems comprising oysters or mussels are often used in bioaccumulation studies. However, this may involve removing the animals from their natural habitat thereby, adding stress to the organisms and confounding the results that are obtained.

32.6.3 Long-Term Monitoring

The pre- and post-construction monitoring program will identify whether there has been a step change in the baseline conditions as a result of the discharge from the marine outfall. Long-term monitoring is used to identify whether further change occurs well after the marine outfall has been commissioned. It can be used to extrapolate trends and, where necessary, design and implement an appropriate mitigation strategy to prevent, or reverse, the trend. The three-pronged attack described in Sect. 32.6.2 is also applicable to long-term monitoring.

However, there is a temptation to simply implement the bulk of the pre- and post-construction monitoring program as part of the long-term monitoring program. Apart from the expense associated in maintaining a de-

tailed monitoring program over a long period of time, environmental changes will be masked by the small time steps between consecutive sets of readings. It may be more effective to implement a low level, long-term monitoring program and revisit the detailed monitoring program, for example, over two consecutive years every 10 yr. If the long-term program indicates a potential problem, it provides the motivation for a more detailed investigation.

Where such an approach is adopted, source characterization combined with numerical modeling are used to estimate environmental impact. If the results indicate a possible impact, confirmation studies can be implemented.

32.6.4 Summary

This chapter provides a synopsis of the discharge of wastewater to the marine environment. Flows of effluent from municipal sewage treatment plants and brine from desalination plants are primarily considered within the context of near-field modeling and outfall hydraulics. The designers of outfalls are under increasing pressure from social, public health and environmental constraints, within a regulatory and economic framework, all of which need to be considered. This compact overview exposes the reader to fundamentals of outfall design and identifies some of the traps and problems that may arise.

Chapter 33. This introductory chapter provides an overview of the state-of-the-art of offshore platforms. The chapter highlights the various structural concepts (such as fixed, gravity, compliant, floating, and subsea platforms) developed during the past 75 years of active offshore exploration and exploitation. The chapter focuses on the various factors that influence the choice of structure during project development and design, and gives an overview of the strength and weaknesses of various offshore development scenarios. The chapter concludes by discussing future trends and developments.

Chapter 34. The *Stability of Offshore Systems* chapter provides the theoretical background to analyze the buoyancy and stability of offshore platforms and discusses the regulatory framework, including IMO regulations, which sets standards of stability. Such standards apply criteria on the righting moment of a floating structure with appropriate safety factors. They aim at preventing incidents related to excessive heel or trim, capsizing, catastrophic loss of buoyancy, or even sinking. Intact stability and damaged stability of floating structures are considered in this chapter. Methods of calculating the righting moment are examined. The spirit and practical application of regulations are discussed in detail.

Chapter 35. The *Wave, Current, and Wind Loads* chapter describes various loads on fixed or floating offshore platforms. Both linear and nonlinear waves are discussed in deterministic and irregular seas. Wave loads on large structures are formulated using linear potential theory in the frequency domain. Morison's equation and the associated drag and inertia coefficients are introduced for slender structures. Also discussed are wave-current interaction and current-induced forces, including vortex-induced vibrations. Both steady and unsteady wind profiles are used to describe wind forces. Model tests and similarity laws are also discussed.

Chapter 36. The *Vortex-Induced Vibrations (VIV) of Slender Structures* chapter reviews the vibrations of flexible structures placed in a cross-flow, caused by vortices forming due to flow instability in the wake. The phenomenon is important for ocean and offshore applications because of possible fatigue damage and increased drag forces, and spans Reynolds numbers from as low as 50, reaching the highest Reynolds numbers recorded. The complex flow-structure interaction mechanisms result in a very rich dynamic behavior, which has made this a canonical problem of flow-structure interaction studies. The focus is on the response of flexible risers and cables, and the review of the effectiveness of vortex cancelation devices.

Chapter 37. The *Structural Dynamics* chapter presents the theory that is especially relevant to dynamics of flexible ocean structures. The primary focus of this chapter is on linear response to regular waves and random seas, but the extension to nonlinear systems is also discussed. Equations of motion in the time and frequency domains for a single-degree-of-freedom system with both viscous and hysteretic damping are presented. Generalization of these concepts to multi-degree-of-freedom systems is then covered. Hydroelasticity, which couples the structural and fluid models, is presented. Numerical solutions including spatial and time discretization and integration are presented. Nonlinear hydroelasticity, viz. fluid-structure interaction, is discussed briefly.

Chapter 38. The *Cable Dynamics* chapter provides information associated with the dynamic behavior of slender cables (e.g., mooring lines) with particular emphasis on marine applications. The scope of the chapter is to associate the aspect of dynamics, linear and nonlinear, with the most typical practical applications of cables in the marine and, especially, in the offshore sector. The chapter first derives a global formulation for the governing dynamical systems, and then numerical methodologies required for their solutions are presented.

Chapter 39. The *Wave-Seabed-Structure Interactions* chapter provides an overview of theoretical models for wave-induced seabed response in marine sediments. This includes the introduction of the existing three well-known models, a new analytical approximation for the wave-induced pore pressure accumulations, a new concept for linking oscillatory and residual mechanisms, and the inclusion of currents in the existing models for wave-seabed interactions. A case of caisson-type breakwater is considered as an application of the proposed numerical models. With the new model, the liquefaction zones around breakwater with different approximations are compared, and the differences identified. Finally, three topics are suggested for future studies in this area.

Chapter 40. The *Buoy Technology* chapter presents an introduction to small buoy systems used for oceanographic or other ocean-monitoring purposes. This chapter outlines typical buoy and mooring types and their applications, buoy and mooring material choices, specialty strength members, and expected dynamic behaviors and specific analysis techniques used to analyze a coupled buoy/mooring system. Tables of material and component properties useful to the designer, as well as a summary of hydrodynamic coefficients for small cylindrical buoys are included. The chapter concludes

with detailed examples of three mooring systems of different types that have been successfully fielded.

Chapter 41. The *Liquid Natural Gas Carrier* chapter discusses the challenges related to the transport of LNG. This chapter first addresses the type of vessels used, both historically and currently. It focuses next on the challenges of transporting such a cold and dangerous cargo and describes the recent advances in solving both environmental and engineering problems, inclusive of sloshing and cargo transfer. The chapter concludes by discussing design methodologies for the various containment systems.

Chapter 42. The *Salvage Operation* chapter presents an introduction to salvage engineering. This chapter outlines the various principles of naval architecture to be able to assess the strength and stability of a damaged vessel. It focuses on the various facets of salvage engineering, focusing on key steps, from planning to survey to reporting, and disseminate the critical information necessary for successful operations. The chapter concludes on types of specific salvages and highlights the differences between them.

Chapter 43. The *Oil Spills and Response* chapter is treats the random phenomenon of oil spills that occur in many sizes and forms. This chapter summarizes the response and cleanup of oil spills. The behavior of oil when spilled dictates the environmental impact it will have. Once spilled, oil on the sea is typically contained using booms and is recovered using skimmers. Dealing with recovered oil and disposing of it are important steps. Spill treating agents are occasionally used. In-situ burning of oil is now being used more frequently. Finally, spilled oil often contacts shorelines, therefore assessment and careful removal techniques for shorelines are essential.

33. Offshore Platforms

Arisi S.J. Swamidas, Dronnadula V. Reddy

An overview of the state-of-the-art on offshore platforms is provided, highlighting the various structural concepts (such as fixed, gravity, and compliant, floating, and subsea platforms) developed during the past 75 years of active offshore exploration and exploitation. It starts with a birds-eye-view of the various platforms that dot the ocean space. Some of the advantages and disadvantages that influence the choice of the structural concepts to be used are discussed. The holistic and integral structural behavior depends on the environmental influences exerted on the important components of the platform in terms of permissible stresses, allowable rotations/deformations, fatigue endurance, vortex-induced-vibration, unobstructed flow of hydrocarbons and overload on the total structural performance; the overview also mentions some effects of the above on marine risers, conductors, wells and pipelines. Finally, possible offshore structural developments that are likely to take place in future are discussed.

33.2.3 Subsea Systems and Pipelines 750
33.3 **Future Trends and Developments in Offshore Platforms** 751
References 752

Offshore drilling and storage platforms play an important role in oil and gas developments around the world. The ever-increasing demand for augmenting our energy needs by offshore exploration and production activities across the globe, and especially by the drilling activities occurring at ultra-deep-water depths, is driving the market. Depending on the water depths at which the oil and gas reserves are available, different types of fixed, floating, and subsea platforms are used for the purpose. In addition, the transportation of oil and gas through subsea pipelines has facilitated the transfer of offshore resources to onshore facilities. For ultra-deep-water depths, semi-submersibles have the highest growth rate and are the most preferred rigs deployed for drilling, in conjunction with other FPSO (floating production storage and offloading) units. Other floating platforms, such as drill-ships, also are being utilized at a decent growth rate for ultra-deep waters, in conjunction with subsea structures. Latin America dominates the global offshore floating drilling platform market since it has high offshore potential reserves of oil and gas in deep and ultra-deep waters. The Asia-Pacific region has the largest increase in shallow-water exploration and production in the waters of Indonesia, Malaysia, and Australia, with the highest growth rate for shallow-water framed and gravity platforms. In spite of the *fracking* of shale (onshore and offshore) decreasing the need for new energy sources in USA and worldwide, dependence on crude oil and natural gas will continue to increase as the global energy demand continues to increase worldwide. In order to satisfy this growing demand for energy, drilling for exploration and exploitation will continue to move offshore from deeper to ultra-deep and colder Arctic waters. In addition, improvements in platform technology in the form of stronger, modular and light-weight construction will impact the structural innovations of existing offshore platforms for many years to come.

33.1 Relevance

A number of platforms, installed in the ocean, exploit the available natural resources, as shown in Fig. 33.1 [33.1]. In addition to the offshore platforms mentioned above, ship types and modes seen in the field of ocean transport include containerization, catamarans, hovercraft, floating terminals, and very large

Fig. 33.1 Opportunities for developing marine structures (after [33.1])

crude oil carriers, along with large numbers of boats and barges that ply the inland rivers. The development of transportation has increased the capability to exploit more of the oceans' alternate energy resources, such as ocean thermal energy conversion (OTEC) and wave and current energy conversion, through direct drive wave energy converters and ocean energy turbines, which have a strong potential for producing energy. Ocean sediments are recognized as a major source of mineral wealth, both hard minerals and petroleum. Offshore oil and gas now supply almost one third of the world's energy needs. While manganese nodules have been recovered from the deep ocean floors of the tropical and subtropical areas, coastal sediments have also been exploited using dredging structures, since they are rich in *industrial minerals* of gold, tin, chromium, platinum, and even sand and gravel [33.2].

Offshore hydrocarbons, a much sought after energy resource, are associated primarily with the continental margins of the world. These margins surround the continents and constitute 25% of the total ocean area. Extending from the shore to the deep ocean floor, the continental margin consists of three units – shelf, slope, and rise. Sediments generally accumulate on the coastal plains and continental shelves. These sediments periodically flow down the continental slopes as turbidity currents to form giant channels of submarine fans and debris flows at their base [33.3].

Due to their thick sedimentary nature, continental margins contain an estimated 99% of the oceans recoverable hydrocarbons, and the deep-ocean sediments only 1% thereof. Furthermore, it has been provisionally estimated that 65% of these hydrocarbons will be found at water depths less than 200 m, 30% from 200 to 2500 m, and only 5% at greater water depths [33.4]; these data are nearly 30 years old. This scenario is likely to change as more of the currently acquired offshore data are consolidated and made available [33.5]. According to the data given in Indexmundi's 2015 crude oil forecast [33.6], the total world consumption of oil per day (for 2013) is given as 90.35 m b/day, and for a year as 32.98 billion barrels.

The world's largest proven oil reserves(in million barrels) are given as (within brackets) [33.7]:

i) Venezuela (297 600)
ii) Saudi Arabia (267 910)
iii) Canada (173 105)
iv) Iran (154 560)
v) Iraq (141 035)
vi) Kuwait (104 000)
vii) UAE (97 800)
viii) Russia (80 000)
ix) Libya (48 010)
x) Nigeria (37 200).

In addition, the top ten oil-consuming countries of the world are listed as [33.8]:

i) USA (19.15 m b/day)
ii) China (9.40 m b/day)
iii) Japan (4.45 m b/day)
iv) India (3.18 m b/day)
v) Saudi Arabia (2.64 m b/day)
vi) Germany (2.50 m b/day)
vii) Canada (2.22 m b/day)
viii) Russia (2.21 m b/day)
ix) South Korea (2.20 m b/day)
x) Mexico (2.07 m b/day).

As a result, the development and use of the older and newly innovated offshore platforms will depend on the investments made in developing the offshore fields by most of the countries mentioned above.

Despite the challenges of offshore ocean exploration, exploitation, and maintenance, nearly 35% of global oil production and 27% of gas production comes from offshore areas. Although it is expected that continental shelves will satisfy a significant part of the future oil and gas requirements, and also that dependence on fossil hydrocarbon resources will last for at least another 50 years, the oil industry is already looking to the ultra-deep-water zones on the continental slopes for future oil supplies. The industry has continued to invest in infrastructure and new techniques for exploitation in deep waters, leading to enhanced underwater facilities. It appears that the huge fixed steel platforms used today will in future be increasingly replaced by floating production platforms and smaller-scale subsea production technology deployed directly on the seabed, similar to those already in existence on the North and Norwegian Sea basin margins,

Brazil's Campos Basin, and the Gulf of Mexico. Exploiting and transporting oil and gas reserves in the harsh and inhospitable Arctic regions, containing nearly 30% of world's undiscovered hydrocarbons, would require innovative structural development and management strategies [33.9].

33.2 Types of Offshore Platforms

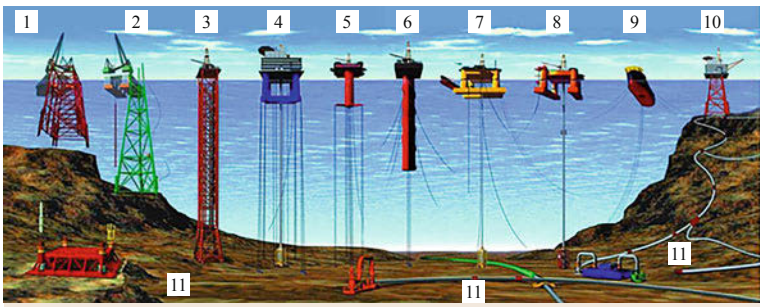
At the present juncture, more than 9500 offshore platforms are being used worldwide, operating in water depths ranging from 10 ft to nearly 10 000 ft. Topside weights range from 5 to 50 000 t, producing oil, gas, or both. Some of the major offshore oil and gas platforms, used in the context of ocean oil and gas exploitation, are shown in Fig. 33.2 [33.10, 11]:

i) Conventional fixed platforms (including gravity platforms) (Shell's *Bullwinkle* at 412 m deep water, in the Gulf of Mexico)
ii) Compliant tower (ChevronTexaco's *Petronius* at 534 m deep water in the Gulf of Mexico)
iii) Vertically moored tension leg and mini-tension leg platform (Conoco-Phillips' *Magnolia* in 1425 m deep water, in the Gulf of Mexico)
iv) Spar (Dominion's *Devils Tower* in 1710 m deep water, in the Gulf of Mexico)
v) Semi-submersibles (Shell's *NaKika* field in 1920 m deep water, in the Gulf of Mexico)
vi) Floating production, storage, and offloading facility (in 1600 m deep water, in the Campos Basin offshore Brazil)
vii) Subsea cluster completions and tie-back to host subsea facility (Shell's *Coulomb* field at 2307 m deep water tied to the *NaKika* field in the Gulf of Mexico)
viii) Subsea system with flow lines to a host fixed framed platform (Shell's *Mensa* field in 1620 m deep water, tied to a shallow-water jacket platform, in the Gulf of Mexico).

The platform concepts range from fixed and compliant, floating and subsea systems.

Referring to Fig. 33.2, platforms listed as categories 1–6 (along with 10) can be classified as fixed and compliant systems. Thus fixed and compliant systems include: steel jackets/towers (with or without tie-backs), concrete gravity platforms, jack-up, compliant towers, tension leg platforms (TLP), and spar concepts. The floating systems include: semi-submersibles, floating production storage, and off-loading units (FPSO), moored ship platforms and barges (listed under categories 7–9 in Fig. 33.2). The subsea systems include: (i) drilling and production units located on the seabed, listed under category 11 in Fig. 33.2 (economical for marginal fields and others in ultra-deep waters – tied to existing installations for access); and (ii) pipeline transportation systems for oil and gas.

Generally speaking an offshore platform has the primary function of allowing the extraction of hydrocarbons from below the sea-bottom, with the minimum treatment and maximum safety. The produced hydrocarbons are then transported safely to hydrocarbon refining plants on the nearby coasts, for treatment prior to commercialization. Due to the high costs of offshore construction, requisite offshore facilities are thus kept



1 & 2: Conventional fixed production platforms
3: Compliant tower production platform
4 & 5: Moored tension leg production platform
6: Spar production platform
7 & 8: Semi-submersible drilling rigs
9: Floating production storage and offloading facility
10: Subsea completion and tie-back to host facility
11: Subsea systems and flow lines

Fig. 33.2 Offshore structural concepts used offshore (after [33.10], courtesy of NOAA)

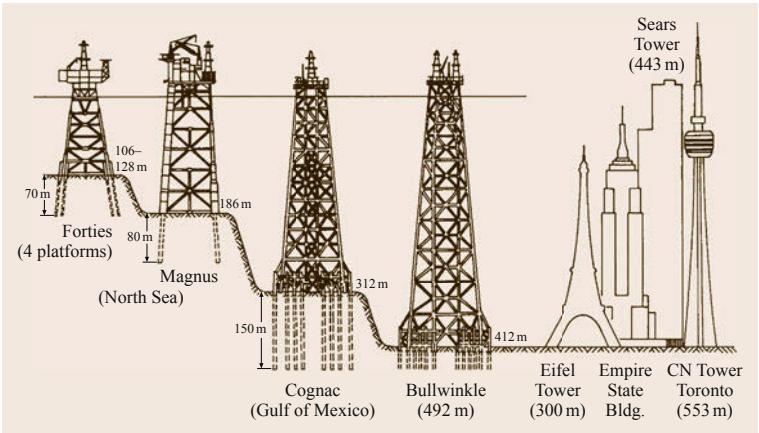


Fig. 33.3 Fixed platforms compared with known landmarks (after [33.12])

to a bare minimum by maximizing onshore prefabrication and modular assembly.

33.2.1 Fixed and Compliant Offshore Platforms

As stated earlier, this group of platforms is governed by fixity to the ocean bed. Depending on the fixity (or bottom supported) conditions the platforms can be classified as:

i) Fixed (rigidly or elastically)
ii) Bottom supported (with or without skirts and piles, providing transverse resistance)
iii) Compliantly restrained.

Use of these platforms is governed mainly by the maximum seawater depths at which they are to be located. Figure 33.3 [33.12] gives a typical comparison of various fixed platforms used in the offshore contexts, comparing them with some noted onshore landmarks. When water depths become deeper than 450 to 500 m, the fixed jacket and bottom supported gravity platform costs become exorbitant; hence the compliantly restrained platforms (at sea bottom) are needed to increase the depths (up to 1300 m), at which these platforms can be located economically. Even though the tension leg platforms and spars are moored to the ocean bottom through elastically restraining tension legs, mooring cables, and marine risers (similar to some floaters like semi-submersibles and FPSOs), they are still listed under fixed or compliant platforms, since their transverse motion is limited by the depths under which the marine riser systems can function properly due to:

i) Large bending stresses exerted on the conductors (from loads transmitted from the riser system)
ii) The need for uninterrupted hydrocarbon flow through the risers due to limited rotation (2°) permitted at its bottom.

In some of the recent TLP and spar systems, these restrictions have been removed (by using new tension riser systems) and they are now listed under floaters where there is no limit on the transverse surge motions [33.13]. These floaters can operate in up to 3000 m water depths.

Fixed platforms have a number of advantages over compliant and floating systems. These platforms can support very large deck loads (with facilities for refining the extracted oil and gas), can be prefabricated (in

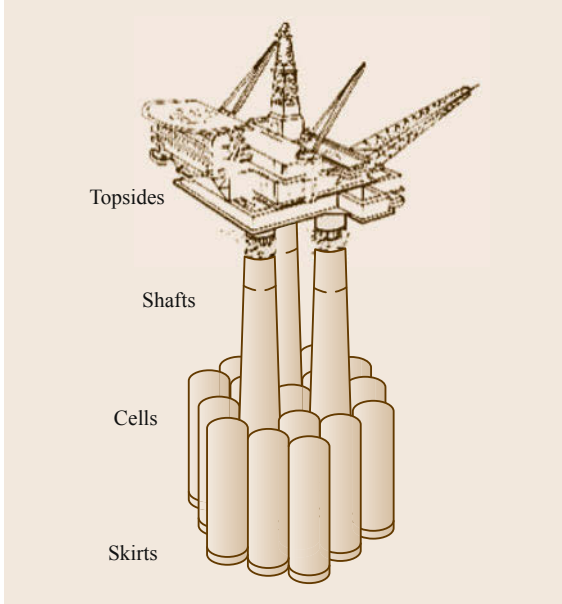

Fig. 33.4 Components of a gravity platform (after [33.14])

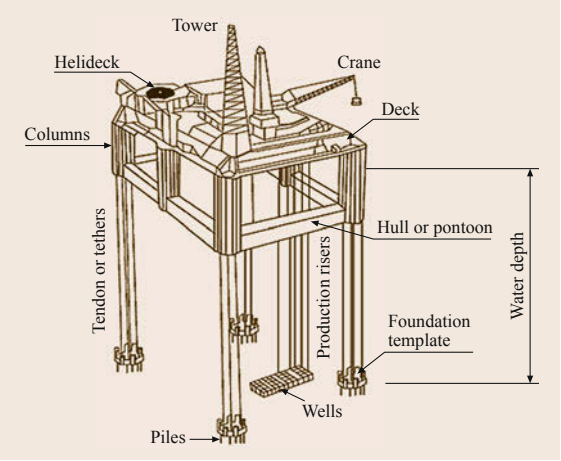

Fig. 33.5 Components of a tension leg platform (after [33.15])

on-land areas or dry docks) off their installation site in modular sections, assembled, and transported to the installation site, provide a stable support for a long-term usage, and are affected very little by sea-bottom scour around the piles. Some of their disadvantages are that the platform costs are very high initially, they have large maintenance costs due to fatigue and corrosion, and they are not reusable. The gravity platform (maximum permissible wear depth is 350 m) (Fig. 33.4 [33.14]), also enjoys similar advantages like the fixed jacket platforms with lower maintenance costs; they are also more resistant to fatigue and corrosion degradation. The main disadvantages are that they are more costly than framed steel jacket platforms and experience much larger foundation settlement/scour during their lifetimes. The jack-up platforms have retractable legs and are used for exploratory drilling and for servicing offshore wind farms. They are easily removable from one site to another. The depth of operation is limited to a maximum of 165 m.

Compliant offshore platforms (listed under this category) have a maximum water depth limitation of 1300 m. These platforms withstand and dissipate large transverse wave forces by moving laterally under the wave excitation. Due to their lower rigidity at the supporting base (with hinged end conditions at its bottom), the surge natural frequencies of these structures are much lower than the wave excitation frequencies. Hence, the phenomenon of resonance is avoided and the structure moves back and forth, executing a slow surge oscillatory motion. The tension leg platform (TLP), shown in Fig. 33.5 [33.15], is similar to a four-legged semi-submersible (with transverse submerged pontoons) held in place (with very small lateral motions) by vertically tensioned tendons, connected to the seafloor through templates and piles driven into the soil through them. TLPs have a water-depth limit of 1300 m; recently TLPs were also used at 2000 m.

The spar platform structure consists of a relatively long cylindrical tower of 200–250 m length (other types of spars, called trussed spars, are square in plan form), with watertight vertical cylindrical tanks (located inside the long cylindrical tower, with ballasting and de-ballasting capabilities). The spar is anchored to the seafloor by tensioned long cylindrical cables, connected to the seabed by suction anchors. Conventional spars have a limit imposed on their transverse motions by the permissible bending stress on the conductor, due to tensioned drilling risers and vortex-induced vibrations. In addition, the rotation at the base of the riser string is limited to 2° to permit proper flow of drilled

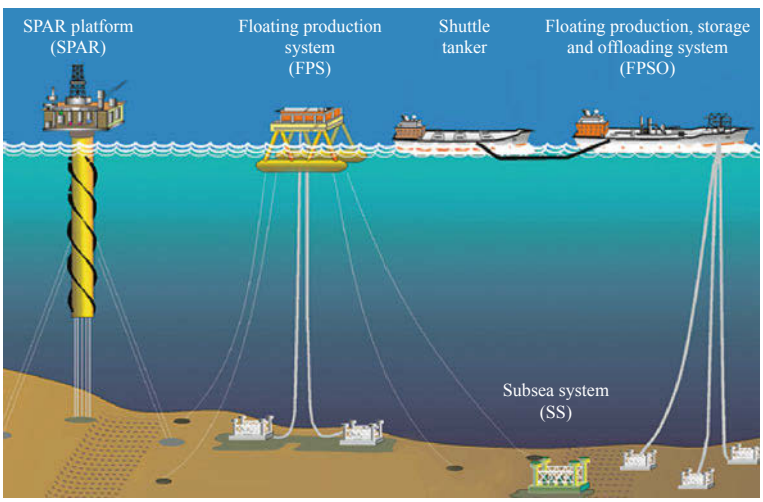

Fig. 33.6 Floating offshore structures (courtesy of The Bureau of Ocean Energy Management, after [33.16] BOEM)

hydrocarbons [33.13]. Initial spars were depth-limited to 1300 m.

33.2.2 Floating Offshore Platforms

As was mentioned before, floating offshore platforms, shown in Fig. 33.6 [33.16], consist of improved spars and TLPs, semi-submersibles, floating production storage and off-loading units (FPSO), moored ship-type platforms, and barges. In using these structures for water depths deeper than 1300 m, the previous limitation on the bending stresses in marine conductors is removed by using large diameter conductor pipes with increased wall thicknesses; the use of large diameter pipes increases their fatigue lives 5 to 10 times [33.13]. The blow-out-preventer (BOP) stacks provided at the top of the conductors have reduced lengths, along with the stick-up length (viz., the distance between the ocean bottom and the bottom of BOP stacks) of the conductors, to optimize the permitted stress levels. In addition, buoyancy provided at riser joints is increased by using syntactic foam elements with embedded micro glass or ceramic spheres. Along with an increase of the tension provided for riser strings, the risers are also provided with strakes to minimize or suppress vortex-induced vibration stresses; moreover the riser joints are provided with choke and kill lines made of titanium to minimize corrosion problems. These improvements have enabled spar platforms and other floating structures to operate efficiently at depths greater than 3000 m.

Floating production storage and off-loading (FPSO) units may be semi-submersibles or ship-shaped vessels, which float by their buoyancy. They are generally moored in place with flexible catenary-shaped wire ropes and/or polyester ropes, although they can also be kept in place by the use of dynamic positioning, if necessary. They are provided with subsea production systems, in which a group of wells is pre-drilled on a template installed on the seabed. Then the production unit is installed over the drilled wells and completed with subsea well heads. The FPSO unit is moored in a central position, with respect to the drilled subsea wells; these subsea wells are then connected by rigid (or flexible) pipelines to carry the reservoir fluids from the wellheads to surface storage vessels (with loading buoys) from which they can be offloaded to oil carriers. Other small-diameter flexible tubes, called umbilicals, connect the subsea production units to the surface units located on the floating vessel; these contain the electrical cables and hydraulic fluids required to control the wellheads from the surface. Drill-ships are vessels that are fitted with drilling equipment. Most often they are used for exploratory drilling for oil or gas wells in deep waters. Most drill-ships are fitted with dynamic positioning systems to maintain position over the well. They can drill in water depths up to 3660 m.

33.2.3 Subsea Systems and Pipelines

A subsea well consists of a wellhead template assembly and a wet Christmas tree, which is the underwater assembly of valves, spools, and fittings, used to control the flow of oil and gas out of the drilled well; since the system functions on the seabed, it is designed

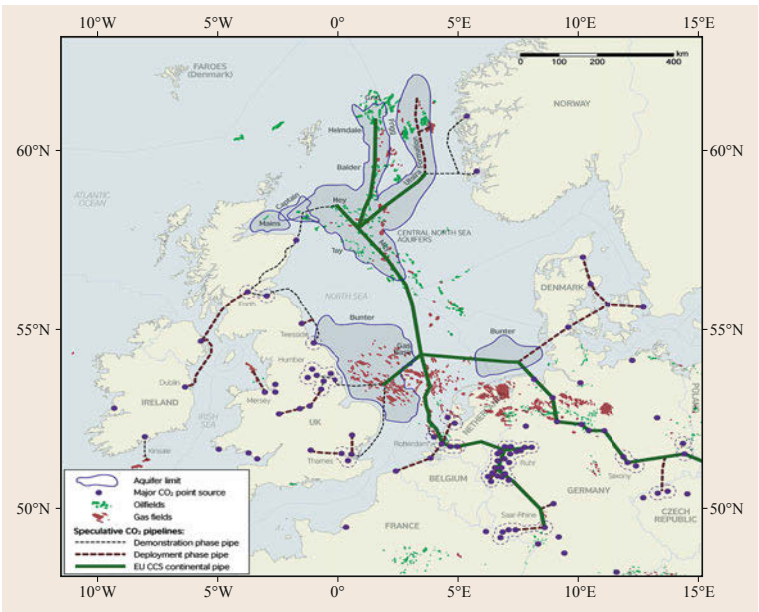

Fig. 33.7 Integrated pipelines in the North Sea Region (after [33.17])

such that it will always operate reliably. Generally, independent subsea wells are used for fixed or floating platforms for recovering reserves located beyond the reach of the horizontal drill-strings. Large multi-well subsea systems have also been installed with remote operating vehicle (ROV) intervention. In some of these subsea system operations they are tied to some existing deep-water or shallow-water platforms. A notable tieback (to a fixed platform located at a depth of 113 m) is the Mensa subsea development connected by flow lines of 101 km length, at a water depth of 1645 m in the Gulf of Mexico. Recently, much longer and deeper water-depth (≈ 1830 m) subsea systems have been developed with tiebacks to onshore systems in Brazil [33.18].

Submarine pipelines, which are laid on the seabed or buried inside a trench on the seabed, are used to carry produced oil and gas from the ocean depths to onshore systems. Figure 33.7 [33.17] shows one of the best and optimally used interconnections of pipelines around the North Sea offshore developments, transporting oil and gas to countries around its shores, viz., Ireland, Scotland, UK, Norway, Denmark, Sweden, Belgium, Holland, France, Germany, and the Czech Republic. The pipeline design and construction took into account the existing seabed ecology to preserve its biodiversity along its route to the shore [33.19, 20], international boundaries, geo-hazards, and the environmental loadings that will be exerted on the system. The pipeline diameters generally vary from 76 mm (for gas lines) to 1800 mm (for high capacity flow), and the wall thicknesses vary between 10–75 mm. The pipelines are protected against corrosion with epoxy or bituminous coatings and are often weighted down with concrete lining. The maximum internal pressure for design is taken as 10 MPa.

33.3 Future Trends and Developments in Offshore Platforms

Global energy consumption is forecast to expand 1.8 times by 2035 compared to that of 2010, and during the same period consumption of crude oil is expected to increase just over 30%, mainly in developing countries. Consumption of natural gas is forecast to rise greatly, by 50% or more in 2035, as compared with 2010. The depletion of existing fields will call for the discovery of new offshore drilling sites to maintain secure oil and gas supplies.

To give a context in terms of possible offshore development around USA, Fig. 33.8 [33.21] gives the undiscovered technically recoverable oil and gas resources available offshore. Hence, there is still a lot of scope for innovative structural developments to take place when the above-mentioned federal offshore acreages become available for development. Figure 33.8 gives the scope for possible offshore development for oil and gas resources around the federal offshore acreage in USA; the area shown consists of 89.9 billion barrels of oil and 404.6 trillion cubic feet of gas. Offshore industries are predicting a large investment (by a factor of three to four times current levels) on offshore structures and related facilities during the coming years [33.22]. It is believed that the Arctic re-

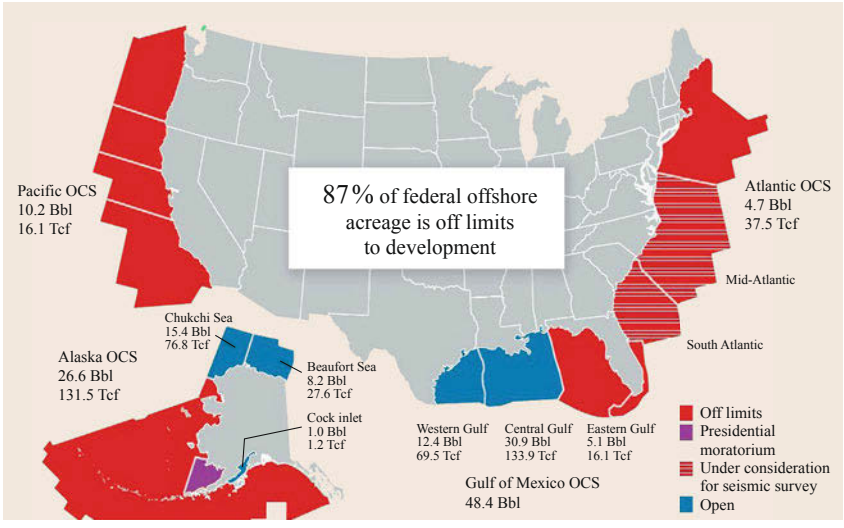

Fig. 33.8 Offshore technically undiscovered recoverable oil and gas resources around USA in federal acreage (Bbl and Tcf) (after [33.21])

gion holds significant volumes of oil and gas; until now investment in Arctic development and production has been rather small and most of it has been in areas with light to moderate ice conditions and relatively shallow waters, using artificial islands or gravity base structures [33.9].

A number of technology development targets are being set and will continue to be pursued. Some of these targets include [33.5, 9, 11, 13, 23, 24]:

- Lightweight, strong, and modular jackets, FPSO, and subsea concepts with storage capabilities for requisite water depths (varying from 1000 m to 4000 m), and with efficient long-distance tie-backs, would require more investment in offshore projects. Multi-phase pumping through pipelines would minimize costs considerably.
- Innovative developments in the float-over and self-installation of complete topsides of jackets and FPSOs (and their mooring systems) in a reliable and optimal manner (to avoid heavy offshore lift, intricate hook-up/commissioning and consequent accidents) is required. Reliable and automatically controlled seabed processing of oil and gas resources, with minimum intervention from above will make the operations economically more attractive.
- Advances in large-diameter, top-tensioned dry-Christmas-tree risers (the connecting valves, spools, and fittings are located on top of riser arrays), and arrays with catenary profiles that permit contact, optimal clashing, flow assurance, and long-term structural integrity at ultra-deep-water depths are very important [33.25].
- Prevention of the specific risks of a blowout in the ultra-deep waters by smart down-the-hole remote monitoring of conductors and risers, and provision of extra horizontal drilling conductors, that will become operative when reservoir pressures build up.

34. Stability of Offshore Systems

Alexia Aubault, R. Cengiz Ertekin

Stability analysis is a major aspect of the design of offshore platforms. It focuses on averting any failures associated with excessive heel or trim, capsizing, catastrophic loss of buoyancy, or even sinking. In this chapter, we cover the buoyancy and stability of offshore platforms from both viewpoints of theoretical and regulatory issues. Intact and damaged stability of floating structures are discussed and essential formulations of the associated problems are introduced. In doing so, the stability of a platform (its ability to be at or to recover equilibrium at acceptable heel and/or trim angles) is assessed by comparison of the righting moment to overturning moments from external loads. Methods of calculating the righting moment that varies with the heel angle are discussed. At small heel and trim angles, the metacentric height and displacement may be used directly to calculate the righting arm. Overturning moments that account for all static loads, including environmental, operational, and live loads are listed as well. Assumptions are needed to calculate the applied loads, and stability analysis does not usually include the upsetting dynamic forces. To address these issues, regulators set criteria, with embedded safety factors, and they require sufficient reserve stability beyond the equilibrium of the platform. These and the risks associated with flooding are addressed through hull subdivision and damaged analysis in this chapter.

Stability is one of the most critical aspects of offshore engineering, and the cornerstone of naval architecture. It aims at verifying that a vessel will remain afloat at equilibrium, and will not heel so much as to breach watertightness. For commercially built vessels, stability analysis follows internationally recognized rules. Rules rely on the calculation of a number of variables, which are common to the stability analysis of any floating body, and are based on classical rigid body mechanics.

The analytical framework for stability, much like many of the concepts of modern mathematics, was established in the mid-eighteenth century. French mathematician *Pierre Bouguer* [34.1] first introduced the concept of metacenter in his 1746 treatise of naval architecture, while, around the same time, Euler derived the notion of righting moment to assess the stability of a ship. As the first classification societies were created, in the nineteenth century, these tools were incorporated in newly devised rules and are still in use today.

The body of regulation has continued expanding to integrate lessons learned from past incidents. It has contributed to reducing casualties at sea. At first, regulations were aimed solely at ship-shaped vessels. However, as other types of floating vessels were built and serviced, new rules were developed. Although the mathematical tools remain the same, floating structures are subjected to varied loads from the environment. They also derive their stability in different ways. A deep draft platform, for instance, relies on a low center of gravity for stability, thus compensating a relatively small waterplane area. Traditional ship-shape vessels by contrast typically derive most of their stability from their large waterplane area. The function of a vessel further justifies variations in stability criteria. While a bulk carrier may be most susceptible to loss of buoyancy due to shifting of cargo, stability criteria must take into account the effect of umbilical and mooring on permanently moored offshore platforms. The variety of vessel types, functions, and exposure to the environment has resulted in a multiplicity of rules for stability. The present chapter focuses on stability criteria for offshore platforms and systems.

34.1 Stability Criteria

Offshore platforms and vessels are generally used for oil storage, exploration, or production. There are many types of offshore platforms; the five basic types are shown in Fig. 34.1.

Jacket-type platforms are the oldest platforms in existence since the late 1940s. The first jacket platform was installed in water depth of only 6 m! Today, jacket platforms can be installed in much deeper water depths. The drilling of oil is achieved by using risers that run from the deck to the ocean floor and then to great depths below the ocean floor depending on the location of the oil reservoir. These platforms are generally carried from the shipyard to the installation site by barges and in a number of pieces (or modules). Then they are upended from the barge(s) at the installation site. Upending and setdown of the modules involve very careful analysis of the buoyancy and stability characteristics of the platform and the barge combination before the installation takes place. This event is simulated through computer runs to make sure that upending will be successful and that modules would be able to mate the other modules when upended [34.2].

Gravity-type platforms are made of either concrete or steel. Although they are supported by their weights, sitting on the ocean floor, they are secured by piles, as are jacket platforms.

Semisubmersibles are the more common offshore platforms. Buoyancy is provided by the submerged pontoons and columns that are below the water surface. As a result, the wave forces that act on the platform are less than they would otherwise be; this in turn results in smaller platform motions, something that is very desirable. The other advantage of a semisubmersible is that it is mobile, that is, it can move on its own power to a new location when necessary, or sometimes transport vessels with caissons can piggyback a semisubmersible to move it to a new location. It can also be positioned dynamically through trusters.

TLPs have been more commonly used in recent years in oil production because of their very favorable motion characteristics. The very little dynamic movement of the platform is achieved by tensioning the tendons (which basically are pipes) attached to the legs (or columns of the platform) and the ocean floor. The vertical (static) equilibrium of the platform must consider the weight, buoyancy, and the pretension in the tendons of the platform (Sect. 34.3.2). There are a number of TLPs currently

operating also in the Gulf of Mexico and in the North Sea.

And finally, there are oil storage and exploration/production platforms that are of gravity-type. They are generally equipped with mud skirts that prevent them from sliding under the action of waves. Their conical shapes are mainly to break the ice sheets and thus prevent the collapse of the structure under the tremendous stresses caused by them. An advantage of such a platform is that it can be transported to a different location if necessary. A number of these platforms currently operate around the world. Installation of such platforms is also a challenging buoyancy and stability problem [34.2].

Basic concepts of naval architecture and mechanics of bodies are reviewed in this chapter. The quantities typical of stability analysis, such as metacenter, and righting moment, are introduced. Their formulas are derived and interpreted. These theoretical calculations apply to any vessel; therefore reference to a ship may be used in some cases for simplicity. In this regard, it is noted that many monographs [34.3–7] on the buoyancy and stability of ships can be used in the intact or damaged stability calculations of offshore structures. Stability analysis is inherently concerned with statics. Yet, dynamic forces may affect stability of a vessel temporarily, and are described as well. Understanding the loads that apply to a vessel is essential to set and apply appropriate stability criteria. Therefore, potential effects on offshore platforms from environmental, operational, as well as dead and live loads are outlined.

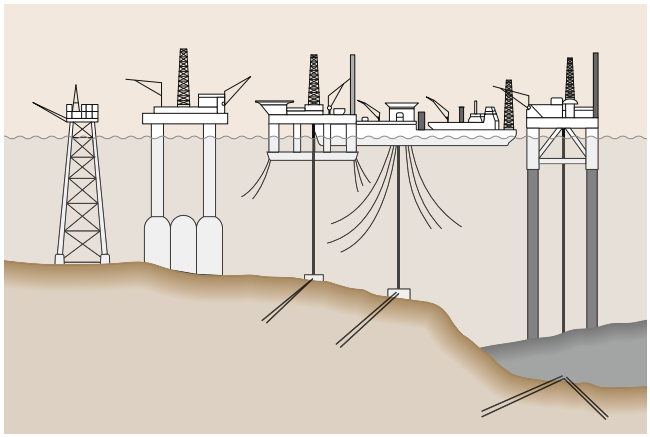

Fig. 34.1 Some offshore platform types. From left to right, they are: jacket-type platform (or *jacket* in short), gravity-type platform, semisubmersible (or *semi* in short), floating production ship or floating production, storage, offloading (FPSO) ship, and tension-leg platform (TLP) (after [34.8])

This chapter discusses performance standards for offshore platforms. A distinction is made between intact and damaged stability. Regulatory bodies enforce rules of stability for offshore platforms, using a set of tools throughout the lifetime of a vessel. The intent and possible implementation of the regulations are outlined herein as well.

34.2 Fundamentals

34.2.1 Static Movements and Hull Position Float

These movements include the three rotations of an offshore platform with respect to the three basic planes:

1. Transverse plane: A platform may heel to either the starboard or port side due to static forces, such as lifting a weight. Statically (when it is time-independent), this movement is called list angle or heel angle, as illustrated in Fig. 34.2. Dynamically (when it is time dependent), it is called rolling.
2. Middle-line plane: A platform may trim to either bow or stern due to a static force, such as cargo movement. Statically, this movement is called trim angle (Fig. 34.3). Dynamically, it is called pitching.
3. Water plane: A platform may drift to either port or starboard side due to a static force such as steady wind or current. Statically, this movement is called drift angle (Fig. 34.4). Dynamically, the rotation is called yawing. We will show that stability is not affected by movement in this plane, whether statically or dynamically.

Superposition of these movements can be done linearly as long as the angles are not very large.

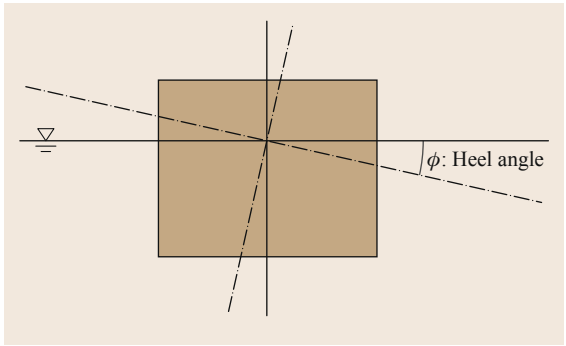

Fig. 34.2 List (heel) of a platform

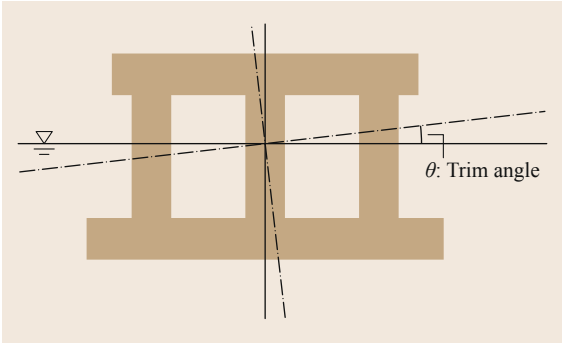

Fig. 34.3 Trim of a platform

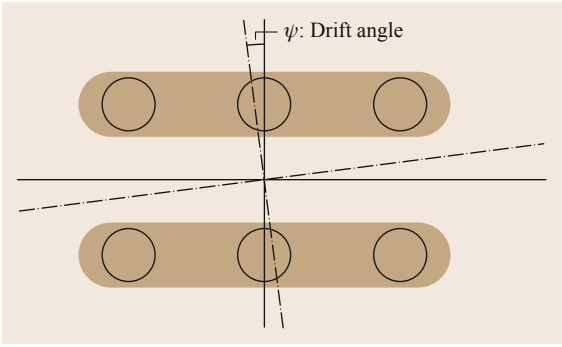

Fig. 34.4 Drift of a platform

34.2.2 Dynamic Movements

Like any three-dimensional rigid object, a ship has six degrees-of-freedom in its motions. These dynamic movements or motions are shown in Fig. 34.5. The x-axis runs through the centerline and positive x-axis points toward the bow. The positive y-axis points toward the port side of the ship and the positive z-axis points up, in the negative direction of the gravitational force.

The time-varying motion in the x-direction is called surge, in the y-direction it is called, sway and in the z-direction it is called heave. These are translational motions. The rotational or angular motion about the x-axis is called roll, about the y-axis pitch, and about the z-axis yaw. The dynamic motions are due to the presence of water waves (that are periodic) and so the six rigid-body motions are also periodic with their periods equal to the wave period. These dynamic translational and rotational motions are beyond the scope of this chapter. They will seldom be discussed further except for heave, roll, and pitch when we refer to the hydrostatic stiffness of offshore platforms in Sect. 34.4.9.

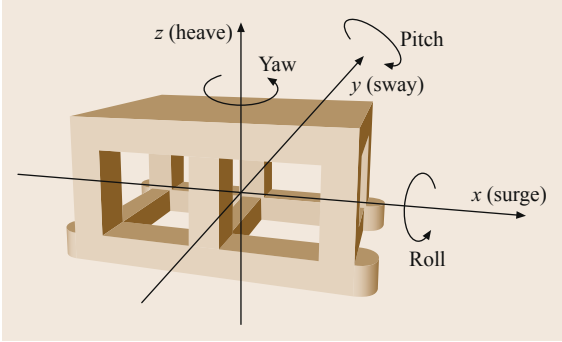

Fig. 34.5 Dynamic motions of a platform

34.2.3 Some Geometric Definitions

The three planes discussed in Sect. 34.2.1 are used both for ships and offshore platforms. Additionally, some essential geometric definitions are provided as follows:

- Keel (K): The baseline that runs at the lowermost of the platform, generally along the lowest surface of the pontoon or column, and generally parallel to the waterline.
- Draft (d): The vertical distance between the keel of the platform and the waterline.
- Freeboard: The vertical distance from the waterline to the uppermost watertight deck.
- Starboard: The right side of the platform when facing the bow.
- Port: The left side of the platform when facing the bow.
- Longitudinal center of flotation (LCF): The center of gravity of the waterplane area of the structure at the desired waterline (say the load or design waterline).

34.2.4 Center of Buoyancy and Gravity

When a structure immerses in water, the centroid of the submerged volume of the structure is called the center of buoyancy B. This centroid of the submerged volume is used in hydrostatics to do a number of calculations that will be discussed in later sections. Similarly, the location of the center of gravity of the structure is an important quantity and this location is used in stability calculations. We assume that the entire weight of the structure acts at the center of gravity G, of the structure. The first moments of both the center of buoyancy and center of gravity are zero with respect to themselves.

The longitudinal position of B, in the middle-line plane, is denoted by LCB; the transverse position, in a transverse plane, is TCB; and the vertical position, measured from the keel, is denoted by VCB (or $\overline{\text{KB}}$ sometimes). Similar notations apply to the position of the center of gravity (LCG, TCG, VCG).

34.2.5 Irregular Shapes and Numerical Integration

In buoyancy and stability calculations, we will see later that we need to determine various integral quantities, such as areas, volumes, and their moments. Most of the time, however, it is not possible to calculate these quantities analytically, but rather numerically. Therefore, we need to discuss first some basic integrals that will be used to do the integrations for some two-dimensional (2-D) and three-dimensional (3-D) shapes.

Areas and First and Second Moments

Most of the time, offshore platforms are made up of several different smaller shapes geometrically, such as rectangles, triangles, circles, and so forth. Then we can write composite equations for areas and their first moments as well as the center of gravity of areas

$$A_\mathrm{T} = \sum_{i=1}^{N} A_i\,, \quad M_x = \sum_{i=1}^{N} y_i A_i\,, \quad M_y = \sum_{i=1}^{N} x_i A_i$$

$$\overline{x}_\mathrm{c} = \frac{\sum_{i=1}^{N} x_i A_i}{A_\mathrm{T}}\,, \quad \overline{y}_\mathrm{c} = \frac{\sum_{i=1}^{N} y_i A_i}{A_\mathrm{T}}\,, \tag{34.1}$$

where N is the number of each smaller area, A_i is the area of each small shape, A_T is the total area, M_x and M_y are the first moments of the total area with respect to the x and y axes, and x_c and y_c are the coordinates of the center of gravity of the area (Fig. 34.6).

The moment of inertia of area (also known as the second moment of area) is used in the calculation of stability due to the presence of the waterplane area, as we will see later. Keeping Fig. 34.6 in mind, we can write, in general,

$$\mathrm{d}I_x = y^2\,\mathrm{d}A = y^2\,\mathrm{d}x\,\mathrm{d}y\,,$$

$$I_x = \sum \mathrm{d}I_x = \sum y^2\,\mathrm{d}x\,\mathrm{d}y\,, \tag{34.2}$$

and

$$\mathrm{d}I_y = x^2\,\mathrm{d}A = x^2\,\mathrm{d}x\,\mathrm{d}y\,,$$

$$I_y = \sum \mathrm{d}I_y = \sum x^2\,\mathrm{d}x\,\mathrm{d}y\,. \tag{34.3}$$

Parallel-Axis Theorem

Sometimes it is necessary to calculate easily the moment of inertia of an area with respect to an axis parallel to another axis (with respect to which we already know the second moment). If we know the moment of inertia of an area about an axis passing through the center of gravity of the area, then we can determine the moment of inertia of the same area with respect to any other axis which is parallel to the original one. Consider Fig. 34.7 for illustration. We write

$$I_x = I_{x'} + \overline{y}^2 A, \quad I_y = I_{y'} + \overline{x}^2 A\,, \tag{34.4}$$

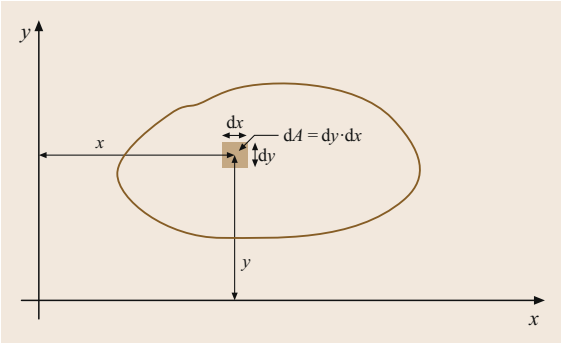

Fig. 34.6 Differential area

where $\overline{x}$ and $\overline{y}$ are the coordinates of the origin of the transformed coordinates measured from the original coordinates as shown in Fig. 34.7. Note that $I_{x'}$ and $I_{y'}$ should be the lesser of the inertia in the equation as both x' and y' pass through the neutral axes of the area (defined as the axes that pass through the center of gravity of the area), and hence the plus signs in front of the second terms on the right sides of the equations in (34.4).

Three-Dimensional Shapes

Three-dimensional shapes involve volumes and their moments. Such calculations are necessary to determine the displacement and the centroid of the submerged volume of the structure. In the case of platforms which have a number of buoyant components (such as columns and pontoons) connected to each other, one can calculate the volume and the center of buoyancy in a straight forward manner. Consider Fig. 34.8 and let $i = 1, 2, \ldots, N$ denote the label (used to identify a structural member) of the buoyancy component. Then, the volume of the platform is calculated by

$$\nabla = \sum_{i=1}^{N} V_i\,, \tag{34.5}$$

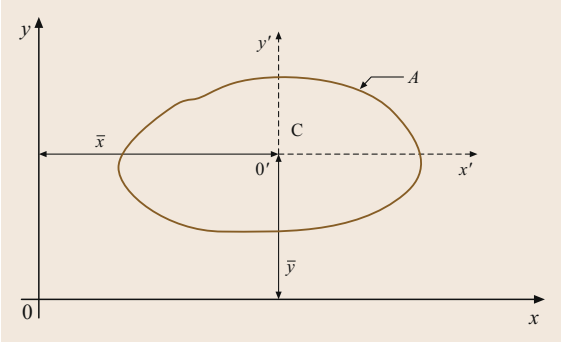

Fig. 34.7 Origin of the transformed coordinates for the parallel-axis theorem calculations

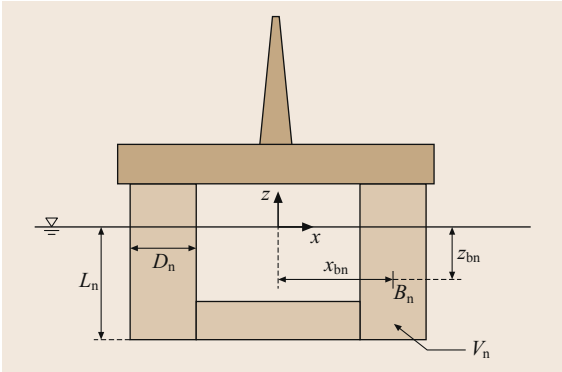

Fig. 34.8 Main dimensions of a floating platform

where V_i is the submerged volume of the i-th structural member.

The center of buoyancy of the platform can be calculated by taking the volume moment of each member, summing them up, and then dividing the sum by the total submerged volume of the platform,

$$x_B = \frac{1}{\nabla}\sum_{i=1}^{N} x_{bi} V_i \,,$$

$$y_B = \frac{1}{\nabla}\sum_{i=1}^{N} y_{bi} V_i \,,$$

$$z_B = \frac{1}{\nabla}\sum_{i=1}^{N} z_{bi} V_i \,, \qquad (34.6)$$

where $(x_{bi}, y_{bi}, z_{bi}) \equiv B_i$ denote the coordinates of the centroid (of the underwater volume) of the structural member i whose underwater volume is V_i.

Numerical Integration

There are many numerical methods of integration; however, the following are the most commonly used methods:

- Trapezoidal rule: Compound trapezoidal rule (Fig. 34.9) can be obtain by summing up the trapezoidal rule of integration for adjacent areas and by use of a first-order polynomial as the approximating polynomial for the ordinates. The area can be calculated, for example, by

$$A = \frac{h}{2}\left(y_0 + 2y_1 + 2y_2 + \cdots + 2y_{n-1} + y_n\right) \,, \qquad (34.7)$$

where n is equal to the number of nodes minus 1, and h is the constant *grid length* or *grid size* or *interval length*. Note that the truncation error in this method is $O(h)$.

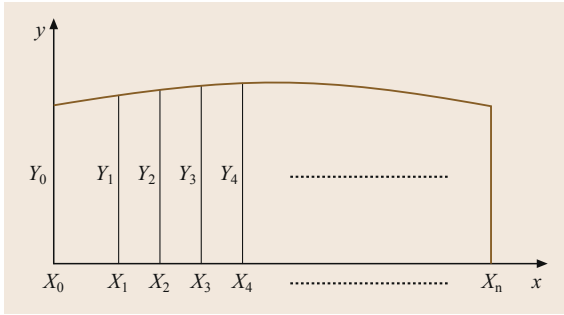

Fig. 34.9 Compound rule of integration

The static moment with respect to the y-axis can similarly be calculated as follows,

$$M_y = \int_0^L xy\,\mathrm{d}x = \frac{h}{2}(0 \times y_0 + h \times 2y_1 + 2h \times 2y_2 + 3h \times 2y_3 + \cdots \cdots + (n-1)h \times 2y_{n-1} + nh \times y_n) \,, \qquad (34.8)$$

where the origin is assumed to be at $x = 0$. The origin can be placed at any desired location, and the distance products, that is, $0, h, 2h, 3h, \ldots, nh$, in

Table 34.1 Unit system conversion

Physical quantity	Imperial unit	SI unit
Length	1.0 ft	0.3048 m
Length	1.0 in	0.0254 m
Length	1.0 yd	0.9144 m
Length	1.0 nautical mile (international)	1852 m
Length	1.0 nautical mile (UK)	1853.18 m
Length	1.0 mile	1609.344 m
Area	1.0 ft^2	0.092903 m^2
Area	1.0 in^2	645.16×10^{-6} m^2
Area	1.0 yd^2	0.836127 m
Volume	1.0 in^3	16.3871×10^{-6} m^3
Volume	1.0 ft^3	0.0283168 m^3
Velocity	1.0 ft/s	0.3048 m/s
Velocity	1.0 knot (international)	0.51444 m/s or 1.852 km/hr
Velocity	1.0 knot (UK)	0.51477 m/s or 1.85318 km/hr
Acceleration (gravitational)	32.174 (32.2) ft/s^2	9.80665 (9.81) m/s^2
Force	1.0 lb f	4.44822 N
Force	1.0 (long)ton f (2240 lb f)	9964.0128 N
Force	1.0 (short)ton f (2000 lb f)	8896.44 N
Mass	1.0 slug	14.59 kg
Mass	68.54 slug	1 ton = 1000 kg (metric)

(34.8), can be adjusted accordingly. Similarly, the equation for the second moment can be obtained.

- Simpson's first rule: This rule can be obtained by fitting a second-order polynomial to the ordinates. Compound Simpson's (first) rule is based on summing the adjacent integrals,

$$A = \frac{h}{3}(y_0 + 4y_1 + 2y_2 + 4y_3 + 2y_4 + \cdots + 4y_{n-1} + y_n) \,. \tag{34.9}$$

Note that the number of points (or nodes) must be an odd number ($n+1 = 3, 5, 7$, etc.) or the number of intervals should be an even number, $n = 2, 4, 6$, etc., to apply this method. Moreover, the interval size is constant. The coefficients in front of the ordinates (or offsets in the case of sectional area calculations), in (34.9) for example, are called *Simpson Multipliers* or in short *S.M.*, that is, $1, 4, 2, 4, \ldots, 4, 1$. Note that Simpson's formula is exact even for a third-degree polynomial. The truncation error in writing (34.9) is $O(h^3)$. Clearly, this is a much smaller error than in (34.7) when dimensionless $h \ll 1$. Similarly, formulas for first and second moments can be obtained.

34.2.6 Unit Systems

Most of the countries today use the SI unit system, and only a handful use the imperial unit system. Table 34.1 shows the unit conversion factors for some physical quantities that may be used in hydrostatics and stability calculations.

34.3 Hydrostatic Forces and Moments

Buoyancy is the ability of a structure in a fluid to be in vertical equilibrium. The subject of buoyancy is typically part of the field of hydromechanics which covers hydrostatics and hydrodynamics. Most problems of buoyancy indeed arise for bodies, including ships and platforms, floating in water, whether it is fresh water or salt water. All theoretical principles discussed herein may, however, be applied to problems in an alternative fluid, provided the value of fluid density is adjusted. When we discuss buoyancy herein, we are referring to the equilibrium of bodies in water, that is, hydrostatics.

34.3.1 Buoyancy and Displacement

Let us first discuss the hydrostatic pressure, and the forces and moments that a fluid element experiences under static conditions.

If a fluid element is in equilibrium, the static forces in the z (vertical) direction must sum up to zero, where

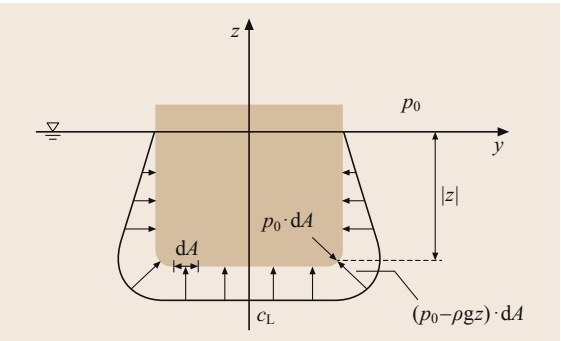

Fig. 34.10 Pressure force around the cross-section of a floating structure

z is positive above the still-water level (SWL), also referred to as the mean-water level (MWL), for a free-floating body. This leads to $p = p_0 - \rho g z$, where p_0 is the atmospheric pressure on the surface ($2116\,\mathrm{lb/ft^2}$ or $304\,704\,\mathrm{lb/in^2}$ (psi) or $101\,325\,\mathrm{Pa}$), and is small compared with p in general. And also, because of the continuity requirement for the pressure on the SWL, p_0 right above and right below the SWL must be the same. The addition of atmospheric pressure to p does not change the net pressure on the structure since inside the structure there is the atmospheric pressure as well; the outer and inner atmospheric pressures cancel each other. Therefore, we ignore p_0 and write

$$p = -\rho g z, \quad z \le 0 \,, \tag{34.10}$$

where p is called the hydrostatic pressure. The typical distribution of the force due to this pressure around a cross-section of a structure is shown in Fig. 34.10.

Archimedes' principle can be stated as *A structure immersed in a fluid is acted upon by a pressure force which is equal to the weight of the displaced fluid*. This force is in the vertical direction only. This principle then leads to hydrostatic forces that act on a floating or submerged structure be equal to

$$F_x = 0, \quad F_y = 0,$$
$$F_z = -w \int_A -\mathrm{d}\nabla = +w\nabla = \rho g \nabla \equiv \Delta \,, \tag{34.11}$$

where ∇ is the underwater (submerged) volume of the structure. In other words, $F_z = w\nabla = \rho g \nabla \equiv \Delta$, where Δ is the displacement (weight or force) or buoyancy

force. Since F_x and F_y are zero, we know that there is no hydrostatic restoration force in the x and y directions. Equations (34.11) can be obtained by integrating the distributed hydrostatic pressure on the wetted surface of the structure or it can be obtained by use of Gauss' divergence theorem.

The hydrostatic moments can be obtained by integration of the distributed pressure in the direction normal to the wetted surface of the structure

$$M_x = wy_B\nabla, \quad y_B = \frac{\int_A y\,d\nabla}{\nabla}, \quad M_y = -wx_B\nabla,$$
$$x_B = \frac{\int_A x\,d\nabla}{\nabla}, \quad M_z = 0, \tag{34.12}$$

where x_B and y_B are the coordinates of the center of buoyancy (centroid of the underwater volume)

$$x_B = \frac{-M_y}{\Delta}, \quad y_B = \frac{+M_x}{\Delta}. \tag{34.13}$$

In writing (34.12) or (34.13), we assumed of course that the first moments of the volumes were calculated with respect to the same coordinate system that x_B and y_B are measured in. Note also that M_x is the transverse moment of the displacement about the longitudinal axis, x, and M_y is the longitudinal moment of the displacement about the transverse axis, y, and that $M_z = 0$ indicates that there is no hydrostatic moment on the still-water level, that is, no static drifting moment (Sect. 34.2.1).

In summary then, there is no hydrostatic force or moment (and therefore no hydrostatic restoration) on the horizontal plane, something that is known intuitively; only the vertical force (displacement) and the two hydrostatic moments about the x-axis (list or heel moment) and the y-axis (trim moment).

34.3.2 Equilibrium of Forces and Moments

Here we refer to the equilibrium of a structure when we discuss the stabilizing forces and moments. Since there is no hydrostatic force or moment on the horizontal plane, we do not discuss equilibrium on that plane. A structure is said to be in vertical and rotational equilibrium if

1. Weight of the structure (W) is equal to the buoyancy force (or displacement) (Δ), i. e., $\sum F = 0$ (force equilibrium), or

$$W = \Delta = \rho g\nabla, \tag{34.14}$$

and

2. The center of buoyancy and the center of gravity must lie on the same vertical line so that $\sum M = 0$ (moment equilibrium). In other words,

$$\sum M_y = 0: \; +Wx_g - \rho g x_B\nabla = 0,$$
$$\sum M_x = 0: \; -Wy_g + \rho g y_B\nabla = 0,$$

after we used (34.14). And therefore,

$$x_B = x_g, \quad y_B = y_g, \tag{34.15}$$

where x_g and y_g are the coordinates of the center of gravity and, as before, x_B and y_B are the coordinates of the center of buoyancy. This means that the longitudinal center of buoyancy (LCB) must be the same as the longitudinal center of gravity (LCG); they are on the same vertical to the keel when the structure is in equilibrium. Similarly, the transverse centers of buoyancy (TCB) and gravity (TCG) must be on the same vertical.

If there are any cables, risers, or mooring lines that are under tension, the equilibrium of forces must take these into account. In the case of a tension-leg platform, for example, the pretension in the tendons must be added to the weight of the platform, and this will be equal to the displacement.

We must next mention the reserve buoyancy which is the volume between the design (or load) waterline and the main (watertight) deck as shown in Fig. 34.11. If we denote the reserve buoyancy by ∇', then

1. If $W > \rho g(\nabla + \nabla')$ the structure will sink, i. e., it is vertically unstable.
2. If $W < \rho g(\nabla + \nabla')$ the structure is vertically stable; it will come back to an equilibrium state if a small weight is added or removed. This is because of the hydrostatic restoration force the water provides in the vertical z direction.

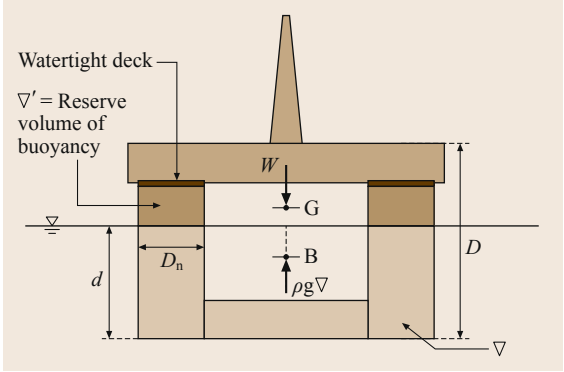

Fig. 34.11 Reserve buoyancy

3. If $W = \rho g(\nabla + \nabla')$ the structure is in neutral equilibrium (after the addition of a small weight, for example, it will not come back to its equilibrium state).

The equilibrium conditions can be thought of as the potential energy being, maximum (unstable), minimum (stable), and constant (neutral) as in an equilibrium model. For example, the equilibrium on the horizontal plane can be considered as neutral.

34.3.3 Shifting of Weight and Volume

Frequently, it is necessary to shift, add, remove weights, masses, areas, volumes, etc. on a structure. There is an elegant theorem called the law of moving (removing/adding) centroids (masses/weights/areas) that allows one to easily do this.

The upsetting forces that act on a floating or submerged structure may be due to, for example, the shift of some weight. It is of interest then to know how the center of gravity will shift as a result of weight movement on board. Similarly, when a platform heels, part of it immerses and part of it emerges, thus causing the centroid of underwater volume to shift. To see how these movements occur, let us consider the following theorem (Fig. 34.12):

Theorem 34.1

Let $\overline{\mathrm{M}}$ denote a structure of mass M with its center of gravity at G_0, and let some part $\overline{\mathrm{m}}$ of mass m (which is part of M) with its center of gravity at g be moved to a new position. Let the new center of gravity of $\overline{\mathrm{m}}$ be g_1. Then the new center of gravity G_1 of the altered structure has the property that the line $\mathrm{G}_0\mathrm{G}_1$ is parallel to gg_1. And furthermore, if $l = \overline{\mathrm{gg}_1}$ and $L = \overline{\mathrm{G}_0\mathrm{G}_1}$, then $ML = ml$.

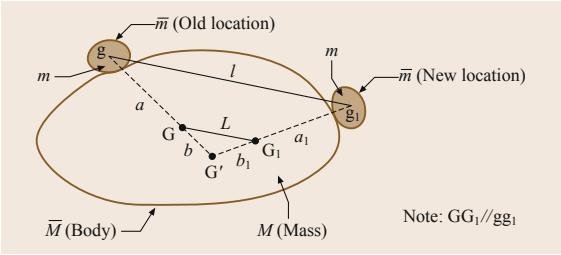

Fig. 34.12 The shifting of part of a structure mass to a new location

Without giving the proof, we give the final result

$$\frac{M}{m} = \frac{a+b}{b} = \frac{a_1+b_1}{b_1} = \frac{l}{L}\,. \tag{34.16}$$

Thus, $ML = ml$. Note that (34.16) of moving (or shifting) mass is applicable to other physical quantities such as volumes or areas or weights. It can also be used for removing and adding such physical quantities and therefore it can be used in hydrostatic and stability calculations. See, for example, Sect. 34.4.4 for some applications of this theorem.

34.4 Stability

The stability of a structure in water can be determined in terms of the existence of an equilibrium position, either at rest or subject to static movements such as sinkage, list or trim, and whether the structure has the ability to recover an equilibrium position after such static movement. This can be achieved by calculating the righting moment of the structure and comparing it with any external moment that will try to incline the structure. Let us start with the concept of righting (static stability) arm and moment.

34.4.1 Righting Arm, Righting Moment, and Metacentric Height for Small Angles

Consider a cross-section of a floating structure as shown in Fig. 34.13. Because of the effect of an externally applied moment (wind moment, moment due to the shifting of a weight, etc.), the structure heels or lists a small inclination angle of $\delta\phi$ and reaches a new equilibrium position. It is noted that *small angle* (less than

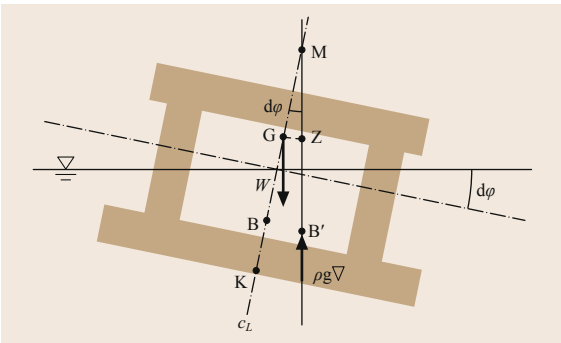

Fig. 34.13 The cross-section of a structure in inclined position (the center of gravity is below the metacenter)

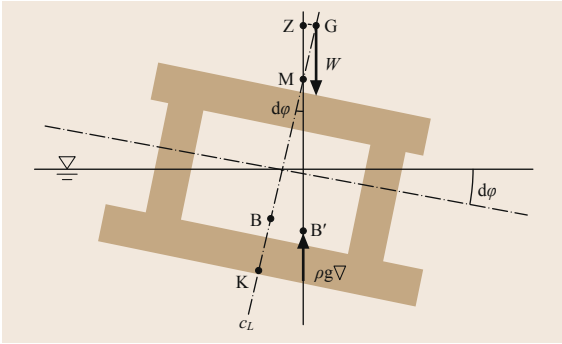

Fig. 34.14 The case of the center of gravity being above the metacenter

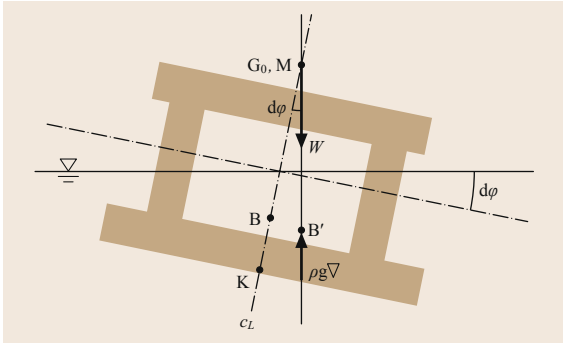

Fig. 34.15 The case of the center of gravity being on the metacenter

about 10°) is the key word here to have a fixed metacenter point M. The metacenter point is the intersection of the ship centerline with the line perpendicular to SWL and originating from the new center of buoyancy B′. The calculation of a fixed M point relies on the condition that as the platform lists, the volume that comes out of the water on one side is symmetrical to that which sinks under the waterline on the other side. It is valid only for small angles, when $\sin(\delta\phi) \approx \tan(\delta\phi) \approx \delta\phi$. The buoyancy force (or the displacement), $\Delta = \rho g \nabla$, remains the same (since no weight is added or removed and thus $\Delta = W$), but the center of buoyancy moves to a new position B′ because we lost some underwater volume on one side and gained the same on the other side.

The reaction (or righting) moment is $W\overline{GZ}$, and it can be determined from the following equation,

$$W\overline{GZ} = \Delta\overline{GZ} = \rho g \nabla \overline{GZ} = w\nabla\overline{GM}\sin\delta\phi \approx w\nabla\overline{GM}\delta\phi, \quad \delta\phi \ll 1\,\text{rad}\,, \tag{34.17}$$

where $\overline{GM}$ is called the transverse metacentric height (similarly, there also exists the longitudinal metacentric height). In short, these are referred to as the metacentric height or initial metacentric height. The term *initial* refers to the fact that small inclination angle assumption ($\delta\phi < 10^\circ = 0.175\,\text{rad}$) is used in the derivation of (34.17), and this is stressed. $\overline{GZ}$ is known as the righting-moment arm, or simply the *righting-arm*.

The metacentric height, $\overline{GM}$, is actually a measure of stability. To see this, consider the case in which G is above M, $\overline{GM} < 0$, as seen in Fig. 34.14. The weight causes the reaction moment in the same direction of list. This will result in the capsizing of the structure. If $\overline{GM} = 0$ then there is no reaction moment and the ship will be in neutral equilibrium as shown in Fig. 34.15. If $\overline{GM} > 0$, the righting moment will oppose heeling as was shown in Fig. 34.13. Therefore, $\overline{GM}$ can be used to determine the initial stability of the structure. Note that the metacentric height is given by

$$\overline{GM} = \overline{KB} + \overline{BM} - \overline{KG} = \overline{KM} - \overline{KG}\,, \tag{34.18}$$

where $\overline{KB}$ = centroid of the underwater volume (vertical component)(calculated), $\overline{BM} = \overline{BM}_T$ = transverse metacentric radius (calculated), and $\overline{KG}$ = vertical component of the center of gravity (either calculated/estimated or determined through inclining experiments).

34.4.2 Transverse Metacentric Radius

The transverse metacentric radius included in (34.18) need to be calculated for small list angles. This can be done by considering a longitudinal slice of a wedge of water at the waterline and calculating the amount of displacement shifted as a result of some external moment that inclines the structure. For small list angles, it can be shown that

$$\overline{BM} \equiv \overline{BM}_T = \frac{1}{\nabla}\frac{2}{3}\int_L y^3\,dx = \frac{I_T}{\nabla} = \frac{I_x}{\nabla}\,, \tag{34.19}$$

where I_x or I_T (the subscript T stands for transverse) is the second moment of the entire waterplane area with respect to the x-axis and ∇ is the underwater volume of the structure. To indicate that $\overline{BM}$ refers to the transverse rotation or rotation about the x-axis, the notation $\overline{BM}_T$ is generally used to denote the transverse metacentric radius.

34.4.3 Trim and Longitudinal Initial Stability

Trim by the stern means that excess trim is at A.P. (aft perpendicular) and trim by the bow (stem) means that

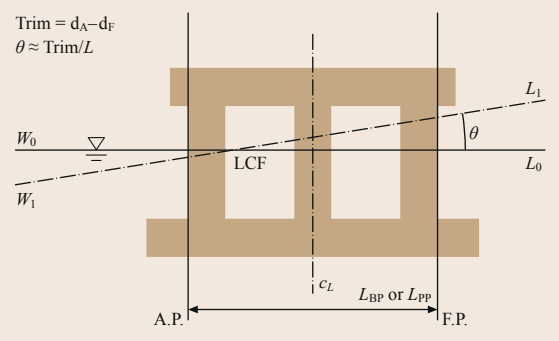

Fig. 34.16 Trim by the bow

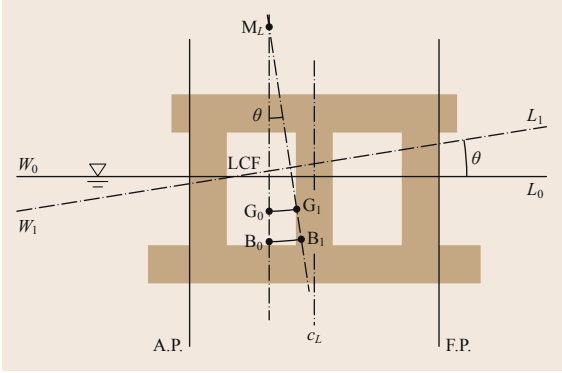

Fig. 34.17 The longitudinal metacenter

excess trim is at F.P. (forward perpendicular). For example, in Fig. 34.16, the trim is by the bow. We write

$$\text{trim} = t = d_A - d_F \,,$$
$$\tan\theta = \frac{t}{L} \Rightarrow \theta = \frac{t}{L} \text{ for small } \theta(< 10^\circ) \,, \quad (34.20)$$

where θ is the trim angle. With the (rather arbitrary) definition of trim given by (34.20), negative trim would mean that trim is by the bow.

If the *displacement* of the structure remains the *same* during trim, it can be proven that the structure must rotate about the LCF.

Trim can be calculated once the moment that causes the trim is known as

$$t = \frac{\text{Moment to change trim}}{\text{MCTC}} \,,$$
$$\text{MCTC} = \frac{\Delta\,\overline{G_0M_L}}{100\,L}, \text{ (ton m/cm)} \,, \quad (34.21)$$

where t is in centimeter, Δ is in ton, and $\overline{G_0M_L}$ and L in m, and the division by 100 is due to the definition of MCTC, that is *per centimeter*. Moment to change trim by one centimeter (MCTC) is used to calculate the trim easily as it is given in *hydrostatic curves*. In imperial unit system, the trim is written as

$$t = \frac{\text{Moment to change trim}}{\text{MCT1}''} \,,$$
$$\text{MCT1}'' = \frac{\Delta\overline{G_0M_L}}{12L}, \text{ (tonf ft/in)} \,, \quad (34.22)$$

where t is in inch, Δ is in longtonf (1 longtonf is 2240 lbf) and $\overline{G_0M_L}$ and L are in feet.

The longitudinal initial stability can be calculated very similar to the transverse one. The initial metacentric height for longitudinal inclination (trim) is written as

$$\overline{GM}_L = \overline{KB} + \overline{BM}_L - \overline{KG} \,, \quad (34.23)$$

where $\overline{GM}_L$ is the longitudinal metacentric height (initial) and $\overline{BM}_L$ is the longitudinal metacentric radius (Fig. 34.17). The vertical locations of the center of buoyancy, $\overline{KB}$, and center of gravity, $\overline{KG}$, are clearly the same as the ones used in the transverse stability calculations.

The longitudinal metacentric radius $\overline{BM}_L$ in (34.23) is obtained from

$$\overline{BM}_L = \frac{I_L}{\nabla} \,, \quad (34.24)$$

where I_L is the second moment of the waterplane area about the transverse axis, y', passing through the LCF.

The longitudinal metacentric height is much larger than the transverse metacentric height for ship-shaped vessels, and thus, the longitudinal intact stability of a vessel is not of concern most of the time, unless, of course, the displacement is very small. Nevertheless, it should be calculated in any case, and moreover, the knowledge of the longitudinal metacentric height is necessary in trim calculations as well as in damaged stability calculations.

34.4.4 Weight Addition, Removal, and Shift

When weights are added or removed or shifted, the centers of gravity and buoyancy will move. These movements can be calculated rather easily by use of the law of moving centroids, discussed in Sect. 34.3.3.

For example, assume that a weight, already onboard, is shifted to one side a distance of $\overline{g_0g_1}$ (Fig. 34.18). Both the center of gravity and the center of buoyancy will move to the same side until they are on the same vertical line which passes through the metacenter M. Note that, from the law of moving centroids, we must have G_0G_1 parallel to g_0g_1. Hence,

$$\tan\varphi = \frac{\overline{G_0G_1}}{\overline{G_0M}} \,. \quad (34.25)$$

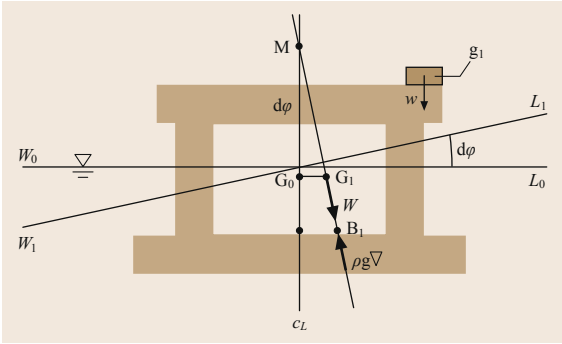

Fig. 34.18 A structure with a weight already onboard shifted to one side

This equation can be used to determine the new location G_1, of the center of gravity given by φ, G_0 and M. It can also be shown (or using the law of moving centroids when $L = \overline{G_0G_1}$, $M = W$, $m = w$, $l = \overline{g_0g_1}$ in (34.16)) that

$$\overline{G_0G_1} = \frac{w\overline{g_0g_1}}{W} , \tag{34.26}$$

so that the list angle is calculated from $\tan\varphi = \overline{G_0G_1}/\overline{G_0M}$, or

$$\varphi = \arctan\left\{\frac{w\overline{g_0g_1}}{W\overline{G_0M}}\right\} . \tag{34.27}$$

The list can then be calculated easily since

$$\text{List} = d_{\text{port}} - d_{\text{starboard}} ,$$
$$\tan\varphi = \frac{\text{List}}{\text{B}} \Rightarrow \text{List} \approx \text{B}\varphi$$

for small φ, where d_{port} and $d_{\text{starboard}}$ are the drafts on the port and starboard sides, respectively.

In the case of weight addition, there is a very useful quantity, called TPC (or TPI, depending on the unit system) that can be used. In deriving the new center of buoyancy of a floating structure when a weight, w, is added, we considered a slice of volume added to the ship. Can we find the approximate thickness of this slice? To answer this question, consider the weight, w, that sinks the structure by 1.0 cm. And let it float in water of mass density ρ. Then, for not *very large* weights, it is true that $A_{\text{WP}} \times 1.0\,\text{cm}$ is approximately equal to the added volume, and of course, this is exact for a wall-sided structure. The mass of the weight added must then be equal to $m_{\text{w}} = w/g = A_{\text{WP}} \times \rho \times 1.0\,\text{cm}$.

We can now define TPC as the ton (mass) per centimeter immersion (when the waterplane area A_{WP} is given in m^2 in SI units)

$$\text{TPC} = \frac{m_{\text{w}}}{1.0\,\text{cm}} = \frac{\rho A_{\text{WP}}}{100} = 0.01025 A_{\text{WP}} , \tag{34.28}$$

where 100 on the denominator comes from the *meter* to *centimeter* conversion, and the last equality above uses $\rho = 1.025\,\text{ton/m}^3$ (salt water). Note again that *ton* refers to mass, and not to weight (1000 kg = 1 ton), and A_{WP} is in m^2.

In the imperial unit system, the tonf-per-inch immersion of a waterplane is defined as the weight required to effect a parallel sinkage of a structure, at that waterline, of 1.0 in. If A_{WP} is given in ft^2, then the weight required to immerse the structure by 1.0 in is given by TPI (tonf per inch immersion)

$$\text{TPI} = \frac{w}{1.0\,\text{in}} = \frac{\rho g A_{\text{WP}}}{12} , \tag{34.29}$$

which, for $\rho = 2.0\,\text{slug/ft}^3$ (salt water) and $g = 32.0\,\text{ft/s}^2$, becomes

$$\text{TPI} = \frac{A_{\text{WP}}}{12}\frac{64\,\text{lb/ft}^3}{2240\,\text{lb/tonf}} = \frac{A_{\text{WP}}}{420} ,$$

where $1/(\rho g) = 2240/64 \approx 35\,\text{ft}^3/\text{tonf}$ is called the reciprocal weight density of salt water, and 1.0 longtonf = 2240 lb, and A_{WP} is given in ft^2.

We can now define parallel sinkage as

$$s = \frac{w(\text{tonf})}{\text{TPI}}\,(\text{in}) \quad \text{or} \quad s = \frac{w(\text{ton})}{\text{TPC}}\,(\text{cm}) , \tag{34.30}$$

where w is the added weight (similarly, r = rise can be defined if w is the removed (or negative) weight). Equation (34.30) is exact for wall-sided structures, and approximate for others.

When a weight is removed along the centerline, the same arguments used for parallel sinkage apply, except the weight becomes $-w$, and the structure will rise (this is called parallel rise) and is denoted by r.

34.4.5 Effects of Liquid Free-Surface in Internal Tanks

There may be many internal tanks in a floating structure that is partially or fully filled with a liquid. These can be ballast tanks, oil tanks, septic tanks, etc. When the structure heels due to some external force, the free surface of the liquid in these tanks will incline and, therefore, there will be a shift of liquid weight due to the movement of the liquid free-surface. This shift of weight will cause the metacentric height, $\overline{GM}$, to reduce, and thus, the stability of the ship will suffer as a result.

One can calculate the moment of weight of the shifted liquid due to the free surface of the liquid inside the tank and determine the amount the center of gravity

of the structure is shifted. This way, one can calculate the reduction in the righting (static stability) arm of the structure since the metacentric height is now different, and obtain

$$\overline{\mathrm{GM}_{\mathrm{Eff}}} = \left\{\overline{\mathrm{G_0M}} - \frac{\rho_\mathrm{l}}{\rho_\mathrm{s}}\frac{i_\mathrm{T}}{\nabla}\right\}, \qquad (34.31)$$

where ρ_l is the density of the liquid in the tank, ρ_s is the density of water that the structure floats in, ∇ is the submerged volume of the structure, and i_T is the second moment of the free-surface area of the tank with respect to its own longitudinal axis; $\overline{\mathrm{GM}_{\mathrm{Eff}}}$ is called the virtual or effective metacentric-height. The second term on the right-side, $(\rho_\mathrm{l}/\rho_\mathrm{s})(i_\mathrm{T}/\nabla)$, is called the virtual loss in metacentric height. If there is more than one tank, then the losses due to each tank's liquid free-surface must be summed. Note that this result is obtained by assuming that the list angle is *small*.

The loss of stability due to the presence of liquid free-surface in internal tanks can be reduced in some cases by creating subdivisions in each tank so that the virtual loss in metacentric height becomes $(\rho_\mathrm{l}/\rho_\mathrm{s})(i_\mathrm{T}/\nabla)(1/n^2)$, where n is the number of subdivisions.

34.4.6 Scribanti's Formula

There is a formula that can be used to calculate the righting arm, $\overline{\mathrm{GZ}}$, of a wall-sided (or nearly wall-sided around the still-water level) structure or vessel for inclining angles up to about 25°. This formula can be derived by calculating the vertical and horizontal moment of the sectional wedge volume and integrating along the length of the structure, and then determining the new value of the righting arm, see [34.3] Chapt. 4, Sect. The Wall-Sided Formula

$$\overline{\mathrm{GZ}} = \left(\overline{\mathrm{GM}} + \frac{1}{2}\overline{\mathrm{BM}}\tan^2\phi\right)\sin\phi\,. \qquad (34.32)$$

It is noted that for small ϕ, we had $\overline{\mathrm{GZ}} = \overline{\mathrm{GM}}\,\phi$ previously. The righting-arm, $\overline{\mathrm{GZ}}$, formula given by (34.32) is known as Scribanti's formula. The righting moment follows from $M_\mathrm{st} = \Delta\overline{\mathrm{GZ}}$.

34.4.7 Stability at Large Angles of Inclination

Recall that the static moment or righting moment of a floating structure or vessel for small inclination angles is given by (34.17). This assumes that the metacenter is a fixed point. In the case of large list/trim angles, however, the metacenter M is no longer fixed but moves along a curve called the metacenter curve or M-curve. A vessel rotates about the point where the centerline meets the waterline when the list/trim angle ϕ is small. For large inclination angles, this is no longer true in general unless the vessel is wall-sided.

To calculate the righting arm, $\overline{\mathrm{GZ}}$, for any list/trim angle, one needs to determine the location of the center of buoyancy as well as the center of gravity. The latter is generally assumed initially and then a correction due to it can easily be made in calculating the righting arm, once the exact location of the center of gravity is determined.

We can summarize the procedure for these calculations as follows:

1. Assume that the vessel is in upright position, meaning G and B are on the same vertical line (and no trim) as shown in Fig. 34.19.
2. Rotate it without trim, about the x-axis as shown in Fig. 34.20. The center of buoyancy may move horizontally and, therefore, B and G will not be on the same vertical line.
3. Allow it to trim so that the weight-buoyancy and trim equations are satisfied; i. e., B and G are on the same vertical line as shown in Fig. 34.21. The righting arm, $\overline{\mathrm{GZ}}$, shown on the right, is now the correct one which must be determined in this position.
4. To determine $\overline{\mathrm{GZ}}$, calculate the static/righting moment M_st of the structure/vessel. The righting arm is then obtained from $\overline{\mathrm{GZ}} = M_\mathrm{st}/\Delta$.

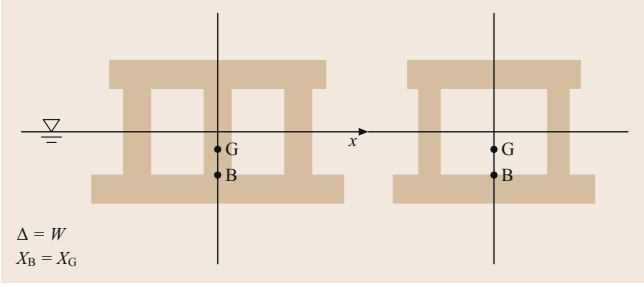

Fig. 34.19 The vessel is in upright position

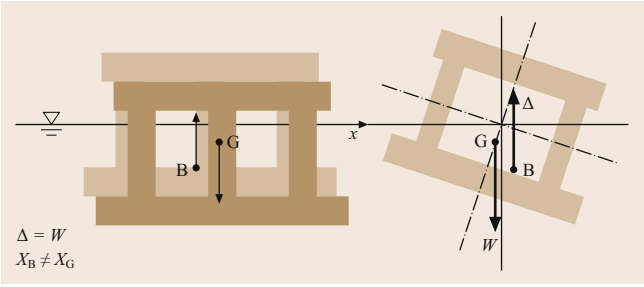

Fig. 34.20 The vessel lists with no trim

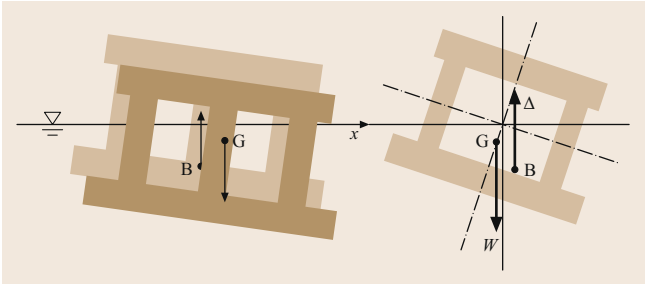

Fig. 34.21 The vessel lists and trims

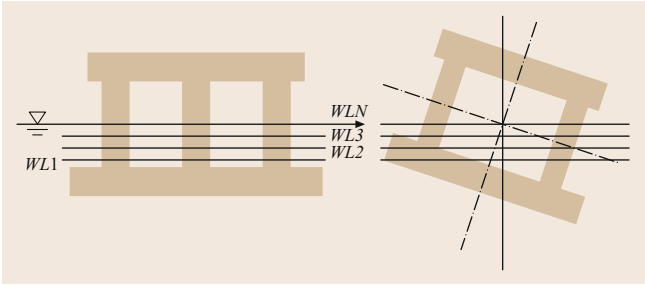

Fig. 34.22 The water lines used in righting-arm calculations

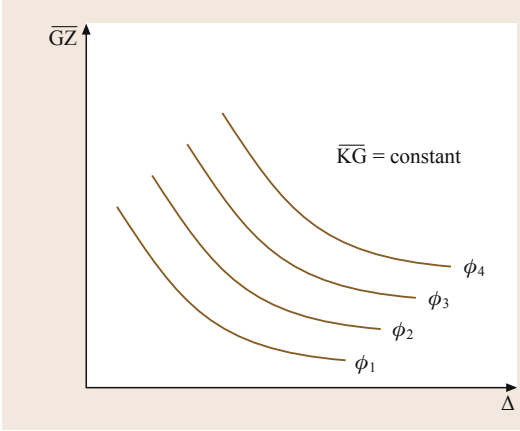

Fig. 34.23 Cross-curves of stability for different list angles

5. The above procedure is repeated for a series of waterlines as shown in Fig. 34.22, and for a constant list angle ϕ, and similarly for a constant trim angle θ. This way, one can obtain $\overline{\mathrm{GZ}}$ as a function of the displacement Δ for a given set of ϕ (or θ) and $\overline{\mathrm{KG}}$ as shown in Fig. 34.23, called the cross-curves of stability.
6. The procedure in the previous step should be repeated for a series of inclination angles to obtain the cross-curves of stability, for a constant $\overline{\mathrm{KG}}$, as shown in Fig. 34.23. Or, one can plot the constant-displacement curves that are called the static-stability curves shown in Fig. 34.24.

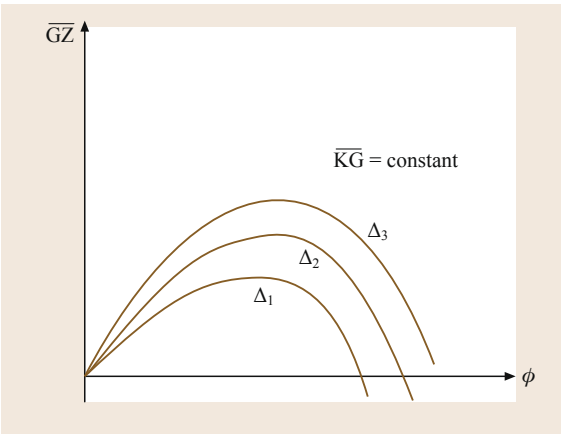

Fig. 34.24 Static-stability curves

34.4.8 Dynamical Stability: Energy to Incline

A suddenly applied heeling moment (drop of heavy cargo, gusty wind, etc.) can cause dynamical stability problems. Let us discuss this next by considering the following heeling moment M,

$$M = 0 \quad \text{for} \quad t < 0\,,$$
$$M = \text{constant} \quad \text{for} \quad t \geq 0\,, \tag{34.33}$$

where $t = 0$ denotes the initial time. This moment heels the structure to a new angle.

We now define dynamical stability as the work done in inclining the structure to an angle ϕ. To see the relation between the work done and the list of a ship, consider the stability of an object that is discussed in mechanics (Fig. 34.25). The weight, which is equal to mg, where m is the mass acting at G which is at a distance of h_0 above the floor. R is the reaction force exerted by the floor. Now, if the object is raised from one side, its center of gravity G will move up and will be h_1 away from the floor. Therefore, a moment couple is formed and the object will return to its initial position when the object is released if $h_1 > h_0$, that is, potential energy is increased by moving the object up. Before the object was raised, the potential energy was minimum (stable equilibrium). The work done on the object is equal to the change in potential energy. In other words, the vertical separation distance $(h_1 - h_0)$ between the center of gravity G and the location of the reaction force R determines the change in potential energy, which we

define by dynamical stability, that is,

$$E_{\mathrm{st}} = mg\,(h_1 - h_0)\ , \tag{34.34}$$

in the example above. E_{st} has the unit of work. Note that the moment equilibrium is reached when

$$Pz = mgy\,. \tag{34.35}$$

In the case of a floating body, Pz is the heeling (or overturning) moment and mgy is the righting (or restoring) moment. It can be shown that

$$E_{\mathrm{st}} = \Delta \int_0^{\phi} \overline{\mathrm{GZ}}\,\mathrm{d}\phi'\,, \quad \Delta = W\,. \tag{34.36}$$

This is the dynamical stability of the floating structure when it heels to an angle ϕ, and it shows that the area under the $\overline{\mathrm{GZ}}(\phi)$ function is equal to the change in potential energy. The unit of E_{st} is ton m, therefore, ϕ must be in radians in these calculations, and not degrees. The work done by the heeling (or overturning) moment M is

$$W_{\mathrm{h}} = \int_0^{\phi} M\,\mathrm{d}\phi'\,. \tag{34.37}$$

Equilibrium is reached when $W_{\mathrm{h}} = E_{\mathrm{st}}$.

34.4.9 Hydrostatic Stiffness Coefficients

A rigid body has six degrees-of-freedom (surge, sway, heave, roll, pitch, yaw) in motions. These modes of motions can be labeled 1 through 6, respectively. We already have seen that hydrostatic restoration in modes 1, 2, or 6 is zero (Sect. 34.3.1).

The forces and moments that act on a floating structure are governed by the equations of motion so that a floating body can be in static and dynamic equilibrium through Newton's second law of motion, that is, that forces must be equal to mass times translational accelerations, $F_i = m_{ij}a_j$, and moments must be equal to mass moment of inertia times rotational accelerations. The arranged (linear) equations of motion of a floating body can be written as

$$\left(M_{ij} + \mu_{ij}\right)\ddot{x}_j + \lambda_{ij}\dot{x}_j + C_{ij}x_j + k_{ij}x_j = F_i + \cdots\,, \tag{34.38}$$

where there is summation from 1 to 6 over the repeated index j Einstein's summation convention, M_{ij} are the elements of the mass matrix, x_j are the time-dependent motions (or displacements) in mode j, $\dot{x}_j$ are the body velocities, $\ddot{x}_j$ are the accelerations, μ_{ij} are the elements of the added-mass matrix, λ_{ij} are the elements of the damping matrix, C_{ij} are the elements of the hydrostatic restoration matrix, k_{ij} are the elements of the mooring stiffness matrix, F_i are the elements of the wave exciting force/moment vector, and $i, j = 1, 2, \ldots, 6$, i = force or moment, j = direction of motion. The elements of the hydrostatic restoration forces and moments are such that

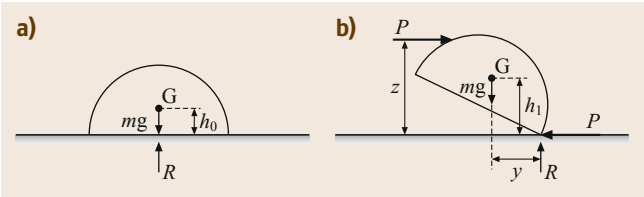

Fig. 34.25a,b Stability of an object

$$F_{\mathrm{H}i} = -C_{ij}x_j \quad i,j = 1, 2, \ldots, 6\,. \tag{34.39}$$

Since hydrostatic restoring coefficients for the movements on the horizontal plane are zero, $C_{ij} = 0$, $i, j = 1, 2, \ldots, 6$. Also, C_{ij} can be shown to be the elements of a symmetric matrix, that is, $C_{ij} = C_{ji}$.

The heave restoring force is written as $F_{\mathrm{H3}} = -(C_{33}x_3 + C_{34}x_4 + C_{35}x_5)$, where the heave restoring coefficient is given by

$$C_{33} = \rho g A_{\mathrm{WP}}, \quad A_{\mathrm{WP}} = \sum_{m=1}^{M} A_{\mathrm{WP}m}\,. \tag{34.40}$$

Clearly, if there is no waterplane area, there is no vertical restoration hydrostatically, provided, of course, that the body is in equilibrium. The index $m = 1, 2, \ldots, M$ refer to the surface-piercing members only. In other words, if a member is not surface piercing, then it is not included in (34.40) since a motion in the x_3 direction is not going to result in a change in volume (as this would be the case for a completely submerged structure).

The heave-roll restoring coefficient is given by (Fig. 34.26)

$$C_{34} = C_{43} = \rho g \iint_{A_{\mathrm{WP}}} y\,\mathrm{d}S = \rho g \sum_{m=1}^{M} y_m A_{\mathrm{WP}m}\,. \tag{34.41}$$

Note that $C_{34} = C_{43} = 0$ if there is symmetry with respect to the x–z plane of the platform, and this is common.

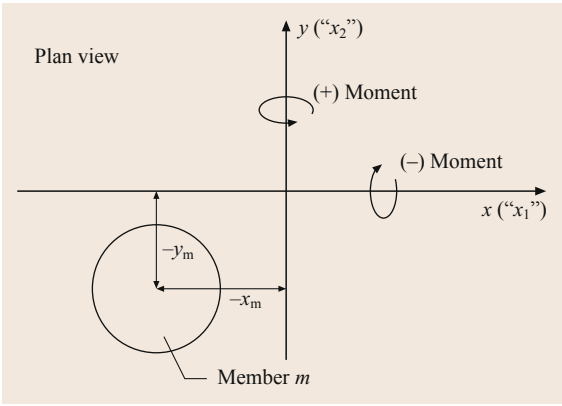

Fig. 34.26 Calculations for the heave-roll and heave-pitch restoring coefficients (z is positive up)

On the other hand, the heave-pitch restoring coefficient is given by (Fig. 34.26 again)

$$C_{53} = C_{35} = -\rho g \iint_{A_{WP}} x \, dS = -\rho g \sum_{m=1}^{M} x_m A_{WPm} \, . \tag{34.42}$$

Note that $C_{53} = C_{35} = 0$ if there is symmetry with respect to the y–z plane of the platform. This can be seen directly from (34.42). This also is a common occurrence.

The roll-restoring moment is written as $F_{H4} = -(C_{43}x_3 + C_{44}x_4 + C_{45}x_5)$, where the roll-restoring coefficient C_{44} is given by (Fig. 34.27)

$$\begin{aligned} C_{44} &= \rho g \nabla (z_B - z_G) + \rho g \iint_{A_{WP}} y^2 \, dS \\ &= -\rho g \nabla \overline{BG} + \rho g \nabla \overline{BM}_T = \Delta \, \overline{GM}_T \, . \end{aligned} \tag{34.43}$$

Note that this assumes that the angular displacements (roll and pitch) are *small* (definitely less than about 10°, linear theory). Also *note that* $C_{44}\,x_4$ is the transverse righting moment, where $x_4 = \phi$ is the list angle.

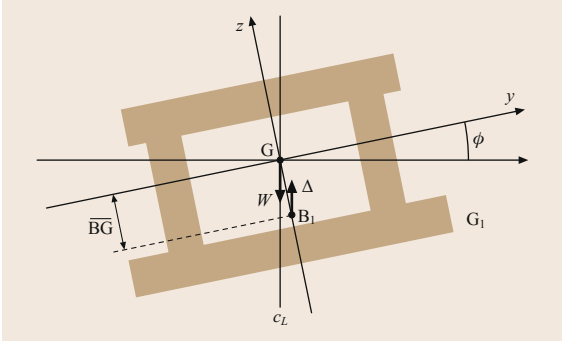

Fig. 34.27 Calculations of the roll-restoring coefficient

The roll-pitch restoring coefficient, on the other hand, is given by

$$C_{45} = C_{54} = -\rho g \iint_{A_{WP}} xy \, dS = -\rho g \sum_{m=1}^{M} x_m y_m A_{WPm} \, . \tag{34.44}$$

Note that if there is symmetry with respect to both the x–z and y–z planes of symmetry, then $C_{45} = C_{54} = 0$.

The pitch-restoring moment is written as $F_{H5} = -(C_{53}x_3 + C_{54}x_4 + C_{55}x_5)$, where the pitch-restoring coefficient is given by

$$\begin{aligned} C_{55} &= \rho g \nabla (z_B - z_G) + \rho g \iint_{A_{WP}} x^2 \, dS \\ &= -\rho g \nabla \overline{BG} + \rho g \nabla \overline{BM}_L = \Delta \, \overline{GM}_L \, , \end{aligned}$$

and $C_{55}\,x_5$ is the longitudinal righting moment and $x_5 = \theta$ is the trim angle. Note that all these hydrostatic restoring coefficients are valid when the motions are *small* or linear.

34.4.10 Stability of Submersibles

When a submersible is completely submerged, it has no water-plane area, and therefore the metacentric radius, $\overline{BM}_T$ or $\overline{BM}_L$, tends to zero. This means that B → M and would rise over G. This is just the opposite of what we have in the case of a floating structure. As a result, the stability moment becomes very simple,

$$M_{St} = \Delta \, \overline{GZ} = W \overline{BG} \sin\phi = W \overline{GM} \sin\phi \, . \tag{34.45}$$

The period of submerging and surfacing need to be treated very carefully because of the presence of ballast tank free-surfaces that do reduce the metacentric height further. The stability criteria for submersibles must at least require positive values of $\overline{GM}$.

34.4.11 Purpose

Service Requirements

Stability analysis applies to any floating structure. It aims at determining if the structure will be able to remain afloat within an allowable range of list angles when subjected to overturning loads. The extent of stability of a hull is typically assessed by comparison of the righting-moment curve with the extreme overturning curve, under all predicted loading conditions. This is exemplified in a typical righting-moment curve in Fig. 34.28. The overturning-moment curve meets the righting-moment curve at equilibrium, and must be lower than it at higher heel angles to provide reserve stability.

Insufficient stability of a floating structure may lead to:

1. Capsizing, the loss of righting moment resulting in the hull heeling beyond acceptable limits, and in some cases turning upside down, or
2. Loss of buoyancy of the hull, which is due to ingress of water through loss of watertight integrity or progressive flooding, and may lead to sinking.

The durability of stability is ensured by preserving watertightness of the hull within the range of operational drafts and heel angles of the hull. The minimum extent of watertightness is defined as an envelope of draft and heel conditions as illustrated on heel angle in Fig. 34.28. If the mean waterline under any load condition extends beyond this envelope, the hull may start taking in water from outside through nonwatertight openings. Some hull openings may be within the extent of watertightness so long as they are designed to be watertight when fully submerged with an appropriate pressure head. This may be the case of bolted hatches, or some capped sounding pipes for instance.

Additionally, we define the extent of weathertightness as the acceptable limit of reach of *green water*, or wave dynamics, above the mean waterline. The waterlines to which weathertightness extend on a typical semisubmersible hull are shown in Fig. 34.29. Openings within the extent of weathertightness shall be designed to withstand a low water pressure. Vents with nonreturn valves or blind flanges, some quick-open manways, and similar openings are designed for weathertightness for instance.

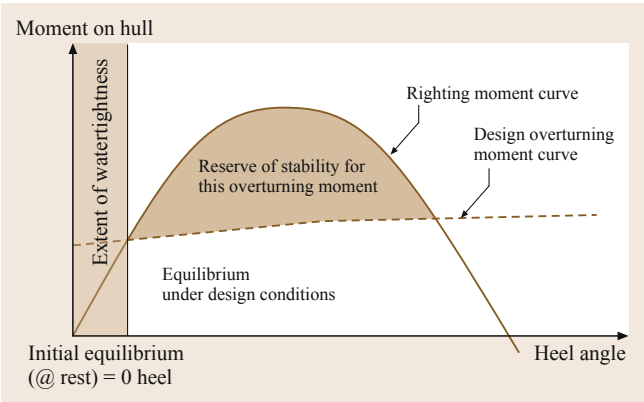

Fig. 34.28 A typical righting-moment curve

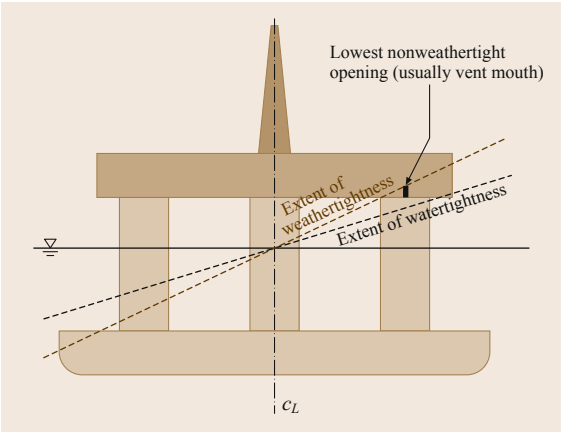

Fig. 34.29 Example of the extent of watertightness and weathertightness on a semisubmersible

Capsizing

Capsizing may be defined as the loss of static righting moment which leads to increasing heel of the vessel past the range of acceptable angles. Some hulls, such as monohull sailboats, may be designed to minimize the extent of the equilibrium once the boat is capsized upside down so that it will not remain in a capsized position, but right itself back up.

For a free-floating structure, capsizing typically results from one of two phenomena:

1. If the hull is intact, the center of gravity and center of buoyancy are unchanged from their original envelope. However, overturning loads in excess of predicted loads may result in loss of equilibrium and heel of the platform. Excessive loads may be static or dynamic. If the righting moment is comparatively too small at any given heel angle, the hull will keep heeling until a position of equilibrium is found. Unless the energy to incline increases again as the hull heels or the overturning energy starts decreasing, it will capsize and may end up lying on its side or upside down. This is illustrated on a righting-moment curve in Fig. 34.30.
2. Capsizing can also be due to a change in mass or buoyancy characteristics of the hull. These affect the metacentric height of the structure, and consequently modify the righting-moment curve. The righting moment may become negative or too small compared to expected overturning moment. This is illustrated in Fig. 34.31.
   Loss of buoyancy, resulting in a shift in the center of buoyancy location, thus in a shift of the righting-arm curve, typically occurs in case of loss of watertight integrity of the hull. This may be due to flooding of a compartment due to loss of structural integrity on an external bulkhead. It can also be due to accidental water ingress, such as downflooding or progressive flooding.
   Changes in mass properties may be linked to events such as accidental loss of cargo, internal leaking,

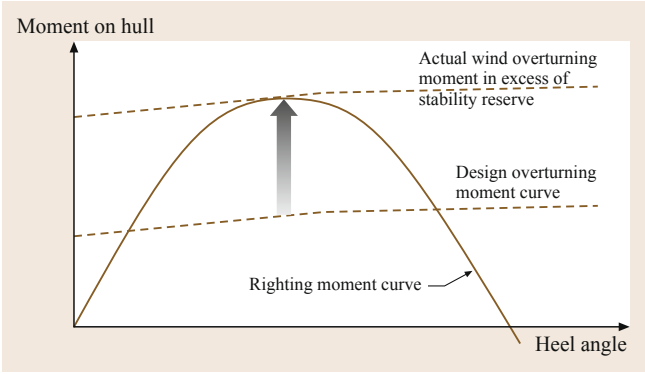

Fig. 34.30 Capsizing due to excess of overturning moment: the effect on the moment curves

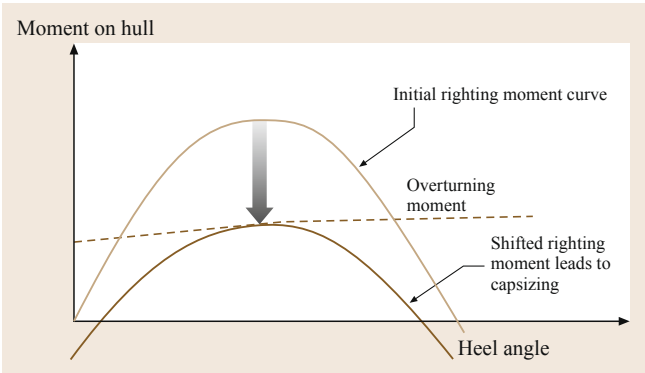

Fig. 34.31 Capsizing due to changes in stability characteristics: the effect on the moment curves

or accidental transfer of cargo. These may result in draft changes as well as a shift of the center of gravity. The latter will affect the metacentric height and may lead to capsizing.

Other mechanical failures may lead to capsizing in the case of a structure with additional static constraints. This is the case of moored structures with high mooring pretension, such as a TLP. The pretension on the mooring contributes to stability. This may be modeled as a correction on the center of gravity and weight, thus affecting the displacement

$$W_{\text{corr}} = W + T\,,$$
$$\text{VCG}_{\text{corr}} = \frac{\text{VCG} \times W + z_{\text{fairlead}} \times T}{W_{\text{corr}}}\,, \qquad (34.46)$$

where W is the weight, T the pretension of the mooring, VCG the vertical position of the center of gravity, and z_{fairlead} the vertical position of the fairleads. Similar formulas may be used for the horizontal position of the center of gravity, TCG (transverse) and LCG (longitudinal).

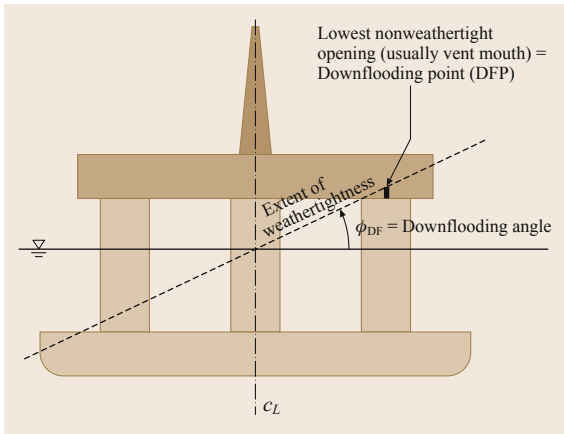

Fig. 34.32 Example of downflooding angle on a semisubmersible hull

If loss of pretension in the tendons occurs, the corrected mass properties are affected, and the platform may capsize.

Downflooding

The downflooding point of a hull marks the limit of the extent of weathertightness. If green water from wave action reaches this point, there is water ingress in the hull. A loss of weathertightness may result in flooding of the hull.

The downflooding point is usually a vent, a door, or any similar nonweathertight opening on deck or in external bulkheads. For each operational draft condition, a downflooding angle may be defined. It is the heel angle at which the waterline reaches the downflooding point. Figure 34.32 shows an example of a downflooding angle on a semisubmersible. For stability of the hull to be preserved, the downflooding angle must be greater than the angle of equilibrium of the hull, under all predicted extreme overturning loads.

If the hull heels beyond the downflooding angle, water ingress in the hull may lead simultaneously to sinking, due to loss of buoyancy (or increase in weight), and to heeling, due to change of metacentric height and weight distribution. Depending on the hull design and on the location of water ingress, the hull may sink or it may capsize first. Even if the mean heel angle of a platform remains below the downflooding angle, consideration should be given to the effect of dynamic heel and wave elevation, which would contribute to a loss of weathertightness and flooding. For this reason, regulations typically require that a reserve of stability exists between the maximum mean heel angle under static loads and the downflooding angle. The downflooding angle of a hull is an important parameter to add to the righting-moment curve (Fig. 34.33).

Progressive Flooding

Progressive flooding refers to the accidental ingress of water due to system failure. For instance, it may involve open-looped piping systems, which have the capability of pumping external sea water into tanks. Due to human errors or control failures, such a system may pump sea water from the ocean beyond acceptable limits. Progressive flooding may also occur if marine systems or bulkhead openings are operated in a way that spreads flooding between compartments. This results in a change of mass properties of the hull, with risks of sinking or capsizing.

A variety of solutions may be implemented to mitigate the risks of progressive flooding:

- Redundant alarms, to alert operators of unusual levels of water in tank, unusual draft or heeling conditions, internal leaking, etc.
- Fail-safe systems, where tanks may be limited in capacity to avoid catastrophic failure in case of progressive flooding.
- A bilge system, with controls integrating the flood detection systems. This is especially useful in case progressive flooding occurs due to internal leaking of a compartment into other tanks or voids, thus triggering the pumping of external water to replace the loss.

Human Factors

Floating platforms are equipped with complex systems and watertight openings (manways, hatches), and these help to manage compartmentalization. These systems are implemented, maintained, and operated by designers and mariners. Errors in design, fabrication, or operation can lead to lack of sufficient stability, loss of watertight integrity, or progressive flooding among other things.

Human errors in design often stem from overlooking or underpredicting critical overturning loads, as well as errors in calculating metacentric height and righting-arm curves. Such errors are mitigated by quality control and quality assurance. Regulatory bodies routinely require third-party reviews, which often entail independent calculation of stability quantities to verify design.

Conversely, safe design practices may enhance stability in operation. Better control of stability conditions may be achieved when appropriate fail-safe approaches are implemented in design. These include the redundancy of control systems or the design of passive control systems. Closed-loop marine systems are passive systems, since they do not allow the intake or egress of ocean water. The use of redundancy or nonreturn valves to close pipes and the use of watertight tank subdivisions are also passive solutions. Additionally, operational contingency plans should be incorporated

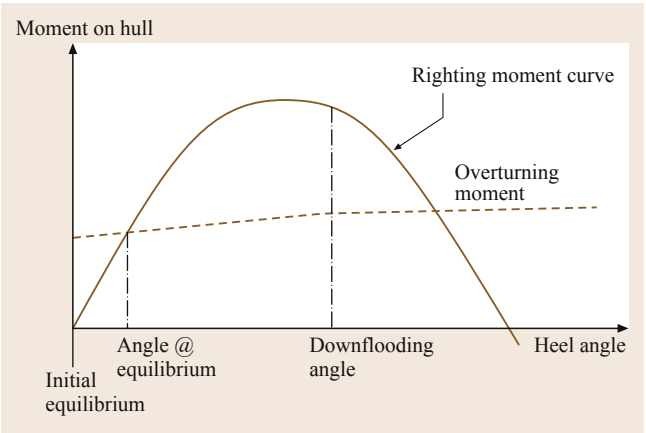

Fig. 34.33 Downflooding angle on a righting-moment curve

in design. In terms of stability, the design of a bilge system allows corrective action to be taken in case of loss of watertight integrity. Control systems shall be designed to identify all failure modes and react appropriately, through alarm systems and direct action.

Fabrication and installation are also critical phases for hull stability. Human errors in bulkhead construction, assembly of piping systems, or even marking of the hull may lead to rapid loss of stability of the hull, once it is put in service. Improperly mounted check valves on an open-loop system is not an uncommon encounter, and may result in progressive flooding. These issues are addressed through system testing, watertight boundary testing, and surveying throughout fabrication.

In operations, the risks to stability are addressed procedurally and manuals detail proper operation of piping systems, including ballast systems, and procedures for opening and closing watertight compartments. Operation manuals also mention acceptable draft limits and live load patterns, and their impact on stability. Inspection and maintenance of watertight boundary, corrosion systems, bilge systems, and flood detection systems should also be part of the overall mitigation plan, to minimize risks of and from external flooding.

34.4.12 Industry Practice

Regulatory

Industry practice is guided by international recommendations, such as the International Code on Intact Stability of the International Maritime Organization (IMO) [34.9]. These IMO guidelines are typically adopted by local regulatory agencies such as the US Coast Guard and by classification societies which adapt them into class rules.

The intent of the rules is to prevent vessels from losing stability leading to the point of capsizing or sink-

ing in any operational condition. They lay a common ground for all vessels at sea. Regulations also enforce a certification process aimed at validating that intended stability properties are met by a given vessel. The process is applied throughout the lifecycle of the vessel. Classification societies typically require third-party design reviews and both class rules and flag authorities enforce a regular cycle of surveys to record actual stability characteristics and ensure conformity with plans. Stability rules are updated regularly to take into account technological changes and learnings from vessel operations and recorded casualties.

Rules are adjusted for different types of vessels, according to their shapes, their operational conditions, static loads and specific sensitivity to dynamic loadings, such as wave loads. They are stated in general terms for ship-shape hulls. Additional considerations are typically made for special applications: passenger vessels, oil tankers, cargo ships, high-speed crafts, fishing vessels, offshore supply vessels, tug boats, and mobile offshore drilling units (MODU) all are subject to special rules. Classification societies and national regulatory bodies may define additional subcategories to refine the criteria further according to the type and application of vessels. MODU rules, from ABS (American Bureau of Shipping) [34.10] or Det Norske Veritas (DNV) [34.11] for instance, both distinguish between self-elevating (jack-up rigs), surface-type units and column-stabilized units (semisubmersible for instance). The variables that require calculation and analysis are the same for all these types. However, the exact criteria are slightly different accounting for differences in shape and typical response to the environment.

Requirements are also adjusted according to the risk to life at sea and to the environment. This is reflected in the difference between stability criteria for otherwise similar vessels. Passenger ships, for instance, must meet additional criteria compared to other ships, which reflect both the specific loading of such vessels and the increased risk to human life. Although the shape and configuration of hulls used for renewable energy applications is often very similar to those in the oil and gas extraction industry, stability guidelines differ significantly, acknowledging the lower risk associated with the former.

Regulations use a few variables to define criteria that apply to a given class of vessel. These variables consist of a number of aforementioned characteristic values for a given hull. In particular, metacentric height, equilibrium heel angle, and righting-arm curves are commonly used to assess stability. For hull types with constant displacement over given operational conditions, the use of righting-moment curves instead of righting-arm curves is widespread. Limits are applied to these basic parameters; they form the set of criteria for a given hull type. The most typical criteria are reviewed in the following section. Although criteria vary slightly from one classification society or national regulator to the other, they are based on similar principles and rely on the same set of variables. Also, international organizations, such as IMO and the International Association of Classification Societies (IACS), have helped significantly to standardize criteria imposed by regulators throughout the world.

First Principles

Stability criteria are designed to ensure that a vessel stays within an acceptable range of heel angles under all operating conditions. Criteria are set by industry guidelines and rely heavily on a few calculated parameters to assess overall stability of a vessel. In most standards, a one size fits all approach is assumed for a given category of vessel. Minimum values are set for all relevant parameters. This is motivated by the difficulty to predict reliably at the design level the destabilizing combinations of loads the vessel will encounter. Standards rely on statistical analysis of similar vessels to define an acceptable envelope of static loading, given the risk associated with the type of vessel and its applications.

The following variables are typically considered to define stability criteria:

- Metacentric height, $\overline{\mathrm{GM}}$, on an upright vessel shall be positive in all operating conditions. This is the minimum stability requirement, since a negative $\overline{\mathrm{GM}}$ means that the vessel righting moment is negative at small heel angles, resulting in excessive list or trim and potentially in capsizing. It is good practice to ensure a minimum positive $\overline{\mathrm{GM}}$ to provide sufficient righting moment to counteract any overturning moment. IMO regulations recommend a minimum $\overline{\mathrm{GM}}$ of 0.15 m for all vessels. This number is derived from statistical analysis of casualties and includes a minimum safety factor to account for errors in calculating the metacentric height. Industry standards may fix larger values depending on the type of vessel.
- Criteria are also applied to the righting-arm curve (since it represents the reserve righting capacity of a heeling vessel). The righting curve of an intact vessel is expected to increase at low heel angles, and up to an acceptable value (called α herein). IMO recommends that vessels have an increasing righting arm up to $\alpha = 25°$ of heeling; this is adjusted for special vessels. This is ensured by verifying that the point at which the righting arm starts decreasing is larger than α, as illustrated in Fig. 34.34. The

righting arm needs to remain positive over an extensive range of heel angles.

- To guarantee that there is sufficient reserve stability to right the vessel, a criterion should also be applied to energy. It combines the amplitude of the righting curve with the extent of acceptable heel angles to assess the stability of the vessel. This is typically achieved by requiring a minimum value λ be attained for the integral under the righting arm or righting-moment curve as a function of heel, from 0° heel to a limiting heel angle (Fig. 34.35). The limiting angle is defined according to the characteristics of the vessel. It is typically the lesser of the downflooding angle and the angle at which the righting arm becomes negative. Where weather and operating conditions are considered, it may also involve an angle of equilibrium between the righting moment and the overturning moment due to external loading. This is explained further below.
- The effect of weather is typically considered by calculating the overturning moment due to external loads, especially wind. Industry rules provide guidance on the minimum wind speed to consider, as well as on the method to calculate the overturning arm. These methods vary with the type and applications of the vessel. In general the overturning moment can be calculated by

$$M_O = \boldsymbol{OP} \times \boldsymbol{F} \,, \tag{34.47}$$

where $\boldsymbol{P}$ is the center of application of the horizontal force $\boldsymbol{F}$ and $\boldsymbol{O}$ is the center of rotation.

It is common to require that the overturning moment arm $\boldsymbol{OP}$ be taken as the vertical distance between the center of wind pressure and the center of lateral pressure on the submerged hull since there are uncertainties on the exact position of the center of rotation of the vessel. The applied force $\boldsymbol{F}$ should represent extreme static overturning loads acting on the vessel. As a minimum, it should include the effect of wind, calculated as the product of the lateral wind pressure by the projected wind-exposed surface area, or windage area. The windage area may vary with the heel angle.

Stability analysis of floating offshore platforms is usually performed by comparison of the moment curves. Most ship-shaped vessels will experience the largest overturning moment with a wind direction associated with the lowest righting moment. Indeed, the longitudinal windage area is larger than the transverse windage area on ship-shaped vessels leading to larger rolling moment, while these vessels are most sensitive to rolling, due to lower transverse metacentric height. However, in some cases, alternative directions may be associated with lower stability, due to different loading patterns, involving current for instance, or when the vessel is not ship-shaped. On semisubmersible and spar platforms, all directions of the heel angle must be studied, to determine the worse one.

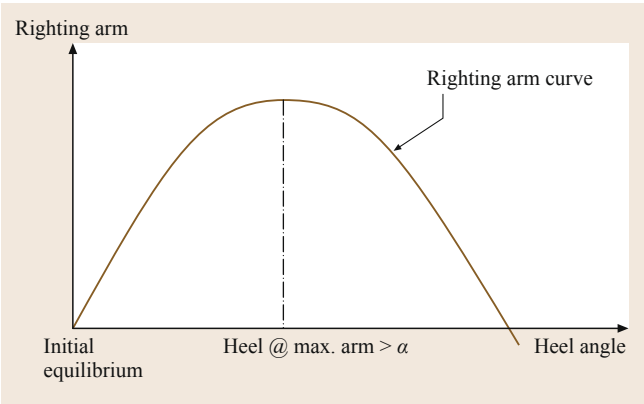

Fig. 34.34 Illustration of a righting arm criterion for stability

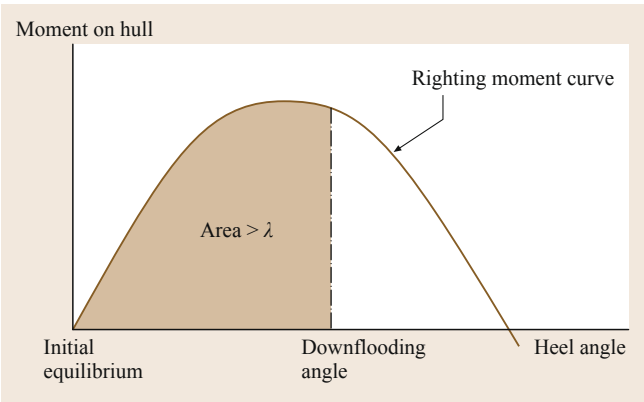

Fig. 34.35 Illustration of an energy criterion for stability

There exists no criteria on the overturning moment alone. Its adequacy with stability criteria is determined by comparison with the righting moment. This comparison must be made for all relevant directions of the loading and heel angle.

In comparing the overturning moment and the righting moment, two sets of variables are of interest:

- The angle of equilibrium of the vessel subject to the overturning moment. There are two such angles of particular interest, referred to as the first intercept and the second intercept. The first intercept is the first angle of equilibrium, where the righting-moment curve crosses the overturning moment curve. It is also the limit of watertightness. The downflooding angle may be smaller than the angle at the second intercept. However it must be sufficiently larger than

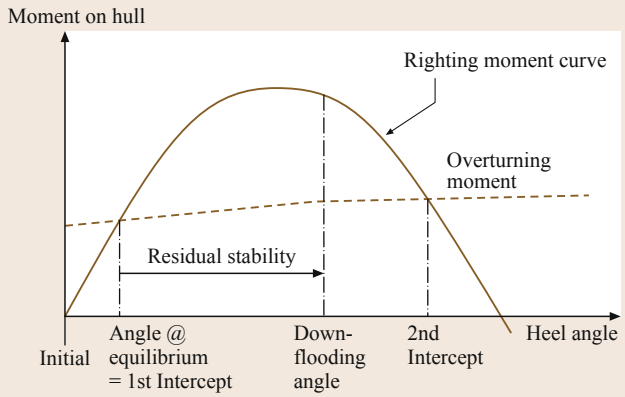

Fig. 34.36 Righting and overturning moment intercepts

the angle at the first intercept to provide reserve stability for dynamic loads. These variables are illustrated in Fig. 34.36.

- The ratio of righting energy to overturning energy can also be used to assess the extent of stability. This criterion usually considers the energy up to the downflooding angle – meaning within the extent of weathertightness.

Usually, wave dynamics is not directly accounted for in the basic stability criteria. The overturning moment is meant to capture the effect of extreme static loads on the vessel. Rather, waves and other dynamic effects, such as wind turbulence, are addressed by applying safety factors on the variables above. Ratios of righting energy versus overturning energy within the extent of weathertightness must be large enough (1.4 for general MODUs for instance) to allow for a temporary increase in overturning moment.

Alternative Performance Standards

Stability criteria cover very broad ranges of vessels. In some cases, meeting the regulatory requirements may be overly conservative or inadequate. This is especially true of novel concepts, which scarcely fall into any predefined category.

In such cases, alternative criteria may be derived. The criteria must consider all the variables defined above. However, rather than using standard formulas to account for dynamic effects and assess stability, criteria may be derived from vessel-specific data. Alternative variables may be defined from stability parameters, if deemed more appropriate. For instance, criteria on the ratio of righting to overturning energy may be replaced by criteria on a ratio of reserve righting energy to initial righting energy.

When alternative criteria are derived, the uncertainties on loadings as well as adequate margins of error on the vessel characteristics and righting capacity must be considered.

A common alternative criterion considers the specific dynamic response of a vessel rather than using the standard dynamic heel angle. Local metocean data, rather than broader wind speed, may also be accepted by local authorities. This is especially useful for vessels with restricted operational envelopes. Numerical analysis may be used to demonstrate the validity of the predicted alternative response of the platform. Regulators will often require that calculations are backed up by model tests and wind tunnel tests, to justify drag coefficients and numerical parameters.

34.5 Loads

We have mentioned earlier that the righting moment needs to be compared to any external moments that may try to overturn a floating structure. Some kind of an upsetting external force or moment may act on the structure, and this may change the equilibrium position either temporarily of permanently. These forces may be due to environmental factors, like wind, or to activities on board the vessel (lifting of a weight overside), or to accidental or operational weight shifts. Common loads and their effect on the stability of offshore platforms are briefly discussed in this section.

34.5.1 Environmental Loads

Environmental loads need to be considered in the derivation of righting- and overturning-moment curves. These loads may be adjusted according to the applications and areas of operation of the vessel. In particular, the following effects should be considered.

Wind Loads

Wind pressure exerts a force which is mostly concentrated on the superstructure since wind velocity grows exponentially as we are farther above the still-water level, and thus causes a moment which tries to heel or trim the structure from its upright position. Wind force is proportional to wind speed squared times the drag coefficient times the projected surface area of the ship exposed to the wind action, that is, above the SWL, and including the superstructure. The only opposing force is the viscous drag-force or water-resistance force for a nonconstrained body (a body which is not moored).

The equilibrium is reached when the moment due to the weight and buoyancy of the ship equals the moment developed by the wind force. The destabilizing effect of wind on the vessel is considered by calculating the overturning moment on the topsides.

The general formula for the wind force applied on the vessel is given by

$$F = \int_{\substack{\text{Windage}\\ \text{Area}}} p \, \mathrm{d}A \,, \tag{34.48}$$

where p is the wind pressure. Depending on the type of vessel, p may be fixed by stability standards, or may be recalculated. IMO provides a minimum pressure of 756 Pa (of which 504 Pa corresponds to steady winds) for general applications. It is typically calculated based on a drag formula

$$p = \frac{1}{2} C_\mathrm{d} \, \rho_\mathrm{air} \, U^2 \,, \tag{34.49}$$

where C_d is the drag coefficient and U is the extreme wind velocity. The drag coefficient C_d may vary for different types of structures on deck, according to their shapes, and their orientation to the wind direction. For MODUs, a set of accepted values of drag coefficients is commonly used in the pressure calculations and generally accepted by regulatory bodies. The C_d of extraneous shapes must be determined by model tests.

The wind velocity may be fixed by the standard. For intact stability, it is typically higher than 50 kn. This wind velocity is commonly increased to 100 kn for intact stability of permanently moored structures.

Alternative wind speeds may be considered acceptable in special cases, based on local meteorological data and specific applications such as renewable energy applications. Adequate statistical analysis must be run to determine the extreme wind speed. The effect of wind gust must also be included in the local wind assessment.

Also, extreme wind speed is often expressed in terms of the wind speed at 10 m height above the mean waterline. For a vessel with a windage center of area higher than 10 m, the effect of shear in the wind should be considered. Formulas for wind shear calculations are provided in many standards.

Current Loads

Current loads may be detrimental to stability, especially if it is foreseen that they will act in opposite direction to wind effects. They should be taken into account where the extreme wind speed is based on meteorological data. They can be calculated based on drag force calculations on the wetted surface of the vessel. When deemed necessary, the effect of current loads should be added to the overturning moment to assess stability.

Wave Loads

Wave loads are dynamic. They are addressed by enforcing appropriate safety factors that provide reserve stability to withstand these dynamic loads and induced motions (rolling and pitching). In some cases, higher order wave loads, such as slow drift, combined with station-keeping of a vessel, may indirectly result in trimming or listing. This may happen in the case of a moored vessel, for instance. The mooring resisting the drift motion may pull the vessel down on one side. These detrimental mooring effects should be taken into account in the stability analysis. They are addressed in the description of operational loads below.

Ice Loads

The effect of icing on stability is associated with ice accretion on topsides of a vessel. The built-up of an ice layer on deck results in a change in the weight properties of the vessel. In particular, the formation of an ice sheet on deck may affect the following:

- The overall displacement of the vessel (change of mass). This should translate in an adjustment of the righting-moment curve.
- The location of the center of gravity. Ice on deck will result in a higher center of gravity, which has a destabilizing effect on the vessel. But the ice sheet may not be uniformly distributed, which could result in a horizontal shift of the center of gravity as well, leading to the list and/or trim of the hull. This effect should again be associated with a correction on the righting-arm curve.
- In some cases, ice accretion could increase the windage area of the vessel, thus affecting the overturning-moment curves.

The effect of ice should be included as a variation on the stability conditions. However, it will have a larger effect on small vessels, such as small passenger vessels, and on vessels with large deck area to displacement ratios (ship-shaped platforms).

When ice is considered, the maximum ice thickness and distribution patterns are generally defined according to local standards for the area of operation. The effect of ice accretion should be considered for all vessels operating in the Arctic ocean, in the Bering Sea, and close to the Antarctica in the Southern Ocean. The IMO stability code defines minimum icing layer thickness to be considered, as well as the exact location where icing occurs. However, local authorities may apply different standards, based on local meteorological knowledge.

Vessels which are foreseen to operate in icing regions should be designed to minimize the accumulation of ice on topsides.

Water Retention from Wave Splashing and Rain

If water accumulates on deck, subject to heavy rain or wave splashing or for some other reason, stability of a vessel may be affected. The effect is similar to that of ice loads: the mass properties of the vessel should be adjusted to account for the accumulation of water. The center of gravity can be shifted upward or sideways, and the displacement may increase, thus leading to a loss of righting arm. Moreover, the effective $\overline{GM}$ may reduce due to a partial loss in the waterplane area.

The topsides of a vessel should be designed with adequate draining system to minimize the collection of water on deck.

34.5.2 Dead Loads

Dead loads correspond to the weight of permanently installed structures and equipment on the vessel. The following elements shall be included in the inventory of dead loads:

- Lightship weight from structure and permanently installed systems, as of the end of construction.
- Any permanently installed topsides.
- The weight of any permanent ballast, and its effect on the location of the center of gravity.
- The equivalent weight from mooring pretension when applicable. This is especially important in cases where mooring may have a destabilizing effect on the vessel. When mooring has a stabilizing effect, a mooring damage case may be recommended to ensure that the vessel would remain stable in the event of a broken line.

34.5.3 Live Loads

Live loads are the weight of the structure hull and its components that may vary and move throughout the life of it. If a weight which is already on board is moved, for example, transversely, to a new location, the center of gravity of the structure will also move and the platform will heel. As a result, the center of buoyancy will shift and a new equilibrium will be reached when the two centers are on the same vertical line. The longitudinal movement of a weight which is already on board will also cause the structure's center of gravity to move longitudinally, resulting in the trim of it. Live loads include the following:

- Ballast: During a vessel's operation, ballast water may be pumped from seawater, moved between tanks and ejected to the ocean. These changes of configuration of ballast affect the mass properties of the vessel. The displacement may change as ballast water is pumped in and out. The center of gravity of the vessel shifts. All these effects must be taken into account in the calculation of the righting-moment curves. Ballast tanks should be clearly identified and extreme loading situations should be described and used for stability analysis. The stability of intermediate ballast configurations should also be investigated.
  Additionally, particular attention needs to be paid to the effect of the freely moving water surface in partially filled tanks. In such tanks, heeling of the vessel will displace liquid toward the heeling side, thus shifting the center of gravity further to that side, and potentially increasing the heel. This is referred to as the free-surface effect. For deep tanks (tanks with large depth to breadth ratios), it can be accounted for in the stability analysis by calculating the drop of metacentric height due to the presence of the free surface (Sect. 34.4.5). For shallower tanks, or tanks where the moving water may reach the top of the tank, the righting-arm correction may have to be recalculated at each heel angle. For rectangular tanks, and at typical filling ratios (50%, 95%, and 98%), parametric tables are usually available. Such tables may be found, for example, in Lewis' principles of naval architecture [34.5].
- Cargo and passenger loads. These loads encompass all types of cargos, from liquid oil and gas in tanks, to bulk cargo, and including containers, cars, and people. For liquid cargo, the detrimental effect of free surfaces shall be included in the stability analysis, by correction of the righting arm, as described for ballast tank above. The destabilizing effect of freely moving loads, such as grains and gravel in bulk carrier, or suspended loads (fish nets on fishing vessels, or load on a crane) shall be considered as well. For cargo and passengers, an envelope of allowable live loads must be derived, with associated displacement and center of gravity. Stability must be ensured within the envelope of loads. International and national standards typically set minimum requirements of magnitude and distribution on cargo and passenger loads, according to the type and application of a vessel. General guidelines may be found in IMO stability code [34.9].

34.5.4 Operational Loads

Operational loads correspond to additional loads related to the operation of the vessel. They stem from passive and active control systems, as well as from the use of equipment on the vessels. These loads must be included in the analysis if they have a detrimental ef-

fect on stability. Stabilizing effects may be included as well, provided that there is enough redundancy in the controls and systems involved in starting and maintaining the load on the vessel. Operational loads include the following:

- Propulsion and dynamic positioning loads from propellers or thrusters, as well as loads from antirolling device. Using the stabilizing effect of the latter in analysis is only allowed in cases where the antirolling system is equipped with sufficient levels of redundancy.
- Detrimental mooring loads due to drift should be considered in the stability analysis as well.
- Overside weight lifting: When a weight is lifted over the side of a structure, the center of gravity will move up and toward the lifted weight. As a result, the structure will heel/trim until the new center of buoyancy and the new center of gravity are on the same vertical line.
- Additionally, any load associated with the functionality of the vessel should be investigated. Offshore wind turbines, for instance, have special overturning wind loads due to the thrust on the turbine. Similarly, wave energy converters may experience increased static and dynamic loads from electricity generators. MODUs and oil production platforms, under operation are under loading from well-head activities or riser connection. The effect of umbilical and riser connection to a platform is of special interest to stability because it may affect the platform displacement and effective center of gravity, much as mooring pretension does.

34.5.5 Accidental Loads

Accidental loads result from incidents which extend beyond the operational envelope of the platforms. They include loads from collision, grounding, loss of cargo, etc. The static forces resulting from such incidents may also be considered in stability analysis:

- Grounding: If a vessel runs aground, there will be a reaction force applied to the ship at the point of grounding. This force produces a list and/or trim moment. Recalling the vertical equilibrium of forces due to weight and buoyancy in the floating structure case, we must then include this new reaction force due to grounding in the vertical equilibrium equation such that the weight of the vessel is now equal to the reaction force plus the buoyancy force. Since the weight of the vessel remains the same, the buoyancy force must be less, the vessel rises (parallel) as a result of grounding as expected.

34.6 Lightship Parameters

34.6.1 Technical and Commercial Significance

As discussed in previous sections, the stability assessment of a vessel depends heavily on the ability of the designers and operators to predict and control the displacement and position of the center of gravity accurately. This is possible if the mass properties of the vessel are known. This means, in particular, the following:

- The cargo, passenger, and operating loads on the vessel are well understood and may be calculated with acceptable precision. Typically, designers make assumptions, which are stated in the operational manual of the vessel. Operators are responsible to control their cargo and passenger loads to remain within this envelope.
- The weight and weight distribution of the hull structure, with all permanent systems, must be calculated adequately. These parameters are used throughout design to assess stability.

Operators later have access to lightship parameters stated in the operational manual. These parameters can be used to recalculate the exact stability characteristics of a vessel when combined with known cargo conditions.

To ensure a consistently accurate projection of lightship parameters, regulatory bodies have set procedures and milestones.

34.6.2 Regulatory Approach

Regulatory bodies rely on reviews and surveys during the lifecycle of the vessel to ascertain that stated lightship parameters are accurate for a given vessel. Three phases are of particular importance:

- Reviews at the design level focus on regulatory conformity of plans and design calculations. In particular, stability calculations and plans of watertight and weathertight integrity as well as compartment plans are reviewed. Lightship parameters are predicted at this stage.

- During fabrication, surveys and inspections ensure the consistency between the plans and the erected hull. They also witness the testing of the hull to verify the lightship parameters. This is the determination phase.
- The operating vessel is surveyed on a regular basis throughout its operating lifetime to verify continued adequacy with the plans. This is the control phase.

Completion of each phase results in the issuance of a certificate by the regulatory body, to certify the adequacy of the vessel design, construction, and operation with national, international, or class regulations.

34.6.3 Prediction

During design and construction, lightship weight cannot be directly measured. Instead they must be calculated from projected weight distribution on the hull.

This is achieved during careful weight management. All components of the ship, their weight, and location are recorded and the lightship weight and center of gravity are calculated by summation of all parts. Construction plans must be updated constantly with any design modification or construction adjustment, and the effect on weight recorded.

Modern software, using 3-D modeling and extensive database, typically provide very accurate calculations of weight and center of gravity.

34.6.4 Determination

Lightship parameters are also measured directly using surveys of the vessel throughout construction and at the time of loadout. In particular, the following tests and inspections are carried out:

- A survey of draft marks to confirm their conformity with design drawings and regulatory requirements. Draft marks are positioned around the hull to allow reading of the draft of the vessel at any load line. They may also be used to determine the trim and list of the hull, if placed at extremities of the hull.
- Other elements of stability are surveyed during construction. In particular, watertightness is typically ensured by airtightness testing on watertight bulkheads. Hull openings are inspected for watertightness and weathertightness depending on their location. Tank sizes and bulkhead dimensions are also surveyed to ensure that the buoyancy and tank dimensions are in accordance with engineering design.
- At the time of load out, the weight of the hull, free of any cargo or operational load, may be verified by reading the draft using the marks. This reading is compared to the predicted draft of the lightship, which confirms the weight predictions of the hull free of cargo. This is the lightship weight.
- Finally, an inclining experiment is often requested to confirm the weight distribution of the lightship hull and the exact location of the center of gravity of the structure. It is easy to see that taking moments of every bit of weight in the *light* structure to determine the position of the center of gravity is a very tedious task (but of course it can be done). On the other hand, $\overline{\mathrm{KG}}$ can be found quite accurately by conducting inclining experiments on the *light* structure (after it is launched or in service). An inclining experiment consists of loading the vessel with a known mass (typically weights on deck, or if allowed ballast water in tanks) offset from the center. The heel angle of the hull is recorded during the test, allowing accurate calculation of the position of the center of gravity. A pendulum (plumb line) is used during the inclining experiments as shown in Fig. 34.37. Setting the list moment equal to the moment due to the weight shifted, we must have (so that the structure is upright)

$$w\,\overline{\mathrm{g_0g_1}} = \varphi\, W\left(\overline{\mathrm{KB}} + \overline{\mathrm{BM}} - \overline{\mathrm{KG}}\right) \quad \text{or}$$

$$\overline{\mathrm{KG}} = \overline{\mathrm{KB}} + \overline{\mathrm{BM}} - \frac{w\,\overline{\mathrm{g_0g_1}}}{W\,\varphi}\,. \tag{34.50}$$

The quantities $\overline{\mathrm{KB}}$ and $\overline{\mathrm{BM}}$ can be determined from the hydrostatic curves for the structure, as well as the weight from $W = \Delta$. Then, once φ is measured (since the length of the pendulum and the deflection are known by measurements), one can calculate $\overline{\mathrm{KG}}$ from (34.50) quite accurately. The initial metacentric height can also be obtained from these experiments. One would normally use several weights shifted transversely for greater accuracy.

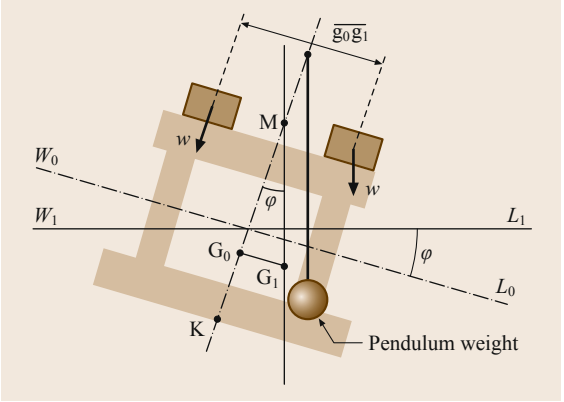

Fig. 34.37 Inclining experiments done by use of a pendulum and shifting a weight

There are many important conditions that must be satisfied during the inclining experiments, that is, all weights onboard must be secured or no (or very small) wind present, and these conditions are specified by the certification agencies and must be strictly followed. The calculated center of gravity is compared with predicted values from design and construction drawings. For an inclining experiment to be successful, the difference between the predicted and measured location is expected to be within a few percent. These experiments may also be conducted during marine surveys requested by the owner, regulatory agencies or insurance companies, after for example, the structure is overhauled.

Local authorities and classification agencies witness these surveys and ensure that they follow approved procedures. Such procedures are typically set by international standards, and adjusted for each type of vessel. Standards determine the conditions of the vessel before the tests, acceptable means of measurements of lightship weight, and inclination and extent of the inclining experiment. The results of the lightship weight measurement and inclining experiment are submitted to relevant authorities and to the class surveyor where applicable. They are recorded in the vessel's manuals, and may be used for further stability calculations.

In cases where identical vessels have been built and the lightship weight is confirmed within an acceptable margin, local authorities may waive the need for an inclining experiment. Upon successful completion of the lightship weight and inclining experiment, a certificate is provided to the vessel's owner.

34.6.5 Control

Lightship parameters are controlled throughout the life of the ship. Most types of vessels undergo regular inspection, at least every 5 years. At a minimum, the lightship weight may be verified at such inspection by survey of the draft. The measured draft should correspond to the predicted load line according to the given cargo conditions.

Retrofit or modifications of the hull usually triggers recertification of the lightship parameters.

34.7 Subdivision

34.7.1 Purpose and Criteria

Offshore platforms are susceptible to flooding due to collision with boats, such as supply vessels, and due to cracks in the structure from corrosion or environmental loads. The latter may be adverted by regular inspection. Procedures mitigate the risks of collision. Yet, for maximum reliability at sea, vessels are designed to retain sufficient stability in the event of flooding of a compartment. This is typically ensured by subdivision of the vessel.

Offshore platforms, like most commercial ships, are divided internally in compartments. These compartments, whether they are voids, tanks for ballast or cargo, machinery compartments or living quarters, are arranged to prevent the spreading of flooding throughout the hull. They are insulated from each other by watertight boundaries (bulkheads, decks, or flats). Openings between compartments are provided with means of closure to prevent progressive flooding, which must develop the same watertightness characteristics as the boundary they cross.

If damaged stability is considered, the extent of watertightness is defined as the worse of the extreme waterline defined in intact stability and the final damaged waterline. Watertight boundaries are designed to withstand water pressure due to a head to the damaged waterline.

The purpose of damaged stability analysis is to ensure that an arrangement of compartments within a vessel provides sufficient subdivision, that is, that the vessel does not capsize or sink with one compartment flooded, and that progressive flooding is avoided.

34.7.2 Regulatory Requirements

Most classes of offshore vessels are subject to regulatory requirements of damaged stability by local authorities and classification companies. The requirements depend, however, on the risk to life at sea and to the environment posed by the potential loss of the vessel.

Within a vessel, a distinction is often made between those compartments wholly or partially adjacent to sea at operating draft and in operating trim conditions and other compartments.

The most stringent requirements apply to compartments which are associated with collision damage. Most rules require that any internal bulkhead or flat within a defined extent be assumed damaged so that consecutive compartments separated by these bulkheads and flats be flooded simultaneously. The extent

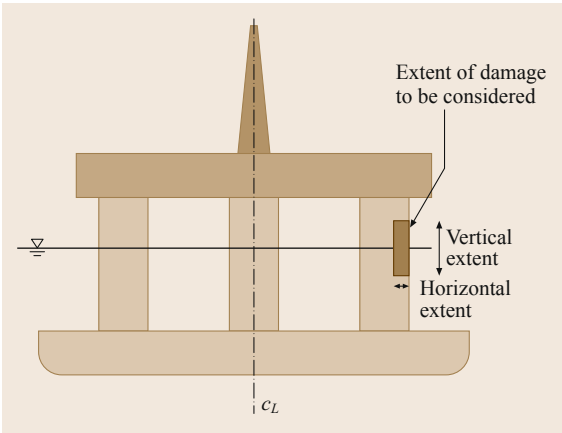

Fig. 34.38 Illustration of the extent of damage on a semisubmersible hull

of damage is defined horizontally by a depth of penetration and vertically by a vertical extent of damage. These variables are identified in Fig. 34.38. The values of depth of penetration and vertical extent vary by type of platform and function. Most offshore platforms are designed with a 1.5 −m depth horizontal penetration (see ABS MODU rules [34.10], and DNV Offshore Standard C301 [34.11]). Consequently, watertight bulkheads are usually located farther than 1.5 m from the external hull for maximum efficiency in design.

On column-stabilized units and deep-draft platforms, such as spars, considerations of damage may be limited to compartments within a predefined vertical extent, in the region of the waterline. The collision damage may also be limited to outer portions of the hull, disregarding those parts of columns and hulls which are unlikely to be hit by approaching vessels. However, all possible transit and operating waterlines are considered. For other types of platforms, such as self-elevated platforms, or ship-shape hulls, all compartments adjacent to sea from the keel upward may be considered damaged.

Additionally, depending on the type of units, a damage stability criterion may also apply to all compartments, regardless of their locations, or, in the case of column-stabilized units, to all compartments wholly or partially below the operating waterline. Flooding of machinery compartments, regardless of their locations, may also be considered.

Ultimately, the extent of damage to be considered in the analysis is determined by class regulation and local and international regulations based on the risk associated with the vessel. For instance, column-stabilized units designed as offshore wind turbine installations are not required to meet damage stability requirements for collision damage, unlike MODUs, due to the low risk of collision in absence of large supply vessels.

A designer should determine which compartments may be flooded for damaged stability purposes according to the following:

- The type of vessel to be considered (ship-shape, self-elevated unit, deep-draft platform, etc.)
- The function of the vessel (MODU, accommodations, renewable energy production, etc.)
- The body of regulations which apply to the design. If the unit is expected to be classed, class rules by a given classification society should apply. Local authorities, such as US Coast Guard, also may have specific requirements.

34.7.3 Damaged Stability and Residual Stability

Damaged stability criteria depend on the calculation of stability characteristics in a damaged condition. These calculations are very similar to stability calculations in intact conditions. As for the intact stability, righting-moment and overturning-moment curves are calculated to assess damaged stability. However, the inclination angle is usually defined with reference to the equilibrium at rest of the intact hull. Two methods are used to determine the righting-moment curves:

- Lost-buoyancy method: In the first method, called the lost-buoyancy method, we consider the total weight (or displacement) and center of gravity of the ship to remain constant before and after it is damaged. The buoyancy is lost in that part of the flooded compartment below W_0L_0, and equal amount of buoyancy is added between W_0L_0 and W_1L_1. This method is also called the constant-buoyancy method (which is a more appropriate terminology). In this case, if the flooded compartment was free of liquid cargo or ballast, the mass properties of the vessel are unchanged.
  The waterline and center of buoyancy will be modified to account for the lost buoyancy at operating draft. Due to flooding, the hull will sink to recover the displacement of the platform as determined by the mass and additional static forces (mooring pretension, etc.). The adjusted waterline and center of buoyancy may be used to calculate the damaged draft and damaged inclination of the platform. The inclination is calculated with respect to the intact even-keel position. The waterplane area may also be affected if the flooded compartment crosses the waterplane area at any relevant heel angle, causing a loss of waterplane area of the hull.
  These losses of buoyancy in the compartment and waterplane area result in a loss of metacentric height. Righting arm and righting-moment curves

Table 34.2 Comparison of the lost- (or constant-) buoyancy method (LBM; CBM) versus added-weight method (AWM) of damaged-stability calculations showing when the physical quantities remain the same or are different, before and after bilging occurs

Quantity	CBM (LBM)	AWM
Δ, ∇	Same	Different
Center of Flotation	Different	Same
I_L , I_T	Different[a]	Same
$\overline{BM}_T$, $\overline{BM}_L$	Different	Different
$\overline{GM}_T$, $\overline{GM}_L$	Different	Different
$\overline{KG}$	Same	Different
$\overline{KB}$	Different	Different
MCTC, MCT1″	Different	Same
TPC, TPI	Different	Same

[a]Unless there are horizontal water tight bulkheads (or flats) above the damaged compartment (but below the intact waterline) that would keep the waterplane area intact after bilging occurred.

are calculated similar to the intact stability case. At zero-degree trim, which may correspond to the intact inclination angle, the damaged righting arm is negative. The hull recovers stability at an equilibrium point which identifies the damage inclination angle.

- Added-weight method: In the second method, called the added-weight method, we assume that the structure remains completely intact after flooding, although its equilibrium position changes. We do this by assuming that a *weight* is added to the structure. The weight is the weight of water that enters one or more of the compartments. The problem here is that the weight is not known since it depends on the final waterline that must be determined as part of the solution. This then suggests an iterative solution procedure when we consider the flooding of a compartment. In this case, the hull volume, center of buoyancy, and waterplane area are the same as in intact stability.
  The displacement and center of gravity are adjusted to reflect the new mass properties. The damaged waterline is calculated and this results in an adjusted center of buoyancy location. The damaged inclination angle is also calculated based on the equilibrium between adjusted buoyancy and adjusted weight.

Table 34.2 lists which quantities are different or remain the same in the use of the two different methods before and after damage occurs

The righting-moment curves can be calculated for any damaged compartment as they were for any intact load line following one of the approaches described above. It may be corrected for internal free surfaces. The righting moment may be compared to an overturning moment from static external forces. The overturning moment is typically associated with a mean wind speed corresponding to a storm of lesser intensity than those considered in intact stability.

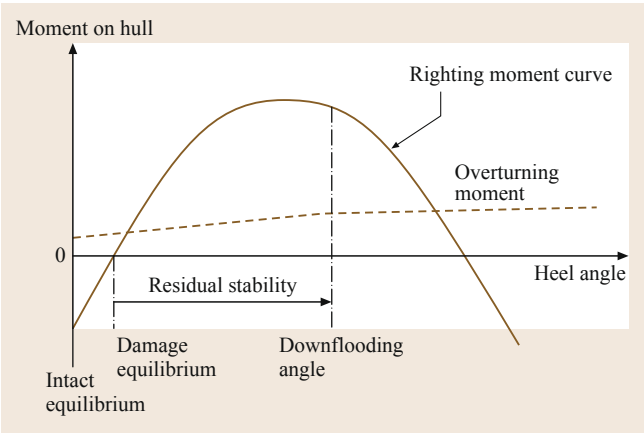

Fig. 34.39 Righting-moment curve after damage has occurred (0° heel corresponds to the equilibrium position of the intact hull)

For damaged stability to be deemed sufficient, a number of criteria may be applied. The major variables at stake are shown in Fig. 34.39:

- Equilibrium in damaged conditions: An analysis of the righting-moment curve provides basic information. Although the righting moment is negative at 0° inclination, the damaged inclination, where the moment becomes positive again, should be significantly lower than the downflooding angle. Some

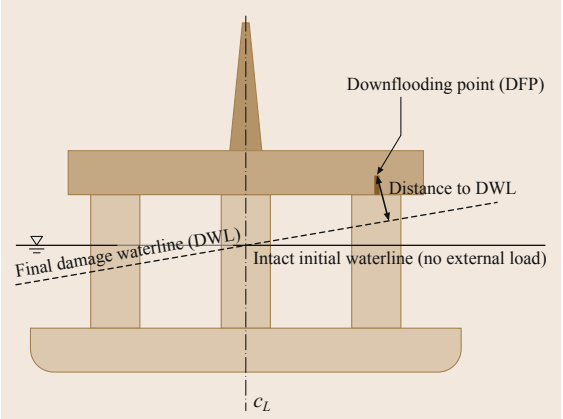

Fig. 34.40 Stability criteria associated with residual stability of column-stabilized vessels: minimum distance between final waterline (including overturning moment) and downflooding point

design codes require that the righting moment remain positive for a predefined range of trim angle beyond the damaged inclination angle.

- Residual stability: Additional criteria are usually applied to verify that the hull has sufficient residual stability. Residual stability may be defined as the range of heel angles at which the hull righting moment remains sufficient (positive or greater than applied overturning moment, depending on the regulatory authorities and type of vessels). For column-stabilized units for instance, a first and second intercept between the righting-moment curve and the overturning moment curve is defined. The residual stability in this case is defined as the difference of the heel angles between the first intercept and the downflooding angle or the second intercept. It is sometimes enforced by verifying that the downflooding point is positioned sufficiently far from the final damaged waterline at the first intercept. The final damage waterline, shown on a semisubmersible in Fig. 34.40, is defined as the maximum angle at equilibrium of the damaged hull under static-load conditions. More generally, residual stability is often defined as the range of heel angles over which the righting-moment curve of the vessel is positive.

34.8 Analysis

34.8.1 Static- and Quasi-Static Analysis

Hydrostatic analysis relies on the definition of the external boundaries of the hull combined with either an even-keel displacement or draft, and the position of the center of gravity of the hull. Designers may use commercial tools or do hand calculations to determine the corresponding center of buoyancy, initial metacentric height, and righting-arm curves based on this data, and using the methods presented herein.

For complex geometries, designers often rely on commercial software, which can update stability properties for each inclination angle, accounting for geometric discontinuities in the submerged hull.

Similarly, simple models are used to calculate the overturning moment. The wind-overturning moments may be calculated based on numerical determination of the windage coefficient according to the wind direction. These may be calculated by hand from the projection of the wind expose-area in any direction. Alternatively, for complex topside geometries, numerical programs and commercial software may be used.

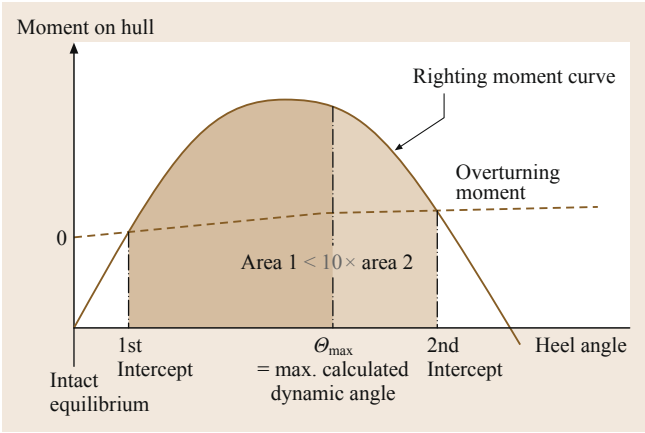

Fig. 34.41 Dynamic angle stability criteria

34.8.2 Dynamic-Response-Based Analysis

A common alternative stability criterion involves the response-based analysis. With the rising accuracy and availability of numerical analysis, it has become easier to demonstrate the divergence between the one-size-fits-all rules applied to entire categories of vessels, and the behavior of specific designs. Some categories of vessels are more design-sensitive than others. This is especially true of semisubmersibles within the MODU category. Column-stabilized semisubmersibles are less constrained than other MODUs, and design strategy influences significantly the response in waves of the platform. Traditional stability criteria, however, would not capture the better dynamic performance of a platform, penalizing more dynamically stable semisubmersible designs.

As an alternative, stability criteria which take into account the actual dynamic response of a vessel, rather than projected averages, have been derived. Some codes published by classification companies provide detailed methods to carry out the dynamic-response-based analysis. This is the case in [34.10] for column-stabilized mobile offshore drilling units. When a dynamic-response-based approach is adopted, the constant ratio of the righting moment to overturning moment is abandoned and replaced by the following considerations:

- A dynamic-angle criteria, to verify that there is sufficient reserve stability between the maximum predicted dynamic inclination angle and the second intercept with the overturning moment. This is typically achieved by ensuring that the energy to incline

between the maximum dynamic angle and the second intercept is at least 10% of the energy to incline between the first intercept and the maximum dynamic angle, as illustrated in Fig. 34.41. It ensures that design accounts for uncertainties in loadings and dynamic response calculations.

- A downflooding criteria, which ensures sufficient clearance between the maximum wave crest and the downflooding point, in reduced wind speed. The initial downflooding distance between the mean waterline and the downflooding point is compared to the predicted reduction in downflooding distance. The latter is computed according to preset formulas provided in the IMO stability code, and in many classification societies' guidelines. The formula includes safety factors and takes into account the relative motions of the platform.

These criteria rely on the determination of dynamic motions of the vessels. Two approaches are typically acceptable for this. Designers may use empirical formulas based on the vessel's geometric characteristics and mass properties. Alternatively, a full-fledged numerical analysis may be used. If so, the numerical model must account for linear and nonlinear loadings on the vessel, and, if calibration is necessary, model test results comparing the numerical model to measured data may be required.

35. Wave, Current and Wind Loads

R. Cengiz Ertekin, George Rodenbusch

This chapter describes wave, current, and wind loads on fixed or floating offshore platforms. Both linear and nonlinear waves are discussed in deterministic and irregular seas. Linear waves are written as a subset of the more general wave theory based on the perturbation method. Nonlinear waves include Stokes waves in deep waters and cnoidal and solitary waves in shallow waters. Wave loads on both large and slender structures are formulated, and solution methods, such as the Green function method, are introduced. For large structures, linear potential theory is formulated in the frequency domain. However, time-domain methods and drift loads are also discussed. For slender structures, Morison's equation and the associated drag and inertia coefficients are introduced.

These are followed by wave–current interaction, many types of uniform and nonuniform currents, wave–current kinematics, and current-induced forces, as well as vortex-induced vibrations. A number of important quantities, such as the Doppler shift, velocity estimation through the power law, lift and drag coefficients are also introduced.

Wind forces on offshore structures are discussed through both the steady and unsteady wind profiles and forces, and through spectral analysis. Other considerations include sections on model tests and similarity laws and how various physical quantities can be scaled to prototype, both commercial and open-source computational fluid dynamics (CFD) tools, and extreme response estimation.

35.1 Wave Loads

35.1.1 Linear Waves

Linear waves are characterized by the ratio of the wave amplitude to its wavelength as a *small* quantity. The fluid is assumed to be incompressible and inviscid, and the flow is irrotational, so that the particle velocity vector is given by

$$\boldsymbol{u} = \nabla\phi \,, \tag{35.1}$$

where ϕ is the velocity potential. Because of the incompressible fluid assumption, the continuity (or the con-

servation of mass) equation is given by $\nabla \boldsymbol{u} = 0$. And as a result, the continuity equation becomes Laplace's equation

$$\Delta\phi = 0\,. \tag{35.2}$$

We also have Euler's integral given by

$$\frac{\partial\phi}{\partial t} + \frac{1}{2} \parallel \nabla\phi \parallel^2 + \frac{p}{\rho} + \mathrm{g}x_2 = \frac{p_\mathrm{A}}{\rho}\,, \tag{35.3}$$

where p_A is the atmospheric pressure, ρ is the mass density of the fluid, g is the gravitational acceleration, and x_2 is the vertical coordinate (Fig. 35.1). Equation (35.3) is to be used in the determination of the pressure; it is called unsteady Bernoulli's equation by some. This equation is a result of the conservation of momentum equation which need not be simultaneously solved with the conservation of mass equation since that equation only involves a single unknown, the velocity potential.

On any material surface, whether free or not, we have the general kinematic boundary condition

$$\boldsymbol{u}\cdot\boldsymbol{n} = \frac{\partial\phi}{\partial n} = \boldsymbol{q}\cdot\boldsymbol{n}\,, \tag{35.4}$$

where $\boldsymbol{u}$ is the fluid particle velocity vector, $\boldsymbol{q}$ is the solid boundary velocity vector, and $\boldsymbol{n}$ is the unit normal vector on the boundary, pointing out of the fluid. Clearly, (35.4) is also the body-boundary condition and the seafloor boundary condition since it represents no flux through the surface. By defining the boundary surface by the equation, $F(x_1, x_2, x_3, t) = x_2 - \eta(x_1, x_3, t) = 0$, where η is the free-surface elevation, and requiring that the material derivative of F vanishes, we obtain the kinematic free-surface condition

$$\frac{\partial\phi}{\partial x_2} - \frac{\partial\eta}{\partial t} - \frac{\partial\phi}{\partial x_1}\frac{\partial\eta}{\partial x_1} - \frac{\partial\phi}{\partial x_3}\frac{\partial\eta}{\partial x_3} = 0 \quad \text{on } x_2 = \eta\,. \tag{35.5}$$

The dynamic condition on the free surface is that the pressure is continuous, that is, $p = p_\mathrm{A} \cong 0$ on $x_2 = \eta$, where we have taken the atmospheric pressure equal to zero without loss in generality. The surface tension is ignored, which means that the water waves we deal with here exclude the capillary waves (whose lengths are less than about 1.5 cm). Therefore, from Euler's integral, (35.3), we obtain the dynamic free-surface condition

$$\frac{\partial\phi}{\partial t} + \frac{1}{2}\|\nabla\phi\|^2 + \mathrm{g}\eta = 0 \quad \text{on } x_2 = \eta\,. \tag{35.6}$$

The two difficulties associated with these boundary conditions are: (i) they must be imposed on a boundary which is unknown, and (ii) they are nonlinear. Note, however, that the governing equation (35.2) is linear.

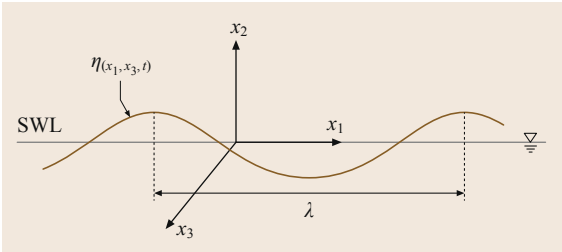

Fig. 35.1 Free surface of a wave of length λ

Perturbation Expansion

To overcome the difficulties associated with solving the nonlinear free-surface boundary conditions, one generally resorts to the use of the perturbation expansion of the quantities involved, and then linearizing the problem. To do this, one usually assumes that the wave motion is *small* and, therefore, the nonlinear terms can be discarded as a result of the argument that their magnitudes will be smaller than those of the linear terms. In this respect, one can assume that the velocity potential, as well as the surface elevation, can be expanded in a perturbation series for which a perturbation parameter ϵ is taken to be equal to, for example, Ak, where A is the wave amplitude and k is the wave number, that is, $k = 2\pi/\lambda$, where λ is the wavelength. In shallow-water wave problems, however, one would rather deal with two small parameters, one representing the nonlinearity and the other representing the dispersion of long waves.

A perturbation series is a series expansion of an unknown function about a known function, provided that the deviation of the unknown function from the known function is *small* (say the known function is the potential which can, for example, be taken as constant everywhere; this corresponds to a quiescent fluid). Then, we can write

$$\begin{aligned}
\phi &= \epsilon\phi^{(1)} + \epsilon^2\phi^{(2)} + \epsilon^3\phi^{(3)} + \cdots\,,\\
\eta &= \epsilon\eta^{(1)} + \epsilon^2\eta^{(2)} + \epsilon^3\eta^{(3)} + \cdots\,,\\
\epsilon &= Ak\,,
\end{aligned} \tag{35.7}$$

where $\phi^{(1)}$ is called the first-order potential, $\phi^{(2)}$ is the second-order potential, etc., and similarly for η, that is, $\eta^{(1)}$ is called the first-order surface elevation, $\eta^{(2)}$ is called the second-order surface elevation, etc. The expansion in (35.7) is such that when $\epsilon = 0$, there is no fluid motion; therefore, ϕ and η vanish.

Now, if the wave motion is small, meaning $\epsilon \ll 1$, we may, without giving any necessary justification, discard all the higher order terms after we substitute these

expansions in the boundary conditions. Moreover, we can expand each of the terms of the boundary conditions in a Taylor series about the still-water surface, $x_2 = 0$. For example, the time derivative of the potential is written as

$$\frac{\partial \phi}{\partial t}(x_1, x_2 = \eta, x_3, t) = \frac{\partial \phi}{\partial t}(x_1, 0, x_3, t) + \eta \frac{\partial^2 \phi(x_1, 0, x_3, t)}{\partial t \partial x_2} + \cdots . \tag{35.8}$$

Since η and ϕ are small, the higher order terms can sometimes be ignored. This means that only the linear terms involving ϕ and η have to be evaluated on the still-water level ($x_2 = 0$) instead of on the exact boundary surface, $x_2 = \eta(x_1, x_3, t)$. This is required to be consistent with the perturbation expansion. Therefore, we have the linearized versions of the boundary conditions, given by (35.5) and (35.6), as follows

$$\frac{\partial \eta^{(1)}}{\partial t}(x_1, x_3, t) = \frac{\partial \phi^{(1)}}{\partial x_2}(x_1, 0, x_3, t) \text{ (kinematic)} , \tag{35.9}$$

$$\eta^{(1)}(x_1, x_3, t) = -\frac{1}{\mathrm{g}} \frac{\partial \phi^{(1)}}{\partial t}(x_1, 0, x_3, t) \text{ (dynamic)} . \tag{35.10}$$

In summary, the first-order problem, $O(\epsilon)$ problem, becomes

$$\begin{aligned} &\Delta \phi^{(1)}(x_1, x_2, x_3, t) = 0 , \\ &\phi^{(1)}_{x_2}(x_1, -h, x_3, t) = 0 , \\ &\phi^{(1)}_{x_2}(x_1, 0, x_3, t) - \eta^{(1)}_t(x_1, x_3, t) = 0 , \\ &\phi^{(1)}_t(x_1, 0, x_3, t) + \mathrm{g}\eta^{(1)}(x_1, x_3, t) = 0 , \end{aligned} \tag{35.11}$$

where subscripts indicate differentiation with respect to the indicated variable. And for this $O(\epsilon)$ problem, the dynamic pressure is given by the linearized Euler's integral

$$p^{(1)}(x_1, x_2, x_3, t) = -\rho \phi^{(1)}_t(x_1, x_2, x_3, t), \quad x_2 < 0 , \tag{35.12}$$

anywhere in the fluid.

We can now assume that we have two-dimensional or long-crested, linear water waves so that the associated functions do not depend on the x_3-coordinate. Of course, in the case of short-crested waves, which represents the real situation in the oceans, we cannot rule out the x_3-dependence.

Let us now assume that a monochromatic wave, propagating in the positive x_1-direction, is given by

$$\eta(x_1, t) = A \cos(kx_1 - \omega t) . \tag{35.13}$$

Here, A is the wave amplitude. Equation (35.13) does not depend on time in a moving coordinate system, whose constant (phase) speed is given by $c = \frac{\omega}{k}$. In other words, the motion is steady in the moving coordinates. In a fixed coordinate system, η is a time-harmonic function. Because η is periodic, ϕ must also be periodic, so that we can write

$$\phi(x_1, x_2, t) = \mathrm{Re}\left\{ Y(x_2) \mathrm{e}^{\mathrm{i}[kx_1 - \omega t]} \right\} . \tag{35.14}$$

Equation (35.14) is a result of the separation-of-variables technique used in solving linear partial differential equations.

By enforcing the dynamic free-surface boundary condition and the no-flux sea-floor condition, the linear solution for the velocity potential can be obtained

$$\phi(x_1, x_2, t) = \frac{\mathrm{g}A}{\omega} \frac{\cosh[k(x_2 + h)]}{\cosh(kh)} \sin(kx_1 - \omega t) . \tag{35.15}$$

However, we have not yet used the kinematic free-surface condition given by the third equation in (35.11). When we enforce this condition by using (35.15), we obtain the dispersion relation

$$\omega^2 = \mathrm{g}k \tanh(kh) , \tag{35.16}$$

where h is the water depth and k is the wave number. In deep water, $kh \to \infty$, so that we have $\omega^2 = \mathrm{g}k$, and in shallow water, $kh \ll 1$, so that $\omega^2 = \mathrm{g}hk^2$.

In the deep-water case, the real part of the velocity potential of the incoming wave (or incident wave potential) becomes

$$\phi(x_1, x_2, t) = \frac{\mathrm{g}A}{\omega} \mathrm{e}^{kx_2} \sin(kx_1 - \omega t) . \tag{35.17}$$

It is useful to give particle velocity components (linear) for finite water depth by using (35.15)

$$\begin{aligned} u_1 &= \frac{\partial \phi}{\partial x_1} = \frac{\mathrm{g}Ak}{\omega} \frac{\cosh[k(x_2 + h)]}{\cosh(kh)} \cos(kx_1 - \omega t) , \\ u_2 &= \frac{\partial \phi}{\partial x_2} = \frac{\mathrm{g}Ak}{\omega} \frac{\sinh[k(x_2 + h)]}{\cosh(kh)} \sin(kx_1 - \omega t) . \end{aligned} \tag{35.18}$$

Table 35.1 Some physical quantities resulting from linear theory

Vertical particle displacement	$\zeta = A\dfrac{\sinh[k(x_2+h)]}{\sinh(kh)}\cos(kx_1-\omega t)$
Horizontal particle displacement	$\xi = A\dfrac{\cosh[k(x_2+h)]}{\sinh(kh)}\sin(kx_1-\omega t)$
Group velocity	$c_\mathrm{g} = \dfrac{1}{2}\left[1+\dfrac{2kh}{\sinh(2kh)}\right]c$
Mean energy density	$E_\mathrm{m} = \dfrac{1}{2}\rho g A^2$
Energy flux	$P = E_\mathrm{m}c_\mathrm{g}$

The total pressure (linear) can then be obtained from Euler's integral as

$$p(x_1,x_2,t) = \rho g A\frac{\cosh k(x_2+h)}{\cosh(kh)}\cos(kx_1-\omega t) - \rho g x_2\,, \tag{35.19}$$

where the first term on the right-hand side represents the dynamic and the second term represents the hydrostatic pressure.

Water particle accelerations (linear) are given by

$$\begin{aligned}\frac{Du_1}{Dt} &\cong \frac{\partial u_1}{\partial t}\\ &= \mathrm{g}Ak\frac{\cosh[k(x_2+h)]}{\cosh(kh)}\sin(kx_1-\omega t)\,, \qquad (35.20)\\ \frac{Du_2}{Dt} &\cong \frac{\partial u_2}{\partial t}\\ &= -\mathrm{g}Ak\frac{\sinh[k(x_2+h)]}{\cosh(kh)}\cos(kx_1-\omega t)\,,\end{aligned} \tag{35.21}$$

where D/Dt is the material derivative, approximated here as the local time derivative only, due to the linearity of the problem. Some other physical quantities for linear water waves are listed in Table 35.1.

35.1.2 Nonlinear Waves

To obtain the linear wave solution, the perturbation expansion introduced in the last section was truncated at $O(\epsilon)$. Clearly, this expansion can be carried out to higher orders, and this is generally done in offshore engineering and in deep-water applications, up to the fifth order. The higher order infinitesimal wave theory based on the systematic power series expansion in $\epsilon = Ak$ is due to [35.1]. The proof of convergence can be found in [35.2]. *Schwartz* [35.3] obtained the infinite-depth expansion up to $O(\epsilon^{117})$ by using a computer algorithm. However, because of the complexity of algebra and the rapid convergence of the asymptotic series, it is mostly unnecessary to consider problems of $O(\epsilon^6)$ and higher, unless, perhaps, if the water depth is very shallow. But then the Stokes expansion in shallow water gives inaccurate results in general, and thus should not be used if the water depth is shallow. Instead, a cnoidal wave theory can be used in shallow waters [35.4, 5]. The fifth-order Stokes waves, commonly used in offshore engineering, were calculated by [35.6].

After using the Taylor series expansion of the functions and its derivatives, and substituting them in the boundary conditions for each of the perturbation terms seen in (35.7), one can obtain, for example, the kinematic free-surface boundary condition at the first and second orders in two dimensions

$$\begin{aligned}&O(\epsilon): \phi^{(1)}_{x_2} - \eta^{(1)}_t = 0\,,\\ &O(\epsilon^2): \phi^{(2)}_{x_2} - \eta^{(2)}_t = \phi^{(1)}_{x_1}\eta^{(1)}_{x_1} - \phi^{(1)}_{x_2x_2}\eta^{(1)}\,.\end{aligned} \tag{35.22}$$

Note that once the first-order problem is solved, the right-hand side of the second-order boundary condition in (35.22) is known, and thus it can be treated as an applied or external pressure on the free surface located on the still-water level.

Let us consider the dynamic free-surface boundary condition given by (35.6) in two dimensions. Following the same procedure, that is, by using the Taylor series expansion of the functions in each term of the perturbation expansion, one can obtain

$$\begin{aligned}\phi_t &= \epsilon\phi^{(1)}_t + \epsilon^2(\phi^{(2)}_t + \phi^{(1)}_{x_2t}\eta^{(1)})\\ &\quad + \epsilon^3(\phi^{(3)}_t + \phi^{(1)}_{x_2t}\eta^{(2)} + \cdots) + O(\epsilon^4)\,,\\ \frac{1}{2}\{\phi^2_{x_1} + \phi^2_{x_2}\} &=\\ &\frac{1}{2}\{[\epsilon\phi^{(1)}_{x_1} + \epsilon^2(\phi^{(1)}_{x_2x_1}\eta^{(1)} + \phi^{(2)}_{x_1}) + \cdots]^2\\ &+ [\epsilon\phi^{(1)}_{x_2} + \epsilon^2(\phi^{(1)}_{x_2x_2}\eta^{(1)} + \phi^{(2)}_{x_2}) + \cdots]^2\}\\ &+ O(\epsilon^5)\,.\end{aligned} \tag{35.23}$$

Then, we have

$$\begin{aligned}&O(\epsilon): \phi^{(1)}_t + \mathrm{g}\eta^{(1)} = 0\,,\\ &O(\epsilon^2): \phi^{(2)}_t + \mathrm{g}\eta^{(2)} =\\ &\qquad -\phi^{(1)}_{x_2t}\eta^{(1)} - \frac{1}{2}(\phi^{(1)^2}_{x_1} + \phi^{(1)^2}_{x_2})\,.\end{aligned} \tag{35.24}$$

The dynamic and kinematic free-surface conditions can be combined into one equation for each $O(\epsilon)$ and $O(\epsilon^2)$

as follows

$$
\begin{aligned}
&O(\epsilon): \phi_{tt}^{(1)}(x_1,0,t) + g\phi_{x_2}^{(1)}(x_1,0,t) = 0\,,\\
&O(\epsilon^2): \phi_{tt}^{(2)}(x_1,0,t) + g\phi_{x_2}^{(2)}(x_1,0,t) =\\
&\qquad -\eta^{(1)}\left[\phi_{ttx_2}^{(1)} + g\phi_{x_2x_2}^{(1)}\right]\\
&\qquad -2(\phi_{x_1}^{(1)}\phi_{tx_1}^{(1)} + \phi_{x_2}^{(1)}\phi_{tx_2}^{(1)})\,. \qquad (35.25)
\end{aligned}
$$

The first equation in (35.25) is the combined form of the third and fourth equations, respectively, in (35.11).

It is important to note that the first-order potential, which will be given explicitly later, also satisfies the second-order problem if the water depth is infinite. In other words,

$$
\phi(x_1,x_2,t) = \frac{gA}{\omega}e^{kx_2}\sin(kx_1-\omega t) + O(\epsilon^3)\,. \qquad (35.26)
$$

However, the second-order surface elevation, that is,

$$
\eta = \epsilon\eta^{(1)} + \epsilon^2\eta^{(2)} + O(\epsilon^3) \qquad (35.27)
$$

is not the same as the first-order surface elevation given by (35.13) [35.4]. The second- and fifth-order solutions of Stokes waves are given, for example, in [35.5, Tables 4.3–4.4].

Next, we briefly discuss another type of nonlinear waves that occur when the water depth is relatively shallow.

35.1.3 Shallow-Water Waves

In relatively shallow waters, when the wavelength is greater than about eight water depths, the Stokes expansion no longer works, and an alternative wave theory must be used. One such theory is called the cnoidal wave theory as established by [35.7]. Subsequently, other cnoidal wave theories were developed by [35.4, 8–10].

The infinite length limit of cnoidal waves is known as solitary waves. These waves are generally used to model tsunami propagation and arrival times in the oceans. A number of solitary wave solution are available [35.8, 11, 12]. In more recent years, solitary waves based on the Green–Naghdi theory were also developed [35.13, 14].

Some of the equations that can be used in engineering calculations of cnoidal and solitary waves are listed in [35.5].

35.1.4 Random Waves

Irregular sea waves can be thought of as the sum of an infinite number of sinusoidal waves (each of which has a different amplitude and frequency) whose phase angles are random. In general then, the amplitude of each component wave may be represented by $A(\omega,\gamma)$, which is a random variable itself. Here, ω is the angular wave frequency and γ is the heading angle of incoming waves. Because of this randomness of waves, a probabilistic approach is necessary to describe various parameters associated with a *confused sea*. First, *Denis* and *Pierson* [35.15] introduced the probabilistic description of confused seas in marine hydrodynamics involving ship motions. As an example of the superposition of regular waves of different (however, infinitesimal) heights and frequencies, consider Fig. 35.2. Even this limited number of regular waves gives an irregular wave pattern when they are superposed. Furthermore, the resulting irregular shape is totally random, that is, a slight change in wave amplitude, frequency, or phase of the waves will result in a different pattern for irregular waves (Fig. 35.3, which also shows how the frequency domain and time domain representations of waves are related to each other in long-crested seas). Therefore, irregular waves cannot be identified by their shapes (surface elevation).

Because we cannot characterize an irregular sea by its shape, we need another criterion to base our approach on. This criterion is that the total (potential and kinetic) energy E of an irregular wave train is the sum of the energies of all components of individual waves, that is,

$$
E = \frac{\rho g}{2}\{A_1^2 + A_2^2 + \cdots\} = \frac{1}{2}\rho g\sum_{n=1}^{N}A_n^2\,. \qquad (35.28)
$$

This concept leads us to the energy spectrum in which waves of many frequencies are present. In the limit,

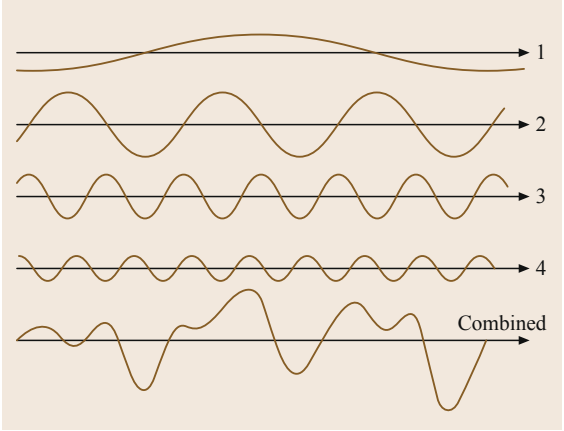

Fig. 35.2 Superposition of four regular waves with different amplitudes and lengths, shifted randomly (after [35.16])

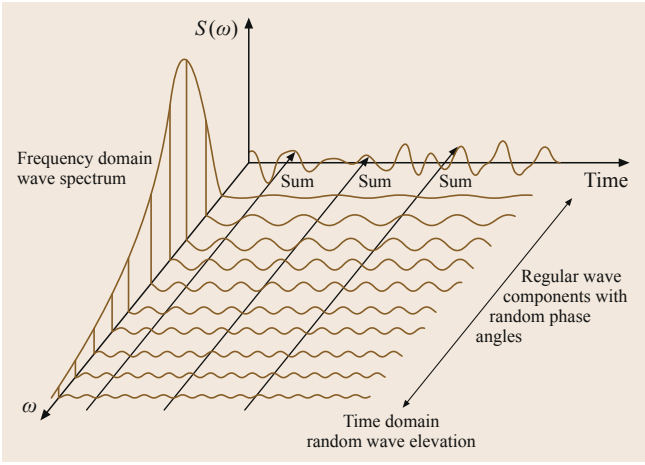

Fig. 35.3 The relation between the frequency-domain and time-domain representations of waves in long-crested seas (after [35.17])

the number of individual wave components N tends to infinity, and the summations become integrals, for example

$$\eta(x_1, x_3, t) = \mathrm{Re}\left\{\int_0^{\infty}\int_0^{2\pi} A(\omega,\gamma)\exp\{\mathrm{i}k(\omega)(x_1\cos(\gamma) + x_3\sin(\gamma)) - \mathrm{i}\omega t\}\,\mathrm{d}\gamma\,\mathrm{d}\omega\right\}, \tag{35.29}$$

where the wave amplitude $A(\omega,\gamma)$ is a random quantity. Equation (35.29) admits all possible wave directions and frequencies.

The wave spectrum can also be calculated by considering the auto-correlation function (of the surface elevation) defined by

$$R_\mathrm{T}(\tau) = \frac{1}{\mathrm{T}}\int_{-\frac{\mathrm{T}}{2}}^{\frac{\mathrm{T}}{2}} \eta_\mathrm{T}(t)\,\eta_\mathrm{T}(t+\tau)\,\mathrm{d}t\,. \tag{35.30}$$

The one-sided wave spectrum for a long-crested irregular wave system (unidirectional) is then given by

$$S(\omega) = \frac{1}{2\pi}\int_0^{\infty} R_\mathrm{T}(\tau)\cos(\omega\tau)\mathrm{d}\tau\,. \tag{35.31}$$

The total mean energy of the wave system is

$$\bar{E} = \frac{1}{2}\rho g\int_0^{\infty}\int_0^{2\pi} S(\omega,\gamma)\mathrm{d}\gamma\mathrm{d}\omega\,. \tag{35.32}$$

Since the mean square value of a monochromatic wave is $A^2/2$, we can represent a random process by

$$\eta(t) = \lim_{\Delta\omega\to 0}\left\{\sum_{n=1}^{N}\sqrt{2S(\omega_n)\Delta\omega}\cos(\omega_n t + \epsilon_n)\right\}, \quad N\to\infty\,, \tag{35.33}$$

where ϵ_n is a random phase angle uniformly distributed in the interval 0–2π, and $\omega_n = n\Delta\omega$. Even though different choices of ϵ_n would produce different time histories, the resulting wave spectrum would be the same. The mean square value of $\eta(t)$ is the area under the spectral density versus the frequency curve.

Let us consider the mean value of $\eta(t)$

$$\langle\eta(t)\rangle = \frac{1}{\mathrm{T}}\int_0^{\mathrm{T}}\eta(t)\mathrm{d}t\,, \tag{35.34}$$

and the standard deviation σ

$$\sigma = \sqrt{\frac{1}{\mathrm{T}}\int_0^{\mathrm{T}}(\eta(t) - \langle\eta(t)\rangle)^2\,\mathrm{d}t}\,. \tag{35.35}$$

The standard deviation σ is a measure of how η deviates from the mean. Water-surface elevation is assumed to have a Gaussian probability distribution, with zero mean. Thus, the variance σ^2 becomes

$$\sigma^2 = \langle\eta^2(t)\rangle = \frac{1}{\mathrm{T}}\int_0^{\mathrm{T}}\eta(t)^2\mathrm{d}t = \int_0^{\infty} S(\omega)\mathrm{d}\omega = m_0\,, \tag{35.36}$$

that is, the area under the spectral density function is the variance of $\eta(t)$ and m_0 is known as the zeroth-moment of the spectrum. In other words, the root mean square (RMS) of $\eta(t)$ is equal to the standard deviation given by (35.35) if the probability distribution is Gaussian, that is

$$\mathrm{RMS} = \sqrt{\langle\eta^2(t)\rangle} = \sqrt{m_0} = \sigma\,. \tag{35.37}$$

The spectrum of any quantity of interest, such as the motion of a platform or forces acting on it, can be obtained in a random seaway by

$$S_y(\omega) = |H(\omega)|^2 S_x(\omega) \,, \tag{35.38}$$

where the modulus (or magnitude) of $H(\omega)$ is indicated since the transfer function, $H(\omega)$, can also be a complex function of the frequency. In other words, the output spectrum is linearly proportional to the square of the transfer function. A typical transfer function could be equal to the force divided by the wave amplitude. The force clearly varies with the angular frequency ω(rad/s) (the cyclic frequency, $f = \omega/2\pi$ is used sometimes).

The transfer function, $H(\omega)$, can represent the wave force, wave run-up, surface-elevation amplitude, etc., as long as the system is linear. In other words, $L[\,]$ is an operator such that for the input $x(t)$ and the output $y(t)$, and the relation $y(t) = L[x(t)]$ between them, we must have $L[x_1(t) + x_2(t)] = L[x_1(t)] + L[x_2(t)]$. Also, for any constant α, $L[\alpha x(t)] = \alpha L[x(t)]$ needs to be satisfied. This is just the definition of a linear operator. Here, $x_1(t)$ and $x_2(t)$ are the two inputs corresponding to the two outputs $y_1(t)$ and $y_2(t)$, respectively.

For a narrow-banded spectrum (most of the energy present in waves is concentrated around a rather small interval of wave frequencies), it can be shown for any physical quantity of interest by using the Rayleigh probability distribution that

$$\bar{y}^{1/3} \cong 4.0\sqrt{m_0} = 4.0\,\sigma \,, \tag{35.39}$$

where m_0 is the area under the spectrum curve and σ is the root mean square (RMS) as given by (35.37). If, for instance, $y(t)$ is equal to the wave height, $H(t)$, we have

$$H_{1/3} = 4.0\sqrt{m_0} = 4.0\sqrt{\int_0^\infty S(\omega)\,\mathrm{d}\omega} \,, \tag{35.40}$$

where $H_{1/3}$ is called the significant wave height and $S(\omega)$ is the wave spectrum. Note that if m_0 is taken as the area under the response spectrum, $y_{1/3}$ would give the significant height (double amplitude) of the force, moment, motion, etc., whatever the response (output) corresponds to.

If one is interested in the significant amplitude response, then, for example

$$\begin{aligned} F_{1/3} &= 2.0\sqrt{m_\mathrm{R}} = 2.0\sqrt{\int_0^\infty S_\mathrm{R}(\omega)\,\mathrm{d}\omega} \\ &= 2.0\,\mathrm{RMS\ (Force)} \end{aligned} \tag{35.41}$$

will be the significant force amplitude, while $S_\mathrm{R}(\omega)$ is the force amplitude response spectrum,

$$S_\mathrm{R}(\omega) = |H(\omega)|^2\, S_W(\omega) \,, \tag{35.42}$$

where $H(\omega)$ is the force amplitude transfer function, $F(\omega)/A$, and $S_W(\omega)$ is the wave amplitude spectrum.

Once the significant response is known, it is possible to predict (if the Rayleigh distribution is valid) the short-term design extreme by the following formula (for a derivation of this equation, see for example [35.18, p. 319]),

$$y_\mathrm{extreme} = y_{1/3}\left(\frac{1}{2}\log\frac{N}{0.01}\right)^{1/2} \,, \tag{35.43}$$

where N is the number of waves expected to be encountered during a storm. For example, if the storm lasts for 3 hours and the average wave period is 15 s, then $N = 3 \times 60 \times 60/15 = 720$, and, therefore, $y_\mathrm{extreme} = 1.5584\, y_{1/3}$.

Sometimes we may know the spectrum given as a function of one quantity, say cyclic wave frequency or period or encounter frequency, and we may need to convert it to a wave spectrum as a function of another quantity. To do this, one has to keep in mind that the energy content of the waves must remain the same no matter what coordinate system is used (this is called *Galilean Invariance*), including the steadily moving one. It is common, for example, to see that the cyclic wave frequency, $f = 1/T$ (Hz), is used in calculations. In such cases, one can convert the angular-frequency spectrum into the cyclic-frequency spectrum by writing

$$S(f)\mathrm{d}f = S(\omega)\mathrm{d}\omega,\ \omega = 2\pi f \ \Rightarrow\ S(f) = 2\pi S(\omega) \,. \tag{35.44}$$

So far, we have concentrated on the long-crested wave spectrum. The waves in the ocean are, in fact, short crested, meaning that they move in different directions in general. If waves are multidirectional, and, therefore, are short crested, with a dominant wave heading angle γ, the directional wave-energy spectral density can be written as

$$\begin{aligned} &\bar{S}_\mathrm{W}(\omega,\theta) = S_\mathrm{W}(\omega)G(\theta) \,, \\ &G(\theta) = \frac{2}{\pi}\cos^2\theta \,, \\ &-\frac{\pi}{2} \le \theta \le \frac{\pi}{2} \,, \end{aligned} \tag{35.45}$$

where θ, the heading angle of each component wave, is measured from the axis of the dominant wave heading,

and $G(\theta)$ is called the spreading function, which, by assumption, is set to zero if $|\theta| > \pi/2$. Note that there exist spreading functions that are different from (35.45). This is because of a better fit of a particular spreading function to observational data at a specific ocean site.

The wave spectrum for a given location is, in general, not available from observational data. As a result, we must use one or more of a number of formulas developed for estimating the wave spectrum. Here, we summarize some of them, and the reader is referred to other works for more detailed analysis of and references on the subject [35.5] or [35.19].

The Bretschneider spectrum is based on the significant wave height H_s and peak wave (angular) frequency, $\omega_p = 2\pi/T_p$, where T_p is the peak period of the wave spectrum, that is, it is a two-parameter spectrum. For fully developed seas, the wave spectrum is

$$S(\omega) = \frac{5H_s^2}{16\omega_p}\frac{1}{(\omega/\omega_p)^5}\exp\left\{-\frac{5}{4}\left(\frac{\omega}{\omega_p}\right)^{-4}\right\} . \tag{35.46}$$

The dimension of the wave spectrum is L^2T. An example of a Bretschneider spectrum is shown in Fig. 35.4.

The Pierson–Moskowitz (P–M) spectrum is based on the wind speed U_w(m/s) alone, it is a one-parameter spectrum, and is given by

$$S(\omega) = \frac{\alpha g^2}{\omega^5}\exp\left(-\frac{B}{\omega^4}\right) , \tag{35.47}$$

where $\alpha = 8.1\times10^{-3}$ is Phillips' constant, $B = 0.74(g/U_w)^4$, and g is the gravitational acceleration. It is possible to express the P–M spectrum in terms of the significant wave height, H_s, that is the average height of the highest one-third of the waves. Recall that H_s is given by (35.40)

$$H_s = 4.0\sqrt{m_0} = 4.0\sqrt{\int_0^\infty S(\omega)\mathrm{d}\omega}$$
$$= \frac{2{U_w}^2}{g}\sqrt{\frac{\alpha}{0.74}} \quad \text{or} \quad {U_w}^{-4} = \frac{0.044}{g^2(H_s)^2} , \tag{35.48}$$

where we used (35.47). Therefore, we can now write the one-parameter P–M spectrum in terms of H_s

$$S(\omega) = \frac{8.1-3g^2}{\omega^5}\exp\left(-0.032\frac{g^2}{\omega^4(H_s)^2}\right) . \tag{35.49}$$

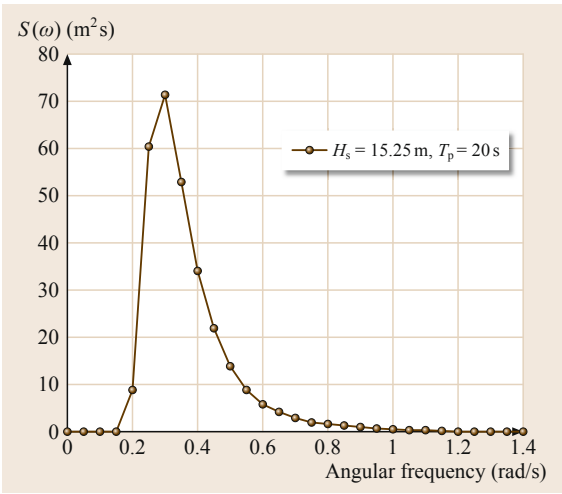

Fig. 35.4 Bretschneider spectrum for significant wave height of 15.25 m and peak period of 20 s

35.1.5 Large Bodies

When an offshore structure is *large* (generally the dimensions of the structure and perhaps even of each member is not small compared with the wavelength), one would assume that the viscous effects are much smaller than the inertial effects as far as the wave loads are concerned. In this section, we discuss wave loads on large structures by using linear potential theory valid for rather small wave slopes and under the assumptions of inviscid and incompressible fluid and irrotational flow.

Potential Theory

Since we have a linear system, meaning that the governing equation (Laplace's equation) and the boundary conditions do not contain any nonlinear terms, all physical quantities related to the response should be linearly proportional to wave amplitude. As a result, the complicated problem of a freely floating structure impacted by linear waves can be decomposed into multiple problems, each of which are easier to solve. The sum of all the solutions will then be the solution of the complicated problem, as long as the linearity assumption made holds true, that is, that the wave slope is small.

Consider a freely floating body in the *absence* of forward motion. We assume that the body makes *small* motions in six degrees of freedom, and that they can be written as

$$x_j = x_j^0 e^{-i\omega t} , \quad i = \sqrt{-1}, \quad j = 1, 2, \ldots, 6 . \tag{35.50}$$

Each x_j, $j = 1, 2, 3$, refers to the translational displacements of surge, heave, and sway, respectively, and each x_j, $j = 4, 5, 6$, refers to the angular displacements (or rotations) of roll, yaw, and pitch, respectively, and x_j^0 denotes the complex amplitude of the motion.

The complex total potential due to the interaction of waves with the body can be written in a compact form as

$$\Phi_{\mathrm{T}} = \sum_{j=0}^{7} \phi_j(x_1, x_2, x_3) \mathrm{e}^{-\mathrm{i}\omega t} \,, \tag{35.51}$$

where $\phi_0 \equiv \phi_I$ is the incoming wave potential, ϕ_j, $j = 1, 2, \ldots, 6$, are the radiation potentials, and $\phi_7 \equiv \phi_D$ is the diffraction potential, all being complex functions of the independent spatial variables. The incoming wave potential is only due to the periodic linear waves propagating in the absence of the body, the diffraction potential is due to a fixed body impacted by the incoming waves, and the radiation potentials are due to a body oscillating in a prescribed mode of motion, one at a time, and in the absence of any incoming waves.

Each potential in (35.51) must satisfy

$$\begin{aligned} \nabla^2 \phi_j(x_k) &= 0, \quad x_k \in D \,, \\ \frac{\partial \phi_j(x_k)}{\partial x_2} - \frac{\omega^2}{\mathrm{g}} \phi_j(x_k) &= 0, \quad x_k \in S_{\mathrm{f}} \,, \\ \frac{\partial \phi_j(x_k)}{\partial x_2} &= 0, \quad x_k \in S_{\mathrm{s}} \,, \end{aligned} \tag{35.52}$$

for $j = 0, 1, 2, \ldots, 7$ and $x_k \equiv (x_1, x_2, x_3)$ (Fig. 35.5). The sea-floor condition (as used here) implies that the water depth is constant (although this is not a necessary assumption in general).

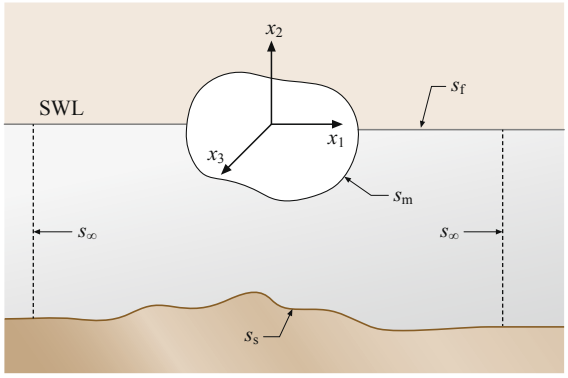

Fig. 35.5 A control volume in the fluid, bounded by the body, still-water surface, sea floor, and a large control cylinder of radius R

In addition, we must have the following body-boundary conditions to be satisfied

$$\begin{aligned} \frac{\partial \phi_j(x_k)}{\partial n} &= n_j \,, \; j = 1, 2, \ldots, 6, \; x_k \in S_{\mathrm{m}}; \\ \frac{\partial \phi_7(x_k)}{\partial n} &= -\frac{\partial \phi_0(x_k)}{\partial n} \,, \; x_k \in S_{\mathrm{m}} \,. \end{aligned} \tag{35.53}$$

And all ϕ_j, $j = 1, 2, 3, \ldots, 7$, except the incident wave-potential, must also satisfy the Sommerfeld radiation condition:

$$\lim_{r \to \infty} \left[\sqrt{r} \left(\frac{\partial}{\partial r} - ik \right) \phi_D \right] = 0 \,. \tag{35.54}$$

This equation basically states that the particle velocities $\to 0$ as $r \to \infty$ and that the waves are outgoing. Equation (35.54) is called the radiation condition (or the Sommerfeld condition) for a three-dimensional (3-D) body of bounded extent in a fluid (with a free surface) of unbounded extent on the horizontal plane. Note that

$$r = \sqrt{x_1^2 + x_3^2}$$

on the horizontal plane. This equation must be satisfied by the diffraction and radiation potentials, but not by the incoming potential.

The total pressure can be obtained from linearized Euler's integral

$$p_{\mathrm{T}} = -\rho \mathrm{g} x_2 - \rho \frac{\partial \Phi_{\mathrm{T}}}{\partial t} \,; \tag{35.55}$$

and the total force ($j = 1, 2, 3$) and moment ($j = 4, 5, 6$) are obtained from

$$F_{\mathrm{T}j} = -\int_{S_{\mathrm{m}}} p_{\mathrm{T}} n_j \, \mathrm{d}S \,, \quad j = 1, 2, \ldots, 6 \,. \tag{35.56}$$

The hydrostatic forces and moments due to the first term on the right hand side of (35.55) can be written as

$$F_{\mathrm{S}i} = -k_{ij}^{(\mathrm{S})} x_j \,, \quad i, j = 1, 2, \ldots, 6 \,, \tag{35.57}$$

where $k_{ij}^{(\mathrm{S})}$ are the hydrostatic stiffness (or restoring) coefficients, $k_{22}^{(\mathrm{s})} = \rho \mathrm{g} A_{\mathrm{WP}}$ is the restoring coefficient in heave, where A_{WP} denotes the water-plane area of the body. Because there is no restoration in the horizontal plane, it is clear that $k_{ij}^{(\mathrm{s})} = 0$ if $i, j = 1, 3, 5$. Also, note that, in a linear system and for a rigid body, $k_{ij}^{(\mathrm{S})} = k_{ji}^{(\mathrm{S})}$, that is, the hydrostatic stiffness matrix (or tensor) is

symmetric. For elastic (or deformable) bodies, this can also be shown [35.20].

The total forces and moments given by (35.56) includes the hydrostatic, wave-exciting and radiation forces, and moments. The wave-exciting forces can be written as

$$F_{Wj} = -\rho e^{-i\omega t} \int_{S_m} \left(\frac{\partial \phi_0}{\partial t} + \frac{\partial \phi_7}{\partial t} \right) n_j dS$$
$$= AE_j e^{-i\omega t}, \quad j = 1, 2, \ldots, 6, \tag{35.58}$$

where E_j is the complex amplitude of the exciting force divided by the wave amplitude A. Note that (35.58) includes both the Froude–Krylov force ($\partial\phi_0/\partial t$ term) and the scattering force ($\partial\phi_7/\partial t$ term).

The hydrodynamic (or radiation) forces due to the motion of the body in each mode can be determined, once the radiation potentials are solved for. They are given by

$$F_{Ri} = -\mu_{ij}\ddot{x}_j - \lambda_{ij}\dot{x}_j, \quad i, j = 1, 2, \ldots, 6, \tag{35.59}$$

where

$$\mu_{ij} = \rho \int_{S_m} \phi_j^{(R)} \frac{\partial \phi_i^{(R)}}{\partial n} \, dS,$$
$$\lambda_{ij} = \rho\omega \int_{S_m} \phi_j^{(I)} \frac{\partial \phi_i^{(R)}}{\partial n} \, dS, \tag{35.60}$$

where $\phi_j^{(R)}$ is the real and $\phi_j^{(I)}$ is the imaginary part of j-th radiation potential. The components of the second-order tensor μ_{ij} are called the added-mass coefficients, and λ_{ij} are called the wave-damping or, simply, damping coefficients. Note that, in the unbounded-fluid case, there is no free surface and, as a result, there is no wave generation. And, therefore, the damping coefficients do not exist since no energy is carried by waves toward infinity. See, for example, [35.21] for some added-mass and damping coefficients for a floating structure of a semisubmersible type.

By considering a control volume enclosed by the free surface, the body surface, sea floor, and an imaginary cylinder at $r = \infty$, one can show that $\mu_{ij} = \mu_{ji}$ and $\lambda_{ij} = \lambda_{ji}$ by using Green's second identity. Note that these results are valid if there is no forward motion. It can also be shown that the average rate at which work is done by the body upon the fluid is directly proportional to λ_{ij}, and, therefore, that the matrix λ_{ij} must be positive definite for all ω. In particular, $\lambda_{ii} > 0$ for all $i = 1, 2, \ldots, 6$ and ω, but in some cases $\lambda_{ij}, i \neq j$ may be negative [35.22].

There may be mooring lines which are attached to the body to keep it in location. These mooring lines tend to restore the motion of the body, and, thus, can be treated as restoring coefficients

$$F_{Mi} = -k_{ij}^{(M)} x_j, \quad i, j = 1, 2, \ldots, 6. \tag{35.61}$$

And they can provide restoring (however small) in all modes of motion unlike the hydrostatic restoring.

We can now assemble the forces and moments to obtain

$$F_{Ti} = -(k_{ij}^{(S)} + k_{ij}^{(M)})x_j - \mu_{ij}\ddot{x}_j - \lambda_{ij}\dot{x}_j + AE_i e^{-i\omega t}, \tag{35.62}$$

where we have also included the mooring line loads in (35.62) (they were not included in (35.56)).

We are now ready to consider Newton's equations which govern the motions of a body. These equations can be written as

$$F_{Ti} = m_{ij}\ddot{x}_j, \quad i, j = 1, 2, \ldots, 6, \tag{35.63}$$

where

$$m_{11} = m_{22} = m_{33} = m, \; m_{44} = I_1, \; m_{55} = I_2,$$
$$m_{66} = I_3, \; m_{54} = m_{45} = -I_{12}, \; m_{46} = m_{64} = -I_{13},$$
$$m_{56} = m_{65} = -I_{23},$$
$$I_{jk} = \int_V \bar{x}_j \bar{x}_k \rho_B \, dV, \; I_1 = I_{22} + I_{33}, \; I_2 = I_{11} + I_{33},$$
$$I_3 = I_{11} + I_{22}, \tag{35.64}$$

where any unspecified mass or mass moment, m_{ij}, is zero, provided that F_{Tj} refers to a coordinate system which is fixed in the mean position, S_m, of the body, and whose origin coincides with the center of gravity of the body. Here, ρ_B is the mass density of the body and I_{ij} are called the moment of inertia coefficients when $i = j$, and products of inertia when $i \neq j$ [35.23].

We can now set (35.62) equal to (35.63) and arrange the equation by moving some terms around to obtain

$$(m_{ij} + \mu_{ij})\ddot{x}_j + \lambda_{ij}\dot{x}_j + (k_{ij}^{(S)} + k_{ij}^{(M)})x_j = AE_i e^{-i\omega t}. \tag{35.65}$$

Considering (35.50), we can write the equations of motion given by (35.65) as

$$\frac{x_j^0}{A} = \left[-\omega^2(m_{ij} + \mu_{ij}) - i\omega\lambda_{ij} + \left(k_{ij}^{(S)} + k_{ij}^{(M)}\right) \right]^{-1} E_i. \tag{35.66}$$

Recalling that x_j^0 is complex, we can write it as

$$x_j^0 = x_j^{0R} + \mathrm{i}x_j^{0I} = |x_j|\mathrm{e}^{-\mathrm{i}\delta} ,$$

where δ is the phase angle of the motion relative to the incoming-wave crest. As a result, (35.66) becomes two sets of simultaneous 6×6 linear equations to be solved for the motion response, $|x_j^0|/A$. These motion responses are commonly called transfer functions. The square of a transfer function is sometimes known as the response amplitude operator (RAO). However, it is not uncommon that a transfer function, itself, is called an RAO, rather than its square. RAOs are used in irregular sea analysis to determine the random or stochastic response of a floating body in random waves. It is also noted that the term *transfer function* is also used for wave forces or moments per unit wave amplitude A.

Solution Methods

The boundary-value problems above can be solved to obtain the diffraction and radiation potentials so that the hydrodynamic coefficients and wave loads can be calculated. These potentials can be evaluated using the 3-D source-distribution method [35.24–26]. The pulsating source potential, which is a complex function, in infinite water depth can be found in [35.27, Art. 13]. This Green function can be written in an alternate form [35.28]. A different series expansion of the Green function is also given in [35.27]. Although this series expansion is more accurate and more computationally efficient to evaluate, compared with the integral form given in [35.27], it is limited to cases where kr is not very small. On the other hand, the evaluation of the Green function given by [35.28] is much more efficient, and no difficulty with regard to the size of kr is expected.

The solution of the integral equation for the unknown strengths of the distributed sources requires the discretization of the body surface by panel elements. Once the unknown strengths of the sources are determined on the body boundary (discretized by constant panels) by enforcing the body boundary condition, the diffraction and radiation potentials can be determined. These calculations can be performed by a number of commercially available computer programs.

A Green function is also called a source function, and it is one of the bases for finding solutions to diffraction and radiation problems in coastal and offshore engineering. A numerical method, called the boundary-element method (BEM), uses this approach. However, the BEM uses the simple Rankine source rather than the complicated Green function, and, as a result, all boundaries of the flow field need to be discretized. The Green function (GFM), requires the discretization of the boundaries on which there are distributed singularities with unknown strengths. For example, in the case of the linear problem of a floating body, only the body boundary need to be discretized. The BEM or the GFM is in contrast with the finite-element method (FEM) which requires that the entire fluid domain and its boundaries be discretized to solve for the velocity potential, and, therefore, the velocities. For more information on the BEM, the readers are referred to [35.29].

One of the alternative methods for solving hydrodynamic problems is the FEM. The disadvantage of this method compared to the GFM, provided that a particular Green function exists and is available, is that ϕ has to be calculated everywhere inside the domain. On the other hand, i) the FEM results in a banded matrix which can be solved efficiently, ii) the function calculated in the FEM is simpler, and iii) the FEM requires less knowledge of mathematics and fluid mechanics than the GFM does. Another numerical method that can be used is the finite-difference method, although it is used infrequently in fluid–structure interaction problems involving floating bodies.

Time-Domain Methods

Sometimes, the frequency-domain method discussed before is inadequate to incorporate certain nonlinearities and/or interactions in the system, and, as a result, one needs to resort to a time-domain method of calculating the loads and/or motions of an offshore structure. Typical examples could include problems involving the current and wave interaction, and low-frequency motions of platforms. These time-domain methods are based, in most cases, on the hydrodynamic coefficients and loads that have been previously calculated through a frequency-domain method and utilize the fact that the frequency and time contents of a system are related through the Fourier transforms. It is noted that some of the loads and/or the equations of motion could be nonlinear in these calculations.

Memory effects are included through the velocity-based convolution integrals. The memory effects considered are largely based on the early works of [35.30, 31] and [35.22] in the application of linear potential theory in the time domain, and on the work of [35.32]. Viscous effects may be included through the nonlinear drag term of Morison's equation. An earlier review of linear and nonlinear methods of time-domain calculations of motions can be found in [35.33]. This is an important reference as it is not always possible to use a time-domain method based on the linear hydrodynamic coefficients or exciting forces obtained through a frequency-domain method, by a Green function panel method, as some physical events are nonlinear and even transient.

There are many applications of the mentioned time-domain methods applied to various ocean engineering

problems, including to wave-energy conversion (WEC) problems [35.34]. There also are software packages, for example, ANSYS AQWA, that use some of these methods.

Drift Loads

The first-order wave loads discussed so far are time harmonic and, therefore, do not produce a steady component. This is mainly because the second-order component of the pressure on the body was assumed to be zero in the linear problem, see (35.3). Clearly, if this term was included, the time-mean force would have been of second order even though the first-order (linear) potential was used. Moreover, if a body is surface-piercing, there would be an additional term related to the runup on the body. In regular waves, this mean force is called the drift force in brief. In irregular waves, there is the mean drift force, but in addition there is also the slowly varying drift force. All these forces, although smaller in magnitude compared with the first-order forces, may become very important especially for bodies that are moored, as they may amplify motions due to a possible resonance in the system.

Maruo [35.35] showed that the mean drift force can be shown to be proportional to the square of the reflected wave amplitude, and since the reflected wave can be thought of as the reflection coefficient times the incoming wave amplitude, the mean drift force can be seen to be proportional to the square of the incoming wave amplitude. Reference [35.36] used the far-field radiation potentials (momentum) approach to obtain the drift forces on a floating body, and these were used later by [35.25] to calculate the drift force and moment on a floating body. The momentum approach results in expressions that involve the Kochin function. *Pinkster* [35.37], on the other hand, used the near-field potentials to calculate the mean drift forces and moments in all six degrees of freedom, and this approach was used later by [35.38] in conjunction with the panel method based on the Green-function method for a 3-D floating structure. These studies are for single bodies; multi-body calculations of drift forces became important later due to plans to build very large floating stuctures (VLFS) [35.39, 40].

The slowly varying component of the drift force on rigid bodies in irregular waves appears to have been first studied experimentally by [35.41] and later theoretically by [35.42].

35.1.6 Slender-Member Bodies

A slender member of a body is defined as a structural member whose characteristic dimension, for example, diameter, is *small* compared to the wavelength. With this in mind, we discuss Morison's equation which is sometimes used in offshore engineering during the preliminary design stage.

Morison's Equation

Wave forces on cylindrical structural members, such as the pontoons or columns of a platform or a pile that extends to the sea floor, when both the inertia and viscous forces are important, are discussed here. Due to the nonlinear nature of the Navier–Stokes equations and the boundary conditions, many have attempted to simplify the computation of wave forces on cylindrical piles. Most of the studies have been based on the experimental determination of the inertia and drag coefficients that appear in Morison's equation [35.43]. Morison's equation was developed as an ad hoc approach to a limited set of experimental data. However, because of the importance of cylindrical piles both in offshore engineering (jack-up platforms) and coastal engineering (pier piles, bridge columns, etc.), there have been many investigations on the proper coefficients to be used in almost every different case that one can imagine. A few of the different cases include inclined cylinders, group of cylinders, roughened cylinders, and horizontal cylinders [35.5].

The original form of Morison's equation is given by

$$\delta F = (1 + C_a)\rho\pi \left(\frac{D}{2}\right)^2 \dot{u}_1 + \frac{1}{2}\rho D C_d u_1 |u_1| \,, \tag{35.67}$$

where δF is the sectional (in the x_2 (vertical) direction) horizontal force, D is the diameter of the vertical pile, u_1 is the wave horizontal velocity, $\dot{u}_1$ is the wave horizontal acceleration, C_a is called the added-mass or virtual-mass coefficient, and C_d is the form-drag coefficient. C_a and C_d are dimensionless. $C_m = (1 + C_a)$ is called the inertia coefficient. Note that u_1 is the particle velocity only due to the incoming wave, there is no diffraction effects accounted for, unlike in the theory of *MacCamy* and *Fuchs* [35.44] based on the linear potential theory. The justification for this is that the diffraction effects are small because the cylinder is *slender*; therefore, u_1 and $\dot{u}_1$ are evaluated along the cylinder axis, since the errors made would be *small*.

Consider an oscillatory flow, in an *unbounded fluid* (no free surface or sea floor), with a period $T = 2\pi/\omega$, and velocity $u_1(t) = U\cos(\omega t)$, where U is the amplitude of velocity. The functional dependence of the force (per unit length) acting on the body, whose characteristic length is D, can be written as

$$\delta F = f(U, D, \rho, \nu, T) \,. \tag{35.68}$$

By applying dimensional analysis to (35.68), in which the set (ρ, U, D) is chosen as dimensionally independent, one can obtain

$$\frac{\delta F}{\frac{1}{2}\rho D U^2} = C_\mathrm{d}\left(\frac{UD}{\nu}, \frac{UT}{D}\right) , \tag{35.69}$$

or for the total force,

$$\frac{F}{\frac{1}{2}\rho D^2 U^2} = C_\mathrm{d}(\mathrm{Re}, \mathrm{KC}) , \tag{35.70}$$

where $\mathrm{Re} = UD/\nu$ is the usual diameter-based Reynolds number, and $\mathrm{KC} = UT/D$ is called the Keulegan–Carpenter(KC) number [35.45]. For large values of the KC number, $\mathrm{KC} \gg 1$, we expect the force coefficient, C_d, in (35.70) to approach the value of the steady (form-)drag coefficient, since large KC numbers correspond to long periods. In other words

$$C_\mathrm{d}(\mathrm{Re}, \mathrm{KC}) \to C_\mathrm{d}(\mathrm{Re}) \quad \text{if} \quad \mathrm{KC} \gg 1 . \tag{35.71}$$

On the other hand, when $\mathrm{KC} \ll 1$, the inertia effects will dominate viscous effects since the end of the time duration necessary to develop the boundary layer and flow separation could not have been reached. Therefore, we have basically an inviscid fluid since $\mathrm{Re} \to \infty$, or

$$C_\mathrm{d}(\mathrm{Re}, \mathrm{KC}) \to C_\mathrm{d}(\mathrm{KC}), \quad \mathrm{Re} \gg 1, \quad \mathrm{KC} \ll 1 . \tag{35.72}$$

If we now consider the presence of a *periodic free surface*, we can then anticipate that the force depends on

$$F = f(h, H, \lambda, D, \rho, \mathrm{g}, \nu) , \tag{35.73}$$

where h is the water depth, λ is the wavelength, and H is the wave height. In fact, it should not be difficult to obtain

$$\frac{F}{\rho \mathrm{g} H D^2} = f\left(\frac{h}{\lambda}, \frac{H}{\lambda}, \frac{D}{\lambda}, \mathrm{Re}\right) \tag{35.74}$$

by using dimensional analysis. If the problem is linear and the fluid is inviscid, we can write (35.74) as

$$\frac{F}{\rho \mathrm{g} H D^2} = f_1\left(\frac{D}{\lambda}, \frac{D}{h}\right) . \tag{35.75}$$

Therefore, if the fluid is inviscid, the force coefficient given in (35.74) does depend only on the ratio D/λ for a fixed-body geometry and water depth, that is, D/h is constant. So that $F = F(\omega)$ only, where ω is the angular wave frequency related to the wavelength through the linear dispersion relation. If we had explicitly included the frequency (or period) in the equations above, the KC number would also appear.

To see the effect of body dimension, wave height, and wavelength on the forces on a vertical, circular cylinder, consider Fig. 35.6. We see that as D/λ becomes small, the viscous effects (i. e., separation) become important. For a circular cylinder, and if $D/\lambda > 0.15$, the diffraction effects are more important. The KC number given in Fig. 35.6 is

$$K \equiv \mathrm{KC} = \frac{\pi H/\lambda}{\frac{D}{\lambda}\tanh(kh)} , \tag{35.76}$$

and it is evaluated at the still-water level and is for finite water depth. In infinite water, (35.76) becomes $\mathrm{KC} = \pi H/D$, since $\tanh kh \to 1.0$. Also, one can deduce from Fig. 35.6 that if $H/D > 1$, the viscous effects become important for a fixed ratio of D/λ. Therefore, in engineering calculations, it is recommended that, for a vertical circular cylinder that extends to the sea floor:

- If $\frac{H}{D} < 1.0$ and $\frac{D}{\lambda} \geq 0.15$, diffraction theory be used
- If $\frac{H}{D} \geq 1.0$ and $\frac{D}{\lambda} < 0.15$, Morison's equation be used.

It is noted that these should be cautiously used for other body geometries. In Fig. 35.6, $(H/\lambda)_{\max}$ is the maximum wave steepness (before wave breaking occurs) given by (for finite but large meaning not shallow-water depth, h)

$$\frac{H}{\lambda} = 0.14\tanh(kh) . \tag{35.77}$$

In deep water, this clearly becomes $H/\lambda = 0.14$.

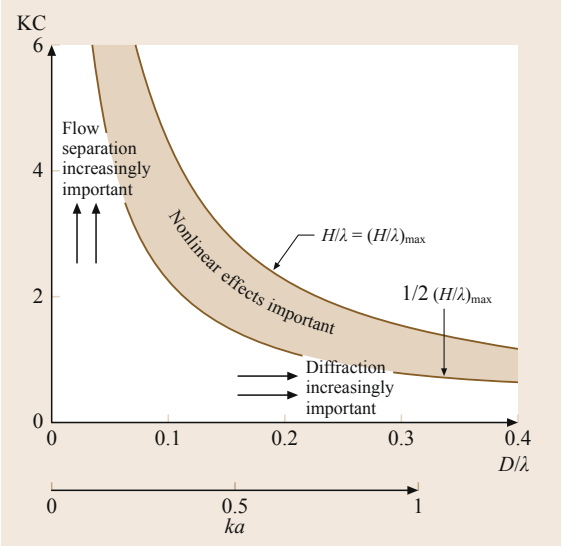

Fig. 35.6 Different wave force regimes (after [35.46])

Morison's equation is obtained by summing the inertia and drag terms. There can be no rational basis for this summation, especially since the coefficients C_a and C_d are intended to be constants and it can be shown easily that the $(1 + C_a)$ term is nothing but the sum of the Froude–Krylov force and the virtual mass force, that both can be obtained through the inviscid fluid and irrotational flow assumptions. In reality, the inertia and drag coefficients are also functions of the wave frequency. However, this formula is widely used in offshore and coastal engineering to determine wave and current forces on slender cylinders, such as drilling risers or jetty piles, and rather successfully.

Clearly, the drag term is nonlinear. This causes a slight problem in using Morison's equation, especially when the body is freely floating since the location where u_1 is calculated is unknown, and one must use the total *relative velocity* rather than u_1 alone if the body is freely floating. To overcome this problem, and also, to be consistent with the assumption of linearity, the drag term is linearized by defining a linear drag coefficient. There is one more reason for linearizing the drag force, and it is related to the use of spectral analysis in irregular waves which require that the system be linear.

To turn to the question of the linear drag coefficient, we write the horizontal component of the particle velocity as

$$u_1 = u_0 \cos(\omega t) \quad \text{at } x_1 = 0\,, \tag{35.78}$$

where u_0 is the amplitude of the velocity. The drag force in the direction of wave motion becomes

$$\delta F_d = \frac{1}{2}\rho D C_d u_0^2 \cos(\omega t)|\cos(\omega t)|\,. \tag{35.79}$$

The linear drag force can now be defined by equating the net work done (on a differential cylinder element) by the drag force δF_d, given by (35.79), and the linearized drag force, given by

$$\delta F_{dL} = \frac{1}{2}\rho D C_{dL} u_0 \cos(\omega t)\,. \tag{35.80}$$

This means that the viscous energy dissipated (per wave cycle) is the same whether we use (35.79) or (35.80). Therefore, by requiring equal energy dissipation per wave cycle, we must have $E_d = E_{dL}$

$$E_d = \int_0^\lambda \frac{1}{2}\rho C_d D u_0^2 \cos(\omega t)|\cos(\omega t)|\,\mathrm{d}x_1$$

$$= E_{dL} = \int_0^\lambda \frac{1}{2}\rho C_{dL} D u_0 \cos(\omega t)\,\mathrm{d}x_1\,. \tag{35.81}$$

Recalling also that $u_1 = \mathrm{d}x_1/\mathrm{d}t$ or $\mathrm{d}x_1 = u_0\cos(\omega t)\mathrm{d}t$, and $|\cos(\omega t)|\cos(\omega t) = \cos^2(\omega t)$ if $0 \le t \le T/4$, and that the total energy is equal to four times the energy per quarter of a wavelength for constants C_d and C_{dL}, we obtain, from (35.81)

$$C_{dL} = C_d \frac{\int_0^{T/4} u_0^3 \cos^3(\omega t)\mathrm{d}t}{\int_0^{T/4} u_0^2 \cos^2(\omega t)\mathrm{d}t} = \frac{8}{3\pi} C_d\, u_0\,. \tag{35.82}$$

Note that C_{dL} has the dimension of velocity, unlike C_d (which is dimensionless).

The amplitude of the horizontal velocity, u_0, is given, in linear potential theory, by

$$u_0 = \frac{gAk}{\omega}\frac{\cosh[k(x_2 + h)]}{\cosh(kh)}\,. \tag{35.83}$$

Substituting (35.82) into (35.80), we obtain

$$\delta F_{dL} = \frac{4}{3\pi}\rho D C_d u_0^2 \cos(\omega t)\,. \tag{35.84}$$

We need to note that there are other methods of linearization of the drag term, different from the method discussed here. Also, see [35.47–49] on the linearization of the drag force when a current is present, and when the waves are random.

There may also be current in the vicinity of the cylinder. Let us denote the steady shear-current velocity by $u_c = u_c(x_2)$. Also, it is possible that the cylinder is moving. In the case of a cylinder that extends to the sea floor, the only possible mode of motion is in the horizontal plane, $x_1 - x_3$, and this is called surging. However, Morison's equation is used not only to determine the forces on fixed platforms, such as

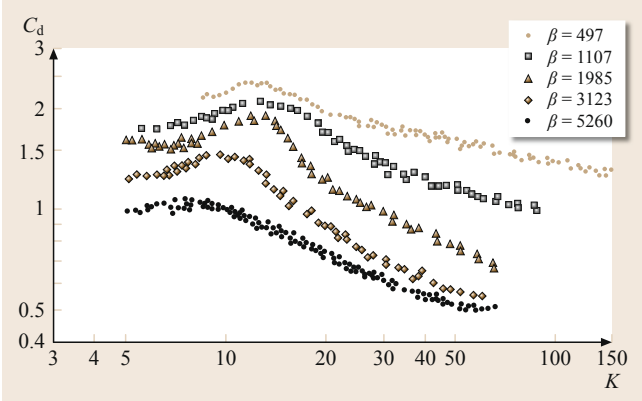

Fig. 35.7 Drag coefficient for a smooth circular cylinder as a function of the Reynolds and Keulegan–Carpenter numbers (after [35.51])

jack-up rigs, but also on floating platforms, such as semi-submersibles, which may have tubular structural members, such as columns, pontoons, or braces. These members may also be inclined, rather than just be vertical or horizontal. Therefore, in general, one can have three translational and three rotational (or angular) velocity components for the structure motion. In such cases, the velocity calculated in (35.67) must be the relative velocity

$$u_r = u_p + u_c - u_b \,, \tag{35.85}$$

where u_r is the relative velocity, u_p is the particle velocity, u_c is the current velocity, and u_b is the body velocity.

Drag and Inertia Coefficients

There have been many experimental studies on the drag and inertia coefficients used in Morison's equation. The most comprehensive references on the subject are the two monographs, [35.5] and [35.50]; they cite almost all previous experimental works on the inertia and drag coefficients. For example, [35.51] gives Figs. 35.7 and 35.8 for the drag and inertia coefficients, respectively, for smooth cylinders that were tested in a U-tube water tunnel as functions of the KC number and $\beta = \mathrm{Re}/\mathrm{KC}$, where KC is the Keulegan–Carpenter number and Re is the Reynolds number (Sect. 35.1.6).

A number of organizations also publish their recommended coefficients, For example, [35.52] recommends the following drag and inertia coefficients ($C_A = C_m - 1$) shown in Figs. 35.9 and 35.10

Some other organizations that recommend the use of certain coefficients are American Petroleum Institute, American Bureau of Shipping and Society of Naval Architects and Marine Engineers, and many other classified organizations whose publications are frequently referenced by regulatory agencies.

Viscous Drift Loads

Viscous drift forces originate mainly due to the existence of the drag force over the instantaneous submerged length of the members of platforms, due to the presence of current, and due to wave–current interaction effects. Traditionally, these forces have been computed using the drag force term of Morison's equation [35.43] to determine the mean forces and moments. Most of the studies on viscous drift forces prior to 1995 concentrated on analytical and/or experimental results for a single circular cylinder. For example, *Chakrabarti* [35.53] presented analytical expressions for viscous and potential drift forces on a vertical cylinder and compared the predictions with experimental data. The relative importance of the viscous and potential drift contributions has also been discussed.

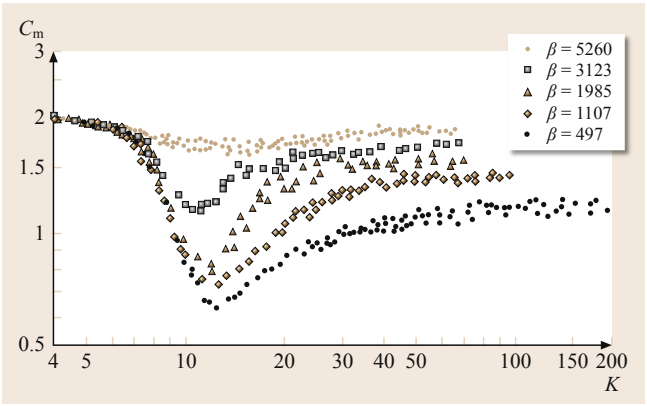

Fig. 35.8 Inertia coefficient for a smooth circular cylinder as a function of the Reynolds and Keulegan–Carpenter numbers (after [35.51])

Burns [35.54] used the relative velocity model of Morison's equation where the platform motion in surge is considered in determining the total relative velocity between the body and fluid. A method to obtain nonlinear viscous drift force transfer functions that can be used to determine the mean and slowly varying surge drift forces in irregular seas has also been presented. Other studies of viscous drift forces on the tension leg platform (TLP) [35.55] were also limited to the analysis of surge drift forces and motions. *Ertekin* and *Chitrapu* [35.56] computed the wave- and current-induced viscous drift forces and moments in all six degrees of freedom of a TLP. In that study, as well as in [35.57], first-order motions of the platform in all six degrees of freedom, given by the

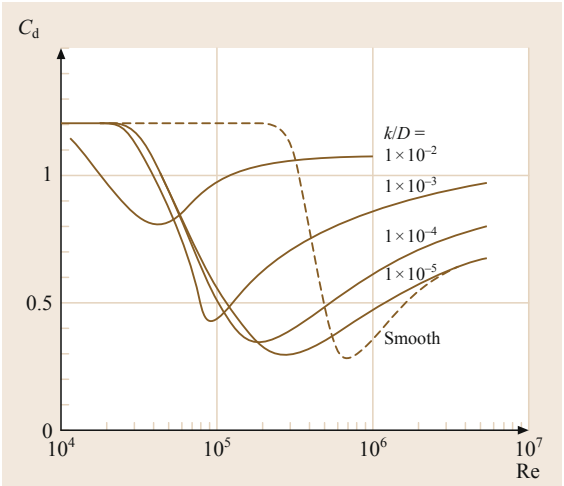

Fig. 35.9 Drag coefficient for a circular cylinder as a function of the roughness coefficient and Reynolds number (after [35.52])

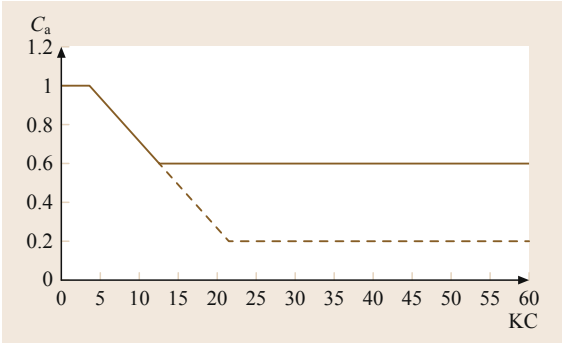

Fig. 35.10 Inertia coefficient for a circular cylinder as a function of the Keulegan–Carpenter number; *solid line* smooth cylinder and *dotted line* rough cylinder (after [35.52])

frequency-domain motion transfer functions are used to calculate the body velocity, and the resulting relative velocity is used to compute the drift forces and moments.

The evaluation of viscous drift forces in irregular waves is complicated due to the fact that the drift force is a nonlinear function of the wave height. From the results obtained in regular wave analysis, it appears that the viscous drift force, in the presence of current, is proportional to the third power of the wave amplitude as compared to the potential drift force which is proportional to the wave amplitude squared. Suitable methods have been developed to obtain potential drift forces in irregular waves using the regular wave results in conjunction with spectral analysis methods. The alternative is to use a time-domain method in which all nonlinearities can be included. However, frequency-domain methods for the computation of viscous drift forces in irregular waves are preferred in the preliminary design stage since they are computationally more efficient, although time-domain analysis is indispensable for the final design purpose [35.17, 57]. For this reason, several investigations are being carried out to develop frequency-domain methods for computing viscous drift forces in irregular waves [35.58, 59].

35.2 Current Loads

For the purpose of offshore engineering, it is the horizontal current that is of interest. Currents are important for vessel anchoring, installation work, riser interference, and vortex-induced vibration (VIV). Surface and mid-depth currents cause in-line and transverse forces on fixed and floating structures. Sea-floor currents may cause scour around structures and pipelines. This scour may compromise structural foundations or create unsupported spans in pipelines. The bottom current may also induce VIV in the unsupported spans of pipelines.

There are many components of the current in the ocean. Some of these currents extend to depths of several thousand meters and are poorly understood. Current types include:

1. Tidal currents
2. Wind driven
3. Ocean circulation
4. Boundary currents including loop and eddy currents
5. Internal waves and solitons.

The superposition of these current components generates the total current which can be represented by a current profile which gives speed and direction as a function of depth.

Currents are generally considered time invariant for purposes of offshore structure design, though in most cases, they comprise turbulent flow and vary in speed and direction with time. Currents are usually characterized by averages of the horizontal current vector over several minutes. Figure 35.11 illustrates how currents may vary in direction and magnitude at different depths and with time.

A description of currents should include the general circulation pattern in the area, tidal currents, and wind-driven currents. In most parts of the world, there is scarce current data because of the expense and the need for long-term observations required to capture a reasonable number of severe events. Yet design, planning for installation, and operation require information regarding the frequency of occurrence and seasonal variations of the current speed and direction. Whenever possible, site-specific measurements should be obtained throughout the water column and over sufficient time to capture several major events. When current models are used in lieu of site-specific measurements, the model should be validated against nearby measured data.

For design purposes, sufficient current information should be gathered to permit an estimate of the 100 year (1% annual probability of exceedance) event.

35.2.1 Nonuniform Currents

Current is rarely uniform with depth. Current profiles are frequently modeled as piecewise linear functions with the profile described in a table of depth, speed, and direction. Simple profiles, such as a uniform cur-

rent near the surface and zero elsewhere in the water column, are often used for design. Frequently, directional variation with depth is ignored or simplified for the purpose of design calculations. These simplifications are used when the simplification is conservative and yet does not appear to increase cost unreasonably.

The currents in a region will be a function of the local topography and oceanography, including density distribution and the flow into or out of the area (Fig. 35.12). Shallow-water currents are frequently driven by tides, and simple profiles of speed versus depth provide an adequate description. Deepwater currents as illustrated in Fig. 35.11 can vary greatly in the speed and direction with depth and may require a more complex description.

Shallow-water and near-bottom currents will often exhibit a power-law profile, such as given by (35.86).

$$U_c(z) = U_{c0}\left(\frac{z+h}{h}\right)^{\alpha}, \tag{35.86}$$

where $U_c(z)$ is the current speed at elevation z, where $z = 0$ at the surface; U_{c0} is the surface current speed; h is the water depth; α is an exponent (typically $1/7$).

A method for developing design current profiles from long-term measured current profile data sets is described in [35.62]. The data are parameterized using empirical orthogonal functions, and then the design current profile with the required return period is selected through a process involving an inverse first-order reliability method (FORM).

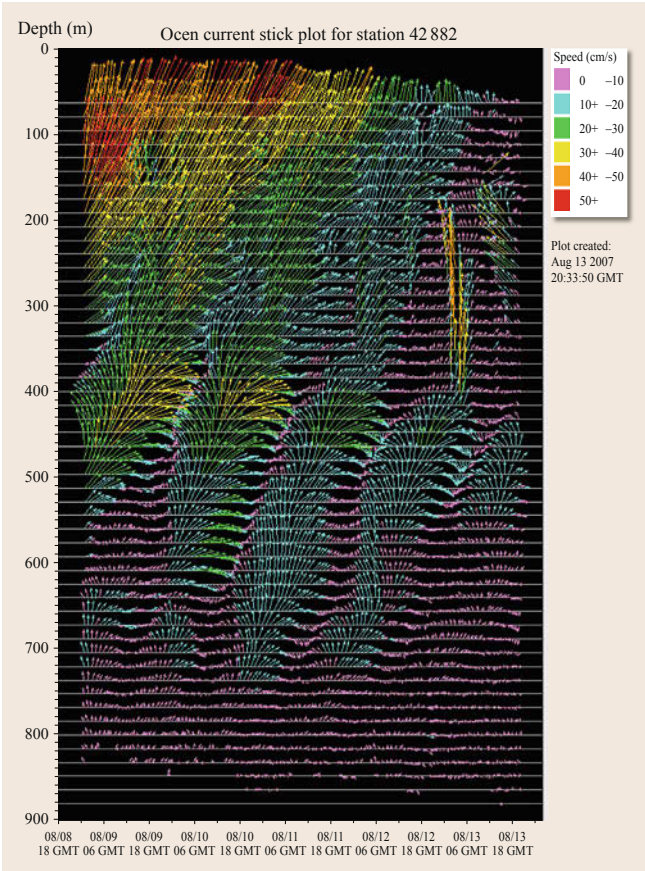

Fig. 35.11 National Data Buoy Center (NDBC) stick plot of currents acquired by oil and gas companies in the northern Gulf of Mexico (after [35.60])

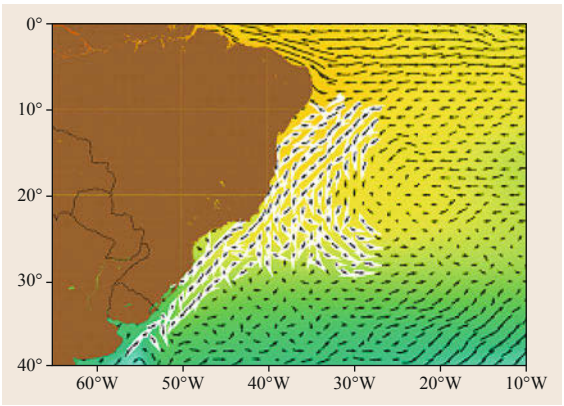

Fig. 35.12 The Brazil current as represented by the Mariano Global Surface Velocity Analysis (MGSVA) (after [35.61])

35.2.2 Wave–Current Interaction

When waves propagate on a current, the encounter frequency of the wave encountering a fixed body is different from the intrinsic frequency of the waves. It is the intrinsic frequency that determines the wavelength and the wave kinematics. Much wave data are collected from fixed platforms that measure the encounter frequency. This fixed platform data must be corrected to the intrinsic frequency since wave spectra for criteria are usually represented in terms of the intrinsic frequency.

For an effective current speed U, moving in the same direction as the waves, the encounter wave frequency is higher than the wave frequency alone. The encounter frequency is $\omega_A = 2\pi/T_A$, where T_A is the encounter period seen by a fixed observer. The two frequencies are related by the Doppler shift as

$$\omega = \omega_A - kU\,, \tag{35.87}$$

where k is the wave number and ω is the intrinsic frequency. The last term in (35.87) is called the convective frequency. The Doppler effect is computed based on the component of the ambient current in the direction of

waves U. If the current profile is not uniform, *Kirby* and *Chen* [35.63] showed that the encounter wave period is computed from (35.87) and the following equations

$$\omega^2 = gk \tanh(kh) \,. \tag{35.88}$$

$$U = \frac{2k}{\sinh 2kh} \int_{-h}^{0} U_c(z) \cosh[2k\,(z+h)]\,\mathrm{d}z \,, \tag{35.89}$$

where h is the water depth and $U_c(z)$ is the current profile.

The frequency parameter in wave spectra formulations (Sect. 35.1.4) is the intrinsic frequency. A fixed or floating stationary structure in a wave field with current responds to the encounter frequency rather than to the intrinsic frequency. For wave-response calculations, the wave-frequency spectrum should be transformed into the encounter frequency. The wave energy per frequency band is independent of the reference frame so that $S(\omega)\,\mathrm{d}\omega = S(\omega_A)\,\mathrm{d}\omega_A$. Equation (35.87) is used to make the frequency transformation, where the wave number k is a function of the intrinsic wave frequency ω through (35.88).

35.2.3 Wave Current Kinematics

The kinematics of waves propagating through a uniform current can be modeled simply by adding the current vector to the wave velocity vector. When the current profile varies significantly through the wave zone, this simple model does not apply. Several approximations have been put forward to model the combined regular wave and current velocity. These approximations are extensions of the same approximations used to estimate wave kinematics near the free surface when no current is present.

A current profile is defined from the mean water line to the bottom. Waves change the location of the free surface and transform the current profile as they pass [35.64, 65].

A linear transformation of the current profile incorporates a stretching factor F_s

$$F_s = \frac{\eta + h}{h} \,, \tag{35.90}$$

where η is the water-surface elevation measured upward from the still-water level and h is the still-water depth.

The transformed current beneath the instantaneous water surface is $U_c\left(\frac{h+z_s}{F_s} - h\right)$, where z_s is the elevation measured upward from the still-water level and $U_c(z)$ is the current profile absent waves. A linearly stretched current profile is exactly analogous to the stretching of linear wave kinematics as applied by [35.66].

The nonlinear transformed current at an elevation z_s is $U_c(z)$, where z is determined by solving

$$z_s = z + \eta \frac{\sinh(k_{nl}(z+h))}{\sinh(k_{nl}h)} \,, \tag{35.91}$$

where k_{nl} is the wave number for the regular wave under consideration for water depth h, crest elevation η, and the intrinsic wave frequency ω. k_{nl} is calculated using the dispersion relationship of the nonlinear wave theory being used.

A simple modification of the nonlinear regular wave method described above can be used for random waves. In this case, the wave period and length correspond to the period and length of the spectral peak frequency.

Once the current profile is transformed to correspond to the instantaneous wave, the total horizontal water velocity at an elevation is the sum of the current vector and the wave velocity vector at that elevation.

35.2.4 Current-Induced Forces

Forces induced by currents on offshore structures are usually modeled as constant. These forces are nonlinear and, thus, the interaction with waves and with structure motions must be considered. The members of a structure in a steady flow experience a drag force proportional to the square of the flow velocity

$$f = \frac{1}{2}\rho U^2 A C_d \,, \tag{35.92}$$

where ρ is the mass density of the fluid, U is the flow velocity, A is the area of the member, and C_d is the drag coefficient. The drag coefficient is a function of the Reynolds number (Re) and the relative roughness of the surface (e) (Sect. 35.1.6).

This same drag force is a component of the force on a member in the oscillating flow, in waves calculated using the Morison equation (Sect. 35.1.3). In oscillating flows the drag coefficient is also a function of the Keulegan–Carpenter(KC) number already discussed in Sect. 35.1.3. Note also that the combination of the steady-current velocity and the oscillating wave-induced velocity causes an increase in the average drag force on a body due to the quadratic nonlinearity of the drag term in the Morison equation.

A current also induces a nonlinear time-varying force transverse to the direction of the current known as the lift force

$$f_L = \frac{1}{2}\rho U^2 A C_L \,, \tag{35.93}$$

where C_L is the lift coefficient. The lift force even in a steady flow is time varying. Thus, the lift coefficient reflects the RMS lift force or the maximum lift force over a period encompassing a number of oscillations of the lift force. These transverse forces are also referred to as vortex-induced forces and can cause large deflections of slender members free to vibrate known as VIV or large deflections of flexible structures known as vortex-induced motion (VIM) when the shedding period of vortices in the wake of the structure is close to natural periods of structure vibration. The shedding of vortices in the wake of a body also induces unsteady forces in line with the current direction. These unsteady inline forces are generally smaller than the transverse forces and much smaller than the average inline current force. The unsteady inline forces usually occur at twice the frequency of the transverse forces but can induce significant motions when they occur at a frequency close to the natural frequency of vibration of the structure.

Structures which appear transparent to currents can induce significant current blockage. The structure causes some of the current to go around the structure rather than through it. Current flows through these structures at a reduced velocity. Accounting for the reduced currents may be of interest for the design structures, especially when they accommodate a large number of conductors or risers. Current speed reduction factors ranging between 7 and 9 for jacket-type structures are provided in [35.67]. These factors are applied to the undisturbed current profile to obtain the current to use in force calculations.

The wake of an object located within a few diameters upstream of another object will influence the forces on the downstream object. Shielding will reduce the drag force on the downstream object and shear in the wake will induce lift forces on the downstream object. The drag and lift forces will depend on the spacing of the objects. The average current speed U_w in the turbulent wake of a cylinder at a point x downstream and y transverse to the current per [35.68] is

$$U_w = U - k_2 U \sqrt{\frac{C_d D}{x_s}} e^{-0.693\left(\frac{y}{b}\right)^2}, \tag{35.94}$$

$$x_s = x + \frac{4D}{C_d}, \tag{35.95}$$

$$b = k_1 \sqrt{C_d D x_s}, \tag{35.96}$$

where the empirical coefficient $k_1 = 0.25$ and coefficient $k_2 = 1.0$, and D is the upstream cylinder diameter and C_d is the upstream cylinder drag coefficient. This current in the wake is used to calculate the drag force on the downstream object.

The shielding may be beneficial in that it reduces forces on the downstream object, or it may be detrimental if the reduced forces lead to reduced distance between the objects which leads to clashing. This clashing is of particular concern for closely spaced risers in deep water.

For configurations comprising multiple closely spaced cylinders, experimental data possibly supported by computational fluid dynamics (CFD) should be used. Otherwise, interference effects should be ignored where beneficial and experiments should be considered where clashing is a concern.

Forces due to currents are calculated using the Morison equation (Sect. 35.1.6). The superposition of current and wave velocities should be considered when the local amplitude of the wave-induced water motion is larger than the radius of the member under consideration. The current vector and wave particle velocity vector should be added before the force is computed. Due to the nonlinear nature of the drag force in the Morison equation, currents can affect dynamic forces and should thus be modeled when dynamics is important.

35.2.5 Vortex-Induced Vibrations

VIVs can be caused by the flow of any fluid past a structure. Vortices are shed in the wake of the structure causing force transverse to the direction of the flow which may cause motions transverse to the flow which in turn may reinforce the vortex shedding. This may lead to large oscillations particularly in long slender elements normal to their long axis.

Parameters that influence these VIVs include: slenderness (L/D), mass ratio ($m^* = m/\left(\frac{1}{4}\pi\rho D^2\right)$), damping ration ($\zeta$), Reynolds number ($\mathrm{Re} = UD/\nu$), reduced velocity ($V_R = U/f_n D$), and flow properties, such as oscillations, turbulence (σ_U/U), and profile, where L is the member length, D is the member diameter, m is the mass per unit length, ζ is the ratio between damping and critical damping, ρ is the fluid density, ν is the fluid kinematic viscosity, U is the mean fluid speed, f_n is the natural frequency of the member, and σ_U is the standard deviation of the flow speed.

For the steady flow, the vortex shedding frequency is

$$f_s = \mathrm{St}\frac{U}{D}, \tag{35.97}$$

where St is the Strouhal number. For a smooth fixed circular cylinder in the steady flow, the Strouhal number is a function of the Reynolds number as shown in Fig. 35.13.

Table 35.2 Efficiency of helical strakes and helical wires (after [35.52])

	Number of windings	Height of strakes	Pitch	Lift coefficient C_L	Drag coefficient C_d
Helical strakes	3	.11D	4.5D	0.238	1.6
	3	.11D	15D	0.124	1.7
Helical wires	3–4	.118D	5D	0.2	1.17
	3–4	.118D	10D	0.2	1.38
No spoilers				0.9	0.7

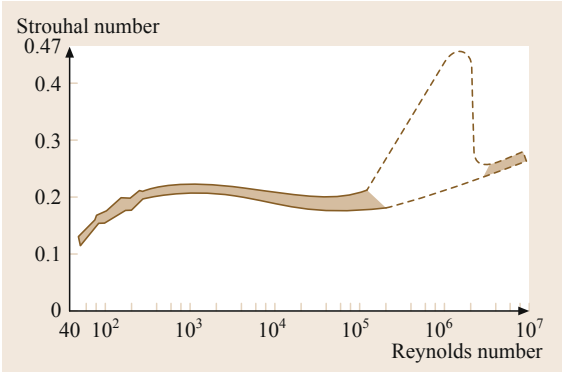

Fig. 35.13 Strouhal number for a circular cylinder as a function of the Reynolds number (after [35.69])

When the vortex shedding frequency coincides with natural frequencies of vibration, large-amplitude motions may arise. This phenomenon is called lock-in because the motions and vortex shedding will occur at the natural frequency of the body over a range of flow speed. The natural frequency of the body may be different from that observed in still water due to flow-induced variation in added mass. Lock-in can occur in line with the flow as well as transverse to the flow. Lock-in occurs when the reduced velocity V_R is close to the inverse of the Strouhal number.

The mass ratio m^* is an indication of the relative importance of the body mass and the fluid forces. A high mass ratio indicates that the fluid force is relatively small compared to the body inertia. For situations with a low mass ratio, such as a pipe in water, the lock-in range is $3 < V_R < 16$ and for a high mass ratio, such as wire in air, the lock-in range is $4 < V_R < 8$.

VIV on a slender member will cause fatigue damage, may increase the drag coefficient of the member causing additional load and possibly clashing, and may excite vibration and VIV of downstream objects.

The responses of structures to flow-induced vibrations can be estimated via model tests, response-based methods, force-based methods, or flow-based methods. Response-based methods [35.70, 71] estimate steady-state responses of systems as a function of structural and hydrodynamic parameters making use of conservative envelopes of experimental data. Force-based methods make use of a structural model excited by inertia and damping forces determined from empirical data. They attempt to model the flow explicitly and include CFD which solve the Navier–Stokes equations coupled with a structural model.

Vortex shedding may also induce motions in the hull of floating systems. These motions are important because these motions can influence mooring and riser design. Cross-flow oscillations are generally larger than inline oscillations and are, thus, of most interest. For large circular cylinders, like Spars, the amplitude of VIMs can be up to 80% of the diameter. This can be reduced to 40% or less with suppression devices. Model tests are generally used to estimate the motions of these structures with and without suppression devices.

The suppression of VIV is generally done with devices which spoil the wake and reduce the coherence of vortex shedding along the structure. This can be done with fins which weather a vane and help keep the wake symmetric and reduce the size of shed vortices. The wake can also be spoiled by making the member irregular along its length by wrapping it with helical strakes or wires (Table 35.2).

35.3 Wind Loads

Offshore platforms are exposed to wind fields which pose a serious overload threat to the overall platform structural system as well as to topside components, such as helidecks, drilling derricks, cranes, and living quarters. Fluctuating wind loads as well as VIVs can cause fatigue damage and lead to failures. Reliable design to resist these failure mechanisms requires a good understanding of the wind environment and as well as the mechanisms of wind loading.

The wind speed and direction vary in space and time. Sufficient data to describe the spatial and time variations in a great detail are rarely available and for most applications are unnecessary. Wind field descriptions are based on statistical parameters, such as the

mean and the standard deviation of the speed, as well as the mean direction. Both length scales and time scales influence the definition of these statistical parameters.

Both local and global wind effects on platforms must be considered. The local effects influence the design of the deck structure and equipment. Global effects, such as overturning moments and total lateral loads, drive the design of foundations and mooring systems. Both mean and fluctuating forces must be considered. Compliant structures such as TLPs have natural frequencies of motion in the horizontal plane which can be excited by wind forces and make them sensitive to the slowly varying fluctuations of the wind.

Extreme and normal wind conditions should be specified when designing offshore structures. The response of the structure to wind will influence which conditions are of interest. Three-dimensional spatial scales of wind are related to the durations of turbulent gusts. Thus, gusts of a few seconds duration will have less influence on a large structure than will gusts of a minute duration. The time variation of the wind, usually characterized by a spectrum, should be considered for structures with appreciable dynamic response.

A description of the wind environment for a location should include an estimate of extreme wind speeds in specified directions and specified averaging times as a function of the recurrence interval. Information about the measurement sites and a description of the measured data used to generate the environment description should be available. The frequency of exceedance of specified thresholds from specified directions during the service life should be estimated. The types of storms causing high winds should be described. Similar information should be provided for normal or short-term conditions providing descriptions by month or season. Figure 35.14 is an example of such a monthly description.

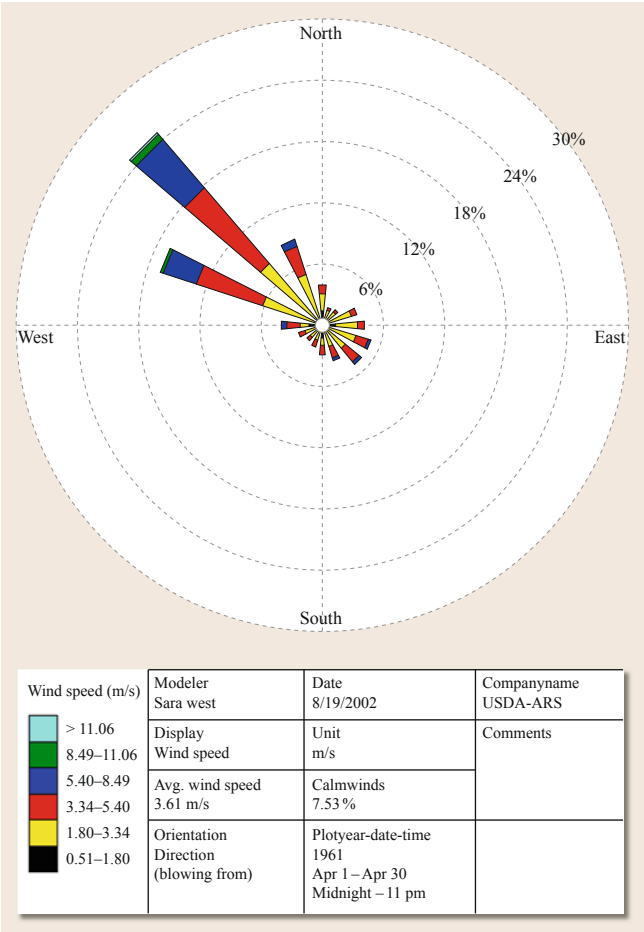

Fig. 35.14 Wind rose showing the statistical variation of wind direction and speed during the month. The length of each *line* indicates the percentage of time the wind blew from that direction during the month. The *colors* indicate different wind-speed bins (after [35.72])

35.3.1 Wind-Speed Profile

On length scales typical of even the largest offshore structures, the mean and standard deviation of the wind speed, averaged over durations of the order of an hour, do not vary horizontally, but they do change with elevation. For averaging durations shorter than an hour, there will be periods with higher mean speeds and the spatial variations will increase. To be meaningful, a wind-speed value must be qualified by an elevation and a duration over which it is averaged. An elevation of 10 m above the mean sea level is used as a standard reference height.

According to *Planning* [35.67], the mean wind-speed profile $U_w(z)$ under storm conditions can be more accurately described by a logarithmic profile as given in (35.98) than by the traditional power-law profile

$$U_{w,1h}(z) = U_{w0}\,[1 + C \ln (z/z_r)\,]\,, \qquad (35.98)$$

where $U_{w,1h}(z)$ is the 1 hour sustained wind speed at a height z above the mean sea level; U_{w0} is the 1 hour sustained wind speed at the reference elevation z_r and is the standard reference speed for sustained winds; C is a dimensionless coefficient, the value of which is dependent on the reference elevation and the wind speed, U_{w0}. For $z_r = 10\,\text{m}$, $C = 0.0573\sqrt{1 + 0.15U_{w0}}$, where U_{w0} is in units of meters per second (m/s); z is the height above the mean sea level; and z_r is the reference elevation above the mean sea level ($z_r = 10\,\text{m}$).

For the same conditions, the mean wind speed for averaging times shorter than 1 hour may be expressed

by (35.99) using the 1 hour sustained wind speed $U_{w,1h}(z)$ of (35.98)

$$U_{w,T}(z) = U_{w,1h}(z)\left[1 - 0.41 I_u(z) \ln\left(\frac{T}{T_0}\right)\right], \tag{35.99}$$

where $U_{w,T}(z)$ is the sustained wind speed at height z above mean sea level, averaged over a time interval $T < 3600\,\mathrm{s}$; $U_{w,1h}(z)$ is the 1 hour sustained wind speed at height z above mean sea level, see (35.98); T is the time-averaging interval with $T < T_0 = 3600\,\mathrm{s}$; T_0 is the standard reference time-averaging interval for the wind speed of $1\,\mathrm{h} = 3600\,\mathrm{s}$; $I_u(z)$ is the dimensionless wind turbulence intensity at a height z above the mean sea level, given by (35.100), where U_{w0} is in m/s

$$I_u(z) = 0.06\,(1 + 0.043 U_{w0})\left(\frac{z}{z_r}\right)^{-0.22}. \tag{35.100}$$

Note that the equations in this section are derived from curve fitting through available data [35.73] and contain numerical constants that are only valid in the SI units of meters and seconds. The above equations are not valid for the description of winds in short-lived events, such as squalls and tornados, since the duration is often less than 1 hour. Adjustments to the wind profile at a particular location or under certain conditions can be made when specific appropriate measured data from an offshore location are available (i. e., measured data for the kind of event used in design).

35.3.2 Wind Spectra and Gusts

The wind spectrum characterizes the time-varying properties of the wind. These variations are due to boundary-layer turbulence which depends on the wind speed and the thermal stability of the air. The following wind spectrum formulation is based on measurements under conditions of nearly neutral thermal stability as documented in [35.73].

Equation (35.101) describes the spectrum of wind speed at a point in space and is analogous to the spectra used to describe the time-varying kinematics of waves in Sect. 35.1.4.

$$S(f,z) = \frac{320\left(\frac{U_{w0}}{U_{ref}}\right)^2\left(\frac{z}{z_r}\right)^{.45}}{\left(1+\tilde{f}^n\right)^{5/(3n)}}, \tag{35.101}$$

where $S(f,z)$ is the wind spectrum (spectral or energy density function) at frequency f and elevation z in m^2/s; U_{w0} is the 1 h sustained wind speed at the reference elevation z_r (the standard reference speed for sustained winds); U_{ref} is the reference wind speed, $U_{ref} = 10\,\mathrm{m/s}$; f is the frequency in cycles per second (hertz) over the range $0.00167\,\mathrm{Hz} < f < 0.5\,\mathrm{Hz}$; z is the height above the mean sea level; z_r is the reference elevation above the mean sea level ($z_r = 10\,\mathrm{m}$); $\tilde{f}$ is a non dimensional frequency defined by (35.102) where the numerical factor 172 has the unit of second (s)

$$\tilde{f} = 172 f\left(\frac{z}{z_r}\right)^{2/3}\left(\frac{U_{w0}}{U_{ref}}\right)^{-.75}. \tag{35.102}$$

n is a coefficient equal to 0.468.

Integrating the spectrum over the applicable frequency range yields the standard deviation of the wind speed. When comparing the spectrum to data, comparable frequency ranges should be used.

The spatial and temporal wind fields are correlated. Thus, the wind spectrum should be complemented with a description of the spatial coherence. It is generally conservative to assume that the wind speed is fully correlated over a complete structure. But it is reasonable to take advantage of the reduced correlation when estimating loads on structures. Equation (35.103) describes the coherence between two points P_1 and P_2, with positions in the wind directions of x_1 and x_2, and position transverse to the wind directions of y_1 and y_2, and elevations above the mean water of z_1 and z_2

$$F_{Coh}(f, P_1, P_2) = \exp\left[-\frac{1}{U_{w0}}\left(\sum_{i=1}^{3} {A_i}^2\right)^{1/2}\right], \tag{35.103}$$

where $F_{Coh}(f, P_1, P_2)$ is the coherence function between turbulence fluctuations at P_1 and at P_2; U_{w0} is the 1 hour sustained wind speed at 10 m above the mean sea level in meters per second (m/s); A_i is a function of frequency and the position with units of m/s calculated from (35.104)

$$A_i = \alpha_i f^{r_i} D_i^{q_i}\left(\frac{z_g}{z_r}\right)^{-p_i}, \tag{35.104}$$

where f is the frequency in Hertz (Hz), D_i is the distance, measured in meters (m), between points P_1 and P_2 in the x, y, and z directions for $i = 1, 2$, and 3, respectively (Table 35.3); z_g is the geometrical mean height of the two points, $z_g = \sqrt{z_1 z_2}$; z_r is the reference elevation above the mean sea level, $z_r = 10\,\mathrm{m}$; α_i, p_i, q_i, r_i are coefficients given in Table 35.3.

The concept of a wind spectrum is only applicable to steady wind conditions. The time and spatial variation of the wind speed in a squall or tornado cannot be described by a wind spectrum. The analysis of forces

Table 35.3 Coefficients in (35.103) for points P_1 and P_2

i	D_i	a_i	p_i	q_i	r_i
1	$\lvert x_1 - x_2 \rvert$	2.9	0.4	1.00	0.92
2	$\lvert y_1 - y_2 \rvert$	45.0	0.4	1.00	0.92
3	$\lvert z_1 - z_2 \rvert$	13.0	0.5	1.25	0.85

and responses caused by squalls and tornados requires the specification of a time series of wind velocity.

Wind speeds are frequently classified as sustained winds or gusts. Sustained winds are usually hourly averages and gusts are usually the hourly maxima of averages of a minute or less. In either case, the averaging duration should always be stated as well as the elevation. The duration of interest depends on the dimensions and natural period of the structure being analyzed. Small structures should be designed for a shorter gust duration (and hence a higher gust wind speed) than a larger structure. Gusts naturally arise due to the turbulence in wind and can be considered local maxima rather than transient wind conditions. Gust wind speeds are generally derived from the wind spectrum.

Equation (35.99) may be used to calculate the gust speed for various gust durations. Squalls, thunderstorms, downbursts, tornados, and water spouts are relatively short-lived phenomena which can induce extreme winds. The ratio of the maximum gust wind speed to hourly mean wind speed at any one location in these examples can be large. Turbulence alone generates gusts during periods of high mean wind speed, but in this case the ratio of the maximum gust wind speed to hourly mean wind speed over the sea is typically less than about 1.5.

35.3.3 Steady-State Forces

For fixed structures, global wind forces are generally much less important than those caused by waves and currents. Wind forces on individual components of these structures can be significant, however. Global forces on structures are determined using a time-averaged wind speed in the form of a sustained wind speed. For the design of individual structural components, a time-averaged wind speed can also be adequate, but the averaging duration should be reduced to allow for the smaller turbulence scales that can affect individual components. The wind in a 3-s gust is appropriate for determining the maximum static wind load on individual members; 5-s gusts are appropriate for maximum total loads on structures whose maximum horizontal dimension is less than 50 m; and 15-s gusts are appropriate for the maximum total static wind load on larger structures.

Wind acts on a structure above the water, as well as on any equipment, deck houses, bridges, flare booms, and derricks that are located on the topsides. The height of the component above the sea level should be taken into account when estimating the wind speed.

Table 35.4 Wind shape coefficients

Area	Shape coefficient C_S
Beams	1.5
Sides of buildings	1.5
Cylindrical sections	0.5
Overall projected area of platform	1.0

Equation (35.99) can be used to calculate the gust speed for various gust durations for a given elevation z.

The steady wind pressure q is calculated as

$$q = \frac{1}{2}\rho U^2 \,. \tag{35.105}$$

And the force F, acting normal to the body axis or surface, is calculated as

$$F = qC_S A \sin\alpha \;\;, \tag{35.106}$$

where ρ is the density of air (1.22 kg/m^3 for standard temperature and pressure), U is the wind speed (m/s), A is the object area (m^2), α is the angle between the direction of the wind and the axis of the exposed member or surface, and C_S is the shape coefficient.

For smooth circular tubular structures, the shape coefficient is $C_S = 0.65$ for the Reynolds number $> 5 \times 10^5$, and $C_S = 1.2$ for the Reynolds number $< 5 \times 10^5$. A good collection of shape coefficients for long bodies and bodies of finite length is presented in [35.52]. Table 35.4 provides shape coefficients recommended in [35.67] for several bodies for the perpendicular wind approach angle.

On most structures, objects exposed to wind loads are closely spaced and shield each other from the wind depending on the wind direction. If a detailed model of the wind-loaded objects is used, shielding coefficients should be included to account for this interaction. Wake models similar to that presented in (35.94) can be used to estimate shielding.

Wind tunnel tests should be considered to determine pressures and resulting loads on complex structures. Testing should include the variation of wind speed with elevation as well as turbulence.

35.3.4 Unsteady Forces

Modeling the time and spatial variation of the wind should be considered for structures and components which respond dynamically to wind loads. A dynamic analysis of a structure is generally necessary when the wind field contains energy at frequencies near the natural vibration frequencies of the structure; this is

generally the case for compliant bottom-founded platforms as well as for floating structures. Time-varying wind forces can cause resonant surge, sway, and yaw motion of floating anchored structures.

Good load and response estimates can be obtained from boundary-layer wind tunnels and from CFD. Reasonable results can be obtained by simulating forces and responses using a time-domain synthesis of the wind spectrum, (35.101), and adding it to the mean wind. The spatial variation of the wind speed can also be modeled by making use of the coherence function (35.103).

The instantaneous wind force can be calculated by the summation of the forces on individual members exposed to wind. The pressure q can be estimated by

$$q = \frac{1}{2}\rho_a \left|U_{w,T} + u - \dot{x}\right| \left(U_{w,T} + u - \dot{x}\right) , \quad (35.107)$$

where $U_{w,T}$ is the mean wind velocity, u is the gust velocity which may vary spatially as well as with elevation, $\dot{x}$ is the velocity of the body, and ρ_a is the mass density of air ($1.226\,\mathrm{kg/m^3}$ for dry air at 15 °C).

When the structural velocity $\dot{x}$ is negligible compared to the wind speed, the wind pressure can be linearized to

$$q = \frac{1}{2}\rho_a {U_{w,T}}^2 + \rho_a U_{w,T} u . \quad (35.108)$$

These time-varying pressures can be used with (35.106) to calculate time-varying forces.

A special case of dynamic response is VIV of relatively slender structures subjected to steady winds in which alternate vortex shedding excites components. Components of fixed steel offshore structures can be exposed to wind VIV during construction and transportation. Flare structures and telecommunication towers can also be susceptible to wind VIV throughout their lives. Vortex shedding and VIV in wind are much the same as for currents. See Sec. 35.2.5 for a discussion of these phenomena.

35.4 Model Tests

Regardless of how good we think the theoretical predictions of a physical quantity is, there will always be errors, however small, due to the particular modeling we use, or errors in the numerical analysis we perform. We may also have truncation and round-off errors, not to mention any human errors that may be present. All these potential errors can be assessed in a comprehensive way by conducting model tests. However, one has to realize that model tests themselves are not necessarily free of potential errors either, mainly due to the fact that the tests are conducted in a rather finite domain that may be the cause of reflections from tank walls, the wavemaker and absorption beach(es) that in turn may contaminate the measured data.

Physical modeling is the most important area that dimensional analysis can be applied to. By physical modeling, we refer to the technique of reproducing a physical phenomenon on a greater or smaller scale. The motions of or the wave loads on offshore platforms that can be measured by means of model tests in a test basin are the examples to model testing at a smaller scale. There are two basic issues that need to be addressed in any model testing: 1) how do we conduct the experiments so that the data obtained at the model scale are accurate, and 2) how do we extrapolate the data to the prototype scale?

In most offshore engineering problems, the three dimensions, length (L), mass (M), and time (T), are the fundamental dimensions. All physical quantities can then be measured in terms of these three fundamental dimensions. However, some physical quantities, such as temperature and angle, may occasionally be used as one of the fundamental dimensions. If a measurement results in a real number, which can directly be compared to one of these fundamental dimensions, then the measurement is called a direct measurement. For example, a distance of 5 m is a direct measurement since its unit is one of the fundamental units, namely the length. On the other hand, if a measurement is a result of various comparisons that give a real number, whose dimension is a combination of two or more fundamental units, then the measurement is called a derived measurement. A typical example is the velocity, since both length and time have to be measured to obtain the velocity. In derived measurements, there is always a function that expresses the relation between the direct measurements. In the case of velocity measurements, for example, this function is $f(x,t) = \mathrm{d}x/\mathrm{d}t$.

35.4.1 Principles and Similarity Laws

The scale model of any prototype system has to satisfy certain conditions called the laws of similarity or similitude so that the behavior of the prototype phenomenon can accurately be reproduced. The similarity can refer to one or more of:

1. Geometric similarity (refers to length)
2. Kinematic similarity (refers to velocity)
3. Dynamic similarity (refers to force).

The wave loads or motions of offshore platforms or any other physical quantity of interest have to obey one or more of these similarity laws in order that one can properly conduct experiments [35.74].

It is necessary at this point to introduce various force mechanisms that are present in the flow of real fluids. This necessity arises because, under certain conditions of the specific problem being investigated, some force mechanisms may be dominant over the other. As a result, we may isolate, or even neglect, the smaller forces by choosing a proper similarity law. The three principal types of internal force mechanisms in a real fluid are:

1. Inertial force
2. Gravitational force, and
3. Viscous force.

The inertial force is due to the fluid particle acceleration and is proportional to $\rho u(\partial u/\partial x)$, where ρ is the fluid mass density, and u is the particle velocity component in the x direction (other terms are left out without loss of generality). The gravitational force is due to the weight of the fluid itself and is proportional to ρg, where g is the gravitational acceleration. The viscous force is due to the difference between the shear forces acting on a fluid element, and is proportional to $\mu\partial^2 u/\partial x^2$, where μ is the dynamic viscosity coefficient (again other terms are left out). All these forces are included in the Navier–Stokes equations.

The ratios of the internal forces (per unit volume) with one another give us the relative importance or dominance of these forces. For example, we can write the ratio of

$$\frac{\text{Inertial force}}{\text{Gravitational force}} \propto \frac{\rho u\frac{\partial u}{\partial x}}{\rho g} = \frac{u}{g}\frac{\partial u}{\partial x} \propto \frac{U^2}{g\ell} \,. \tag{35.109}$$

In (35.109), U is a characteristic velocity, ℓ is a characteristic length of the problem, and ρ and g are the fluid mass density and gravitational acceleration, respectively. It is seen that the ratio is proportional to $U^2/g\ell$. Similarly, we can write the ratio of

$$\frac{\text{Inertial force}}{\text{Viscous force}} \propto \frac{\rho u\frac{\partial u}{\partial x}}{\mu\frac{\partial^2 u}{\partial x^2}} \propto \frac{U\ell}{\upsilon} \,, \tag{35.110}$$

where $\upsilon = \mu/\rho$ is the kinematic viscosity coefficient. The third ratio, the ratio of the gravitational force to viscous force, can be obtained by a combination of (35.109) and (35.111), and, therefore, it need not be considered. The square root of (35.109) is the Froude number Fr and (35.110) itself is the Reynolds number Re. So, for small Fr, for instance, we can say that the flow is gravity dominated, and for large Re, for instance, we can say that the flow is inertia dominated or viscosity is negligible (or the inviscid fluid assumption is a good one).

If we require that the flow about a body be similar fully both in the model and prototype scales, then it is necessary that both the Fr and Re numbers be the same for the model and prototype. In other words, the Froude number of the model scale must be the same as the Froude number of the prototype scale, that is, $\mathrm{Fr_m} = \mathrm{Fr_p}$, and similarly for the Reynolds number, that is, $\mathrm{Re_m} = \mathrm{Re_p}$, where the subscripts m and p refer to the model and prototype, respectively. Unless under very special circumstances, it is not practically possible to scale a prototype by holding both the Fr and Re numbers the same. To see this, consider the Froude number and the Reynolds number, keeping both constant for the model and prototype scales, that is

$$\begin{aligned} \mathrm{Fr_m} &= \frac{U_\mathrm{m}}{\sqrt{g_\mathrm{m}\ell_\mathrm{m}}} = \mathrm{Fr_p} = \frac{U_\mathrm{p}}{\sqrt{g_\mathrm{p}\ell_\mathrm{p}}} \,, \\ \mathrm{Re_m} &= \frac{U_\mathrm{m}\ell_\mathrm{m}}{\upsilon_\mathrm{m}} = \mathrm{Re_p} = \frac{U_\mathrm{p}\ell_\mathrm{p}}{\upsilon_\mathrm{p}} \,. \end{aligned} \tag{35.111}$$

The first equation in (35.111) requires that if $\ell_\mathrm{m} < \ell_\mathrm{p}$, then $U_\mathrm{m} < U_\mathrm{p}$, assuming that $g_\mathrm{m} = g_\mathrm{p}$, whereas the second requires that if $\ell_\mathrm{m} < \ell_\mathrm{p}$, then $U_\mathrm{m} > U_\mathrm{p}$, assuming that $\upsilon_\mathrm{m} = \upsilon_\mathrm{p}$. Therefore, unless the gravitational acceleration is considerably increased during the experiments (this is not uncommon considering, for example, some soil-mechanics experiments conducted in a centrifugal apparatus) or ν_m is considerably decreased or some combination of the two, the ratio of Fr to Re can not be held constant simultaneously.

One of the two similarity laws, that is, Froude's law, given by the first equation in (35.111), or Reynolds' law, given by the second, has to be used depending on the particular application in mind. Froude's law (or scale) is generally used in conjunction with the experiments on platform motions and surface waves. Reynolds' law or scale, on the other hand, is used in experiments related to deeply submerged bodies, pipe flow, etc.

Another force mechanism is the surface tension, although it is not a principle one. For example, if we consider the ratio of the inertial force to surface tension force (per unit volume), we obtain

$$\frac{\text{Inertial force}}{\text{Surface tension force}} \propto \frac{\rho u\frac{\partial u}{\partial x}}{\frac{\sigma}{L^2}} \propto \frac{\rho U^2}{\frac{L\sigma}{L^2}} = \frac{\rho L U^2}{\sigma} \,, \tag{35.112}$$

Table 35.5 Some of the frequently used dimensionless numbers

Dimensionless number	Symbol	Definition
Froude number	Fr	$U/\sqrt{gL}$
Reynolds number	Re	UL/υ
Strouhal number	St	fD/U
Keulegan–Carpenter number	KC	UT/D
Euler number	Eu	$p/\rho U^2$
Cauchy number	Cy	$\rho U^2/E$
Ursell number	Ur	HL^2/h^3
Weber number	We	$\rho U^2 L/\sigma$

where σ is the surface tension (lb/ft or N/m). The last equality is called the Weber number, that is

$$\mathrm{We} = \frac{\rho L U^2}{\sigma} \,. \tag{35.113}$$

There are a number of other important numbers used in offshore engineering: the Strouhal number, $\mathrm{St} = fD/U$, where f is the vortex shedding frequency and D is the characteristic length, for example, diameter, and KC number, $\mathrm{KC} = UT/D$, where T is the wave period, are two examples. Some of the dimensionless numbers used are shown in Table 35.5, where U is the velocity, g is the gravitational acceleration, L or D is the characteristic length, f is the cyclic frequency, υ is the kinematic viscosity of water, T is the wave period, H is the wave height, h is the water depth, E is Young's modulus, p is the pressure, and σ is the surface tension.

35.4.2 Scaling of Loads

In planning model tests, one has to decide which scaling law to be used. In most offshore engineering model tests, the Froude scaling law is used as offshore platforms mostly encounter gravity waves in nature. This means that during such experiments, one must make sure to satisfy that $\mathrm{Fr_m} = \mathrm{Fr_p}$. Having also decided what length scale, $S_\mathrm{L} = L_\mathrm{m}/L_\mathrm{p}$, to use, one can scale the other physical quantities, accordingly. For example, if we want to scale the wave forces by using Froude's law, so that $U_\mathrm{m} = U_\mathrm{p} S_\mathrm{L}^{1/2}$, we can first determine the scaling of time and acceleration

$$\begin{aligned} U_\mathrm{m} &= \sqrt{S_\mathrm{L}} U_\mathrm{p} = \frac{L_\mathrm{m}}{t_\mathrm{m}} = \sqrt{S_\mathrm{L}} \frac{L_\mathrm{p}}{t_\mathrm{p}} \Rightarrow t_\mathrm{m} = \sqrt{S_\mathrm{L}} t_\mathrm{p} \,, \\ a_\mathrm{m} &= \frac{U_\mathrm{m}}{t_\mathrm{m}} = \frac{\sqrt{S_\mathrm{L}} U_\mathrm{p}}{\sqrt{S_\mathrm{L}} t_\mathrm{p}} = a_\mathrm{p} \,, \end{aligned} \tag{35.114}$$

where t is the time. That the scales for accelerations are the same in the model and prototype scales is not surprising since the gravitational acceleration in the model and prototype scales is the same, $g_\mathrm{m} = g_\mathrm{p}$.

We also need to scale the masses of the model and the prototype. It is

$$S_\mathrm{m} = \frac{m_\mathrm{m}}{m_\mathrm{p}} = \frac{\rho_\mathrm{m} L_\mathrm{m}^3}{\rho_\mathrm{p} L_\mathrm{p}^3} = S_\rho S_\mathrm{L}^3 \,. \tag{35.115}$$

Therefore, the force scaling can be written as

$$S_\mathrm{F} = \frac{m_\mathrm{m} \dot{U}_\mathrm{m}}{m_\mathrm{p} \dot{U}_\mathrm{p}} = \frac{m_\mathrm{m}}{m_\mathrm{p}} = S_\mathrm{m} = S_\rho S_\mathrm{L}^3 \,, \tag{35.116}$$

since the acceleration scale is 1.0.

This method of obtaining the scaling for forces can be used on any other physical quantity to determine how it is scaled to the model. However, there is another way of obtaining the same scaling result. Let us show this by way of an example. Consider the dimension of force and write it as $[F] = (L, M, T^{-2}) = (1, 1, -2)$, that is, as a vector in the 3-D (L, M, T) space. Writing the functional form of force as $F = f(\rho, L, \mathrm{g})$, and taking the set (ρ, L, g) as a dimensionally independent set of quantities, one can use the Pi theorem [35.75] to obtain the single dimensionless π

$$\begin{aligned} [F] &= (L, M, T^{-2}) = (1, 1, -2) = [\rho]^p \, [L]^q \, [\mathrm{g}]^r \\ &= (-3, 1, 0)^p \, (1, 0, 0)^q \, (1, 0, 2)^r \\ &\text{or} \\ p = 1, q = 3, r = 1 &\Rightarrow \frac{F}{\rho L}^3 \mathrm{g} = \pi \Rightarrow \frac{F_\mathrm{m}}{\rho_\mathrm{m} L_\mathrm{m}^3} \\ &= \frac{F_\mathrm{p}}{\rho_\mathrm{p} L_\mathrm{p}^3} \Rightarrow S_\mathrm{F} = S_\rho S_\mathrm{L}^3 \,. \end{aligned} \tag{35.117}$$

This is the same result given by (35.116).

In Table 35.6, we show the model scales for some of the physical quantities that would be of interest during an offshore engineering experiment (L: length, M: mass, T: time, $S_\mathrm{L} = L_\mathrm{m}/L_\mathrm{p}$ is the length ratio, and $S_\rho = \rho_\mathrm{m}/\rho_\mathrm{p}$ is the specific gravity of salt water). Many others are given in [35.74], but for the special case of $S_\rho = 1.0$.

35.4.3 Elastic Structures

Model tests of elastic structures bring additional complexities to the problem as it is not practical in many cases to correctly scale the stiffness of the structure at the model scale. Such elastic structures could be TLP tendons, oil-production risers, catenary-mooring lines, etc., but the structure itself may be elastic as well, especially very large floating structures (VLFS) [35.76]. To see this, consider a tubular, beam-like object, and write the scalings, from Table 35.6, of the axial and bending

Table 35.6 Some model scaling obtained by using Froude's scaling law

Quantity	Dimension	Scale
Length	L	S_L
Mass	M	$S_\rho S_L^3$
Mass moment of inertia	L^2M	$S_\rho S_L^5$
Moment of inertia of area	L^4	S_L^4
Time	T	$S_L^{1/2}$
Acceleration	LT^{-2}	1
Velocity	LT^{-1}	$S_L^{1/2}$
Linear spring constant	MT^{-2}	$S_\rho S_L^2$
Axial stiffness	LMT^{-2}	$S_\rho S_L^3$
Bending stiffness	L^3MT^{-2}	$S_\rho S_L^5$
Work	L^2MT^{-2}	$S_\rho S_L^4$
Power	L^2MT^{-3}	$S_\rho S_L^{7/2}$
Energy	L^2MT^{-2}	$S_\rho S_L^4$
Force	LMT^{-2}	$S_\rho S_L^3$
Moment	L^2MT^{-2}	$S_\rho S_L^4$
Stress	$L^{-1}MT^{-2}$	$S_\rho S_L$
Pressure	$L^{-1}MT^{-2}$	$S_\rho S_L$
Modulus of elasticity	$L^{-1}MT^{-2}$	$S_\rho S_L$

stiffness, and its diameter as

$$S_{EA} = \frac{(EA)_m}{(EA)_p} = \frac{F_m}{F_p} = S_F = S_m = S_\rho S_L^3 ,$$
$$S_{EI} = \frac{(EI)_m}{(EI)_p} = \frac{F_m L_m^4}{L_m^2}\frac{L_p^2}{F_p L_p^4} = S_F S_L^2 = S_\rho S_L^5 ,$$
$$\frac{D_m}{D_p} = \frac{L_m}{L_p} = S_L . \qquad (35.118)$$

Either the bending or shear stress, τ, is scaled as

$$S_\tau = \frac{F_m}{L_m^2}\frac{L_p^2}{F_p} = \frac{S_F}{S_L^2} = \frac{S_\rho S_L^3}{S_L^2} = S_\rho S_L . \qquad (35.119)$$

And the area moment of inertia is scaled as

$$S_I = \frac{I_m}{I_p} = \frac{L_m^4}{L_p^4} = S_L^4 . \qquad (35.120)$$

Therefore, Young's modulus is scaled as

$$S_E = \frac{E_m}{E_p} = \frac{S_{EI}}{S_I} = \frac{S_\rho S_L^5}{S_L^4} = S_\rho S_L . \qquad (35.121)$$

There are basically two problems one encounters as a result of these scalings. One is that it is very difficult to scale the geometry because D_m is typically 50–100 times smaller than D_p. The other is that the modulus of elasticity of the material used in the experiments is also 50–100 times smaller than what is used in the prototype, for example, steel. Some engineering solutions to these kinds of problems is necessary to conduct the experiments. For example, *Dillingham* [35.77] suggested in modeling the tendons of a TLP that all parameters are correctly scaled for the tendon except the axial stiffness that is modeled by a spring placed at the top or bottom of the tendon to provide the correct stiffness. Even this approximation involves some errors that must be carefully assessed.

The structural rigidity can sometimes be reduced by distorting the structure as discussed, for example, by [35.78]. Another type of a distorted model can be achieved in offshore model tests in rather shallow water where the horizontal length dimensions are much larger than the vertical length dimension. In such cases, two different model scale ratios are used in the experiments [35.74, 79]. Let us again set the horizontal length scale to S_L but set the vertical length scale to $S_V = h_m/h_p$, where h_m and h_p are the water depths in the model and prototype scales, respectively, and S_V, in general, is different from S_L. Next, let us consider the linear shallow-water phase speed, $c_p = (gh)^{1/2}$, and use S_V to write the Froude scaling law to obtain

$$\frac{c_m}{\sqrt{gh_m}} = \frac{c_p}{\sqrt{gh_p}} \Rightarrow c_m = \sqrt{S_V} c_p , \qquad (35.122)$$

and since $c = \lambda/T$, where λ is the wavelength, scaled by S_L, $S_L = \lambda_m/\lambda_p$, we have the following scaling for the wave period

$$\frac{T_m}{T_p} = \frac{\lambda_m}{C_m}\frac{C_p}{\lambda_p} = \frac{S_L}{\sqrt{S_V}} \Rightarrow T_m = \frac{S_L T_P}{\sqrt{S_V}} . \qquad (35.123)$$

If the water is not very shallow, of course, the full dispersion relation based on the linear wave theory can be used in deriving the corresponding scales that will now involve hyperbolic functions. Finally, recall that the accelerations scale as 1.0 if a single length scale is used according to the Froude scaling. In the distorted model used, however, that will not be the case. The accelerations in a distorted model would scale as

$$a_m = \frac{U_m}{T_m} = \frac{\sqrt{S_V} U_p \sqrt{S_V}}{S_L T_p} \Rightarrow \frac{a_m}{a_p} = \frac{S_V}{S_L} . \qquad (35.124)$$

35.5 CFD Tools

With the very rapid advancement in personal and server-based computer hardware and numerical methods, as well as the development of commercial software in recent years, CFD is becoming a viable tool in the computations of wave, current, and wind loads on and the resulting motions of offshore platforms. Here, we use the term CFD to mean the solution of the exact governing equations subject to the instantaneous boundary conditions. The governing equations could be the Reynolds-averaged Navier–Stokes (RANS) equations (steady or unsteady) or Euler's equations in which viscosity is assumed to be negligible, although the definition of CFD computations generally is reserved for viscous flows. We do this since there are many problems in offshore engineering in which the effect of viscosity is negligible.

Even though there is very rapid growth in computer hardware and software, the stumbling blocks in the use of CFD tools are concentrated [35.80] around the user-related problems (some of which are related to training and lack of user-friendly GUI) and theoretical problems (some of which are (1) continuation of computations after wave breaking, (2) radiation/reflection conditions for simulating wave tanks or open ocean conditions, (3) fluid–structure interaction including multiphase flow structural modeling, (4) higher order discretization methods, (5) viscous model selection, which one to use and when, among many other problems). Of course the speed at which the computations can be completed is another major issue even if parallel computing is heavily utilized. It is estimated that by the year 2030 the transistor count will be more than 10^{11} and the computing speed will be more than $1.0E^{+18}$ (Exascale). With the estimated increase in the computing speed, it is expected that the cost of running the same model-scale or full-scale case in the year 2030 would be 250 times less than what it was in the year 2013 for as many as 2500 cores.

With these shortcomings of the field at present, however, there are many commercially available or open-source software that are used to solve problems related to offshore platforms. Some of them are ANSYS AQWA, CD-ADAPCO, Reef3D, FLOW3D, and OpenFOAM. The last open-source software appears to be the most popular one currently, not only because it is free, but also because of its relative ease of use, flexibility, and speed. As examples to the use of OpenFOAM software, see [35.81] for the calculations of wave and current forces (viscous fluid) on a semisubmersible and [35.82] for the calculations of nonlinear (inviscid fluid) wave loads on a coastal bridge deck.

35.6 Extreme Response Estimation

Offshore structure design is based on proportioning a structure so that it resists actions (forces) which may occur during its design life with an appropriate reliability. For a random environment, such as that presented by offshore wind, wave, and current, the extreme loads or responses imposed by the environment are required to assess the fitness of the structure for its intended purpose. A target probability of exceedance in combination with a long-term distribution of the response is used to set these extreme responses.

Annual exceedance probabilities of 10^{-2} or 10^{-4} are used to characterize environmental forces for ultimate and accidental limit states. Scatter diagrams and joint probability density functions are used to describe the variability of forces from multiple sources or with multiple parameters of interest, such as frequency and direction. These diagrams or functions are used to generate combinations of environmental parameters which correspond to exceedance probabilities of interest.

The joint probability of occurrence is used to create combinations of wind, wave, and current conditions causing the extreme loads. For most fixed, tower, gravity, and caisson types of platforms, the design environmental load is predominantly due to waves, with current and wind playing secondary roles. The design conditions comprise the design waves and the currents and winds likely to coexist with the design waves. For compliant structures, response to waves is reduced, so that winds and currents become relatively more important.

For fixed structures, the collinear environment usually controls a design and intensities for various sources of environmental load can be selected from Table 35.7 per [35.83].

For floating installations, environmental conditions that involve large differences in direction need to be considered.

When design forces due to wind need to be combined with forces due to waves and current, the following is appropriate:

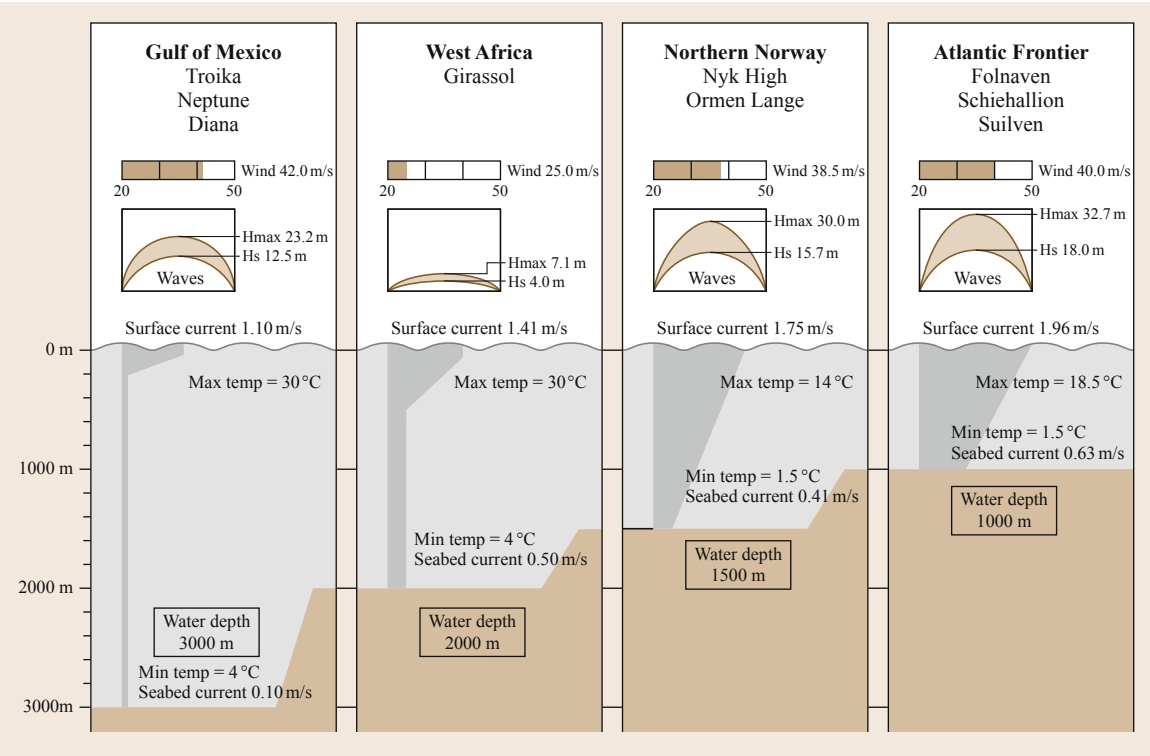

Fig. 35.15 Environmental conditions at a number of deep water sites (after [35.84])

Table 35.7 Combination of environmental forces with expected mean values and annual probability of exceedance

Limit state	Wind	Waves	Current
Ultimate limit state	10^{-2} 10^{-1} 10^{-1} – –	10^{-2} 10^{-1} 10^{-1} – –	10^{-1} 10^{-2} 10^{-1} – –
Accidental limit state	10^{-4} 10^{-2} 10^{-1} – –	10^{-2} 10^{-4} 10^{-1} – –	10^{-1} 10^{-1} 10^{-4} – –

1. For structures with negligible dynamic response, the 1 h sustained wind can be used to determine quasi-static global actions caused by wind in conjunction with ultimate or accidental loads due to waves and currents
2. For structures that are moderately dynamically sensitive, but do not require a full dynamic analysis, the 1 min mean wind can be used to determine quasi-static global loads caused by wind, again for wind in conjunction with ultimate or accidental quasi-static loads due to waves and currents
3. For structures with significant dynamic response to excitation with periods longer than 20 s, a full dynamic response analysis to fluctuating winds should be considered.

Reduced design requirements can be used for the design or relocation of structures that are unmanned or evacuated during the design event or where the loss of or severe damage to the structure would not result in a high consequence of failure. Risk analysis may justify either longer or shorter recurrence intervals for design criteria. Where sufficient information available about the variation under environmental conditions expected to occur from different directions can be considered.

Figure 35.15 illustrates some examples of combined wind, wave, and current environments in four different ocean basins.

36. Vortex-Induced Vibrations

Michael S. Triantafyllou, Rémi Bourguet, Jason Dahl, Yahya Modarres-Sadeghi

Starting at a low Reynolds number of about 50, and reaching the highest Reynolds numbers recorded, bluff bodies placed within an external flow form an unstable wake that results in the formation of a regular pattern of vortices, the Karman street. If the structure is flexible or flexibly mounted, these vortices may cause vibrations, leading to stresses and fatigue damage. This motion of the body influences, in turn, the vortex formation process, establishing a feedback mechanism that may lead to stable or unstable dynamic equilibria. As a result, vortex-induced vibrations are controlled by complex physical mechanisms characterized by rich dynamic properties. When elongated, flexible structures are placed in a sheared cross-flow, the fluid–structure interaction process is distributed along their length, resulting in added complexity, as parts of the structure act to transfer energy from the flow to the structure, while other parts damp the response.

Vortex-induced vibrations can be a serious concern for operations and for the structural integrity of mooring cables, towing hawsers, marine risers, and moored bluff structures, such as spar buoys. We review some of the basic properties of vortex-induced responses and the effectiveness of vortex cancellation devices.

The literature on the subject of vortex-induced vibrations (VIV) is so vast that one cannot hope to be all-inclusive, or even to make justice to all significant contributions. Besides, several review articles and books have already covered several topics [36.1–10]. In this chapter, we will provide an outline of those concepts that are essential to understanding the physics of VIV, and then we will cover recent developments while identifying outstanding issues. Particular emphasis is placed on vibrations in water, where the added mass force plays a very significant role in shaping the properties of VIV.

The topic of VIV of flexibly mounted bluff bodies has become the canonical problem for studying the

flow–structure interaction of nonstreamlined objects, because of the richness of the dynamic behavior. At the same time, VIV is of great importance to applications, such as risers and floating structures used in offshore oil and gas production, towing and anchoring of ships and buoys, acoustic towed arrays, remotely operated vehicles, and cable laying. Also, structures with bluff shapes are moored within currents, such as spar buoys and tension leg platforms, which also exhibit vortex-induced motions (VIM). We will collectively refer to such responses as *vortex-induced vibrations* (VIV), while sometimes we will refer to the VIM of spar buoys.

In towed cables and hawsers, the drag coefficient of the cable can be amplified due to VIV from a value near 1.2 for stationary cylinders to a value of 3.0 or higher, depending on the amplitude of VIV. The drag coefficient affects the static shape, while unsteady loads can cause relatively high-frequency vibrations and hence failure by fatigue [36.11–16]. Similarly, in moored ships and structures, especially in open waters, the drag coefficient may be amplified due to VIV, causing the damping of the overall system, which depends on the drag force acting on the mooring lines, to rise substantially. Since moored systems at sea have long-period natural frequencies, of the order of 100 s, and which are underdamped, a good estimate of the total damping is crucially important. The damping due to the presence of mooring lines can be from 30 to 80% of the total damping [36.17–20]. Another application where drag coefficient amplification due to VIV has significant effect is in cable-laying, because the precise location of where the cable will eventually land, and the amount of tension needed to avoid buckling depends on the drag force. For oceanographic moorings in the open ocean, the most crucial loads are those due to VIV, which seriously limit their life at sea [36.15]. Offshore moorings and risers are used routinely today at depths of 2500 m and beyond. It is widely recognized that, particularly for risers, VIV is the most important problem leading to large static loads and fatigue due to dynamic loads [36.21–23]. Finally, very large structures in the shape of spar buoys are used in the ocean today, such as the Genesis platform with a diameter of 37 m and a vertical height of 198 m, fitted with strakes to reduce VIV. These platforms, operating at Reynolds number around $Re = 10^8$ exhibit VIV, which cannot be reliably predicted on the basis of low Reynolds number VIV data.

The hydrodynamic problem of VIV, which involves interaction of a flexible structure with vortex shedding in a turbulent wake, has been, and still is an area of intense research effort, as evidenced by a vast literature [36.6, 24–28]. The viscous flow behind vibrating cables and risers is dominated by complex flow mechanisms, including changing patterns of vortex formation, formation of secondary vortical structures, turbulence in the wake, and correlation length effects. A series of at-sea experiments has demonstrated that the behavior of cables at sea is strongly influenced by shear and can result in substantial changes in the drag coefficient [36.14, 15]. In the offshore industry, similar VIV problems apply for risers. At shallow depths, risers are dominated by their bending stiffness and behave principally like beams, hence very few modes may be excited and the prediction of VIV is somewhat easier because single-mode prediction procedures, based on empirical models [36.21, 22] or laboratory experiments, can lead to realistic predictions. As the water depth increases, however, risers tend to behave increasingly closer to tensioned cables, with the possibility of having multimodal response in a sheared current. Intense activity in the offshore industry has led to the development of experiment-based predictive programs for risers whose results are usually compared successfully against full-scale experiments, although predicting multimodal response and high Reynolds number behavior, remain outstanding problems [36.29–32].

One of the basic outstanding problems today is the sparsity of data in the open literature for VIV at high Reynolds numbers. While for a stationary cylinder in cross-flow it is well known that significant transitions occur with dramatic effects on the loads and frequency of vortex formation [36.33], far less information is available for vibrating cylinders [36.34, 35].

36.1 VIV Prediction of Wide-Span Rigid Cylinders in Uniform Cross-Flow

We start by outlining the basic concepts for VIV prediction as applied to a uniform, wide-span, flexibly mounted cylinder of circular diameter in a uniform flow, because they are well understood, while many of these concepts can be extended to shear flow as well. The literature on this topic is vast because it has become a canonical problem of flow-induced vibration, as it exhibits an impressive richness of behavior.

36.1.1 Flow Instability and the Formation of the Karman Street

The primary cause of all the phenomena we describe is, at least initially, the formation of the Karman street, a remarkable phenomenon because it occurs at practically every scale beyond a threshold value of the Reynolds number $Re \approx 50$; for example, formation of

vortex streets behind islands, observed in the clouds, occurs at $Re \approx 10^{11}$ (Fig. 36.1). The Karman street consists of a staggered array of vortices forming at a frequency f, which obeys the Strouhal law: based on the cylinder diameter d and current speed U, $fd/U = \mathrm{St}$, where the Strouhal number $\mathrm{St} \approx 0.20$ for subcritical flows above $Re = 150$, and takes somewhat higher values for supercritical flows.

The Karman street forms spontaneously due to an instability of the separated flow behind bluff bodies [36.36–38]. This instability is equivalent to an unstable pole in finite-dimensional systems, and it is always excited by even minute perturbations. The variation of the Strouhal number as a function of the Reynolds number parallels the variation of the drag coefficient, underlining the fact that the Strouhal number is basically a wake parameter, and hence it is related closer to the width of the wake, rather than the diameter of the cylinder. In fact, if the width of the wake h is used to define the Strouhal number, that is, $\mathrm{St}_h = fh/U$, a nearly universal value can be obtained for all Reynolds numbers.

We distinguish, then:

a) The regime below $Re = 50$ where no Karman street forms.
b) The regime above $Re = 50$ and below $Re = 150$, where the Strouhal number varies nearly linearly with Re from a value of $\mathrm{St} \approx 0.1$ to a value of $\mathrm{St} \approx 0.2$.
c) The regime above $Re = 150$ and below roughly $Re = 250\,000$, where the Strouhal number stays roughly at a value of $\mathrm{St} \approx 0.2$.
d) The regime above $Re = 250\,000$ and below roughly $Re = 500\,000$, where the Karman street disappears for perfectly smooth cylinders placed in a very low turbulence stream.
e) And the regime above roughly $Re = 500\,000$ when the Karman street re-appears eventually reaching a higher constant value of $\mathrm{St} \approx 0.26$.

While the value of the Strouhal number is interesting for stationary cylinders, for VIV, several other parameters are equally important, as we outline below.

Starting at Reynolds number roughly 250, a secondary instability sets in the flow. Regularly spaced vortices, whose axis of rotation is roughly parallel to the stream (streamwise vortices), appear on top of the Karman street. The distance between the vortices is between 1 and 2 cylinder diameters; these have high vorticity but small circulation, and they are called *braid* or *hairpin* vortices because of their shape (Fig. 36.2). As the Reynolds number increases, these hairpin vortices cause the flow to become increasingly turbulent; above the Reynolds number 1000 the wake of a circular cylinder is fully turbulent. The braid vortices reduce significantly the value of the lift coefficient and lead to a stabilization of the basic properties of the Karman street. Finally, there are also secondary instabilities at the critical Reynolds number, around $Re = 250\,000$.

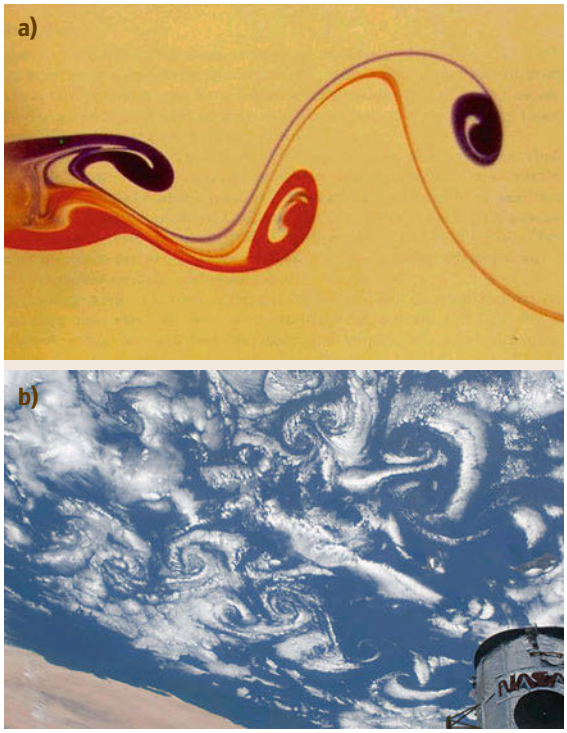

Fig. 36.1 **(a)** Karman street behind a circular cylinder at $Re = 250$ (after [36.39]); **(b)** Karman street behind islands at $Re \approx 10^{11}$ (courtesy of NASA)

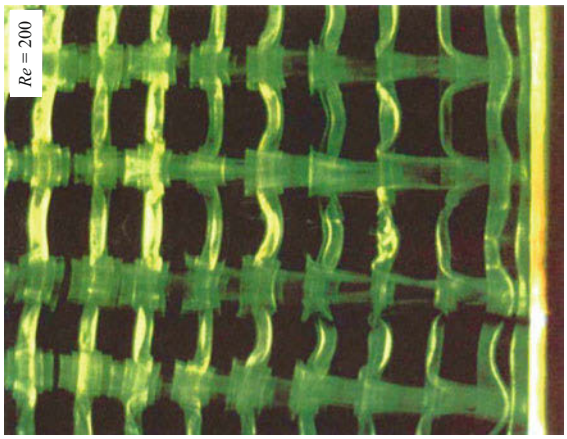

Fig. 36.2 A secondary instability causes the formation of *braid* vortices, that affect the lift force and the Karman street properties (after [36.5])

In the beginning of the critical regime, at $Re \approx 250\,000$, the drag crisis occurs, wherein the boundary layer becomes turbulent, forcing the flow separation points to move from an average position of 86°, with respect to the front stagnation point, to a value of 120°; the drag coefficient drops from a value of nearly 1.2 to a value as low as 0.20. Most importantly, asymmetric re-attachment of the flow occurs before the final separation point is reached, and hence the symmetry of the time-averaged flow is broken. As a result, the instability of the flow is altered and no Karman street forms. The roughness of the cylinder surface or turbulence in the external flow can trip the flow, which is extremely sensitive to such perturbations – in particular, roughness can cause the recovery of symmetric separation. As a result, the reported properties within the critical regime can vary substantially depending on the conditions of the experiment [36.33].

The richness of the Karman street formation properties behind stationary cylinders as a function of the Reynolds number and the conditions of the cylinder surface and the flow turbulence is remarkable [36.6, 10]. We limit the discussion herein to only an outline of these results, because we focus on the vibrations resulting from the Karman street, when the cylinder is flexibly mounted.

36.1.2 VIV of Flexibly Mounted Cylinders in Cross-Flow

Consider a circular cylinder allowed to oscillate transverse to the incoming flow. The cylinder is mounted on linear springs with constant k, a linear damper with constant b, and the cylinder has mass m. For this cylinder, VIV may be excited as periodically shed vortices exert unsteady loads on the cylinder. Under synchronization conditions, where vortex shedding occurs at the frequency of vibration of the structure, the system will oscillate at a frequency relatively close to the structural natural frequency in quiescent fluid, but the precise frequency will depend on the oscillation amplitude, frequency, and the structure of the wake.

Figure 36.3 shows an example of the amplitude of the transverse response, nondimensionalized by the diameter, A/d, as a function of the reduced velocity $V_{rn} = U/f_n D$, where f_n denotes the natural frequency of the system in quiescent water, that is, with added mass coefficient equal to 1. The response, depending on the ratio of the cylinder mass m to the displaced mass m_d, $m* = m/m_d$, where $m_d = \rho\pi sd^2/4$, with ρ the water density, and s the span, covers, typically, a wide range of nominal reduced velocities, in contrast with the classical underdamped mass–damping–spring system, which exhibits a high response only over a narrow parametric frequency range, close to the natural frequency. As we explain below, the reason for this difference is that the effective added mass of a vibrating cylinder within cross-flow is a strong function of the reduced velocity; in fact, it can take on negative values. This is one of the most significant concepts in VIV.

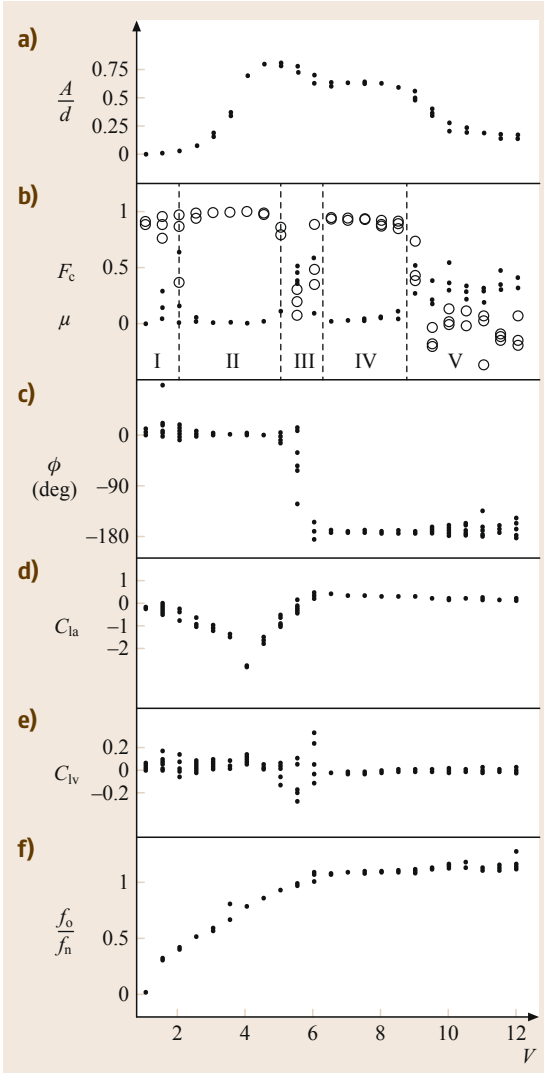

Fig. 36.3a–f Response of a flexibly mounted cylinder versus nominal reduced velocity. **(a)** A/d, **(b)** correlation coefficient between cylinder ends, **(c)** lift force phase angle with respect to the motion, **(d)** lift coefficient in phase with acceleration, **(e)** lift coefficient in phase with velocity, **(f)** response frequency to natural frequency, versus reduced velocity. Reynolds number is 30 000, aspect ratio 26, mass ratio 3, damping ratio 3.5% (after [36.40])

As shown in Fig. 36.3, there are different regimes that characterize the VIV response. As V_{rn} increases,

the response initiates at a value around 3 and increases, reaching a maximum value at about $V_{rn} = 5$, and then the amplitude of response reduces and reaches a plateau at around $V_{rn} = 6$, which lasts all the way to a value of 10. Beyond this value, response decreases rapidly and eventually vanishes.

36.1.3 Forced Cylinder Vibrations

In dynamics, forced vibrations of a system are caused by an external oscillatory input. Although a (steady) external flow is imposed in the case of VIV, the resulting vibrations are caused by an instability in the flow that also determines the frequency and magnitude of the forcing function. Hence, only in a loose way can these vibrations be viewed as forced vibrations. Likewise, in classical dynamics, free vibration refers to the transient oscillations of a dynamic system due to nonzero initial conditions, when there is no external forcing function. VIV, then, is not a free vibration since there is a fluid forcing that continuously drives such vibrations. Finally, it should be mentioned that in forced vibrations of a lightly damped extended structure, the natural frequencies of the structure largely determine the frequency and amplitude content of the response; however, in VIV the forcing function is affected significantly by the motion of the structure. This feedback mechanism renders the use of the original natural frequencies and, especially, the natural modes, in most cases of questionable value in VIV.

Moreover, the terms *forced* and *free* vibration when pertaining to VIV have very specific meanings, as established in the relevant literature. A forced vibration VIV experiment refers to an experiment where the body is fixed to an actuator and forced to move through the fluid with a prescribed trajectory. Typically, hydrodynamic forces exerted on the body are measured during these forced motions. In this case, the body does not respond to the fluid forces since the trajectory is prescribed. This differs from the classical definition of forced vibration.

Also, a VIV experiment where a cylinder is elastically mounted on springs and free to react to the fluid forces is referred to as a *free vibration*. The vibration is called *free* since there is no oscillatory external forcing to drive this oscillation; the energy input is at the expense of the kinetic energy of the oncoming fluid stream, extracted through the instability in the flow. Under steady-state oscillations, fluid forces cancel the structural damping forces, thus providing a vibration analogous to the response of an unforced system with zero damping. For the remaining sections, forced and free vibration will refer to the definitions in regards to VIV experimentation.

In order to explain the basic fluid forces in VIV, we will use results from forced vibrations rather than free vibrations. The cylinder is forced to vibrate transversely to an oncoming stream U with a harmonic motion of amplitude A and frequency f, or circular frequency $\omega = 2\pi f$. The transverse and in-line loads, $X(t)$ and $Y(t)$, respectively, are measured as a function of time; the average of the inline force provides the steady drag force. If the cross-flow motion and its derivatives are described by

$$\begin{aligned} y(t) &= A\cos(\omega t)\,, \\ \frac{\mathrm{d}y}{\mathrm{d}t}(t) &= -\omega A\sin(\omega t)\,, \\ \frac{\mathrm{d}^2y}{\mathrm{d}t^2}(t) &= -\omega^2 A\cos(\omega t)\,, \end{aligned} \tag{36.1}$$

then the inline force contains a constant drag term $\overline{X}$ and an unsteady term whose principal components are even harmonics of the frequency of vibration; the second-harmonic X_2 is typically the most significant. The cross-flow force is found to contain a large harmonic component, $Y_h(t)$, which has a phase ϕ with respect to displacement, and hence can be written as

$$\begin{aligned} Y_h(t) &= Y_o\cos(\omega t+\phi) \\ &= Y_o\cos(\phi)\cos(\omega t) - Y_o\sin(\phi)\sin(\omega t) \\ &= -(-Y_o\cos(\phi))\cos(\omega t) \\ &\quad -(Y_o\sin(\phi))\sin(\omega t) \\ &= -Y_a\cos(\omega t) - Y_v\sin(\omega t)\,. \end{aligned} \tag{36.2}$$

Hence, the harmonic transverse force is decomposed into a component in phase with acceleration Y_a and a component in phase with velocity Y_v, as shown in (36.2); the latter determines whether energy is transferred from the flow to the structure (when positive), or the other way around if negative.

The forces, properly nondimensionalized, provide the mean drag coefficient c_D and unsteady components of the drag coefficient, such as the second-harmonic component, at twice the frequency of vibration c_{d2}. Perpendicular to the direction of flow, the decomposition and normalization of the lift force gives the lift coefficient in phase with velocity c_{lv}, and the lift coefficient in phase with acceleration c_{la}, which can be reformulated to provide the added mass coefficient c_m assuming harmonic body motion [36.41]

$$\begin{aligned} c_D &= \frac{\overline{X}}{\rho dsU^2/2}\,, \\ c_{d2} &= \frac{X_2}{\rho dsU^2/2}\,, \end{aligned} \tag{36.3}$$

$$c_{lv} = \frac{Y_v}{\rho d s U^2/2}\,,$$
$$c_{la} = \frac{Y_a}{\rho d s U^2/2}\,,$$
$$c_m = \frac{Y_a}{A\omega^2 \rho \pi d^2 s/4}\,. \qquad (36.4)$$

Variable Effective Added Mass and Frequency of Response

The concept of an added mass force is well established for inviscid flow, where it is shown that the acceleration of a body, along a straight line for example, within an unbounded fluid causes a reactive force whose magnitude is equal to a constant times acceleration. This constant depends only on the shape of the body and hence is equivalent to a (constant) *added mass*. The general motion of a body in six degrees of freedom can be similarly formulated with a tensor of added masses and moments of inertia [36.42].

However, even within a potential flow, the added mass may not be constant if the body, for example, is vibrating near the free surface of a fluid. For the harmonic motion of a body piercing the surface, the added mass (and damping due to the radiated waves) is a strong function of the frequency. This is an *effective* added mass, in the sense that it is strictly valid for harmonic motion. The variability of the added mass is due to the different wave patterns forming at the fluid surface as a function of the frequency. If the motion is not harmonic, one must take the inverse Fourier transform of the effective added mass as a function of the frequency to find the impulse response and then perform convolution with the acceleration of the body to evaluate forces exerted on the body. What is remarkable is that there are cases when the added mass can be negative. For a submerged body very close to a free surface, the added mass in heave can become negative due to the flux of the fluid mass contained between the body and the free surface at rest.

Hence, for someone familiar with free-surface flows, it is not surprising to discover that the added mass of a vibrating cylinder in cross-flow is a function of the frequency and can even become negative, as there is a similarity with free-surface flows because the wake of a bluff body also supports the formation of waves. The additional complication for VIV is that nonlinearities play a strong role and hence the superposition principle, which is very useful for linearized free-surface flows, are not applicable. Reference to a negative mass without further explanation, may be confusing; however, it is important to note that this is an effective mass, resulting from the confluence of two mechanisms, on one hand, the inertia of the displaced fluid particles (classical added mass definition), and on the other hand, the forces in phase with acceleration due to the forming vortices, which are synchronized and have the same frequency. As a result, as shown in Table 36.1, we define the natural frequency in vacuo (no added mass), the nominal NF with added mass coefficient 1, and the actual NF in water, which varies with reduced velocity.

An alternative explanation of a negative effective added mass is provided in [36.7], where it is explained that the effective added mass force is not a true added mass force and is the result of a vortex force, that

Table 36.1 Definition of the natural frequency (NF) of a mass (m) – spring (k) – dashpot (b) system, as used in the text. m_a is the added mass in quiscent fluid, m_{ae} is the effective added mass

NF in vacuo	$\sqrt{(k/m)}$
Nominal NF in water	$\sqrt{(k/(m+m_a))}$
NF in water	$\sqrt{(k/(m+m_{ae}))}$

is, a force caused by the shed vorticity. This explanation provides further understanding of the physics of the problem and underlines the importance of vortex shedding synchronization with the motion of the cylinder.

When the added mass coefficient and the lift in phase with velocity are plotted as a function of the amplitude and frequency of response, as shown in Fig. 36.4, it is easy to see the strong dependence of these quantities on the frequency of vibration. The variation in the added mass coefficient is particularly striking, since it can be as low as −0.5 and can exceed a value of 2 – all compared to a nominal value of 1.

The cause of the variation in the added mass is the variation in the timing of vortex formation relative to the cylinder motion measured, for example, by the timing of shedding a clockwise vortex relative to the time when the oscillating cylinder reaches a maximum in the oscillatory motion. As shown in Fig. 36.5, as the frequency of oscillation varies, the formation of a clockwise vortex moves earlier in the cycle; note that the value of the nondimensional frequency where this occurs is exactly the value of rapid variation in the added mass coefficient (Fig. 36.5). The variation in the lift force is easy to explain, since when a vortex is close to the cylinder, it causes a suction force due to the low pressure associated with the vortex. Hence, the timing of vortex formation alters the suction force caused by the vortex on the cylinder. If the suction force is in the direction of cylinder acceleration, it will reduce the inertia force, resulting in a reduced added mass; if the suction force is in the opposite direction, the apparent added mass increases.

36.1.4 Lift Coefficient, Velocity and Amplitude

Just as the lift force in phase with acceleration provides for an effective added mass of the system, the lift force in phase with velocity provides for an effective overall damping. When the effective damping is negative (the lift force in phase with velocity minus the structural damping force is positive), it will drive the system to higher amplitudes and when the effective damping is positive, it will drive the system to smaller amplitudes. Hence, the balance of this fluid-forcing term with the structural damping of the system governs the amplitude of the oscillation.

In nondimensional terms, the lift coefficient in phase with velocity, c_{lv} provides the energy to drive VIV. The coefficient reaches peak positive values at around the reduced frequency

$$f^* = fd/U \approx 0.17 \,.$$

This frequency of peak excitation is of critical importance to the prediction of VIV and also coincides with the maximum variability of the effective added mass.

A critical property of c_{lv} can be established when it is plotted as a function of the amplitude of response, for constant frequency of vibration. It follows the curve shown in Fig. 36.6, namely, as the amplitude increases,

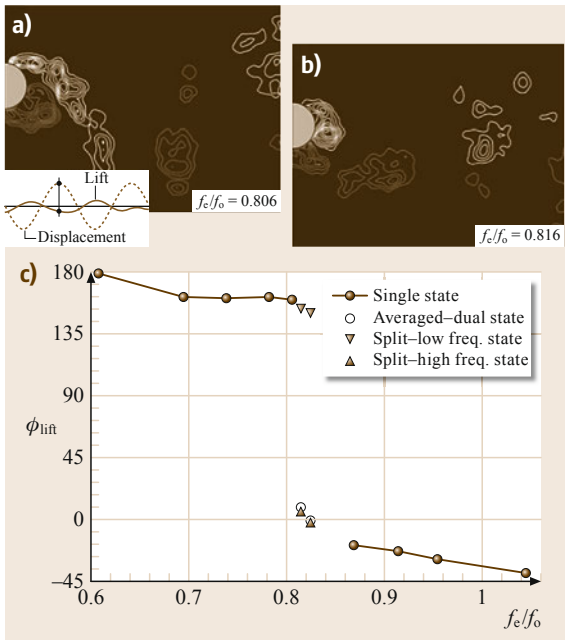

Fig. 36.5 Variation in the timing of vortex shedding (after [36.44])

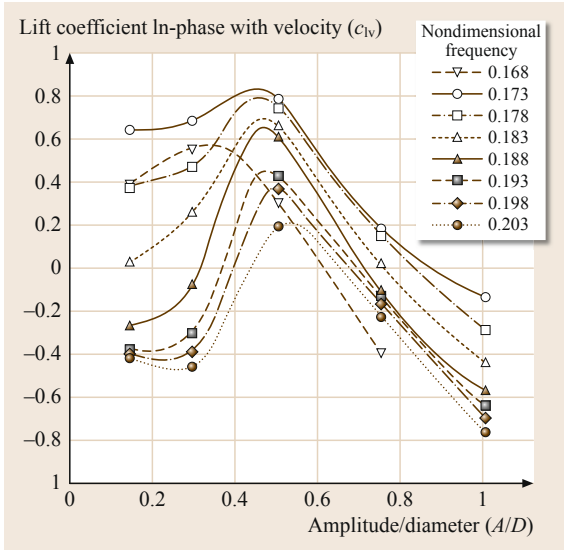

Fig. 36.6 Lift coefficient in phase with velocity as a function of amplitude of vibration (after [36.45])

it initially increases as the lift force becomes increasingly better correlated along the span, but then, beyond a value of typically $A/D = 0.5$, it decreases nearly linearly with A/D, reaching a value of zero at around one diameter (this value varies from 0.6 at low Reynolds numbers to a value of 1.2 or even larger at large subcritical Reynolds numbers, and then returns to a value of around 0.9 for supercritical Reynolds numbers). For large amplitudes, where c_{lv} becomes negative, the effective damping of the system will always be positive, driving the system to have a smaller amplitude. The eventual sign change of c_{lv} at high amplitudes explains the self-limiting nature of VIV, since vibrations beyond typically one diameter are unsustainable.

From an energy balance point of view, in a freely vibrating system, the ultimate value of c_{lv} must be such as to balance the structural damping. When damping is negligible, c_{lv} must be equal to zero. This implies that a condition of *dynamic equilibrium* must be reached.

Strouhal Frequency and Peak Excitation Frequency

As mentioned earlier, the instability in the flow is the cause of VIV, so one might expect that the cylinder is excited most strongly for frequencies close to the Strouhal frequency. One should note, however, that when the cylinder is allowed to vibrate, the process of vortex formation is affected; also, vibrations occur at those frequencies that the added mass coefficient dictates, as we will explain in the next section. As a result, the value of peak VIV response is close, but not equal to the Strouhal frequency, with a nondimensional value close to 0.17 for subcritical Reynolds numbers (as compared to a Strouhal number of around 0.20 for subcritical Reynolds numbers). It should also be noted that this is the value where the added mass coefficient undergoes its largest variation.

Free Versus Forced Vibrations

When free vibrations exhibit purely harmonic motion, there is direct correspondence between forces and motions in free-vibration and forced vibration experiments. Indeed, as shown in Fig. 36.4, the free-vibration results closely follow the iso-contours of constant C_{lv}.

As a result, hydrodynamic coefficients determined through the forced motion of a cylinder in a streaming flow act as fundamental building blocks for predicting VIV. One can write the equation of motion for the vibrations of an elastically mounted cylinder $y(t)$

$$m\frac{\mathrm{d}^2}{\mathrm{d}t^2}y(t) + b\frac{\mathrm{d}}{\mathrm{d}t}y(t) + ky(t) = f(t)\,, \tag{36.5}$$

where $f(t)$ denotes the fluid force, which we decompose into a part in phase with velocity and one in phase with acceleration, as explained earlier. By assuming harmonic motion with the complex amplitude Y and frequency $\omega = 2\pi f$, $y(t) = \Re[Y\mathrm{e}^{\mathrm{i}\omega t}]$, we write

$$f(t) = \Re\left[\left(-c_{\mathrm{m}}\frac{\pi}{4}d^2s\omega^2 Y + \mathrm{i}\frac{1}{2}\rho c_{\mathrm{lv}}dsU^2\frac{Y}{|Y|}\right)\mathrm{e}^{\mathrm{i}\omega t}\right], \tag{36.6}$$

where $\Re[x]$ stands for the real part of x. By substituting into (36.5), and resolving the real versus imaginary part, we find

$$M\omega^2 = k\,, \quad b\omega A = \frac{1}{2}\rho c_{\mathrm{lv}}dsU^2\,, \tag{36.7}$$

where $M = m + m_{\mathrm{a}}$ is the mass plus added mass, with $m_{\mathrm{a}} = c_{\mathrm{m}}\pi/4D^2s$, and A is the absolute value of Y. Equations (36.7) can be solved to provide the amplitude and frequency of response. Their solution must be iterative because the added mass and damping coefficients are functions of the amplitude and frequency.

The second equation expresses the fact that the energy from the fluid is balanced by the damper; hence, if the damping is negligible, free vibrations will take place at values of $c_{\mathrm{lv}} = 0$. The first of (36.7) simply expresses the fact that vibrations occur at resonance; except that the natural frequency varies because of the variability of the added mass coefficient. Indeed, this variability, which can be significant, is the root cause of the noted VIV response over a wide parametric range, and is a crucially important concept for accurate VIV prediction.

We can put (36.7) in a nondimensional form using the definitions of the mass ratio m^*, damping ratio ζ, natural frequency in a vacuum ω_n, added mass coefficient c_{m}, lift coefficient in phase with velocity c_{lv}, reduced velocity V_{r}, and nondimensional frequency f/f_{n}

$$m^* = \frac{m}{\rho\pi\frac{D^2}{4}S}\,, \tag{36.8}$$

$$\omega_n = \sqrt{\frac{k}{m}}\,, \tag{36.9}$$

$$\zeta = \frac{b}{2m\omega_n}\,, \tag{36.10}$$

$$V_{\mathrm{r}} = \frac{U}{fD}\,, \tag{36.11}$$

$$f^* = \frac{f}{f_{\mathrm{n}}}\,. \tag{36.12}$$

In a nondimensional form, we find that (36.5) gives two equations from the real and imaginary parts, where the nondimensional amplitude and frequency are deter-

mined directly from the fluid forcing terms

$$\frac{A}{D} = \frac{c_{\mathrm{lv}} V_{\mathrm{r}}^2 f^*}{4\pi^3 m^* \zeta}\,, \tag{36.13}$$

$$f^* = \sqrt{\frac{m^*}{m^* + C_{\mathrm{m}}}}\,. \tag{36.14}$$

We can see the importance of added mass variability with two simple examples:

- Let us assume that the natural frequency of a system with $m^* = 1$, using a nominal added mass coefficient $c_{\mathrm{m}} = 1, \hat{f}_{\mathrm{n}}$, provides $\hat{f}_n d/U = 0.10$, at the edge of excitation. When we account for the true value of the added mass coefficient, however, $c_{\mathrm{m}} = -0.5$, we realize that the true natural frequency changes to give $f_{\mathrm{n}} d/U = 0.16$, near peak excitation.
- Next we assume that the velocity changes, so that using again the nominal natural frequency, we find $\hat{f}_{\mathrm{n}} d/U = 0.20$, at the other side of the edge of excitation. When we account, again, for the true value of the added mass coefficient, however, $c_{\mathrm{m}} = 2.0$, we realize that the true natural frequency changes to give $f_{\mathrm{n}} d/U = 0.163$, back to near peak excitation.

These two examples show why the specific form of the added mass variation shown in Fig. 36.4 causes the excitation to spread to a wide range of the nondimensional parameter *nominal reduced frequency*, $f_{\mathrm{n}}^* = \hat{f}_{\mathrm{n}} d/U$, or, equivalently, in terms of the *nominal reduced velocity*, $V_{\mathrm{rn}} = U/(\hat{f}_{\mathrm{n}} d)$. If the added mass had the reverse trend, that is, negative values at large frequencies and large values at lower frequencies, VIV would be an insignificant phenomenon, because it would be virtually impossible to find a resonant peak.

Wake Capture and Excitation Cause Lock-In

Two basic concepts that result from forced vibrations are those of *wake capture* and *wake excitation* regions. Wake capture is the gray-shaded region in Fig. 36.7, wherein the wake of a vibrating cylinder forms vortices at exactly the frequency of cylinder vibration, rather than at the Strouhal frequency. Outside this region, the loads are found to contain two frequencies, one at the cylinder vibration frequency, and another close to the Strouhal frequency.

The second shown region, denoted as the positive energy region in the graph, is the region where the lift coefficient in phase with velocity is positive (Fig. 36.7), hence providing energy from the flow to the system. Free vibrations will take place only within this region, since the fluid provides the needed energy for vibration, which is dissipated through the structural damping. Vibrations in the overlap region between these two regions are monochromatic free vibrations; hence the overlap region is what is usually referred to as the *lock-in region*.

A defining feature of lock-in is effective resonance. In classical dynamics, resonance occurs when a system is excited at its natural frequency. Large motions occur at resonance as energy is stored in a balance between the kinetic energy of the moving system mass and potential energy in the system springs. In VIV, as described above, the frequency at which the system oscillates is dependent on the added mass, which in turn is a function of the oscillation frequency and amplitude. The dynamic equilibrium achieved results in the system's oscillation frequency acting as an effective natural frequency for the cylinder, such that

$$f_{\mathrm{n,eff}} = \sqrt{\frac{k}{m + m_{\mathrm{a}}}}\,. \tag{36.15}$$

Since the effective natural frequency changes as a function of the effective added mass and this effective natural frequency is equal to the frequency at which the system oscillates, the cylinder is always in a state of effective resonance when lock-in occurs.

Vortical Patterns of an Oscillating Body

Once the body is set in motion, the fluid forces are altered, and hence the vortical patterns change. If a steady-state vibration sets in, this is a dynamic equilibrium between the structural forces and the fluid forces, where one must account for the strong feedback mechanism that alters the fluid forces.

We start with bodies undergoing free cross-flow vibration only. As a function of the reduced velocity V_{rn}, initially the wake resembles the Karman street, forming two vortices per period (*2S* mode). After the peak response has been reached, however, four vortices per cycle form, appearing as two pairs of counter-rotating vortices (*2P* mode); initially, the two additional vortices

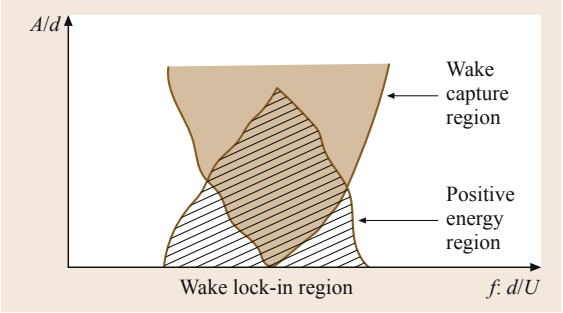

Fig. 36.7 Wake capture versus wake excitation (positive energy) regions

are weak and grow in strength with increasing reduced velocity. *Williamson* and *Roshko* [36.25] mapped the form of the wake for forced cross-flow vibrations as a function of the amplitude and frequency of vibration, discovering a variety of patterns. The basic patterns, as applicable to one degree of freedom, free vibrations are the *2S* and *2P* patterns.

More complex patterns can appear for large enough forced oscillatory motion of a cylinder [36.25], including asymmetric patterns. When in-line motions of the body are allowed in combination with transverse oscillations, such as in two degree of freedom oscillations or cantilevered cylinder oscillations, multiple vortex patterns may form [36.7, 46, 47], including a *2T* pattern, where triplets of vortices form per half-cycle.

The particular vortex shedding pattern combined with the motions of the cylinder govern the magnitude, phasing, and frequency content of the forces exerted on the body. The particular shedding patterns can be directly related to observations in the change of the phase between the lift force and transverse motion of the body along with a change in the sign of the effective added mass. In the *2S* mode of vortex shedding, the body moves toward the nearest shedding vortex in the wake. The motion slightly lags behind the force if there is positive damping in the system; however, the phase difference between the force and body motion will be very small. When the wake transitions to the *2P* mode, the second vortex of the pair forms as the body is moving away from the pair. Hence, the body is moving away from the nearest shed vortex, rather than toward it. This leads to a 180° phase shift, since the sign of the body's motion is switched with respect to the force exerted by the vortices. This sign change also corresponds to a change in the sign of the effective added mass, as the force exerted by the vortex now opposes the body motion (but is completely in phase with acceleration of the body).

36.1.5 Correlation Length

In order for significant VIV to occur, the vortex shedding, and hence the excitation force, must be well correlated with the length of the structure, that is, forces must have the same phase along the span. Studies show that the motion of the cylinder reinforces correlation; a three-dimensional (3-D) instability that causes the appearance of streamwise intense-vorticity, but of low circulation (compared to the Karman vortices) *rib* vortices, is the cause of an apparent drop in correlation. Nonetheless, by applying proper filtering, it is found that the correlation length is large in vibrating cylinders in uniform or mildly sheared flow.

It has been found, however, that for values of the reduced velocity near peak response, the correlation between the lift forces measured at the ends of a finite-span cylinder section drops to very low values [36.41]. For a tapered cylinder in a uniform flow, this lack of correlation has been associated with the appearance of a *hybrid mode* of vortex shedding [36.48]. Numerical simulations [36.49] have shown the details of such hybrid mode formation in uniform-section cylinders placed in linearly sheared flow.

The drop in correlation has been found for a wide range of Reynolds numbers, showing that the basic phenomenon is controlled by large-scale vortex dynamics. A comparison of the response and correlation length in a smooth cylinder to that of a cylinder fitted with tripping wires, used to force earlier transition to turbulence in the boundary layer of the cylinder (following the procedure of [36.50–52]), shows that there is a decrease in the reduced velocity region where the correlation drops for the cylinder with wires, but the qualitative features remain the same. Remarkably, the region of low correlation is associated with a region of very high amplitude response. Detailed studies in the wake of a cylinder [36.40], using hot wire anemometry, show that the lack of correlation manifests itself in the velocity fluctuations at various locations downstream and along the cylinder span.

The lack of correlation is resolved by considering the fact that, especially when the structural damping is small, the free vibrations are found to occur at the transition between *2S* and *2P* patterns. It is possible, therefore that part of the cylinder is under the *2S* regime and the rest under *2P*. Small variations in the incoming flow or the diameter can trigger such variations in the vortical patterns which are better viewed when the cylinder diameter is tapered [36.48]. The paradox, however remains, because one has to explain how an uncorrelated lift force causes maximum vibrations.

The fact that low correlation is associated with high amplitude vibrations turns, in fact, not to be a paradox. In the case of the formation of hybrid modes, these are structurally stable patterns, not randomly varying excitation. Also, it is important to note that the magnitude of the lift coefficient in phase with velocity is not what controls how high the response will be, at least for very low damping systems. The controlling parameter is the value of A/D at which the c_{lv} coefficient becomes zero. In Fig. 36.6, we show a typical c_{lv} versus A/D curve for constant reduced velocity, as well as the related lift coefficient in phase with acceleration. The slope at the zero down-crossing is equal to the hydrodynamic damping [36.53], while the maximum value of lift is not a crucial quantity as far as maximum amplitude is concerned.

Combined In-Line and Cross-Flow Motions

In experimental testing, the dynamics involved with VIV are typically simplified to study only cross-flow motion of the body since for a fully flexible structure, transverse oscillations of the body are typically larger compared with in-line oscillations. The constraints imposed by this simplification, however, lead to different forces exerted on the body, since the cylinder is not free to react to fluid forces in the in-line direction. Allowing combined in-line and cross-flow motions undergoing VIV leads to larger amplitude oscillations, larger magnitude forces, and larger harmonic components of the forces due to changes in the relative motion of the cylinder with respect to vortices shed in the wake.

As explained earlier, the peak frequency in the oscillatory drag force is typically at twice the frequency in lift. This unsteady drag force may also lead to a significant oscillation of a flexible body in the in-line direction. If the 2 : 1 frequency ratio is maintained in the resulting in-line and cross-flow motion, the structure oscillates with either a figure-eight or crescent shape motion, depending on the phase relation between the two motions. If we define a harmonic motion in the cross-flow direction $y(t)$ with frequency ω, and a harmonic motion in the in-line direction $x(t)$ with twice the cross-flow frequency, we can denote the phase difference between these motions, θ,

$$y(t) = A_y \sin(\omega t) \,, \tag{36.16}$$

$$x(t) = A_x \sin(\omega t + \theta) \,. \tag{36.17}$$

The phase angle θ alters the orbital motion of the cylinder, such that the cylinder may oscillate with a figure-eight shape, curved figure-eight, or crescent shape as illustrated in Fig. 36.8. Depending on the value of this phase, the curved figure eight or crescent shape may be oriented to curve toward the upstream or downstream current. Additionally, the direction of the path of the orbital shape is also dependent on the phase. For example, both phases of 0 and 180° will look like a regular figure-eight; however, the direction of the path relative to the free stream will be opposite in these cases. To define the direction of the figure-eight motion, we can use the direction of the motion when the cylinder is at the top of the cross-flow motion. For example, if the fluid is flowing left to right and the cylinder is oscillating such that it moves upstream at the two extremes of the cross-flow motion, then the cylinder is defined to be moving counterclockwise and the phase is between −90 and 90°. If the cylinder is moving in the opposite direction, such that its motion is downstream at the extremes of the cross-flow response, then it is said to be moving in a clockwise motion and the phase if between −180 to −90° and 90 to 180°.

Since the excitation frequency of the in-line motion will typically be at twice the excitation frequency of

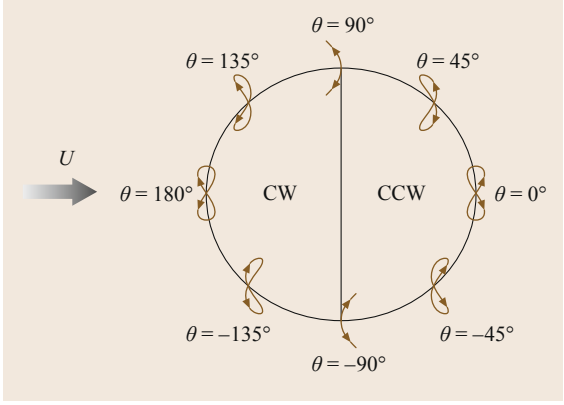

Fig. 36.8 Definition of phase angle between in-line and cross-flow motion θ based on sine motion. Flow is defined as left to right. Definition of counterclockwise (CCW) and clockwise (CW) orbits are noted. Cosine motion of the body will result in a 90° phase shift of θ

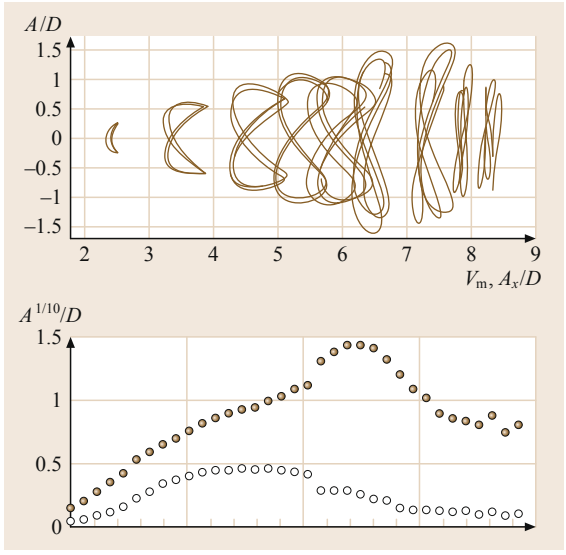

Fig. 36.9 **(a)** Horizontal axis V_{rn}, A_x/D; vertical axis A_y/D. (The horizontal axis plots both V_{rn} which is marked 2, 3, 4, etc., as well as the inline motion A_x for several subfigures shown) **(b)** Horizontal axis V_{rn}; vertical axis $A^{1/10}/D$. Definitions: D is the diameter of the cylinder, A_x is the amplitude of motion in the in-line direction, A_y is the motion in the cross-flow amplitude of motion, $A^{1/10}$ is the one-tenth highest average amplitude of cross-flow (*black circles*) and in-line (*open circles*) motion; V_{rn} is the reduced velocity, defined as $V_{rn} = U/(f_n D)$, with U the current velocity, and f_n the natural frequency of the flexible cylinder [36.54]

the cross-flow motion, a condition of dual resonance may be defined where the cylinder will oscillate with a 2 : 1 in-line to cross-flow frequency ratio, such that the effective natural frequencies of the system have this 2 : 1 ratio [36.35]. For long, flexible structures, the structure will behave as a tensioned beam or tensioned string, such that there are a large number of natural frequencies associated with various modal excitations of the structure. It is therefore possible for long, flexible structures to have varying natural frequency ratios along the length of the structure, depending on which modes of the structure are excited. This phenomenon may be modeled using an elastically mounted rigid cylinder by tuning the vacuum natural frequency of the cylinder separately in the in-line and cross-flow directions. A natural frequency ratio of 1 : 1 would denote equal natural frequencies in the in-line and cross-flow directions, which would result in the excitation of the same mode on a long, flexible structure. A frequency ratio of 2 : 1 would denote the in-line natural frequency to be twice the cross-flow natural frequency. For an infinite string, for example, this would result in exciting the cross-flow motion at the fundamental mode and the in-line motion at the second mode.

Figure 36.9 shows the in-line and cross-flow responses, as well as the trajectories at mid-length of a flexible beam towed at constant velocity as a function of the reduced velocity. Figure 36.9 counterclockwise trajectories dominate the peak vibratory response [36.54].

This experimental technique has been implemented to study the response of a freely vibrating rigid cylinder, elastically mounted, allowing combined cross-flow and in-line motions [36.35, 46, 55, 56]. In general, the magnitude of the observed response of a cylinder free to oscillate in two degrees of freedom can be significantly larger than for a cylinder constrained to cross-flow motion only. Whereas a cylinder with low mass ratio and damping, constrained to cross-flow motions will typically reach a maximum response near $A_y/D \approx 1$, a similar cylinder free to oscillate in both the in-line and cross-flow directions may exceed transverse amplitudes of $A_y/D = 1.5$. As a function of the increased response for these motions, additional vorticity may shed in the wake in the form of vortex triplets, leading to the *2T* wake mode, which consists of two triplets of vortices shedding per cycle of motion [36.46].

In addition to increased cylinder motion and slight alterations to the wake, the forces exerted on a cylinder in combined cross-flow and in-line motion may be significantly different than those observed for equivalent cross-flow motion only [36.57]. The largest difference is the presence of higher harmonic forces in the lift and drag forces. Large magnitude third-harmonic forces in lift have been observed for two degrees of freedom VIV [36.46, 47]. As vortices shed from the cylinder, the relative motion of the cylinder with respect to the shed vortices governs the magnitude and frequency of the forces exerted on the body. For a cylinder shedding a typical Karman street and oscillating with a figure-eight pattern, the relative motions of the body can

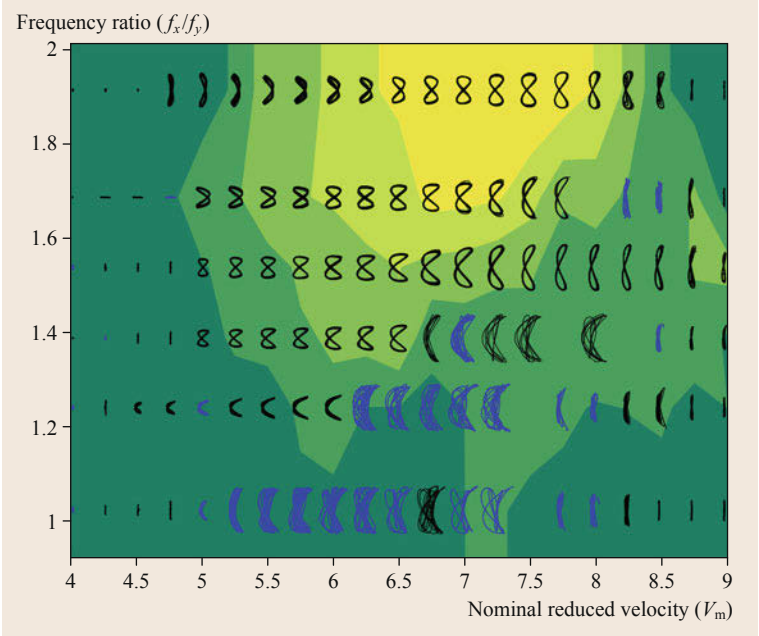

Fig. 36.10 Response trajectory of a flexibly mounted cylinder as a function of reduced velocity and ratio of natural frequencies in the in-line and cross-flow directions f_x/f_y (after [36.35]). *Black* denotes counterclockwise motion, *blue* clockwise motion. Color denotes intensity of high harmonic forces (*yellow* highest, *green* lowest)

lead to a dominant third-harmonic force, even though the dominant response of the cylinder occurs at the fundamental frequency [36.35]. Figure 36.9 illustrates how the relative magnitude of the third-harmonic force varies as a function of the natural frequency ratio and orbital shape.

Although the ratio between the natural frequencies in the in-line and cross-flow directions may vary, due to the significant variation in the effective added mass, the effective natural frequency ratio between in-line and cross-flow directions will be 2 : 1 when lock-in occurs in both directions. This condition is referred to as dual resonance [36.35], since the system resonates in both the in-line and cross-flow directions. Regardless of the nominal natural frequency ratio, in dual resonance, the values of the effective added mass in both the in-line and cross-flow directions vary until they provide a double resonance condition. This is sustained as long as the wake vortical patterns can be sustained to provide the appropriate values of added mass (Fig. 36.10).

In an analogous phenomenon, it has been shown that in cross-flow oscillations and for a mass ratio less than a threshold value of about 0.56, the effective added mass adjusts to a negative value that expands the effective natural frequency over an infinite range of reduced velocity [36.7].

36.2 VIV Prediction of Flexible Structures in Nonuniform Flow

Moving to the case of a flexible cylinder placed in steady cross-flow, one must reformulate the governing equations to account for the fact that the vibration is a function of length along the span as well as time. Equations (36.7) turn to integral relations (integrating across the span) rather than algebraic relations. The details including numerical implementation can be found in [36.58].

Slender flexible bodies undergoing VIV can be modeled as linear tensioned beams subjected to fluid forcing. If, as previously introduced in Sect. 36.1.3, x and y denote the in-line and cross-flow displacements, respectively, which are now functions of time t and spanwise position z, and X and Y denote the sectional forces exerted by the flow on the body, then the dynamics of such structure can be expressed as follows,

$$\begin{cases} m\dfrac{\partial^2 x}{\partial t^2} - T\dfrac{\partial^2 x}{\partial z^2} + EI\dfrac{\partial^4 x}{\partial z^4} + b\dfrac{\partial x}{\partial t} = X\,, \\ m\dfrac{\partial^2 y}{\partial t^2} - T\dfrac{\partial^2 y}{\partial z^2} + EI\dfrac{\partial^4 y}{\partial z^4} + b\dfrac{\partial y}{\partial t} = Y\,, \end{cases} \tag{36.18}$$

where m is the structure mass per unit length, T is its tension, EI is its bending stiffness, and b is the structural damping. This second-order system must be complemented by initial and boundary conditions such as, for example, $x = y = \partial^2 x/\partial z^2 = \partial^2 y/\partial z^2 = 0$ at the ends, for a simply supported structure. The expansion of the body displacements on a suitable modal basis and the Galerkin projection of expression (36.18) onto this basis lead to the following dispersion relation, which links in vacuum, the n-th structural mode of nondimensional spatial wavelength $\lambda_n = 2L/nD$, to the corresponding nondimensional natural frequency f_n

$$f_n = \frac{nD}{2L}\sqrt{\frac{1}{mU^2}\left(T + EI\frac{n^2\pi^2}{L^2}\right)}\,, \tag{36.19}$$

where U is the oncoming flow velocity. A slender flexible structure presents an infinite set of natural frequencies. Since VIV are characterized by synchronization of body oscillation and vortex formation over a range of frequencies in the vicinity of the Strouhal frequency, the above dispersion relation may provide a rough estimate of the possible excited modes. It also shows that when such a body is immersed in a sheared current, that is, with a frequency of vortex shedding that varies along the structure span, the vibrations may involve multiple structural modes.

36.2.1 Traveling Structural Waves and Multi-Modal Responses in Sheared Flows

When the oncoming flow is sheared, it is known to reduce the amplitude of vibration [36.59, 60]. An important effect of shear, however, in long tethers and risers is to cause the appearance of multifrequency response. Indeed, various parts of the structures are subject to excitation at different frequencies, since the oncoming velocity varies. Energy is input in a certain location – at or near the local Strouhal frequency – travels along the structure, and then is dissipated at another location. This necessitates the introduction of complex modes in the numerical prediction of VIV [36.27, 58]. In a classical standing wave analysis, energy cannot travel beyond nodes, and hence a different methodology is needed, one that allows standing waves, or traveling waves, or a combination of the two. This is achieved by assuming the amplitude to be complex, which introduces an amplitude and a constant phase at each location of the structure. An outstanding problem today is the partitioning of energy among the multiple frequencies existing in a long structure in shear flow.

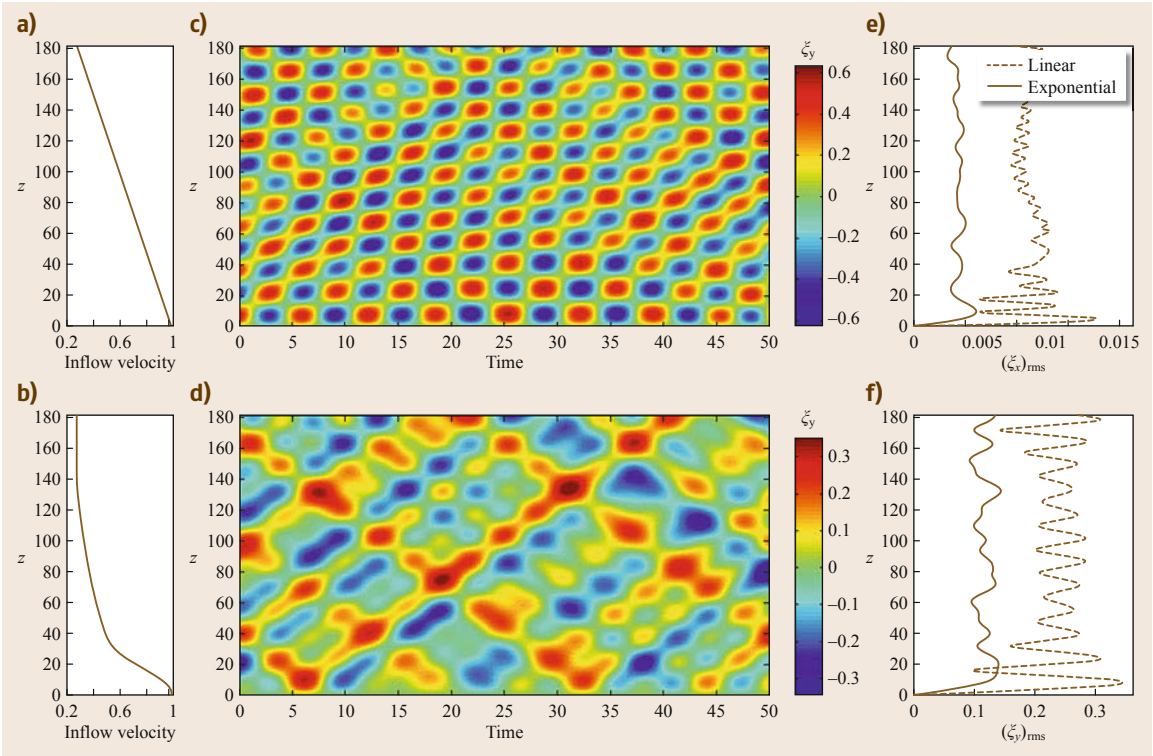

Fig. 36.11 **(a)** Linear and **(b)** exponential inflow velocity profiles, **(c,d)** selected time series of the cross-flow displacement along the span in the **(c)** linear and **(d)** exponential shear flow cases, **(e,f)** RMS value of the **(e)** in-line and **(f)** cross-flow displacements, along the span (after [36.61])

Gopalkrishnan et al. [36.62] treated the problem of a rigid cylinder section undergoing multifrequency vibration (two or three simultaneous frequencies). The total energy transfer from fluid to structure, under these conditions, is divided among the participating frequencies; also, the lift and the drag coefficients are affected. There is no general theory, however, available to model the partition of energy among the (several) frequencies that a very long cable or riser may be subjected to in a sheared flow.

Ocean engineering structures, such as marine cables or risers, are often exposed to currents with nonuniform velocity profiles. The VIV of slender flexible cylinders in nonuniform currents generally involve high structural modes and consist of a mixture of standing and traveling wave patterns [36.42, 63–67].

To illustrate the typical vibrations observed in this context, the structural responses obtained from coupling the system (36.18) with direct numerical simulation of the 3-D Navier–Stokes equations, are presented in Fig. 36.11. In these simulations, the cylindrical tensioned beam has a length-to-diameter aspect ratio equal to 200; it is immersed in sheared cross-flow with two distinct velocity profiles, either a linear or an exponential profile, as shown in Fig. 36.11a,b. In both cases, the Reynolds number based on the maximum inflow velocity is equal to 330. Selected time series of the cross-flow displacement are plotted along the span for the linear and exponential flow velocity profiles in Fig. 36.11c,d. In the case of linear shear, the structural waves appear mainly oriented from the high to the low inflow velocity regions. On the contrary, no preferential orientation of the waves can be identified in the exponential shear case. This aspect will be explained by the spanwise distribution of the excitation/damping regions in Sect. 36.2.2. Root mean square (RMS) values of the vibration amplitudes along the span are presented in Fig. 36.11e,f. The absence of vibration nodes along the span confirms the strong traveling-wave nature of the structural responses. These plots also illustrate the impact of the velocity profile shape on the response amplitudes.

Spatio-temporal spectral analysis based on a two-dimensional fast Fourier transform of the structural responses allows us to clarify the link between excited frequencies and structural wavenumbers/wavelengths, what we refer to as *modes*. In Fig. 36.12, the cross-flow displacement power spectral densities (PSD) associated

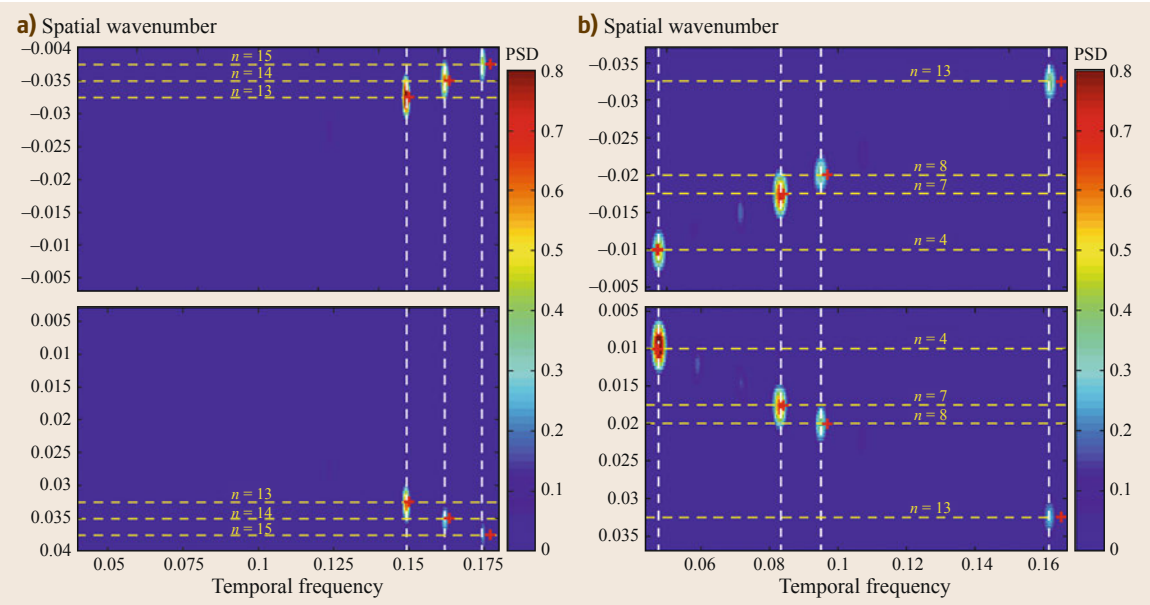

Fig. 36.12a,b Spatio-temporal spectral analysis of the cross-flow displacement in the **(a)** linear and **(b)** exponential shear flow cases. Selected vibration frequencies are identified by *white vertical dashed lines*. The wavenumbers of selected modes are indicated by *yellow horizontal dashed lines*. *Red crosses* denote the natural frequencies associated with these wavenumbers (after [36.61])

with the above vibrations are plotted as functions of the temporal frequency and spatial wavenumber. Both inflow velocity profiles lead to vibrations at multiple frequencies, but the structural responses differ in the width of the excited frequency band. Three main frequencies are excited along the span within a narrow band in the linear profile case, while a broadband response is observed in the exponential profile case. As a consequence, both *narrowband* and *broadband* VIV may be excited, depending on the shape of the oncoming flow velocity profile. It should be mentioned that, even under sheared current conditions, responses at a single frequency are also possible, in particular when the effect of the flow shear is counterbalanced by the curvature of the body [36.68]. Each excited frequency is generally associated with a single structural wavenumber.

In order to estimate the natural frequencies of the excited structural modes when the structure is submerged in the fluid, the dispersion relation in vacuum (36.19) may be modified as follows,

$$f'_{\mathrm{n}} = f_{\mathrm{n}} \sqrt{\frac{m}{m + c_{\mathrm{m}} \rho \pi \frac{D^2}{4}}} \,, \tag{36.20}$$

where c_{m} is the added mass coefficient, which is assumed to be constant along the span to derive this new relation. The natural frequencies predicted by considering an added mass coefficient $c_{\mathrm{m}} = 1$ (the theoretical value in potential flow) are indicated by red crosses in Fig. 36.12. Significant departures from the actual peaks may be observed; this is related to the strong variability

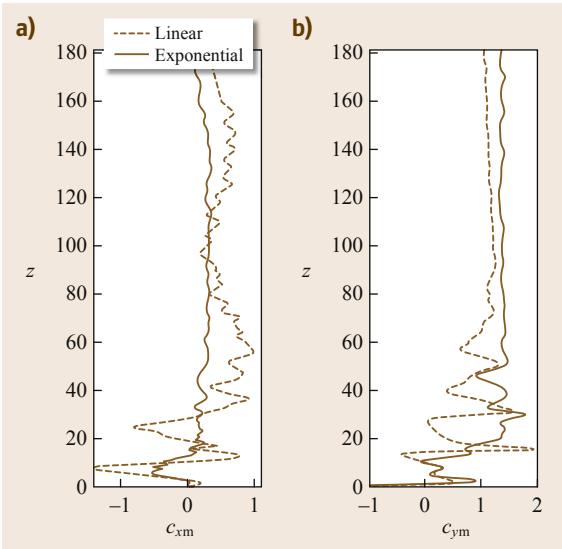

Fig. 36.13a,b Effective **(a)** in-line and **(b)** cross-flow added mass coefficients along the span. The potential flow value is equal to 1 (after [36.69])

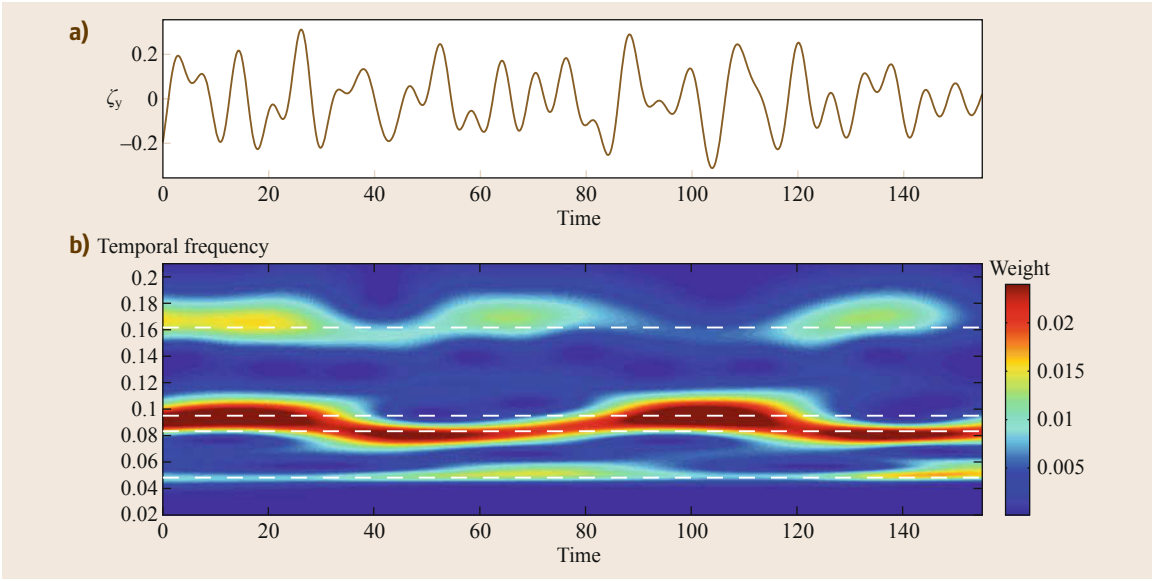

Fig. 36.14 **(a)** Selected time series of the cross-flow displacement and **(b)** corresponding frequency content as a function of time (scalogram). *Dashed lines* denote the predominant frequencies identified in Fig. 36.12

of the effective added mass as also noted for rigid-cylinder VIV. As can be observed in Fig. 36.13, the effective in-line and cross-flow added mass coefficients present large spanwise modulations and differ substantially from the potential flow value of 1.

As also noted in the rigid cylinder case, each excited frequency in the cross-flow direction can be related to an excited frequency in the in-line direction through a ratio of 2. Contrary to the pairs of in-line/cross-flow response frequencies, the corresponding spatial wavenumbers (structural modes) generally exhibit a ratio different from 2; this behavior is expected because of the nonlinear dispersion relation of tensioned beams, relating frequency and wavenumber.

The spectral analysis shows the existence of multi-frequency responses, where different structural modes are excited. At a given spanwise location, several structural wavenumbers can thus contribute to the total vibration. The question that arises is whether the response is instantaneously mono-frequency, with a shifting frequency in time, or it is multifrequency at all times. Typical time series of the cross-flow displacement in a spanwise region where several vibration frequencies exhibit significant contributions is plotted in Fig. 36.14a; the corresponding scalogram, which represent the instantaneous frequency content as a function of time using wavelets, is plotted in Fig. 36.14b. A temporal shift can be noted between frequencies associated with adjacent structural modes. However, if all vibration frequencies are considered, it clearly appears that multiple frequencies, and thus structural modes, can respond simultaneously. As a consequence, VIV of a flexible body can be *instantaneously multifrequency*.

36.2.2 Lock-In and Fluid-Structure Energy Transfer Within Shear Flow

For a freely vibrating rigid cylinder, the lock-in condition, under which energy is transferred from the flow to the structure, is defined as the VIV associated with synchronization between the vortex shedding and the body vibration. This definition can be extended to the case

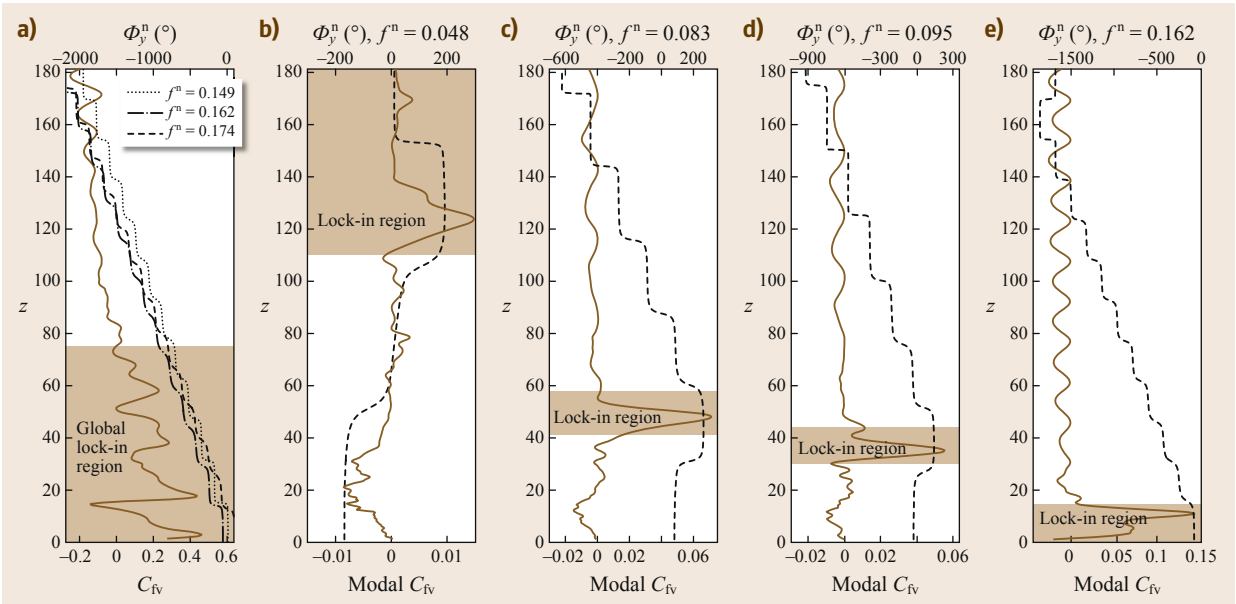

Fig. 36.17a–e Force coefficient in phase with the structure velocity (lower axis, *plain brown line*) and spatial phase of the cross-flow vibration (upper axis, *discontinuous black line*), along the span: **(a)** total c_{lv} and spatial phases of the three predominant vibration components in the narrowband response case, **(b–e)** modal c_{fv} and spatial phase of the vibration components in the broadband response case. The global lock-in region (in **(a)**) and the lock-in region associated with each vibration frequency (in **(b–e)**) are colored in *brown* (after [36.61])

of slender flexible bodies subjected to multifrequency VIV. The lock-in condition is defined at each spanwise location and each cross-flow vibration frequency as the local synchronization between the frequency of body oscillation and the local frequency of vortex formation; otherwise we refer to a nonlock-in condition. The vortex shedding frequency is plotted along the span in the previously considered linear and exponential shear flow cases in Figs. 36.15a,b respectively. The predominant cross-flow vibration frequencies are indicated by vertical dashed lines in these figures.

As also noted for stationary cylinders with varying spanwise conditions, that is, with either varying body diameter or nonuniform velocity profile, the wake exhibits a discontinuous pattern composed of cells of constant vortex shedding frequency [36.70–72]. The decrease of the vortex shedding frequency between two adjacent cells is globally driven by the decrease of the inflow velocity through the Strouhal relation. In the narrow-band response cases (Fig. 36.15a), the lock-in condition occurs over a limited length, on the high-inflow velocity side, while vortex shedding and body oscillation are not synchronized on the rest of the body. In contrast with this *localized* occurrence of the wake-body synchronization, the broadband vibration case (Fig. 36.15b) is characterized by a lock-in condition which is *distributed* along the span. Within a sheared current, the lock-in condition may thus appear simultaneously along most of the structure length, leading to broadband vibrations. As previously observed for rigid cylinder VIV, large deviations from the Strouhal shedding frequency are noted under lock-in. Under the lock-in condition, the wake is generally synchronized with a single structural frequency at each point of the span, even if several vibration frequencies coexist. As a consequence, the lock-in phenomenon remains a locally mono-frequency event, even in the case of broadband structural responses [36.61].

For a better visualization of the wake patterns, instantaneous iso-surfaces of spanwise vorticity downstream of a flexible cylinder subjected to VIV in linear shear flow, at three Reynolds numbers ($Re \in \{110, 330, 1100\}$), are presented in Fig. 36.16. The partitioning of the wake into spanwise cells of constant vortex shedding frequency leads to an oblique orientation of the vortex rows as they form, due to the variation of the vortex convection velocity within each cell. To ensure the continuity of the spanwise vortex filaments while the vortex shedding frequency is discontinuous, vortex splitting events similar to the *vortex dislocations* [36.69, 71, 73, 74] occur between adjacent cells.

As for the rigid cylinder, the transfer of energy between the flow and the oscillating structure is quantified by means of the fluid force coefficient in phase

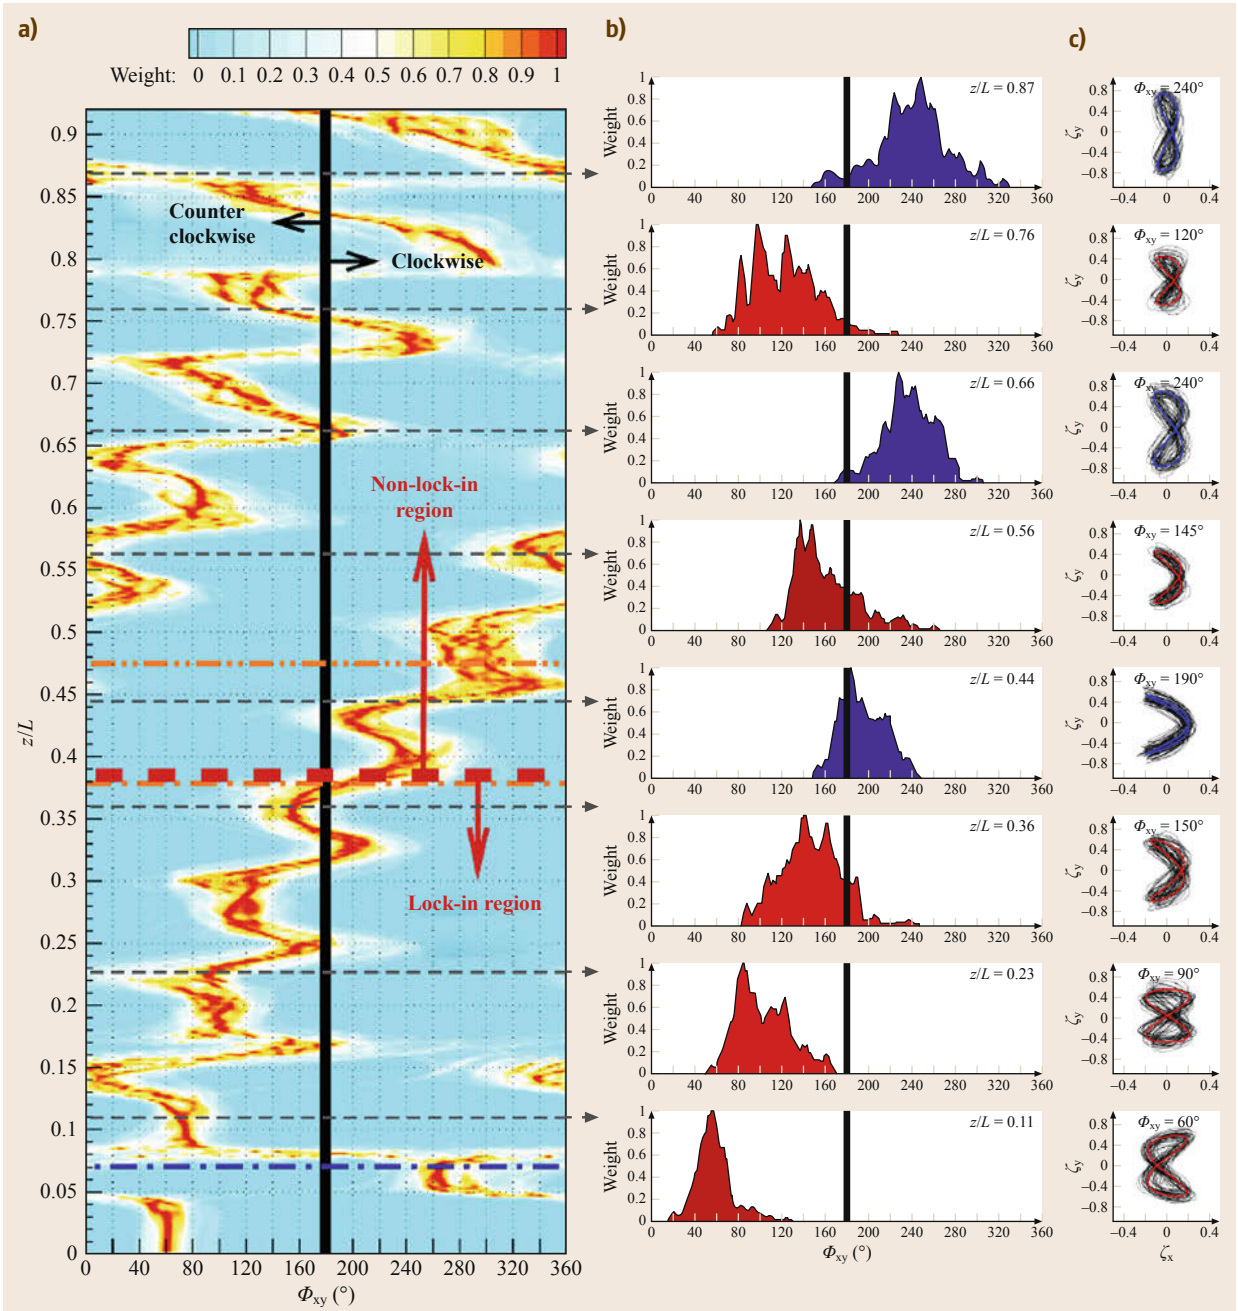

Fig. 36.18a–c Spanwise evolution of the histogram of phase difference between the in-line and cross-flow displacements (Φ_{xy}): **(a)** numerical simulation, **(b)** experiment. In **(a)**, the limit of lock-in region is indicated by a *red dashed line* (simulation); for the experiment, the estimated upper limits are indicated by *orange dashed-dotted* and *dashed-double-dotted lines*, lower limit by a *blue dashed-dotted line*. Locations of measurement points in **(b)** are indicated by gray *dashed arrows* in **(a)**. **(c)** Cross-flow versus in-line displacements. In **(b,c)** histograms and characteristic orbits are colored according to the preferential orientation: counter-clockwise/clockwise in *red/blue* (after [36.68])

with the body velocity. As shown in Fig. 36.17, where the spanwise evolution of this quantity is plotted for cases of narrowband and broadband vibrations, zones of positive energy transfer, that is, where the flow excites the structural vibrations, are located within the lock-in regions. Outside of the lock-in regions, the flow damps the body oscillations. Unlike the narrowband case, for broadband response it can be noted that the excitation zones are distributed along the length of the structure; high-wavenumber vibrations are excited from the high flow velocity side and low-wavenumber responses from the low inflow velocity side. For each excited frequency and regardless of the narrowband or broadband nature of the vibrations, the structural waves travel from the excitation region toward zones of damping, as illustrated in Fig. 36.17 by the orientation of the spatial phases of the waves. As a consequence, a broadband structural response may be composed of waves traveling in both directions, that is, toward decreasing or increasing inflow velocity directions. This behavior contrasts with the narrowband response case where the traveling waves are all oriented from the high to the low inflow velocity regions.

36.2.3 Synchronization of In-Line and Cross-Flow VIV

As in the case of rigid cylinder VIV, the in-line and cross-flow responses of a flexible body are coupled nonlinearly through the fluid forces and their synchronization is closely related to the occurrence of the lock-in condition and therefore to the energy transfer between the structure and the fluid. The in-line and cross-flow vibration components generally exhibit a relative frequency ratio of 2. In the case of mono-frequency responses, this leads to figure-eight trajectories in the plane perpendicular to the body axis, similarly to the rigid cylinder case. The shape and orientation of the figure-eight trajectories are controlled by the phase difference between the in-line and cross-flow displacements. Compared to the rigid body case, the flexibility of the structure allows this phase difference to vary along the span. The difference between the instantaneous phases of the in-line and cross-flow displacements (ϕ_x and ϕ_y respectively) may be evaluated as follows [36.75],

$$\Phi_{xy} = [\phi_x - 2\phi_y, \quad \mod 360^\circ] \,. \tag{36.21}$$

Values of Φ_{xy} in the range 0–180° (180–360°, respectively) correspond to figure-eight orbits where the beam moves upstream (downstream respectively) when reaching the cross-flow oscillation maxima. These two types of trajectories are referred to as *counter-clockwise* and *clockwise*, respectively [36.47].

Examples of spanwise evolutions of the in-line/cross-flow response phase difference issued from numerical simulation and experiment are presented in Fig. 36.18. In both cases, the studied system is composed of a long tensioned beam placed in linear shear flow; the structure exhibits mono-frequency VIV in each direction. A striking phenomenon is that the spanwise region where the lock-in condition is established is dominated by counter-clockwise orbits. Hence in-line and cross-flow vibrations are locked to a specific phase difference range within the lock-in region. The clockwise orbits primarily occur outside the lock-in region and are thus principally associated with damping fluid forces. The mechanism of phase-locking of the vibration components under wake-body synchronization is found to extend to the case of multifrequency VIV, including the case of broadband responses, where both high and low structural wavenumbers are excited: a Fourier expansion of the in-line and cross-flow responses and the association of in-line to cross-flow components with frequencies in the ratio of 2 to 1, allows the identification of a relative phase difference for each such pair; the phase difference angle is contained within the same range, associated with counter-clockwise orbits, as for mono-frequency responses [36.32].

36.3 Experimental Studies and Fatigue Analysis

Several experiments have been conducted to study VIV of flexible cylinders, in a controlled lab environment or in the field. In these tests, structural response at various points along the length of the cylinder is measured using strain gauges or accelerometers. Some of these tests are available online at the MIT VIV data repository [36.76]

The Norwegian Deepwater Programme (NDP) Riser High Mode VIV tests [36.77] are one of the most comprehensive laboratory experiments conducted to study VIV of flexible cylinders. The tests comprise uniform flow cases, where the flow velocity is constant along the riser and varies from $U = 0.3$ to $2.2\,\mathrm{m/s}$ with $0.1\,\mathrm{m/s}$ steps in various test cases; and linearly sheared flow cases, where the flow velocity is zero at one end and increases linearly along the length, with maximum flow velocity varying from $U = 0.3$ to $2.2\,\mathrm{m/s}$ with $0.1\,\mathrm{m/s}$ steps. Physical properties of the riser used in the experi-

Table 36.2 Physical properties of the NDP riser

Outer diameter (D)	0.027 m
Length (L)	38 m
Displaced water/length (m_a)	0.576 kg/m
Mean tension (T)	4000–6000 N
Modulus of elasticity (E)	2.25 GPa

EA	3.322 MN
Weight in seawater	0.1972 kg/m
Weight in air	0.760 kg/m
Density of pipe material	1383 $\mathrm{kg/m}^3$
Effective mean tension	3225 N
Material	Glass fiber
Length	152.524 m

ments are given in Table 36.2. The model riser was taut horizontally and towed at various speeds, producing either uniform flow profiles if the two ends were towed at the same speed, or linearly sheared flow profiles if one end was fixed and the other end was towed. The in-line strain was measured at 40 points along the length, the cross-flow strain at 24 points, and the in-line and cross-flow accelerations at 8 points. There are 8 points along the length with measurements of both strain and acceleration, and in both cross-flow and in-line directions. The experiments were conducted on bare risers as well as risers with varying strake coverage.

Another series of experiments are the Gulf Stream tests [36.30, 78], which were conducted using a composite circular cylinder with properties listed in Table 36.3 [36.78] to observe high mode numbers VIV (modes greater than approximately 10th mode). The experiments were conducted by towing the cylinder from a boat. A railroad wheel was attached at the bottom end of the riser to provide tension. The riser was a simply supported tension dominated one, where universal joints were used at its two ends to create the pinned connections. The oscillations were measured using fiber optic strain gauges. An acoustic Doppler current profiler (ADCP) was used to measure the magnitude and direction of the incident flow profile.

36.3.1 Riser Orbital Motions and Excitation Region

The riser response data are not temporally statistically stationary. However, there are data segments consisting of dozens of cycles which are stationary. For such a stationary segment, the orbital motion of the structure – obtained by plotting the cross-flow oscillations versus the inline oscillations – shows either a figure-eight or a crescent like motion. If the signal is cut into subintervals, each corresponding to one cross-flow and two in-line periods, the direction of motion of the riser orbit for each subsignal can be found by calculating the phase difference between the cross-flow and the in-line displacements. The short period considered in each subsignal makes it possible to assume that the signal is sinusoidal. Therefore, one can assume

$$y = Y \sin(\omega t) \,, \tag{36.22}$$

$$x = X \sin(2\omega t + \psi) \,, \tag{36.23}$$

where ψ can be obtained by measuring the time difference between the cross-flow displacement zero up-crossing (the first point in each subsignal) and the following in-line displacement zero up-crossing (δ). Once this is measured, the phase difference can be calculated as

$$\psi = 2(2\pi/\delta)/(\Delta t) \,. \tag{36.24}$$

Based on the orbit and the calculated phase differences, the motion is characterized as clockwise or counterclockwise; counterclockwise is defined when the riser is at the top of its trajectory and moving upstream with the cross-flow from left to right. For the NDP data cases, the orbital motion of the riser at every point, where acceleration measurements were obtained, was calculated. The counterclockwise figure eight motions are observed mainly in the region with high local flow velocity.

36.3.2 Higher Harmonic Strain and Acceleration Components in Flexible Structures

In many experimental VIV data, if the fundamental frequency of oscillation for the cross-flow strain and acceleration signals is denoted by f_{CF}, a peak at three times this frequency, that is, around $f_{3\mathrm{CF}} = 3f_{\mathrm{CF}}$ is also observed. This is called a higher harmonic component. Higher harmonics are observed in various experimental data [36.79, 80].

As an example, Fig. 36.19 shows a sample PSD plot for an acceleration signal of one of the uniform flow cases with $U = 1.3\,\mathrm{m/s}$ from the NDP data. The fundamental frequency is at $f_{\mathrm{CF}} \simeq 7\,\mathrm{Hz}$, which is in the neighborhood of the expected Strouhal shedding frequency, $f = U\mathrm{St}/D \simeq 8\,\mathrm{Hz}$. A large third-harmonic peak exists at $f_{3\mathrm{CF}} \simeq 21\,\mathrm{Hz} = 3f_{\mathrm{CF}}$ and a rather smaller one at $f_{5\mathrm{CF}} \simeq 35\,\mathrm{Hz} = 5_{\mathrm{fCF}}$. The main frequency in the in-line direction is around $f_{\mathrm{IL}} = 2f_{\mathrm{CF}}$, as expected. The

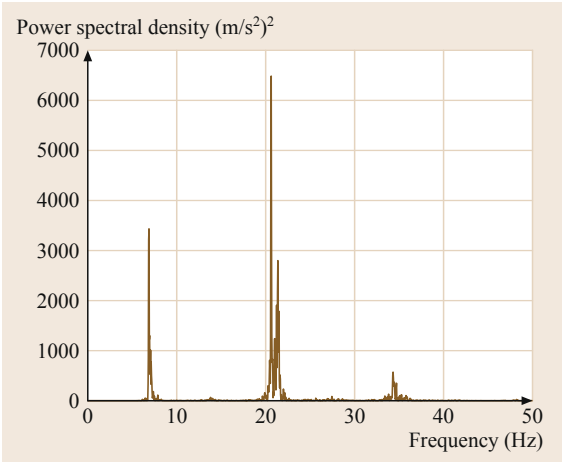

Fig. 36.19 A typical PSD plot of a measurement point with a large peak at the third harmonic (around 21 Hz) and a small peak at the fifth harmonic (around 35 Hz) (after [36.80])

contribution of higher harmonic components in the transverse direction is determined by evaluating the ratio of the area under the higher harmonic peak in the PSD plot over the total area under the PSD. For example, in Fig. 36.19, if the areas under the third-harmonic and the fifth-harmonic peaks are denoted by A_3 and A_5, respectively, then the ratios A_3/A_{Total} and A_5/A_{Total} are the measures of the relative importance of these higher harmonic components, where A_{Total} is the total area under the PSD.

For the NDP uniform current cases, a third-harmonic component of around 0.5 (50%) is widely observed. For linearly sheared cases, the third-harmonic contribution is mainly around 30–40% with some exceptional points where a relatively large contribution of up to 80% is observed. The influence of a third harmonic of around 0.3 (30%) on fatigue life is enough to be nonnegligible. For the fifth-harmonic components a contribution of mainly 15–20% is observed both for the uniform and the linearly sheared cases, with some cases of the fifth harmonic up to 30%.

36.3.3 Periodic (Type-I) and Chaotic (Type II) Signals

The riser response data are not always statistically stationary; in fact, the VIV of long flexible risers are characterized by time intervals of chaotic response, followed or preceded by periods of statistically stationary response. Regions of chaotic response contain distinctly different response features and have significant implications on riser fatigue analysis. While regions of statistically stationary response are characterized by nearly mono-frequency traveling waves, with small standing wave contributions, near the ends of the riser, and possibly accompanied by sharply peaked third- and fifth-force harmonics, the chaotic response is characterized by a wide-band spectrum with several individual peaks and a mix of traveling and standing waves.

Figure 36.20a shows the time history of a rare case which was specifically selected to exhibit the statistically stationary response that is typically assumed to occur. Figure 36.20b shows a more commonly occurring response, exhibiting features of a chaotic signal.

Using experimental data of VIV of long flexible cylinders, three types of VIV behavior are observed:

i) Cases where the entire signal is mainly quasi-periodic
ii) Cases where the signal exhibits quasi-periodic oscillations interrupted by bursts of chaos
iii) Cases where the entire signal is chaotic and even the smallest subsignals confirm chaotic features.

Focusing on the Strouhal region of the response spectrum gives adequate results for the statistically stationary response, if the higher harmonics are also accounted for, but it is inadequate for the chaotic response, whose fatigue properties are influenced by the entire broad-band spectrum. It is remarkable that both sheared and uniform current profiles cause both quasi-periodic and chaotic responses. Chaotic oscillations are

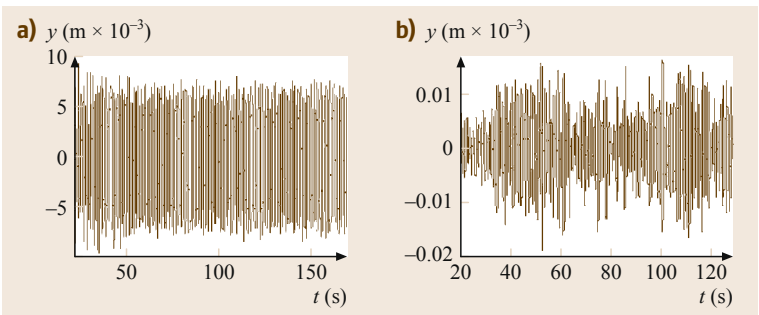

Fig. 36.20a,b The entire signal at **(a)** point 1 ($z \simeq 4$ m), case 2310 of the NDP data, with a linearly sheared flow profile, $U_{\max} = 0.3$ m/s, showing steady-state VIV behavior, which is rare in practice; **(b)** point 1 ($z \simeq 4$ m), case 2320 of the NDP data, a linearly sheared flow case, showing chaotic response, a commonly found VIV behavior in field tests (after [36.81])

observed not only at various intervals of time, but also at various locations of the riser, and both for the uniform and linearly sheared flow cases.

36.3.4 Response Reconstruction Using Experimental Data

Response measurements are conducted at some points along the length of a flexible structure, typically using strain gauges and accelerometers. A continuous VIV response can be reconstructed using data from limited number of sensors placed along its length. When the number of sensors (N_s) is sufficient (namely, $N_s \geq N_m + 1$, where N_m is the number of spatial harmonics), the problem of reconstructing the riser VIV response can be posed as a spatial Fourier decomposition. The displaced shape of the riser at any instant of time is written as a spatial Fourier series. The reconstruction problem is posed as a system of linear equations, where the unknown spatial Fourier coefficients at every instant of time are evaluated. Since the number of sensors is larger than the critical number, this is an over-determined system of linear equations. This system is solved using a pseudo-inverse method, where the least-squares error is minimized. This method allows estimation of the continuous motion of the riser (at every point along its length) and therefore fatigue life estimation is not limited to only the measurement points [36.82]. There are three main sources of uncertainties in this reconstruction method:

1. Uncertainty due to the presence of noise in experimental data
2. Uncertainty due to the use of limited number of sine and cosine terms, and
3. Uncertainty due to the presence of both acceleration and strain measurements.

Due to these uncertainties, the amplitude of reconstructed response at every point along the length will have an upper bound and a lower bound.

36.3.5 Fatigue Calculations

In order to calculate fatigue damage of the riser an S-N curve of the form $N = A(1/S)^B$ is used, where N is the number of cycles, S is stress in MPa, and A and B are constants, depending on the material. For the riser used in the NDP tests, these parameters are $A = 4.8641 \times 10^{11}$ and $B = 3.00$ [36.83]. Fatigue damage calculations are conducted based on rainflow fatigue prediction method [36.84].

The Influence of Higher Harmonics on Fatigue Damage

In the NDP experimental cases, higher harmonic components of strain and acceleration are significant. Fatigue damage calculations, by taking into account the higher harmonic components, give fatigue damage values of up to one order of magnitude larger than those calculated based on only first-harmonic signals. Two examples of uniform and linearly sheared NDP cases are discussed in what follows.

Fatigue calculations can be conducted using the measured signals directly. Using the unfiltered signals, the most realistic fatigue damage can be calculated. These are shown by triangles in Fig. 36.21 for two sample cases of NDP data. Using the signals filtered around their fundamental frequency, a smaller fatigue damage is calculated (circles shown in Fig. 36.21), since the influence of higher harmonic components is not considered. These points can be compared with the continuous line which is fatigue damage calculated based on the reconstructed (and therefore purely first harmonic) signals. The limits due to uncertainties arising in reconstruction procedure are shown by thin lines. Once the fatigue damage is calculated using the purely first-harmonic signal, the following procedure can be used in order to estimate a more realistic fatigue damage. Assuming a worst case scenario in which the magnitude of the total stress is equal to the summation of the magnitudes of the stress due to each of the harmonics, the total stress is written as

$$S_T = S_1 + S_3 + S_5 \tag{36.25}$$

or

$$S_T = S_1(1 + H_3 + H_5)\,, \tag{36.26}$$

where, S_1, S_3, and S_5 are magnitudes of the first, third- and fifth-harmonic stress, respectively and are not functions of time, and H_3 and H_5 are the higher harmonic components calculated using the unfiltered signals. Therefore the life can be predicted as $N = A(1/S_T)^B$. The asterisks in Fig. 36.21 show the estimated fatigue damage following this procedure for the measured signals. These values can be compared relatively well with the damage predicted using the unfiltered signals. In this method, it is assumed that the amplitude of the third-harmonic stress is equal to H_3 times the amplitude of the first-harmonic stress, and H_3 is a time-averaged value over the entire time. The use of these time-averaged higher harmonic coefficients leads to the differences between estimated (asterisks) and actual (triangles) fatigue life values shown in Fig. 36.21.

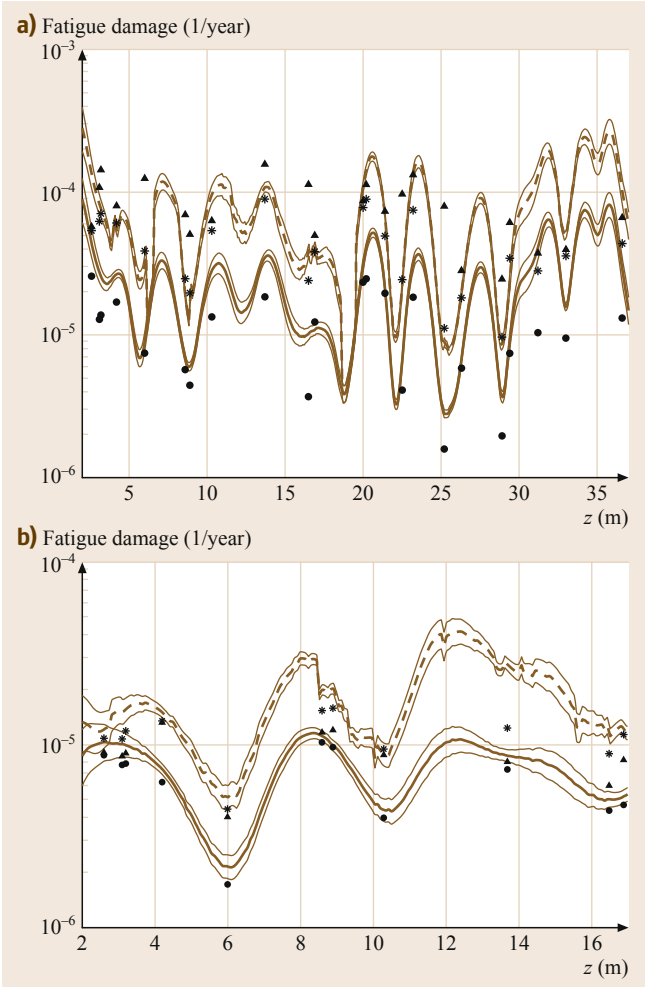

Fig. 36.21a,b Fatigue damage for two sample NDP cases of **(a)** uniform and **(b)** linearly sheared flow. Values are calculated based on purely first-harmonic reconstructed cross-flow (CF) motion (*continuous line*), and based on the first, third and fifth harmonics using higher harmonic predictions of the forced database (*dashed line*), while the *thin lines* correspond to the limits due to uncertainties arising in reconstruction procedure; direct fatigue calculations are conducted using the measured CF strain signals based on: only the first harmonic (•); the first, third, and fifth harmonics (∗); and the unfiltered signal (△)

This method can also be applied to the reconstructed response; in this case H_3 and H_5 are estimated using the rigid cylinder database. The dashed lines in Fig. 36.7 are the resulting fatigue damage calculations, while the thin lines around them show the limits due to uncertainties in the first-harmonic response reconstruction. It can be observed that the maximum fatigue damage is around 3.3×10^{-4} years^{-1} at $z\simeq 35$ m for the uniform case of Fig. 36.21a, while if one is limited to using the filtered signals and only at the measurement points, the maximum damage is calculated as 0.2×10^{-4} years^{-1} at $z\simeq 20$ m. The interesting fact about the predicted critical fatigue damage is that it occurs at a point where no measurement point is available ($z\simeq 35$ m). Similar observation can be made for the linearly sheared case of Fig. 36.21b. The critical fatigue damage is predicted as 3.3×10^{-5} years^{-1} at $z\simeq 12$ m, where the filtered measurement points would give 1×10^{-5}*years*$^{-1}$ at $z\simeq 9$ m.

Influence of Chaotic Signals on Fatigue Damage

If a chaotic signal is approximated through an *equivalent* periodic signal containing primarily the Strouhal frequency, as is often the practice in semi-empirical methods, fatigue life calculations seriously underpredict the fatigue damage.

Chaotic signals have relatively small third- and fifth-harmonic components. As an example, the third-harmonic component of the strain for case 2480 of the NDP data, a sheared flow case with $U_{\max}=2$ m/s, is 0.05 of the total strain. One could then argue that because this is a negligible higher harmonic component, one can consider only frequencies near the Strouhal frequency. If this is done, however, the resulting fatigue life will be over-predicted by 70%, as the filtered strain provides a fatigue life of 13.7×10^4 years, while the actual fatigue life is 4.1×10^4 years. Hence, in general, it is not safe to use the filtered part of the strain (around the Strouhal frequency) in order to calculate fatigue life, even when higher strain harmonics are small, because the signal might be chaotic. The difference between fatigue life calculated using a filtered VIV signal and the actual fatigue life is large when the signal is chaotic, mainly because the spectrum is broad-band.

36.3.6 VIV Prediction Tools

The most widely used methods for predicting the riser VIV are semi-empirical prediction programs, such as VIVA [36.29], SHEAR7 [36.85], and VIVANA [36.86]. Such programs typically consist of two parts:

1. A fluid–structure interaction model, and
2. Laboratory-derived or empirical databases, often adjusted to account for scale effects, as a result of comparison with full scale or pilot scale studies.

The fluid–structure interaction model consists of a fluid force model and the equations of structural dynamics.

The hydrodynamic databases primarily contain hydrodynamic information in the form of the lift force

coefficients (lift coefficient in phase with velocity and added mass coefficient) and drag coefficients. These force coefficients are often obtained from extensive laboratory experiments using rigid cylinders. It is a common practice [36.29] to use a strip theory approach to subdivide the flexible structure into small segments, which act similar to a series of interconnected, elastically mounted rigid cylinders, and estimate the vortex-induced forces on each of these segments: the excitation force in phase with velocity and the excitation force in phase with acceleration. As shown by *Triantafyllou* and *Grosenbaugh* [36.58], estimating these forces requires databases of added mass coefficient and lift coefficient in phase with velocity. From a structural dynamics viewpoint, the structure is adequately modeled as a tensioned beam with appropriate boundary conditions, acted upon by the external hydrodynamic forces induced by the forming vortical structures.

The available extensive databases used in VIVA were obtained in the MIT Towing Tank [36.87] and in high Reynolds number (supercritical regime) experiments at Memorial University in Newfoundland [36.35]. The lift coefficients and added mass coefficients are functions of reduced velocity and amplitude of response. The databases were obtained (i) at a Reynolds number around 10 000, and (ii) for cylinders undergoing harmonic motion at a single frequency and restricted to the cross-flow direction only.

To overcome these limitations, *Mukundan* et al. [36.82] developed a systematic method to extract information from field and experimental data from risers and update the existing databases. A formal procedure to optimize this process was discussed by *Mukundan* et al. [36.82] and a heuristic method, whereby a small number of parameters were allowed to vary, was used by *Chasparis* et al. [36.88].

36.4 Effectiveness of Vortex Canceling Devices

As we have seen in the previous sections, the effects of VIV on long slender structures may include significant fatigue damage to the structure due to regular oscillations as well as increased static loading on the structure due to amplification of the mean drag coefficient. These problems can lead to structural failure or unacceptable deflections of risers for offshore operations; hence in many cases, it is desirable to cancel VIV altogether. Vortex cancellation devices are designed with the purpose of addressing three main issues associated with VIV: (1) oscillatory motions, (2) increased drag coefficient, and (3) possible omni-directionality of the flow. In designing vortex cancellation devices, it is therefore desirable for devices to reduce the amplitude of vibratory motions, have a low drag coefficient, and be capable of handling changing directionality of the flow.

Vortex cancellation devices are used to inhibit VIV by either reducing the magnitude of oscillatory forces on the body, or by reducing the correlation of forces along the length of the body, or, finally, by avoiding separation on the body altogether. Vortex cancellation devices may be divided into two subgroups: passive devices and active devices. Passive devices do not require any energy input and are either stationary alterations to the shape of the body or passive structures that align to the oncoming flow, as reviewed in [36.3, 6]. Examples of passive cancellation devices include strakes and fairings.

In contrast, active suppression devices require energy input to control vortex formation. The devices may involve momentum injection into the boundary layer or active manipulation of the body surface. Since most active control devices are expensive to implement in practice, they are not typically found in use on large scale ocean structures. We will therefore focus primarily on passive cancellation devices, which have widespread use in industry.

36.4.1 Helical Strakes

A strake is a triangular, rectangular, or trapezoidal protrusion attached to the surface of a cylinder and wrapped along the length of the cylinder in a helix. Strakes are often implemented in a triple helix form, where three strakes are wrapped along the length of the cylinder. Effective VIV suppression occurs for triple strakes with pitch to diameter ratios in a range between 15 and 17; single strakes are effective with pitch ratio close to 5. It is interesting that accounting for a triple strake configuration, the effective pitch to diameter ratio is in a range between 5 and 6. The height of the strake must be sufficiently high to extend past the boundary layer on the cylinder. A height to diameter ratio of 0.15 has been observed to be effective at suppressing VIV.

Strakes do not suppress vortex shedding, but rather define a sharp separation point for which vortex shedding will occur. By implementing the strake in a helical pattern along the length of the cylinder, the strake provides this clear separation point at different angular positions along the length of the cylinder. At any

given cross-section, the phasing of vortex shedding will be slightly different than the phasing at different span locations on the cylinder. This alteration of the vortex shedding phasing leads to uncorrelated oscillatory forces along the length of the cylinder, reducing the amplitude of the oscillatory forces. The resulting response of the body may be significantly reduced with appropriate orientation of the strakes.

Although strakes may be extremely effective at reducing the vibrational response cylindrical structures, this reduction in vibration amplitude comes at a cost of increased drag. As mentioned previously, a vibrating cylinder will experience an increased mean drag coefficient due to the large wake deficit behind the oscillating structure. Since strakes significantly reduce the oscillation of the structure, the wake deficit is less than the deficit observed when the structure is oscillating. However, due to the presence of the protruding strakes on the cylinder, the wake deficit is still larger than if the cylinder were stationary in the flow with no strakes. For example, a flexible cylinder at subcritical flow speeds oscillating due to VIV with a maximum oscillation amplitude around one diameter may experience a mean drag coefficient between 1.8 and 3, depending on the shear in the flow. The same cylinder held stationary in the flow would experience a drag coefficient of 1.2, while the equivalent cylinder, outfitted with strakes with height equal to 25% of the diameter, oscillates little but incurs a drag coefficient around 1.7. This increased drag coefficient may be undesirable in certain operating conditions, hence strakes are not always suitable for VIV suppression.

Strakes are characterized by reduced excitation lift forces in phase with velocity [36.31], which can be modeled in semiempirical codes to provide predictions of straked or partially straked risers [36.89].

36.4.2 Fairings

A fairing is a streamlined, usually foil-shaped fitting that surrounds the cylinder. It works by alleviating the adverse pressure gradient on the downstream side of the body, reducing the possibility of separation and eliminating the formation of large scale correlated vortex structures in the wake of the body; substantial reduction in drag coefficient is also obtained.

Since a fairing is effective only if aligned with the flow velocity, it must be free to rotate, otherwise it can cause severe problems such as kiting or galloping. For example, a fairing on a towed cable may become stuck if the cable is curved and hence become ineffective. When the fairing is not aligned with the flow, steady lift develops, causing the cable to deviate in the cross-flow direction, in what is called *kiting*. At the same time, the drag force can increase substantially on the fairing, while a torque moment develops that can twist the cable.

The unsteady lift and torque caused by a misaligned fairing can induce galloping under certain conditions. The asymmetry in the streamlines around the misaligned fairing can cause increased force and moment as the cable vibrates; the positive feedback can result in large amplitude vibrations above a critical speed that depends on the structural damping, or galloping, that can lead to catastrophic failure of the structure. Galloping, which is not self-limiting, occurs at much lower frequencies than in self-limiting VIV.

36.4.3 Other VIV Suppression Devices

In addition to strakes and fairings, *Zdravkovich* [36.3] compiles data on several passive VIV suppression devices. One group of devices includes helical grooves made along the length of the body to achieve a similar result to applying extruding strakes. Helically wound cables are also presented as a variation on the strake as the cable itself acts as a helical protrusion on the body.

Zdravkovich [36.3] presents several other suppression devices including devices where small cylinders are attached to a the larger main cylinder. Appropriately placing a small control cylinder near the main cylinder has been shown to alter the fluid momentum in the wake of the large cylinder, leading to unseparated flow under the right placement conditions of the control cylinder [36.90]. Similar to the placement of control cylinders, *Grimminger* [36.91] tested various arrangements of vanes on a cylinder to redirect flow in the wake of the cylinder. These vanes were found to eliminate VIV and reduce drag, however they still required a directional orientation to the flow direction. More recently, *Galvao* et al. [36.92] tested various combinations of attached foil sections near a cylinder for redirecting flow in the wake of the cylinder.

Zdravkovich [36.3] also introduces shrouds as possible VIV suppression devices. A shroud is an outer covering that may include a pattern of holes to allow fluid to pass through the shroud and around the cylinder. Various percentages of hole distribution lead to varying effectiveness of the shroud in suppressing VIV. Additional variations on VIV suppression devices include splitter plates, ribbon fairings, haired fairings, and open channels that allow fluid to pass through the cylinder. These devices work with a variety of success dependent on the orientation and flow conditions [36.93].

Other active and passive means to decorrelate vortex shedding by introducing periodic variations along the span of a cylinder, such as in [36.94–99], have

proved effective in reducing the mean drag force by about 20% and the unsteady lift force significantly, for certain parametric combinations. *Lee* and *Nguyen* [36.100] note that when the wavelength to mean diameter ratio, λ/D_m is close to 2, their effectiveness is maximized. *Lam* et al. [36.96] noted that there is a second optimal value of $\lambda/D_m = 6$, which provides even better performance. The effectiveness of the spanwise undulations is attributed to the formation of an undulating wake, which decorrelates the induced forces, as well as the formation of streamwise vortices. The latter value, $\lambda/D_m = 6$, agrees with the reported optimal wavelength to diameter ratio for strakes, which is around 5 for single strakes, and between 15 and 17 for triple start strakes, that is, effectively, between 5 and 5.6.

36.5 Multiple Interfering Bluff Bodies

Cylinders with parallel axes placed in a cross-flow are subject to wake interference phenomena. This problem arises in many applications, such as arrays of offshore risers, multiple mooring lines, and power transmission lines. For nonoscillating cylinders, distinct flow regimes exist, which depend on the axial and transverse separation distance to diameter ratios [36.101–103]. For small axial separation to diameter ratios, s, below typically 2.5 [36.104], the reattachment of the leading cylinder's shear layer to the trailing cylinder can lead to bistable gap flows. Quasi-steady recirculation cells, with coupled vortex formation, occur for larger separation ratios, up to 4, while vortex roll-up from the leading cylinder occurs for distance ratios higher than 4, where such coupling is diminished.

For forced vibrations of two tandem cylinders, a wake lock-in exists for the extreme motion phase angles of zero and 180°, and lock-in of the wake to the motion occurs over a dramatically expanded region of amplitude and frequency, for small values of s [36.105]. In tests where both cylinders are compliantly mounted, large-amplitude vibrations of both cylinders can occur when the separation ratio is about 5–7, and for lateral offset ratio up to 1.5 [36.102]. The vibrations are limited to a specific range of reduced velocities, typically beginning at lower values than for a single cylinder. *Bokaian* and *Geoola* [36.106] considered the case of a fixed leading cylinder, and a compliantly mounted trailing cylinder and find initially a vortex-induced region, occurring over a specific range of reduced velocities, and then galloping instabilities, where motions persist for high reduced velocities. These two types of responses can occur independently or can overlap, depending on the separation distance.

The wake frequency behind the leading cylinder is typically unaffected by the proximity to the trailing cylinder, but the wake of the trailing cylinder exhibits a lower Strouhal frequency, consistent with reduced mean flow due to shielding effects. Hence, frequency lock-in occurs at a higher value than for a single cylinder [36.107]. *Hover* and *Triantafyllou* [36.108] considered compliantly mounted cylinders in Reynolds number 3×10^4, finding vibratory response of the trailing cylinder up to separation ratios of 17.

Assi et al. [36.109] showed that the galloping-like response is caused by a physical mechanism that they call *wake stiffness*, a spring-like restoring force caused by the impinging vortical structures from the upstream to the downstream cylinder. The mechanism explains well the observed behavior of the downstream cylinder.

36.6 Effect of Reynolds Number

The Reynolds number, Re, has a significant effect on the Strouhal number and drag coefficient of a fixed smooth cylinder in a cross-flow only over two regions: First, at low Re, below typically 1000, when the first instability occurs at $Re = 56$ leading to the formation of the Karman street, and then the secondary instabilities appear starting at around $Re \approx 250$ leading to turbulence in the wake. Second, in the *critical* Reynolds number regime, which starts at around $Re \approx 250\,000$, where the transition of the boundary layer at the flow separation points transitions from laminar to turbulent flow, affecting substantially the location of the separation points and the vortex formation process in the wake. The drag coefficient undergoes a dramatic drop from around $c_d = 1.2$ to $c_d = 0.25$, in what is termed the *drag crisis*. The drag recovers from these low values, as Re increases, reaching a value of around $c_d = 0.7$ for $Re \approx 10^6$, where the critical regime ends. Outside these ranges, the effect of Re is gradual and at most moderate.

Similarly, when a cylinder is allowed to oscillate transverse to the flow direction or with combined cross-flow and in-line motion, the Reynolds number plays an important role in the development of the boundary layer and separation points on the dynamically moving cylinder. Recent studies have shown that at subcritical Reynolds numbers, Re affects the fluid forces exerted

on the body by altering wake state transitions. Small variations in the shedding point on the surface of the cylinder can significantly alter the phasing of vortex shedding in the wake with respect to the cylinder motions [36.110].

Since the phasing of vortex shedding may be altered slightly for subcritical Reynolds numbers, this alteration leads to a change in the forces exerted on a cylinder, leading to changes in the resulting cylinder motions. For subcritical Reynolds numbers, it has been observed that unsteady lift force magnitudes increase with increasing Reynolds number, resulting in increased cylinder motions [36.111]. *Govardhan* and *Williamson* [36.111] estimate limits of the response amplitude for an oscillating cylinder at various subcritical Reynolds numbers based on the mass-damping characteristics of the system. It has also been shown that for cross-flow free vibrations, the maximum amplitude of oscillation is purely a function of system damping and the Reynolds number [36.112].

Few experimental data exist for VIV at critical and supercritical Reynolds numbers. For a freely oscillating cylinder in cross-flow, it has been observed that a cross-flow response in excess of two diameters may be achieved at the beginning of the critical Reynolds number regime [36.34]. These large amplitude motions at the onset of the critical Reynolds number regime have been observed even in cases with large mass-damping [36.113]. The use of roughness on the cylinder surface to influence the boundary layer and hence cause effects similar to those observed in the critical regime, can spark large amplitude motions at different Reynolds numbers as well [36.114]. Well within the critical Reynolds number regime, a smooth cylinder exhibits very small VIV; however, introducing even small amounts of roughness or external stream turbulence alters this condition, leading to substantial VIV. Hence, the exact VIV response shape in the critical regime is highly dependent on the surface roughness of the body [36.34].

At supercritical Reynolds numbers, cross-flow VIV is always present with an amplitude of response smaller than in the subcritical region, not exceeding 0.9 diameters. When combined in-line and cross-flow oscillations of a circular cylinder occur, similar trends are observed, that is, the amplitude of body oscillations is observed to be smaller than for a comparable system at subcritical Reynolds numbers [36.35]. Although motions are slightly smaller due to Reynolds number effects, it must be noted that the resonant phenomenon of lock-in still occurs, such that the same dynamic relations between vortex shedding and body motion occur at supercritical Reynolds numbers as those observed at subcritical Reynolds numbers.

37. Structural Dynamics

H. Ronald Riggs, Solomon Yim

This chapter presents the basics of structural dynamics theory that is especially relevant to dynamics of flexible ocean structures. The primary focus herein is on linear structural dynamics, but the extension to nonlinear systems is also discussed. Section 37.1 introduces the single-degree-of-freedom, spring-mass-damper system. The equations of motion in the time and frequency domains are given, viscous and hysteretic damping models are discussed, and general solutions are provided. Topics of particular interest to ocean structures are discussed, followed by a discussion of numerical schemes for time-domain response. The generalization of these concepts to multi-degree-of-freedom systems is covered in Sect. 37.2. Hydroelasticity involves coupling the multi-degree-of-freedom, flexible structural model with the fluid model, such as used in Chap. 35, to obtain the coupled fluid–structure response. This is discussed in Sect. 37.3, in which the concepts of added mass and hydrodynamic damping are extended to the flexible structural model. Section 37.3.6 discusses the linear response to regular waves, and Sect. 37.4 extends this to random seas. Nonlinear hydroelasticity, viz. fluid–structure interaction, and corresponding solution strategies are discussed briefly in Sect. 37.5.

37.1 **Single Degree-of-Freedom System** 852
37.1.1 Equation of Motion 852
37.1.2 Response in the Time Domain – Free Vibration 854
37.1.3 Response in the Time Domain – Harmonic Loading 854
37.1.4 Response in the Frequency Domain 856
37.1.5 Structural Damping 856
37.1.6 Time Domain Response from Frequency Domain Response 858
37.1.7 Fluid Contribution 858
37.1.8 Nonlinear Systems 860
37.2 **Multi-Degree of Freedom Systems** 861
37.2.1 Equations of Motion 861
37.2.2 Modal Superposition 862
37.2.3 Numerical Time-Domain Solution 863
37.3 **Linear Hydroelasticity for Inviscid Fluid Flow** 864
37.3.1 Finite Element Structural Modeling 864
37.3.2 Hydrostatic Stiffness 864
37.3.3 Added Mass, Damping, and Exciting Forces 865
37.3.4 Reduced Basis Solution 865
37.3.5 Mapping from Structural Mesh to Fluid Mesh 866
37.3.6 Linear Response to Regular Waves – RAOs 866
37.3.7 Time-Domain Response 867
37.4 **Linear Response to Random Seas** 867
37.4.1 Specification of Long-Crested Random Seas 867
37.4.2 Specification of Short-Crested, Directional Random Seas 868
37.4.3 Response in Random Seas 869
37.4.4 Estimation of Extreme and Fatigue Response in Random Seas 869
37.5 **Nonlinear Hydroelasticity (Nonlinear FSI)** 870
37.5.1 Nonlinear Frequency Domain Analysis 871
37.5.2 Nonlinear Time-Domain Analysis 872
References 873

Although the basics of structural dynamics are covered, it is a rich topic and many books delve into it far more deeply than can be done here. A brief survey of some references is provided, as they may be useful for more detailed study (as well as providing a historical sense of the development of structural dynamics). One of the first books on the general topic of structural dynamics was [37.1]. It covered basic

linear elastic problems including linear vibrations of single-degree-of-freedom (SDOF) and multi-degrees-of-freedom (MDOF) discrete systems, as well as continuous systems. A much later edition added coverage on vibrations of rings, membranes, and plates [37.2]. In addition to the foundations of the structural dynamics of discrete and continuous systems, *Thomson* [37.3] covered nonlinear and random vibrations. An introduction to the application of the finite element method (FEM) to structural dynamics was added in later editions [37.4, 5]. *Hurty* and *Rubinstein* [37.6] covered the energy differential equation and integral equation methods. They also covered in detail nonproportional damping and response to random excitations. An even more detailed treatment of the dynamics of SDOF and MDOF discrete systems and continuous systems can be found in [37.7].

Structural response to earthquakes (seismic response) is an important application area for structural engineering. Starting in the 1970s, structural dynamics books began to cover this application. Specifically, *Clough* and *Penzien* [37.8, 9] provide an excellent introduction to structural dynamics, including random vibrations and seismic response. The work of *Chopra* [37.10], which first appeared in 1995, is a more specialized introduction to structural dynamics as it relates to seismic response of structures. *Tedesco* et al. [37.11] cover earthquake and blast loads and also some content related to the dynamics of ocean structures.

For a more offshore structure focus, *Brebbia* and *Walker* [37.12] present the fundamentals of random seas, forces on slender members, and diffraction problems for SDOF and MDOF discrete structural systems. *Hooft* [37.13] describes fluid motion and properties and hydrodynamic excitation forces, and covers motions of linear and nonlinear SDOF and MDOF systems. *Wilson* [37.14] provides detailed descriptions of deterministic and stochastic ocean waves, applications to SDOF and MDOF structural systems including pile foundation supports, fracture mechanics, and fatigue behavior of offshore structures. Books that focus on hydrodynamic loading include [37.15, 16]. *Chakrabarti* [37.17–20] contributed significantly to the topic of dynamics of offshore structures via a series of books. [37.17] covers hydrodynamics of offshore structures focusing on fluid loads and effects. [37.19] provides an in-depth description of physical modeling of offshore structures in large-scale wave laboratory experiments. He followed up with another book [37.20] that describes the theory and practice of hydrodynamics and vibration, which provides an excellent synopsis of the two topics. Nonlinear behavior of ocean structures is a challenging topic. Because ocean waves are inherently stochastic, random vibration behavior has to be included. [37.18] describes the short and long-term stochastic characteristics of wind, wave and current, and the corresponding motion responses of nonlinear offshore structures. For a detailed summary on the behavior of stochastically excited nonlinear ocean structures, see [37.21].

37.1 Single Degree-of-Freedom System

37.1.1 Equation of Motion

The spring-mass-damper system in Fig. 37.1a is a schematic of the classic single-degree-of-freedom (SDOF) system used to introduce structural dynamics. The SDOF classification means that there is a single variable $u(t)$ that uniquely and completely describes the motion of the mass, which as indicated is restricted to move in one direction only. The velocity $\dot{u}(t)$ and acceleration $\ddot{u}(t)$ follow. The spring represents the structural restoring forces, the structural stiffness; these forces f_r are principally a function of displacement. However, if f_r is a multi-valued function of u, then it will also depend on the history of the displacement (path dependence) and potentially on $\dot{u}(t)$. Energy dissipation is represented by the damper, and the force that the damper applies to the mass is denoted f_d. In the most common formulations in the time domain, the damping force is assumed to depend on the velocity, although it is possible that it may depend on the displacement as well. The excitation depicted in the figure is an applied external force $p(t)$. Figure 37.1b is a free-body diagram of the system. Unless otherwise noted, the discussion below will refer to this system.

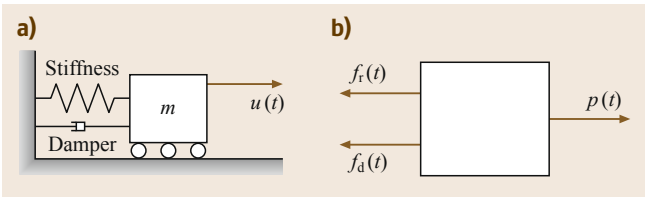

Fig. 37.1 (a) Spring-mass-damper system and (b) free-body diagram

The equation of motion in the time domain follows directly from Fig. 37.1b and Newton's second law; specifically, the sum of the external forces is equal to the change in momentum. Generally, in problems in

structural dynamics the mass does not vary with time. Therefore, the equation of motion can be written fairly generally as

$$p(t) - f_d - f_r = f_I \,, \tag{37.1}$$

in which f_I represents the product of mass and acceleration. In structural dynamics, the equation is more often written as

$$f_I + f_d + f_r = p(t) \,, \tag{37.2}$$

and f_I is referred to as the inertia force à la d'Alembert's principle. The equation can then be interpreted as the sum of the *internal* resistive forces is equal to the sum of the external forces. This gives rise to the concept of *dynamic equilibrium*, which is frequently used in structural dynamics.

Equation (37.2) covers both linear and nonlinear systems. A linear system requires a linear spring, such that $f_r(t) = ku(t)$, in which the constant stiffness k has units of force per unit displacement. It also requires a linear dashpot, such that $f_d(t) = c\dot{u}(t)$, in which the damping constant c has units of force per unit velocity. For a system with constant mass m, $f_I(t) = m\ddot{u}(t)$, where m has units of mass, or force per unit acceleration. The equation of motion becomes

$$m\ddot{u}(t) + c\dot{u}(t) + ku(t) = p(t) \,. \tag{37.3}$$

Note that this discussion assumes linear viscous damping; as discussed subsequently, an alternative damping model may be more convenient for ocean structures.

The above form assumes that the dynamic excitation of the structure is a result of an externally applied dynamic force. It is also possible that the excitation is a result of support motion instead, such as from earthquake ground motion. In Fig. 37.1a, let $p(t) = 0$ and assume that the support undergoes a *ground* displacement $u_g(t)$ and associated acceleration $\ddot{u}_g(t)$. The total displacement of the mass can be written as the sum of a rigid body motion $u_g(t)$ and the motion relative to the ground, $u(t)$. The inertia force depends on the total acceleration, but the structure's resistive forces f_r and f_d depend only on the relative motion. The linear equation of motion (37.3) can then be written as

$$m\ddot{u}(t) + c\dot{u}(t) + ku(t) = -m\ddot{u}_g(t) \,. \tag{37.4}$$

The term $-m\ddot{u}_g(t)$ can be viewed as an effective load. Note that the equation is written in terms of relative motion, and if commercial software is being used, the user should understand whether the relative displacements or the total displacements are being reported.

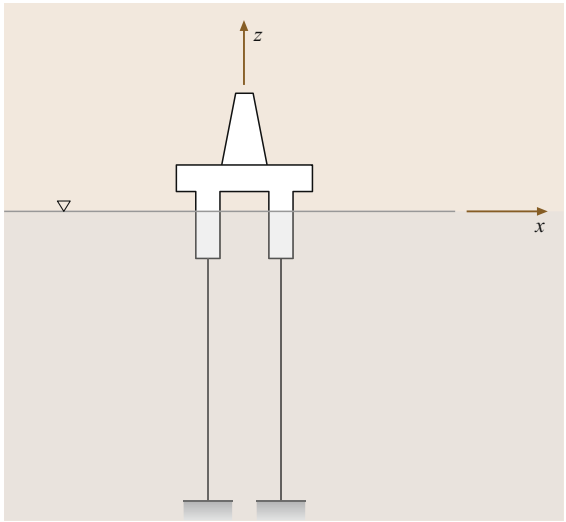

Fig. 37.2 Schematic of a TLP

Although the system in Fig. 37.1a may not look like any practical structure, it provides an excellent basis to understand structural dynamics. Furthermore, some systems can be reasonably well represented by a single degree-of-freedom, at least for initial studies. For example, Fig. 37.1a may be a reasonable model to study the linear vertical response of a tension leg platform (TLP), if that motion is assumed uncoupled from motion in other directions and the mass of the tendons is either ignored or partially lumped with the TLP mass; see the schematic in Fig. 37.2. If the fluid is ignored temporarily, m would be the mass of the platform, which would be assumed rigid; k would be the sum of the vertical stiffness of the tendons (again, ignoring buoyancy at the moment); and c a constant that would have to be specified. Dynamic energy dissipation in structures results from a variety of physical mechanisms that, for the most part, are not well understood quantitatively and are not modeled explicitly. Rather, a damping model, such as the viscous damper shown in Fig. 37.1a, is given equivalent properties to provide approximately the same level of energy dissipation that is found in field tests.

A slight modification to the free body in Fig. 37.1b makes it applicable to the uncoupled pitch motion of the TLP. In that case, u represents the rotational displacement (in radians) of the TLP, the forces are moments, m the rotational inertia of the TLP, and k the resistance to pitch provided by the tendons (moment per radian). Again, c would have to be based on experimental data. Hence, all the equations in this section apply to both uncoupled heave motion and pitch motion. This TLP application will be used to give more physical interpretation to the subsequent discussions. It also illustrates that practical structures will have more

than one degree-of-freedom; multi-degree-of-freedom structures are considered subsequently.

37.1.2 Response in the Time Domain – Free Vibration

The primary focus herein is on linear dynamic response because 1) analytically tractable solutions are possible, and 2) an understanding of linear structural behavior is critical prior to understanding nonlinear behavior.

The term free vibration in structural dynamics refers to the response of the system to initial displacement $u(0)$ and initial velocity $\dot{u}(0)$ (initial conditions), but with no loading, i. e., $p(t) = 0$. It is convenient to divide (37.3) by m to obtain

$$\ddot{u}(t) + 2\xi\omega_n\dot{u}(t) + \omega_n^2 u(t) = 0\,, \tag{37.5}$$

in which $\omega_n = \sqrt{k/m}$ is the undamped natural frequency (radians per second) and $\xi = c/(2m\omega_n)$ is the (dimensionless) ratio of the damping coefficient c to the critical damping of the system. The critical damping is the minimum level of damping that prevents oscillation during free vibration. For most practical structures, damping is relatively small and is often referred to as a percent of critical damping, such as *the structure has 2% damping*. If the damping is less than critical, the solution to (37.5) is

$$u(t) = \mathrm{e}^{-\xi\omega t}\left(\frac{\dot{u}(0) + u(0)\xi\omega_n}{\omega_D}\sin\omega_D t + u(0)\cos\omega_D t\right)\,, \tag{37.6}$$

in which $\omega_D = \omega_n\sqrt{1-\xi^2}$ is the damped natural frequency. The undamped and damped natural periods are $T_n = 2\pi/\omega_n$ and $T_D = T_n/\sqrt{1-\xi^2}$, respectively. It is also convenient to write (37.6) in a different form

$$u(t) = \rho\mathrm{e}^{-\xi\omega_n t}\cos(\omega_D t - \theta)\,, \tag{37.7a}$$

with

$$\rho = \sqrt{\left(\frac{\dot{u}(0) + u(0)\xi\omega_n}{\omega_D}\right)^2 + [u(0)]^2}\,, \tag{37.7b}$$

$$\theta = \tan^{-1}\frac{\dot{u}(0) + u(0)\xi\omega_n}{\omega_D u(0)}\,. \tag{37.7c}$$

Several aspects of the response can be seen from (37.6) and (37.7). First, for nonzero levels of damping, the response decays exponentially with time, whereas when there is no damping the response continues harmonically with no decay in amplitude. Second, with no damping, the structure vibrates with frequency ω_n and period T_n. In the case of damping, the structure vibrates with frequency ω_D and period T_D. The small levels of structural damping in structures of interest, often less than 5%, mean that the damped and undamped natural frequencies are essentially the same for many practical purposes. The undamped, 2 and 5% damped structural responses are illustrated in Fig. 37.3 for about five cycles of motion. Whereas viscous damping lengthens the period a little bit, the differences in periods between the damped and undamped systems for these levels of damping are very small. The amplitude decay as a result of damping is also evidenced in the figure. It is straightforward to show that the natural log of the ratio of successive peak amplitudes, which is defined as the logarithmic decrement δ, is given by

$$\delta \triangleq \ln\frac{u_j}{u_{j+1}} = \frac{2\pi\xi}{\sqrt{1-\xi^2}} = 2\pi\xi\frac{\omega_n}{\omega_D}\,, \tag{37.8}$$

in which u_j is the peak displacement at the j-th peak. At 5% damping, the amplitude is reduced by about 50% in two cycles of vibration, whereas for 2% damping it takes over five cycles to reduce by 50%.

In the TLP example discussed above, we saw that our SDOF model can be applied separately to vertical motion and pitch motion as long as they are uncoupled, i. e., if heave does not cause pitch and pitch does not cause heave. It is, therefore, clear that there will be a heave natural frequency and a pitch natural frequency. Generally, as we shall see, structures have as many natural frequencies as there are dynamic degrees-of-freedom.

37.1.3 Response in the Time Domain – Harmonic Loading

The general equation of motion, including loading, is

$$\ddot{u}(t) + 2\xi\omega_n\dot{u}(t) + \omega_n^2 u(t) = \frac{p(t)}{m}\,. \tag{37.9}$$

Analytical solutions are usually expressed as a sum of the complementary solution and a particular solution. The complementary solution is obtained when $p(t) = 0$ and the particular solution is the solution for the specific $p(t)$ for a given problem. The complementary solution has two undetermined constants, which are evaluated so that the combined solution satisfies the initial conditions at $t = 0$.

Wave loading on offshore structures is often random and nonlinear. However, for linear structural response analysis the wave loading can be considered a sum of harmonic (sinusoidal) forces with random phases, as in

$$p(t) = \sum_q p_q\cos(\omega_q t + \varepsilon_q)\,, \tag{37.10}$$

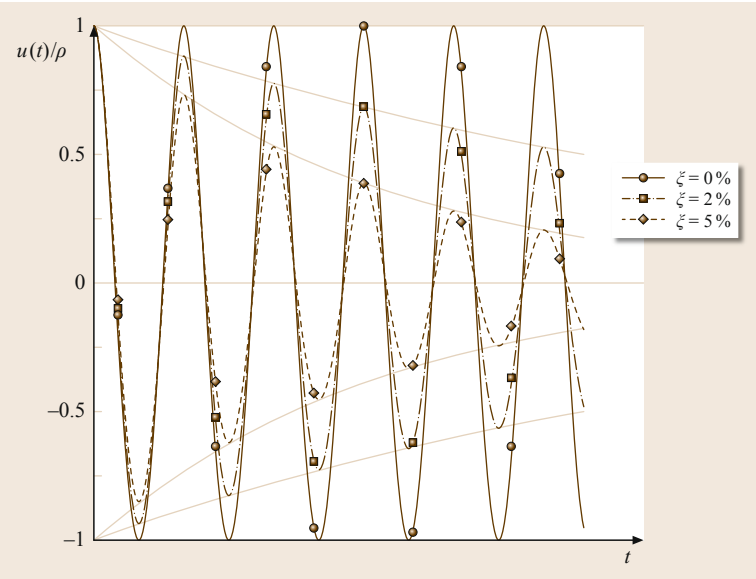

Fig. 37.3 Free vibration response for three values of the damping ratio. The *dashed bounding lines* indicate the decay in amplitude with damping

in which ε_q is the random phase angle for the q-th component. The structural response is then the sum of the response to each harmonic wave component (Sect. 37.5). For this reason, it is advantageous to first study the response of a structure to periodic loading. Periodic loadings can be decomposed into a Fourier series as a summation of sine and cosine terms. Similarly, because of linearity the response can be represented as the summation of the response to each harmonic component. It is, therefore, sufficient at this point to focus the discussion on the response to a single harmonic component of the load. If we assume, therefore, that the loading is $p(t) = p_q \cos(\omega_q t)$, in which p_q is the magnitude for the excitation frequency component ω_q, the response is

$$u(t) = \mathrm{e}^{-\xi\omega t}\left(A \sin \omega_\mathrm{D} t + B \cos \omega_\mathrm{D} t\right) + \frac{p_q}{k} \frac{\left(1-\beta^2\right)\cos\left(\omega_q t\right) + 2\xi\beta \sin(\omega_q t)}{\left(1-\beta^2\right)^2 + (2\xi\beta)^2}\,, \tag{37.11}$$

in which $\beta = \omega_q/\omega_\mathrm{n} = T_\mathrm{n}/T_q$. The solution for a sine variation in force can be obtained from (37.11) by replacing $\sin(\omega_q t)$ with $-\cos(\omega_q t)$ and $\cos(\omega_q t)$ with $\sin(\omega_q t)$. The first term, the complementary solution, involves the coefficients A and B; it is straightforward to determine them such that the complete solution satisfies the initial conditions. However, damping causes the complementary solution to decay relatively quickly with time, because it is multiplied by $\mathrm{e}^{-\xi\omega_\mathrm{n} t}$, and it is, therefore, referred to as the transient response. The second term, the particular solution, is referred to as the steady-state (harmonic) response.

For ocean structures, the excitations from waves occur over a long period of time, and the transient response is assumed to have decayed such that it can be ignored. Note that this may not be the case for other types of loading, such as slamming, collision, blast or ground (seismic) motion. However, we are concerned primarily with wave-induced response, and, therefore, we will focus on the steady-state solution and assume that the transient response can be ignored. We do note that for nonlinear wave response, one has to include the initial conditions and the transient response; the simulation must be run sufficiently long for the transients to decay and for the solution to converge to one of the (possibly multiple) stable solutions as a result of the path-dependence of the structure.

The peak displacement of the steady-state response, obtained from (37.11), is

$$\frac{u_\mathrm{peak}}{(p_q/k)} = \frac{1}{\sqrt{\left(1-\beta^2\right)^2 + (2\xi\beta)^2}} = R_\mathrm{d}\,, \tag{37.12}$$

in which the displacement has been nondimensionalized by the displacement that would result if the structure responded statically, that is, p_q/k. R_d is called the deformation response factor, the displacement response factor, or sometimes just the dynamic amplification factor. R_d is shown in Fig. 37.4 for various damping levels. As $\beta \to 0$, i. e., when the load varies very slowly relative to the structure's natural frequency, the response approaches the static displacement ($R_\mathrm{d} \to 1$). This provides the justification for static or quasi-static analysis for such slowly-varying loads. The maximum displacement response is obtained when $\omega_q = \omega_\mathrm{n}\sqrt{1-2\xi^2}$. For

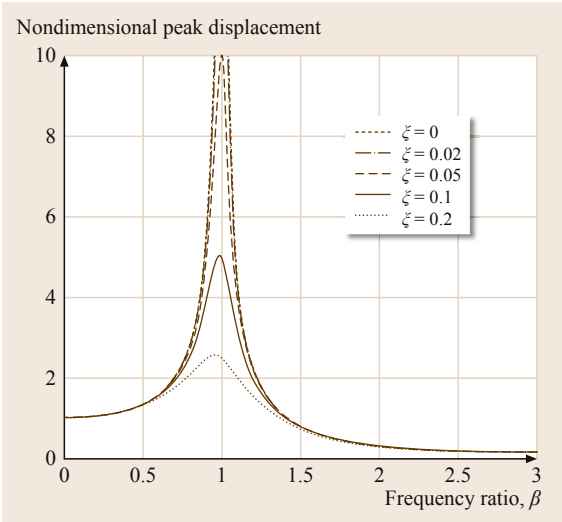

Fig. 37.4 Displacement response factor

practical values of structural damping, the excitation frequency corresponding to the peak displacement is very close to the undamped natural frequency. If $\beta = 1$ is substituted into (37.12), the peak response is $1/(2\xi)$ times the static response. Because damping is small, this means that the structure's response at resonance can be very large relative to the static response to the same load magnitude. Hence, especially for periodic excitation such as wave excitation, it is important to ensure that the structure's natural frequency is not in the frequency range of significant excitation. As the excitation frequency increases to values much larger than the natural frequency (large β), the displacement response goes to zero. A convenient physical explanation for this phenomenon is to imagine a large mass on a soft spring; as the load varies at high frequency, the mass simply does not have time to respond as the load changes direction.

Considering Fig. 37.4, design of ocean structures often involves ensuring that the important natural periods of the structure are either above or below the periods of significant wave energy. For example, for fixed jacket platforms, the significant natural frequencies are usually higher than the dominant wave energy; that is, they are to the left of $\beta = 1$ in the figure. For moored floating structures, such as semisubmersibles and tension-leg platforms, the significant natural frequencies are smaller than the dominant wave frequencies and they are to the right of $\beta = 1$.

37.1.4 Response in the Frequency Domain

As mentioned above, if the loading is periodic then it can be represented as a summation of harmonic components and the response can be represented as the summation of the response to each harmonic component. The situation is the same as considered above, that is, for damped systems the initial transients die out over a sufficient number of loading periods and the long-term (or steady-state) response is harmonic with the same frequency as the load. We again focus the discussion on the response to a single harmonic component of the load, $p_q e^{i\omega_q t}$, in which p_q is the magnitude for the excitation frequency component ω_q. Therefore, the displacement corresponding to this excitation component will be of the form $u_q e^{i\omega_q t}$. Substitution of these expressions into (37.3) results in the equation of motion for each component in the frequency domain

$$\left(-\omega_q^2 m + i\omega_q c + k\right) u_q = p_q \,. \tag{37.13}$$

Equation (37.13) is an algebraic equation that is much easier to solve than the differential (37.3). It is straightforward to obtain the solution as

$$u_q = \frac{p_q}{k} \frac{1}{1-\beta^2 + i(2\xi\beta)} \,, \tag{37.14}$$

in which $\beta = \omega_q/\omega_n$. We should note that (37.14) must be solved for each frequency component ω_q and that (37.14) and u_q are complex. The magnitude of the peak displacement from (37.14) is the same as that from (37.12). We therefore obtain the same definition for R_d.

If p_q corresponds to a unit value of a load parameter (unit wave amplitude), then evaluation of (37.14) for a range of wave (excitation) frequencies results in the complex, frequency-domain transfer function for the displacement, also frequently referred to as the complex frequency response function in structural dynamics. The magnitude of the transfer function is called the response amplitude operator (RAO) in ocean engineering. The symbol H is often used for the transfer function. If it is determined for a unit value of p_q, then

$$u_q = H_u\left(\omega_q\right) p_q \,. \tag{37.15}$$

An important advantage of (37.15) as compared to (37.3) is that it is much easier to treat the situation in which the properties m, c and/or k are frequency dependent. As we shall see, this is usually the case for m and c with ocean structures.

37.1.5 Structural Damping

Energy dissipation in structures excluding hydrodynamic effects is a combination of a number of mechanisms, such as internal energy dissipation in the material, friction in structural components and connections, and possibly concrete cracking. The amount of dissipation under linear behavior is typically quite small,

amounting to damping that is just a few percent of critical damping. There do not exist the same physics-based models for this energy dissipation as for determining the stiffness, and sophisticated modeling would be quite difficult. Fortunately, because it is small the energy dissipation can be modeled fairly crudely. In the time domain, a linear viscous damping model is adopted because it is so convenient. The equations remain linear and analytical solutions are tractable. However, viscous damping is not necessarily the best model for the physics involved in energy dissipation. The actual energy dissipation is more nearly proportional to displacement than velocity [37.9], and in the frequency domain an alternative model, sometimes called linear hysteretic damping, is easily accommodated. In linear hysteretic damping, the dissipation force f_d is still out of phase with the displacement, and can be modeled by $f_d = i2\xi k u_q$. Replacing the linear viscous damping in (37.13) with this expression results in

$$\left[-\omega_q^2 m + (1 + i2\xi)k\right] u_q = p_q \,, \tag{37.16}$$

the solution of which is

$$u_q = \frac{p_q}{k} \frac{1}{1 - \beta^2 + i(2\xi)} \,. \tag{37.17}$$

For practical levels of damping, the peak magnitude of (37.17) is very nearly the same as (37.14), although the peak is obviously now at the undamped natural frequency. The two models result in the same energy dissipation per cycle of vibration when the excitation frequency ω_q is equal to the natural frequency ω_n; otherwise, they are different. Actually, hysteretic damping is typically superior because it results in rate-independent energy dissipation. That is, the energy dissipated in a cycle of motion is independent of the frequency, which often reflects reality better than linear viscous damping, in which the energy dissipation varies with frequency. When the frequency domain approach is applicable, it is often preferable to use the hysteretic damping model. However, when the time-domain approach is used, linear viscous damping is used for convenience.

Both linear viscous damping and hysteretic damping require specification of the damping ratio ξ. Typical values usually come from field tests on similar structures. One common method to determine the level of damping in a structure is to measure the decay in the amplitude of motion during free vibration. For example, based on (37.8), it is straightforward to show that

$$\ln\left(\frac{u_j}{u_{j+m}}\right) = 2\pi m \xi \frac{\omega_n}{\omega_D} \,. \tag{37.18}$$

With this equation one can measure the peak amplitude of the motion over multiple cycles of vibration and obtain an estimate of the damping ratio. Of course, it must be practical to initiate the free vibration for this to be an option.

An alternative approach is based on the response to harmonic excitation. From Fig. 37.4 it is clear that damping not only reduces the peak amplitude, but it also broadens the shape of R_d as a function of frequency. The half-power bandwidth method utilizes this characteristic to estimate the damping. The structure is excited harmonically, the transients are allowed to die out, and the peak steady-state response is measured. This must be done over a range of frequencies to obtain an experimental plot of peak displacements vs. frequency. For small levels of damping, the frequency at peak response can be taken as ω_n. Then the frequency ω_L, to the left of the resonant frequency, that corresponds to a displacement magnitude equal to $1/\sqrt{2}$ of the peak amplitude is determined. Similarly, the frequency ω_R, to the right of the resonant frequency, that corresponds to a displacement magnitude equal to $1/\sqrt{2}$ of the peak amplitude is determined. For small levels of damping, the damping can be estimated as

$$\xi = \frac{\omega_R - \omega_L}{2\omega_n} \,. \tag{37.19}$$

Of course, one must be able to excite the structure harmonically to apply this procedure. Vibration generators, which consist of counter-rotating eccentric weights, have been developed to do this [37.10]. There are other approaches to determine damping from field data, such as from response from random ambient vibrations; see, for example, [37.22].

The issue of specifying the appropriate level of damping for marine structures can be challenging. The discussion by *Bishop* and *Price* [37.23] on the difficulties and unknowns is largely still valid. In that work, they provide a summary of experimentally determined damping ratios obtained by different researchers for different classes of ships. These hull-damping ratios range from about 0.5 to about 2%. Ambient and forced vibration measurements on a steel offshore platform in the North Sea indicated damping ratios between 1 and 3% [37.24]. Some of the difficulties of measuring damping of offshore structures is discussed by *Ruhl* [37.25], who measured damping of four jacket platforms. He also found a range of 1 to 5%, depending on what approach was used to obtain the damping coefficient. According to him, the most credible values seemed to be 2 to 3%, which agree well with *Gundy* et al. [37.24]. Although these are values for structures in water, and therefore reflect some the fluid, it is likely that most of the damping measured in these cases

is from structural damping. In any event, these small damping ratios indicate how small structural damping can be.

37.1.6 Time Domain Response from Frequency Domain Response

The transfer function $H_u(\omega_q)$ is the response in the frequency domain for a unit harmonic load, assuming the load has acted *forever*, so there are no remaining transients. The response in the frequency domain can be used to obtain the response in the time domain for an arbitrary periodic load. Let the periodic load $p(t)$ have a period T_p. It is assumed that the load has acted *forever*, so that the response in any given period is equal to the response in all other periods.

Because the load is periodic, it can be represented as a Fourier series. To match the period T_p, the smallest cyclic frequency in the series is $f_0 = 1/T_p$, and all other frequency components must be integer multiples of f_0, otherwise the load would not have period T_p. Therefore,

$$p(t) = \sum_{n=-\infty}^{\infty} P_n e^{i(2\pi n f_0)t} , \tag{37.20}$$

in which

$$P_n = \frac{1}{T_p} \int_0^{T_p} p(t) e^{-i(2\pi n f_0)t} dt . \tag{37.21}$$

Of course, practical analysis requires 1) truncation of the series in (37.20), and 2) usually a discretization of the load. One approach to obtain the discrete Fourier series representation is to use the trapezoidal method for the integral in (37.21). The period is divided into N segments, such that $\Delta t = T_p/N$, the inverse of which gives the largest cyclic frequency considered. The value of N must be large enough such that it 1) captures the frequency content of the loading, and 2) captures the largest natural frequency of the structure that needs to be included in the response. The load is sampled at discrete times $t_s = s\Delta t$, with $s = 0, 1, \ldots N-1$, because of the periodicity, $p(t_0) = p(t_N)$. Numerical evaluation of (37.21) results in

$$P_n = \frac{1}{N} \sum_{s=0}^{N-1} p(t_s) e^{-i\left(\frac{2\pi ns}{N}\right)}, \quad n = 0, \ldots \frac{N}{2} . \tag{37.22}$$

For real $p(t)$, P_{-n} is the complex conjugate of P_n.

Once the frequency domain representation of the load has been obtained, the frequency domain response is simply

$$u_n = H_u(2\pi n f_0) P_n . \tag{37.23}$$

To obtain the response in the time domain, one only needs to take the inverse Fourier series

$$u(t_s) = u_0 + 2 \sum_{n=1}^{N/2} \mathrm{Re}\left(u_n e^{i\left(\frac{2\pi ns}{N}\right)}\right) . \tag{37.24}$$

The approach requires the transfer functions to be evaluated at $N/2$ frequencies, which can be a large number. If the corresponding computations are excessive, one option is to use some interpolation scheme to reduce the frequencies for which the transfer functions must be computed. Practical applications of this approach also invariably use the fast Fourier transform (FFT). The classic FFT algorithm was developed by *Cooley* and *Tukey* [37.26], although others have been developed subsequently, for example [37.27].

The discrete Fourier transform can also be used to obtain the solution for finite duration loading that is not periodic. The basic strategy is to extend the *period* of the loading beyond the time at which the actual load ends. The load in this extended section is zero. The extension must be sufficiently long that the response from the previous *cycle* has damped to nearly zero. *Veletsos* and *Ventura* [37.28] discuss the procedure and some of the pitfalls associated with its use. *Chopra* [37.10] also provides a concise summary of errors associated with the discrete Fourier transform for nonperiodic loads. Reference [37.29] discusses the application of this approach to the seismic response of a structure in the context of soil–structure and fluid–structure interaction.

37.1.7 Fluid Contribution

Static Effect – Hydrostatic Stiffness

The resistance to heave and pitch displacement of the TLP comes both from structural elements, the tendons, but also from the fluid as the hydrostatic pressure acting on the structure changes with vertical displacement. Integration of these pressure changes over the wetted surface results in the hydrostatic restoring force coefficients, or hydrostatic stiffness. Whether for heave or pitch of the TLP, we denote the corresponding stiffness by k_f. The total system stiffness is the sum of the structure stiffness from the tendons, now denoted k_s, and the hydrostatic stiffness, such that k in the above equations is now given by $k = k_s + k_f$. Of course, (37.16) would have to be modified slightly because the damping term should only multiply k_s; the water provides no displacement-related energy dissipation.

Dynamic Effect – Added Mass, Damping, and Exciting Forces

To determine the dynamic effects of the fluid, a specific fluid model needs to be adopted. This is the same

situation as in rigid body hydrodynamics in Chap. 34. For the linear analysis of large ocean structures, linear potential theory is usually adopted, and this will be the basis of the discussion here. For the TLP model, the heave or pitch added mass, m_f, the hydrodynamic damping, c_f, as well as the wave exciting (incident and diffraction) forces, F_f, are the same as would be calculated in Chap. 34 if the tendons were ignored.

Because the added mass, hydrodynamic damping, and wave exciting forces are functions of the wave frequency ω_q, an obvious difficulty arises with including them in the equation of motion in the time domain, Here, the advantage of the frequency domain approach becomes apparent, because there is no difficulty to include the frequency dependence. Equation (37.13) now becomes

$$\left[-\omega_q^2\left(m_s+m_f\right)+\mathrm{i}\left(\omega_q c_f+2\xi k_s\right)+\left(k_s+k_f\right)\right]u_q = F_f\,. \tag{37.25}$$

Equation (37.25) is easily solved to obtain the response in the frequency domain and to develop the RAO of the response. Of course, hidden within the equation is the necessity to determine the fluid coefficients, which can entail a large computational effort, as discussed in Chap. 34.

Equation (37.25) is often adequate for the wave response of linear structures, but when it is desired to introduce nonlinearities, for example, in the structure stiffness or the forces involved in active control systems, then a time-domain solution is required. The frequency dependence of the fluid effects can be transferred to the time domain through an inverse Fourier transform. In structural dynamics, it is not uncommon to transform the linear response in the frequency domain to the response in the time domain, and this can be done conveniently using the fast Fourier transform. The situation here is a little different, however, because it is not the response that is transformed. The cosine transform proposed by *Cummins* [37.30] and discussed further by *Ogilvie* [37.31] is generally used; see, for example [37.32], while *Taghipour* et al. [37.33] and *Sheng* and *Lewis* [37.34] provide good summaries. For zero mean speed, the basic equation of motion becomes

$$\left(m_s+m_{f\infty}\right)\ddot{u}(t)+\int_0^t K\left(t-\tau\right)\dot{u}(t)\mathrm{d}\tau + \left(k_s+k_f\right)u(t)=F_f(t)\,, \tag{37.26}$$

in which $m_{f\infty}$ is the infinite frequency added mass and the retardation function $K(t)$ is given by

$$K(t)=\frac{2}{\pi}\int_0^\infty c_f(\omega)\cos(\omega t)\mathrm{d}\omega\,. \tag{37.27}$$

The convolution integral in (37.26), which is often referred to as the fluid memory effect, must be evaluated at each time step. This can be computationally significant.

Recent work on this approach seems to have focused on wave-energy conversion devices, including their control. Optimization and control of wave energy extraction may be performed most efficiently with a state-space formulation of the equation of motion [37.35]. Examples can be found in [37.33, 36–39].

Dry and Wet Natural Frequencies

The so-called dry or *in-air* (undamped) natural frequency of the system is obtained when the fluid is ignored

$$\omega_n=\sqrt{\frac{k_s}{m_s}}\,. \tag{37.28}$$

The wet natural frequency when the structure is in water is

$$\omega_n=\sqrt{\frac{k_s+k_f}{m_s+m_f(\omega_n)}}\,, \tag{37.29}$$

in which the functional dependence of the added mass on the frequency of motion is made explicit. (37.29) is clearly nonlinear, and an iterative process is required to find the wet natural frequency. This process requires repeated solution of the radiation problem to obtain m_f. The iteration would cease once the frequency for which m_f was calculated is sufficiently close to ω_n given by (37.29). Because of the need to solve multiple radiation problems, finding the wet natural frequency can be computationally significant. One option to approximate the wet natural frequency is to ignore the added mass, such that

$$\omega_n\approx\sqrt{\frac{k_s+k_f}{m_s}}\,. \tag{37.30}$$

There is probably little reason to do this for the SDOF model. However, it could be useful in multiple degrees-of-freedom models, as discussed subsequently.

Natural frequencies are determined primarily for two reasons. First, they can help to understand the dynamic response. Knowing the natural frequency helps understand which excitation frequencies will cause large response and which will cause small response, viz. Fig. 37.4. For multiple degrees-of-freedom (MDOF) systems, one also gains an understanding of how the structure will deform. While the RAOs, computed for a range of wave frequencies, will reveal the frequency-dependence of the response, the shape of the deformations is admittedly more difficult to obtain from the RAOs. The second reason to solve for the natural frequencies is to develop solution procedures in the time domain that are computationally more efficient than would otherwise be possible. This is not as relevant to the SDOF system, but can be very useful for structural dynamics of linear MDOF systems. However, because of the frequency dependence of added mass and damping, the computational efficiency that would otherwise be provided by the wet natural frequencies is typically lost. As a result, the wet natural frequencies are usually not calculated explicitly, and resonance is identified through peaks in the RAOs. One can also approximate the wet natural frequencies with (37.29) by using an added mass for a frequency relatively close to the calculated natural frequency.

Direct Coupling for Fluid–Structure Interaction

The above discussion has assumed the most common approach to consider the coupled fluid–structure problem. For example, a typical diffraction (panel) code is used to obtain the hydrodynamic coefficients, which are then included in the structural model. A more tightly coupled approach could be used, in which the two systems are solved simultaneously. See [37.40] for an example of such an approach. The direct coupling obviates the iteration discussed above to find the wet natural frequencies.

The discussion herein will focus on the former strategy, which is still the most common approach for linear hydroelasticity of ocean structures. The reason for that may be as much historical as anything. Linear hydroelasticity evolved out of linear rigid body dynamics based on diffraction codes [37.23, 41, 42]. These codes were well developed to calculate the added mass, damping, and wave exciting forces for rigid ocean structures. As will be seen, the equations involved in these codes need only slight modifications to be applied to linear flexible structures. A completely separate, existing structural analysis code can be used for the structural model. With this architecture, the loose coupling only requires some modest interchange of data. Furthermore, the solution of (37.25) to obtain the wave-induced response does not require iteration. Therefore, there does not appear to be a disadvantage to the loose coupling if one does not need the wet natural frequencies.

37.1.8 Nonlinear Systems

The discussion so far has focused on linear systems. Analysis of practical structures involving nonlinearities almost always involves a numerical solution in the time domain. An incremental equation of motion can be written such that the solution is progressed from displacement $u(t)$ at time t to displacement $u(t+\Delta t) = u(t) + \Delta u$ at time $t+\Delta t$. Equation (37.2) is written at time $t+\Delta t$, and then linearized about time t. The resulting incremental equation of motion is

$$m\Delta\ddot{u} + c_T\Delta\dot{u} + k_T\Delta u = p(t+\Delta t) - m\ddot{u}(t) - f_d(t) - f_r(t)\,. \tag{37.31}$$

k_T is the tangent stiffness at time t; that is, it is the slope of the $f_r - u$ function at $u(t)$. Most structural materials such as steel and concrete are nonlinear hysteretic. Therefore, the tangent will depend also on the previous path, or history of the displacement, as well as on whether the material is loading or unloading. (Consider, for example, the nonlinear uniaxial stress-strain curve for steel, as it yields, unloads, and then is loaded past yielding again.) Similarly, c_T is the tangent damping coefficient. When only typical energy dissipation in the structure is considered, this is very often assumed to be a constant c. If equilibrium is satisfied exactly at time t, then the right-hand-side of (37.31) is just Δp. However, equilibrium is rarely satisfied exactly and using the form in (37.31) can help to control errors. Nevertheless, iteration is often required.

An important source of nonlinearity for offshore structures is the nonlinearity from the fluid loading, even if the structure itself remains linear elastic. The Morison equation formulation is a practical formulation of nonlinear fluid forces on *small structures* [37.43]. For wave flow around an oscillating slender structure, such as the members of a jacket platform, the presence of the structure induces a wake immediately in the downstream of the instantaneous wave flow but does not significantly affect the flow field away from the vicinity of the structure [37.15, 17]. Under this *small structure* assumption, the fluid loads on the structure can be represented by the Morison inertia force f_{fI} and drag force f_{fD}

$$f(t) = f_{fI} + f_{fD}\,, \tag{37.32a}$$

$$f_{fI}(t) = C_M A_I \dot{U}(t) - C_A A_i \ddot{u}(t)\,, \tag{37.32b}$$

$$f_{fD}(t) = C_D A_D\,[U(t) - \dot{u}(t)]\,|U(t) - \dot{u}(t)|\,, \tag{37.32c}$$

in which C_M is the inertia force coefficient, and C_A and C_D are the inertia and drag coefficients, A_I and A_D are the projected areas of the structure in the direction of the fluid flow, and $U(t)$ and $\dot{U}(t)$ are the (absolute) fluid flow velocity and acceleration, respectively. The above equation is called the relative velocity Morison equation. In the literature, the density of water sometimes is written explicitly in the latter two equations, and a factor of $1/2$ is included in the third expression. However, often these factors are absorbed into the inertia and drag coefficients [37.17, 44], which is the case here. The Morison equation works well when the flow velocity is oscillatory, such as for a small structure in periodic waves [37.17, 44]. If the fluid flow consists of a combination of periodic waves and a steady current, the Morison drag force can be written as

$$f_{fD}(t) = C_D A_D \left(U(t) + U_C(t) - \dot{u}(t)\right) \left|U(t) + U_C(t) - \dot{u}(t)\right| , \qquad (37.33)$$

where $U_C(t)$ is the steady current. It is clear from these equations that the system is nonlinear because of the drag term.

There are several options available to include these Morison forces acting on the structure in the incremental equation of motion. For simplicity, we will assume that the only forces are the Morison forces, and hence $p(t+\Delta t)$ is equal to $f(t+\Delta t)$. We will assume further that equilibrium has been achieved at time t such that the right-hand side is just $\Delta p(t+\Delta t) = f(t+\Delta t) - f(t)$. Substitution into (37.31) results in

$$(m + C_A A_I)\,\Delta\ddot{u} + c_T \Delta\dot{u} + k_T \Delta u = C_M A_I \Delta\dot{U} + f_{fD}(t+\Delta t) - f_{fD}(t) . \qquad (37.34)$$

Although the fluid inertia term is handled easily, the nonlinear drag term is not. The right-hand side depends on the unknown $\Delta\dot{u}$. To resolve this problem, the simplest approach is to calculate $f_{fD}(t+\Delta t)$ using $\dot{u}(t)$ instead of $\dot{u}(t+\Delta t)$. Errors resulting from this approximation can likely be controlled by using a sufficiently small time step. Another option is to use iteration within a time step such that at iteration i, $f_{fD}(t+\Delta t)$is calculated using the value of $\dot{u}(t+\Delta t)$ obtained in iteration $i-1$.

A more involved approach to deal with nonlinearity is to linearize the drag term about time t, and then move the term involving $\Delta\dot{u}$ to the left-hand side. The difficulty here is that the coefficient on $\Delta\dot{u}$ will involve $U(t+\Delta t)$ and $\dot{u}(t)$. Because the coefficient will be a function of time, it will need to be updated for each time increment. *Sarpkaya* and *Isaacson* [37.15] and *Veletsos* et al. [37.45] discuss options for such formulations in more detail.

It must be emphasized that the Morison force equations work for cases that correspond to the conditions for which the empirical inertia and drag coefficients have been determined experimentally. For significantly different flow conditions, a different set of *Morison coefficients* C_M and C_D will have to be determined experimentally. There is no analytical means of extending the range of applicability of these empirical coefficients.

37.2 Multi-Degree of Freedom Systems

37.2.1 Equations of Motion

The response of very few structures can be represented adequately by a single displacement. As a result, models that involve multiple degrees-of-freedom are required, just as a floating rigid body requires six degrees of freedom to completely define its motion. As such, the equation of motion in the time domain for a flexible structure becomes

$$\mathbf{M}_s\ddot{\boldsymbol{u}}(t) + \mathbf{C}_s\dot{\boldsymbol{u}}(t) + \mathbf{K}_s\boldsymbol{u}(t) = \boldsymbol{P}(t) , \qquad (37.35)$$

in which $\boldsymbol{u}(t)$ is a vector of N nodal displacements that are required to approximate sufficiently the motion of the structure. $\mathbf{M}_s$, $\mathbf{C}_s$, and $\mathbf{K}_s$ are the $N \times N$ structural mass, damping, and stiffness matrices, and $\boldsymbol{P}(t)$ is the vector of N forces corresponding to the N displacements. The term displacement is generalized to include both translational displacements and rotational displacements, and hence, the term force is generalized to include both actual forces and moments. The structure is most often modeled by the finite element method, the details of which can be found in a number of texts; for example, see [37.46]. The method provides a methodology to obtain the mass and stiffness matrices and the load vector. However, no such formulation is generally available to obtain the damping matrix based on a physical model of the damping mechanisms. One approach to construct $\mathbf{C}_s$ is to use Rayleigh damping, wherein the matrix is formed from a linear combination of $\mathbf{M}_s$ and $\mathbf{K}_s$ to obtain a target proportional damping ξ. This issue will be discussed in more detail subsequently.

As before, the equation of motion can be written in the frequency domain as

$$\left[-\omega_q^2\mathbf{M}_s + (1 + \mathrm{i}2\xi)\mathbf{K}_s\right]\boldsymbol{u}_q = \boldsymbol{P}_q , \qquad (37.36)$$

This formulation again has the advantage of a simpler representation of damping. It should be noted that (37.36) indicates that a single value of ξ is used to multiply the stiffness matrix, but in fact, it is quite easy to use different values for different parts of the structure, in case they exhibit different energy dissipation characteristics. In that case, the stiffness matrices from the different parts of the structure are simply multiplied by different values of ξ to assemble the imaginary component of the now complex stiffness.

37.2.2 Modal Superposition

When the homogenous, undamped form of (37.36) is considered (no damping and $\boldsymbol{P}(t) = \boldsymbol{0}$), then the solution is harmonic and an eigenvalue equation results

$$\left[\mathbf{K}_\mathrm{s} - \omega_j^2 \mathbf{M}_\mathrm{s}\right] \boldsymbol{\psi}_j = \boldsymbol{O} \,, \tag{37.37}$$

in which there are up to N eigenvalues ω_j^2 and eigenvectors, or normal mode shapes, $\boldsymbol{\psi}_j$, $j = 1, \ldots N$. The undamped natural frequencies are usually ordered such that $\omega_1 \le \omega_2 \le \ldots \le \omega_N$. These natural frequencies have the same interpretation as the undamped natural frequency of the SDOF system, except now the vibration shape at frequency ω_j is described by $\boldsymbol{\psi}_j$.

The natural frequencies and (normalized) mode shapes satisfy two very important characteristics

$$\boldsymbol{\psi}_j^\mathrm{T} \mathbf{K}_\mathrm{s} \boldsymbol{\psi}_q = \begin{cases} \omega_q^2, j = q \\ 0, j \neq q \end{cases} \,, \tag{37.38a}$$

$$\boldsymbol{\psi}_j^\mathrm{T} \mathbf{M}_\mathrm{s} \boldsymbol{\psi}_q = \begin{cases} 1, j = q \\ 0, j \neq q \end{cases} \,. \tag{37.38b}$$

That is, the mode shapes are orthogonal with respect to both the mass and stiffness matrices. If Raleigh damping is assumed, they are also orthogonal with respect to the damping matrix. The *magnitude* of an eigenvector is not specified by (37.37). Equation (37.38b) has assumed that the eigenvectors have been mass normalized, such that $\boldsymbol{\psi}_j^\mathrm{T} \mathbf{M}_\mathrm{s} \boldsymbol{\psi}_j = 1$, a convention that is adopted by virtually all structural dynamic computer programs.

It is important to note that the N mode shapes form a basis for the same vector space in which $\boldsymbol{u}(t)$ exists, and therefore we can represent the displacements as a linear combination of these basis vectors with no loss in accuracy,

$$\boldsymbol{u}(t) = \sum_{j=1}^{N} \boldsymbol{\psi}_j Y_j(t) \,, \tag{37.39}$$

in which $Y_j(t)$ is the nondimensional generalized coordinate of mode shape j. With (37.38), the equations of motion (37.35) can be decoupled as

$$\ddot{Y}_j(t) + 2\xi_j \omega_j \dot{Y}_j(t) + \omega_j^2 Y_j(t) = \boldsymbol{\psi}_j^\mathrm{T} \boldsymbol{P}(t) = P_j^*(t) \,, \quad j = 1, \cdots N \,, \tag{37.40}$$

in which ξ_j is the modal damping ratio for mode j. These can be specified independently for each mode, but it is not uncommon to assume that they are the same for all modes. Note that with this approach, the damping matrix $\mathbf{C}$ need never be defined, much less formed. The modal force P_j^* is a measure of how much the spatial distribution of the load excites mode j.

Although it is a significant amount of work to solve (37.37) for the ω_j and $\boldsymbol{\psi}_j$, it can be well worth the effort given this result. Specifically, we have converted a large system of coupled equations into a set of uncoupled equations, which we can solve using the solution strategies and even the analytical solutions outlined for SDOF systems. That notwithstanding, the primary reason for doing this is that for relatively slowly-varying loading, such as with wave loading, the response of the structure is dominated by the response of the lower modes, and typically we let $j = 1, \ldots m$, $m \ll N$. That is, we represent the displacement vector with a reduced set of basis vectors. In this way, the effort to determine the natural frequencies and mode shapes can be justified. The process described here is referred to as modal superposition in structural dynamics. It should be noted that the high frequency modes, i. e., mode shapes greater than $j = m$, while they may not respond dynamically (Fig. 37.4 for small β), may respond statically. Hence, procedures to include this so-called static correction may be used to add the higher mode static response to the dynamic response.

The mode shapes from (37.37) are not the only alternative basis in which to represent the response. In earthquake structural dynamics in particular, so-called Ritz vectors are also used very successfully, and may be even more efficient than the normal modes because they are based on the spatial variation of the loading. However, the application of Ritz vectors to wave loading appears limited because the spatial variation of the loading changes with the wave frequency. Hence, this approach will not be discussed further.

Equation (37.40) illustrates an important difference between the SDOF system and the MDOF system. Dynamic response of the MDOF system depends not just on the ratio of excitation frequency to natural frequency, β, as shown in Fig. 37.4, but also on how the spatial distribution of the load excites a given mode shape, as quantified by the modal load P_j^*. That is, while R_d provides a measure of how much the loading frequency excites a given natural frequency of the structure, P_j^*

provides a measure of how much the spatial variation of the load excites the associated normal mode of the structure. For example, consider a structure with a natural frequency and a mode shape in one plane. A force in the orthogonal plane, even at the natural frequency of the structure, will not excite that mode because $P_j^* = 0$.

37.2.3 Numerical Time-Domain Solution

In Sect. 37.1.2, it was possible to obtain an analytical solution for the linear response in the time domain of a SDOF system subjected to a simple harmonic loading when the mass, damping, and stiffness are constant. For large MDOF systems, this approach is not practical, and in any event the loading is rarely a simple analytical function and often there is some source of nonlinearity, both of which preclude a simple analytical solution, even for SDOF systems. Therefore, we must numerically integrate the equations of motion to obtain the solution at discrete points in time, specifically at times Δt, $2\Delta t$, $3\Delta t$, etc., where Δt is the time step (assumed here to be constant for simplicity).

There are many different numerical schemes to obtain the time history of the response. Integration schemes can be categorized broadly as either explicit or implicit. Only implicit schemes can be unconditionally stable, their numerical stability does not require an upper limit on the size of the time step. Explicit schemes require for stability the time step to be based on the smallest natural period of the structural model. For very short duration loading, such as blast and impact that involve wave propagation in the structure, a small time step may be required for accuracy, and explicit time integration methods are frequently adopted. For such applications in structures, the central difference method is a common choice.

As mentioned, wave loading (and earthquake ground motion) has frequency content that is relatively low compared to the largest natural frequencies (smallest periods) contained in MDOF structural models. As such, the dynamic response of the higher modes in the structural model is not significant, and explicit methods are not efficient. As a result, for such low-frequency loading, unconditionally stable implicit schemes are almost always used for structural dynamics. One of the most widely-used schemes is Newmark's method, which we will consider here. Accuracy always depends on the time step, however, and of course the integration time step should be no larger than the time step required to resolve adequately the time variation of loading. In addition, the structural natural frequencies that are important for the response also limit the time step; a common rule of thumb is that the time step should not be larger than about one-tenth of the structure's smallest natural period that is significant to the response, although we prefer an even smaller time step.

Newmark's method is a single-step method, which means that we only use the information at time $i\Delta t$ to step to time $(i+1)\Delta t$. Actually, Newmark's method refers to a family of methods, but the parameters most often chosen result in the average (thus constant) acceleration member of the family. The acceleration in the time step is assumed to be the average of the accelerations at each end of the time step, that is, $(\ddot{\boldsymbol{u}}_i + \ddot{\boldsymbol{u}}_{i+1})/2$. It is then straightforward to obtain

$$\Delta\dot{\boldsymbol{u}}_i = \Delta t\ddot{\boldsymbol{u}}_i + \frac{\Delta t}{2}\Delta\ddot{\boldsymbol{u}}_i \,, \tag{37.41a}$$

$$\Delta\boldsymbol{u}_i = \Delta t\dot{\boldsymbol{u}}_i + \frac{1}{2}(\Delta t)^2\ddot{\boldsymbol{u}}_i + \frac{1}{4}(\Delta t)^2\Delta\ddot{\boldsymbol{u}}_i \,, \tag{37.41b}$$

in which, for example, $\Delta\boldsymbol{u}_i = \boldsymbol{u}_{i+1} - \boldsymbol{u}_i$.

The equation of motion (37.35) written at time step $i+1$ in terms of the increments in displacement, velocity, and acceleration is

$$\begin{aligned}&\mathbf{M}_\mathrm{s}\Delta\ddot{\boldsymbol{u}}_i + \mathbf{C}_\mathrm{s}\Delta\dot{\boldsymbol{u}}_i + \mathbf{K}_\mathrm{T}\Delta\boldsymbol{u}_i \\ &\quad = \boldsymbol{P}_{i+1} - \mathbf{M}_\mathrm{s}\ddot{\boldsymbol{u}}_i - \mathbf{C}_\mathrm{s}\dot{\boldsymbol{u}}_i - (\boldsymbol{F}_\mathrm{r})_i \,,\end{aligned} \tag{37.42}$$

in which it has been assumed for simplicity that the mass and damping are constant while the force–displacement relationship of the structure is represented by $\boldsymbol{F}_\mathrm{r}(\boldsymbol{u})$ and may be nonlinear. The first-order expansion is represented here, such that $(\boldsymbol{F}_\mathrm{r})_{i+1} \approx (\boldsymbol{F}_\mathrm{r})_i + \mathbf{K}_\mathrm{T}\Delta\boldsymbol{u}_i$, in which $\mathbf{K}_\mathrm{T}$ is the tangent stiffness matrix. For a linear system, $\mathbf{K}_\mathrm{T} = \mathbf{K}_\mathrm{s}$ and $(\boldsymbol{F}_\mathrm{r})_i = \mathbf{K}_\mathrm{s}\boldsymbol{u}_i$. However, for a linear system it is not necessary to write the equation in incremental form.

The displacement, velocity, and acceleration at time i are known, and the only unknowns are the increments. Equations (37.41) can be used to write $\Delta\dot{\boldsymbol{u}}_i$ and $\Delta\ddot{\boldsymbol{u}}_i$ in terms of $\Delta\boldsymbol{u}_i$. These relations can then be used in (37.42) to obtain an equation in $\Delta\boldsymbol{u}_i$ only. This is the typical strategy used in the time integration of the equations of motion. Of course, if (37.42) is nonlinear, iteration within a time step may be necessary to control errors.

Newmark's method as outlined above can be modified to handle the convolution integral as in (37.26). See, for example, [37.47].

It should be noted that the form of Newmark's method described above is equivalent to the trapezoidal method for numerical integration of an ordinary differential equation. It, therefore, has the accuracy and convergence characteristics of that method, as well as the same lack of numerical damping.

It is clear that to use (37.42), an explicit damping matrix $\mathbf{C}$ is required. As mentioned earlier, Rayleigh

damping is often assumed

$$\mathbf{C}_s = a_0\mathbf{M}_s + a_1\mathbf{K}_s\,, \tag{37.43}$$

in which a_0 and a_1 are coefficients. Note that this form of damping ensures that the normal modes of vibration are also orthogonal with respect to the damping matrix. With Rayleigh damping, the damping in mode n with natural frequency ω_n is given by

$$\xi_n = \frac{a_0}{2}\frac{1}{\omega_n} + \frac{a_1}{2}\omega_n\,. \tag{37.44}$$

The values of the coefficients are determined by requiring (37.44) to provide target values of modal damping for two modes important to the response.

It is obvious from (37.44) that for low natural frequencies the mass-proportional term dominates, whereas for larger natural frequencies the stiffness-proportional term dominates (subject to the values of the coefficients, of course). It should also be noted that the mass-proportional term provides damping to rigid body modes, which may not be desired for floating structures. The stiffness-proportional term does not damp rigid body modes, but the modal damping does increase as the natural frequency increases. This may not be altogether bad, however, because typically one wants the higher modes that are not important to the dynamic response to be damped out anyway so as not to affect the solution. Because of this *physical* damping, it is probably not necessary to use a numerical method that has numerical damping to accomplish the same thing [37.48].

Rayleigh damping, as well as some other forms of damping, are discussed in most structural dynamics books; see, for example, [37.10].

37.3 Linear Hydroelasticity for Inviscid Fluid Flow

37.3.1 Finite Element Structural Modeling

Structural analysis of offshore structures almost always involves the finite element method (FEM). In the displacement-based FEM, the displacements everywhere in the structure are related to the N nodal displacements through interpolation functions. Specifically

$$\boldsymbol{u}\,(x_1, x_2, x_3, t) = \mathbf{N}\boldsymbol{u}(t)\,, \tag{37.45}$$

in which the notation $x_1 - x_2 - x_3$ is used for the coordinate axes for convenience in the following. The 3×1 vector $\boldsymbol{u}\,(x_1, x_2, x_3, t)$ contains the displacements u_1, u_2, u_3 in the coordinate directions. The $3\times N$ matrix of interpolation functions $\mathbf{N}$ includes the spatial variation of the displacements, while the nodal displacements $\boldsymbol{u}(t)$ have the temporal variation. Equation (37.45) also applies to rigid body motion as well. In that case, the $\boldsymbol{u}(t)$ would be the six degrees-of-freedom surge, sway, heave, roll, pitch, and yaw, and $\mathbf{N}$ would contain the kinematic constraints that relate the six rigid body displacements to the displacement at any point in the body. In the case of flexible structures, however, the interpolation functions include deformation of the body.

Equation (37.45) provides the necessary mechanism to incorporate the effect of the fluid in the equations of motion, specifically, $\mathbf{K}_f$, $\mathbf{M}_f$, $\mathbf{C}_f$, and $\boldsymbol{F}_f$, the matrix equivalents of the hydrostatic stiffness, added mass, hydrodynamic damping, and wave exciting force in (37.35).

37.3.2 Hydrostatic Stiffness

The hydrostatic stiffness in rigid body hydrodynamics has two components. One component results from the change in hydrostatic pressure acting on the wetted surface as well as the change in orientation of the wetted surface as a result of rotation. The second component comes from a shifting of the gravitational loads in the structure as a result of rotation. The same is true for flexible structures, although the formulation is more complex.

Several formulations for the hydrostatic stiffness have been proposed, but at this point it appears that the most accurate formulation for the i, j element of the hydrostatic stiffness matrix is [37.49]

$$K_{fij} = -\rho g \int_{S_o} N_q^i \left(N_3^j + x_3 N_{l,l}^j\right) n_q \mathrm{d}S + \rho g \int_{S_o} x_3 N_l^i N_{q,l}^j n_q \mathrm{d}S + \int_{\Omega_s} \sigma_{lm} N_{q,l}^i N_{q,m}^j \mathrm{d}\Omega\,, \tag{37.46}$$

in which ρ is the mass density of water, g is gravitational acceleration, S_o is the wetted surface, N_q^i is the interpolation function for the displacement in the q-th direction for nodal degree-of-freedom i, n_q is the q-th component of the outward directed unit normal to the wetted surface, $()_{,q} \stackrel{\text{def}}{=} \partial()/\partial x_q$; Ω_s is the structural volume, σ_{lm} is the structural stress under gravitational

loads in calm seas, repeated indices imply summation, q, l, m range from 1 to 3, i, j range from 1 to N, and it is assumed that the origin of the coordinate system is at the still water level and x_3 is directed vertically up. The last integral in (37.46) is the well-known geometric stiffness matrix [37.46]. This term is an integral component of the hydrostatic stiffness matrix for flexible structures, as it contains the effect of the shifting of the gravitational loads as a result of rotation. Although including the geometric stiffness in $\mathbf{K}_\mathrm{f}$ instead of $\mathbf{K}_\mathrm{s}$ may seem odd to a structural engineer, it is done so that (37.46) is consistent with the traditional hydrostatic stiffness of rigid bodies. (37.46) is somewhat complex, and there is some evidence that practical results can be obtained with simplified implementations [37.50].

37.3.3 Added Mass, Damping, and Exciting Forces

To obtain added mass, hydrodynamic damping, and exciting forces, it is necessary to adopt a specific fluid model. Linear hydroelasticity of offshore structures is based predominantly on an inviscid fluid model, and specifically the potential flow formulation, such as discussed in Chap. 34. The previous comments on direct coupling of fluid and structure are also valid here.

The approach to determine the added mass matrix $\mathbf{M}_\mathrm{f}$, the hydrodynamic damping matrix $\mathbf{C}_\mathrm{f}$, and the wave exciting force vector $\boldsymbol{F}_\mathrm{f}$ is the same as is used in Chap. 34 to find the corresponding quantities for a rigid body. For each nodal displacement j that causes a displacement of the wetted surface $\phi_{\mathrm{R}j}$, the radiation velocity potential for a unit amplitude motion of displacement j, must be determined for wave frequency ω_q. The only difference is that the body-boundary displacements used to determine the radiation potentials are based on the modes of motion that include deformation, not just rigid body hydrodynamics. The i, j terms of $\mathbf{M}_\mathrm{f}$ and $\mathbf{C}_\mathrm{f}$ are, respectively

$$\mu_{ij} = \rho \mathrm{Re} \int_{S_o} \phi_{\mathrm{R}j} n_i^* \, \mathrm{d}S \,, \tag{37.47}$$

$$\lambda_{ij} = -\rho \omega_q Im \int_{S_o} \phi_{\mathrm{R}j} n_i^* \, \mathrm{d}S \,, \tag{37.48}$$

in which n_i^* is the *generalized normal*, the normal displacement of the wetted surface as a result of a unit nodal displacement of degree-of-freedom i: $n_i^* = \boldsymbol{n} \cdot \boldsymbol{u}_i(x_1, x_2, x_3)$. As mentioned above, $\boldsymbol{n}$ is the outward-directed unit normal of the wetted surface. $\boldsymbol{u}_i(x_1, x_2, x_3)$ is obtained from (37.45) when displacement i is 1 and all other nodal displacements are 0. Similarly, the j component of $\boldsymbol{F}_\mathrm{f}$ is

$$F_{\mathrm{f}j} = \mathrm{i}\rho\omega_q \int_{S_o} (\phi_\mathrm{I} + \phi_\mathrm{D}) n_j^* \, \mathrm{d}S \,, \tag{37.49}$$

in which ϕ_I and ϕ_D are the same incident and diffraction potentials as for the rigid body and $\mathrm{i} = \sqrt{-1}$. Application of these equations can be found in many references, e.g., [37.51].

The equation of motion in the frequency domain for wave frequency ω_q then becomes

$$\left[-\omega_q^2 \left(\mathbf{M}_\mathrm{s} + \mathbf{M}_\mathrm{f}\right) + \mathrm{i}\left(\omega_q \mathbf{C}_\mathrm{f} + \mathbf{C}_\mathrm{s}\right) + \left(\mathbf{K}_\mathrm{s} + \mathbf{K}_\mathrm{f}\right)\right] \boldsymbol{u}_q = \boldsymbol{F}_\mathrm{f} \,, \tag{37.50}$$

which is the MDOF counterpart to (37.25). $\mathbf{C}_\mathrm{s}$ is the structural damping matrix. As mentioned, in a frequency domain formulation, this will usually be hysteretic damping, but (37.50) admits viscous damping as well (with ω_q folded into the matrix).

37.3.4 Reduced Basis Solution

Equation (37.50) in practice does not present an efficient, and in many cases a tractable, solution scheme. The structural model often involves tens of thousands, and even hundreds of thousands, of degrees-of-freedom. These size problems are tractable, even for common computing, because the structural matrices are sparse. There are two problems with applying the above formulation for hydroelastic analysis. First, the radiation potential for each displacement degree-of-freedom that causes displacement of the wetted surface is required. Second, the matrices $\mathbf{M}_\mathrm{f}$ and $\mathbf{C}_\mathrm{f}$ are full. As a result, the computational requirements could be enormous. The typical solution to this problem is to use the reduced basis strategy of modal superposition. The wave response of a structure will be dominated by the lower natural frequencies, both because of the frequency content of ocean waves and the spatial variation of the loading. Hence, we can choose a reduced basis of $m \ll N$ dry modes and form the $N \times m$ modal matrix $\boldsymbol{\Psi}$, in which column j is $\boldsymbol{\psi}_j$. The displacement is then approximated as

$$\boldsymbol{u}_q \approx \boldsymbol{\Psi} \mathbf{Y}_q \,, \tag{37.51}$$

in which $\mathbf{Y}_q$ is the vector of modal displacements Y_j for wave frequency ω_q. Substitution of (37.51) into (37.50) and premultiplying by $\boldsymbol{\Psi}^\mathrm{T}$ results in

$$\left[-\omega_q^2 \left(\mathbf{M}_\mathrm{s}^* + \mathbf{M}_\mathrm{f}^*\right) + \mathrm{i}\left(\omega_q \mathbf{C}_\mathrm{f}^* + \mathbf{C}_\mathrm{s}^*\right) + \left(\mathbf{K}_\mathrm{s}^* + \mathbf{K}_\mathrm{f}^*\right)\right] \boldsymbol{Y}_q = \boldsymbol{F}_\mathrm{f}^* \,, \tag{37.52}$$

in which $\mathbf{M}_\mathrm{s}^* = \boldsymbol{\Psi}^\mathrm{T} \mathbf{M}_\mathrm{s} \boldsymbol{\Psi}$ is the identity matrix and $\mathbf{K}_\mathrm{s}^* = \boldsymbol{\Psi}^\mathrm{T} \mathbf{K}_\mathrm{s} \boldsymbol{\Psi}$ is a diagonal matrix with the square of

the natural frequencies on the diagonal. $\mathbf{C}_s^* = \boldsymbol{\Psi}^T \mathbf{C}_s \boldsymbol{\Psi}$, but it may not be necessary to form $\mathbf{C}_s$ directly. If hysteretic damping is used, and ξ is constant such that $\mathbf{C}_s = 2\xi \mathbf{K}_s$, then $\mathbf{C}_s^*$ is a diagonal matrix with $2\xi\omega_j^2$ in diagonal j. A similar result can be obtained for viscous damping. $\mathbf{K}_f^* = \boldsymbol{\Psi}^T \mathbf{K}_f \boldsymbol{\Psi}$, which is not diagonal but is a much smaller matrix than $\mathbf{K}_f$.

The modal matrices $\mathbf{M}_f^*$, $\mathbf{C}_f^*$, $\boldsymbol{F}_f^*$ are formed directly by obtaining the radiation potential ϕ_{Rj} for mode shape $\boldsymbol{\psi}_j$, and using the generalized normal for mode shape $\boldsymbol{\psi}_i$ in (37.47)–(37.49). In this way, only $m \ll N$ radiation potentials need be solved.

The above assumes that $\boldsymbol{\psi}_j$ is obtained from structural mass and stiffness properties only using (37.37). If the sum of the structural and fluid stiffness matrices $(\mathbf{K}_s + \mathbf{K}_f)$ is used instead of just the structural stiffness matrix $\mathbf{K}_s$ to obtain the natural frequencies and mode shapes, then the sum $(\mathbf{K}_s^* + \mathbf{K}_f^*)$ is a diagonal matrix with the square of the natural frequencies. There is no computational advantage to doing this, however.

It is not practical to use $\mathbf{M}_f$ in (37.37) to obtain the wet natural frequencies and mode shapes. However, they can be approximated by solving the homogeneous, undamped form of (37.52). As discussed previously for SDOF systems, this involves an iterative procedure because of the frequency dependence of the added mass. Some researchers have then used the wet modes for the reduced basis. However, in this approach the wet modes are simply linear combinations of the dry modes. Therefore, if the same number of dry and wet modes are used, the calculated response should be the same, everything else being equal.

37.3.5 Mapping from Structural Mesh to Fluid Mesh

To solve the coupled fluid–structural dynamics problem, there will be a finite element mesh of the structure and a panel mesh of the fluid–structure interface. To evaluate the radiation potentials and the integrals in (37.47)–(37.49), the displacement on the wetted surface from the structural model must be mapped to the fluid panels, typically either the panel nodes or the panel centers. The fluid mesh requires a much higher fidelity to the geometry of the wetted surface than does the structural model. For example, depending on the application a reasonable model of a TLP might involve beam elements for the columns and pontoons, whereas the panel mesh would follow the wetted surface. Alternatively, a very fine structural mesh may be required to resolve stress concentrations. Unfortunately, there exists neither an easy nor unique mapping strategy to adopt. Significant research on this problem has been carried out not just in hydroelasticity, but also in aeroelasticity. Nonlinear hydroelasticity also requires the pressures from the fluid panels to be mapped back to the structural mesh.

The simplest solution is to use a structural mesh that conforms to the fluid panel mesh, such that the mapping between structural elements and fluid panels is one-to-one. This will usually require shell finite elements for the structure. While such a model may be more detailed and complex than would normally be adopted for the structure under other circumstances, it may be worth the effort to simplify the mapping. It is not always possible for practical applications, however.

37.3.6 Linear Response to Regular Waves – RAOs

As mentioned previously, the linear response for periodic waves is almost always found in the frequency domain. That is, (37.52) is solved for N_w wave frequencies to obtain the complex $m \times N_w$ matrix $\mathbf{Y}$, the q-th column of which is $\boldsymbol{Y}_q$. Note that because $\boldsymbol{F}_f$ and $\boldsymbol{F}_f^*$ depend on the wave direction, this process must be done for each wave direction of interest. This is typically done for a unit wave amplitude, and $\mathbf{Y}$ is then the matrix of transfer functions for the modal displacements.

Because (37.52) is a relatively small set of equations, the computational effort to solve it is not significant. The computational demand of the solution is dominated first by the solution of the velocity potentials. The m radiation velocity potentials must be determined for each wave frequency, but the diffraction potential must be solved for each wave frequency and wave direction. The solution of the structural eigenvalue problem can also be significant, but it must be done only once.

The transfer function for each nodal displacement is given by

$$\mathbf{H}_u = \boldsymbol{\Psi}\mathbf{Y}\,, \tag{37.53}$$

in which $\mathbf{H}_u$ is an $N \times N_w$ complex matrix, the q-th row of which is the transfer function for nodal displacement q. The magnitude (absolute value) of the elements of $\mathbf{H}_u$ result in the RAOs. For every response quantity of interest, such as displacement, force, or stress at a specific point, the RAO must be determined explicitly, similarly to (37.53). For example, let $\mathbf{H}_\tau$ be a $p \times N_w$ matrix of transfer functions for p response quantities, which might be a mixture of displacements, forces and stresses. Then

$$\mathbf{H}_\tau = \boldsymbol{\Psi}_\tau \mathbf{Y}\,, \tag{37.54}$$

in which $\boldsymbol{\Psi}_\tau$ is a $p \times m$ real matrix, component i,j of which is the value of response quantity i in mode shape $\boldsymbol{\psi}_j$.

For an application involving different formulations of hydroelasticity, see [37.51].

37.3.7 Time-Domain Response

Time-domain calculation of the response in linear hydroelasticity is not very common. The discussion in Sect. 37.1.7 regarding the transform of the frequency-dependent coefficients to the time domain for solution therein is equally valid for MDOF structures as SDOF structures. Now, everything has to be done on a matrix basis, rather than the scalars indicated earlier. In fact, this is the most common case, because even for rigid bodies multiple degrees-of-freedom are almost always considered. For larger, flexible structures, the computations become more extensive. For wave-induced response, the frequency domain approach is more efficient. However, for some class of loading, such as impulsive and short duration transient loading, the frequency domain approach has its own limitations. Although the authors are not aware of a lot of work done in this area for linear hydroelasticity, there are certainly some applications. For example, *Kashiwagi* [37.52] considered the transient response of a floating runway during aircraft take-off and landing.

37.4 Linear Response to Random Seas

The linear response of offshore structures to random seas is presented in this section. First, the characteristics of long-crested random seas are described in Sect. 37.4.1 and extended to include shorted-crested random seas in Sect. 37.4.2. Computation of the response of MDOF systems to random seas is then described in Sect. 37.4.3, and finally estimation of extreme response and mean time to fatigue failure are presented in Sect. 37.4.4.

37.4.1 Specification of Long-Crested Random Seas

The sea surface often shows a random behavior composed of waves with a large variety of wave lengths moving independently in arbitrary directions. A first step to capture this randomness is to represent waves of different lengths, but all moving in the same direction. To characterize such random behavior we introduce the concept of the *significant wave*, which is represented by the significant wave height, H_s or $H_{1/3}$, and the significant wave period, T_s or $T_{1/3}$. These are defined as the average wave height and average wave period, respectively, of the highest one-third of all waves that are observed over an appropriate time interval. In fact, the significant wave is found to be close to the wave reported by sight observation. The significant wave is obtained from wave-by-wave analysis, which divides the random wave into individual waves by means of a zero-up crossing or zero-down crossing method. The significant wave is convenient to characterize the scale of the wave field because it expresses the wave field with a single wave parameter, but it does not provide information on the wave-height scatter or the corresponding wave energy distribution.

To represent the frequency distribution of wave energy in random seas, a frequency spectrum is used. The frequency spectra can be obtained from observational wave data by means of a Fourier transform. Many design spectra have been developed to describe ocean waves [37.17, 44]. They are generally based on one or more parameters, e.g., significant wave height, wave period, and peak frequency. Of those spectra, the Pierson–Moskowitz, Bretschneider, and JONSWAP spectra are perhaps the most commonly used at present. These spectra are defined for deep water.

The Pierson–Moskowitz (P–M) spectrum is defined as

$$S(\omega) = 0.0081 g^2 \omega^{-5} \exp\left[-1.25\left(\frac{\omega}{\omega_0}\right)^{-4}\right], \tag{37.55}$$

where ω denotes the spectral peak.

The Bretschneider spectrum is given in terms of the significant wave height H_s and the significant wave frequency ω_s

$$S(\omega) = 0.1687 H_s^2 \omega_s^4 \omega^{-5} \exp\left[-0.675\left(\frac{\omega}{\omega_s}\right)^{-4}\right]. \tag{37.56}$$

It can be applied to both fully developed and partially developed wave fields.

The JONSWAP spectrum (derived from the Joint North Sea Wave Project) is given as

$$S(\omega) = 0.0081 g^2 \omega^{-5} \exp\left[-1.25\left(\frac{\omega_p}{\omega}\right)^4\right] \times \gamma^{\exp\left[\frac{(\omega-\omega_p)^2}{2\tau^2\omega_p^2}\right]}, \tag{37.57}$$

where γ represents the peakedness parameter or the ratio of the maximum spectral density to that of the corresponding P–M spectrum. The values of ω_p denote the peak frequency at which $S(\omega)$ is a maximum, and τ denotes the shape parameter. The quantities of the parameters are given by

$$\tau = \begin{cases} 0.07 & \text{for } \omega \le \omega_p \,, \\ 0.09 & \text{for } \omega > \omega_p \,. \end{cases} \tag{37.58}$$

The value of γ generally varies from 1 to 7; a frequently used value is 3.3.

To obtain the stochastic response in the frequency domain, the wave spectrum is all that is required to define the wave field. However, to simulate the structural response in the time domain, time series of the wave fields of interest may be reconstructed from a wave spectrum, such as the one shown in Fig. 37.5. We assume that the random waves observed at a spatial point are composed of a large number, N_w, of sinusoidal waves

$$\eta(t) = \sum_{q=1}^{N_w} A_q \cos\left(\omega_q t + \varepsilon_q\right) \,, \tag{37.59}$$

in which A_q is the amplitude $(H_q/2)$, ε_q is the (random) phase, and ω_q is the frequency of the q-th wave component. The wave spectrum is divided into N_w frequency bins. One such bin is the shaded area in Fig. 37.5. The $\Delta\omega$ may be chosen either uniformly or such that the energy contained in each bin (the shaded area) is constant. For the q-th bin, ω_q is the average frequency in the bin. The corresponding (single-sided) wave amplitude is given by

$$A_q = \sqrt{2S\left(\omega_q\right)\Delta\omega_q} \,. \tag{37.60}$$

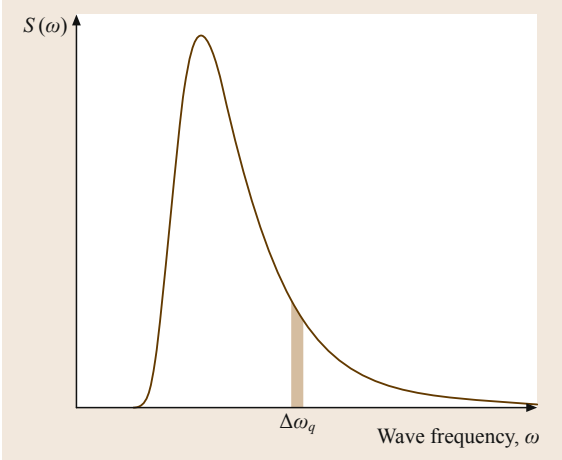

Fig. 37.5 Sample wave spectrum

A phase angle ε_q that is uniformly distributed in the range of $(0, 2\pi)$ is selected randomly. The wave number k_q is calculated from the frequency, and the wave profile is computed from

$$\eta(x,t) = \sum_{q=1}^{N} A_q \cos\left(k_q x - \omega_q t + \varepsilon_q\right) \tag{37.61}$$

to define a long-crested wave field.

37.4.2 Specification of Short-Crested, Directional Random Seas

In actual seas, the wave profile varies in both spatial directions, such that the actual wave crests are *short*. A means to characterize these fluctuations is through a stochastic description of the wave profile as

$$\eta(x,y,t) = \sum_{q=1}^{\infty} A_q \cos\left[\left(k_q \cos\theta_q\right) x + \left(k_q \sin\theta_q\right) y - \omega_q t + \varepsilon_q\right] \,, \tag{37.62}$$

where θ_n represents the wave incident angle. Then a two-dimensional (2-D) directional spectrum is defined as

$$S(\omega,\theta)\,\Delta\omega\Delta\theta = \sum_{\omega}^{\omega+\Delta\omega} \sum_{\theta}^{\theta+\Delta\theta} \frac{1}{2} A_q^2 \,. \tag{37.63}$$

The integral of a two-dimensional directional spectrum from 0 to 2π consistent with a frequency spectrum $S(\omega)$ is defined as

$$S(\omega) = \int_0^{2\pi} S(\omega,\theta)\mathrm{d}\theta \,. \tag{37.64}$$

It is convenient to separate a frequency spectrum for engineering use, thus

$$S(\omega,\theta) = S(\omega)G(\omega,\theta) \,. \tag{37.65}$$

$G(\omega)$ is called a directional spreading function with

$$\int_0^{2\pi} G(\omega,\theta)\mathrm{d}\theta = 1 \,. \tag{37.66}$$

Various expressions for $G(\omega,\theta)$ have been proposed [37.15]. $G(\omega,\theta)$ is, in general, a function of

ω, but the simplest expression considers G to be independent of ω. One possibility is the cosine-squared function

$$G(\theta) = \begin{cases} \frac{2}{\pi}\cos^2\theta & \text{for } |\theta| < \frac{\pi}{2}\,, \\ 0 & \text{otherwise}\,, \end{cases} \tag{37.67}$$

where θ is referred to as the base direction.

The wave profile is computed from

$$\eta(x,y,t) = \sum_{q=1}^{N_w}\sum_{m=1}^{M} A_{q,m}\cos\left[(k_q\cos\theta_m)x + (k_q\sin\theta_m)y - \omega_q t + \varepsilon_{q,m}\right]\,. \tag{37.68}$$

The amplitude of a wave at a particular frequency and direction is given by

$$A_{q,m} = \sqrt{2S\left(\omega_q,\theta_m\right)\Delta\omega\Delta\theta}\,. \tag{37.69}$$

Phase angles $\varepsilon_{q,m}$ are typically chosen to be uniformly distributed in the range of $(0, 2\pi)$, but sometimes they are assumed to be constant for a given frequency, ε_q.

37.4.3 Response in Random Seas

The procedure to compute the response of an offshore structure to random seas is the same, whether it is for long-crested (unidirectional) seas or short-crested (multidirectional) seas. In the case of linear behavior, the response to wave excitation composed of the sum of a number of frequencies is the sum of the response to the individual frequencies. Thus the response to each wave frequency can be solved independently. That is, for each excitation frequency ω_q, we first determine the response from (37.52)

$$\left[-\omega_q^2\left(\mathbf{M}_s^* + \mathbf{M}_f^*\right) + \mathrm{i}\left(\omega_q\mathbf{C}_f^* + \mathbf{C}_s^*\right) + \left(\mathbf{K}_s^* + \mathbf{K}_f^*\right)\right]\boldsymbol{Y}_q = \boldsymbol{F}_f^*\,. \tag{37.70}$$

Note that $\mathbf{M}_f^*$, $\mathbf{C}_f^*$ and $\boldsymbol{F}_f^*$ are functions of the wave frequency, and $\boldsymbol{F}_f^*$ is also a function of wave direction. If there is no directional spreading, then $M = 1$ in (37.68), and the equation corresponding to this value of ω_q needs to be solved only once. Otherwise, the same equation is solved for each spreading angle θ_m for $m = 1,\ldots M$, and the responses for frequency ω_q for each spreading angle are then summed. This process needs to be repeated for each excitation frequency q for $q = 1,\ldots,N_w$, and the total response to random seas is thus the sum of all the responses to each excitation frequency including all spreading angles θ_m for $m = 1,\ldots M$.

In some situations, it is not necessary to know the full time history of a particular response quantity. Rather, a measure of the stochastic response suffices. For response quantity τ, for any combination of wave frequency q and wave angle θ_j, the corresponding RAO for τ_{qj} can be obtained from (37.54), and the spectral value of the response can be computed by

$$S_{\tau_{qj}}\left(\omega_q,\theta_j\right) = |H_{\tau_{qj}}|^2 S\left(\omega_q,\theta_j\right)\,, \tag{37.71}$$

where $S\left(\omega_q,\theta_j\right)$ is the directional wave spectral density at ω_q and θ_j. The corresponding variance of the response τ_j for the wave angle θ_j, $\sigma_{\tau_j}^2$, is the area under the spectrum, $S_{\tau_{qj}}\left(\omega_q,\theta_j\right)$, of the response quantity τ_j. Assuming that the response of quantities τ_j to each wave angle θ_j are pairwise mutually independent, then the variance σ_τ^2 of response quantity τ is given by

$$\sigma_\tau^2 = \sum_1^{N_A}\sigma_{\tau_j}^2\,, \tag{37.72}$$

where N_A is the number of wave angles. This is a conservative assumption since usually there is a positive but weak correlation between adjacent wave angles.

37.4.4 Estimation of Extreme and Fatigue Response in Random Seas

The stochastic characteristics of the response of a MDOF structure to directional random seas including extreme and fatigue responses can be estimated when the corresponding characteristics for each individual response quantity τ are known using some stochastic combinational analyses such as (37.70) above. For this reason, we will focus on estimation of stochastic properties of SDOF systems in this section.

For random waves describable by linear wave theory, it is often assumed that the wave excitation is Gaussian with the characteristics described in Sects. 37.4.1–37.4.2. It is assumed that the transfer function for the response quantity τ_k has been obtained as outlined above. Then the statistics for any particular response quantity, e.g., the mean m_{τ_k}, $m_{\dot\tau_k}$ and standard deviation σ_{τ_k}, $\sigma_{\dot\tau_k}$, of the k-th response quantity τ, i. e., τ_k, respectively, and the cross-correlation coefficient between the displacement and velocity, $\rho_{\tau_k\dot\tau_k}$, can be computed. If the response quantities τ_k are defined as deviations from the mean position of the structure in random seas, then the mean displacement and velocity are zero [37.53], i. e., $m_{\tau_k} = 0$, and $m_{\dot\tau_k} = 0$. The standard deviation of the response quantity, nodal displacement, τ_k, and ve-

locity, $\dot{\tau}_k$ can be computed as

$$\sigma_{\tau_k} = \sqrt{\int_0^\infty S_{\tau_k}(\omega)\mathrm{d}\omega}\,, \tag{37.73}$$

where $S_{\tau_k}(\omega)$ is the single-sided spectral density of response quantities τ_k. Note that $S_{\tau_k}(\omega)$ may be obtained from (37.70). Similarly, the standard deviation of the nodal velocity $\dot{\tau}_k$ is given by

$$\sigma_{\dot{\tau}_k} = \sqrt{\int_0^\infty \omega^2 S_{\dot{\tau}_k}(\omega)\mathrm{d}\omega}\,. \tag{37.74}$$

Because displacement and velocity of a Gaussian dynamical quantity are statistically independent, the cross-correlation coefficient, $\rho_{\tau_k\dot{\tau}_k}$, is zero. The terms displacement and velocity were used above to refer to the response quantity τ_k, and its time rate of change, $\dot{\tau}_k$. However, τ_k may not be displacement but, e.g., stress. Regardless, the time rate of change is needed to compute positive crossing rates for extreme and fatigue failure computations, as shown below.

The probability density function $p(\tau_k)$ of the response quantity τ_k and the joint probability density function $p(\tau_k, \dot{\tau}_k)$ of the response quantity τ_k and velocity $\dot{\tau}_k$, respectively, are given by

$$p(\tau_k) = \frac{1}{\sqrt{2\pi}\sigma_{\tau_k}} \mathrm{e}^{-\frac{\tau_k^2}{2\sigma_{\tau_k}^2}}\,, \tag{37.75}$$

$$p(\tau_k, \dot{\tau}_k) = \frac{1}{2\pi\sigma_{\tau_k}\sigma_{\dot{\tau}_k}} \mathrm{e}^{-\frac{1}{2}\left(\frac{\tau_k^2}{\sigma_{\tau_k}^2} + \frac{\dot{\tau}_k^2}{\sigma_{\dot{\tau}_k}^2}\right)}\,. \tag{37.76}$$

The positive crossing rate (or crossing frequency), ν_{a}^+, at a level a_k of the random variable τ_k can be computed from the joint probability density function, and for a Gaussian process $\tau_k(t)$, the positive crossing rate is given by [37.53]

$$\nu_{\mathrm{a}k}^+ = \frac{\sigma_{\dot{\tau}_k}}{2\pi\sigma_{\tau_k}} \mathrm{e}^{-\frac{1}{2}\frac{a_k^2}{\sigma_{\tau_k}^2}}\,. \tag{37.77}$$

The probability distribution of the peaks of the response quantity τ_k is Rayleigh,

$$p_{\mathrm{p}}(a_k) = \frac{a_k}{\sigma_{\tau_k}^2} \mathrm{e}^{-\frac{a_k^2}{2\sigma_{\tau_k}^2}}\,, \quad 0 \le a \le \infty\,. \tag{37.78}$$

The expected time to failure (or mean life time to failure), T_a, or for a Gaussian random process $\tau_k(t)$ to exceed an extreme value a_k, is given by

$$T_a = \frac{1}{\nu_{\mathrm{a}k}^+ \int_0^\infty \left(\frac{1}{N(S)}\right) p_{\mathrm{p}}(S)\mathrm{d}S}\,, \tag{37.79}$$

where $N(S)$ is the S-N curve for the material under consideration [37.53]. Correspondingly, the probability of failure P_{f} due to the crossing of an extreme value a_k, for a Gaussian process τ_k discussed above is given by [37.53]

$$P_{\mathrm{f}}(T_{a_k}) = 1 - \mathrm{e}^{-\nu_{a_k}^+ T_{a_k}}\,. \tag{37.80}$$

As mentioned earlier, once the probabilistic characteristics of the response quantities τ_k are determined, the global response probabilistic characteristics of a MDOF system can be determined using a stochastic combination procedure.

37.5 Nonlinear Hydroelasticity (Nonlinear FSI)

The discussions in the previous sections involve only small amplitude wind-wave or earthquake excitations and small amplitude responses, and linear superposition applies. For large wave excitations, the waves will need to be described by a higher-order nonlinear theory. The response to each excitation frequency ω_q may also become nonlinear, or the amplitude of the total response may become too large, and the response among different frequencies ω_l and ω_k, $l \neq k$, may be coupled. In this case, the principle of superposition may cease to apply and some form of nonlinear analysis is required. For small nonlinearity, the perturbation method that is used to derive the linear equations of motion can again be used by including second-order terms in the expansion series of both the waves and the structure responses, thus including sum and difference frequency terms in the wave loads and the structural responses. However, for vary large wave excitations, hurricanes, tsunamis, and storm surges, the nonlinearity may become so large that the perturbation method, if it remains applicable, will involve too many terms in the expansion to be practical, and a direct coupled fluid-dynamics/structural mechanics computational approach will have to be used.

37.5.1 Nonlinear Frequency Domain Analysis

For large amplitude or shallow water waves, the linear theory of sinusoidal waves may no longer be adequate to describe the wave field, and a nonlinear wave theory that takes into account the steeper and narrower peaks, and wider and shallower troughs of the physical waves will have to be employed [37.18]. The nonlinear wave phenomenon (and the associated incident wave potential) can be described by higher-order perturbation wave theory. Correspondingly, theories of equal order perturbation have to be developed for the associated diffraction and radiation potentials for consistent and accurate treatment of the structural response computation. A second-order theory is briefly described in this section to demonstrate the gist of nonlinear perturbation expansion formulation and solution of the wave–structure interaction problem.

Higher Order Wave Description

General theories of nonlinear waves, including Stokes higher-order theory, Cnoidal theory, and stream functions, may be found in [37.17, 54–56]. For gravity waves described by potential flow, the incident wave potential can be expressed in a perturbation form as

$$\phi_{\mathrm{I}}(x,y,x;t) = \varepsilon^1\phi_{\mathrm{I}}^1(x,y,x;t) + \varepsilon^2\phi_{\mathrm{I}}^2 + \varepsilon^3\phi_{\mathrm{I}}^3 + \cdots , \tag{37.81}$$

where ε is the perturbation expansion parameter, and ϕ_{I}^j is the j-th order incident wave potential.

For Stokes second-order wave theory, the horizontal water particle velocity can be expressed as

$$u(x,t) = \frac{\pi H}{T}\frac{\cosh ky}{\sinh kd}\cos(kx-\omega t) + \frac{3}{4c}\left(\frac{\pi H}{T}\right)^2\frac{\cosh 2ky}{\sin h^4 kd}\cos 2(kx-\omega t) , \tag{37.82}$$

where H, T, k, ω, and $c = L/T$ are the first-order wave height, wave period, wave number, wave frequency, and celerity, respectively, with L being the first-order wave length, and d is the water depth. Note that the first term, which corresponds to that of linear wave theory, is proportional to $\frac{\pi H}{T}$, while the second term, which is proportional to $\left(\frac{\pi H}{T}\right)^2$, is a second-order correction term, and $\frac{\pi H}{T}$ can be considered the perturbation parameter. Similarly, the vertical water particle velocity is expressed as

$$v(x,t) = \frac{\pi H}{T}\frac{\sinh ky}{\sinh kd}\sin(kx-\omega t) + \frac{3}{4c}\left(\frac{\pi H}{T}\right)^2\frac{\sinh 2ky}{\sinh^4 kd}\sin 2(kx-\omega t) . \tag{37.83}$$

To determine the structural response to Stokes second-order wave excitations, these expressions would be used for wave load computations.

Higher Order Wave Load and Large-Body Structural Response Computation

Corresponding to incident wave perturbation expansion, the diffracted wave and radiation wave potentials can also be described as

$$\phi_{\mathrm{D}}(x,y,x;t) = \varepsilon^1\phi_{\mathrm{D}}^1(x,y,x;t) + \varepsilon^2\phi_{\mathrm{D}}^2 + \varepsilon^3\phi_{\mathrm{D}}^3 + \cdots , \tag{37.84}$$

and

$$\phi_{\mathrm{R}}(x,y,x;t) = \varepsilon^1\phi_{\mathrm{R}}^1(x,y,x;t) + \varepsilon^2\phi_{\mathrm{R}}^2 + \varepsilon^3\phi_{\mathrm{R}}^3 + \cdots . \tag{37.85}$$

The formulation for the second-order problem is similar to that of the first-order (linear) problem presented in the previous sections in this chapter. However, there are several major differences in the derivation of the second-order transfer functions and computation of the second-order responses that the readers need to be aware of.

First, the transfer functions (see $\mathbf{H}_\tau$ in (37.54)) of the second-order responses are functions of frequency pairs (ω_i, ω_j), instead of just a single frequency. The derivation of these second-order functions are beyond the scope of this chapter. Interested readers may want to consult the literature [37.18].

Second, it is important that in formulating the second-order load and response computations, second-order effects originating from first-order quantities have to be included. It is well known that (second-order) drift forces are caused by first-order (linear) waves, and play an important role in the low frequency response of compliant structures.

Third, other nonlinear effects that may cause second-order responses include large displacement and rotation (geometric effects) and need to be included in the perturbation expansion of the equations of structural motion.

As one can observe, computation of second-order response in the frequency domain can be quite complex. The study of stochastic response and extreme load

and motion, and fatigue failure predictions are active research topics.

Stochastic Higher Order Wave Load and Small-Body Structural Response Computation

An investigation of a second-order stochastic method for representing the second-order Morison hydrodynamic drag forces on a SDOF marine structure subjected to random waves showed that the method may be used to obtain good statistical approximation of the nonlinear effects via analysis in the frequency domain [37.57]. A distinct advantage of the approach is that a linear analysis of the structure in the frequency domain can be used to acquire detailed statistical information on the response to the nonlinear drag force. The resulting response statistics can then be used to obtain long-term fatigue life estimation and extreme value estimates for the response, based on the procedures described in Sect. 37.4.4.

37.5.2 Nonlinear Time-Domain Analysis

An alternative to obtain nonlinear fluid–structure interaction responses is to solve the coupled fluid–structure interaction problem as an initial boundary value problem numerically in the time domain. This method can capture the nonlinear transient and steady-state effects under arbitrary high sea states (at least theoretically) without any limit on the form of nonlinearity. However, the computational effort required can be very high (see discussion below).

Potential-Flow Field Approximation

For moderately high sea states where there is no breaking, the wave field can be assumed inviscid and irrotational, thus a potential flow model can be used to describe the hydrodynamics. The fully nonlinear hydrodynamic flow field can be solved, usually with the boundary-element method (BEM) without making any assumption on the degree of nonlinearity. In theory, the free surface can even be multi-valued, except the fluid domain has to be simply connected, thus no breaking and reentry/reconnection are allowed. The computational effort for fully nonlinear potential flow coupling with the structural dynamics of the large body (floating platform) and the mooring system is rather expensive. In general, some approximations on the flow field and the fluid–structure interaction problem are assumed to make the problem computationally efficient for practical industrial use.

An efficient approximation of the coupled three-dimensional (3-D) fluid–structure interaction (hybrid) time-domain solution under regular wave excitation is to keep the solution of the fluid linear (obtained in the frequency domain as shown in previous sections), but model the wave forces on the (rigid) structure in the time domain as follows

$$\mathbf{M}_s\ddot{x}(t) = \boldsymbol{F}_r(\omega,t) + \boldsymbol{F}_d(\omega,t) + \boldsymbol{F}_h(t) + \boldsymbol{F}_f(t) + \boldsymbol{F}_{vis}(t) + \boldsymbol{F}_g(t) + \boldsymbol{F}_m(t)\,, \tag{37.86}$$

where $\boldsymbol{x}(t)$ is the structural displacement vector, t is time, ω is the incident wave frequency, $\mathbf{M}_s$ is the structural mass matrix, $\boldsymbol{F}_r(\omega,t)$ is the frequency and time dependent radiation force vector, $\boldsymbol{F}_d(\omega,t)$ is the frequency and time dependent diffraction force vector, $\boldsymbol{F}_h(t)$ is the instantaneous hydrostatic force vector, $\boldsymbol{F}_f(t)$ is the instantaneous Froude–Krylov force vector, $\boldsymbol{F}_{vis}(t)$ is the viscous force vector, $\boldsymbol{F}_g(t)$ is the instantaneous gravity force vector, and $\boldsymbol{F}_m(t)$ is the instantaneous mooring force vector.

Under this formulation, the radiation and diffraction forces are calculated using linear wave theory and BEM, while the nonlinear hydrostatic, Froude–Krylov, gravity and mooring forces are calculated based on their instantaneous position. The nonlinear viscous force, which represents the effect of viscous dissipation, is often modeled in a Morison form with the drag coefficient as a parameter obtained from experimental results.

Mooring forces are usually quite nonlinear. They can be obtained using a cable dynamic model and solved numerically using the finite-element method. This approach can also be used for flexible structure models.

Navier–Stokes Flow Field Approximation

For highly nonlinear transient effects, an increasingly popular approach is to solve numerically the fluid and structural domain responses of the coupled fluid–structure interaction problem directly using high-performance computing.

One approach to include nonlinearity in the waves is to solve the potential problem directly in the time domain using a step-by-step solution procedure. The nonlinear potential flow problem can be solved using either the boundary-element method (BEM) see [37.58] or the finite-element method (FEM) see [37.59]. For computational fluid-structure interaction (FSI), both the BEM and the FEM approaches coupling with FEM structural modeling have seen success [37.60]. However, potential flow can only approximate flows that are inviscid and irrotational (mostly for diffraction problems of *large* structures). For highly nonlinear violent flow around a structure, such as wave slamming, these assumptions will no longer be valid, and viscous flow governed by the Navier–Stokes equation (NSE) will

need to be employed. When compressibility is important (wave–structure impact), the governing equations for conservation of mass and momentum of the NSE (as shown below) have to be used

$$\frac{\partial \rho}{\partial t} + \rho \nabla \cdot \boldsymbol{u} = 0\,,$$
$$\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} = -\frac{1}{\rho}(\nabla P + \frac{2}{3}\mu \nabla \cdot \boldsymbol{u}) + \frac{\mu}{\rho}\nabla^2 \boldsymbol{u} + \boldsymbol{g}\,, \qquad (37.87)$$

where ρ is the fluid density; $\boldsymbol{u}$ is the fluid particle velocity vector, P is the fluid pressure, μ is the bulk viscosity, and $\boldsymbol{g}$ is the body force vector due to gravity. However, under many applications the water can be assumed incompressible and the conservation of mass equation can be simplified to $\nabla \cdot \boldsymbol{u} = 0$.

The fully nonlinear wave forces on a rigid structure can be calculated based on the fluid pressure which is obtained by solving the NSE equation above.

An advantage of using a NSE fluid solver is its capability to couple with a computational structural mechanics solver, thus allowing the direct computation of fully coupled fluid–flexible structure interaction. Currently, there are a number of commercially available coupled fluid–structure interaction software applications using the FEM solution for computational structural mechanics (CSM) and a computational fluid dynamic (CFD) solver using either FEM or the finite-volume method (FVM). Some of these CSM-CFD coupling software applications are maturing and ready for standard practice. References for commercial software can be found readily on the internet. Readers who are interested in learning the details of these solvers should consult the CFD and CSM literature in general, and coupled fluid–structure interaction (FSI) literature in particular.

38. Cable Dynamics for Marine Applications

Ioannis K. Chatjigeorgiou, Spyros A. Mavrakos

It is the purpose of this chapter to provide most of the information associated with the dynamic behavior of slender cables (mooring lines), with particular emphasis on marine applications. The basics of its content are based on the personal fundamental research of the authors as regards the applications of cables in the marine environment, giving special consideration to the details of their time varying response.

The dynamics of cables have been investigated for decades, but admittedly, the specific subject attracted profound attention by the global research community with respect to the use of cables in offshore deep water applications. The interested reader can find an enormous amount of very important and thorough studies in the literature, which address relevant problems, from statics to very complicated nonlinear dynamics, using various mathematical formulations, and from simple to sophisticated numerical solution schemes.

The scope of the present effort is to associate the aspect of dynamics, linear and nonlinear, with the most typical practical applications of cables in the marine environment and especially in the offshore sector. The methodology that was chosen to perform this task relies on a global formulation for the governing dynamical systems. A generic analysis that is based on the assumption of line dynamics exploiting the fact that relevant representations may be effectively considered as two-point boundary value problems.

Cables and elastic lines are used in a plethora of technologically advanced applications, on land, in the air, and at sea. The present effort aims at investigating the dynamic behavior of cables as regards their marine applications. Examples of the use of cables in naval architecture, marine, and offshore engineering include, but are not limited to, towing applications, elastic hoses, guides of remote operating vehicles, deployment of fiber ropes, cables for deployment of instrumentation packages on the seafloor, mooring systems, etc. Among the preceding list, the latter is the most frequent and at the same time the most demanding application.

A cable is virtually a slender structure that, depending on the application, can be (considered) inelastic (metallic) or very elastic (synthetic). However, contrary to analogous applications of slender structures where the bending stiffness is the prevailing component (risers and pipelines), the main concern for cables is the axial force, which will be referred herein as the tension or effective tension. Due to their small cross-sectional area the bending stiffness of cables admits very small values, meaning that cables are not capable of undertaking bending effects and, accordingly, the tension becomes the most crucial component. Ten-

sion is important for cables for two major reasons: firstly, tension is the term that stabilizes the lengthy structure and secondly it affects its integrity. If a cable is going to fail, that will occur due to extreme axial loading when it exceeds the breaking tension. In specific applications, such as mooring cables, the tension is the component that provides the necessary restoring characteristics to the moored vessel and restrains its displacements. Hence, the analysis of the dynamic equilibrium of cables intends primarily that task, namely the anticipation of the most possible accuracy of the component that adds to the static tension (when applicable). The variability of the dynamic components is tightly correlated with fatigue and, hence, relevant effects should be properly and accurately addressed.

Admittedly, the ability of omitting the bending stiffness from the group of physical and mechanical properties of cables leads to significant simplifications of the theoretical formulation. It is also true that, as far as the cable dynamics is concerned, the inclusion or not of the actual bending stiffness will not change the axial loading computations. In fact, this is exactly the approach that is taken by the majority of the research endeavors in the field. Nevertheless, the inclusion of the bending effects, regardless of their insignificant contribution on the dynamics of cables, resolves many problems in the numerical simulation, giving special attention to singular applications such as high or low tension cables. In addition, it should be admitted that the incorporation of all relevant effects in a system is conceptually the most accurate and advisable approach.

Marine applications of cable structures involve several peculiarities and crucial aspects. These arise from the fact that similar applications require the employment of lengthy cables, whilst in addition the cables operate in an extremely hostile and variable environment. Cables in the sea are always under motion and variable configuration, making their dynamic behavior the most important and, at the same time, the most interesting part of their design and analysis processes. Areas of interest and concern as far as the dynamics of marine cables are concerned are resonance regimes (both linear and nonlinear), low and high tension impacts, zero tension singularities, cable bottom interaction effects, mooring-induced damping effects, vortex-induced vibrations (VIV), induced fatigue, etc. It should be admitted that from the previous list specific parts are adapted to specific applications.

For the purposes of the present contribution, the authors attempt to address most of the preceding features, excluding VIV effects. The text that follows should not be regarded as material that focuses on a specific field. Is rather a survey that tries to cover the details of marine cables' dynamic behavior in the majority of their typical operations, and it is based on the long-term knowledge, experience, and efforts of the authors in the field.

The chapter on cable dynamics of the handbook at hand is structured as follows. Section 38.1 outlines the mathematical formulation of the problem and derives the complete nonlinear governing set that is accordingly reduced to provide the simplified linearized formulas. Section 38.2 treats the eigenvalue problems of both in-plane and out-of-plane vibrations and this is extended to highlight the differences that occur when a cable line has a part lying on the seafloor. Section 38.3 is dedicated to high and low tension regimes of marine cables; in other words, the snap-slack conditions as they are encountered in highly demanding applications such as in tendons of tension leg platforms. Section 38.4 analyzes the dynamics of mooring cables and the effect of intermediate buoys attached along their suspended length, whilst it exploits the employed solution to quantify and discuss the so-called mooring-induced damping phenomenon that contemporarily attracts major attention in mooring systems of wave energy converters. Section 38.5 presents a novel frequency domain-based approach for assessing the nonlinear dynamics of cables combined with a sophisticated methodology that allows accounting for cable bottom interaction effects.

The authors have avoided providing extensive numerical computations, and thus the results shown in each section are indicative of the application considered. The goal of the carefully selected plots is to provide evidence on the details of the dynamic response of cables and, obviously, to support the relevant discussion.

38.1 Mathematical Formulation

The cable is modeled as a Euler–Bernoulli beam with the following physical and mechanical properties: mass per unit unstretched length m, weight per unit unstretched length w_0, diameter d_O, cross-sectional area A, polar moment I_p, second moment I, material density ρ_c, modulus of elasticity E, and shear modulus G. It is noted that the quantities d_O, A, I_p, and I refer to the unstretched condition. The balance of the loading components (moments and forces) is shown schematically in Fig. 38.1. The stretched differential length of the element is $(1+e)\,\mathrm{d}s$, where $\mathrm{d}s$ is the unstretched differential length, e is the axial strain, and s denotes the Lagrangian coordinate that takes values along the unstretched length of the cylindrical element. All vari-

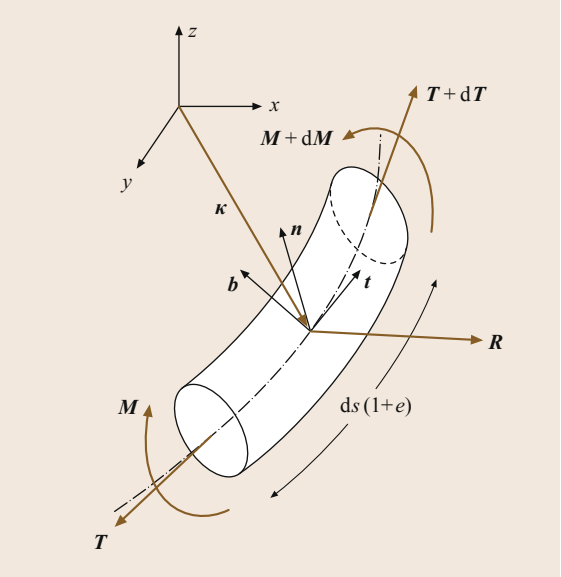

Fig. 38.1 Dynamic equilibrium of the stretched element

ables are defined with respect to the local Lagrangian coordinate system, which is determined by the unit vectors $\boldsymbol{t}$, $\boldsymbol{n}$, and $\boldsymbol{b}$. The unit vector $\boldsymbol{t}$ is tangent to the axis, $\boldsymbol{n}$ is perpendicular to $\boldsymbol{t}$, and the unit vector $\boldsymbol{b}$ is defined such that the system of vectors is orthogonal and right handed. In the following, the motions and the velocities parallel to $\boldsymbol{n}$ and $\boldsymbol{b}$ will be referred to as *normal* and *bi-normal*, respectively. By analogy, the loading components parallel to $\boldsymbol{n}$ and $\boldsymbol{b}$ will be referred to as *in plane* and *out of plane*.

In Fig. 38.1 $\boldsymbol{T} = T\boldsymbol{t} + S_\mathrm{n}\boldsymbol{n} + S_\mathrm{b}\boldsymbol{b}$, $\boldsymbol{M} = M_1\boldsymbol{t} + M_2\boldsymbol{n} + M_3\boldsymbol{b}$ denote respectively the vectors of forces and moments. Furthermore, T, S_n, S_b, M_1, M_2, M_3 denote, respectively, the tension, the in-plane and the out-of-plane shear forces, the moment due to torsion, the out-of-plane bending moment, and the in-plane bending moment. Finally, let $\boldsymbol{R}$ denote the vector summation of the distributed forces applied on the cable.

38.1.1 Derivatives in Time and Space

The material derivatives in time and space are complicated to some extent due to the selection of the Lagrangian coordinate system. This can be traced back to the fact that aside from the variation of the dynamic components in time and space, the coordinate system itself also varies with time t and the local coordinate s. The associated derivatives will first be expressed for an arbitrary vector $\boldsymbol{H}$, which in terms of the Lagrangian coordinate system of Fig. 38.1 is given by

$$\boldsymbol{H} = H_1\boldsymbol{t} + H_2\boldsymbol{n} + H_3\boldsymbol{b} \,. \tag{38.1}$$

The material derivative of $\boldsymbol{H}$ with respect to s is written as

$$\frac{\mathrm{D}\boldsymbol{H}}{\mathrm{D}s} = \frac{\partial \boldsymbol{H}}{\partial s} + H_1\frac{\partial \boldsymbol{t}}{\partial s} + H_2\frac{\partial \boldsymbol{n}}{\partial s} + H_3\frac{\partial \boldsymbol{b}}{\partial s} \,. \tag{38.2}$$

If $\boldsymbol{\Omega}$ denotes the Darboux vector of rotation for a space curve [38.1]

$$\boldsymbol{\Omega} = \Omega_1\boldsymbol{t} + \Omega_2\boldsymbol{n} + \Omega_3\boldsymbol{b} \,, \tag{38.3}$$

then for calculating the spatial derivatives of the unit vectors in (38.2), the symmetrical properties of the Darboux vector will be employed. These are [38.1]

$$\frac{\partial \boldsymbol{k}}{\partial s} = \boldsymbol{\Omega} \times \boldsymbol{k} \,, \tag{38.4}$$

for $\boldsymbol{k} = \boldsymbol{t}, \boldsymbol{n}, \boldsymbol{b}$.

After introducing (38.4) into (38.2), the later becomes

$$\frac{\mathrm{D}\boldsymbol{H}}{\mathrm{D}s} = \frac{\partial \boldsymbol{H}}{\partial s} + \boldsymbol{\Omega} \times \boldsymbol{H} \,. \tag{38.5}$$

With regard to the material derivative with respect to t, $\mathrm{D}/\mathrm{D}t$, of the arbitrary vector $\boldsymbol{H}$, the equivalent of the Darboux vector is the rotation vector of the classical dynamics

$$\boldsymbol{\omega} = \omega_1\boldsymbol{t} + \omega_2\boldsymbol{n} + \omega_3\boldsymbol{b} \,, \tag{38.6}$$

where ω_1, ω_2 and ω_3 are the associated angular velocities. Thus, the material derivative of $\boldsymbol{H}$ with respect to the time is written as [38.2]

$$\frac{\mathrm{D}\boldsymbol{H}}{\mathrm{D}t} = \frac{\partial \boldsymbol{H}}{\partial t} + \boldsymbol{\omega} \times \boldsymbol{H} \,. \tag{38.7}$$

The components of vectors $\boldsymbol{\omega}$ and $\boldsymbol{\Omega}$ are expressed in terms of the Euler angles ϕ, θ, and ψ as

$$\omega_1 = \frac{\partial \psi}{\partial t} - \frac{\partial \phi}{\partial t}\sin\theta \,, \tag{38.8}$$

$$\omega_2 = \frac{\partial \theta}{\partial t}\cos\psi + \frac{\partial \phi}{\partial t}\cos\theta\sin\psi \,, \tag{38.9}$$

$$\omega_3 = \frac{\partial \phi}{\partial t}\cos\theta\cos\psi - \frac{\partial \theta}{\partial t}\sin\psi \,, \tag{38.10}$$

$$\Omega_1 = \frac{\partial \psi}{\partial s} - \frac{\partial \phi}{\partial s}\sin\theta \,, \tag{38.11}$$

$$\Omega_2 = \frac{\partial \theta}{\partial s}\cos\psi + \frac{\partial \phi}{\partial s}\cos\theta\sin\psi \,, \tag{38.12}$$

$$\Omega_3 = \frac{\partial \phi}{\partial s}\cos\theta\cos\psi - \frac{\partial \theta}{\partial s}\sin\psi \,, \tag{38.13}$$

where ψ is the angle of torsion, ϕ is the angle which is formed between the tangent of the cable and the horizontal in the plane of reference, and θ is the out-of-plane angle. It is also noted that the elements of the

vector of moments are associated with the curvatures according to

$$\begin{aligned}\boldsymbol{M} &= M_1\boldsymbol{t} + M_2\boldsymbol{n} + M_3\boldsymbol{b} \\ &= GI_\mathrm{p}\Omega_1\boldsymbol{t} + EI\Omega_2\boldsymbol{n} + EI\Omega_3\boldsymbol{b}\,. \end{aligned} \tag{38.14}$$

38.1.2 Dynamic Equilibrium

Applying Newton's law to the stretched cable element along with the conservation of mass yields

$$m\frac{\mathrm{D}\boldsymbol{V}}{\mathrm{D}t} = \frac{\mathrm{D}\boldsymbol{T}}{\mathrm{D}s} + \boldsymbol{R}(1+e)\,. \tag{38.15}$$

Next, we expand the material derivatives in the local coordinate system to yield

$$m\left(\frac{\partial \boldsymbol{V}}{\partial t} + \boldsymbol{\omega}\times\boldsymbol{V}\right) = \frac{\partial \boldsymbol{T}}{\partial s} + \boldsymbol{\Omega}\times\boldsymbol{T} + \boldsymbol{R}(1+e)\,. \tag{38.16}$$

In (38.15) and (38.16), $\boldsymbol{V}$ denotes the velocity vector, which is expressed as

$$\boldsymbol{V} = u\boldsymbol{t} + v\boldsymbol{n} + w\boldsymbol{b}\,, \tag{38.17}$$

where u, v and w denote the velocities of the cable element parallel to the unit vectors $\boldsymbol{t}$, $\boldsymbol{n}$, and $\boldsymbol{b}$ of the local Lagrangian coordinate system. Also, after having defined the Euler angles and recalling that the distributed forces are composed by the gravitational components, the added mass terms and the nonlinear drag forces $\boldsymbol{R}(1+e)$ will be given by the following expression

$$\begin{aligned}\boldsymbol{R}(1+e) = &-(w_0\sin\phi\cos\theta - R_{\mathrm{d}t})\boldsymbol{t} \\ &-\left(w_0\cos\phi + m_\mathrm{a}\frac{\partial v_{2\mathrm{r}}}{\partial t} - R_{\mathrm{d}n}\right)\boldsymbol{n} \\ &-\left(w_0\sin\phi\sin\theta + m_\mathrm{a}\frac{\partial v_{3\mathrm{r}}}{\partial t} - R_{\mathrm{d}b}\right)\boldsymbol{b}\,, \end{aligned} \tag{38.18}$$

where

$$R_{\mathrm{d}t} = -\frac{1}{2}\pi\rho d_\mathrm{O} C_{\mathrm{d}t} v_{1\mathrm{r}}\,|v_{1\mathrm{r}}|\,\sqrt{1+e}\,, \tag{38.19}$$

$$R_{\mathrm{d}n} = -\frac{1}{2}\rho d_\mathrm{O} C_{\mathrm{d}n} v_{2\mathrm{r}}\sqrt{v_{2\mathrm{r}}^2 + v_{3\mathrm{r}}^2}\sqrt{1+e}\,, \tag{38.20}$$

$$R_{\mathrm{d}b} = -\frac{1}{2}\rho d_\mathrm{O} C_{\mathrm{d}b} v_{3\mathrm{r}}\sqrt{v_{2\mathrm{r}}^2 + v_{3\mathrm{r}}^2}\sqrt{1+e} \tag{38.21}$$

are the drag forces in axial, normal, and bi-normal directions depending on the associated drag coefficients $C_{\mathrm{d}t}$, $C_{\mathrm{d}n}$, and $C_{\mathrm{d}b}$, while $v_{1\mathrm{r}}$, $v_{2\mathrm{r}}$, and $v_{3\mathrm{r}}$ are the relative velocities in the case of the present of current. Clearly, ρ denotes the water density.

Further, the balance of moments equation is obtained by taking moments about the left-hand side of the differential element and expressing the results in terms of unstretched quantities. This yields [38.3]

$$\begin{aligned}\frac{1}{1+e}\frac{\mathrm{D}}{\mathrm{D}t}[\rho_\mathrm{c}\mathbf{I}\boldsymbol{\omega}] = &\frac{1}{(1+e)^2}\frac{\mathrm{D}\boldsymbol{M}}{\mathrm{D}s} + \mathrm{d}\boldsymbol{\kappa} \\ &\times\boldsymbol{R}(1+e) + \frac{\mathrm{d}\boldsymbol{\kappa}}{\mathrm{d}s}\times\boldsymbol{T}\,, \end{aligned} \tag{38.22}$$

where $\boldsymbol{\kappa}$ denotes the vector from the origin to the beam element (Fig. 38.1). In the limit $\mathrm{d}\boldsymbol{\kappa}\to 0$ it holds that

$$\mathrm{d}\boldsymbol{\kappa}\times\boldsymbol{R}\to 0\,, \tag{38.23}$$

$$\frac{1}{1+e}\frac{\mathrm{d}\boldsymbol{\kappa}}{\mathrm{d}s}\to\boldsymbol{t}\,. \tag{38.24}$$

Thus, (38.22) renders the following simplified form that provides the balance of moments equations

$$\frac{1}{1+e}\frac{\mathrm{D}}{\mathrm{D}t}[\rho_\mathrm{c}\mathbf{I}\boldsymbol{\omega}] = \frac{1}{(1+e)^2}\frac{\mathrm{D}\boldsymbol{M}}{\mathrm{D}s} + \boldsymbol{t}\times\boldsymbol{T}(1+e)\,, \tag{38.25}$$

where $\rho_\mathrm{c}\mathbf{I}$ is a diagonal 3×3 matrix with $\mathrm{diag}[\rho_\mathrm{c}\mathbf{I}] = (\rho_\mathrm{c}I_\mathrm{p}, \rho_\mathrm{c}I, \rho_\mathrm{c}I)$. After expanding the material derivatives, (38.25) is transformed into

$$\begin{aligned}\frac{\rho_\mathrm{c}\mathbf{I}}{1+e}\left(\frac{\partial\boldsymbol{\omega}}{\partial t} + \boldsymbol{\omega}\times\boldsymbol{\omega}\right) = &\frac{1}{(1+e)^2}\left(\frac{\partial\boldsymbol{M}}{\partial s} + \boldsymbol{\Omega}\times\boldsymbol{M}\right) \\ &+\boldsymbol{t}\times\boldsymbol{T}(1+e)\,. \end{aligned} \tag{38.26}$$

Finally, the compatibility relation will be derived, which requires that the element is free of discontinuities. Therefore, the vector $\boldsymbol{\kappa}(s,t)$ must be a continuous function of both independent variables. In other words,

$$\frac{\mathrm{D}}{\mathrm{D}t}\left[\frac{\mathrm{D}\boldsymbol{\kappa}}{\mathrm{D}s}\right] = \frac{\mathrm{D}}{\mathrm{D}s}\left[\frac{\mathrm{D}\boldsymbol{\kappa}}{\mathrm{D}t}\right]. \tag{38.27}$$

Taking into account that (Fig. 38.1) $\boldsymbol{V} = \mathrm{D}\boldsymbol{\kappa}/\mathrm{D}t$, $(1+e)\boldsymbol{t} = \mathrm{D}\boldsymbol{\kappa}/\mathrm{D}s$ and assuming a linear stress-strain relation $e = T/EA$, (38.27) is cast into

$$\frac{1}{EA}\frac{\partial T}{\partial t}\boldsymbol{t} + (1+e)\boldsymbol{\omega}\times\boldsymbol{t} = \frac{\partial\boldsymbol{V}}{\partial s} + \boldsymbol{\Omega}\times\boldsymbol{V}\,. \tag{38.28}$$

38.1.3 Final System

The governing dynamic equilibrium system is derived by expanding the cross products in (38.16), (38.26), and (38.28). As a result, a system of partial differential equations is obtained, which is given in detail in the following,

$$\begin{aligned}&\frac{\partial T}{\partial s} + S_\mathrm{b}\Omega_2 - S_\mathrm{n}\Omega_3 - w_0\sin\phi\cos\theta - m\frac{\partial u}{\partial t} \\ &\quad - mw\left(\frac{\partial\theta}{\partial t}\cos\psi + \frac{\partial\phi}{\partial t}\cos\theta\sin\psi\right) \\ &\quad + mv\left(\frac{\partial\phi}{\partial t}\cos\theta\cos\psi - \frac{\partial\theta}{\partial t}\sin\psi\right) + R_{\mathrm{d}t} = 0\,, \end{aligned} \tag{38.29}$$

$$\frac{\partial S_\mathrm{n}}{\partial s} + \Omega_3 T - \Omega_1 S_\mathrm{b} - w_0 \cos\phi - m\frac{\partial v}{\partial t} - mu\left(\frac{\partial \phi}{\partial t}\cos\theta\cos\psi - \frac{\partial \theta}{\partial t}\sin\psi\right) + mw\left(\frac{\partial \psi}{\partial t} - \frac{\partial \phi}{\partial t}\sin\theta\right) + R_{dn} = 0\,, \tag{38.30}$$

$$\frac{\partial S_\mathrm{b}}{\partial s} + \Omega_1 S_\mathrm{n} - \Omega_2 T - w_0 \sin\phi\sin\theta - m\frac{\partial w}{\partial t} - mv\left(\frac{\partial \psi}{\partial t} - \frac{\partial \phi}{\partial t}\sin\theta\right) + mu\left(\frac{\partial \theta}{\partial t}\cos\psi + \frac{\partial \phi}{\partial t}\cos\theta\sin\psi\right) + R_{db} = 0\,, \tag{38.31}$$

$$\frac{\partial u}{\partial s} + \Omega_2 w - \Omega_3 v - \frac{1}{EA}\frac{\partial T}{\partial t} = 0\,, \tag{38.32}$$

$$\frac{\partial v}{\partial s} + \Omega_3 u - \Omega_1 w - \frac{\partial \phi}{\partial t}\cos\theta\cos\psi + \frac{\partial \theta}{\partial t}\sin\psi = 0\,, \tag{38.33}$$

$$\frac{\partial w}{\partial s} + \Omega_1 v - \Omega_2 u + \frac{\partial \theta}{\partial t}\cos\psi + \frac{\partial \phi}{\partial t}\cos\theta\sin\psi = 0\,, \tag{38.34}$$

$$GI_\mathrm{p}\frac{\partial \Omega_1}{\partial s} - \rho_\mathrm{c} I_\mathrm{p}\left(\frac{\partial^2 \psi}{\partial t^2} - \frac{\partial^2 \phi}{\partial t^2}\sin\theta - \frac{\partial \phi}{\partial t}\frac{\partial \theta}{\partial t}\cos\theta\right) = 0\,, \tag{38.35}$$

$$EI\frac{\partial \Omega_2}{\partial s} + (GI_\mathrm{p} - EI)\Omega_1\Omega_3 - S_\mathrm{b} - \rho_\mathrm{c} I\left(\frac{\partial^2 \theta}{\partial t^2}\cos\psi - \frac{\partial \theta}{\partial t}\frac{\partial \psi}{\partial t}\sin\psi + \frac{\partial^2 \phi}{\partial t^2}\cos\theta\sin\psi - \frac{\partial \phi}{\partial t}\frac{\partial \theta}{\partial t}\sin\theta\sin\psi + \frac{\partial \phi}{\partial t}\frac{\partial \psi}{\partial t}\cos\theta\cos\psi\right) = 0\,, \tag{38.36}$$

$$EI\frac{\partial \Omega_3}{\partial s} + (EI - GI_\mathrm{p})\Omega_1\Omega_2 + S_\mathrm{n} - \rho_\mathrm{c} I\left(\frac{\partial^2 \phi}{\partial t^2}\cos\theta\cos\psi - \frac{\partial \phi}{\partial t}\frac{\partial \theta}{\partial t}\sin\theta\cos\psi - \frac{\partial \phi}{\partial t}\frac{\partial \psi}{\partial t}\cos\theta\sin\psi - \frac{\partial^2 \theta}{\partial t^2}\sin\psi - \frac{\partial \theta}{\partial t}\frac{\partial \psi}{\partial t}\cos\psi\right) = 0\,. \tag{38.37}$$

A similar, simplified system omitting torsion effects was derived by *Howell* [38.4].

Clearly, EI and GI_p in the above relations were assumed to be independent of s. Further, (38.29)–(38.37) are combined with the curvatures, (38.11)–(38.13), to form a system of 12 partial differential equations with the same number of unknowns. For slender structures with very small cross-sectional areas, such as cables, torsional effects can be considered negligible. The flexural rigidity is retained, however, for practical reasons to eliminate possible zero tension singularities when solving the dynamics of the governing equilibrium system. Thus, after eliminating the terms that govern torsion, the system is reduced to

$$\frac{\partial T}{\partial s} + S_\mathrm{b}\Omega_2 - S_\mathrm{n}\Omega_3 - w_0 \sin\phi\cos\theta + R_{dt} - m\frac{\partial u}{\partial t} - m\left(w\frac{\partial \theta}{\partial t} - v\frac{\partial \phi}{\partial t}\cos\theta\right) = 0\,, \tag{38.38}$$

$$\frac{\partial S_\mathrm{n}}{\partial s} + \Omega_3(T + S_\mathrm{b}\tan\theta) - w_0\cos\phi + R_{dn} - m\frac{\partial v}{\partial t} - m\frac{\partial \phi}{\partial t}(u\cos\theta + w\sin\theta) - m_\mathrm{a}\frac{\partial v}{\partial t} = 0\,, \tag{38.39}$$

$$\frac{\partial S_\mathrm{b}}{\partial s} - \Omega_2 T - \Omega_3 S_\mathrm{n}\tan\theta - w_0\sin\phi\sin\theta + R_{db} - m\frac{\partial w}{\partial t} + m\left(v\frac{\partial \phi}{\partial t}\sin\theta + u\frac{\partial \theta}{\partial t}\right) - m_\mathrm{a}\frac{\partial w}{\partial t} = 0\,, \tag{38.40}$$

$$\frac{\partial u}{\partial s} + \Omega_2 w - \Omega_3 v - \frac{1}{EA}\frac{\partial T}{\partial t} = 0\,, \tag{38.41}$$

$$\frac{\partial v}{\partial s} + \Omega_3(u + w\tan\theta) - (1+e)\frac{\partial \phi}{\partial t}\cos\theta = 0\,, \tag{38.42}$$

$$\frac{\partial w}{\partial s} - \Omega_3 v\tan\theta - \Omega_2 u + (1+e)\frac{\partial \theta}{\partial t} = 0\,, \tag{38.43}$$

$$EI\frac{\partial \Omega_2}{\partial s} + EI\Omega_3^2\tan\theta - S_\mathrm{b}(1+e)^3 = 0\,, \tag{38.44}$$

$$EI\frac{\partial \Omega_3}{\partial s} - EI\Omega_2\Omega_3\tan\theta + S_\mathrm{n}(1+e)^3 = 0\,, \tag{38.45}$$

$$\frac{\partial \theta}{\partial s} - \Omega_2 = 0\,, \tag{38.46}$$

$$\frac{\partial \phi}{\partial s}\cos\theta - \Omega_3 = 0\,. \tag{38.47}$$

38.1.4 Reduced Model Omitting Bending Stiffness

The basic mathematical model is composed of (38.38)–(38.47) and can describe effectively the global three-dimensional (3-D) nonlinear dynamics of any nonspinning slender structure, regardless of whether or not flexural rigidity is considered significant. It can also account for variable physical and mechanical properties

along its length. The latter can be realized by letting w_0, m, m_a, EA, and EI to be functions of the coordinate s.

Typically, when we are referring on cables, or chains, it is usual to assume negligible bending stiffness. This, in turn, will lead to a significant simplification of the governing set, allowing faster calculations. In particular, by letting $EI \to 0$, the generic nonlinear system of (38.38)–(38.47) is reduced to only six partial differential equations with an equal number of unknowns, the elements T, ϕ, θ, u, v, and w. The reduced system can be compacted to the following matrix form

$$\begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & -v\cos\theta & w & 1 & 0 & 0 \\ 0 & \cos\theta(u+\tan\theta) & 0 & 0 & 1 & 0 \\ 0 & -v\sin\theta & -u & 0 & 0 & 1 \end{bmatrix} \frac{\mathrm{d}}{\mathrm{d}s} \begin{bmatrix} T \\ \phi \\ \theta \\ u \\ v \\ w \end{bmatrix}$$

$$= \begin{bmatrix} w_0\cos\theta\sin\phi - R_{\mathrm{d}t} \\ \dfrac{w_0}{T}\dfrac{\cos\phi}{\cos\theta} - \dfrac{R_{\mathrm{d}n}}{T}\dfrac{1}{\cos\theta} \\ -\dfrac{w_0}{T}\sin\theta\sin\phi + \dfrac{R_{\mathrm{d}b}}{T} \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

$$+ \begin{bmatrix} 0 & -mv\cos\theta & mw & m & 0 & 0 \\ 0 & \dfrac{m}{T}(u+w\tan\theta) & 0 & 0 & \dfrac{m+m_a}{T\cos\theta} & 0 \\ 0 & \dfrac{m}{T}v\sin\theta & \dfrac{m}{T}u & 0 & 0 & -\dfrac{m+m_a}{T} \\ \dfrac{1}{EA} & 0 & 0 & 0 & 0 & 0 \\ 0 & (1+e)\cos\theta & 0 & 0 & 0 & 0 \\ 0 & 0 & -(1+e) & 0 & 0 & 0 \end{bmatrix}$$

$$\times \frac{\mathrm{d}}{\mathrm{d}t} \begin{bmatrix} T \\ \phi \\ \theta \\ u \\ v \\ w \end{bmatrix} . \qquad (38.48)$$

It is immediately apparent that as far as the cable dynamics are concerned, the assumption that the model cannot undertake any bending effects leads univocally to the probability of the occurrence of a singularity, usually referred as the *zero tension singularity*. Virtually, this singularity characterizes only the theoretical formulation of the cable dynamical problem, meaning that when the total tension at any point along the cable becomes zero, then the theoretical model and, accordingly, the numerical solution scheme collapses. There is a practical, mostly empirical, way to avoid the associated singularity during numerical calculations by stopping the computations during the associated time interval and artificially putting the tension equal to zero. This is the approach taken by *Papazoglou* et al. [38.5] and, accordingly, by *Johanning* et al. [38.6], although in the latter study the authors do not arrive at a condition that fully cancels the effective tension. It should be admitted, however, that it is conceptually more accurate to simulate a cable as a slender beam given the fact that it undertakes, admittedly to a marginal extent, some bending effects. With this approach, the zero tension singularity, which may occur in specific applications such as in low tension cables, is virtually eliminated.

38.1.5 Equivalent Linearization

The basic dynamical model that is considered herein is the complete 3-D nonlinear continuous system given by (38.38)–(38.47). It is apparent that the solution of that system can be achieved only by applying appropriate time domain solution techniques. Typically, the solution in the time domain requires post-processing of the time histories of the dynamic components, which inevitably results in additional computational effort. Most of the time, however, the actual dynamic behavior can be accurately approximated by only the linear components, whereas the nonlinear terms are significant only in specific conditions. Hence, it is advisable for any nonlinear dynamic system to start from the study of its linearized equivalent, which is obtained by ignoring or by linearizing the nonlinear terms. For the nonlinear system at hand, the linearization procedure begins by considering that the time varying terms are given by the summation of static and dynamic counterparts. Thus, the vector of the unknowns (38.38)–(38.47)

$$\boldsymbol{Y}(s,t) = \left[T \;\; S_{\mathrm{n}} \;\; S_{\mathrm{b}} \;\; u \;\; v \;\; w \;\; \Omega_2 \;\; \Omega_3 \;\; \theta \;\; \phi \right]^{\mathrm{T}} , \qquad (38.49)$$

is written as

$$\boldsymbol{Y}(s,t) = \boldsymbol{Y}_0(s) + \boldsymbol{Y}_1(s,t) , \qquad (38.50)$$

where

$$\boldsymbol{Y}_0(s) = \left[T_0 \;\; S_{\mathrm{n}0} \;\; S_{\mathrm{b}0} \;\; 0 \;\; 0 \;\; 0 \;\; 0 \;\; \Omega_{30} \;\; 0 \;\; \phi_0 \right]^{\mathrm{T}} , \qquad (38.51)$$

and

$$\boldsymbol{Y}_1(s,t) = \left[T_1 \;\; S_{\mathrm{n}1} \;\; S_{\mathrm{b}1} \;\; u \;\; v \;\; w \;\; \Omega_{21} \;\; \Omega_{31} \;\; \theta_1 \;\; \phi_1 \right]^{\mathrm{T}} . \qquad (38.52)$$

The static quantities for the out-of-plane angle θ_0 and the out-of-plane curvature Ω_{20} were set equal to zero as in the static equilibrium position the cable was considered to have a perfect two-dimensional (2-D) configuration. It is noted that in the context of the linear problem,

the velocities u, v, and w can be immediately replaced by the corresponding motions $u = \partial p/\partial t$, $v = \partial q/\partial t$, and $w = \partial r/\partial t$. After introducing (38.50) into the nonlinear governing equation (38.38)–(38.47) and omitting higher order terms, the original set is recast to

$$m\frac{\partial^2 p}{\partial t^2} = \frac{\partial T_1}{\partial s} - S_{n1}\Omega_{30} - S_{n0}\Omega_{31} - w_0\cos\phi_0\phi_1 \,, \tag{38.53}$$

$$(m+m_a)\frac{\partial^2 q}{\partial t^2} = \frac{\partial S_{n1}}{\partial s} + T_1\Omega_{30} + \Omega_{31}T_0 + w_0\sin\phi_0\phi_1 - c\omega\,|q|\,\frac{\partial q}{\partial t} \,, \tag{38.54}$$

$$(m+m_a)\frac{\partial^2 r}{\partial t^2} = \frac{\partial S_{b1}}{\partial s} - S_{n0}\Omega_{30}\theta_1 - T_0\Omega_{21} - w_0\sin\phi_0\theta_1 - c\omega\,|r|\,\frac{\partial r}{\partial t} \,, \tag{38.55}$$

$$T_1 = EA\left(\frac{\partial p}{\partial s} - \Omega_{30}q\right) , \tag{38.56}$$

$$\phi_1 = \frac{\partial q}{\partial s} + \Omega_{30}p \,, \tag{38.57}$$

$$\theta_1 = -\frac{\partial r}{\partial s} \,, \tag{38.58}$$

$$EI\frac{\partial \Omega_{21}}{\partial s} - EI\Omega_{30}\theta_1 = S_{b1} \,, \tag{38.59}$$

$$EI\frac{\partial \Omega_{31}}{\partial s} = -S_{n1} \,, \tag{38.60}$$

$$\frac{\partial \theta_1}{\partial s} = \Omega_{21} \,, \tag{38.61}$$

$$\frac{\partial \phi_1}{\partial s} = \Omega_{31} \,, \tag{38.62}$$

where it was assumed that $1 + e \approx 1$ and the drag force in axial direction was omitted as it depends on a very small drag coefficient. In the realm of linear theory, the nonlinear drag forces must be linearized as well, and that was exactly the approach that was taken herein as it is manifested by the last terms of (38.54)–(38.55). The linearization requires that the drag forces must be approximated by a Fourier series expansion from which only the linear components are retained [38.7]. Here, c denotes the linearized damping coefficient $c = (4/3\pi)\rho C_d d_O$, where d_O is the outer diameter. Clearly, for a cylindrical structure the drag coefficients in normal and bi-normal directions are equal, i. e., $C_d = C_{dn} = C_{db}$.

A careful inspection of the system of equations (38.53)–(38.62) reveals that the out-of-plane and the in-plane motions are virtually decoupled. In fact, the assumption that enabled decoupling was the omission of torsion. For more information the interested reader is referenced to [38.8]. Hence, (38.53)–(38.62) can be split into two independent sets that can be treated separately. Accordingly, the in-plane and the out-of-plane linear dynamics of the cable are governed by the sets of equations (38.53), (38.54), (38.56), (38.57), (38.60), (38.62), and (38.55), (38.58), (38.59), and (38.61), respectively.

The vectors of the associated unknown dynamic components for the in-plane and the out-of-plane linear systems are, respectively, given by

$$\boldsymbol{X}(s,t) = \begin{bmatrix} T_1 & S_{n1} & p & q & \Omega_{31} & \phi \end{bmatrix}^T \,, \tag{38.63}$$

$$\boldsymbol{Z}(s,t) = \begin{bmatrix} S_{b1} & r & \Omega_{21} & \theta_1 \end{bmatrix}^T \,. \tag{38.64}$$

The response is considered harmonic and the problem is treated in the complex space $\mathbb{C}$. Thus, the vectors of (38.63)–(38.64) are expressed as

$$\boldsymbol{X}(s,t) = \mathrm{Re}\{\boldsymbol{x}(s)e^{i\omega t}\} \,, \tag{38.65}$$

$$\boldsymbol{Z}(s;t) = \mathrm{Re}\{\boldsymbol{z}(s)e^{i\omega t}\} \,, \tag{38.66}$$

where ω is the frequency of excitation and

$$\boldsymbol{x}(s) = \begin{bmatrix} \bar{T}_1(s) & \bar{S}_{n1}(s) & \bar{p}(s) & \bar{q}(s) & \bar{\Omega}_{31}(s) & \bar{\phi}(s) \end{bmatrix}^T \,, \tag{38.67}$$

$$\boldsymbol{z}(s) = \begin{bmatrix} \bar{S}_{b1}(s) & \bar{r}(s) & \bar{\Omega}_{21}(s) & \bar{\theta}_1(s) \end{bmatrix}^T \,. \tag{38.68}$$

The spatial vectors $\boldsymbol{x}(s)$ and $\boldsymbol{z}(s)$ are complex.

Next, (38.67) and (38.68) are introduced into the in-plane and the out-of-plane linear systems. After separating real and imaginary parts, the following matrix equations are obtained

$$\frac{\mathrm{d}}{\mathrm{d}s}\begin{bmatrix} \bar{T}_1 \\ \bar{S}_{n1} \\ \bar{p} \\ \bar{q} \\ \bar{\Omega}_{31} \\ \bar{\phi}_1 \end{bmatrix} = \begin{bmatrix} 0 & \Omega_{30} & -\omega^2 m & 0 & S_{n0} & w_0\cos\phi_0 \\ -\Omega_{30} & 0 & 0 & -(m+m_a)\omega^2 + ic\omega^2|\bar{q}| & -T_{30} & -w_0\sin\phi_0 \\ \frac{1}{EA} & 0 & 0 & \Omega_{30} & 0 & 0 \\ 0 & 0 & -\Omega_{30} & 0 & 0 & 1 \\ 0 & \frac{-1}{EI} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix} \times \begin{bmatrix} \bar{T}_1 \\ \bar{S}_{n1} \\ \bar{p} \\ \bar{q} \\ \bar{\Omega}_{31} \\ \bar{\phi}_1 \end{bmatrix} \,, \tag{38.69}$$

$$\frac{\mathrm{d}}{\mathrm{d}s}\begin{bmatrix}\bar{S}_{\mathrm{b}1}\\ \bar{r}\\ \bar{\Omega}_{21}\\ \bar{\theta}_1\end{bmatrix} = \begin{bmatrix} 0 & -(m+m_{\mathrm{a}})\omega^2 + \mathrm{i}c\omega^2|\bar{r}| & T_0 & S_{\mathrm{n}0}\Omega_{30} + w_0\sin\phi_0 \\ 0 & 0 & 0 & -1 \\ \dfrac{1}{EI} & 0 & \Omega_{30} & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix} \times \begin{bmatrix}\bar{S}_{\mathrm{b}1}\\ \bar{r}\\ \bar{\Omega}_{21}\\ \bar{\theta}_1\end{bmatrix}. \tag{38.70}$$

The reduced systems that represent the eigenvalue problem the solution of which provides the natural frequencies and the mode shapes of the cable, are derived through (38.69)–(38.70) after omitting the imaginary terms that express the contribution of the nonlinear drag forces. The solution of the eigenvalue problems requires the employment of valid assumptions regarding the boundary conditions. For a cable structure it is sufficient to assume that the motions as well as the curvatures at both ends are zero. A rational conclusion that is reasonably drawn from (38.69) and (38.70) is that the mode shapes, as well as the natural frequencies, strongly depend on the static components, namely the initial configuration of the cable. This feature is specifically highlighted to note that the popular sinusoidal mode shapes which are frequently adopted in the literature may lead to erroneous results, as they omit the all-important weight of the cable that provides the pattern of the static configuration. The weight effect on the eigenvalue problem of a string simulating a cable was thoroughly discussed by *Triantafyllou* and *Triantafyllou* [38.9], who also introduced the bending system to avoid zero tension singularity on the lower boundary layer of the assumed hanging string. An analogous procedure that relied on singular perturbations aiming at treating the eigenvalue problem of a vertical slender structure was applied recently by *Chatjigeorgiou* [38.10].

38.2 The Eigenvalue Problem of a Catenary Mooring Cable

A thorough investigation of the dynamic equilibrium system should obviously include the solution of the associated eigenvalue problem. This will provide the mode shapes and, most importantly, the natural frequencies that detect the locations of potential resonances. As far as the dynamics of cables are concerned the eigenvalue problem was systematically investigated in series of studies led by *Triantafyllou* et al. [38.11–14] (see also [38.9]).

For a continuous system such as a cable structure the number of eigenfrequencies and, accordingly, the number of eigenmodes are infinite. The calculation of the shapes of eigenmodes is crucial from many viewpoints. Firstly, they provide generic information on how the structure will vibrate. Secondly, they allow the construction of series expansions for the solution of the associated dynamic problem, which accordingly can be simplified by applying the orthogonality relations of the eigenmodes resulting in reduced systems of ordinary differential equations. The latter procedure could provide insight on the details of the nonlinear oscillations of the system investigated. Analytic solutions for the eigenvalue problem are, indeed, feasible provided that several simplistic assumptions are made [38.9] and [38.15]. Nevertheless, they have specific limitations in their range of application.

The details of the eigenvalue problem strongly depend on the initial configuration of the structure investigated, namely, the parameters that govern its static equilibrium. Cables in marine applications typically obtain a catenary shape either as mooring lines or as towing cables of underwater structures, or during deployment. Here, a catenary mooring cable is considered with the following physical and the mechanical properties: length 1000 m, mass 94.5 kg/m, added mass 16 kg/m, weight 770 N/m density 6052 kg/m^3, Young's modulus 207 GPa, diameter 0.141 m, static tension at the top 780 kN, and installation depth 375 m. According to the above, approximately 212 m of the cable will lie on the assumed horizontal bottom. The specific configuration was purposely selected to investigate potential differences on the natural frequencies and the mode shapes due to the part lying o the bottom. The out-of-plane eigenvalue problem was also considered. Nevertheless, the latter concerned only the suspended part.

Both the in-plane and the out-of-plane eigenvalue problems incorporated the bending stiffness which, however, was set to a very small (but not zero) value. Apart from the *principally accurate* approach, the inclusion of flexural rigidity allows considering the out-of-plane problem as well. The sought solution was achieved by treating the mathematical models ((38.69) and (38.70), letting $c = 0$) as a two-point boundary value problem. Zero motions and curvatures at the end points were employed, whilst the required calculations were performed using the dedicated *bvp4c* routine of

Table 38.1 In-plane eigenfrequencies [rad/s]

Mode no	1	2	3	4	5
Resting on bottom	0.4270	0.6619	0.8637	1.1116	1.3362
Suspended part	0.5479	0.8231	1.1470	1.4251	1.7357

Table 38.2 Out-of-plane eigenfrequencies [rad/s]

Mode no	1	2	3	4	5
Suspended part	0.2294	0.5847	0.8762	1.1682	1.4607

Matlab which integrates the system of equations. An important aspect as regards the in-plane problem is the formulation of the part lying on the bottom. To overcome this difficulty, the solution of the static equilibrium problem considered in that region is neutrally buoyant, resulting in a straight line. The same assumption was made for the dynamic eigenvalue problem as well, which additionally required that the effective weight must be variable along the complete length of the cable.

Results from the eigenvalue problem are given in Tables 38.1 and 38.2 and in Figs. 38.2–38.7 (first five modes). Tables 38.1 and 38.2, respectively, list the natural frequencies in the in-plane and the out-of-plane directions. In Table 38.1 it is immediately apparent that the inclusion of the bottom resting part profoundly changes the values of the eigenfrequencies. In fact, these shift towards lower values. The changes observed are indicative of the different configurations of the dynamic systems, which obey different particulars. Accordingly, it can be safely said that approximating a mooring cable with only its suspended part could be a deficient approach. Table 38.2 provides the natural frequencies for the out-of-plane dynamics (suspended part only), which are sufficiently lower than the in-plane ones.

Evidence of the dynamic response of the mooring cable concerned are provided by the mode shapes, which are depicted in Figs. 38.2–38.5 for the in-plane vibrations and in Figs. 38.6–38.8 for the out-of-plane

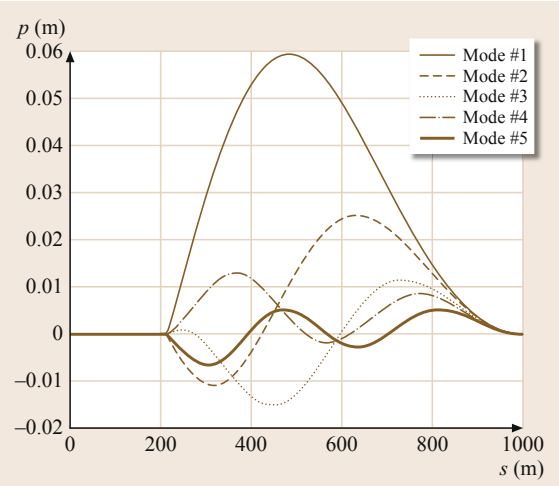

Fig. 38.2 In-plane axial motion eigenmodes of a cable resting on the bottom of the sea

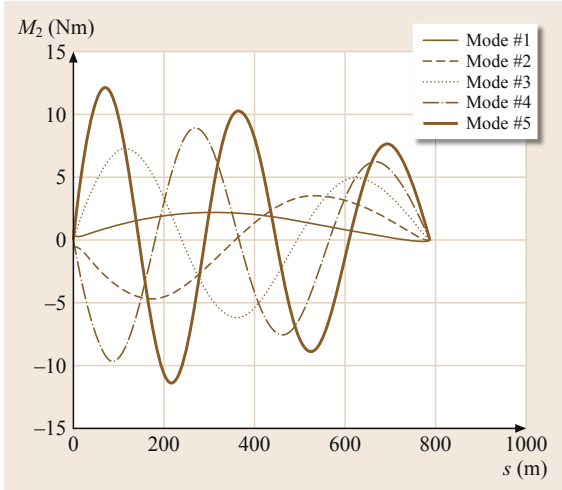

Fig. 38.8 Out-of-plane bending moment eigenmodes of the suspended part

vibrations. Although insignificant due to the selection of a negligible bending stiffness, the bending moments and the shear forces are provided as well (Figs. 38.4 and 38.5). The very small values of the (dimensionalized) shear force and bending moment are confirmative of the insignificant impact of bending as far as the dynamics of cables are concerned.

Here, only the bottom resting case results are shown, as they contain the most striking characteristics. The axial motions (the stretching) of the cable are examined with the aid of Fig. 38.2. This is the only depiction that explicitly shows the lying part and demonstrates that the axial dynamic stretching along that portion is zero. It should be said that the axial modes provide the pattern for the variation of the dynamic tension amplification as well. Along the suspended, part the axial mode shapes obey the rule of $n-1$ crossings with the horizontal, with n being the successive mode number. An important feature that is common with the normal motions as well (Fig. 38.3) is related to the progressive decay of the mode magnitude for increasing mode number.

The normal modes, however, do not cross the horizontal axis (the s coordinate) $n-1$ times. On the contrary, there are n crossings for the n-th mode. This immediately distinguishes the actual mode shapes from the simplified sinusoidal modes, implying that the latter are indeed a deficient approach that involves a high

rate of uncertainty in terms of the final accuracy as it omits the all-important weight of the cable. It should be also observed that the complete length of the cable, including the part lying on the bottom, is set into motion in the normal direction. This is the outcome of the assumption of a perfectly horizontal bottom. Evidence of the fact that a part of the cable resting on the bottom is not shown in Fig. 38.3. The exact location of the touch-down point, however, is immediately detectable a fortiori in the mode shapes of the shear force and secondarily in the modes of the bending moment. The touch-down point can be realized as a point of discontinuity, and that is clearly demonstrated in Fig. 38.4.

The out-of-plane vibrations in the bi-normal direction are examined through the depictions of Figs. 38.6–38.8, which provide, respectively, the motions, the shear force, and the out-of-plane bending moment. The last two parameters are again very small and indicative of the fact that bending effects are negligible for cables. For line structures such as cables, however, the flexural rigidity can be effectively used as a tool for avoiding numerical difficulties in regimes that are characterized by occurrences of potential singularities. The magnitude of the out-of-plane modes (Fig. 38.6) is again reduced for increasing mode number. That remark assures beyond any doubt that the employment of the actual mode shapes in a series expansion of potential solutions will result in a convergent formulation. Further, it should be mentioned that the out-of-plane mode shapes are characterized by asymmetry, contrary to the frequently employed harmonic shapes which are symmetrical with respect to the midpoint. The maxima, which are more easily detectable in the first mode, shift towards the bottom point, which, accordingly, implies that the maximum motions should be expected to occur at that region. The last remark is also valid for the bending moments and the shear forces as well (Figs. 38.7 and 38.8).

38.3 High Tension Cables; Snap-Slack Conditions

The present section investigates an indicative *practical* case that experiences the impact of high dynamic tension amplification. The cable is purposely guided to an excitation regime that eventually cancels the total tension applied on the cable. The term *high* herein is correlated with dynamic tension and it is distinguished from static tension. In fact, when the latter is sufficiently large, it is increasingly difficult for the total tension to be canceled, thus discouraging possible dynamic instabilities.

In several practical applications high tension and low tension realms may occur simultaneously, say during a period of the response. Other practical applications involve only low tension cables, e.g., deployed cables. In this section, emphasis is on the former, which, among others, allow investigation of the so-called snap-slack phenomenon. In particular, snapping occurs during maximum tension amplification and can be interpreted as a shock loading that incurs the complete length of the cable, and unwanted slacking occurs whenever the tension is canceled. Relevant examples are the highly tensioned tendons of tension leg platforms or cables that are used for the deployment of instrumentation packages on the seafloor or cables that tow underwater vehicles.

To avoid tension cancelation and the inevitable collapse of the numerical scheme that treats the dynamic equilibrium problem, the most advisable method is to include the bending effects in the mathematical formulation. This allows the cable to undertake the so-called compression loading that is governed by the induced negative tension [38.16]. In other words, the cable stops functioning as a chain and becomes a beam that experiences the action of bending. Nevertheless, in reality the very small flexural rigidity is incapable of allowing large compression that would lead to buckling. Practically, the tension never becomes zero.

There have been studies, mostly experimental, that explicitly show the occurrence of the concerned phenomenon. For more details, the interested reader is referred to the works due to *Papazoglou* et al. [38.5] and *Mavrakos* et al. [38.17]. The most difficult part, however, as far as the computations are concerned is the simulation of the time interval during which the total tension approaches zero at specific location(s) along the cable. Relevant studies avoid the numerical difficulties involved by artificially letting the tension be zero [38.5, 18, 19]. This approximation, however, has specific limitations and does not provide answers for the small negative tension that is applied on cables.

It is apparent that in order to capture the compression loading regime, a robust and reliable methodology should be developed and employed. The complete system assumes the involvement of the flexural rigidity and, in fact, this is the proper way to proceed. To obtain successful computations an inevitable price has to be paid. This is associated with the employment of an implicit numerical scheme and the use of dense discretizations in both time and space. For the purposes of the present contribution this is achieved by employing an unconditionably stable implicit methodology.

Without providing exhaustive details, it is admitted that the most popular solution techniques rely on finite element methods. The latter have provided the tools to de facto standard software programs in the maritime and offshore industry for analyses of submerged cables, e.g., RIFLEX [38.20]. The general finite element method has been widely covered in the literature during the last decades and, thus, only two indicative examples are cited herein. These are the studies due to *Wang* et al. [38.21] and *Aamo* and *Fosen* [38.22].

Use of the method of finite differences on cable dynamics problems was first proposed by *Ablow* and *Schechter* [38.23], and their method was accordingly modified by *Milinazzo* et al. [38.24]. Improved schemes of the finite difference approximation were subsequently developed and employed in a series of studies on a variety of cable dynamics problems, such as low tension cables [38.25, 26], cable deployment [38.27], free hanging lines [38.28], highly extensible cables [38.29], and mooring line dynamics [38.30]. The finite differences method is explicitly mentioned here as it is the method that was applied for the derivation of the present numerical results. In particular, both the nonlinear and linearized systems were treated by the centered differences scheme [38.31]. For the nonlinear system, the centered differences were applied for the discretization of both temporal and the spatial nodes, resulting in a second-order accurate $O(\Delta t^2) + O(\Delta s^2)$ algorithm. For the linear system the centered differenced approximation is required only for the spatial discretization, again resulting in a second-order accurate scheme. It should be mentioned that the method developed focuses on two-point boundary value problems and accounts for only first derivatives in time and space. If additionally second-order derivatives have to be considered, say if torsion is included, then a more complicated scheme has to be constructed. Here the final system was elaborated numerically by the relaxation method [38.22].

The numerical results presented in this section concern a TLP tendon with the following physical and mechanical properties: length 100 m; installation depth 100 m; mass 20.8 kg/m, added mass 5.15 kg/m; Young's modulus 0.8×10^9 N/m^2; diameter 0.08 m; submerged weight 153.5 N/m; normal drag coefficient 1.0; and tangential drag coefficient 0. The pretension at the top was equal to the total submerged weight of the cable, whereas the cable was assumed to be excited by a combined monochromatic excitation in surge and heave in its plane of reference with equal frequency 1.5 rad/s and zero phase amplitudes 1 m and 2.5 m, respectively.

The solution to the particular problem was sought by applying the complete 3-D nonlinear system of (38.38)–(38.47); albeit the physical problem is defined only in 2-D. Simply, no binormal motion was employed. For the solution of the system the governing equations were supplemented by the boundary conditions, which assumed pinned ends and zero motions at the bottom, whilst the external motions at the top explicitly defined the top boundary conditions. Only indicative results are shown herein, which emphasize the most interesting regime, namely the slacking condition. If the effective tension including its dynamic amplification is going to be canceled, that will occur primarily at the bottom point where the static tension admits the lowest value. Hence, particular attention is paid to the lower connection of the cable; the exerted loading is depicted in Figs. 38.9 and 38.10, where the total effective tension and the shear force are given, respectively. The cable was discretized by 600 nodes and the computations were run with a time step equal to 0.01 s. It should be admitted that the preceding figures correspond to a relatively coarse grid and sufficiently large time step. However, convergence at each time step is achieved with only five to six iterations. These remarks imply a very efficient, stable, and robust numerical scheme, contrary to the criticism that the box (centered-centered) method received by *Gobat* and *Grosenbaugh* [38.32].

Coming back to the physical model and the results on its dynamic behavior, the first (and the most important) feature that attracts our attention is associated with the zero effective tension (here shown for the bottom end point). The zero tension interval when the cable slacks, is followed by a rapid increase in tension, which can be characterized as the snapping interval. It is also

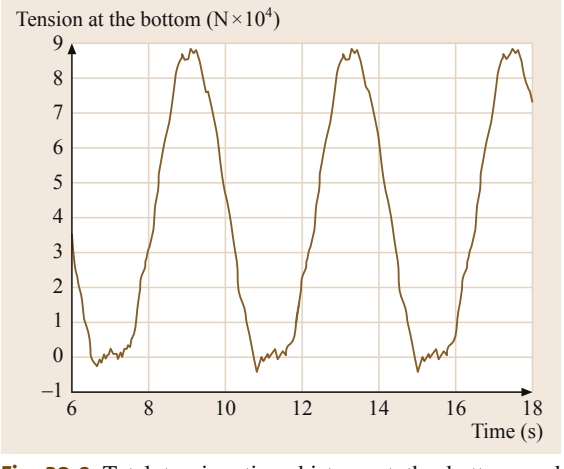

Fig. 38.9 Total tension time history at the bottom end point of a vertical tendon under snap-slack loading (amplitude of excitation = 1 m surge, 2.5 m heave; freq. = 1.5 rad/s)

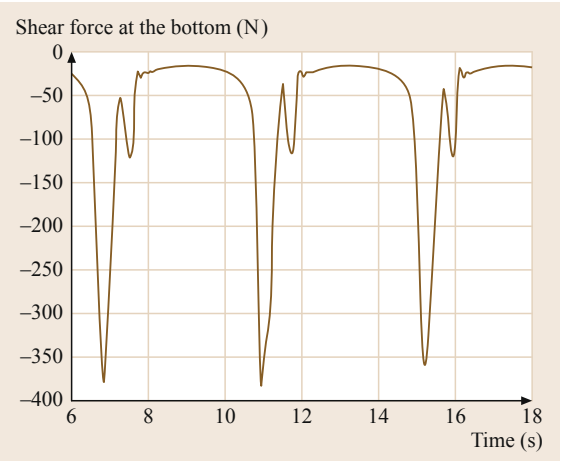

Fig. 38.10 Total shear force time history at the bottom end point of a vertical tendon under snap-slack loading (amplitude of excitation = 1 m surge, 2.5 m heave; freq. = 1.5 rad/s)

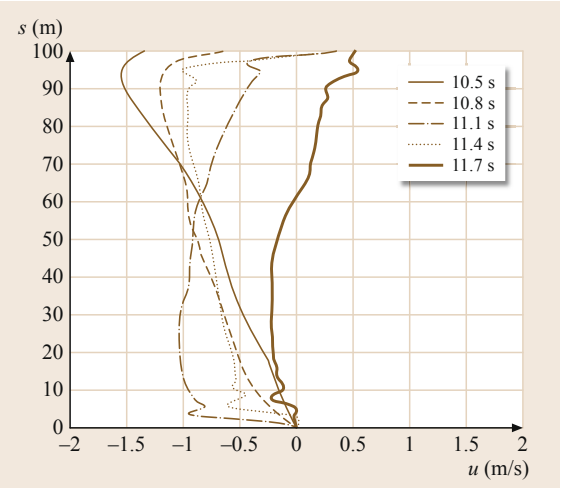

Fig. 38.11 Snapshots of the axial structural velocity along the cable during the slack condition interval. The snapshots correspond to 10.5, 10.8, 11.1, 11.4, and 11.7 s (see also Fig. 38.9)

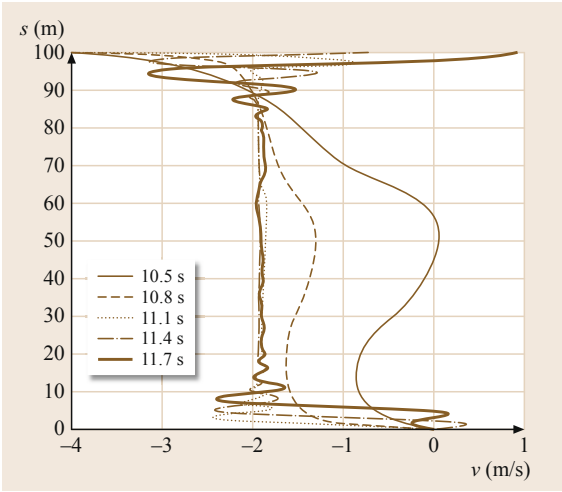

Fig. 38.12 Snapshots of the normal structural velocity along the cable during the slack condition interval. The snapshots correspond to 10.5, 10.8, 11.1, 11.4, and 11.7 s (see also Fig. 38.9)

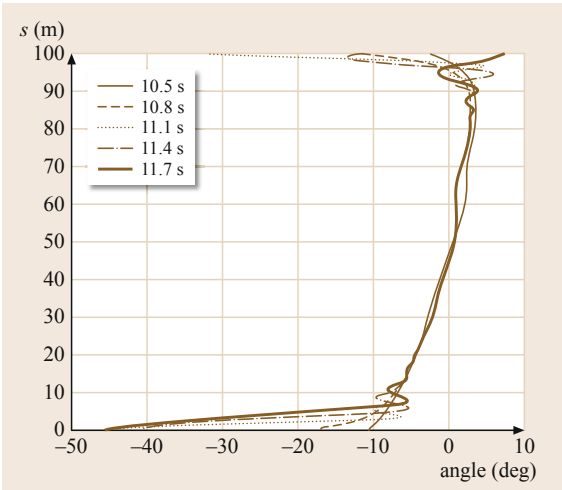

Fig. 38.13 Snapshots of the angle along the cable during the slack condition interval. The snapshots correspond to 10.5, 10.8, 11.1, 11.4, and 11.7 s (see also Fig. 38.9)

important to note that the cable indeed admits a small negative tension during which a slight compression occurs. During the extreme stretching of the cable the shear force approaches zero (Fig. 38.10), whereas the mathematical formulation during slacking is supported by the bending terms (see the sharp increase in the shear force of Fig. 38.10).

Details on the actual configuration of the tendon during the zero tension interval are given in Figs. 38.11–38.13, where the axial structural velocity, the normal structural velocity and the angle with respect to the horizontal are shown. The configuration of the cable during slacking can be assessed through Fig. 38.12, where the normal (along the x axis) velocity is provided. According to that depiction, the cable can be assumed vertical as along the major part of its length the velocity is nearly constant, but the lower region slacks profoundly. Analogous characteristics can be seen in the snapshots of the angle which reaches approximately 45° with respect to the perpendicular. During the interval concerned the loss of tension causes the destabilization of the cable.

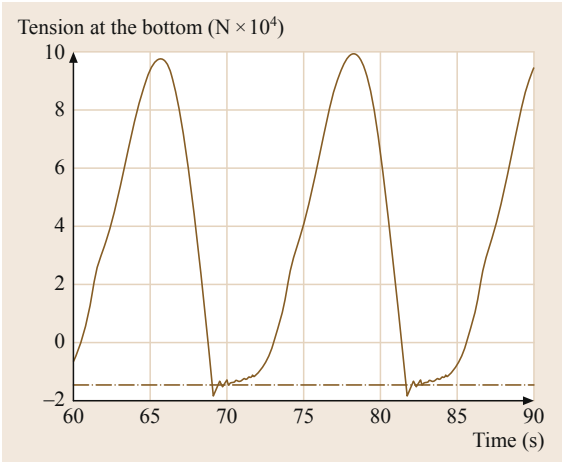

Fig. 38.14 Dynamic tension time history at the bottom end point of a vertical tendon under snap-slack loading (amplitude of excitation = 3 m surge, 3.5 m heave; freq. = 0.5 rad/s)

Further, a more visible slack cable condition is investigated and discussed. Here the frequency of excitation, always applied at the top, was reduced to 0.5 rad/s to obtain an extended interval during which the dynamic tension becomes negative and cancels the static tension. Due to the slower vibrations of the cable, the amplitudes of the excitation were considered to be sufficiently large, i. e., 3.0 and 3.5 m along the x and the z directions, respectively. Focus is on the dynamic tension amplification time history, and the associated signal is provided in Fig. 38.14. The chained line was artificially introduced to show the level of the static tension. Again, it can be deduced that virtually the cable is not capable of undertaking any bending effects and thus responds with nearly zero effective tension. This is due to the very small bending stiffness that originates from the small cross-sectional area. It should be mentioned that we would not be able to obtain the depicted results if the bending stiffness were omitted. The omission of EI would result in an ill-posed problem (according to the term used by *Triantafyllou* and *Howell* [38.16]), which becomes well posed after the inclusion of the bending stiffness. In Fig. 38.14 it is easy to see that the total effective tension instantly becomes negative and accordingly reverts to positive (although small) values. In fact, the zero tension interval is not practically *zero*. The total tension advances with very small positive increments until extreme stretching is attained. It should be noted that the depicted behavior has been verified experimentally by *Papazoglou* et al. [38.5].

38.4 Dynamics of Catenary Moorings

The technological advances of offshore industry to deeper water fields required the use of moored facilities that are restrained in waves, not necessarily with tendons or taut inclined cables. In fact, the most popular mooring method is the use of catenary mooring systems that provide the necessary restoring characteristics to the moored platform through the submerged weight of the mooring lines. Admittedly there is a huge amount of relevant studies in the literature which deal with both statics and dynamics of catenary moorings, the majority of which have been presented at specialized conferences. Nevertheless, the classical book of *Irvine* [38.33] should be mentioned.

Typically, the dynamics of catenary moorings are investigated in terms of the slowly varying and the wave frequency motions of the moored floater. The former can be investigated quasi-statically, meaning that the loading exerted on the catenary can be approximated by the static equilibrium solution, except in the case where slowly-varying drift loads are taken into account. The wave frequency motions, however, cannot admit that approach and, hence, the solution of the dynamic equilibrium system is required. This can be performed either by using time or frequency domain techniques. Here, both solution schemes have been developed but the numerical results presented in the sequel were obtained only by the frequency domain approach in (38.69) and (38.70), which provides a fast estimate of the actual dynamics of a mooring cable. This section is divided into three parts: the first part is dedicated to the dynamics of catenaries alone, the second part considers intermediate buoys attached on the mooring line, and the last part addresses the so-called mooring-induced damping phenomenon. Only indicative results are presented in an attempt to cover the most of the important characteristics as regards the dynamic behavior of mooring cables in a wet environment.

38.4.1 A Single Mooring Cable

The results and the subsequent discussion concern a single mooring line with uniform physical and mechanical properties along its complete length, taken from the work of *Mavrakos* and *Chatjigeorgiou* [38.34]. In particular, the cable is 3000 m long installed in a 375 m deep water field. The horizontal pretension at the top is 7.8×10^6 N. Also, the cable has the following properties: mass 94.5 kg/m, added mass 16 kg/m, submerged

weight 770 N/m, diameter 0.141 m, and elastic stiffness 10^9 N. The normal and the tangential drag coefficients were set equal to 1.0 and 0.0, respectively. Finally, a single excitation amplitude of 2 m was applied separately in the horizontal and bi-normal directions for the in-plane and the out-of-plane problems, respectively. It should be mentioned that the static configuration of the model concerned has a small part (approximately equal to 200 m) lying on the assumed horizontal seafloor. This could be approximated by a spring and a damper to simulate the elastic stiffness and the Coulomb friction. However, here we rely on its relatively insignificant length compared to the suspended part and we omit the associated effects including the friction with the bottom. The cable was considered fully suspended and approximation was allowed by the relatively small part resting at the bottom. Given the fact that that part was not particularly formulated, it is expected that its occurrence will not be reflected on the variation graphs of the dynamic components along the cable.

The most important dynamic parameter as far as the dynamics of mooring cables are concerned is the tension applied at the top. This is because the dynamic tension amplification supplements the static counterpart, which obtains its maximum at the top terminal point. Relevant results for the dynamic tension amplification at three points along the cable are given in Fig. 38.15. The transfer function of the dynamic tension amplification of Fig. 38.15 must be seen in correlation with the corresponding curve of Fig. 38.20, as the solution methods employed are different. Figure 38.15 assumes the cable to be a slender beam with $EI = 1$ (38.69), whilst the numerical predictions were obtained by the centered differences approximation along with the relaxation method outlined briefly in Sect. 38.3. On the contrary, the corresponding results of Fig. 38.20 were delivered by the artificial centered differences method described in [38.35]. It can immediately be seen that the comparisons as far as the single cable case is concerned are extremely favorable, which in turn proves the efficacy and the accuracy of both methods.

There are several interesting characteristics in Fig. 38.15 that must be properly highlighted and discussed. First, all resonances predicted by the eigenvalue problem are canceled by the strong action of the drag forces. Further, the dynamic tension amplification as predicted by linear theory at the top end is quite low,

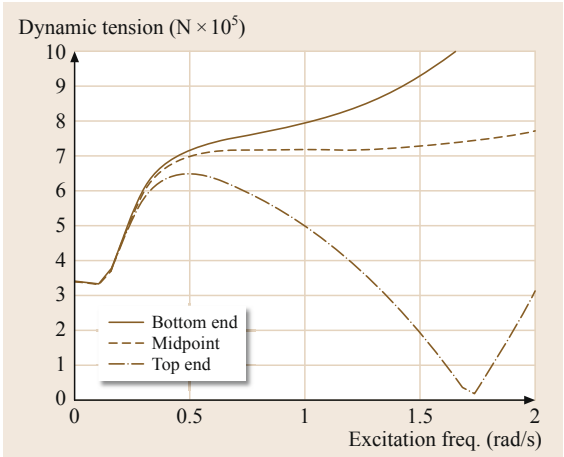

Fig. 38.15 Dynamic tension amplification for three points along a catenary cable (at the top, middle, and bottom end of the suspended part) under in-plane surge excitation at the top with amplitude $\alpha_x = 2$ m

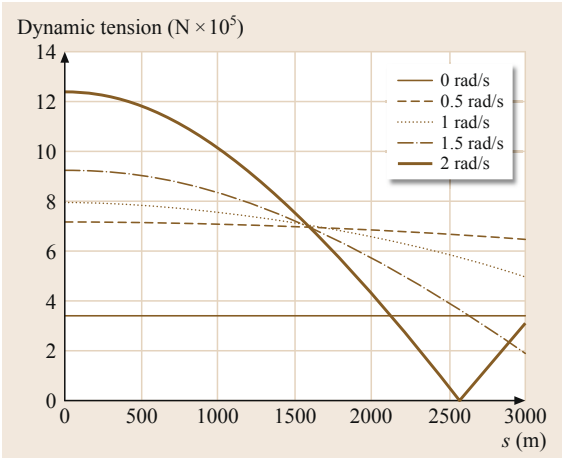

Fig. 38.16 Dynamic tension amplification along a catenary cable under in-plane surge excitation at the top with amplitude $\alpha_x = 2$ m and at four distinct frequencies

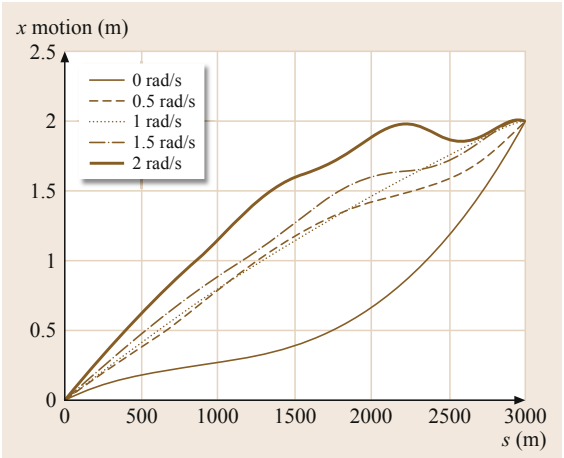

Fig. 38.17 Surge structural motions along a catenary cable under in-plane surge excitation at the top with amplitude $\alpha_x = 2$ m and at four distinct frequencies

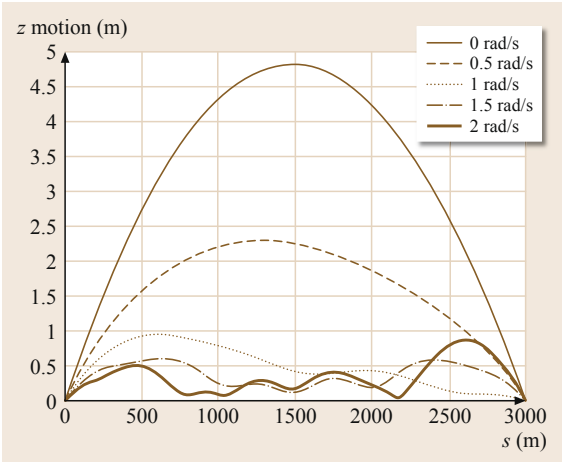

Fig. 38.18 Heave structural motions along a catenary cable under in-plane surge excitation at the top with amplitude $\alpha_x = 2\,\text{m}$ and at four distinct frequencies

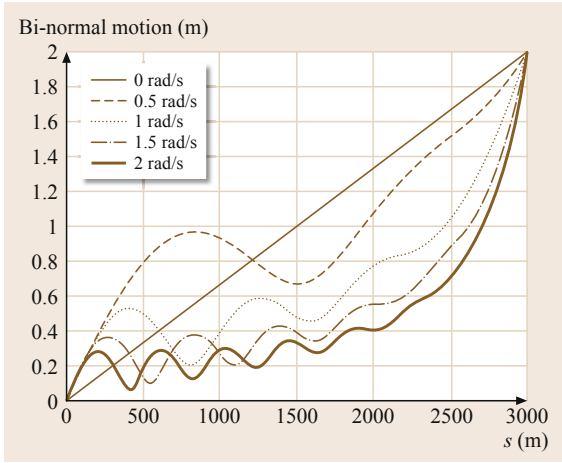

Fig. 38.19 Bi-normal structural motions along a catenary cable under out-of-plane excitation at the top with amplitude $\alpha_b = 2\,\text{m}$ and at four distinct frequencies

here approximately 10% of the static tension. In addition, it progressively decays at the high frequency range, reaches a lower cancelation point and, accordingly, exhibits a sharp increase at a frequency that coincides with the first elastic eigenfrequency.

Clearly, the dynamic tension is not equal along the cable, as implied by the three depicted curves. They admit comparable magnitudes only at the low frequency range and after that the dynamic tension obtains very large magnitudes close to the lower portion of the suspended part. In fact, the illustrated curves remedy the glitch of the assumption due to *Papazoglou* et al. [38.5], according to which the dynamic tension is constant along the suspended part, which in turn allowed the simplification of the formula for the dynamic tension calculation. In fact, this is true only for low frequencies, as is explicitly demonstrated in Figs. 38.15 and 38.16.

Typically for marine mooring cables, the variable of concern is the axial loading and especially the tension that is applied at the fairlead. However, it is undoubtedly interesting to realize how the group of governing parameters varies along the cable, and this task is performed with the aid of Figs. 38.16–38.19. Figures 38.16–38.18 concern the in-plane vibrations and provide the tension and the surge, and heave motions along the suspended part for five equally spaced frequencies. Again, it can be seen that the dynamic tension is nearly constant only for small frequencies. Strong variations occur for higher frequencies, whereas the tension at the bottom is increased for faster oscillations. The applied tension is obviously related with to induced motions that exhibit strong variations as the excitation frequency is increased (Figs. 38.17 and 38.18). The heave structural oscillations in particular tend to vanish for fast imposed motions as manifested by the 2.0 rad/s curve of Fig. 38.18.

It should be admitted that the vast majority of studies on mooring dynamics is performed in 2-D and the cable's plane of reference. This is due to the fact, as previously said, that the parameter of concern is the tension. To enrich the value of the present chapter, additional results concerning the bi-normal behavior are provided. These were obtained through the matrix system (38.70) and the bending stiffness was again set equal to unity. The linear system assumes decoupled in-plane and bi-normal motions leading to the consideration that the bi-normal behavior does not add to dynamic tension amplification.

This is indeed true and it can be demonstrated by the solution of the nonlinear problem in (38.38)–(38.47). In addition, the shear loading that is developed along the cable is inevitably small due to the negligible bending stiffness. The same is valid for the bending moment as well. Thus, only the out-of-plane motions are considered herein, and the results obtained for 2 m bi-normal top imposed excitation are shown in Fig. 38.19. The quasi-static excitation with $\omega \to 0$ delivers linear variation along the cable, as expected. Large bi-normal vibrations occur for small frequency excitations, which accordingly decay in magnitude and exhibit strong wavy trends for faster imposed motions.

38.4.2 Effect of Attached Intermediate Buoys

The use of intermediate buoyancy devices (buoys) attached along mooring cables is, in fact, a practical technique that aims at altering the static and dynamic

characteristics of the actual line through reducing its effective submerged weight. This technique results in immediate differentiations in the dynamics of the mooring line as compared to the same line without the buoys. Also, the formulation and the solution techniques should be updated in order to properly take into account the various segments that are formed between the buoys regardless of whether or not they have the same properties. Additionally, the complicated mooring line-buoys system requires considering the dynamics of the buoys as well, which depend, among others things, on their geometry, their physical properties, and the points of attachment.

The number of studies reported on the subject is significantly lower than for those dealing with simple moorings. Moorings with buoys have been studied by [38.34, 36–44], to mention a few.

Here, the outlined analysis is based on the theory and the solution method presented by the present authors in [38.34], who, among others, investigated potential impacts due to buoy rotation. The solution method adopted in that respect was based on a centered differences algorithm analogous to that developed by *Bliek* [38.35]. The numerical predictions discussed in the following refer to the linearized problem of the mooring line described in Sect. 38.4.1. For the purposes of the present section, the specific mooring line was assumed to have a buoy attached at 2450 m from the bottom. The buoy was assumed to be spherical with a drag coefficient equal to 0.8. The detailed properties of the buoy can be found in [38.34]. For a detailed discussion on the effect of multiple buoys attached at various locations along mooring cables with different segment properties along with experimental results, the interested reader can refer to the study due to *Mavrakos* et al. [38.36].

In the following, the results of three indicative cases are provided which are distinguished by the buoy's net buoyancy offered to the cable, i. e., 20, 35, and 50% of the cable's total submerged weight. The excitation at the top was assumed to be horizontal and of 2 m magnitude. For reference, the no-buoy case of the single mooring line was considered as well. The predictions shown in Figs. 38.20 and 38.21 depict the transfer functions of the dynamic tension amplification applied at the top (Fig. 38.20) and immediately below the buoy (Fig. 38.21).

It is immediately apparent that buoy's insertion at some point along the mooring line modifies the top applied tension (as well as the tension along the complete length of the line) profoundly and, accordingly, the line's restoring characteristics offered to the floating vehicle. The first specific remark concerns the differences in the tension at the top and immediately below the buoy. The latter are greater than the former, in accordance to the findings of the previous section. Moreover, the buoy, indeed, reduces the tension applied at the top, although not drastically.

The most important feature however, originates from the cancelation frequency and, accordingly, from the subsequent elastic frequency. The cancelation frequency shifts toward slower excitations and approaches the region of the typical wave frequencies encountered in the sea. The tension at the top appears to be influenced increasingly by the amount of the net buoyancy, whereas the tension immediately below the buoy is not

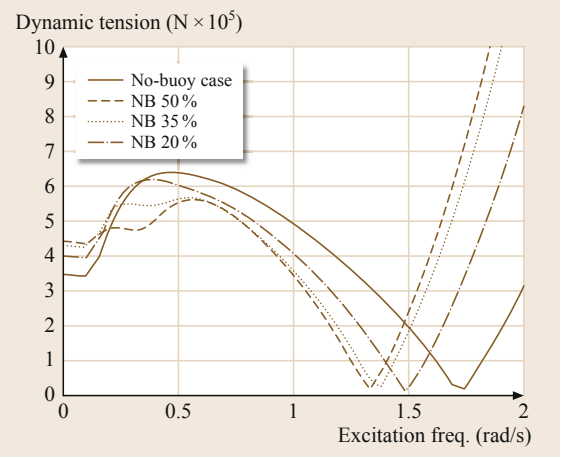

Fig. 38.20 Dynamic tension amplification at the top of the mooring cable under horizontal monochromatic excitation with amplitude $\alpha_x = 2\,\mathrm{m}$

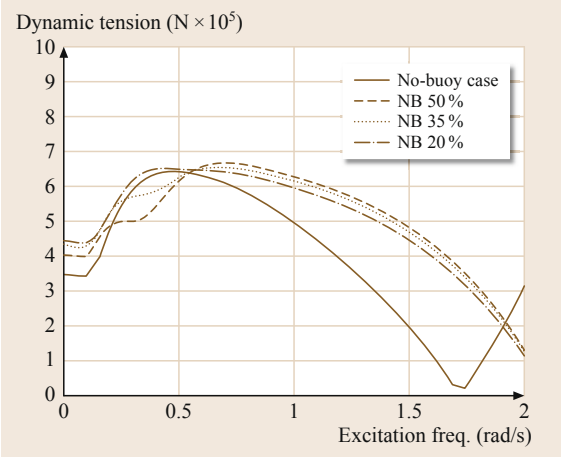

Fig. 38.21 Dynamic tension amplification immediately below the buoy. The cable was assumed excited at the top with horizontal monochromatic motion with amplitude $\alpha_x = 2\,\mathrm{m}$ (the nobuoy legend applies to the tension at the top)

affected so much by the parameter concerned. Further, contrary to what is happening at the top, the cancelation frequency for the tension immediately below the buoy admits higher values. It is apparent that this is due to the fact that the segment at this location can be regarded as a separate line with different properties and, accordingly, with different eigenvalue particulars.

Figures 38.20 and 38.21 indeed prove the efficacy of buoys at reducing the dynamic tension amplification. As the dynamic tension is the quantity that adds to the possibility of failure of a mooring cable, the reduction mechanism introduced by buoys is of paramount importance, especially in survival conditions. It should be mentioned, however, that the proposed technique requires a comprehensive survey in terms of the optimum size, number, and location of the attached buoys. It should be admitted that not much work has been done in this direction. A relevant example is the contribution mentioned in [38.45].

38.4.3 Mooring Line-Induced Damping

The concept of the so-called mooring line-induced damping phenomenon was introduced originally in the 1980s by *Huse* [38.46] and *Huse* and *Matsumoto* [38.47]. According to that, the oscillations of the mooring line into a wet environment, which are caused by the motions of the moored floater, induce energy dissipation that originates mainly from the damping mechanism of the drag forces. According to the inspirers of that idea, which was a breakthrough idea at the time, the loss of energy can be translated into a nonconservative force that absorbs energy and adds to the total damping on the moored structure. *Huse* [38.46] estimated that mooring line-induced damping can add up to 25% of the total damping rate and hence, the omission of that term overestimates the magnitudes of the floater motions.

There were several studies after *Huse* [38.46] that dealt with the mooring-induced damping phenomenon. *Liu* and *Bergdahl* [38.48] proposed an improvement to the *Huse* [38.46] model. *Brown* and *Lyons* [38.49] claimed that the mooring system may under certain circumstances provide up to 80% of the total damping available, and thus significantly reduce the peak line tensions. Further, *Brown* and *Mavrakos* [38.50] presented the results of a comparative study initiated by the International Ship and Offshore Structures Congress (ISSC 1997), Committee I2 (Loads), whereas *Bauduin* and *Naciri* [38.51] addressed the problem only quasi-statically. Contemporary, focus is made on the damping induced by moorings of wave energy converters (WEC) [38.52]. Recently, *Chatjigeorgiou* et al. [38.53] introduced the so-called risers-induced damping using the same formulation as for cables.

Mooring line-induced damping is quantified by an equivalent linearized damping coefficient that can be introduced into the dynamic equilibrium system of the moored floater, the latter being assumed to act as a single or multiple degree oscillator. A prerequisite is the solution of the dynamic equilibrium problem of the mooring line, and evidently in a multi-leg mooring system the total mooring line damping is composed by the superposition of the individual damping coefficients of all mooring lines. Hence the linearized coefficients can be obtained using either frequency domain or time domain techniques. The former require the solution of the linear dynamic equilibrium problem in complex space. Accordingly, the linearized damping coefficient is obtained through the imaginary part of the horizontal component of the dynamic tension applied at the top according to

$$c_x = \Im\left[\frac{F_x}{\alpha_x \omega}\right], \tag{38.71}$$

where α_x denotes the amplitude of the horizontal motion applied at the top and ω is the frequency of the excitation. Clearly, an analogous relation holds for the mooring-induced damping in heave direction. The same expression can be used for the calculation of linearized damping in the bi-normal direction as well, provided that F_x is replaced by the out-of-plane shear force $\bar{S}_{b1}$ applied at the top, and α_x by the associated imposed motion. It is evident, therefore, that out-of-plane linearized damping requires the solution of the homonymous linear problem and, accordingly, the inclusion of the bending stiffness into the governing equilibrium problem.

The derivation of the damping coefficient via time domain solution techniques requires the evaluation of the energy dissipated per cycle [38.50]. This is obtained by

$$E_k = \int_0^\tau F_k \frac{\mathrm{d}q_k}{\mathrm{d}t}\,\mathrm{d}t\,, \tag{38.72}$$

for $k = x, y, z$, and τ denotes the period of the response. Here, y denotes the out-of-plane direction. According to the notations used for formulating the nonlinear dynamic equilibrium problem, (38.72) admits the following expressions in a Cartesian system

$$E_x = \int_0^\tau (T\cos\phi)(u\cos\phi - v\sin\phi)\,\mathrm{d}t\,, \tag{38.73}$$

$$E_y = \int_0^\tau S_\mathrm{b} w \, \mathrm{d}t \,, \tag{38.74}$$

$$E_z = \int_0^\tau (T \sin\phi)(u \sin\phi + v \cos\phi) \, \mathrm{d}t \,. \tag{38.75}$$

Clearly, the contribution of the in-plane shear force was ignored in (38.73) and (38.75) due to the negligible in-plane shear force S_n compared to the extreme values of tension T. It should be noted that the integration can be performed either by using total quantities or their dynamic counterparts only. The results should be the same given the fact that the static component is constant. Accordingly, the linearized damping coefficients are given by

$$c_k = \frac{E_k \tau}{2\pi^2 a_k} \,, \tag{38.76}$$

for $k = x, y, z$, where a_k denotes the oscillation amplitude associated with the period τ.

Indicative results for the linearized mooring-induced damping coefficients and the energy dissipation loops are provided in Figs. 38.22–38.24. Again, the subject of investigation was the mooring cable described in Sect. 38.4.1. The in-plane dynamics are considered with and without buoys (Fig. 38.22), whereas the dynamic behavior in the bi-normal direction assumes no buoy connections (Fig. 38.23). Both figures depict calculations that have been obtained via the frequency domain approximation.

Observing the curves shown in Fig. 38.22, it is deduced that the variation pattern of the damping coefficients as a function of the excitation frequency is dictated by the trends of the dynamic tension (Fig. 38.20). The progressive reduction of the dynamic tension and, accordingly, of its horizontal component, before the cancelation point and the first elastic eigenfrequency, combined with the increased excitation frequency results in a relative sharp decrease of the damping coefficient. It is also interesting to note that the local maximum of the damping coefficient does not coincide with the maximum of the tension. In addi-

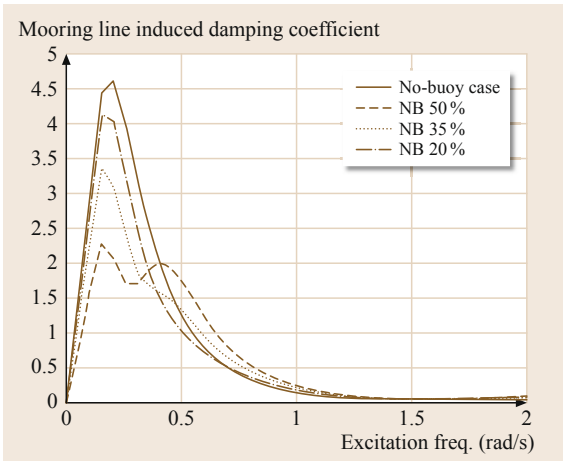

Fig. 38.22 Mooring line-induced damping coefficient in surge direction $c_x = \Im[F_x/\alpha_x\omega] * 10^{-5}$. The cable was assumed to be excited at the top with a horizontal monochromatic motion with amplitude $\alpha_x = 2\,\mathrm{m}$

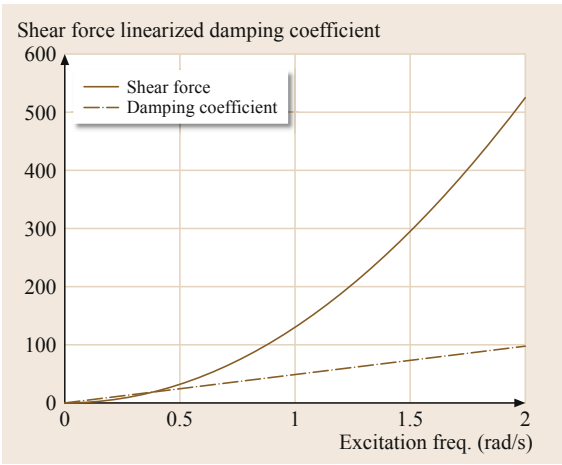

Fig. 38.23 Shear force $\bar{S}_{\mathrm{b}1}$ (N) and mooring line-induced damping coefficient in the bi-normal direction $c_\mathrm{b} = \Im[S_\mathrm{b}/\alpha_\mathrm{b}\omega]$ [N/m/s]. The cable was assumed excited at the top with a bi-normal monochromatic motion with amplitude $\alpha_\mathrm{b} = 2\,\mathrm{m}$

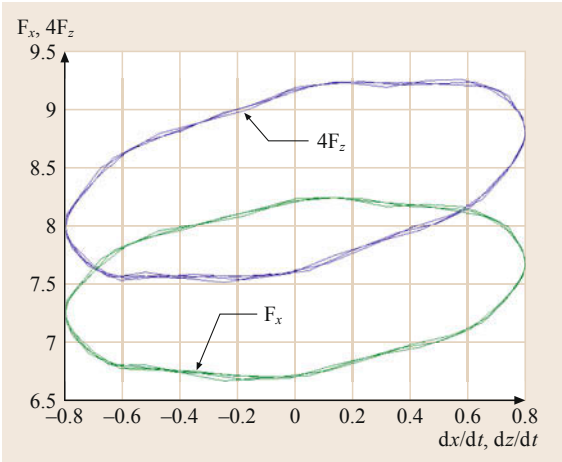

Fig. 38.24 Energy dissipation loops in x and z directions obtained via the 3-D time domain simulation of the dynamic response of a mooring cable subjected x, y, and z monochromatic motions at the top with equal amplitude 2 m and excitation frequency 0.4 rad/s

tion, the use of buoy(s) along the line, albeit it has a positive effect as far as the dynamic tension amplification is concerned, results in damping reduction. Figure 38.22 provides results for increasing net buoyancy up to 50% of the total submerged weight. Clearly, the largest net buoyancy case results in a bump around 0.3 rad/s. It should be noted that numerical tests performed for even larger net buoyancy indicate that the maximum damping coefficient (the local maximum) shifts toward higher frequencies. This is indeed the direct outcome of the transfer function of the dynamic tension amplification which follows the same trend. Hence the conclusion that is easily deduced is that the selection of buoys should be properly put into an optimization procedure that must take into account several dynamic effects. It is important to note the magnitude of the damping coefficient, which admittedly obtains relatively large values. It is apparent that in the linear equation of motion of an equivalent oscillator, this figure will be divided by the (typically) large mass of the floater. However, it should be mentioned that the total mooring line damping will be composed of the individual damping terms of the constituent mooring lines in a multi-leg arrangement, and hence, it is expected that a non-negligible term will be constructed.

Figure 38.23 shows the out-of-plane damping coefficient of the same mooring line, again as a function of the excitation frequency. The calculations depicted were obtained via the frequency domain approach of the out-of-plane equilibrium system in (38.70). For reference, the bi-normal shear force at the top of the cable is provided as well. Contrary to the findings that refer to the in-plane vibrations of the cable, here the damping coefficient demonstrates an increasing trend and in particular a linear variation. Nevertheless, it should be emphasized that the bi-normal damping offered to the vessel is extremely small compared to the surge motion mooring line damping.

The last part of the present discussion is dedicated to the energy dissipation due to cable's oscillation in the marine environment. As has been said, this is determined via time domain techniques, and since the solution is performed in the time domain it is advisable to use the original system for completeness. The loops depicted in Fig. 38.24 were derived through the solution of the fundamental nonlinear dynamic equilibrium system in (38.38)–(38.47). In fact, the energy dissipation is the measure of the mooring line damping and is represented by the area contained in the loops depicted for the surge and heave motions of the floater. In the case depicted, the energy dissipated per cycle in surge is approximately four times greater than the energy in heave. The loops that refer to the bi-normal (sway) direction are not provided due to the insignificant value of the damping in which they result.

38.5 Second-Order Nonlinear Dynamics of Cables Formulated as Euler–Bernoulli Beams

38.5.1 Background

When a study focuses on nonlinear impacts, the obvious approach is the employment of time domain solution techniques. This approach provides only time signal(s) of the output component(s). To provide insight into the details of the response, further analyses are required, typically using Fourier transformation techniques, which convert the time domain results into the frequency domain. In fact, even for the simplest possible excitation, e.g., harmonic fluctuations, the Fourier analyses of the output signals describing the response of nonlinear systems will most probably reveal the occurrence of several harmonics with, evidently, different magnitudes [38.54].

The previous discussion that refers to time domain numerical calculations, ostensibly disagree with reported theoretical formulations on the subject. For example, the complete three-dimensional dynamic system outlined in the present (38.38)–(38.47) that was derived using a Newtonian procedure involves nonlinear terms up to the third-order. Therefore, the question that arises concerns the mechanism that stimulates the, hypothetically, infinite harmonics that occur in the form of integer multiplications of a fundamental harmonic.

The present section is dedicated to the development of an advanced frequency domain methodology for studying the second-order double-frequency nonlinear responses of catenary cables formulated as Euler–Bernoulli beams. Emphasis is given to marine applications where the distributed drag forces are very influential. The process provides insight to the actual mechanism that stimulates the higher-order harmonics of the response, with the cable excited by a monochromatic motion. To this end, the governing nonlinear set is elaborated by employing a perturbation approach. In fact, the associated expansion stops at the second harmonic but it is noted that the employment of the same procedure can capture all subsequent harmonics. Here, only the in-plane vibrations are taken into considera-

tion, but it should be noted that the same procedure could be applied to capture the associated details of the out-of-plane dynamics as well.

The method results in two distinct systems, which are solved separately and successively. The second-order system requires knowing the first-order dynamic components and, accordingly, the solution of the n-th order system requires knowing the dynamic components of all previous orders up to $(n-1)$.

Also, the outlined theoretical formulation is combined with a novel mathematical approach aiming at assessing the impact of the bottom-cable interaction phenomenon. The theoretical model relies on the assumption that the bottom end point oscillates around an average location, which is assumed to coincide with the static equilibrium touchdown point (TDP). The proposed model is incorporated in both the linear and the second-order systems.

38.5.2 The Governing 2-D Nonlinear System

The complete 3-D nonlinear set of (38.38)–(38.47) is reduced to 2-D after omitting the out-of-plane components. The tangential drag coefficient was also omitted whilst it was assumed that $e \approx 0$. The reduced system reads

$$\frac{\partial T}{\partial s} - S_\mathrm{n}\Omega_3 - w_0 \sin\phi - m\frac{\partial u}{\partial t} + mv\frac{\partial \phi}{\partial t} = 0\,, \tag{38.77}$$

$$\frac{\partial S_\mathrm{n}}{\partial s} + \Omega_3 T - w_0 \cos\phi + R_{\mathrm{d}n} - (m+m_\mathrm{a})\frac{\partial v}{\partial t} - m\frac{\partial \phi}{\partial t}u = 0\,, \tag{38.78}$$

$$\frac{\partial u}{\partial s} - \Omega_3 v - \frac{1}{EA}\frac{\partial T}{\partial t} = 0\,, \tag{38.79}$$

$$\frac{\partial v}{\partial s} + \Omega_3 u - \frac{\partial \phi}{\partial t} = 0\,, \tag{38.80}$$

$$EI\frac{\partial \Omega_3}{\partial s} + S_\mathrm{n} = 0\,, \tag{38.81}$$

$$\frac{\partial \phi}{\partial s} - \Omega_3 = 0\,. \tag{38.82}$$

The unknown dynamic components of the above system are written in vector form according to

$$\boldsymbol{V} = \begin{bmatrix} T & S_\mathrm{n} & u & v & \Omega_3 & \phi \end{bmatrix}^\mathrm{T}\,. \tag{38.83}$$

Again, the elements of vector $\boldsymbol{V}$ denote total quantities, i. e., the summation of static and dynamic components. The associated vector that describes the static configuration of the cable, obtained by the solution of the 2-D static equilibrium problem, is written as

$$\boldsymbol{V}_0 = \begin{bmatrix} T_0 & S_{\mathrm{n}0} & 0 & 0 & \Omega_{30} & \phi_0 \end{bmatrix}^\mathrm{T}\,. \tag{38.84}$$

Accordingly, the dynamic amplification terms are the elements of the vector

$$\boldsymbol{V}_1 = \begin{bmatrix} T_1 & S_{\mathrm{n}1} & u & v & \Omega_{31} & \phi_1 \end{bmatrix}^\mathrm{T}\,, \tag{38.85}$$

and they are functions of both s and t. In (38.84) and (38.85), the indices 0 and 1 are used to denote static and dynamic terms, whereas it is evident that $\boldsymbol{V}$ is obtained by adding $\boldsymbol{V}_0$ and $\boldsymbol{V}_1$.

Next, after introducing (38.83)–(38.85) into the governing set of (38.77)–(38.82) and omitting the static equilibrium components, the following dynamic system is derived,which provides only the dynamic amplification terms and the velocities along the cable

$$\frac{\partial T_1}{\partial s} - \Omega_{30}S_{\mathrm{n}1} - S_{\mathrm{n}0}\Omega_{31} - S_{\mathrm{n}1}\Omega_{31} - w_0\cos\phi_0\phi_1 - m\frac{\partial u}{\partial t} + mv\frac{\partial \phi_1}{\partial t} = 0\,, \tag{38.86}$$

$$\frac{\partial S_{\mathrm{n}1}}{\partial s} + \Omega_{30}T_1 + T_0\Omega_{31} + \Omega_{31}T_1 + w_0\sin\phi_0\phi_1 + R_{\mathrm{d}n1} - (m+m_\mathrm{a})\frac{\partial v}{\partial t} - m\frac{\partial \phi_1}{\partial t}u = 0\,, \tag{38.87}$$

$$\frac{\partial u}{\partial s} - \Omega_{30}v - \Omega_{31}v - \frac{1}{EA}\frac{\partial T_1}{\partial t} = 0\,, \tag{38.88}$$

$$\frac{\partial v}{\partial s} + \Omega_{30}u + \Omega_{31}u - \frac{\partial \phi_1}{\partial t} = 0\,, \tag{38.89}$$

$$EI\frac{\partial \Omega_{31}}{\partial s} + S_{\mathrm{n}1} = 0\,, \tag{38.90}$$

$$\frac{\partial \phi_1}{\partial s} - \Omega_{31} = 0\,. \tag{38.91}$$

Equations (38.86)–(38.91) constitute the system that will be further elaborated in the frequency domain to investigate the contribution of the second-order nonlinear effects. Clearly, the treatment of the nonlinear system of (38.86)–(38.91) using a frequency domain technique requires a sophisticated approximation, as apart from the nonlinear drag force, which admittedly can be effectively linearized, the mathematical formulation contains products of time-dependent terms. To this end, the system under consideration will be further manipulated using an appropriate perturbation technique [38.55, 56].

38.5.3 Perturbation Series Expansion

Let ε be a measure of the amplitude of motion. Accordingly, it is assumed that all time-varying terms can be expanded in perturbation series according to

$$\boldsymbol{V}_1 = \varepsilon\boldsymbol{V}_1^{(1)} + \varepsilon^2\boldsymbol{V}_1^{(2)} + \cdots\,, \tag{38.92}$$

where for $k = 1, 2$

$$V_1^{(k)} = \left[T_1^{(k)} \quad S_{n1}^{(k)} \quad u^{(k)} \quad v^{(k)} \quad \Omega_{31}^{(k)} \quad \phi_1^{(k)} \right]^T . \tag{38.93}$$

The same holds for the drag force as well. Hence,

$$R_{dn1} = \varepsilon R_{dn1}^{(1)} + \varepsilon^2 R_{dn1}^{(2)} + \cdots . \tag{38.94}$$

The drag force is expressed in terms of Morison's formula and, consequently, the perturbation components will be given by

$$R_{dn1}^{(k)} = -b\,|v|\,v^{(k)} , \tag{38.95}$$

where $b = 1/2\rho C_d d_O$. Given the fact that the second-order components are expected to be significantly smaller than the corresponding linear terms, the magnitude of the normal velocity is approximated as $|v| = |\varepsilon v^{(1)}|$.

Next, after introducing (38.92)–(38.94) into the system of (38.86)–(38.91), omitting the $O(\varepsilon^3)$ terms, and equating the terms of like powers of ε, the following first and second-order systems are derived.

First-Order System $O(\varepsilon)$

$$\frac{\partial T_1^{(1)}}{\partial s} - \Omega_{30} S_{n1}^{(1)} - S_{n0}\Omega_{31}^{(1)} - w_0 \cos\phi_0 \phi_1^{(1)} - m\frac{\partial u^{(1)}}{\partial t} = 0 , \tag{38.96}$$

$$\frac{\partial S_{n1}^{(1)}}{\partial s} + \Omega_{30} T_1^{(1)} + T_0 \Omega_{31}^{(1)} + w_0 \sin\phi_0 \phi_1^{(1)} + R_{dn1}^{(1)} - (m + m_a)\frac{\partial v^{(1)}}{\partial t} = 0 , \tag{38.97}$$

$$\frac{\partial u^{(1)}}{\partial s} - \Omega_{30} v^{(1)} - \frac{1}{EA}\frac{\partial T_1^{(1)}}{\partial t} = 0 , \tag{38.98}$$

$$\frac{\partial v^{(1)}}{\partial s} + \Omega_{30} u^{(1)} - \frac{\partial \phi_1^{(1)}}{\partial t} = 0 , \tag{38.99}$$

$$EI\frac{\partial \Omega_{31}^{(1)}}{\partial s} + S_{n1}^{(1)} = 0 , \tag{38.100}$$

$$\frac{\partial \phi_1^{(1)}}{\partial s} - \Omega_{31}^{(1)} = 0 . \tag{38.101}$$

Second-Order System $O(\varepsilon^2)$

$$\frac{\partial T_1^{(2)}}{\partial s} - \Omega_{30} S_{n1}^{(2)} - S_{n0}\Omega_{31}^{(2)} - w_0 \cos\phi_0 \phi_1^{(2)} - m\frac{\partial u^{(2)}}{\partial t} = S_{n1}^{(1)}\Omega_{31}^{(1)} - m v^{(1)}\frac{\partial \phi_1^{(1)}}{\partial t} , \tag{38.102}$$

$$\frac{\partial S_{n1}^{(2)}}{\partial s} + \Omega_{30} T_1^{(2)} + T_0 \Omega_{31}^{(2)} + w_0 \sin\phi_0 \phi_1^{(2)} + R_{dn1}^{(2)} - (m + m_a)\frac{\partial v^{(2)}}{\partial t} = -\Omega_{31}^{(1)} T_1^{(1)} + m u^{(1)}\frac{\partial \phi_1^{(1)}}{\partial t} , \tag{38.103}$$

$$\frac{\partial u^{(2)}}{\partial s} - \Omega_{30} v^{(2)} - \frac{1}{EA}\frac{\partial T_1^{(2)}}{\partial t} = v^{(1)}\Omega_{31}^{(1)} , \tag{38.104}$$

$$\frac{\partial v^{(2)}}{\partial s} + \Omega_{30} u^{(2)} - \frac{\partial \phi_1^{(2)}}{\partial t} = -\Omega_{31}^{(1)} u^{(1)} , \tag{38.105}$$

$$EI\frac{\partial \Omega_{31}^{(2)}}{\partial s} + S_{n1}^{(2)} = 0 , \tag{38.106}$$

$$\frac{\partial \phi_1^{(2)}}{\partial s} - \Omega_{31}^{(2)} = 0 . \tag{38.107}$$

The sets of (38.96)–(38.101) (first-order) and (38.102)–(38.107) (second-order) compose two discrete systems that can be treated separately. Virtually, the first system is identical to the system of (38.53), (38.54), (38.56), (38.57), (38.60), and (38.62) with the note that it is expressed in terms of velocities instead of displacements. Clearly, the solution of the second-order system requires knowing the solution of the first-order system. Assuming that the cable is excited at one end by a monochromatic excitation (without reference yet to the other end), this motion constitutes a boundary condition for the first-order (linear) problem. Unquestionably, the solution of that problem will yield equal frequency variations for the motions, rotations, and internal loading components, whereas the frequency of the response will coincide with the excitation frequency. On the contrary, we cannot assume that the second-order system is subjected to an external excitation. Therefore, the question which arises concerns the nature of the excitation experienced by the second-order system. To provide an appropriate answer we must first inspect the right-hand side terms of (38.102)–(38.105). According to these terms, the mechanism that forces the cable to respond at second order and subsequently induces the double-frequency effects can be regarded as a distribution of generalized nonlinear springs along the complete length of the cable, which mainly originate from geometric nonlinearities. Evidently, the main contribution arises from the geometric nonlinearity $\Omega_{31}^{(1)} T_1^{(1)}$.

38.5.4 The Frequency Domain Approach

In the context of the linear problem the vector of the unknowns is written as

$$V_1^{(1)} = \mathrm{Re}\{\boldsymbol{\xi}_1^{(1)} e^{i\omega t}\} , \tag{38.108}$$

where

$$\boldsymbol{\xi}_1^{(1)} = \left[T_1^{(1)} \quad S_{\mathrm{n}1}^{(1)} \quad u^{(1)} \quad v^{(1)} \quad \Omega_{31}^{(1)} \quad \phi_1^{(1)} \right]^{\mathrm{T}}$$

is a complex vector depending on ω and the spatial coordinate s. Alternatively, (38.108) admits the following form

$$\boldsymbol{V}_1^{(1)} = \frac{1}{2}\left[\boldsymbol{\xi}_1^{(1)} \mathrm{e}^{\mathrm{i}\omega t} + \bar{\boldsymbol{\xi}}_1^{(1)} \mathrm{e}^{-\mathrm{i}\omega t} \right], \tag{38.109}$$

where the bar above ξ denotes the equivalent complex conjugate.

Next, (38.109) is introduced into the system of (38.96)–(38.101), which accordingly yields the following matrix form

$$\frac{\mathrm{d}\left(\boldsymbol{\xi}_1^{(1)} \mathrm{e}^{\mathrm{i}\omega t}\right)}{\mathrm{d}s} + cc = \mathbf{K}^{(1)} \left(\boldsymbol{\xi}_1^{(1)} \mathrm{e}^{\mathrm{i}\omega t}\right) + cc\,, \tag{38.110}$$

where cc stands for the equivalent complex conjugate. The 6×6 square matrix associated with the linear problem is given by

$$\mathbf{K}^{(1)} = \begin{bmatrix} 0 & \Omega_{30} & \mathrm{i}\omega m & 0 & S_{\mathrm{n}0} & w_0 \cos\phi_0 \\ -\Omega_{30} & 0 & 0 & \mathrm{i}\omega(m+m_{\mathrm{a}}) + b|v| & -T_0 & -w_0 \sin\phi_0 \\ \dfrac{\mathrm{i}\omega}{EA} & 0 & 0 & \Omega_{30} & 0 & 0 \\ 0 & 0 & -\Omega_{30} & 0 & 0 & \mathrm{i}\omega \\ 0 & \dfrac{-1}{EI} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix}. \tag{38.111}$$

A brief inspection of the second-order system, (38.102)–(38.107), immediately confirms that the associated variables will respond with the double of the frequency of the excitation. It is also evident that the quadratic products at the right-hand side terms of the same equations will yield some time-independent terms that will amplify the magnitudes of the double-frequency (2ω) components by a constant amount. These components will originate by the products of terms depending on $\exp(-\mathrm{i}\omega t)$ and $\exp(\mathrm{i}\omega t)$. As far as the solution $\boldsymbol{V}_1^{(2)}$ of the second-order problem is concerned, the latter remark suggests letting

$$\boldsymbol{V}_1^{(2)} = \mathrm{Re}\left\{ \boldsymbol{\xi}_{\mathrm{c}}^{(2)} + \boldsymbol{\xi}_1^{(2)} \mathrm{e}^{2\mathrm{i}\omega t} \right\}, \tag{38.112}$$

where $\boldsymbol{\xi}_{\mathrm{c}}^{(2)}$ and $\boldsymbol{\xi}_1^{(2)}$ denote, respectively, the second-order constant and the double-frequency unknown complex vectors, which are expanded as

$$\boldsymbol{\xi}_{\mathrm{c}}^{(2)} = \left[T_{\mathrm{c}}^{(2)} \quad S_{\mathrm{nc}}^{(2)} \quad u_{\mathrm{c}}^{(2)} \quad v_{\mathrm{c}}^{(2)} \quad \Omega_{3\mathrm{c}}^{(2)} \quad \phi_{\mathrm{c}}^{(2)} \right]^{\mathrm{T}}, \tag{38.113}$$

$$\boldsymbol{\xi}_1^{(2)} = \left[T_1^{(2)} \quad S_{\mathrm{n}1}^{(2)} \quad u^{(2)} \quad v^{(2)} \quad \Omega_{31}^{(2)} \quad \phi_1^{(2)} \right]^{\mathrm{T}}. \tag{38.114}$$

The term *constant* implies that the elements of $\boldsymbol{\xi}_{\mathrm{c}}^{(2)}$ are independent of time. However, they are still functions of the Lagrangian coordinate s. The fact that some of the elements of $\boldsymbol{\xi}_{\mathrm{c}}^{(2)}$ might be zero is irrelevant to the general analysis that is conducted herein. In any event, their actual values depend on the application and the structural model under consideration and they are given by the solution of the second-order problem.

Again, (38.112) is alternatively written as

$$\boldsymbol{V}_1^{(2)} = \frac{1}{2}\left[\boldsymbol{\xi}_{\mathrm{c}}^{(2)} + \bar{\boldsymbol{\xi}}_{\mathrm{c}}^{(2)} \right] + \frac{1}{2}\left[\boldsymbol{\xi}_1^{(2)} \mathrm{e}^{2\mathrm{i}\omega t} + \bar{\boldsymbol{\xi}}_1^{(2)} \mathrm{e}^{-2\mathrm{i}\omega t} \right]. \tag{38.115}$$

The preceding equation is introduced into the system of (38.102)–(38.107), which after several mathematical manipulations provides the following matrix equation

$$\begin{aligned} &\frac{\mathrm{d}\boldsymbol{\xi}_{\mathrm{c}}^{(2)}}{\mathrm{d}s} + \frac{\mathrm{d}(\boldsymbol{\xi}_1^{(2)} \mathrm{e}^{2\mathrm{i}\omega t})}{\mathrm{d}s} + cc \\ &= \mathbf{K}^{(2)} \left(\boldsymbol{\xi}_1^{(2)} \mathrm{e}^{2\mathrm{i}\omega t}\right) + \frac{1}{2}\boldsymbol{N}^{(2)} \mathrm{e}^{2\mathrm{i}\omega t} + \frac{1}{2}\tilde{\boldsymbol{N}}^{(2)} + cc\,. \end{aligned} \tag{38.116}$$

The 6×6 square matrix and 6×1 vectors of the right-hand side of (38.116) are given by

$$\mathbf{K}^{(2)} = \begin{bmatrix} 0 & \Omega_{30} & 2\mathrm{i}\omega m & 0 & S_{\mathrm{n}0} & w_0 \cos\phi_0 \\ -\Omega_{30} & 0 & 0 & 2\mathrm{i}\omega(m+m_{\mathrm{a}}) + b|v| & -T_0 & -w_0 \sin\phi_0 \\ \dfrac{2\mathrm{i}\omega}{EA} & 0 & 0 & \Omega_{30} & 0 & 0 \\ 0 & 0 & -\Omega_{30} & 0 & 0 & 2\mathrm{i}\omega \\ 0 & \dfrac{-1}{EI} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix}, \tag{38.117}$$

$$\boldsymbol{N}^{(2)} = \begin{bmatrix} S_{\mathrm{n}1}^{(1)} \Omega_{31}^{(1)} - \mathrm{i}\omega m v^{(1)} \phi_1^{(1)} \\ -T_1^{(1)} \Omega_{31}^{(1)} + \mathrm{i}\omega m u^{(1)} \phi_1^{(1)} \\ \Omega_{31}^{(1)} v^{(1)} \\ -\Omega_{31}^{(1)} u^{(1)} \\ 0 \\ 0 \end{bmatrix}, \tag{38.118}$$

$$\tilde{N}^{(2)} = \begin{bmatrix} S_{n1}^{(1)}\bar{\Omega}_{31}^{(1)} + i\omega m v^{(1)}\bar{\phi}_1^{(1)} \\ -\bar{T}_1^{(1)}\Omega_{31}^{(1)} + i\omega m\bar{u}^{(1)}\phi_1^{(1)} \\ \bar{\Omega}_{31}^{(1)} v^{(1)} \\ -\Omega_{31}^{(1)}\bar{u}^{(1)} \\ 0 \\ 0 \end{bmatrix} . \tag{38.119}$$

Further, we distinguish between the constant and the time-varying components. Thus, (38.116) is split into two systems of ordinary differential equations, both expressed in convenient matrix form. The first system provides the second-order constant displacement and internal loading terms, whilst the second system yields the respective time-varying double-frequency components. Here, emphasis is given to the dynamic behavior of the structural model under investigation and hence the solution of the constant system is omitted. It should be noted, however, that the occurrence of the elements of vector $\tilde{N}^{(2)}$ and, accordingly, the existence of a time-independent term in the global solution of the second-order problem imply that the double-frequency variables oscillate around a nonzero average. In particular, the system that provides the double-frequency components is

$$\frac{\mathrm{d}\left(\xi_1^{(2)} e^{2i\omega t}\right)}{\mathrm{d}s} + cc = \mathbf{K}^{(2)}\left(\xi_1^{(2)} e^{2i\omega t}\right) + \frac{1}{2}N^{(2)} e^{2i\omega t} + cc\,. \tag{38.120}$$

The forcing terms for that system are involved in $N^{(2)}$ and they virtually represent the excitation for the double-frequency system.

38.5.5 Numerical Solution

The linear and the second-order systems are treated separately as two discrete, two-point boundary value problems. The solution of the double-frequency system relies on the derivation of the first-order components. The systems are transformed in order to be expressed in terms of displacements instead of velocities. Thus,

$$\begin{aligned} u^{(1)} e^{i\omega t} &= i\omega p^{(1)} e^{i\omega t}\,, \\ u^{(2)} e^{2i\omega t} &= 2i\omega p^{(2)} e^{2i\omega t}\,, \\ v^{(1)} e^{i\omega t} &= i\omega q^{(1)} e^{i\omega t}\,, \\ v^{(2)} e^{2i\omega t} &= 2i\omega q^{(2)} e^{2i\omega t}\,, \end{aligned}$$

where again, $p^{(k)}$, $q^{(k)}$, and $k = 1, 2$ are, respectively, the first and second-order complex (ω, s) functions of the axial and normal displacements. In the context of the frequency domain approach, the drag forces in normal direction $R_{dn1}^{(k)}$, $k = 1, 2$ should be replaced by the linearized equivalent terms obtained using a Fourier series expansion technique. It can be shown that the associated coefficients, to first and second-order, are, respectively, equal to $8/(3\pi)$ and $112/(60\pi)$, and accordingly, the drag forces become

$$R_{dn1}^{(1)} = -ib^{(1)}\omega^2 |q|\, q^{(1)};\;\; R_{dn1}^{(2)} = -ib^{(2)}\omega^2 |q|\, q^{(2)}\,, \tag{38.121}$$

where

$$b^{(1)} = 4/(3\pi)\rho d_O C_d$$

and

$$b^{(2)} = 112/(60\pi)\rho d_O C_d\,.$$

Next, after separating into real and imaginary parts, a system of 12 ordinary differential equations with an equal number of unknowns is derived. In order to distinguish between real and imaginary parts, the latter will be denoted in the sequel as bold symbols. Thus, if

$$\boldsymbol{F}^{(k)} = \left[T_1^{(k)} \;\; \boldsymbol{T}_1^{(k)} \;\; S_{n1}^{(k)} \;\; \boldsymbol{S}_{n1}^{(k)} \;\; p^{(k)} \;\; \boldsymbol{p}^{(k)} \;\; q^{(k)} \;\; \boldsymbol{q}^{(k)} \;\; \Omega_{31}^{(k)} \;\; \boldsymbol{\Omega}_{31}^{(k)} \;\; \phi_1^{(k)} \;\; \boldsymbol{\phi}_1^{(k)}\right]^{\mathrm{T}}, \tag{38.122}$$

for $k = 1, 2$ (38.110) and (38.120) are rewritten as

$$\frac{\mathrm{d}\boldsymbol{F}^{(k)}}{\mathrm{d}s} = \mathbf{P}^{(k)}\boldsymbol{F}^{(k)} + \frac{1}{2}\boldsymbol{Q}^{(k)}\,, \tag{38.123}$$

where $\boldsymbol{Q}^{(1)} = 0$. The transformation matrices $\mathbf{P}^{(k)}$ and the excitation vectors $\boldsymbol{Q}^{(k)}$ originated directly from $\mathbf{K}^{(k)}$ and $\boldsymbol{N}^{(k)}$, respectively, after equating real and imaginary parts. The elements of the vector $\boldsymbol{Q}^{(2)}$ literally represent the excitation of the nonlinear system and can be regarded as nonlinear springs composed of products of the first-order components.

The systems denoted by (38.123) are solved using the centered differences method [38.31]. To this end, the length of the structure is discretized using n nodes $(l = 1, \ldots, n)$, and all terms of (38.31) are evaluated at $l - 1/2$. Thus,

$$F_l^{(k)} - F_{l-1}^{(k)} = \frac{\Delta s}{2}\left(P_l^{(k)}F_l^{(k)} + P_{l-1}^{(k)}F_{l-1}^{(k)}\right) + \frac{\Delta s}{4}\left(Q_l^{(k)} + Q_{l-1}^{(k)}\right)\,. \tag{38.124}$$

The index l defines the spatial grid points (the nodes). For n nodal points, (38.124) defines a system of $12 \times (n-1)$ equations to be solved for the $12 \times n$-dependent variables. The 12 equations needed to complete the problem are provided by boundary conditions. The conditions that govern the behavior of the upper end at $l = n$, $s = L$, i. e., where the excitation is applied, are defined explicitly by the following relations

$$p^{(1)} = p_a(t); \quad q^{(1)} = q_a(t); \quad \Omega_{31}^{(1)} = 0;$$
$$p^{(2)} = 0; \quad q^{(2)} = 0; \quad \Omega_{31}^{(2)} = 0\,. \qquad (38.125)$$

In other words it is assumed that the top terminal point is simply supported, which implies that the curvatures at both first and second orders are zero, whereas for a monochromatic excitation the linear motions are predefined functions of time (denoted by $p_a(t)$ and $q_a(t)$). In addition, the specified top end excitation requires that the motions at second order must be zero. This feature is in compliance with a previous remark according to which the excitation for the second-order system is provided by equivalent nonlinear springs formulated mathematically by the linear components.

The derivation of the remaining six boundary conditions at the lower end is combined with a novel approach that tries to formulate mathematically the bottom–structure interaction phenomenon. The relevant procedure is discussed in detail in the following section.

38.5.6 The Bottom–Structure Interaction Approach

Background

The mathematical formulation outlined in the preceding sections is extended to account for an additional impact that is known to occur in real applications. This is the interaction of the cable with the seafloor, which in the context of the present frequency domain approximation is treated with a novel mathematical approach.

There have been several studies reported in the literature that try to assess the impact of the cable–bottom interaction phenomenon from the mathematical perspective. In this context *Chatjigeorgiou* and *Mavrakos* [38.57] evaluated the time-varying TDP using quasi-static considerations and then they solved the dynamic equilibrium system along the time variable suspended part. *Gobat* and *Grosenbaugh* [38.58] investigated the interaction problem for catenary moorings both numerically and experimentally by relating the TDP speed with the transverse wave speed of the mooring line. *Demeio* and *Lenci* [38.59] transformed the free boundary value problem of the moving TDP into a fixed boundary value problem that was successively approached by a perturbation expansion method. In order to detect the main mechanical phenomenon, the authors considered terms up to the second order. In the work due to *Gatti-Bono* and *Perkins* [38.60] the seabed was simulated as an elastic foundation with a prescribed topology that assumes linear damping, whereas *Han* and *Grosenbaugh* [38.61] employed a simplified model based on the static equilibrium system and formulated the seabed by a coupled system consisting of mass, damper, and springs. Finally, although not explicitly connected with mooring lines, the work of *Pesce* et al. [38.62] should be mentioned, in which the authors proposed the employment of a boundary layer technique at TDP to approximate the dynamic curvature amplification at the TDZ.

Here, an alternative novel theoretical approach is taken, the details of which are outlined thoroughly in the following section.

A Mathematical Approach

The following analysis relies on the assumption of a perfectly horizontal bottom. It is apparent that under the external imposed excitation the catenary cable will continuously lift off and lie down. For a monochromatic excitation a lift-off/lie-down cycle will be equal to the displacement cycle. In fact, the length of the cable between the end nodes of maximum lift-off and maximum lie-down can be accurately determined by quasi-static considerations. Having as a base configuration the static equilibrium shape of the catenary cable, it should be noted that the lengths of the segments on either side of the TDP at $t = 0$ are not necessarily equal. That depends on the static configuration and the orientation of the excitation at the top. Nevertheless, it can be assumed that the time-varying TDP will oscillate horizontally around an average location that coincides with the TDP at $t = 0$ (the static configuration TDP). Also, it can be safely assumed that the TDP is instantly a pinned support.

The assumption of a horizontally moving pinned TDP around an average location, suggests the employment of a Taylor series expansion for the variables involved in the boundary conditions. First, using velocity terms and assuming that $f^{(k)}$, $k = 1, 2$ is a global notation for axial velocity, normal velocity, and curvature at k-th order, the Taylor series expansion of $f^{(k)}$ is written as

$$f^{(k)}|_0 + \left.\frac{\partial f^{(k)}}{\partial s}\right|_0 \Delta s + \cdots = 0\,. \qquad (38.126)$$

The index 0 in the above relation denotes that the term concerned is calculated at the static equilibrium TDP ($t = 0$). The $O(\Delta s^2)$ terms and above have been omitted.

Further, by using the perturbations technique, equating the terms of like powers of ε and employing (38.98)–(38.100) and (38.104)–(38.106) the following are derived

$$u^{(1)}|_0 + \left(\frac{1}{EA}\frac{\partial T_1^{(1)}}{\partial t} + \Omega_{30} v^{(1)}\right)\Bigg|_0 \Delta s = 0\,, \tag{38.127}$$

$$v^{(1)}|_0 + \left(\frac{\partial \phi_1^{(1)}}{\partial t} - \Omega_{30} u^{(1)}\right)\Bigg|_0 \Delta s = 0\,, \tag{38.128}$$

$$\Omega_{31}^{(1)}|_0 - \frac{S_{\mathrm{n1}}^{(1)}}{EI}\Bigg|_0 \Delta s = 0\,, \tag{38.129}$$

$$u^{(2)}|_0 + \left(\frac{1}{EA}\frac{\partial T_1^{(2)}}{\partial t} + \Omega_{30} v^{(2)} + \Omega_{31}^{(1)} v^{(1)}\right)\Bigg|_0 \Delta s = 0\,, \tag{38.130}$$

$$v^{(2)}|_0 + \left(\frac{\partial \phi_1^{(2)}}{\partial t} - \Omega_{30} u^{(2)} - \Omega_{31}^{(1)} u^{(1)}\right)\Bigg|_0 \Delta s = 0\,, \tag{38.131}$$

$$\Omega_{31}^{(2)}|_0 - \frac{S_{\mathrm{n1}}^{(2)}}{EI}\Bigg|_0 \Delta s = 0\,. \tag{38.132}$$

Again, using displacements instead of velocities and separating real and imaginary parts, (38.127)–(38.129) are transformed at $O(\varepsilon)$ into

$$p^{(1)}|_0 + \frac{T_1^{(1)}}{EA}\Bigg|_0 \Delta s = 0\,, \tag{38.133}$$

$$q^{(1)}|_0 + \phi_1^{(1)}|_0 \Delta s = 0\,, \tag{38.134}$$

$$\Omega_{31}^{(1)}|_0 - \frac{S_{\mathrm{n1}}^{(1)}}{EI}\Bigg|_0 \Delta s = 0\,. \tag{38.135}$$

It is noted that (38.133)–(38.135) apply identically for both real

$$\left[T_1^{(1)} \quad S_{\mathrm{n1}}^{(1)} \quad p^{(1)} \quad q^{(1)} \quad \Omega_{31}^{(1)} \quad \phi_1^{(1)}\right]$$

and imaginary parts

$$\left[\boldsymbol{T}_1^{(1)} \quad \boldsymbol{S}_{\mathrm{n1}}^{(1)} \quad \boldsymbol{p}^{(1)} \quad \boldsymbol{q}^{(1)} \quad \boldsymbol{\Omega}_{31}^{(1)} \quad \boldsymbol{\phi}_1^{(1)}\right].$$

Finally, for second-order $O(\varepsilon^2)$, the bottom end boundary conditions become

$$p^{(2)}|_0 + \left[\frac{T_1^{(2)}}{EA} + \frac{1}{4}\left(q^{(1)}\Omega_{31}^{(1)} - \boldsymbol{q}^{(1)}\boldsymbol{\Omega}_{31}^{(1)}\right)\right]_0 \Delta s = 0\,, \tag{38.136}$$

$$\boldsymbol{p}^{(2)}|_0 + \left[\frac{\boldsymbol{T}_1^{(2)}}{EA} + \frac{1}{4}\left(q^{(1)}\boldsymbol{\Omega}_{31}^{(1)} + \boldsymbol{q}^{(1)}\Omega_{31}^{(1)}\right)\right]_0 \Delta s = 0\,, \tag{38.137}$$

$$q^{(2)}|_0 + \left[\phi_1^{(2)} - \frac{1}{4}\left(p^{(1)}\Omega_{31}^{(1)} - \boldsymbol{p}^{(1)}\boldsymbol{\Omega}_{31}^{(1)}\right)\right]_0 \Delta s = 0\,, \tag{38.138}$$

$$\boldsymbol{q}^{(2)}|_0 + \left[\boldsymbol{\phi}_1^{(2)} - \frac{1}{4}\left(\boldsymbol{p}^{(1)}\Omega_{31}^{(1)} + p^{(1)}\boldsymbol{\Omega}_{31}^{(1)}\right)\right]_0 \Delta s = 0\,, \tag{38.139}$$

$$\Omega_{31}^{(2)}|_0 - \frac{S_{\mathrm{n1}}^{(2)}}{EI}\Bigg|_0 \Delta s = 0\,, \tag{38.140}$$

$$\boldsymbol{\Omega}_{31}^{(2)}|_0 - \frac{\boldsymbol{S}_{\mathrm{n1}}^{(2)}}{EI}\Bigg|_0 \Delta s = 0\,. \tag{38.141}$$

The first-order (38.133)–(38.135) imply that the bottom end boundary conditions are linear. Nevertheless, according to the proposed mathematical expansion the boundary conditions at $O(\varepsilon)$ become coupled as all dynamic components at the time-varying TDP at $l = 1$ are involved. Also, the present sophisticated formulation of the boundary conditions demonstrates that the displacements and the curvature at the original TDP are not zero. This theoretical finding is in accordance with the actual phenomenon as the original TDP (at $t = 0$) oscillates continuously.

Studies reported on the subject abound in verbal statements regarding the nonlinear nature of the interaction phenomenon. Nevertheless, relevant references are usually correlated with the nonlinear stiffness and the nonlinear stress–strain relations of soil. The mathematical analysis that is conducted herein demonstrates that the phenomenon is itself nonlinear and the nonlinearities involved are not explicitly driven by the distorting behavior of the soil. In fact, the nonlinear boundary conditions (38.136)–(38.139) show the occurrence of double-frequency components, which are stimulated by first-order quadratic terms.

38.5.7 Results of Second-Order Double-Frequency Effects

Succinctly, the analysis conducted in Sect. 38.5 implies that when a cable is subjected to monochromatic excitation it admits contributions from the integer multiplications of the associated frequency. Hypothetically, the excitation frequencies that contribute extend to infinity. The same would occur if, for instance, the cable were excited by two frequencies. In that case, the response would include contributions from all possible sum and minus combinations of these frequencies, in-

cluding combinations of the integer multiplications. Nevertheless, it can be safely said that the impact of the nonlinear effects decays for higher orders and the prevailing component remains the linear term. Nonlinear effects have visual and significant results only under specific conditions, say at nonlinear resonances.

To assess the effect of the nonlinearities on the dynamics of cables, the mooring line, already examined in Sect. 38.4.1, is used as the base structural model. Along with the double-frequency contributions, the discussion is extended to comment on bottom-interaction effects as they are determined with the novel approach outlined in detail in Sect. 38.5.6 herein. Here, the associated numerical predictions are labeled as BI. Two excitation cases are considered, namely in horizontal and vertical directions. In both cases, the amplitude was kept the same, i. e., 2 m.

First the horizontal excitation is considered. The effect of bottom interactions on the linear problem is shown in Fig. 38.25. In fact, the curves of the linear problem are the same as those shown in Fig. 38.15. The symbols denote the results obtained after incorporating the relations that govern the Taylor approach of the bottom-interaction phenomenon. It is immediately evident that for this particular case of excitation and the configuration of the mooring line, the interaction with the bottom has practically zero effect, at least as far as the tension amplification is concerned. It should be noted that to eliminate possible inaccuracies due to the numerical solution of the problem a sufficiently dense grid was employed and the cable was discretized by 1000 nodes along its complete length.

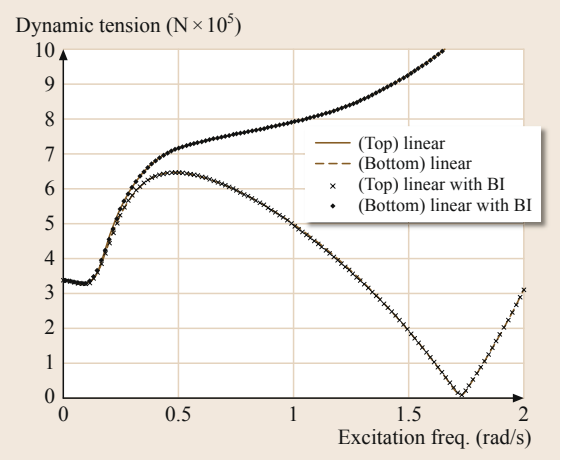

Fig. 38.25 Linear dynamic tension amplification at the top and the bottom of a mooring line, excited by a horizontal monochromatic excitation with amplitude $a_x = 2$ m (BI denotes that bottom interaction effects have been considered)

The next comment refers to the effect of the second-order components of the dynamic tension, which are applied at the top and bottom of the cable at double the frequency of the excitation. The associated quadratic transfer functions are depicted in Fig. 38.26. Here it is interesting to observe that the two curves nearly coincide along the whole frequency range. In fact, a depiction of the tension variation along the cable would reveal that, indeed, the tension exhibits a symmetrical variation about the middle of the structure and that occurs for all frequencies. As regards the details of the plotted quadratic transfer functions, the attention is immediately attracted by the two local maxima, which apparently coincide with specific eigenfrequencies of the dynamic system. The second peak is clearly a resonance that obtains a relatively large value, albeit approximately 10 times lower than the linear contribution. The important aspect is that the sharp amplification occurs at exactly the frequency where the linear dynamic tension is canceled.

Analogous behavior is observed in the linear and the quadratic transfer functions of the motions of the touch-down point (TDP). As has been said, the Taylor approximation allows the originally fixed TDP to move freely in the 2-D plane of reference. The kinematics of that point is described through the axial (stretching) and normal motions of the cable. The stretching is examined in Fig. 38.27 and the normal motions in the Fig. 38.28. The former reveals that the pattern of the dynamic tension amplification is provided directly by the stretching (axial motion). Also, the second-order component is practically zero as compared to the linear term, as it

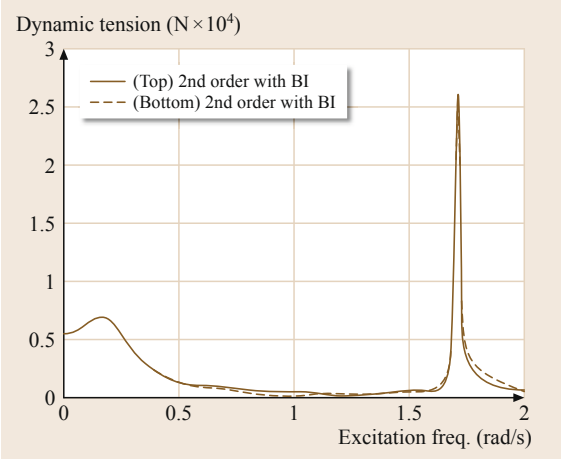

Fig. 38.26 Second-order double-frequency dynamic tension amplification at the top and the bottom of a mooring line, excited by a horizontal monochromatic excitation with amplitude $a_x = 2$ m (BI denotes that bottom interaction effects have been considered)

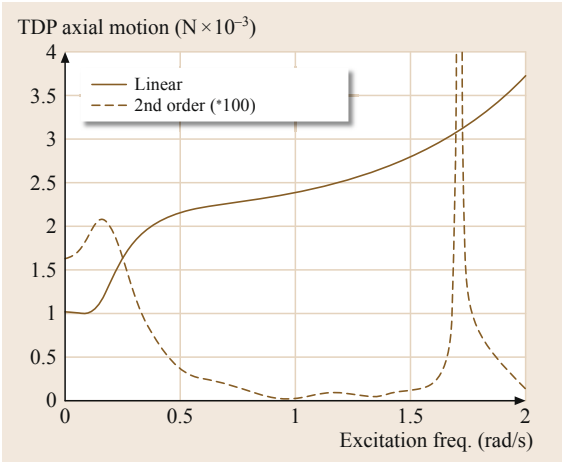

Fig. 38.27 Linear and second-order axial stretching at the bottom of a mooring line, excited by a horizontal monochromatic excitation with amplitude $a_x = 2\,\mathrm{m}$ (bottom interaction effects have been considered)

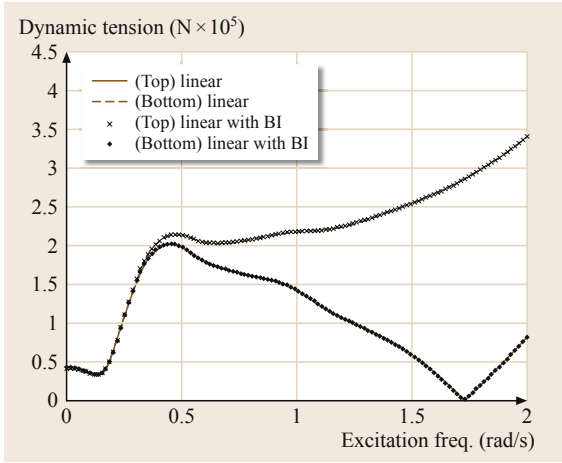

Fig. 38.29 Linear dynamic tension amplification at the top and the bottom of a mooring line, excited by a vertical monochromatic excitation with amplitude $a_z = 2\,\mathrm{m}$ (BI denotes that bottom interaction effects have been considered)

is approximately 100 times smaller, which in turn explains why the transfer functions shown in Fig. 38.25 coincide perfectly.

The last variable that is considered is the normal motion of the TDP, which as manifested in Fig. 38.28 is small but not negligible. According to the demonstrated trends the maximum uplift of the TDP from the bottom approximates 2 cm for the excitation amplitude and the structural model under consideration. It should be mentioned that the variation of the normal motion of the TDP as a function of the excitation frequency does not follow any predictable path complying to a certain rule.

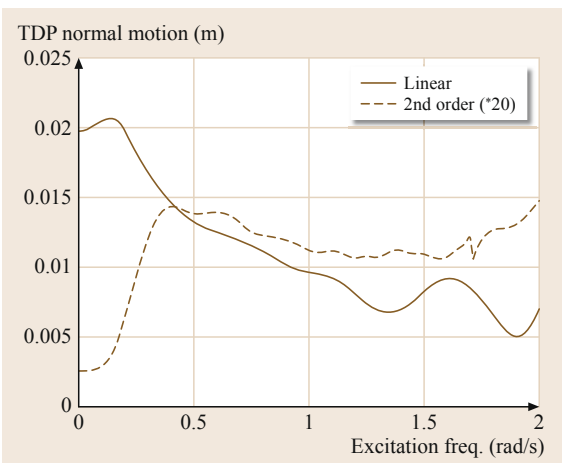

Fig. 38.28 Linear and second-order TDP normal motions of a mooring line, excited by a horizontal monochromatic excitation with amplitude $a_x = 2\,\mathrm{m}$ (bottom interaction effects have been considered)

Next, the heave excitation case is investigated. To this end, Figs. 38.29–38.32 are given, which depict analogous components. The transfer functions of the dynamic tension (linear problem) are shown in Fig. 38.29. The behavior is more or less the same as with the surge excitation case. Again, a cancelation point occurs for the dynamic tension at the top, whilst the dynamic tension is larger at the bottom. The interaction with the bottom has a negligible impact, although the associated curves do not coincide perfectly. However, the curves that coincide perfectly are the quadratic

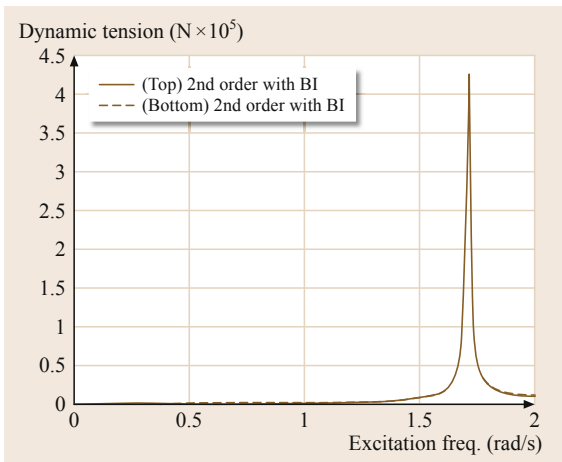

Fig. 38.30 Second-order double-frequency dynamic tension amplification at the top and the bottom of a mooring line, excited by a vertical monochromatic excitation with amplitude $a_z = 2\,\mathrm{m}$ (BI denotes that bottom interaction effects have been considered)

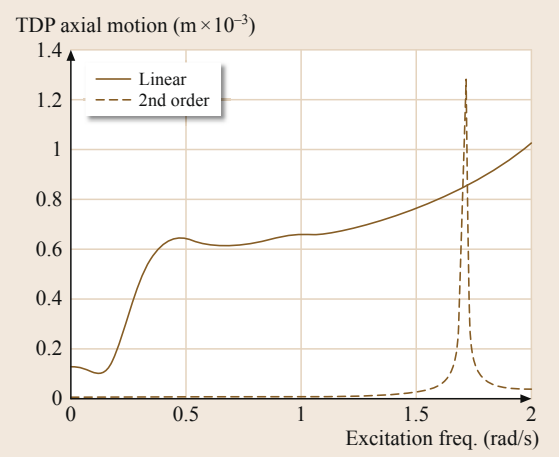

Fig. 38.31 Linear and second-order axial stretching at the bottom of a mooring line, excited by a vertical monochromatic excitation with amplitude $a_z = 2\,\mathrm{m}$ (bottom interaction effects have been considered)

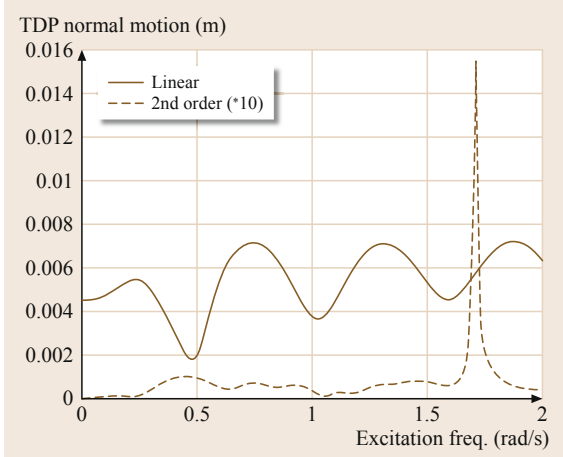

Fig. 38.32 Linear and second-order TDP normal motions of a mooring line, excited by a vertical monochromatic excitation with amplitude $a_z = 2\,\mathrm{m}$ (bottom interaction effects have been considered)

transfer functions of the dynamic tension applied at the top and the bottom (Fig. 38.30).

As has been said and still holds, the variation of double-frequency tension along the cable exhibits a symmetry with respect to the midpoint of the suspended part. The most important characteristic depicted in Fig. 38.30 is that the peak (the resonance) that occurs at the end of the frequency range obtains an unusually large value for a second-order term and reaches the values of the linear components (in fact, it exceeds the maximum linear component). This is indeed a very important finding, which could be correlated with the fatigue response of the cable, since it proves that apart from the linear loading, at a specified frequency the cable will be subjected to a very fast and very strong internal forcing.

With reference to Fig. 38.31 it can be seen that the pattern of the axial stretching at the TDP provides the variation pattern of the dynamic tension amplification in both linear and double-frequency orders. Stretching is one of the two degrees of freedom in the plane of reference. The other is the normal motion, which practically demonstrates the displacements performed by the TDP. The associated linear and quadratic transfer functions are given in Fig. 38.32. The linear displacements follow a wavy trend with respect to the frequency. The second-order normal motions are governed by the well-known peak at the high frequency range, which shows that the maximum expected normal motion of the TDP will not exceed 2 cm.

It is important to mention that the results shown in this section must not lead to simplistic conclusions such as, for instance, the interaction with the bottom or the nonlinear effects being negligible. It is emphasized that the numerical predictions are case sensitive, meaning that they are explicitly adapted to the model investigated and to the excitation conditions. The cable examined herein was sufficiently stretched without allowing the dynamic components to be fully developed. Hence, the computations showed a relatively minor effect arising from the dynamics of the cable. Also, the small motions of the TDP can be attributed to this particular configuration. The condition would definitely be different for structures with large bending stiffness, say for risers. In relevant cases, however, the parameter of concern would be the bending moment and not the tension. Even for the cable investigated, however, which possesses the properties of a typical mooring line, it is important that we have simulated the kinematics of the TDP and shown that is indeed released from the bottom.

39. Offshore Geotechnics

Dong-Sheng Jeng

Offshore geotechnics is a multidisciplines area that cover conventional civil engineering disciplines such as fluid mechanics, coastal engineering, geotechnical engineering, structures engineering, etc. This area has attracted great attention among coastal and geotechnical engineers due to growing activities in marine environment worldwide. An appropriate design of foundations of marine infrastructures, such as breakwater, offshore pipeline, platforms, and offshore wind turbine systems plays an important role in the success of offshore engineering projects. The evaluation of the soil response due to hydrodynamic loading, such as waves and currents around foundation of marine structures and its resultant seabed instability is one of the key factors in the design of foundation.

This chapter is an attempt to give a comprehensive review of wave–seabed interaction around the marine structure. It also takes into consideration all state-of-the art knowledge. We start off with the basic models including a detailed review and summary of existing work. Then, we outline recent advances in the field and their engineering applications.

39.1 Basic Models

Numerous models for the wave-induced seabed response have been developed with various assumptions since the 1940s. The assumptions and the leading governing equations for each model will be summarized here:

- *Simplified model*: In the model, both pore fluid and soil are considered as incompressible medium, and the accelerations due to fluid and soil motion are ignored. This leads to an uncoupled model, in which Laplace's equation is the governing equation [39.1]. Another similar approach is to include the compressibility of pore fluid, which leads to diffusion equation [39.2].
- *Biot's poro-elastic models*: Basically, three poro-elastic models have been developed since the 1970s, including consolidation model (or quasi-static model), *u-p* approximation, and dynamic models.
  - *Consolidation model*: In the consolidation model, both pore fluid and soil skeleton are considered to be compressible, but the accelerations due to fluid and soil motion are ignored. Since the acceleration has been ignored, this model is also called as the quasi-static model [39.3].
  - *u-p approximation*: In this model, the acceleration due to pore fluid is ignored in the general formulation. This model was first proposed by

Zienkiewicz et al. [39.4] with a one-dimensional analysis, and then extended to two-dimensional analysis for the wave–seabed interaction [39.5, 6].
  - *Dynamic model*: The full set of governing equations established by Biot [39.7] is employed in the analysis, in which both accelerations due to pore fluid and soil motion are included. Since this model is rather complicated, only a few investigations are available in the literature [39.8, 9].
- *Poro-elastoplastic model*: Besides linear poro-elastic models, some advanced models such as the poro-elasto-plastic model for the wave-induced seabed response have been developed recently [39.10, 11]. The poro-elastoplastic models will provide better predictions of the potential of the wave-induced seabed instability, which is normally a large deformation.

In the aforementioned models, both analytical and numerical models have been employed to obtain the wave-induced soil response. In the following sections, most previous theoretical investigations for the wave-induced seabed response will be reviewed under the heading of each model.

39.1.1 Simplified Models

Uncoupled models have been used as the first approximation in the area of wave–seabed interaction. In the model, either pore fluid or soil skeleton has been considered as incompressible medium. The accelerations due to both pore fluid and soil motion are ignored in this approach. Since the governing equation is either Laplace's equation or the diffusion equation, for which the analytical solutions have been well developed, most previous investigations with these assumptions are analytical approximations.

Models with the Laplace Equation

Based on the assumptions of a rigid, permeable sandy seabed and incompressible pore fluid, Laplace's equation is the governing equation for the wave-induced pore pressure,

$$\nabla^2 p = \frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} = 0\,, \tag{39.1}$$

where p is the pore pressure in the seabed.

Using a linear wave theory, *Putnam* presented a simple solution for an isotropic porous seabed of finite thickness and concluded that a significant loss of wave energy occurred in the presence of a porous sandy seabed due to viscous percolation of fluid [39.1]. The percolation was activated by the pressure variation at the interface between sea water and seabed. The solution indicated that the pressure distribution within the seabed depended only on the wave characteristics and geometry of the sand layer, and not on the properties of the seabed. However, a possible error of the wave height was observed in *Putnam*'s paper, which overestimated the dissipation function by a factor of 4 [39.12].

Based on the same assumptions as Putnam, the wave-induced pore pressure for a porous seabed of finite thickness with anisotropic permeability was examined by *Sleath* [39.13]. He also conducted laboratory experiments to verify the theory, resulting in the discovery of a phase lag (less than 10°) in the pore pressure. However, these experimental results were inconsistent with his theoretical results. This inconsistence is due to the assumptions of his theoretical approach.

Considering the viscous effect of the boundary layer and energy balance, *Liu* modeled the flow in a permeable bed and determined the damping rate for an infinite seabed [39.14]. The continuity of pressure and velocity is required as boundary conditions at the interface up to order $O(\sqrt{\nu})$, where ν is the viscosity of the pore fluid. His results indicated that there was no relationship between pore pressure and permeability, whilst fluid velocity depended on the porosity and permeability. However, *Liu*'s solution only considered the pressure condition whilst neglecting shear stress [39.14]. Thus, it may not be a complete analysis of viscous flow. With the same framework, *Liu* further developed a solution for the damping of the wave-induced pressure in a two-layered porous seabed [39.15]. Compared with the solution for an infinite seabed [39.14], the pore pressure was found to depend on both the permeability and thickness of the upper layer only to a small degree. However, he only considered the case of a two-layered seabed with uniform permeability in each layer. Later, based on the generalized Darcy's equation [39.16], the boundary layers between the seabed surface and the impervious stratum are included in the model [39.17]. It was concluded that the spatial damping rate depended strongly on the permeability and the water depth, when the physical wave number remained approximately the same over its rigid bottom.

From a different aspect, *Massel* took into account the nonlinear damping and the inertia terms in the momentum equation for a rigid porous seabed [39.18]. His results indicated that the effect of permeability on the pressure distribution in the seabed was negligible and that they were essentially the same as that from Laplace's equation.

In describing the wave-induced soil response, *Mallard* used a set of elastic displacement equations based

on the assumption of stress equilibrium within the soil, neglecting the effect of soil inertia on the response [39.19]. *Dawson* considered the soil inertia term in the model of Mallard and concluded that the effect of the soil inertia term could not generally be ignored without committing a serious error for the case of an incompressible soil [39.20].

Models with the Diffusion Equation

Another type of uncoupled model has been proposed by *Nakamura* et al. [39.2] and *Moshagen* and *Torum* [39.21], based on assumptions of compressible pore fluid and a nondeformable porous soil skeleton. This results in the heat conduction equation or diffusion equation for pore pressure,

$$\nabla^2 p - \frac{\gamma_w n \beta}{K_z} \frac{\partial p}{\partial t} = 0 \,, \tag{39.2}$$

where γ_w is the unit weight of water, n is the porosity, β is the compressibility of pore water that is defined in (39.4), and K_z is the permeability in the z-direction.

Among these, *Nakamura* et al. compared theoretical results of pore pressure with laboratory experiments in fine and coarse sandy beds [39.2]. The experimental results for the latter showed no phase lag and agreed reasonably well with the solution from Laplace's equation. The data for fine sand exhibited a large pressure attenuation and phase lag, which agreed reasonably well with the diffusion theory. However, an unexplainable pressure discontinuity exists near the seabed surface in their experimental data. As *Yamamoto* et al. pointed out, the waves generated in the experiments of *Nakamura* et al. were too steep [39.22]. Therefore, the state of stresses in sandy beds under wave crests and troughs might have reached the limit of equilibrium or the state of liquefaction, thus causing a large pressure drop. Furthermore, a critical error was found in their calculations. The compressibility of the water used in the calculation was 980 times that of the real water. *Yamamoto* et al. showed that the false agreement reported might be explained by the existence of a small amount of air in the sand used.

Moshagen et al. considered the wave-induced flow in a porous medium under the assumption of compressible pore fluid and an incompressible soil skeleton [39.21]. They found that the inclusion of pore fluid compressibility in the analysis of the wave-induced pore pressures in a porous soil significantly altered the vertical seepage forces acting on the soil. However, the assumption made by [39.21] regarding the relative compressibility of the pore fluid and the soil skeleton appeared somewhat unrealistic [39.23]. Thus, serious doubts arise about the validity of *Moshagen* and *Torum*'s [39.21] conclusion.

All the aforementioned theories assumed that the seabed is a rigid porous medium. Because these approaches do not permit the coupling of pore-fluid motion and soil skeleton motion, the governing equation for the pore pressure is Laplace's equation for incompressible fluid, or the diffusion equation for compressible pore fluid for hydraulically isotropic (isotropical permeability) seabeds. However, such solutions for pore pressure are limited to a particular case of soil and wave conditions, that is, Laplace's equation for very permeable beds such as coarse sand, or a diffusion equation for poorly permeable beds such as clay. Furthermore, these approaches provide no information for the effective stresses and soil displacements in the seabed.

39.1.2 Biot's Poroelastic Models

Coupled models generally treat both the soil and the pore fluid as compressible medium. They can more precisely describe the mechanical properties of porous medium and the soil–pore fluid interaction. Recently, the investigations of the consolidation or the dynamic response of seabed soil were conducted using this coupled models. Biot's theory is the coupled model most widely used for the soil–pore fluid interaction. Depending on the inclusion of acceleration of soil particles and pore fluid, and the relative displacement of pore fluid to soil particles, there are three types of expression of Biot's equation: quasi-static model, *u-p* approximation, and full dynamic mdoels.

Consolidation Models (Quasi-Static Model)

Biot first formulated a three-dimensional consolidation equation treating the soil as an isotropic poro-elastic porous medium with compressible pore water and deformable soil particles [39.3] with the following assumptions:

1. The soil is homogeneous and isotropic.
2. The stress–strain relation is reversible under final equilibrium (linear elastic).
3. Small deformation of solid and pore fluid are considered
4. The pore fluid in porous, and soil particles are compressible.
5. The water flows steadily within porous medium, Darcy's flow ($R_e \leq 1$ [39.24]), the quasi-static model was established [39.3].

Based on the conservation of mass, we have

$$\frac{K_x}{K_z}\frac{\partial^2 p}{\partial x^2} + \frac{K_y}{K_z}\frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} - \frac{\gamma_w n \beta}{K_z}\frac{\partial p}{\partial t} = \frac{\gamma_w}{K_z}\frac{\partial \epsilon_s}{\partial t} \,, \tag{39.3}$$

for a hydraulically anisotropic seabed. In (39.3), n is the soil porosity, γ_w is the unit weight of the pore-water, K_x, K_y, and K_z are the soil permeabilities in the x-, y-, and z-directions, respectively; the compressibility of the pore fluid (β) and the volume strain (ϵ_s) are defined as

$$\beta = \frac{1}{K_w} + \frac{1-S}{P_{w0}}, \quad \text{and} \quad \epsilon_s = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}, \tag{39.4}$$

where K_w is the true bulk modulus of elasticity of the pore water that is taken as $1.95\times10^9\,\mathrm{N/m^2}$ [39.22]; u, v, and w are the soil displacements in the x-, y-, and z-directions, respectively; S is the degree of saturation; P_{w0} is the absolute water pressure. If the soil skeleton is fully saturated, then, $\beta = 1/K_w$ since $S = 1$.

On the basis of force balance and Hooke's law, we have the governing equations for overall equilibrium in a pore-elastic medium as

$$G\nabla^2 u + \frac{G}{1-2\mu}\frac{\partial \epsilon_s}{\partial x} = \frac{\partial p}{\partial x}, \tag{39.5}$$

$$G\nabla^2 v + \frac{G}{1-2\mu}\frac{\partial \epsilon_s}{\partial x} = \frac{\partial p}{\partial y}, \tag{39.6}$$

$$G\nabla^2 w + \frac{G}{1-2\mu}\frac{\partial \epsilon_s}{\partial x} = \frac{\partial p}{\partial z}. \tag{39.7}$$

In Biot's poro-elastic theory, the flow of fluid in porous medium is generally treated as steady flow. Therefore, Darcy's law is used in formulating the equations. Furthermore, only the small deformation problem could be applicable. It is worth noting that *Biot*'s consolidation equations [39.3] ignored the inertia terms of the solid and fluid. This kind of simplification is acceptable for the consolidation process with small permeability or low-frequency loading problems as the acceleration of the solid or fluid is apparently small under this situation.

Most previous investigations with Biot's consolidation equations have been directly solved and obtain the wave-induced pore pressure, soil displacements, and effective stresses. This approach was first developed by *Yamamoto* et al. [39.22], *Yamamoto* [39.25] and *Madsen* [39.26], who considered compressible pore fluid in a compressible porous medium. A three-dimensional general consolidation equation [39.3] was adopted in these studies, in which only progressive waves were examined. Among these, *Madsen* [39.26] considered a hydraulically anisotropic and unsaturated porous bed, whilst *Yamamoto* et al. [39.22] studied an isotropic medium. Both considered only an infinite thickness. Moreover, *Yamamoto* [39.25] investigated soil response in a homogeneous soil of finite thickness under isotropic and partially saturated conditions. However, *Yamamoto*'s solution [39.25] was cast in a semianalytical manner that did not have a closed form.

Yamamoto et al. [39.22] concluded that when the stiffness of a porous medium is much smaller than that of the pore fluid (e.g., saturated soft soils), the soil response is independent of the permeability and has no phase lag. On the other hand, when the stiffness of a porous medium is much larger than that of the pore fluid (e.g., partially saturated dense sands), pore pressure attenuates rapidly. In the latter case, the phase lag increases linearly with the distance from the seabed surface.

Madsen [39.26] investigated a hydraulically anisotropic and partially saturated seabed. He found that this had an appreciable effect on the nature of the wave-induced effective stresses in coarse sand. For all soils, the effect of partial saturation on soil response may be significant.

Yamamoto [39.27] developed a semianalytical solution for a nonhomogeneous layered porous seabed, together with a comprehensive verification using data obtained from Mississippi Delta. *Yamamoto* [39.27] pointed out that a layer of concrete blocks had a significant effect on the wave-induced soil response. However, the assumption of treating the concrete blocks as soils seems unrealistic because the properties of concrete blocks are quite different from soil.

Okusa [39.28] used the compatibility equation under elastic conditions and reduced the governing equation of *Yamamoto* et al. [39.22] to a fourth-order differential linear equation. It is noted that *Okusa*'s experiment [39.28] was based on plane stress conditions, while *Yamamoto* et al. [39.22] was based on plane strain conditions. *Okusa* [39.28] found that the wave-induced pore pressure and effective stresses consisted of two parts. The first depended only on the wave characteristics and the second was related to both the sediment and the wave characteristics. He reported that the wave-induced soil response depended only on the wave conditions, not on the soil characteristics for a fully saturated and isotropic sandy seabed of infinite thickness. However, this conclusion is invalid for an isotropic seabed of finite thickness, even under a saturated condition [39.29, 30].

Rahman et al. summarized the previous work with the direct analytical framework in a semianalytical analysis [39.31]. In their model, a general layered seabed is considered, which is particularly important for the design of a cover layer for seabed protection.

The aforementioned investigations have been limited to an isotropic homogeneous seabed, which may be an idealized case. The major difficulty in analyzing the wave-induced soil response in a seabed with vari-

able permeability has been the governing equation that includes variable coefficients. By employing the VS (Varley-Seymour) function [39.32], *Seymour* et al. derived an analytical solution for such a condition [39.33]. In their study, only fine sand is considered. In their model, the first-order derivation of permeability with respect to vertical distance was excluded, which has been reported to play an important role in the evaluation of wave-induced soil response in coarser material [39.34]. Later, *Jeng* and *Seymour* further developed analytical solutions for general soils in seabed of both infinite and finite thicknesses [39.35, 36]. They concluded that the relative difference of the wave-induced pore pressure between variable and uniform permeability might go up to 23% of the amplitude of the wave pressure at the seabed surface.

Recently, another analytical solution for the wave-induced seabed response with variable permeability was proposed by *Kitano* and *Mase* [39.37]. However, their one-dimensional model is limited to the exponential distribution decay of the permeability, although it provides a simpler formulation than that of [39.35, 36].

The inclusion of cross-anisotropic soil behavior in the wave–seabed interaction can also be handled analytically. *Jeng* may have been the first to derive the analytical solution for the wave–seabed interaction in a cross-anisotropic seabed [39.38, 39]. His numerical results show that the conventional solution with the assumption of isotropic soil behavior may overestimate the pore pressure, but underestimate the effective stresses. Consideration of cross-anisotropic soil behavior is particularly important in determining the wave-induced soil displacements. An identical approximation is also proposed by *Yuhi* and *Ishida* [39.40].

A simplified analytical solution for the soil response in a cross-anisotropic seabed was proposed by *Yuhi* and *Ishida* [39.41]. In the model, two parameters related to boundary-layer thickness and the stiffness ratio were introduced. However, their model is only applicable in the region near the seabed surface (e.g., $|z|/L < 0.02$, L is the wavelength of ocean waves), outside this region, the relative difference between the simplified solution [39.41] and exact solution [39.38] is not negligible, as reported in [39.42].

Since the direct analytical solution for the wave-induced seabed response is involved with complicated mathematical presentations, especially for a seabed of finite thickness, it is even impossible to have a closed-form solution for a layered seabed. An alternative approximation, the boundary-layer approximation, was proposed by *Mei* and *Foda* [39.43]. The principle of the boundary-layer approximation is to divide the whole soil domain into two regions: inner and outer regions. In the inner region (near the seabed surface, defined by the boundary layer thickness), the full solution is required. On the other hand, a simplified solution is sufficient in the outer region. This solution agrees well with that of *Yamamoto* for fine sand. However, it may lose accuracy for all soils in unsaturated conditions and for coarse sand under saturated conditions [39.25]. This shortcoming may be attributed to the solution being only suitable for a seabed with low permeability, for which a scaling was carried out [39.44]. However, their solutions are more convenient for engineering application due to their much simpler form, compared to those of *Hsu* and *Jeng* [39.45].

Although the boundary-layer approximation proposed by *Mei* and *Foda* [39.43] is a simple yet fairly accurate analysis, it was restricted to low-frequency waves only. *Huang* and *Chwang* investigated Biot's equation for the acoustic problem and obtained three uncoupled Helmholtz equations to represent each of the three kinds of waves [39.46]. Their approach is applicable for the complete range of wave frequencies.

Later, *Kitano* and *Mase* derived another set of analytical solution to investigate the influence of cross-anisotropic soil behavior on the wave-induced soil response through the boundary-layer approximation [39.47]. Their model agreed well with the exact solution proposed by Jeng for fine sand.

Besides the direct analytical solution and boundary-layer approximation, [39.48] proposed a random-walk model for the wave-induced pore pressure in marine sediments. The principle of the model is based on the shear stress in the marine sediment to determine the build-up pore pressure. However, the determination of the shear stress relied on other analytical solutions such as that of *Hsu* and *Jeng* [39.45].

Madga developed a one-dimensional finite-difference model for the wave-induced pore pressure in a highly saturated sandy bed and applied to the cases of buried pipelines [39.49–51]. He concluded that the time phase in pressure generation is dominated by the degree of saturation, compressibility of the soil skeleton and soil permeability.

Zen and *Yamazak* simplified a two-dimensional boundary value problem to one dimension, based on the assumption of the seabed thickness being very small compared with the wavelength [39.52, 53]. A numerical model (finite difference method) was also established, which was only applicable to a single layer of porous seabed.

Gatmiri developed a simplified finite element model for the wave-induced effective stresses and pore pressure in an isotropic and saturated permeable seabed [39.29]. Two important conclusions were drawn from his paper. First, there exists a critical bed thickness

about 0.2 times the wavelength, in which the horizontal movement of the soil skeleton is maximum and where the unstable state occurs. Second, the soil response is affected by soil characteristics even in a hydraulically isotropic and saturated seabed of finite thickness. This result complemented the solution for a seabed of infinite thickness reported by Okusa. However, the general trend of pore pressure distribution versus the seabed thickness in [39.29] was found to be inconsistent [39.30].

Gatmiri further extended his numerical model to consider the soil response in a cross-anisotropic saturated seabed [39.54]. The numerical results showed that the effects of cross-anisotropic soil parameters are significant and the soil response was affected by the combined parameters in different ways. Compared with the cross-anisotropy, the effect of hydraulic anisotropic permeability on the variation of effective stresses may be insignificant.

A possible error in the results of Gatmiri's model may have stemmed from the boundary condition used. The lateral boundaries at $x/L = 0, 1$ in his paper, $v = 0$, $p = 0$ and u free, were used in his model. However, it has been proved that there is a phase lag in soil response in a fully saturated seabed of finite thickness [39.30]. This implies that the lateral boundary conditions, $v = 0$, $p = 0$, are invalid in a porous seabed of finite thickness. Thus, the numerical results of [39.29, 54] seem doubtful. In fact, this obstacle can be overcome by using the principle of repeatability [39.55], as suggested by the author [39.56].

Thomas developed a one-dimensional finite element method for a two-layered unsaturated seabed [39.57, 58]. His result agreed well with the analytical solutions of Yamamoto and Okusa. It also suggested that the stiffer sediment in the top layer dominated the response of the bottom layer in a two-layered seabed.

With a similar framework, a series of one-dimensional finite element models was developed for the wave-induced seabed response in a nonhomogeneous seabed [39.59–61]. The results of these numerical models agree well with previous two-dimensional experimental data and analytical solutions. In the models, the permeability and shear modulus are considered to vary with burial depth. *Jeng* and *Lin* [39.61] have also examined the influence of nonlinear wave components on the soil response. In addition, they examined the combined effect of cross-anisotropic soil behavior and nonhomogeneous soil characteristics on the wave-induced soil response [39.62].

The advantage of the above one-dimensional finite element models is the reduced computational time. However, such one-dimensional models cannot apply to the case with a structure. Thus, a two-dimensional finite element model was proposed [39.56] by employing the principle of repeatability [39.55].

u–p Model

Zienkiewicz et al. [39.4] proposed a simplified form of *Biot*'s poro-elastic theory [39.7]. In this model, the relative acceleration of fluid to solid is eliminated from the stress equilibrium equations, because the relative acceleration of fluid is apparently small for porous medium with a low permeability, and acted by low-frequency dynamic loading. Then, the governing equations (39.3) and (39.5)–(39.7) can be rewritten as

$$\frac{K_x}{K_z}\frac{\partial^2 p}{\partial x^2} + \frac{K_y}{K_z}\frac{\partial^2 p}{\partial y^2} + \frac{\partial^2 p}{\partial z^2} - \frac{\gamma_w n\beta}{K_z}\frac{\partial p}{\partial t} + \rho_f \frac{\partial^2 \epsilon_s}{\partial t^2} = \frac{\gamma_w}{K_z}\frac{\partial \epsilon_s}{\partial t}\,, \tag{39.8}$$

$$G\nabla^2 u + \frac{G}{1-2\mu}\frac{\partial \epsilon_s}{\partial x} = \frac{\partial p}{\partial x} + \rho\frac{\partial^2 u}{\partial t^2}\,, \tag{39.9}$$

$$G\nabla^2 v + \frac{G}{1-2\mu}\frac{\partial \epsilon_s}{\partial x} = \frac{\partial p}{\partial y} + \rho\frac{\partial^2 v}{\partial t^2}\,, \tag{39.10}$$

$$G\nabla^2 w + \frac{G}{1-2\mu}\frac{\partial \epsilon_s}{\partial x} = \frac{\partial p}{\partial z} + \rho\frac{\partial^2 w}{\partial t^2}\,, \tag{39.11}$$

where ρ_f is the density of the pore water; and $\rho = (1-n)\rho_s + \rho_f$ (where ρ_s is the density of solid).

Based on *Biot*'s poro-elastic theory [39.7, 63], *Zienkiewicz* et al. proposed a one-dimensional so-called *u-p* approximation for waves propagating over a porous medium [39.4]. Their approximation provided a simplified approximation for such a problem. Based on the numerical examples, Zienkiewicz concluded that neither the *u-p* approximation nor the dynamic approximation is required for the case of ocean waves over a seabed. However, in their examples, the compressive wave velocity under ocean wave loading was fixed at 1000 m/s, which is applicable during an earthquake, but may not be a reasonable value for most ocean environments. Thus, the conclusion drawn from the examples was in doubt.

Sakai et al. extended Mei and Foda's boundary-layer approximation to examine the effect of inertia and gravity force of the ocean waves on the seabed response, and verified it with results of their numerical model (finite element method) [39.64]. They concluded that the inertia term (acceleration) could be neglected under normal wave conditions except for breaking, whilst the gravity term can practically be ignored. Later, *Sakai* et al. modified the boundary-layer approximation to take into account the effect of wave-induced bottom shear stress which cannot be neglected in the surf zone [39.65]. In his paper, it was simply assumed

that the amplitude of the wave-induced bottom shear stresses was proportional to the wave pressure, without any phase lag. However, it has been reported that the wave-induced bottom shear stress has a phase lag of 45° to the wave-induced pressure at the seabed surface [39.66].

The one-dimensional *u-p* approximation [39.4] was further extended to two-dimensional waves over a porous seabed [39.5, 6]. The seabed was considered to be either infinite or finite thickness. It was found that the relative differences between the *u-p* approximation and the quasi-static solution may reach 17% of the amplitude of wave pressure.

In addition to the above analytical solutions, the finite element model (SWANDYNE II) was developed by *Chan* [39.67]. This model was initially developed for the earthquake-induced soil liquefaction and adopted for the wave-induced residual soil response around marine structure such as pipelines [39.68] and breakwaters [39.11]. In this model, the *u-p* approximation was used together with poro-elastoplastic constitutive model.

Full Dynamic Model

Based on the stress balance, momentum conservation and mass conservation, [39.7, 63] extended the above consolidation theory to dynamic theory by introducing the inertia terms of solid and fluid, to investigate the propagation of elastic waves in saturated porous medium. Then, *Biot* [39.69] proposed a set of general fully coupled governing equations for saturated porous medium with compressible fluid and incompressible soil particles for consolidation and dynamic problems, in which the effect of inertia terms of solid and fluid, and the interaction (drag force) between soil and pore fluid are taken into consideration. The stress equilibrium equation, momentum equilibrium equation and continuity equation, respectively, are (in the form of tensor)

$$\sigma_{ij,j} + \rho g_i = \rho \ddot{u}_{si} + \rho_f(\ddot{w}_{fi} + \dot{w}_{fj}\dot{w}_{fi,j}) \,, \tag{39.12}$$

$$-p_{,i} + \rho_f g_i = \rho_f \ddot{u}_{si} + \frac{\rho_f}{n}(\ddot{w}_{fi} + \dot{w}_{fj}\dot{w}_{fi,j}) + \frac{\gamma_w}{K_{ij}}\dot{w}_{fj} \,, \tag{39.13}$$

$$\dot{\epsilon}_{ii} + \dot{w}_{fi,i} + \frac{1}{Q}\dot{p} = 0 \,, \tag{39.14}$$

where u_s represents the soil displacement tensor, w_f denotes the related displacements between solid and pore fluid, and Q is defined as

$$\frac{1}{Q} = n\beta + \frac{1-n}{K_s} \,, \tag{39.15}$$

in which K_s is the bulk modulus of solid.

The major difference between dynamic analysis and *u-p* approximation has been the inclusion of acceleration due to pore fluid. With a similar framework to [39.4], *Jeng* and his co-workers investigated the effects of dynamic soil behavior on the wave-induced soil response through a two-dimensional analysis [39.8, 70]. Although their dynamic solution can provide a better prediction of the wave-induced soil response, their solutions were lengthy and difficult to be applied in engineering practice.

Based on the boundary-layer approximation, *Huang* and his co-workers further developed a series of analytical solutions for waves propagating over a soft poro-elastic bed [39.44, 71, 72]. Both linear and nonlinear wave loading were considered. Their approximation provided a simpler formulation, compared with the full closed-form solution.

Alternatively, on the basis of governing equations derived by *Mei* and *Foda* [39.43], *Yuhi* and *Ishida* [39.73] directly solved the boundary value problem, rather than using a boundary-layer approximation. The seabed was considered to be of infinite thickness. The characteristics of three waves within the soil column, including two compressive waves and one shear wave, was discussed in detail. This work has been later extended to the case of finite thickness [39.74].

Applicable Ranges of Biot's Models

To date, the full dynamic model, *u-p* approximation and Biot's consolidation equations have been widely used for investigating the quasi-static and dynamic problems. Basically, the full dynamic is applicable for all quasi-static and dynamic problems due to its relatively complete form to describe the mechanical behavior of porous medium, in which the acceleration of soil particles and pore fluid, and the relative displacement of pore fluid to soil particles are all included. However, some preconditions have been assumed when deriving the *u-p* approximation, and Biot's consolidation equations. Therefore, there are some limitations for applying the *u-p* approximation and Biot's consolidation equations to engineering problems.

Zienkiewicz et al. first made their attempt to investigate the applicable range of the *u-p* approximation and Biot's consolidation equations [39.4]. Based on a simple linear one-dimensional model, in which only one soil layer is contained, and subjected to periodic loading, the full dynamic form, *u-p* approximation, and Biot's consolidation equations are all analytically solved with the same boundary conditions. After comparing the solutions obtained from the three kinds of governing equations, a graph was provided to illustrate the applicable range of frequency and permeability for the *u-p* approximation, and Biot's consolidation equa-

tions. From the figure presented in [39.4, Fig. 3], it was concluded that the full dynamic form can be used in all zones, including I, II, and III. The *u-p* approximation can be used in zones I and II with the largest applicable frequency of approximately 1000 Hz. Biot's consolidation equations can only be used within zone I. It is only applicable for low-frequency and low-permeability problems.

It is noted that the above conclusion was obtained from the simplest one-dimensional soil layer; and the values of some property parameters of soil are assumed, such as $V_c = 1000\,\mathrm{m/s}$. As pointed out by *Jeng* and *Cha* [39.8], the velocity of wave in soil is significantly dependent on the saturation of soil and the water depth. The value of wave velocity used in [39.4] is only a special case. Therefore, the information coming from the figure is just a rough approximation, its applicability is limited.

Later, *Jeng* and *Cha* further analytically investigated the applicable range of the *u-p* approximation and Biot's consolidation equations for the two-dimensional (2-D) model of soil–wave interaction based on the full dynamic form [39.8]. Through solving the partial differential equations in the full dynamic form, they obtained the analytical solution of the pressure of the pore fluid, and the displacement of soil in a finite or an infinite seabed under wave loading. Then the analytical solutions based on the *u-p* form and Biot's consolidation equations are accordingly determined by ignoring the effects of the inertial term in the solution derived from the full dynamic form. In the above three analytical solutions, a linear ocean wave is used as the dynamic loading acting on the seabed. Due to the fact that the frequency of ocean wave is the magnitude of $O(10^{-1})$ Hz. It can definitely be clarified into the range of low frequency. Therefore, it is not surprising that the results from the *u-p* approximation and full dynamic form are always basically the same. A comparison has also been performed between the results obtained from the *full dynamic* form and from Biot's consolidation equations. Figure 39.1 shows the boundary line of applicable ranges for different permeabilities between the conditions under which *full dynamic* form or *u-p* approximation must be adopted and the conditions under which Biot's consolidation equations could be used. In Fig. 39.1, the abscissa Π_1 and the longitudinal coordinates Π_2 are defined as

$$\Pi_1 = \frac{K_z V_c^2 k^2}{\gamma_w \omega} \quad \text{and} \quad \Pi_2 = \frac{\rho_f \omega^2}{\left(\frac{G}{1-2\nu} + \frac{K_f}{n}\right) k^2}\,, \tag{39.16}$$

where K_z is the permeability coefficient, and k is the wave number. V_c^2 is the velocity of the compressibility

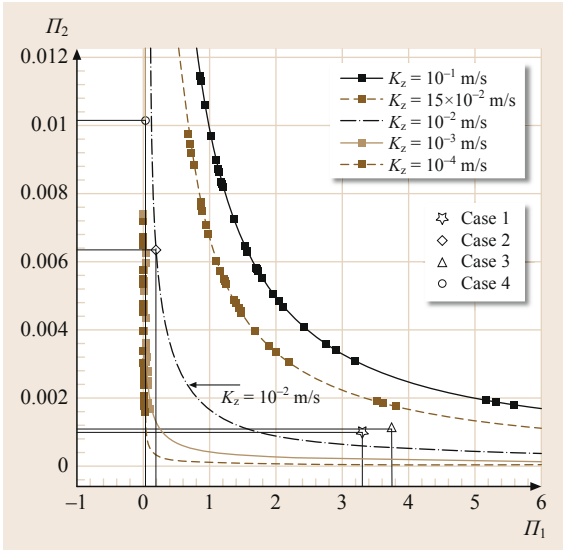

Fig. 39.1 The boundary line of applicable range for different permeabilities for full dynamic form and Biot's consolidation equations (after [39.8, 75])

wave in porous soil, and could be expressed as

$$V_c^2 = \frac{\frac{G}{1-2\nu} + \frac{K_f}{n}}{\rho_f}\,. \tag{39.17}$$

The parameter Π_1 is related to the permeability of soil, and Π_2 is related to the frequency of the ocean wave acting on the seabed. *Jeng* and *Cha* proposed an equation to describe the boundary line in the $\Pi_1 - \Pi_2$ nondimensional space [39.8]

$$\Pi_2 = C\Pi^m = 0.0298\left(\frac{K_z}{\Pi_1}\right)^{0.5356}\,. \tag{39.18}$$

For certain soil conditions, the full dynamic form or *u-p* approximation should be adopted if the point (Π_1, Π_2) is located above the boundary line, else a large computational error would result. The result obtained by [39.8] is more liable than that of [39.4] due to the fact that the soil model used by [39.4] is one dimensional, and the velocity of compressibility wave in the soil is assumed as 1000 m/s which is invalid for most soil layers.

Recently, *Ulker* et al. further investigated the applicable range of the full dynamic form, *u-p* approximation (partial dynamic), and Biot's consolidation equation (quasi static) [39.9, 76]. Firstly, a generalized analytical solution is developed for the wave-induced seabed response by adopting the similar method used by *Jeng* and *Cha* [39.8]. In the analytical solution, the full dynamic form is taken as the governing equation with the addi-

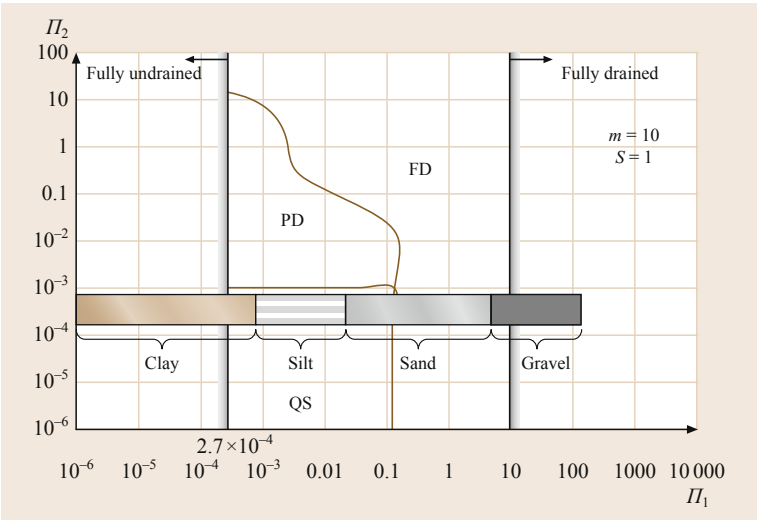

Fig. 39.2 Regions of applicability of the three types of governing equations for the wave-induced seabed response (after [39.9])

tion of the gravitational term, which was not considered by [39.8]. The solutions for the *u-p* approximation and Biot's consolidation equations are obtained by reducing the analytical solution from the full dynamic form. The linear wave and poro-elastic model are adopted as the external loading and the constitutive model of seabed soil. Through comparing the results of pore pressure, shear stress, and effective vertical stress obtained from the three types of governing equations, [39.9] proposed a graph (Fig. 39.2) to illustrate the applicable range of the three types of governing equations. In Figure 39.2, it is found that Biot's consolidation equations are accurate for clay soils; the *u-p* approximation is necessary for silty soils. For a sandy seabed, the formulation depends on the permeability and the loading frequency; the full dynamic model has to be used for gravels whose permeability is generally relatively a large magnitude.

In summary, the *u-p* approximation and Biot's consolidation equations are sufficient for the cases with low-frequency loading and small permeability soils; the full dynamic form has to be used for the cases with high-frequency loading and/or high-permeability soil. In this dissertation, the permeability of seabed is generally from 1.0×10^{-5} m/s to 1.0×10^{-4} m/s (maximum 1.0×10^{-2} m/s for parametric study); and the magnitude of dominant frequency is $O(10^{-1})$ Hz for ocean wave and $O(10^{1})$ Hz for earthquake loading. The *u-p* approximation is sufficient to describe the dynamic behavior of seabed foundation under marine structures.

39.1.3 Poro-Elastoplastic Models

All aforementioned poro-elastic models have been limited to small deformations, which is an idealized condition. However, large deformations will be a more important issue for engineering problems, especially under the action of a storm. In that case, poro-elastoplastic models are required to provide a better estimation of the soil response. Since a poro-elastoplastic model is more complicated than a poro-elastic model, especially in the problem of the wave–seabed interaction, to date, only a few investigations have been published.

Sekiguchi et al. may have been the first to derive an analytical solution for waves propagating over a poro-elastoplastic seabed with Laplace's transformation [39.77]. Their model clearly demonstrated the difference between poro-elastic and poro-elastoplastic models. Also, overall agreement between their model and centrifugal tests was reported. However, their model was based on the assumption of the seabed thickness being much less than the wavelength, which is questionable [39.78].

With the nonassociative bounding surface plastic constitutive model, *Yang* and *Poorooshasb* developed a numerical code to investigate the standing wave-induced soil response in a seabed [39.79]. Their model demonstrated the significant influence of permeability on the wave-induced seabed response. However, no comparison between elastic and their plastic models was made in their paper. Thus, the importance of plastic model was not observed.

Li et al. established a poro-elastoplastic model for wave propagation in saturated media, using the Drucker–Prager criterion to describe nonlinear constitutive behavior of pressure-dependent elastoplasticity for the solid skeleton [39.80]. Based on their model, they further investigated the stationary discontinuities and flutter instability of wave propagation in a saturated seabed, and concluded that the flutter instability may occur prior to stationary discontinuity only if the

derivative effective stress normal to the surface of discontinuity is compressive.

Recently, *Jeng* and *Ou* proposed a three-dimensional (3-D) poro-elastoplastic model for the wave-induced soil response around breakwater heads [39.11]. In the model, the poro-elastoplastic (PZ3) [39.67] was adopted to predict the liquefaction potential of the seabed in the vicinity of breakwater heads. Their study demonstrated the significant effects of large deformation on the prediction of liquefaction zone.

39.2 Mechanisms of Seabed Dynamics

In general, two mechanisms for wave-induced pore pressure have been observed in field measurements and laboratory experiments, as shown in Fig. 39.3. The first mechanism is resulted from the transient or oscillatory excess pore pressure and accompanied by attenuation of the amplitude and phase lag in the pore pressure changes [39.22, 26]. is particularly important for small-amplitude waves and it could only liquefy momentarily in the seabed under wave troughs [39.75]. The second mechanism is termed as the residual pore pressure, which is the build-up of excess pore pressure caused by the contraction of the soil under the action of cyclic loading [39.81, 82]. As reported in [39.75], the residual mechanism is more important for large wave loading.

As mentioned previously, the wave-induced pore pressure within marine sediments consists of two components: oscillatory ($\tilde{p}$) and residual ($\bar{p}$) mechanisms, as shown in Fig. 39.3, which can be expressed as

$$p = \tilde{p} + \bar{p}\,, \tag{39.19}$$

where $\tilde{p}$ represents the oscillatory pore pressure that leads to momentary liquefaction, while $\bar{p}$ represents the period-averaged pore pressure that leads to residual liquefaction, and is defined by

$$\bar{p} = \frac{1}{T}\int_{t}^{t+T} p\,\mathrm{d}t\,, \tag{39.20}$$

where T is the wave period and t is the time. Figure 39.4 illustrates the ranges that each mechanism dominate the process of the wave-induced soil response. In the figure, the scale factor (ϵ) is defined as

$$\epsilon = \frac{\bar{p}_{t\to\infty}}{|\tilde{p}|}\,, \tag{39.21}$$

where $\bar{p}_{t\to\infty}$ denotes the equilibrium residual pore pressure, that is, the pore pressure when time approaches to infinite, as shown in Fig. 39.3; and $|\tilde{p}|$ represents the amplitude of oscillatory pore pressure.

In Fig. 39.4, various coefficients of consolidation (c_v) are used to represent different types of soil. With given wave steepness (H/L) and relative water depth (d/L), we can identify the position of the case we considered. When the case is located above the curve of the given c_v, the residual mechanism will dominate the whole process. On the other hand, if it is located below the curve, the oscillatory mechanism will be more important than residual mechanism. As shown in the figure, residual mechanism will be more important in either shallow water depth or large waves.

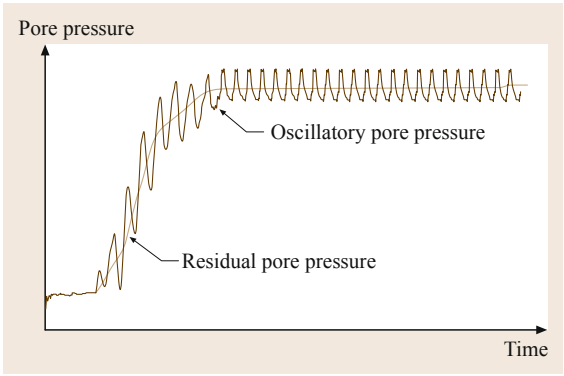

Fig. 39.3 Conceptual sketch of two different mechanisms of pore pressure (not in scale)

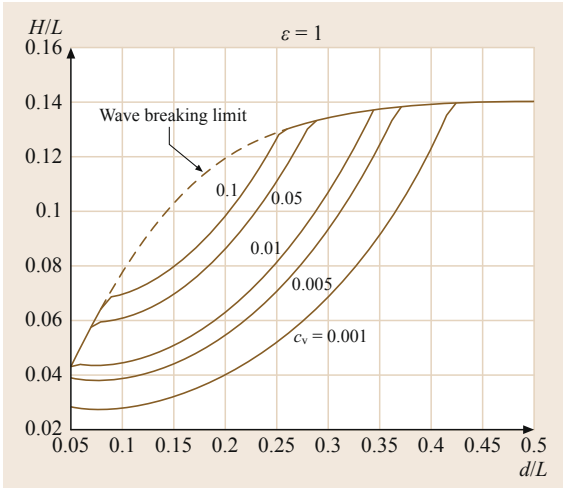

Fig. 39.4 Relationship of two mechanisms with various conefficient of consolidation (after [39.75])

In this section, we will outline the analytical solutions for both mechanisms and present several examples to show the effects of several important parameters. Then, we will present a new model that integrates both mechanisms to have a better understanding of the wave-induced soil response.

39.2.1 Oscillatory Soil Response

Numerous studies for wave-induced momentary seabed response, caused by oscillatory pore pressure, were completed in the past few decades. Among these, *Madsen* [39.26] and *Yamamoto* et al. [39.22] considered an infinite seabed with a similar framework. *Mei* and *Foda* [39.43] proposed a boundary-layer approximation to derive a rather simplified formulation for the wave-induced transient pore pressure, valid for coarse sand [39.45]. *Okusa* [39.28] further demonstrated the significant influence of the degree of saturation on the pore pressure and proposed the criteria of liquefaction. *Jeng* and his co-workers derived a series of analytical solutions for the oscillatory pore pressure within marine sediments with different considerations such as cross-anisotropic and nonhomogeneous soil layers, which were detailed in [39.75]. Here, we only outline the solution in an isotropic homogeneous seabed in two-dimensional.

Based on Biot's consolidation model, outlined in (39.3) and (39.5)–(39.7), we can have the analytical solution for the wave-induced socillatory pore pressure and soil displacements under 2-D progressive waves in an infinite seabed as prese [39.75, 83] as

$$\tilde{p} = \frac{p_o}{1-2\mu}\left[(1-2\mu-\lambda_*)C_1^\infty\, e^{kz} + \frac{\delta^2-k^2}{k}(1-\mu)C_2^\infty\, e^{\delta z}\right] e^{i(kx-\omega t)}, \quad (39.22)$$

$$\tilde{u} = \frac{ip_o}{2G}\left[(C_0^\infty + C_1^\infty z)\, e^{kz} + C_2^\infty\, e^{\delta z}\right] e^{i(kx-\omega t)}, \quad (39.23)$$

$$\tilde{w} = \frac{p_o}{2G}\left[\left(C_0^\infty - \frac{1+2\lambda_*}{k}C_1^\infty + C_1^\infty z\right) e^{kz} + \frac{\delta}{k}C_2^\infty e^{\delta z}\right] e^{i(kx-\omega t)}, \quad (39.24)$$

where the superscripts ∞ denote the coefficients in the solution for a porous seabed of infinite thickness.

Two parameters δ and λ_* are expressed as

$$\delta^2 = k^2\frac{K_x}{K_z} - \frac{i\omega\gamma_w}{K_z}\left(n'\beta + \frac{1-2\mu}{2G(1-\mu)}\right), \quad (39.25)$$

$$\lambda_* = \frac{(1-2\mu)\left[k^2(1-K_x/K_z) + \frac{i\omega\gamma_w n'\beta}{K_z}\right]}{k^2(1-K_x/K_z) + \frac{i\omega\gamma_w}{K_z}\left(n'\beta + \frac{1-2\mu}{G}\right)}. \quad (39.26)$$

In the above equations, the wave frequency ω ($= 2\pi/T$, where T is the wave period), wave number k ($= 2\pi/L$, where L is the wave length), and water depth (d) satisfy the dispersion equation

$$\omega^2 = gk\tanh kd\,, \quad (39.27)$$

and the amplitude of the dynamic wave pressure (p_o) is defined as

$$p_o = \frac{\gamma_w H}{2\cosh kd}\,, \quad (39.28)$$

in which H is the wave height.

The effective normal stresses (σ_x' and σ_z') and shear stress (τ_{xz}) can be expressed as

$$\tilde{\sigma}_x' = -p_o\left\{\left[(C_0^\infty + C_1^\infty z) + \frac{2\mu\lambda_*}{1-2\mu}C_1^\infty\right] e^{kz} + \left(k^2 - \frac{\mu(\delta^2-k^2)}{k(1-2\mu)}\right)C_2^\infty\, e^{\delta z}\right\} e^{i(kx-\omega t)}, \quad (39.29)$$

$$\tilde{\sigma}_z' = p_o\left\{\left(kC_0^\infty + C_1^\infty kz - \frac{2\lambda_*(1-\mu)}{1-2\mu}C_1^\infty\right) e^{kz} + \frac{1}{k(1-2\mu)}\left[\delta^2(1-\mu) - k^2\mu\right]C_2^\infty\, e^{\delta z}\right\} \times \cos nky\, e^{i(kx-\omega t)}, \quad (39.30)$$

$$\tilde{\tau}_{xz} = ip_o\left\{\left[kC_0^\infty + (kz-\lambda_*)C_1^\infty\right] e^{kz} + \delta C_2^\infty e^{\delta z}\right\} \times e^{i(kx-\omega t)}\,, \quad (39.31)$$

In Eqs. (39.22)–(39.31), the C_i^∞ coefficients are given by

$$C_0^\infty = \frac{-\lambda_*[\mu(\delta-k)^2 - \delta(\delta-2k)]}{k(\delta-k)(\delta-\delta\mu+k\mu+k\lambda_*)}\,, \quad (39.32)$$

$$C_1^\infty = \frac{\delta-\delta\mu+k\mu}{\delta-\delta\mu+k\mu+k\lambda_*}\,, \quad (39.33)$$

$$C_2^\infty = \frac{k\lambda_*}{(\delta-k)(\delta-\delta\mu+k\mu+k\lambda_*)}\,. \quad (39.34)$$

It is noted that the above solution is only for an infinite seabed. For more complicated cases, such as a seabed of finite thickness, a layered seabed, cross-anisotropic seabed, or nonhomogeneous seabed, readers can refer to [39.75].

39.2.2 Residual Soil Response

Based on the solution presented previously, (39.22)–(39.31), we have the amplitude of the oscillatory pore pressure ($|\tilde{p}|$) and shear stress ($|\tilde{\tau}_{xz}|$) for a saturated infinite seabed as

$$|\tilde{p}| = p_0\,\mathrm{e}^{-kz} \quad \text{and} \quad \tau_0 = |\tilde{\tau}_{xz}| = p_0 kz\,\mathrm{e}^{-kz}\,. \tag{39.35}$$

The residual pore pressure ($\bar{p}$) in a homogenous, isotropic soil can be derived from the one-dimensional Biot's consolidation equation [39.82]

$$\frac{\partial \bar{p}}{\partial t} = c_\mathrm{v}\frac{\partial^2 \bar{p}}{\partial z^2} + f\,, \tag{39.36}$$

where f is the mean accumulation pore pressure source term associated with the surface water waves [39.84]. A detailed derivation of (39.36) can be found in [39.82]. In (39.36), c_v is the coefficient of consolidation, given by

$$c_\mathrm{v} = \frac{2GK_z(1-\mu)}{\gamma_\mathrm{w}(1-2\mu)}\,. \tag{39.37}$$

Regarding the source term, the laboratory results of *de Alba* [39.85] suggested a nonlinear relationship between the development of pore water pressure and the number of load cycles as

$$\frac{u_\mathrm{g}}{\sigma_0'} = \frac{1}{2} + \frac{1}{\pi}\sin^{-1}\left[2\left(\frac{N}{N_\ell}\right)^{1/\theta} - 1\right], \tag{39.38}$$

where u_g is the pore pressure generation due to cyclic loading, σ_0' is the effect over burden, N is the number of cyclic loading, N_ℓ is the number of cycles to liquefaction, and θ is the shape factor suggested to be 0.7 [39.81].

To simplify the problem, a linear mechanism of pore pressure generation was proposed [39.81, 82]

$$\frac{u_\mathrm{g}}{\sigma_0'} = \frac{N}{N_\ell}\,, \tag{39.39}$$

where N is the number of wave cycle and N_ℓ is the number of cycles to liquefaction, which is a function of the cyclic shear stress ratio [39.81, 82],

$$N_\ell = \left(\frac{\tau_0}{\alpha_\mathrm{r}\sigma_0'}\right)^{-1/\beta_\mathrm{r}}\,, \tag{39.40}$$

where τ_0 is the maximum amplitude of wave-induced shear stress, and α_r and β_r are the functions of the soil type and relative density, respectively. The residual parameter (α_r and β_r) are related to the relative density of soil (D_r) [39.86]

$$\alpha_\mathrm{r} = 0.34D_\mathrm{r} + 0.084 \quad \text{and} \quad \beta_\mathrm{r} = 0.37D_\mathrm{r} - 0.46\,. \tag{39.41}$$

From (39.39), the source term of pore pressure generation can be expressed as

$$f = \frac{\partial u_\mathrm{g}}{\partial t} = \frac{\partial}{\partial t}\left(\sigma_0'\frac{N}{N_\ell}\right) = \frac{\partial}{\partial t}\left(\sigma_0'\frac{t/T}{N_\ell}\right) = \frac{\sigma_0'}{TN_\ell} = \frac{\sigma_0'}{T}\left(\frac{\tau_0}{\alpha_\mathrm{r}\sigma_0'}\right)^{-1/\beta_\mathrm{r}}\,, \tag{39.42}$$

where T is the wave period.

It is noted that the linear mechanism of pore pressure generation was first applied to the wave-induced pore pressure build-up in marine sediment by [39.81]. Since then, this relation has been commonly used in various approaches [39.82, 84, 87].

The shear stress in the source term depends on both wave and soil characteristics. Since the expression for the shear stress in a seabed of finite thickness is complicated, two simplified cases, shallow soil depth ($d/L \le 0.1$) and deep soil layer ($d/L \ge 0.3$) in addition to the finite soil model. We only present the analytical solutions for an infinite seabed, as detailed derivations are available in [39.75, Chap. 9].

For soil depth in the range $h/L \ge 0.3$, we consider the deep (infinite) depth approximation, the source term for deep soil can be expressed as

$$f = Az\,\mathrm{e}^{-\lambda z}\,, \tag{39.43}$$

$$\lambda = \frac{k}{\beta_\mathrm{r}} \quad \text{and}$$

$$A = \frac{\gamma'(1+2K_\mathrm{o})}{3T}\left(\frac{3p_0 k}{\alpha_\mathrm{r}(1+2K_\mathrm{o})\gamma'}\right)^{1/\beta_\mathrm{r}}\,, \tag{39.44}$$

where $\gamma' = \gamma_\mathrm{s} - \gamma_\mathrm{w}$ is the submerged weight of soil.

Then, the residual pore pressure is calculated using a Laplace transformation as

$$\bar{p} = \frac{2A}{c_\mathrm{v}\lambda^3}\left[1 - \left(\frac{\lambda z}{2} + 1\right)\mathrm{e}^{-\lambda z} - \frac{1}{\pi}\int_0^\infty \frac{\mathrm{e}^{-rc_\mathrm{v}\lambda^2 t}}{r(1+r)^2}\sin\left(\sqrt{r}\lambda z\right)\mathrm{d}r\right]. \tag{39.45}$$

The solution (39.45) is similar to the one proposed by *McDougal* et al. with corrections pointed out previously [39.84]. It is noted that the shear stress used in

the [39.84] solution was based on the assumption of an incompressible soil.

Sumer and *Fredsøe* also obtained an analytical solution, but in a different form [39.82]

$$\bar{p} = \frac{2}{\pi}\int_0^t\int_0^\infty\int_0^\infty \mathrm{e}^{-c_\mathrm{v}\xi^2(t-t')} \times \sin(\xi z) f(z') \sin(\xi z') \mathrm{d}z' \mathrm{d}\xi \mathrm{d}t' \,, \tag{39.46}$$

which is in their notation [39.82]. It is noted that both (39.45) and (39.46) are identical, as shown in [39.88].

For engineering practice, the most important task is to examine where liquefaction will occur and how deep it is. The criterion of residual liquefaction is

$$\frac{\bar{p}_{t\to\infty}}{\sigma_0'} = 1 \,, \tag{39.47}$$

which leads to

$$\bar{p}_{t\to\infty} = \frac{2A}{c_\mathrm{v}\lambda^3}\left[1-\left(\frac{\lambda z_\mathrm{L}}{2}+1\right)\exp(-\lambda z_\mathrm{L})\right] = \sigma_0' = \frac{(1+2K_0)}{3}\gamma' z_\mathrm{L} \,, \tag{39.48}$$

where z_L is the liquefaction depth.

Let

$$B = \frac{(1+2K_0)\gamma' c_\mathrm{v}\lambda^2}{6A} \,. \tag{39.49}$$

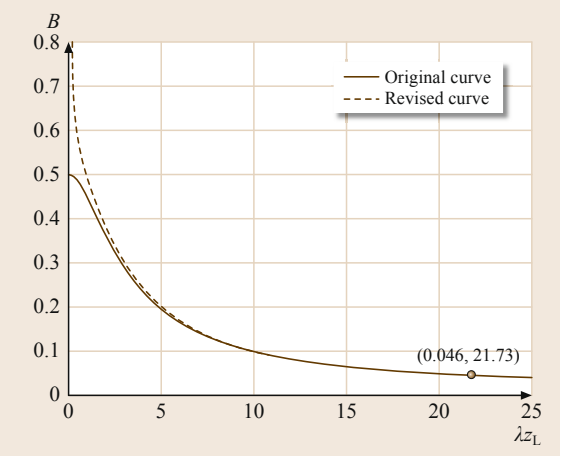

Fig. 39.5 Distribution of the maximum liquefied depth (z_L) and parameter B

Then the relationship of the maximum liquefied depth (z_L) and the parameter B can be plotted (see the original line in Fig. 39.5, called as the *J–S* (Jeng–Seymour) curve [39.88]). For engineering applications, given wave and soil conditions, we can determine the parameter B from (39.49). The maximum liquefied depth can then be easily determined from Fig. 39.5. It is noted that the relation presented in Fig. 39.5 is universal, applicable to all engineering conditions.

Herein, we further consider a special case assuming λz_L is small. With this assumption, we further expend $\exp(-\lambda z_\mathrm{L})$ with Taylor's expansion, and then using the first three terms, we have the solution of (39.48) as $z = 0$ or

$$z_\mathrm{L} = \frac{2}{\lambda}\sqrt{\frac{1}{2}-B} \,. \tag{39.50}$$

Note that (39.50) is only valid under the condition of $B \le 1/2$. It is noted that $B > 1/2$ will provide an unrealistic solution. Under such a condition, $z = 0$ will be the solution (i. e., no liquefaction occurs).

Recently, *Geremew* proposed a simplified model to directly adding oscillatory and residual components to examine the wave-induced liquefaction [39.89]. That is,

$$\frac{2A}{c_\mathrm{v}\lambda^3}\left[1-\left(\frac{\lambda z_\mathrm{L}}{2}+1\right)\mathrm{e}^{-\lambda z_\mathrm{L}}\right] + p_0\,\mathrm{e}^{-kz_\mathrm{L}} = \frac{(1+2K_0)}{3}\gamma' z_\mathrm{L} \,. \tag{39.51}$$

Unfortunately, numerous mistakes were found in their work, for example, the determination of the wavelength, and calculation of the liquefaction depth [39.90]. Based on (39.51), the revised *J–S* curve is illustrated in Fig. 39.5 together with the case presented in [39.89] ($B = 0.046$, $\lambda z_\mathrm{L} = 21.73$). Furthermore, based on the input data used in [39.89], the oscillatory component is only 1/70 of the residual component [39.90].

39.2.3 Integrated Model

In all aforementioned studies for wave-induced residual pore pressures in marine sediments, the source term was considered as the time-independent function because the maximum amplitude of the oscillatory shear stress was used. In fact, this source term was determined by the oscillatory shear stress which should be a time-dependent function. Furthermore, these approaches were one-dimensional (1-D) model, which may be insufficient to represent the real process. In this section, we re-define the source term as a time-dependent function with the instant oscillatory shear stress and re-derive the boundary value problem in 2-D.

New Model

In this study, the previous 1-D model can be re-derived to 2-D as

$$c_v \nabla^2 \bar{p} = \frac{\gamma_w c_v (1 + n\beta)}{K} \frac{\partial \bar{p}}{\partial t} + f(x, z, t) \,. \quad (39.52)$$

$$G\nabla^2 \bar{u} + \frac{G}{1-2\mu} \frac{\partial}{\partial x} \left(\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{w}}{\partial z} \right) = \frac{\partial \bar{p}}{\partial x} \,, \quad (39.53)$$

$$G\nabla^2 \bar{w} + \frac{G}{1-2\mu} \frac{\partial}{\partial z} \left(\frac{\partial \bar{u}}{\partial x} + \frac{\partial \bar{w}}{\partial z} \right) = \frac{\partial \bar{p}}{\partial z} \,, \quad (39.54)$$

where the source term ($f(x, z, t)$) for the new model is defined as

$$f(t) = \frac{\partial u_g}{\partial t} = \frac{\sigma_0'}{T} \left(\frac{|\tilde{\tau}_{ins}(x, z, t)|}{\alpha_r \sigma_0'} \right)^{-1/\beta_r} \,. \quad (39.55)$$

It is noted that the governing equation used in the new model (39.52)–(39.54) integrated the mass conservation with momentum conservation and solved the wave-induced residual pore pressure and soil displacement together, which are different from the previous 1-D model [39.75, 82] in which only the pore pressure is solved and no other soil response information is mentioned.

In addition, the source term used in the previous models [39.75, 82] was generated by the maximum amplitude of transient shear stresses over a wave period, which is a simplified calculation method. While the instant absolute oscillatory shear stress is considered as the source of pore pressure generation in this new model, this new model will reflect the effects of instant oscillatory shear stresses on the pore pressure build-up, which will become a time-dependent function, as shown in (39.55).

To solve the two-dimensional governing equations (39.52)–(39.54) with the new source term, appropriate boundary conditions are required:

a) At the seabed surface ($z = 0$), the residual pore pressure is assumed as zero ($\bar{p} = 0$).
b) At the bottom of the porous seabed with finite thickness ($z = -h$), $\bar{u} = \bar{w} = \frac{\partial \bar{p}}{\partial z} = 0$.
c) Periodical lateral boundary condition is considered in the x direction.

Validations

The major differences between the present and previous models are the definition and numerical simulation method for the source term in (39.42) in which it is only a function of z and being time-independent in the maximum model, while it is a time-dependent function in the present instant model, (39.55).

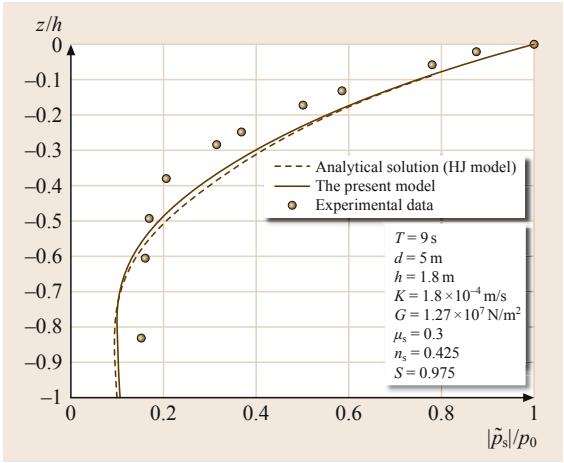

Fig. 39.6 Distribution of vertical distribution of maximum wave-induced oscillatory pore pressure versus relative soil depth for comparison between the present 2-D model (*line*) with 1-D experimental results (*points*) and Jeng's analytical solutions (*dashed line*)

To validate the present model, we compare the present numerical model with the previous experimental data for both oscillatory and residual mechanism, respectively. For the oscillatory mechanism, the numerical results for the maximum vertical oscillatory pore pressure ($\tilde{p}/p_0$) versus relative soil depth (z/h) are presented in Fig. 39.6. In the figure, both analytical solution [39.45] and experimental data [39.91] are included. As shown in the figure, the numerical results match well with both the analytical solution and the experimental data.

The previous experimental data reported in [39.86] are used to validate the residual mechanism of the present numerical model. The numerical results are observed in Fig. 39.7. In the figure, 1-D analytical solutions developed by [39.82, 92] are also included in the comparison. As shown in the figure, the overall trend of the residual pore pressure of the present 2-D instant model can capture the experimental data extremely well, and the value of the build-up pore pressure agrees quite well with the experimental data plotted in the figure, which provides much better prediction than the 2-D maximum model. There is a little difference of the trend of the build up pore pressure between the present instant 2-D model with the 1-D analytical model [39.82, 92], but the final residual pore pressure is acceptable. This comparison validates our new model and demonstrates the significant improvement of the prediction of the wave-induced residual pore pressures in marine sediment with the new definition of the source term in our new 2-D model.

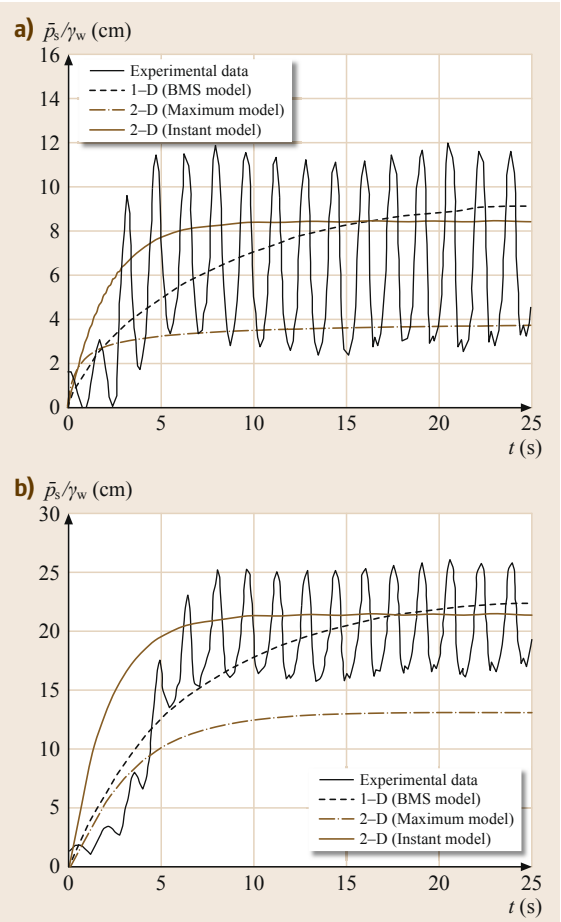

Fig. 39.7a,b Comparison of model results and experimental data (after [39.86]). **(a)** pore pressure at $(x, z) = (0, -0.085)$ m **(b)** pore pressure at $(x, z) = (0, -0.24)$ m. Input data: $H = 0.18$ m, $T = 1.6$ s, $d = 0.55$ m, $K = 1.5\times10^{-5}$ m/s, $n = 0.51$, $G = 1.92\times10^{6}$ N/m^2, $h = 0.4$ m, $\mu = 0.29$, $c_v = 0.0127$ m^2/s, $D_r = 0.28$

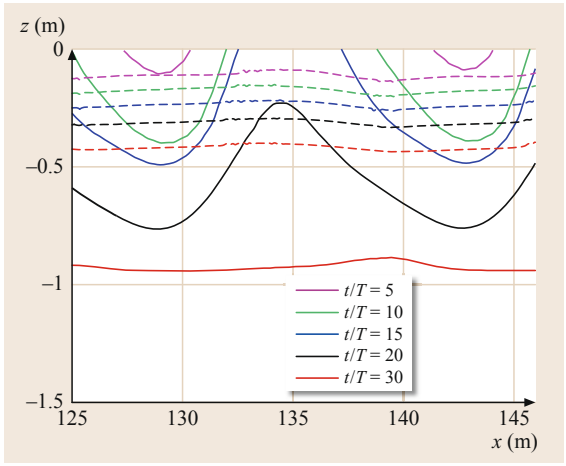

Fig. 39.8 Development of liquefaction zone from 2-D to 1-D for various types of soil with the instant model (*solid lines*) and the maximum model (*dashed lines*). Input data: $H = 2.8$ m, $T = 5$ s, $d = 4$ m, $K = 10^{-4}$ m/s, $n = 0.3$, $G = 3\times10^{6}$ N/m^2, $h = 20$ m, $\mu = 0.35$, $c_v = 0.1325$ m^2/s, $D_r = 0.54$, $\alpha_r = 0.246$ and $\beta_r = 0.165$

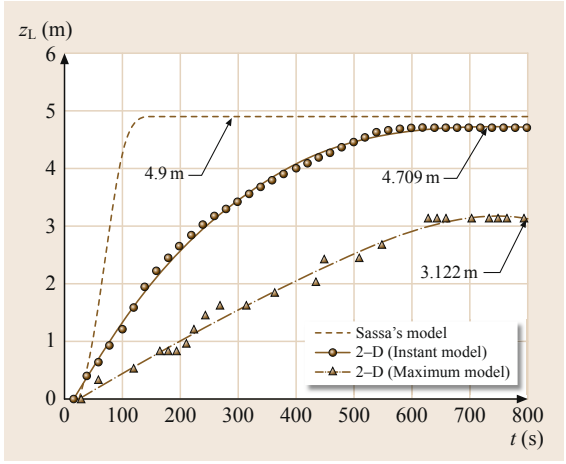

Fig. 39.9 Comparison of progress of wave-induced liquefied zone versus wave cycle (t/T) between Sassa's model (*dashed line*) and the present instant model (*line*) and maximum model (*dash-dotted line*). Input data: $H = 6.5$ m, $T = 10$ s, $d = 20$ m, $K = 1.5\times10^{-4}$ m/s, $n = 0.3$, $G = 2\times10^{5}$ N/m^2, $h = 20$ m, $\mu = 0.35$, $c_v = 0.0133$ m^2/s, $D_r = 0.4$

39.2.4 Wave-Induced Residual Liquefaction

The source term for the residual pore pressure generation is re-defined as two-dimensional and time-dependent function in our new model. This new feature will directly affect the pattern of the liquefaction zone. It is well known that liquefaction will occur when the excess pore pressure reaches the initial effective stress, $\bar{p}_s = \sigma_0'$. Figure 39.8 illustrated the variations of wave-induced residual liquefaction zones against the wave cycle (t/T) for various types of soil with different numerical model. As shown in the figure, for the 2-D instant model, the liquefaction occurs as a 2-D zone first and gradually moves down and behaves as a 2-D zone, after a certain wave cycles (e.g., 30 wave cycles in this example), the liquefaction zone changes from 2-D to 1-D. On the other hand, in the 2-D maximum model, the liquefaction zone always behaves as a 1-D zone and gradually moves down.

Sassa et al. proposed a 1-D elasto-plastic model, in which the source term was related to the rate of plastic volumetric deformation $\partial\epsilon^p/\partial t$, but the stress

ratio τ/σ'_{z0} was still estimated by the poro-elastic solutions [39.93]. *Liu* et al. extended Sassa et al.'s model by considering the effect of viscosity on the liquefied soil [39.94]. The comparison of the distribution of maximum liquefaction depth (z_L) versus time (t) between *Sassa*'s model [39.93] and the present instant and maximum 2-D model is presented in Fig. 39.9. It is clear from the results presented in Fig. 39.9 that the maximum liquefied depth will gradually move down and become a constant when the time will reach to a certain value, and the final liquefaction depth for the present instant model can match well with the results presented in *Sassa*'s elasto-plastic model [39.93], (the difference is only 3.9%) and provide a much better prediction than the 2-D maximum model. This preliminary results demonstrate the capacity of the present 2-D instant model in the prediction of progressive liquefaction.

39.3 Wave(Current)-Induced Soil Response in Marine Sediments

The co-existence of waves and currents in offshore area is a common physical phenomenon and their interaction is an important topic in the practices of coastal and ocean engineering. The presence of a current in a propagating wave will change the original characteristics of wave. For example, the following current will elongate the wave length, and the opposing current will shorten the wave length. In this study, to obtain more accurate results of seabed response under combined wave and current loadings, the third-order solution of wave–current interactions is used to determine the dynamic wave pressures acting on the seabed. On the problem of the third-order wave–current interaction, some works are available in the previous literatures. The interaction between the linear wave and uniform current has been studied by [39.95]. *Baddour* and *Song* investigated the interaction of linear wave and collinear current [39.96]. Later, they further extended this problem to third-order nonlinear wave and an uniform current [39.97]. However, this analytical solution for the interaction between the third-order nonlinear wave and uniform current is not right because the third-order terms are not completed. Recently, *Hsu* et al. gave out the complete form of analytical solution for the problem of the third-order nonlinear wave and uniform current interaction [39.98]. Later, *Jian* et al. develop an analytical solution for the interaction between gravity capillary short crested wave and a uniform current [39.99]. In this study, the analytical solution proposed by [39.98] is adopted to apply the wave pressure on porous seabed without marine structure.

Recently, a series of analytical solutions for the wave(current)-induced soil response in marine sediments were proposed based on various assumptions, for example, consolidation model [39.100], *u-p* approximation [39.101] and full dynamic model [39.102]. In addition to analytical solution, numerical models for the wave(current)-induced soil response were also proposed, based on consolidation model [39.103] and *u-p* approximation [39.104]. All these investigations demonstrated the significant effects of currents on the soil response in marine sediments.

39.3.1 Theoretical Formulations

Using the perturbation technique, *Hsu* et al. derived a third-order approximation of the dynamic pressure acting on the seabed which can be expressed as [39.98]

$$
\begin{aligned}
P_b(x,t) = {} & \frac{\rho_f g H}{2\cosh kd}\left(1-\frac{\omega_2 k^2 H^2}{2\,(U_0 k-\omega_0)}\right)\\
& \times\cos(kx-\omega t)\\
& +\frac{3\rho_f H^2}{8}\left(\frac{\omega_0(\omega_0-U_0k)}{2\sinh^4(kd)}-\frac{gk}{3\sinh 2kd}\right)\\
& \times\cos 2(kx-\omega t)\\
& +\frac{3\rho_f k H^3\omega_0(\omega_0-U_0k)}{512}\,\frac{(9-4\sinh^2(kd))}{\sinh^7 kd}\\
& \times\cos 3(kx-\omega t)\,,
\end{aligned}
\tag{39.56}
$$

where ρ_f is the density of sea water. When there is no current in wave ($U_0 = 0\,\mathrm{m/s}$), H is the wave height of the first-order wave, U_0 is the current velocity, g is the gravity, and the dispersion relation is given by

$$
\omega = \omega_0 + (kH)^2\omega_2\,, \tag{39.57}
$$

where $\omega_0 = U_0 k + \sqrt{gk\tanh kd}$ and

$$
\omega_2 = \frac{(9+8\sinh^2 kd+8\sinh^4 kd)}{64\sinh^4 kd}(\omega_0-U_0k)\,. \tag{39.58}
$$

In this study, the finite element model (SWANDYNE II), originally developed by [39.67] for the soil response under earthquake loading, is adopted for wave loading. The wave module (COBRAS, Cornell breaking wave and structure) to apply the wave loading to porous seabed was developed and integrated to

SWANDYNE II to form part of the numerical model PORO-WSSI II (POROus models for wave–seabed–structure interactions, version II). Details of the generalized FEM (finite element method) formulations are available in [39.11].

39.3.2 Effects of Currents

In this subsection, we compare the seabed response for the cases under waves loading with and without currents. Figures 39.10 a and 39.11a illustrate the vertical distributions of the seabed response under wave and following current ($U_0 = 1\,\mathrm{m/s}$) loading at $x = 125\,\mathrm{m}$ in both coarse and fine sand. Due to the fact that the absolute value of maximum dynamic response in seabed is greatly different under highly nonlinear wave loading, the maximum dynamic responses in seabed are compared, respectively, with their corresponding values when $U_0 = 0\,\mathrm{m/s}$. In the figures for maximum response, all seabed response variables are normalized by the maximum dynamic wave pressure along the seabed surface without current, that is, $(p_0)_{\max}$, given in (39.56) when $U_0 = 0\,\mathrm{m/s}$. It is clearly observed from Figs. 39.10 and 39.11 that the effect of ocean currents on the seabed response is significant in both coarse and fine sand. If a following current exists in the wave field, the magnitudes of the maximum seabed response, including pore pressure and effective stresses, are basically greater than that without currents. For the maximum shear stress in seabed, both cases are almost identical in the upper part of seabed. In the lower part of seabed, the magnitude of shear stress is greater when there is a following current. In coarse sand, the maximum relative difference between

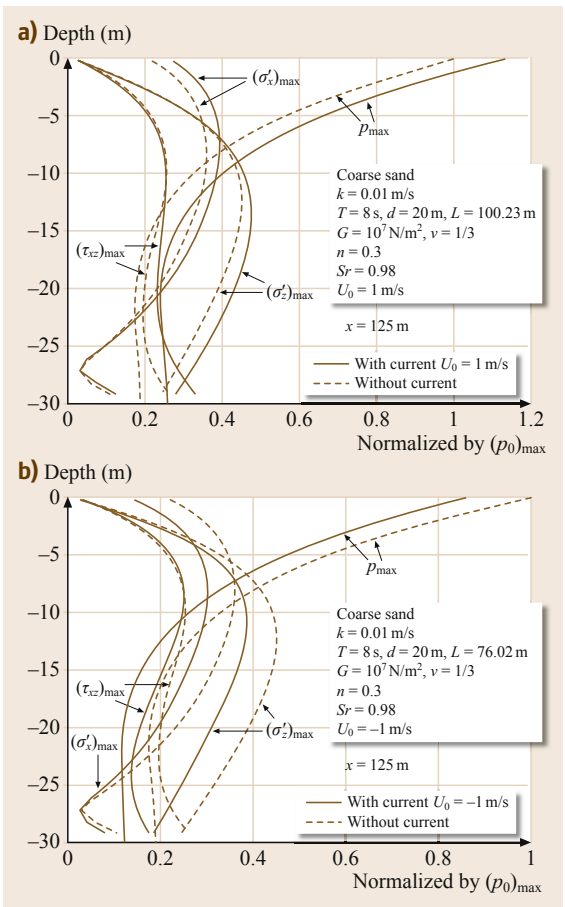

Fig. 39.10a,b Vertical distributions of seabed response under wave and current loading in coarse sand ($K = 10^{-2}\,\mathrm{m/s}$, $n = 0.3$). Input data: $H = 2\,\mathrm{m}$, $T = 8\,\mathrm{s}$, $d = 20\,\mathrm{m}$, $G = 10^7\,\mathrm{N/m^2}$, $h = 30\,\mathrm{m}$, $\mu = 1/3$, $S = 0.98$ **(a)** $U_0 = 1\,m/s$; **(b)** $U_0 = -1\,m/s$

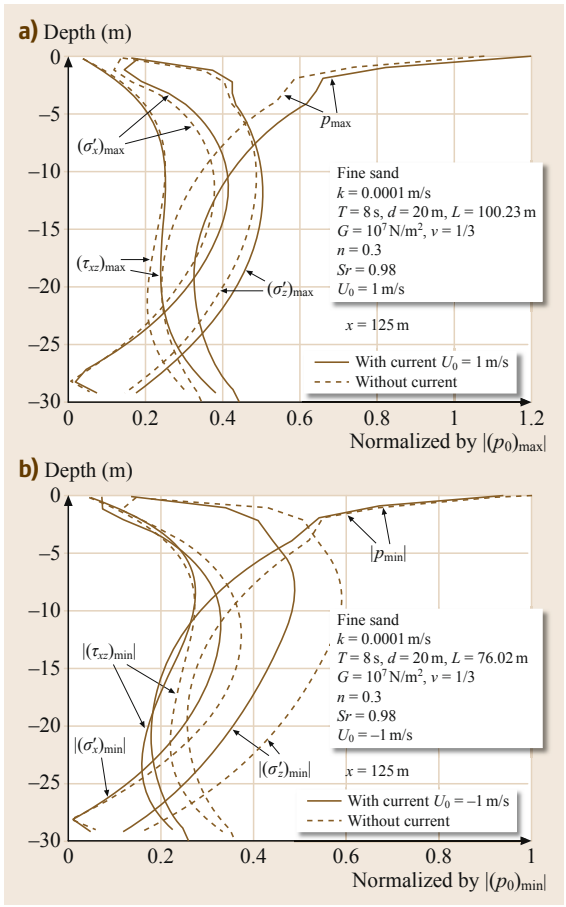

Fig. 39.11a,b Vertical distributions of seabed response under wave and current loading in fine sand ($K = 10 \times 10^{-4}\,\mathrm{m/s}$, $n = 0.2$). Input data: $H = 2\,\mathrm{m}$, $T = 8\,\mathrm{s}$, $d = 20\,\mathrm{m}$, $G = 10 \times 10^7\,\mathrm{N/m^2}$, $h = 30\,\mathrm{m}$, $\mu = 1/3$, $S = 0.98$ **(a)** $U_0 = 1\,m/s$; **(b)** $U_0 = -1\,m/s$

the two cases with/without currents can up to 15% for the maximum pore pressure, and 10% for $(\sigma_z')_{max}$, 5% for $(\sigma_x')_{max}$ and 10% for the shear stress $(\tau_{xz})_{max}$. It is noted that although the magnitude of the relative difference of seabed response between the two cases is not large, the absolute difference is huge because all quantities have been normalized by a great value $(p_0)_{max}$. All these results indicate that the seabed instability (such as liquefaction) is more likely to occur (will show in the latter section) if the ocean wave and following current co-exist simultaneously regardless of soil type.

Figures 39.10b and 39.11b further present the vertical distributions of the maximum seabed response under the nonlinear wave and opposing current loading at $x = 125$ m in coarse sand and fine sand when the current velocity $U_0 = -1$ m/s. It is also clearly observed that the effect of opposing current on the seabed response is also significant, as shown in Figs. 39.10b and 39.11b. However, the seabed response will be smaller than the case without current, which may reduce the potential of seabed instability.

39.3.3 Liquefaction of Seabed Under Combined Nonlinear Wave and Current Loading

It is well known that the porous seabed would liquefy under wave loading due to the build-up of excess pore pressure in seabed. In this study, to investigate the liquefaction properties in seabed under combined nonlinear wave and current loading, the liquefaction criterion proposed by [39.28] is adopted. It is expressed as

$$-(\gamma_s - \gamma_w)z \le \sigma_z' \,, \tag{39.59}$$

where the γ_s is the saturation unit weight of seabed soil, γ_w is the unit weight of water, and σ_z' is the wave-induced vertical dynamic effective stress. Actually, the liquefaction criterion, (39.59) means that the seabed will liquefy if the wave-induced vertical dynamic effective stress σ_z' (Noted: compressive stress is negative) is equal to or greater than original vertical effective stress $-(\gamma_s - \gamma_w)z$. In this study, the dynamic effective stresses are determined through the following three steps:

1. Calculating the consolidation state of seabed under the static water pressure.
2. Calculating the full effective stresses state of seabed under full water pressure including static pressure and the wave-induced dynamic pressure.
3. The dynamic effective stresses is determined by subtracting the effective stresses of consolidation state from the full effective stresses.

The transient liquefied zones move in seabed accompanying the movement of the third-order progressive wave. Therefore, there is no place which is always in the liquefied state if the elastic model is used for porous seabed. Figure 39.12 illustrates the variation process of liquefied depth in fine sand seabed in time domain at $x = 125$ m under nonlinear wave and current ($U_0 = -1$ m/s, 0 m/s and 1 m/s) loading. As shown in Fig. 39.12, the maximum liquefied depth in seabed is 1.16 m, 0.98 m, and 0.58 m when the velocity of current U_0 is 1 m/s, 0 m/s, and −1 m/s. Relative to the condition without current, the following current $U_0 = 1$ m/s makes the maximum liquefied depth increase 18%; while the opposing current makes the maximum liquefied depth decrease 57%. From this result, It is found that the following current makes the liquefied zone in seabed becomes larger than that when there is no current; and the opposing current is beneficial to prevent

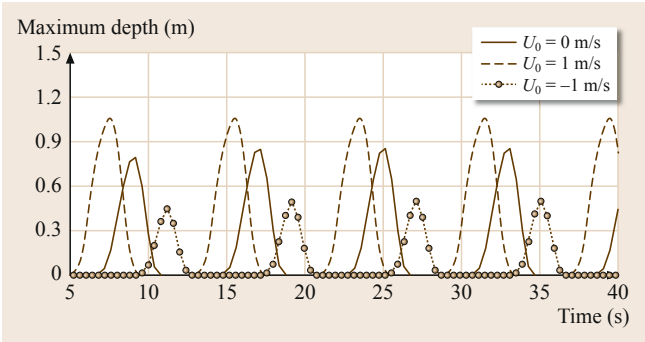

Fig. 39.12 The variation process of the liquefied depth in seabed (fine sand) at $x = 125$ m under nonlinear wave and different current loading. ($H = 3.0$ m, $d = 10$ m, $T = 8.0$ s)

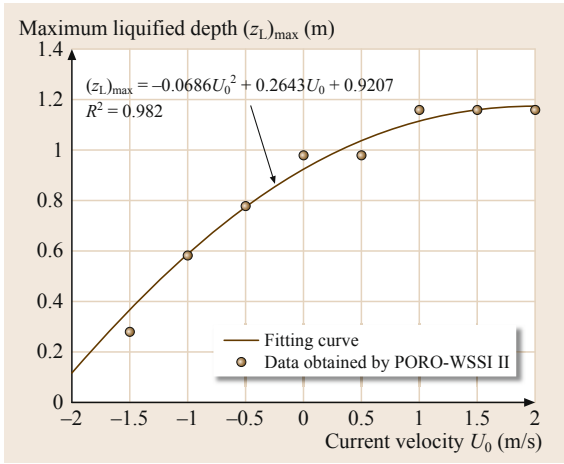

Fig. 39.13 The wave-current-induced maximum liquefied depth in seabed (fine sand) at $x = 125$ m versus different current velocity U_0, and the fitting curve ($H = 3.0$ m, $d = 10$ m, $T = 8.0$ s)

the seabed from liquefying. Figure 39.13 shows the relationship between the maximum liquefied depth and the current velocity. As illustrated in Fig. 39.13, the following current make the fine sand seabed more easy to get liquefied, the opposing current makes the fine sand seabed more difficult to be liquefied.

39.4 Seabed Stability Around Caisson Breakwaters

The phenomenon of wave–seabed–structure interactions (WSSI) has a major bearing on this issue and is central to the design of coastal structures such as breakwaters, pipelines and platforms. Numerous studies of wave-induced seabed response have been conducted since the 1970s, involving the investigations of pore pressures, effective stresses, and displacements [39.22, 26, 43, 45]. Most of them have based on *Biot*'s poro-elastic theory [39.3]. Later, the analytical solutions of dynamic response for a poro-elastic, isotropic seabed under linear wave loading have been developed, in which the inertia effects of the solid and/or pore fluid are included [39.5, 6, 8]. Recently, *Ulker* et al. further examined the applicable ranges of different approximations [39.9]. All these investigations have limited to the dynamic response of seabed under linear/nonlinear wave loading, without a marine structure.

There have been numerous investigations for the interactions of wave–seabed around marine structures, based on Biot's poro-elastic theory. Among these, *Mase* et al. developed a FEM numerical model to investigate the wave-induced pore water pressures and effective stresses under standing waves in a sand seabed and in the rubble mound foundation of a composite caisson-type breakwater based on Biot's consolidation equations [39.105]. Later, *Mizutani* et al. [39.106] and *Mostafa* et al. [39.107] developed a BEM (boundary element method)-FEM (finite element method) combination numerical model to investigate the wave–seabed–structure interaction. In their models, Poisson's equation is used to govern the irrotational wave field for an incompressible, inviscous fluid; and the poro-elastic Biot's consolidation equations are used to govern the porous seabed and structures. *Jeng* et al. developed a 2-D generalized FEM numerical model (GFEM-WSSI) to investigate the wave-induced pore pressure under a linear wave around a composite breakwater located at a finite, isotropic, and homogeneous seabed [39.108]. *Ulker* et al. investigated the dynamic response and instability of the seabed around a caisson breakwater under standing waves with a FEM numerical model [39.109], which is developed by considering the acceleration of relative displacements between solid and pore fluid particles. However, all these models have been based on potential flow theory for wave models.

In addition to the potential flow, models combining the Reynolds-averaged Navier–Stokes equations (RANS) for wave field and the volume-averaged Reynolds-averaged Navier–Stokes (VARANS) equations for the porous flow in porous medium have been developed to examine the phenomenon of wave propagation around marine structures [39.110–113]. The major advantage of using RANS and VARANS instead of potential flow for wave modeling is the capacity of capturing wave breaking, turbulence and detailed information of bottom boundary layers. In these models, the pressure, flow field in whole computational domain, and the flux at the interface between the porous seabed/marine structures and the seawater, are all continuous. However, the variations of effective stresses in the seabed and marine structures cannot be determined.

In this section, to improve the capability of modeling the mechanism of the WSSI problem, an integrated model (PORO-WSSI II) will be proposed. The VARANS equations are used for the description of wave motion and the porous flow in the seabed and marine structures. The dynamic Biot's theory is then used to describe the mechanical behavior of porous seabed. Furthermore, a one-way integrating algorithm, based on the radial point interpolation method, is adopted to link two models through the continuity of the pressure and velocity/flux at the interface between the seabed/marine structures and sea water.

39.4.1 Theoretical Models

The proposed integrated numerical model consists of two submodels: wave and seabed models. The wave model is used for generating waves and describing their propagation in a viscous fluid. The flow field inside and outside of porous media is determined by solving the VARANS equations [39.114], which are derived by integrating the RANS equations over the control volume. The influence of turbulence fluctuations on the mean flow is obtained by solving the volume-averaged $k-\epsilon$ turbulence model. In the VARANS equations, the interfacial forces between the fluid and solids have been modeled according to the extended Forchheimer relationship, in which both linear and nonlinear drag forces between the pore water and the skeleton of porous structures are included. More detailed information of the RANS and VARANS models are available in [39.114] and [39.115].

The seabed model, based on the dynamic Biot's equations (so-called *u-p* approximation) proposed by [39.4], is used to determine the seabed responses to the waves, including the pore pressure, soil displacements, and effective stresses. Unlike previous quasi-static soil behavior [39.3], the accelerations of the pore water and soil particles are considered in the present seabed model, but the relative displacements of pore fluid to soil particles are ignored. The finite element model (SWANDYNE II), originally developed by [39.67] for the soil dynamic response under earthquake loading, is adopted for the seabed response under wave loading. Details of the generalized FEM formulations are available in [39.11, 116].

A one-way integrating algorithm is adopted to integrate both models together. Unlike most previous investigations in which Poisson's equations or Laplace's equations, and the quasi-static Biot's consolidation equations are used, in this study, the VARANS equations and the dynamic Biot's equations are used to govern the wave motions and porous flows in the porous seabed and marine structures, and the dynamic mechanical behaviors of the seabed and marine structures. Due to the fact that the flow fields outside and inside the porous medium are coupled in the wave model, both the pressure and the flow velocity are continuous in the entire computational domain, especially at the interfaces between the seabed, marine structures, and the sea water. In the dynamic Biot's equations, the accelerations of solid and pore water are included.

In the process of integrating the VARANS equations and the dynamic Biot's equations, two types of mesh systems (matching mesh and nonmatching mesh) could be adopted in the numerical computations. In the numerical models proposed by [39.106] and [39.107], the matching mesh system is used, in which the same numbers of nodes are required along the sea floor because they have to share the same nodes along the surface of seabed, and marine structures. However, the size of elements in the fluid domain is generally much smaller than that in the solid domain. The ratio of the size of elements in the solid domain to that in fluid domain could vary between 5 and 20. Therefore, the nonmatching mesh system is used in this study. To integrate the wave and seabed models together at the interface with the nonmatching mesh system, a data exchange port between the VARANS equations and the dynamic Biot's equations is required, in which the radius point interpolation method proposed by [39.117] is adopted to implement the data exchange between the wave and soil models.

In the integrated model, to handle the interactions between wave, seabed, and marine structures, the Navier–Stokes equations for wave and porous flow, and the dynamic Biot's equations for the porous seabed have to be combined together through the continuity of pressure at the interface between the fluid domain and the porous medium. It is noted that there may be an argument of using Biot's poro-elastic model for the simulation of porous flows in rubble mound. However, due to the granular material properties, the pore pressures in the rubble mound predicted by Biot's model and VARANS model are close [39.116]. Furthermore, the main purpose of using Biot's model for rubble mound is to ensure the continuity of pressure field between the fluid domain and porous structures. Therefore, the present approach can provide a good estimation of pressure filed for engineering practice.

In the computation, the wave model is responsible for the simulation of wave propagation and the porous flow in porous structures (seabed, rubble mound, breakwater, etc.), and determines the pressure acting on the seabed and marine structures. Due to the fact that the VARANS equations are coupled at the interface between the fluid domain and the porous structures through the pressure and velocity/flux continuity, the pressure and the flow field are continuous in the whole computational domain. Meanwhile, the pressure/force acting on seabed and marine structures determined by the wave model is provided to the soil model through the data exchange port developed to calculate the dynamic response of seabed and marine structures, including the displacements, pore pressure, and the effective stresses. The proposed process is only valid to the cases with small deformation of seabed. *Liu* et al. proposed a coupled model for the interaction between wave and the pore water in seabed, in which the Navier–Stokes equation for wave motion on seabed, and Darcy's flow for the pore water in seabed are used [39.118]. The pressure and velocity continuity at their interface are implemented for the two models, namely it is a two-way coupling. However, the limitation of this method is that the effective stresses in seabed cannot be determined. It is noted here that although the VARANS equation and Biot's equation are only integrated together in this study, the flow field determined by the VARANS equation is continuous in the whole computational domain because the porous medium, such as rubble mound, seabed all are considered as porous structures in the wave model.

39.4.2 Verifications

To validate the proposed numerical model, four sets of previous experiments available in the literature are used. The experimental setup of these experiments is given in Fig. 39.14.

Lu conducted a series of laboratory experiments for the wave-induced dynamic response of sand bed in a wave flume, which is 60 m long, 1.5 m wide, and

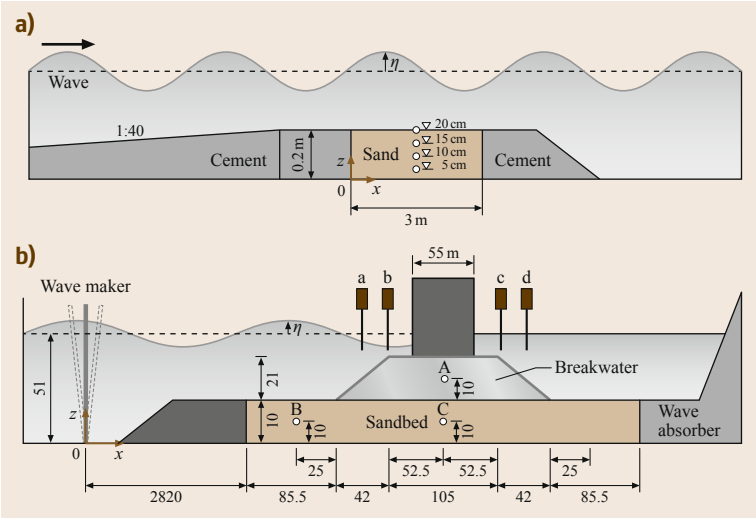

Fig. 39.14a,b Experiment setup of previous wave tank experiments for the validation of the present model: **(a)** *Lu*'s experiment – fifth-order wave and Cnoidal wave (after [39.119]), **(b)** *Mostafa* et al.'s experiment-Composite breakwater (after [39.107])

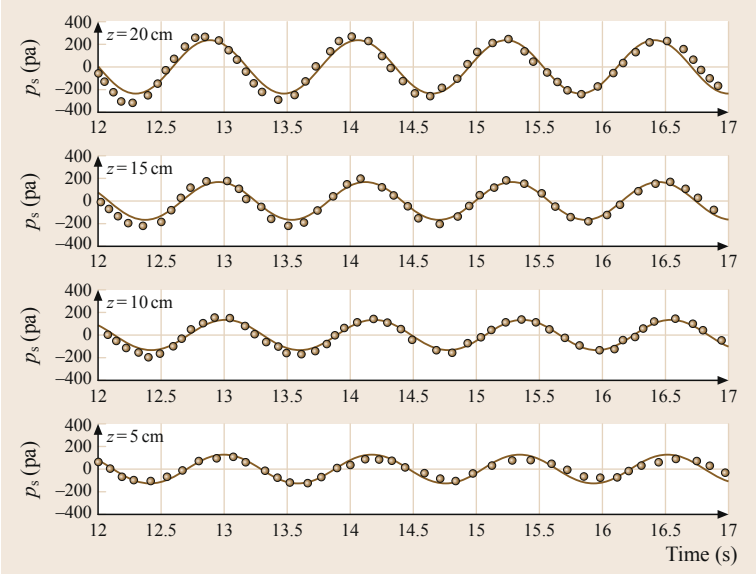

Fig. 39.15 Comparisons of wave-induced dynamic pore pressure on the midline of sand bed between the numerical results and the experimental data in Lu's experiments. —: numerical results; ○: experimental data. Input data: $H = 12\,\text{cm}$, $d = 40\,\text{cm}$, $T = 1.2\,\text{m}$, $G = 10^7\,\text{N/m}^2$, $\mu = 0.3$, $K_z = 10^{-3}\,\text{m/s}$

1.8 m high [39.119]. The waves generated in the wave flume include regular progressive waves and cnoidal waves. The periods of wave vary from 1.0 to 1.8 s and the wave heights vary from 8 to 16 cm. The experiment setup is shown in Fig. 39.14a. The pore pressure at the four points on the midline of sand bed is measured in experiments. In the present model, the fifth-order Stokes wave theory is adopted for the generation of the regular progressive wave ($H = 12\,\text{cm}$, $d = 0.4\,\text{m}$, $T = 1.2\,\text{s}$). As illustrated in Fig. 39.15, the numerical prediction of the wave-induced pore pressures overall agrees well with the experimental data [39.119].

Mostafa et al. conducted a series of experiments in the same wave flume to investigate the interaction between the wave, composite breakwater, and sand bed [39.107], as shown in Fig. 39.14b. In the experiments, a wooden box (the width is 55 cm) is placed on the breakwater to form a composite breakwater in the wave flume. Four wave gages are installed at points a, b, c, and d to monitor the wave profile; two of them are in front of the composite breakwater, while the other two are behind of the composite breakwater. Three pressure sensors are installed at points A, B, and C to record the pore pressure. Here, the wave model with wave maker of the second-order Stokes wave is adopted to simulate the generation, propagation, reflection, and interference of wave.

Table 39.1 Properties of seabed soil, rubble mound and caisson adopted in large-scale model

Medium	G [kN/m^2]	μ_s	k_s [m/s]	n	d_{50} [mm]	S_r
Seabed soil	1.0×10^5	0.33	0.0001	0.25	0.5	98%
Rubble mound	5.0×10^5	0.33	0.2	0.35	400	98%
Caisson	1.0×10^7	0.25	0.0	0.0	–	0%

The present model is adopted to simulate the interaction between the wave, composite breakwater, and sand bed. In computation, the sand bed and the rubble mound of the composite breakwater are treated as different porous structures in fluid domain; the wooden box is treated as impermeable structure in fluid domain in the wave model. The data exchange is implemented at the interface by the integrating algorithm at the interface between the solid domain (sand bed, rubble mound, and wooden box) and the fluid domain. It is noted that the buoyancy acting at the bottom of the wooden box applied by the pore water in the rubble mound has been considered in this case.

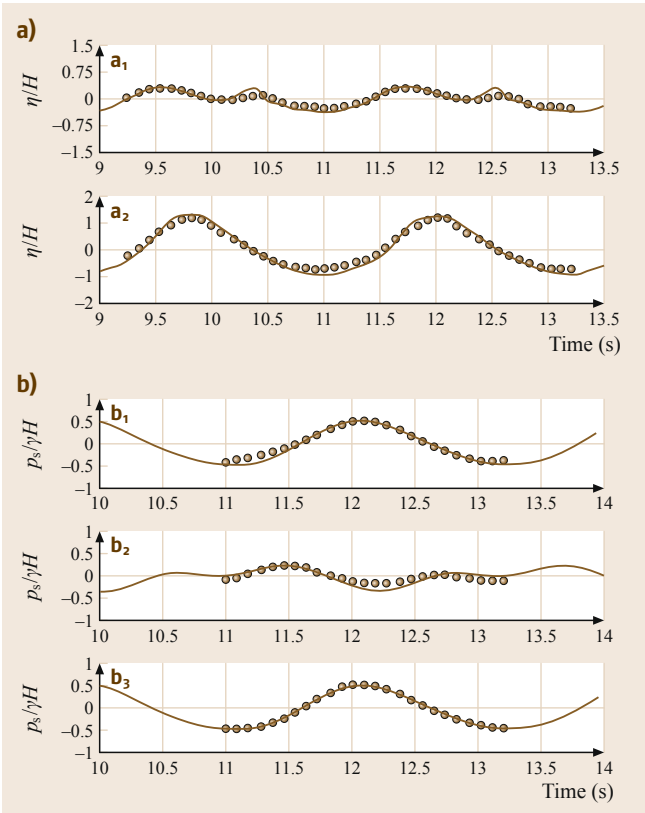

Fig. 39.16a,b Comparison of (a) wave profile and (b) pore water pressure in the seabed between the PORO-WSSI II model and the experimental data in *Mostafa* et al. (after [39.107]) for the wave profile. —: numerical results; ○: experimental data. Input data: $H = 5\,\text{cm}$, $d = 32\,\text{cm}$, $T = 2.2\,\text{m}$, $G = 5\times10^8\,\text{N/m}^2$, $\mu = 0.33$, $K_z = 2.3\times10^{-3}\,\text{m/s}$

The comparisons for the wave profile and the wave-induced dynamic pore pressure in sand bed and the rubble mound between the numerical results predicted by PORO-WSSI II and the experiment data are shown in Fig. 39.16. Due to the blocking effect of the impermeable wooden box, only little water can flow into and out the right side of the composite breakwater through the rubble mound. Therefore, the amplitude of wave behind the composite breakwater is very small. In Fig. 39.16a, only the wave profiles of points a and b are used to make the comparison between numerical results and experiment data. From the figure, it can be seen that the numerical results obtained by the present model agree well with the experiment data both for wave profile and wave-induced dynamic pore pressure.

39.4.3 Dynamic Response of Seabed Around Caisson Breakwaters

Once the initial consolidation state of seabed is determined under the static water pressure and weight of composite breakwater, it will be taken as the initial stress state when determining the dynamic response of seabed under dynamic ocean wave loading. In the model, the seabed and rubble mound are considered as porous medium, while the caisson is considered as impermeable structure in wave model. The full pressure acting on sea floor and composite breakwater is transmitted to the soil model that is used to predict the response of seabed and the composite breakwater. The predicted seabed responses induced by the full pressure are considered as full response, and the wave-induced dynamic response can be determined from the difference between full response and the initial consolidation state.

Figure 39.17 shows the distributions of dynamic effective stresses and pore pressure in the seabed and composite breakwater at $t = 73.6\,\text{s}$ under dynamic wave loading. The properties of seabed soil, rubble mound and caisson are listed in Table 39.1. According to the momentary liquefaction mechanism, the seabed soil will be liquefied when the total stresses become zero in the region, resulting in the failure of foundations in the vicinity of marine structures. On the right-hand side of composite breakwater, the effect of the ocean wave is limited in a range which does not exceed $x = 450\,\text{m}$ due to the blocking of breakwater. In the region far away from the composite breakwater, the effect of

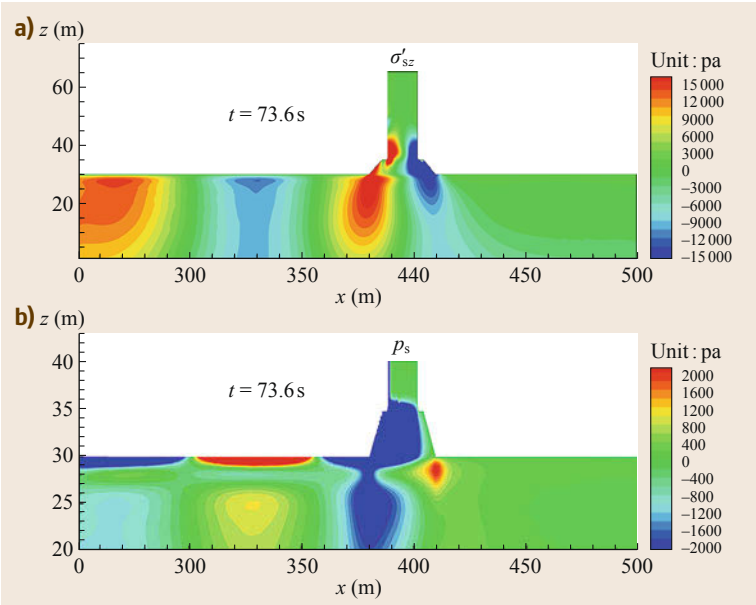

Fig. 39.17a,b The dynamic response of the seabed and composite breakwater under the ocean wave loading at $t = 73.6$ s. Wave characteristics: $T = 10$ s, $H = 3$ m, $d = 20$ m

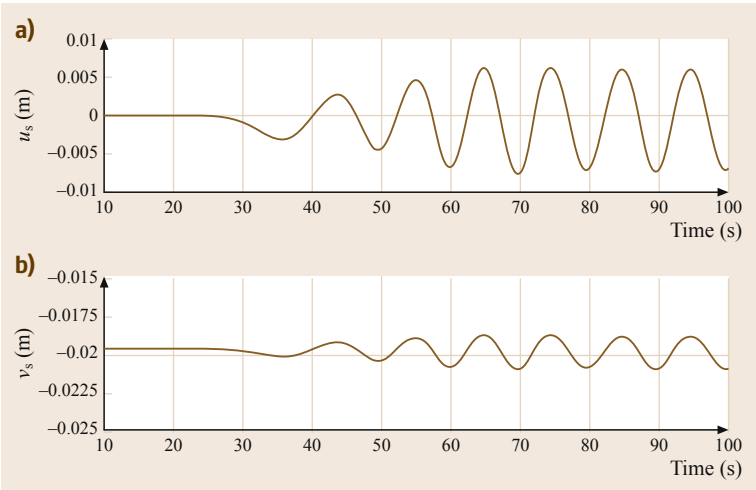

Fig. 39.18a,b The variation of horizontal and vertical displacements of the left corner of the impermeable caisson under ocean wave. Negative value of u_s means moving toward left, negative value of v_s means moving toward down **(a)** horizontal displacement; **(b)** vertical displacement

ocean wave basically disappears. At time $t = 73.6$ s, as shown in Fig. 39.17, the seabed near the rubble mound is likely to be liquefied when the wave trough is propagating on it, and the dynamic effective stresses and pore pressure are negative, which would lead to the collapse of the composite breakwater.

Before the ocean wave arrives at the structure, the composite breakwater gradually moves downward to the seabed due to its weight and reaches the initial consolidation state. Figure 39.18 shows the development of horizontal and vertical displacements of the upper left corner of the caisson. The results indicate that the structure vertically subsides about 19 mm during $0 < t < 25$ s. After the ocean wave reaches the caisson ($t > 25$ s), the caisson begins to vibrate vertically and horizontally with a small amplitude. After the full interaction of wave and structure ($t > 60$ s), the breakwater subjects to a periodical wave force and its induced vibration.

39.4.4 Wave-Induced Liquefaction Around Breakwaters

In this study, to investigate the liquefaction properties in a seabed under ocean wave loading, the liquefaction criterion proposed by [39.28] is used, which was given in (39.59). However, Eq. (39.59) is only applicable to the cases without a structure. For the cases with a ma-

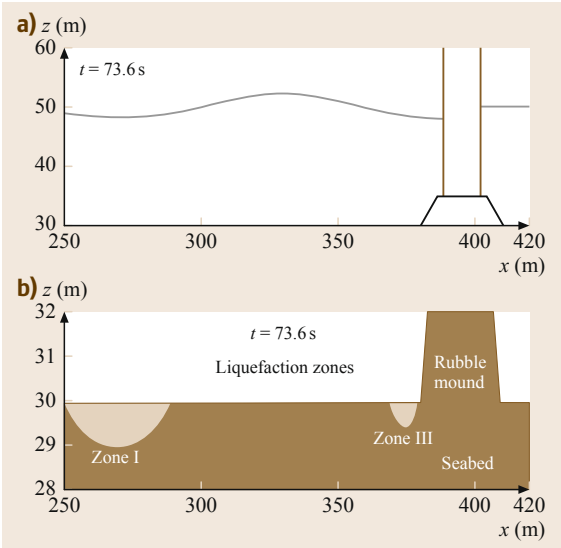

Fig. 39.19a,b The three liquefaction zones in seabed under ocean wave at time $t = 73.6$ sec **(a)** wave profile; **(b)** liquefaction zones

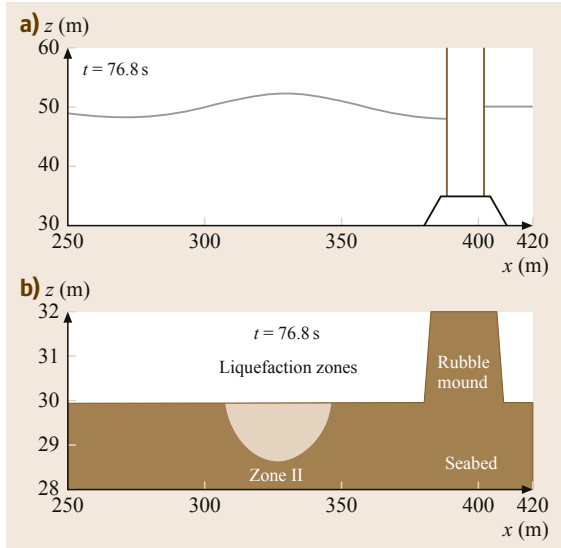

Fig. 39.20a,b The three liquefaction zones in seabed under ocean wave at time $t = 76.8$ sec **(a)** wave profile; **(b)** liquefaction zones

rine structure, it can be modified as

$$|(\sigma'_z)_{\text{initial}}| \le \sigma'_z \,, \tag{39.60}$$

where the $(\sigma'_z)_{\text{initial}}$ is the vertical effective stress at the initial consolidation state.

Figures 39.19 and 39.20 show the liquefaction zones in the seabed under the ocean wave loading at the time $t = 73.6$ s and $t = 76.8$ s, in which the modified liquefaction criterion (39.60) is adopted. As illustrated in the figures, there are two liquefaction zones in the region near the seabed surface at time $t = 73.6$ s; they are located at the range of $250 < x < 290$ m (Zone I) and $370 < x < 380$ m (Zone III), respectively. There is only one liquefaction zone in the region near the seabed surface at time $t = 76.8$ s, which is located at the range of $310 < x < 350$ m (Zone II). Zones II and III are very close to the foundation of breakwater, and they may have a large impact on the foundation stability. Therefore, we will further investigate the (depth, width, and area) development of these two liquefaction zones.

Figures 39.21 and 39.22 illustrate the variations of the liquefaction potential of Zones II and III under the ocean wave loading ($T = 10$ s, $H = 3$ m, $d = 20$ m), respectively. It can be seen from Fig. 39.21 that the liquefaction potential of Zone II is very small when the first wave trough passes through, but it increases largely during the second wave trough. After the interaction between wave and structure develops, the liquefaction depth, width, and area of Zone II further increase. The maximum liquefaction depth, width, and area are about 1.4 m, 41.0 m, and 38.5 m^2 (which occur at $t = 79$ s), respectively. As shown in Fig. 39.22, the liquefaction potential of Zone III has a similar development process as that of Zone II. The maximum liquefaction depth, width, and area of Zone III are about 0.46 m, 11.5 m and 3.85 m^2 (which occur at $t = 74$ s), respectively. The liquefaction potential of Zone III is much smaller than that of Zone II, which can be ascribed to that the weight of composite breakwater significantly increases the vertical effective stress of the initial consolidation state in Zone III.

Although the liquefaction potential in Zone III is small relative to that in Zone II, more attentions need to be paid to the Zone III as it is next to the foundation of composite breakwater. The soil liquefaction may lead to a collapse of composite breakwater. In engineering application, some methods, such as a replacement of the fine sand with gravel material, need to be adopted to protect the structure foundations.

The influence of the inertial terms associated with the accelerations of the pore water and soil particles on the wave-induced dynamic pore pressure and effective was discussed in the previous work [39.8, 9]. It is of interest to examine the effects of inertial term on the liquefaction potential. In Figures 39.21 and 39.22, the predictions of liquefaction zone by the conventional consolidation model are also included as dashed lines. As shown in the figure, the consolidation model [39.108] overestimates the liquefaction depth in Zone II, compared to the present dynamic model. However, the predictions of the consolidation model are slightly greater than that of the dynamic model.

39.5 Remarks

In this chapter, an overview of the existing models for the wave-induced soil response around breakwaters was outlined. A new model integrating both oscillatory and residual mechanisms of the wave-induced soil response was also presented and validated with the existing experimental data. Then, the effects of currents on the

soil response were examined, followed by the application of the porous models to caisson-type breakwaters foundations.

In addition to the summary of the recent advances in the field of offshore geotechnics, the following areas can be further studied in the future:

1. Most existing models were based on the constitutive models (including plastic soil behavior) for onshore soils, rather than marine sediments. It is necessary to further develop the constitutive model for marine sediments.
2. Most previous studies for the wave–seabed–structure interactions have focused on the oscillatory mechanisms. It is desired to have an integrated model for both oscillatory and residual mechanisms for the cases around marine structures.
3. The existing models have been limited to uncoupled or weakly couple or one-way integrated approach, rather than fully coupling analysis, due to the complicate mechanism of wave–seabed–structure interactions. This area has a room for further developments.

40. Buoy Technology

Andrew Hamilton

Small buoy and mooring systems have a long history and many uses ranging from navigation and marking buoys, meteorological monitoring systems, oceanographic measurement systems, wave-measurement buoys, and tsunami warning systems. Many of these designs are very mature and have benefited from decades of field experience. Others are more recent and rely heavily on synthetic materials, modern electronics, and analytical and computer analysis techniques to create high-performance systems that operate in extreme depths, boundary currents, remote locations, enable a power and data connection to submerged instrumentation, or have predictable responses to allow accurate measurement of the sea state. The material presented here applies to systems that are less than approximately 5 m in diameter and have masses less than 5000 kg or so. This chapter outlines the various choices facing designers of these systems, presents approaches to the design of standard systems, presents the material properties of commonly used materials, and describes the analysis techniques and tools typically applied to systems that must meet specialized functional requirements. The chapter concludes with diagrams of several mooring systems that have been successfully fielded.

40.1 Buoy and Mooring Types and Design Considerations

Because of the rich set of trade-offs that must be managed in a successful design, buoy/mooring systems tend to be very customized to each particular application. Differences in deployment depth, sea conditions, current conditions, service intervals, system payload requirements, deployment options, and budget constraints must all be considered. Long-term moorings are inherently high-fatigue systems, with hundreds of thousands of tension and motion cycles per month. Systems deployed for long periods of time with minimal maintenance often fail in unexpected ways that are hard to anticipate ahead of time. For these reasons, experience with what has worked before is very important, and adapting existing successful designs to new applications is generally a good idea where possible.

When designing a mooring system, the size and shape of the surface expression is determined by the requirements of its application and by the environmental conditions it will experience. Properties of the surface expression will impact the rest of the mooring system directly and should be identified early in the design process if possible. Typically the buoy size is set by payload requirements, including the mass and size of any instrumentation, batteries, solar/wind arrays, radio antenna height, and stability requirements. The smallest sized buoy system that meets the require-

ments is usually the most economical solution. The cost of materials, deployment, recovery, and maintenance increases with buoy size, sometimes dramatically as larger mooring components, ships, cranes, and winches are required. A mooring design often proceeds by first identifying the payload requirements and subsequently designing a buoy that can house that payload and be sufficiently stable for operation and maintenance.

Typical installations consist of a floating buoy element held in place by a mooring system. These two components interact with one another significantly enough that the behavior of the entire system should be considered during design. In spite of this coupling, however, it is useful to consider the behavior of the buoy alone without the mooring attached for several reasons. The buoy's behavior without the mooring's influence is generally well approximated by linear analysis, and important frequency domain characteristics such as resonance behaviors can be examined. Additionally, it is possible for the buoy to become separated from the mooring during installation, service, or recovery. Ensuring that the buoy alone has sufficient stability to stay upright dramatically increases the chances of recovery. Additionally, drifting buoys are commonly used for measuring sea-surface velocities and therefore have no mooring loads. However, these devices typically have drogues that affect the buoy dynamics [40.1].

Section 40.1.1 outlines the dynamics of various kinds of small freely floating buoys. Later sections describe more sophisticated ways to analyze the coupled buoy/mooring system that generally rely on time-domain computer simulations due to the nonlinear nature of the mooring dynamics. These techniques have the advantage of providing a good estimate of a particular system's behavior but suffer from the fact that the entire design space must be traversed with individual simulations, making general conclusions about a system's behavior difficult to determine. For instance, for a given sea-state, a mooring system may behave very differently in large currents compared to slack conditions, and each condition must be analyzed separately.

In mooring a buoy, there are a wide variety of mooring system types from which to choose from. Again the selection of the mooring is subject to a large number of considerations including the installation depth, tidal variations, seafloor conditions, seafloor impact restrictions, expected current profiles and sea conditions, system lifetime, accuracy requirements for the buoy location, and sometimes requirements to provide a power or data connection to the sea-floor or elements along the mooring string. The equipment available for deployment and recovery (ships, winches, and cranes) also dictates the options for the mooring system, and it is not uncommon for a system to be designed for a particular class of deployment vessel. Section 40.1.2 outlines the range of mooring options available to the system designer and discusses the capabilities and limitations of each.

40.1.1 Buoys

Discus and toroidal type buoys have shallow drafts and large water-plane areas, resulting in systems that have low drag-to-buoyancy ratios and are subsequently relatively easy to moor. A potentially undesirable characteristic of these kinds of buoys is that they tend to heave and pitch so that they follow the sea surface almost perfectly. This results in pitch behaviors that may interfere with desired measurements and can introduce some wear and fatigue issues into the connection between the surface buoy and the mooring. Additionally, when large enough in diameter these buoys are stable upside down as well as right-side up, so once capsized the restoring moment of the mooring can be insufficient to right the system; they tend to stay capsized. Figure 40.1a presents an estimate of the heave and pitch response of this kind of buoy. These buoys have been widely used by the National Oceanic and Atmospheric Administration (NOAA) National Data Buoy Center for meteorological measurements. That organization has also deployed much larger discus buoys of up to 10 m in diameter [40.2].

Surface buoys of intermediate aspect ratios are often the result of compromises that require the diameter of a system to be small for handling, and the payload or buoyancy of the system to be large enough that the draft must be increased. The result is a draft that is of the same order of magnitude as the diameter. A sphere-shaped buoy naturally falls into this category and is a common choice for marker buoys because of the availability and simplicity of steel spheres. Figure 40.1b illustrates the typical response of a system of this type. As seen in the estimated heave and pitch response curves, this type of buoy will pitch less than the discus buoys but will still follow the wave-surface in heave. What is evident, however, is the presence of a moderate resonance peak that is not present in the low aspect-ratio discus buoy.

For the comparison presented in Fig. 40.1, the initial stability (metacentric height) of the buoys analyzed has been chosen to be the same in each case to highlight the effects of the different geometry. Typically, freely floating discus buoys will be much more stable than intermediate aspect ratio buoys due to the large water-plane area. In the case of moored systems, however, the mooring-line tension contributes significantly to the stability of an intermediate aspect ratio buoy because of the larger distance between the connection point and the

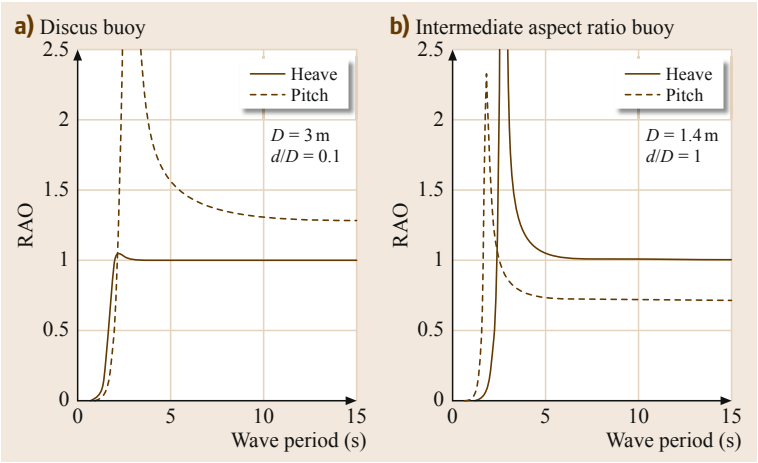

Fig. 40.1a,b Comparison of response amplitude operator (RAO) characteristics for buoys of different aspect ratio: **(a)** discus buoy, **(b)** intermediate aspect ratio buoy (d = draft, D = diameter

waterplane. Therefore, the resulting stability of the two types of buoy are often comparable.

These figures make it clear that small buoy systems are wave followers in almost all cases. Higher aspect ratio buoys have a pronounced heave resonance, located at a frequency below where most of the energy is present in open-ocean waves. The pitch response is broader and depends strongly on the buoys stability and pitch moment of inertia. Therefore, to determine the exact pitch response of a given system the RAO curves need to be computed for the particular buoy design in question; Sect. 40.3.3 presents the needed data to perform these calculations for cylindrically shaped buoys.

Spar buoys are at the other extreme and have large drafts and small water-plane areas. If made large enough the motions of these buoys can be almost totally decoupled from the sea-surface, but systems with that behavior are generally larger than would be considered for the purposes highlighted in this section. In small and intermediate sizes, the spar shape can have some applications. They will heave and be over topped by waves occasionally, but can be engineered for minimum pitch and roll. Figure 40.2 illustrates the expected heave response of three different sizes of spar buoy. As shown, these systems have a very pronounced resonance response, and only the largest systems can be designed to place this resonance at wave periods longer than typical ocean waves.

Regardless of aspect ratio, most buoys are designed to be axisymmetric. There have been boat-shaped systems such as the US Navy's NOMAD buoy that were designed in the 1960s and deployed for decades. These are moored from one end and rotate to face into the wind and waves. In large seas, surfing and slamming of these systems can become an issue. Relatively little recent work has been done with these shapes, and the

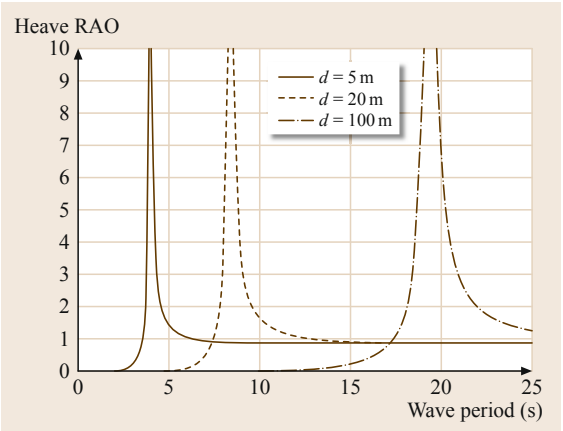

Fig. 40.2 Comparison of response amplitude operator (RAO) characteristics for spar buoys of different lengths (d = draft)

vast majority of systems designed and built today have axisymmetric hulls. Even with axisymmetric hulls the above-water instrumentation and equipment can introduce rotation due to wind loading. A design decision must be made to keep the system as axisymmetric as possible or to install vanes to consistently orient the buoy to the wind. In the latter choice, the prevailing weather conditions must be considered: in many locations the wind rotates consistently with passing weather systems, and care needs to be taken to keep from introducing more rotations than the mooring system can tolerate, or include swivels in the design.

Although buoy systems traditionally have sufficient buoyancy to ensure that the buoy remains on the sea surface in the most severe sea-state expected, systems are also sometimes designed and built with minimal reserve buoyancy. These stay on the surface and operational in moderate sea states but begin to be pulled under water

when faced with large waves. These systems must necessarily be designed to withstand submergence which can be costly, but the mooring size and cost can usually be reduced, and very shallow water deployments in which the system must survive breaking waves become possible. This design approach drives these systems to the middle of the aspect-ratio range but the techniques applied here to estimate buoy-only response curves are not applicable in conditions that lead to the buoy submerging. This is because once the buoy submerges, the water-plane area that provides the restoring force is removed, which introduces a significant nonlinearity into the analysis that is not captured by the linear analysis. Therefore, the occasionally submerging nature of these buoys introduces analysis and modeling challenges that are described in the computer modeling section below.

40.1.2 Moorings

There is a wide variety of mooring types available, and the selection for a given application involves evaluating the trade-off between many factors including water depth, buoy station-keeping performance, deployment strategy, cost factors, and special requirements like the need to provide a power and/or data path between the surface mooring and submerged instrumentation. In almost all cases, a key consideration in the mooring design is the amount of compliance provided to allow the surface buoy to move in response to waves and sea-surface level changes due to tides. There are three main techniques to provide the required compliance: a *chain-catenary* mooring in which part of the mooring string simply lies on the seafloor; a *semi-taut* design that relies on elasticity of the mooring components themselves to stretch when loaded; and an *inverse-catenary* technique in which the mooring line is induced to assume an *S* shape in the water column by weighting and floating different sections of the mooring. These three types of moorings are illustrated in Fig. 40.3. In many cases hybrid designs make use of more than one of these techniques.

Chain-catenary moorings are often the simplest to design and install. This type of mooring has many advantages such as a tolerance to water-depth uncertainty or changes, the use of durable low-cost materials, and a range of anchor options. One downside of this approach is that the design becomes more challenging in deeper water depths. In depths above a few hundred meters, the horizontal forcing of the mooring string and buoy due to currents and winds begins to overwhelm the practical amount of chain that can be placed on the seafloor. Even modest amounts of current lift the chain and pull directly on the anchor. This effectively eliminates the compliance effect. Chain-catenary moorings also have relatively large watch-circles and will have a significant impact on the seafloor. Thus, they are inappropriate in marine-protected areas or other locations where the impact to the seafloor needs to be minimized. Finally, although the wires and chains used in these types of moorings are usually very durable and resistant to damage from fishing operations or ship traffic, the constant wearing of the chain on the seabed can be an issue for some seabed types and may not be suitable at all for rocky seabeds that have a high likelihood of snagging the mooring chain and eliminating all compliance.

Semi-taut moorings rely on the elasticity of the mooring elements themselves to provide the needed compliance. Typically these designs are used in deep-water installations where a relatively small amount of elasticity in the mooring materials translates to a significant extension across the loads seen during service. For reasons of elasticity and in-water weight, these moorings are typically constructed of rope materials such as nylon, polyester, polypropylene, and polyolefin. Although potentially elastic enough, steel wire-rope simply becomes too heavy in long lengths, driving up the system design into a spiral of becoming larger than can be supported by the types of buoy systems considered in this chapter. Semi-taut mooring designs do not include any chain or material on the seafloor aside from the anchor, so they have a minimal seafloor impact and are good candidates for including acoustic release devices. As an exception to the deep-water application of these moorings, some shallow-water moorings utilize rubber-based hoses and cords to provide extreme elasticity to a mooring over a short length. Semi-taut moorings typically are well behaved in that they include a lot of elasticity, and the tension in the mooring string rarely goes to zero. This limits snap loading that can be present in the other types of mooring systems. In all cases of this type of mooring, good knowledge of the water depth at the deployment site is required, and careful attention must be paid to the design and fabrication of the mooring string. In particular, accurately measuring long lengths of ropes is a nontrivial practical issue that has significant bearing on implementation of these systems.

Inverse-catenary moorings do not rely entirely on the elasticity of the mooring string, but instead introduce some compliance by creating an *S-curve* in the geometry of the mooring string. This is accomplished by floating part of the mooring string above the anchor and weighting part of the mooring. There are many ways to do this including the use of ropes of different densities. Polypropylene, Spectra, and polyolefin are all less dense than water while polyester and nylon are

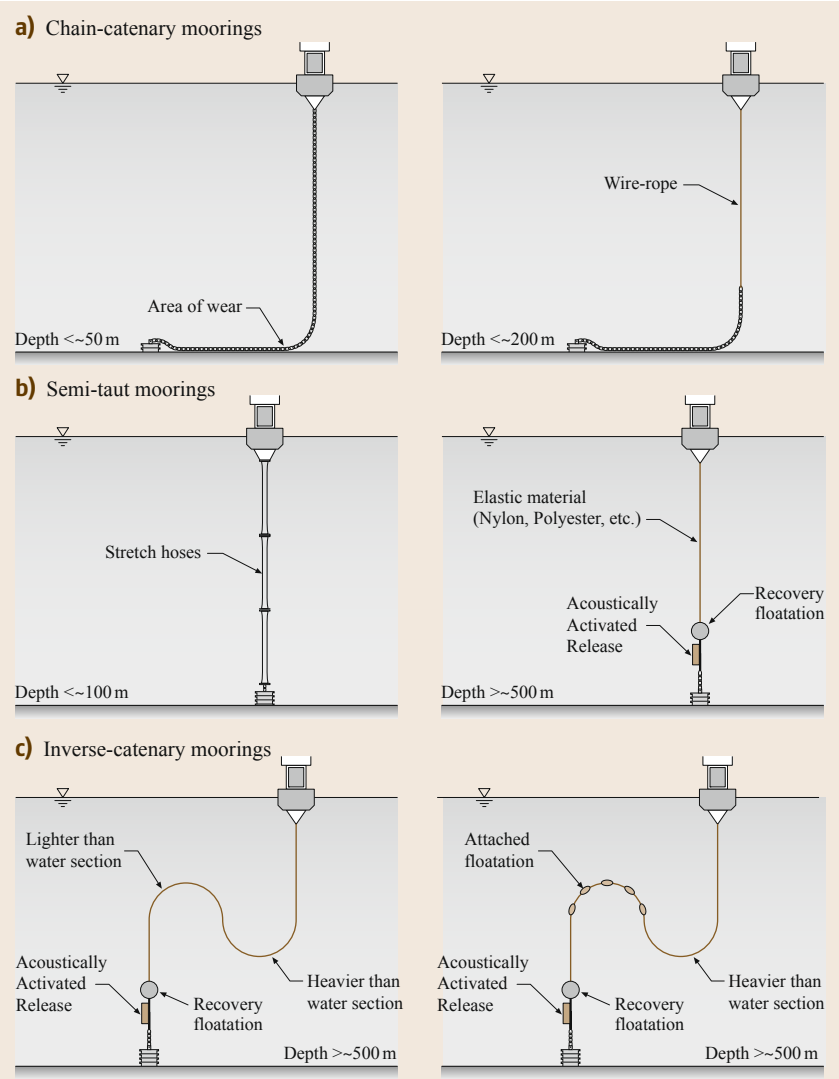

Fig. 40.3a–c Three mooring types typical in small buoy systems: **(a)** chain-catenary mooring, **(b)** semi-taut moorings, **(c)** inverse-catenary moorings

more dense. In other cases when the mooring application requires wire-rope or other heavier-than-water materials (as may be the case if electrical conductors need to be included), direct attachment of flotation to the mooring string may be required. Unlike semi-taut moorings, this type of mooring tends to be poorly behaved in large sea-states. Low-tension conditions at some point in the mooring string are often unavoidable in low-current regimes. In the presence of high currents, the geometric compliance tends to be minimized by the stretching out of mooring string, which can happen in surprisingly low currents for deep moorings. In all cases, abrupt changes in the material properties (stiffness, elasticity, mass) should be minimized as unusual dynamics can be excited at such locations, resulting in highly repetitive motions and premature failure. Techniques of specialty ropes that blend the density of the material gradually from one region to another have been employed, as well as extruded flotation jackets over wire-rope; these solutions are typically highly customized and expensive to fabricate.

Moorings are often also characterized by *scope*, the ratio of mooring length to water depth. Semi-taut moorings have the lowest scope, greater than 1 when deployed, but less than 1 when the mooring materials are measured in a relaxed state. Inverse-catenary moorings are usually designed with a scope between approximately 1.1 and 1.6. Chain-catenary moorings typically require higher scopes for deeper depths; the important consideration in this case is that at least part of the mooring chain remains on the seafloor so that the anchor does not experience vertical loads.

40.1.3 Failures and Hazards

Mooring system failure modes are numerous, but the most common are vandalism, fatigue, corrosion, and fish-bite. Vandalism and interference from commercial traffic is a common cause of the loss of service of a mooring system. Problems include collisions, fishing line and net entanglement, fish operations utilizing buoys as fish-aggregating devices, and theft. These issues depend on location and cannot always be eliminated, but mitigation techniques include armoring rope strength members and making buoys difficult to board [40.3]. Fatigue and corrosion failures are also the causes of mooring failures and careful engineering must be performed to anticipate the possible fatigues issues that can arise [40.4]. Failures due to fish-bite also occur and are hard to anticipate or design for [40.5].

40.2 Buoy and Mooring System Components

A wide variety of materials are used in oceanographic buoys, often depending on local availability and past practices of the designer and builder. This section outlines the specifics of various materials and components typically used and provides tables of approximate physical characteristics for these materials. Table 40.1 compares the fundamental properties of the materials used in oceanographic mooring systems, and more detailed tables throughout this section show the particular characteristics of components made of these materials in a specified construction. In all cases, these tables are meant to guide design, but the specifics of the actual components used should always be checked as there will be some variability around these examples.

40.2.1 Strength Members

Strength members fall into four broad categories: chain, wire-rope, synthetic ropes, and specialty stretch elements that are typically made of rubber compounds. Regardless of the material that the strength members are made of, an important characteristic to consider is the torque and rotation behavior of these elements. Because of the constantly oscillating tensions, even a small tendency to rotate as the element is put under tension can add up to significant rotation after hundreds or thousands of meters. In addition to imparting a torque on the ends, the induced torque and rotation can cause strength members to *hockle* when unloaded, resulting in a tight bend radius that can lead to failure when the load is reapplied. In less severe cases, too much torque-imbalance can cause self-wear of the various strands or components of a strength member where they move past one another. For these reasons, constructions that are inherently *torque-balanced* are primarily used.

Chain

Chain is usually included in mooring systems for its weight and durability, so it is often not necessary to use high-performance chain. Chain grades (30, 43, 70) represent the modulus of the steel in 1E6 psi units. Strengths higher than grade 43 should be avoided if galvanized to avoid hydrogen-embrittlement problems that can occur when high-strength steels are galvanized.

Chain selection is usually made based on size, weight, and availability. Table 40.2 presents chain

weights and strengths for several common sizes used in small mooring systems. Long-link chains are popular also because they are easier to shackle to, especially mid-span. Detailed information on standards for chain used in offshore applications can be found in [40.13].

Wire-Ropes

For wire-ropes used in small mooring systems, the dominant construction for mooring use is a 3X19 arrangement with three twisted main strands, each consisting of 19 wires each. The contra-helical winding of the 19 galvanized steel strands relative to the 3 main strands results in a design that is balanced and rotates little under load. This design has proven itself in thousands of applications and is the usual starting point for wire-rope in oceanographic mooring applications. Most commonly, wire-rope used in mooring systems has a polyethylene or polypropylene jacket extruded over the wire.

In addition to improving durability, the jacket provides a surface to clamp instrumentation to. For low-bandwidth communications, the jacketing forms a current loop through the wire-rope, with the conductive seawater as a return path. By coupling signals to this loop data can be transmitted up or down the wire between instruments and the surface buoy, or between instruments. This is the most common communication technique for retrieving data from submerged instrumentation and is

dramatically less expensive than including a dedicated copper or optical path in the mooring cable.

Synthetic Ropes

Although durable, wire-rope sometimes cannot be used because of its weight (e.g., the self-weight of 5000 m of 3X19 wire-rope introduces a load at the top, which is 80% of its working load), or because the mooring design requires a more elastic element. In these cases synthetic ropes are used. There are a wide variety of material options and construction types, typically characterized into two groups, high-performance synthetic fibers, and industrial fibers. High-performance fibers are defined as having a tenacity of greater than 15 g/denier [40.14], with strengths similar to steel wires, much less weight, and slightly lower modulus. Industrial fibers typically have about half the strength of the high-performance fibers. The strength penalty manifests itself in larger sizes that increases drag, but the higher elasticity and lower cost of these fibers mean they are widely used in mooring systems.

Table 40.1 highlights the material properties of the various fibers described below. Table 40.2 includes the properties of typical ropes manufactured from these materials.

High-Performance Synthetic Fibers.

Kevlar: Kevlar fiber was introduced in 1970 by Dupont and was the first high-performance fiber with a strength close to steel. It is only a little heavier than water with a specific gravity of 1.44, its stretch at break is about 4%. Creep of this fiber is very low which makes it useful for electro-optical-mechanical cables, but it is easily damaged by self-abrasion in repetitive cycling applications such as mooring cables. A specific failure mode known as kink-band formation dramatically weakens the fiber and occurs when the fiber undergoes compression. For this reason, it is a poor choice for surface mooring designs that include low-tension bending in which the inside of the bend allows the fibers to go into compression. Due to its relatively low cost, it is an appropriate choice for subsurface moorings that include electro-optical components and is often used in remotely operated vehicle (ROV) cables where the cable only rarely experiences significant loads.

Vectran: Vectran is a trade name for a liquid crystal polymer fiber introduced by Celanese in the mid 1980s. Its density, strength, and modulus are approximately equal to Kevlar, and the fiber has much less tendency to form kink-bands, making it well suited as a strength material in cables and ropes for surface moorings.

Spectra and Dyneema: These fibers are made from ultrahigh molecular weight polyethylene, and therefore have a density less than water and float (specific gravity = 0.98). With low weight, high strength, and high resistance to self-abrasion, this material is well suited to mooring applications in which a light, stiff strength element is needed. Traditionally the limitation of this fiber is a tendency to creep under sustained load, making it unsuitable for use in electro-optical-mechanical cables. Manufacturing improvements seem to be slowly eliminating this characteristic so this could change in the future.

Zylon: Dow Chemical developed this fiber in 1990 and marketed it under the trade name PBO. It is now manufactured and marketed as Zylon. It is an extremely strong fiber, about 50% stronger than Kevlar and Vectran and has a similar specific gravity of 1.53. Costs remain high, and it is therefore restricted to very specialized applications and has not yet found its way into mooring applications. If costs come down in the future, it is a good candidate for electro-optical-mechanical cables.

Industrial Fibers.

Nylon: Nylon was developed in the 1930s by DuPont and is a very stretchy fiber with elongations of 15–30% at break and has a low specific gravity (1.14). This light, inexpensive, elastic material is a good candidate for semi-taut mooring designs in deep water. Typical construction is a torque balanced 8 strand *Woods Hole* lay [40.11]. It does absorb water readily, which changes its length over long distances so care must be taken in specifying and fabricating moorings using this material.

Polyester: Polyester is the heaviest of the industrial fibers with a specific gravity of 1.38. Stretch at breaking loads is 12–18% but only 3–5% at working load. There is a tendency for some initial stretch at first loading so care is required in specifying and fabricating semi-taut moorings.

Polypropylene: Polypropylene has a low specific gravity (0.91) and floats readily in sea-water. This makes it a common choice for the lower section of an inverse-catenary mooring design. Because polypropylene has strength and stretch behavior similar to polyester, inverse-catenary moorings benefit from compliance created from both the geometry of the mooring and the material stretch under load. Polypropylene does exhibit some creep behavior so is inappropriate for use in center-strength-member electro-optical-mechanical cables, described below.

Electro-Optical-Mechanical Elements

In cases where electrical power needs to be transmitted along the mooring string, or if high data-rate communications along the mooring are required, it can be necessary to include copper or optical-fiber elements in the strength member. This introduces a number of requirements on the behavior of the strength member that affect the component's design and construction, as well as the mooring system's design as a whole. In particular, the total strain of copper wires and optical fibers must be kept very low, below 0.5% at the peak tensions experienced. Although this amount of strain is below the yield point of copper, it is not below the fatigue point, and after many cycles the copper strands will disintegrate. Optical fibers themselves, on the other hand, are fairly elastic, but cannot tolerate exposure to water for long-term use. The fibers are therefore typically encased in a very small diameter stainless-steel tube which acts as a one atmosphere pressure housing for the fiber. However, 0.5% is about the yield point of this tube and once yielded, relaxation of the cable causes the steel tube to kink and fail. There are a range of approaches to housing optical fibers for long-term at-sea use, but all rely on techniques that limit the allowable strain of the assembly.

There are two cable designs that address this low strain requirement. Traditionally, electromechanical cables are of a center conductor core. In this design contra-helical layers of the strength member (high-performance synthetic material or steel) are spiraled around a core consisting of the electrical and/or optical conductors (Fig. 40.4). The cable manufacturing industry has extensive experience with this construction technique from acoustic tow cables and remotely operated vehicle tethers. Unfortunately, this arrangement does little to alleviate the strain in the conductors relative to the strain in the entire cable. For mooring applications, the cables tend to become heavily overbuilt in terms of ultimate strength in order to limit the conductor strains.

An alternative approach is a center-strength-member construction in which the conductors are spiraled around a strength member (Fig. 40.5). In this design, the larger pitch diameter of the conductors provides an opportunity to introduce considerably less strain to the conductors relative to the overall strain of the cable. If the pitch of the spiraled conductors is matched to the diameter reduction of the center strength member under tension, low strains in the conductors can be realized in a cable that maintains high elasticity compared to center conductor core approaches [40.15]. While conceptually appealing, there have been challenges to implementing this type of design related to the terminations, in which a transition from high elasticity in the cable to zero elasticity in the termination must be managed. Although the designs aim for zero strain in the conductors, it is generally impossible to achieve this in practice, and even small amounts of stress in the outer helix of copper can compromise the torque balance of the cable. Compared to center-conductor core cables there is much less experience building this type of design in the cable industry, and some trial and error should be expected. Additionally, in this design approach the conductors are on the outside of the cable, in harm's way, and must be suitably protected during installation and maintenance.

For passing electrical conductors through short lengths that do not require compliance, techniques involving chains encased in polyurethane with the electrical conductors have proven reliable [40.16]. The high axial stiffness of the chain relieves all significant strain from the conductors, and the polyurethane stiffens the assembly to reduce strain due to bending. This technique is typically too heavy for extended lengths, but is useful for transition elements and below surface buoys.

Elastic Hoses and Cords

In cases where the traditional methods of providing mooring compliance are insufficient, specialty elements that stretch hundreds of percent at working loads can be included. There are two main applications of this. The first are very shallow moorings in which a chain-catenary mooring is not an option. The other are deep-water moorings that require a stiff electro-optical-

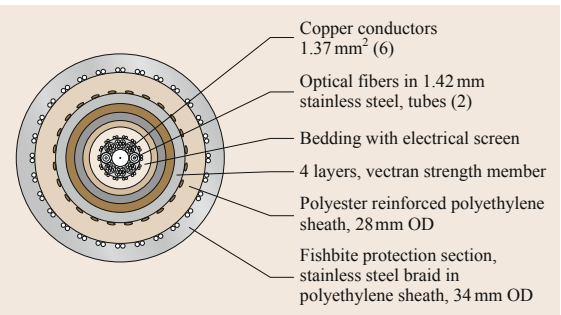

Fig. 40.4 Center conductor cable

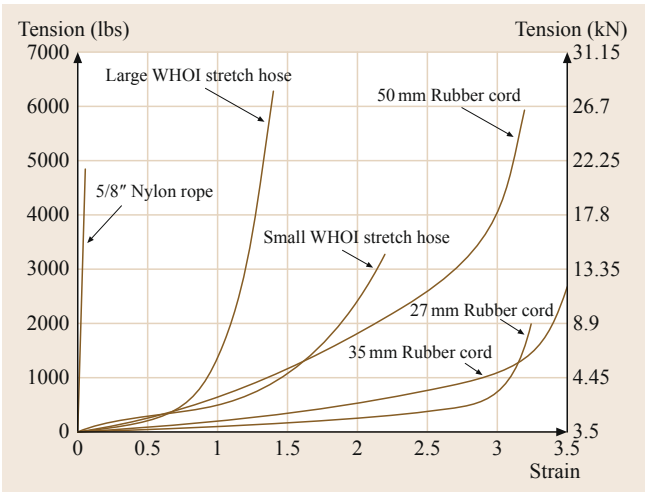

Fig. 40.7 Stress–strain behavior of various typical elastic elements, nylon rope shown for comparison

mechanical cable that does not supply enough compliance even in an inverse-catenary arrangement.

In cases where it is desired that subsurface instrumentation be isolated from surface-buoy-induced wave-motions, the high elasticity of these elements can perform this role provided that the subsurface instrumentation has sufficient mass to avoid being moved around. In the typical arrangement of buoy, stretch-hose, and then instrumentation, a trade-off appears between the tensions in the stretch hose and the amount of motion isolation achieved. This trade-off is dictated by the instrumentation mass: a very massive subsea element will be well isolated by the stretch-hose, but the tensions and elongation of the stretch hose will have a large amplitude.

The two main constructions of these kinds of elements are solid rubber cords with an external extension limiter and a more sophisticated reinforced rubber hose that includes nylon cords that gradually begin to take the load and reduce the elasticity of the element as the hose is stretched. In the latter case, it is possible to include electrical and optical conductors in the hose-wall layout at a neutral stretch angle, providing a durable power and data connection in an elastic component. This design has been used quite successfully. In addition to providing a conductor path, the durability of the rubber hose stands up well to the often difficult environment below the surface buoy [40.17] (Fig. 40.6).

Table 40.2 outlines typical mechanical properties of these stretch-hose elements. The elastic behavior of these components is far from linear however, and an estimate of the stress–strain curve needs to be included in any mooring modeling work that is performed. Figure 40.7 presents the stress–strain curve for a variety of typical elastic elements and shows the typically very soft behavior at low tensions and the gradual stiffening as the component is stretched. In all cases, these elements are designed to stiffen up as they extend and the stress strain curve becomes nearly vertical beyond what is shown. The WHOI stretch hoses accomplish this by including nylon cords in the rubber hose lay-up that bear more and more load at higher extensions. The rubber cords shown in [40.18] include an external safety line that takes over at extensions greater than about $\Delta L/L = 3$.

40.2.2 Terminations and Strain Relief

Terminations of wire-rope are typically a swaged type in which a metal socket is deformed onto and around the wire-rope using appropriate dies. A less common approach is a poured socket in which the wire-strands are spread out into a cone-shaped socket and a hard polyurethane resin is poured into the socket to lock the wires in place. In this approach, careful de-greasing and preparation of the wires and socket is required to develop the full strength, which can be nearly 100% of the breaking strength of the wire-rope. For synthetic ropes, splicing techniques specific to each material and rope construction are used. Termination of electro-optical-mechanical cables depends highly on the construction of the cable, center-conductor-core cables usually have the strength member arranged in contra-helical layers and in this case poured sockets are used similar to those used for wire-ropes. The center-strength-member cables that have been built have had a braided core which is terminated in a splice after the conductors are peeled off the outside. In these designs, it can be challenging to manage the transition from the elastic portion of the cable to the necessarily rigid termination.

In all cases, bending strain reliefs are very important elements of mooring systems. Abrupt changes in material properties along the mooring string can lead to ex-

acerbated motions and repetitive strains. Polyurethane bending strain reliefs can be designed to maintain a minimum bend radius cross the range of expected bending moments. Standard and proven solutions exist for common wire-rope terminations, but are typically engineered specifically for custom EOM cables. Where shackles and chains are included, the requirements on the bending strain reliefs are less stringent because these elements are incapable of supporting significant moments.

40.2.3 Buoys and Floats

Surface Buoys

For surface buoys, there are two main construction techniques: a closed-cell foam construction to which required towers, bridles, and instrumentation are attached; and a hull-like construction of steel, aluminum, fiberglass, or molded polyethylene. A common foam material is a foamed ionomer resin that is a thermoplastic polymer produced by DuPont [40.19]. This material is a closed-cell foam with a density of less than 10% that of water. Although very tough and durable, this material does have some compressibility, so it is only useful on or near the surface. Tests of this material's compressibility and water absorption have been done, and a relatively high variability due to construction technique was found [40.20].

Hull-like constructions for surface buoys can provide significant interior volumes for instrumentation and payload but suffer catastrophic failure in the case of a hull breach. Nevertheless, many buoys have been built and deployed in this manner; with suitable coatings, maintenance, and corrosion protection, steel and aluminum buoy hulls have been very reliable but expensive to maintain. Fiberglass hulls are less common, but provide higher performance from the point of view of weight-to-buoyancy ratio. Hybrid approaches have also been pursued with success for several decades in which lightweight nonstructural expanding foam is poured into a hull cavity.

There are few standards in buoy design aside from the relatively few organizations that deploy and maintain many buoys such as weather service buoys and navigation buoys. Typically, buoy designs are customized for specific applications and designer preferences. Critical parameters that must be considered in all designs such as stability, reserve buoyancy, and resonant behavior are discussed below.

Subsurface Flotation

For subsurface flotation such as that used to support an inverse-catenary mooring design, or provide recovery buoyancy for the anchor end of a mooring string, the critical parameters are material mean density and depth rating. The two primary types include pressure vessels that maintain a low-pressure interior volume and syntactic foam materials that typically consist of microspheres as flotation, bound together with an epoxy or polyester resin. For flotation purposes, evacuated volumes are almost always spherical in nature because of the efficiency of that shape as a pressure vessel. Materials used range from plastics for shallow-water applications, steel for moderate-depth applications, and glass-spheres for very deep applications. It should be remembered that in all cases, a submerged evacuated volume can represent an enormous amount of potential energy that can be released in an implosive manner in the case of failure. In one case of an imploding carbon-fiber electronics housing on an ROV at a depth of 1000 m, nearly all of the surrounding aluminum pressure vessels were deformed to the point at which the O-ring mating surfaces were out of specification and the housings needed to be replaced. For this reason, manned submersibles typically will not operate around this type of flotation, and this needs to be considered in mooring applications that include servicing by ROV or manned submersible.

An alternative to evacuated volumes for subsurface flotation is syntactic foam. This material is typically lower performance (higher density at a given depth rating) than evacuated glass spheres but can be engineered to the exact depth requirement of the system, can be formed or machined into just about any shape, and does not present an implosion hazard.

Table 40.3 compares the characteristics of a range of typical flotation used in small mooring systems.

40.2.4 Hardware

Hardware in small mooring systems usually consists of galvanized low-carbon anchor-bolt shackles, pearlinks, and rings. Table 40.4 contains a summary of typical mechanical properties for these components. Stainless steel is often used when low magnetic influence is required, but stress and crevice corrosion issues need to be considered. Fatigue issues are also important in specifying hardware components. For steel, the fatigue limit is about 50% of the ultimate tensile strength; if all stresses in a component are kept below this level, essentially infinite life is achieved. Manufacturers of shackles and similar components often specify a breaking strength and a safe working load. When the component is intended for overhead lifting, this safe working load includes a five times safety factor, putting the stresses in the component well below the fatigue limit. So adhering to this type of working load specification is one way to address fatigue. For custom elements such as instrument cages that also act as a load path,

more careful fatigue engineering should be performed with attention to stress concentrations and weld heat affected zones. In cases where weight is critical, heat treating, shot peening, and other surface treatments may be appropriate.

40.2.5 Anchors

Dead-weight drag embedment anchors are the most common types of anchor systems used in small buoy and mooring systems. In all cases the nature of the mooring design and conditions on the seafloor affect the anchor selection.

Deadweight anchors rely on their own weight to stay in contact with the seafloor, and the resulting friction to resist horizontal motions. Used train wheels are a popular source of steel anchor material, and when stacked and welded assume a mushroom shape which can significantly increase the anchors' ability to resist movement when the mushroom shape becomes buried. Purpose built steel and concrete pyramid anchors are also available and behave similarly. Key features to dig into the seafloor are sometimes included to increase a deadweight anchors capacity in cases where it is unlikely to become buried. The amount of lateral resistance a given anchor will provide depends highly on the nature of the seafloor. When this is unknown as is often the case for buoys deployed in remote locations, it is necessary to include significant factors of safety in determining the anchor weight.

Chain-catenary moorings with sufficient chain on the seafloor can often use embedment anchors of moderate size. Because these moorings are almost always single-point moorings, the nature of the weather and current conditions affect the suitability of embedment anchors. Changing load directions can pull the anchor from the seafloor. However, the light weight of this type of anchor makes them attractive for ease of deployment and recovery.

The numerical mooring analysis techniques described below in Sect. 40.3.4 usually result in a time history of the anchor loads and direction in various sea conditions. This is a useful information in sizing any anchor system and is a key output of most analyses.

More and more attention is being paid to the effect on the seafloor of mooring systems and many marine sanctuaries require trawl-resistant anchor designs for anchors that are left behind, or are mandating complete recovery of anchors which introduces additional design challenges.

40.2.6 Acoustic Releases

An important component in many mooring systems is an acoustically activated release located near the anchor. This device allows the mooring string to be released from the anchor for recovery, significantly reducing the lifting capacity required on the vessel. This technique leaves the anchor behind on the seafloor. In this scenario, recovery buoyancy above the acoustic release is required, which can unfortunately impact the anchor size requirements since this buoyancy works directly against the weight of the anchor during service. In some cases, an acoustically triggered line-pack with flotation is also included in the system, allowing the anchor to be recovered separately from the mooring string. Table 40.5 includes the properties and specifications of a number of commonly used acoustic release systems.

To reduce the ships lifting capacity requirements, typically moorings with acoustic releases are deployed using an *anchor-last* method in which the anchor is pushed off the ship's deck and allowed to free-fall to the seafloor after the buoy and mooring string have been placed in the water. The load on the mooring string is necessarily less than the anchor weight during this operation. The rapid deceleration of the anchor when it hits the seafloor raises the possibility that an acoustic release or other component just above the anchor could hit the anchor and be damaged. In practice, the mooring string during an anchor-last deployment has a high drag-to-inertia ratio and comes to a rest very quickly after the anchor touches down.

40.3 Analysis Techniques

Once the buoy size and shape, installation depth, mooring type, and environmental conditions for a buoy system have been identified, analysis of the system's behavior can proceed. Typically three levels of complexity are considered. The first is the system's static response to wind and current loading, and buoy pitch/roll stability. This analysis of the buoy and proposed mooring design helps determine if the system has sufficient buoyancy and stability for operation.

The second is a frequency domain analysis of the buoy's response to wave-forcing. The dynamics of the freely floating buoy are much simpler to analyze than the coupled buoy/mooring system, and some important insights can be gained. Although the buoy dynamics are modified by the existence of the mooring line, the buoy-only analysis provides a good general guideline to the buoy's behavior and a starting point for analyzing the more complicated buoy/mooring system.

This dynamic behavior is important to consider in the design so that the final system responds safely to wave forcing and does not exhibit resonance behaviors that could cause damage. Linearized frequency domain analysis provides an estimate of these behaviors but becomes progressively less useful in deep-water systems in which the behaviors of the mooring system begin to dominate the buoy dynamics.

Finally, nonlinear analysis of the coupled mooring–buoy system provides the most accurate prediction of system behavior in any given wind, wave, and current condition. These systems are nonlinear, however, so it is required that this analysis be performed through numerical solution of the governing differential equations. And as a nonlinear system, each environmental condition must be examined individually. This can be time-consuming and expensive to cover the entire range of possible conditions a system may see in service. For instance, a system may behave very differently in large waves and low currents, versus the same large waves in high currents. As such, a given mooring system analysis typically includes a matrix of analysis in low-, medium-, and high-current environments and in moderate, rough, and severe wave conditions. Typically it is assumed that wind forcing and wave forcing are correlated. Even this matrix of nine conditions still leaves a lot of ground unexamined; for instance, in some locations, currents run against the prevailing storm conditions at some times, and with the waves at other times. Therefore, knowledge of the deployment location or the mooring system's sensitivities impacts which conditions are analyzed.

A range of numerical tools have been developed to do this and are described below. Both open source and commercially produced solutions are available. These tools should be applied whenever a buoy and mooring design strays too far from existing proven designs, or when the design requirements of the system require that safety margins in stability and peak loads be reduced. Although it is rare to be able to validate the results of these tools with field measurements, this has been done occasionally [40.29, 30] and decent agreement has been found. In any case numerical analysis can provide good comparative analysis between variations on a given design, and sensitivity analyses are often performed to optimize a given design.

In all cases, analysis provides guidance on the loads that a particular system will experience in service. The factor of safety that is then applied to these estimates for design purposes is highly variable and depends upon the confidence the designer has in the model inputs (environmental conditions), the fatigue strength characteristics of the materials used, the need to reuse components for subsequent deployments, the planned lifetime of the system, the amount of control the designer has over the operation and maintenance of the system, and the tolerance for additional weight and cost in the system.

40.3.1 Environmental Conditions

Characterization of the ocean environment is covered in detail in Chap. 35 and those techniques are used directly in the buoy/mooring analysis described below. In general, three environmental factors are important: wind, waves, and currents. The wind climatology at any given spot in the ocean is probably the most well characterized due to the existence of scatterometer satellite measurements that have been ongoing for several decades [40.31, 32]. The wave environment also needs to be known; ideally the wave climatology can be estimated from time-series measurements of nearby wave-measurement buoys. This requires that such a system is in place, and that a sufficient time history is present to reliably estimate the return period of severe conditions. When these measurements are not available, this data can be estimated from global wave models such as WAVEWATCH III [40.33]. Commercial companies exist that will aggregate available data and provide the expected wave climatology at a particular location, which can be very convenient. Current behaviors at a particular location are the most problematic in that little data typically exists, and the current profile can have significant impact on a mooring system's behavior. Time histories of global surface current measurements made by satellites over many years are available [40.34], but these measurements are limited to the movement of the surface water. Knowledge of the subsurface current profile typically requires direct measurements using Acoustic Doppler Current Profiling (ADCP) technology or discrete current sensors [40.35] and is often not available. In the worst case, the designer of a system must make assumptions about the current profile throughout the water column and it is typical to analyze a range of possibilities; a *slab* current condition in which the entire water column is moving at the same speed, this is only likely to occur in practice in shallow conditions. Other possibilities are a linearly decaying current from the surface to the bottom, or to some depth in the water column. Uncertainty in the current profile magnitude and shape is often the largest uncertainty that a mooring designer faces.

40.3.2 Static Analysis

There are two main elements of the static analysis of a mooring system. The first is the initial stability of the surface buoy itself in which the weight and bal-

ance of the system is considered and the stability of the system is examined. These characteristics can be computed analytically from knowledge of the shape and mass distribution of the buoy. The second is the mooring strings behavior in a range of constant wind and current loading and this must be computed numerically in most cases. This result includes a computation of the mooring strings position and tensions, along with the current and wind loading that would cause the buoy to submerge.

Stability

For buoys that are always on the sea surface, stability in heave is provided by the presence of the water plane. Deeper submergence of the buoy creates an increase in buoyancy so the buoy will rest at a stable equilibrium at all times. The static draft of a freely floating buoy is found by simply equating the weight of the buoy to the buoyancy force, which increases as the buoy is further submerged. Additional vertical forces such as the mooring-line tension will change the draft. Buoy systems are typically designed with a buoyancy reserve of 100% or more; that is, the force required to submerge the buoy entirely is greater than twice the weight of the buoy plus the minimum static mooring load. The amount of reserve buoyancy implemented in a system depends on the mooring type, and expected variation in static loads (winds and currents), peak dynamic loading, and the consequences of having the buoy submerge in extreme conditions.

It is useful to compute the force required to increase the buoy draft. This parameter gives an indication of buoy sensitivity to added payload or weight gain due to bio-fouling. For a cylindrical wall-sided buoy this is

$$\frac{\delta F}{\delta d} = A_{\mathrm{wp}}\rho \mathrm{g} = \frac{\rho \mathrm{g}\pi D^2}{4} \qquad \left(\frac{F}{L}\right) . \tag{40.1}$$

For pitch and roll stability, the buoy is characterized by the well-known metacentric height which includes the righting moment contribution from the water-plane area as a modification of the distance between the center of gravity height above the keel $\overline{\mathrm{KG}}$ and the center of buoyancy height above the keel $\overline{\mathrm{KB}}$. See Fig. 40.8. It is the contribution of the water plane that allows floating objects to remain right-side up in spite of having a center of gravity above the waterline. The metacentric height $\overline{\mathrm{GM}}$ is computed as follows for the case of a freely floating buoy without mooring-line tension,

$$\overline{\mathrm{GM}} = \overline{\mathrm{KB}} - \overline{\mathrm{KG}} + \frac{I_{\mathrm{wp}}}{\nabla} , \tag{40.2}$$

where I_{wp} is the second moment of area of the buoy water plane and ∇ is the buoy displacement. When $\overline{\mathrm{GM}}$ is negative, the system will not be stable in pitch/roll and will heel or capsize in even the calmest seas. For wall-sided buoys of cylindrical geometry, this expression becomes

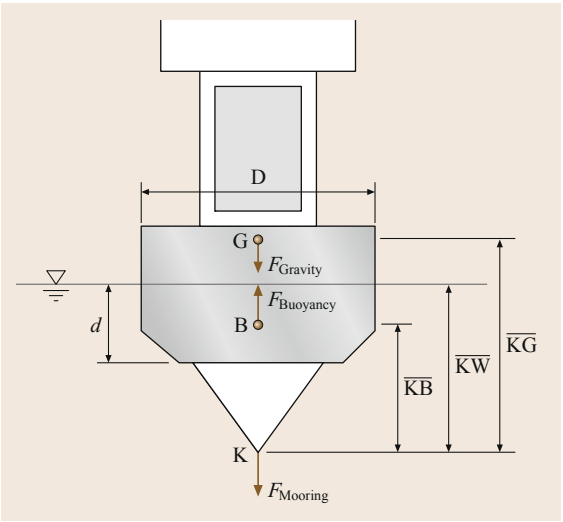

Fig. 40.8 Buoy schematic showing important dimensions for stability calculations

$$\overline{\mathrm{GM}} = \frac{d}{2} + \frac{D^2}{16d} - \overline{\mathrm{KG}} , \tag{40.3}$$

where d and D is the buoy draft and diameter, respectively.

A first-order correction to this expression can be made that incorporates the effect of the mooring-line tension by assuming that the mooring line exerts a vertical force at the keel of the buoy. For this purpose the magnitude of the mooring-line tension can be selected as the weight of the mooring string supported by the buoy. This is the minimum average tension the mooring line can exert. Any current or wind loading increases the tension from there (and introduces a lateral force and heeling moment to the buoy). The inclusion of this force (T) introduces a righting moment to the buoy and increases $\overline{\mathrm{KB}}$ but decreases the righting moment contribution of the water-plane area by increasing the buoy displacement. For wall-sided buoys, the modified meta-centric height expression in terms of $\overline{\mathrm{GM}}$ from the freely floating case is

$$\overline{\mathrm{GM}}' = \overline{\mathrm{KB}} + \frac{\delta\nabla}{2A_{\mathrm{wp}}} + \frac{I_{\mathrm{wp}} - \overline{\mathrm{KG}}\nabla}{\nabla + \delta\nabla} , \tag{40.4}$$

where A_{wp} is the buoy water-plane area and $\delta\nabla$ is the displacement increase due to the mooring-line tension ($\delta\nabla = T/\rho \mathrm{g}$).

This expression can be expanded for small values of $\delta\nabla/\nabla$ to provide insight into how the static mooring-line tensions will affect the buoy stability,

$$\overline{\mathrm{GM}}' \approx \overline{\mathrm{GM}} + \frac{\delta\nabla}{2A_{\mathrm{wp}}} + \frac{\delta\nabla}{\nabla}\left[\overline{\mathrm{KG}} - \frac{I_{\mathrm{wp}}}{\nabla}\right] . \quad (40.5)$$

From this it is clear that the mooring-line tensions have a larger stabilizing effect when the distance from the attachment point is far from the center of gravity (large $\overline{\mathrm{KG}}$), and when the buoy has a small waterplane area and waterplane moment of area. In other words, mooring-line tensions provide a relatively larger stabilizing effect to intermediate aspect ratio buoys than to discus buoys.

Mooring-Static Tensions and Draft

Prediction of the mean position (draft and heel) of a buoy based on current and wind loading is a nonlinear problem and so is less straightforward. Analytical solutions for simplified catenary situations exist but typically numerical solutions are used to predict this behavior. The numerical tools described below include facilities to compute the buoy systems response to constant wind and current loading, and this is usually the first step of the dynamic analysis to provide an initial condition for the dynamic simulation. The numerical simulations can also include point loading in the mooring string and other discontinuities in the material properties and loadings, which is typically not possible in analytical solutions.

40.3.3 Frequency Domain Analysis

The dynamics of the buoy itself can be predicted by equating the sum of forces acting on the buoy to the product of the acceleration and inertia. The simplest case of this analysis relies on assumptions that all forces vary linearly with wave-height and period, which is generally true for long-period waves. The appropriateness of this assumption deteriorates as the wavelengths get shorter (and collapses completely when the waves begin to break), but useful insights from this type of analysis are still possible. Again the two relevant modes of motion are the heave behavior and the pitch motions. This section presents an analysis of the buoys linearized response in the frequency domain and is most relevant to the freely floating buoy case. Non-linear numerical analysis techniques that predict the behavior of the coupled buoy–mooring system are described in the next section.

Response Amplitude

Figure 40.1 shows response amplitude operators for a range of mooring aspect ratios in the freely floating condition. These are examples of typical small moorings and highlight the important feature of resonant behavior due to the interaction of the buoys inertia and hydrostatic restoring force. For high-aspect ratio buoys the heave resonance can be dramatic; for lower aspect ratios this resonance is less pronounced but does mark the frequency at which the buoy motions transition from following the sea-surface to not reacting to the wave excitation. This section outlines how these response curves are generated and provides tools to compute the freely floating response of simple buoy shapes.

For linearized frequency domain analysis, the fundamental assumption is that all motions and forces oscillate at the same frequency as the incoming waves, and that a system's behavior in the presence of many wave frequencies is the sum of its behavior in each individual frequency. Under these assumptions, the differential equations of motion become algebraic equations that are simply solved. To accomplish this, each varying quantity is represented by a complex amplitude which represents the amplitude and phase of the sinusoidal motion. For instance, the complex response amplitude in heave is

$$\begin{aligned} z_3(\omega, t) &= Re\left[Z_3 \mathrm{e}^{\mathrm{i}\omega t}\right] \\ &= Re[Z_3]\cos(\omega t) - Im[Z_3]\sin(\omega t) \\ &= |Z_3|\cos\left(\omega t + \arctan\left(\frac{Im[Z_3]}{Re[Z_3]}\right)\right) . \end{aligned} \quad (40.6)$$

For heave, the solution of the equations of motion is

$$Z_3(\omega) = \frac{X_3(\omega)}{-\omega^2(a_{33}(\omega) + M) + \mathrm{i}\omega b_{33}(\omega) + \rho g A_{\mathrm{wp}}} , \quad (40.7)$$

where X_3 is the complex amplitude of the wave exciting force acting on the buoy, a_{33} is the heave added mass, b_{33} is the heave wave damping, M is the buoys mass, and $\rho g A_{\mathrm{wp}}$ is the buoyancy restoring force, written for cylindrical wall-sided buoys in (40.1). The hydrodynamic coefficients (X_3, a_{33}, and b_{33}) depend upon the geometry of the submerged part of the buoy and are functions of ω, while $\rho g A_{\mathrm{wp}}$ and M are constants for a given buoy and independent of frequency [40.36].

For pitch motions, the mass distribution within the buoy becomes important and is incorporated into the solution for the pitch dynamics in the form of the moment of inertia of the buoy in pitch I_5,

$$Z_5(\omega) = \frac{X_5(\omega)}{-\omega^2(a_{55}(\omega) + I_5) + \mathrm{i}\omega b_{55}(\omega) + mg\overline{\overline{\mathrm{GM}}}} . \quad (40.8)$$

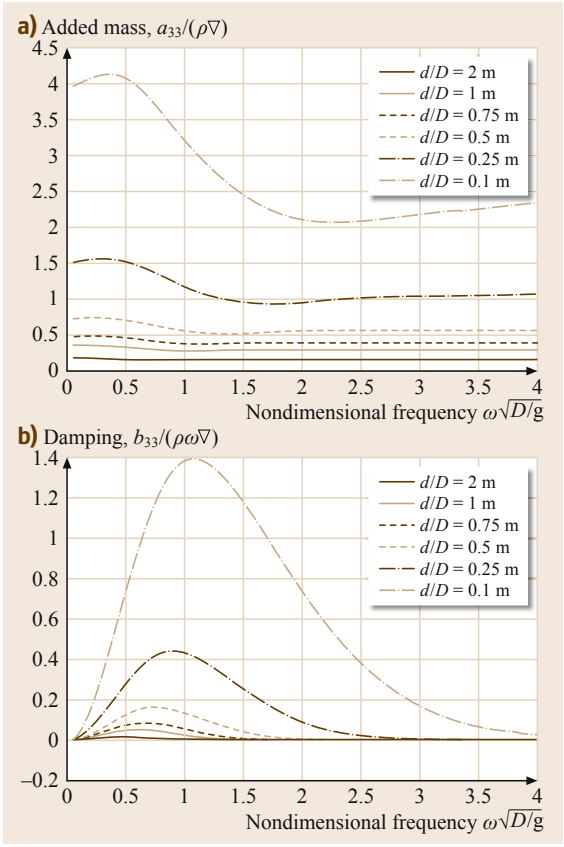

Fig. 40.9a,b Nondimensionalized heave hydrodynamics for cylindrical buoys

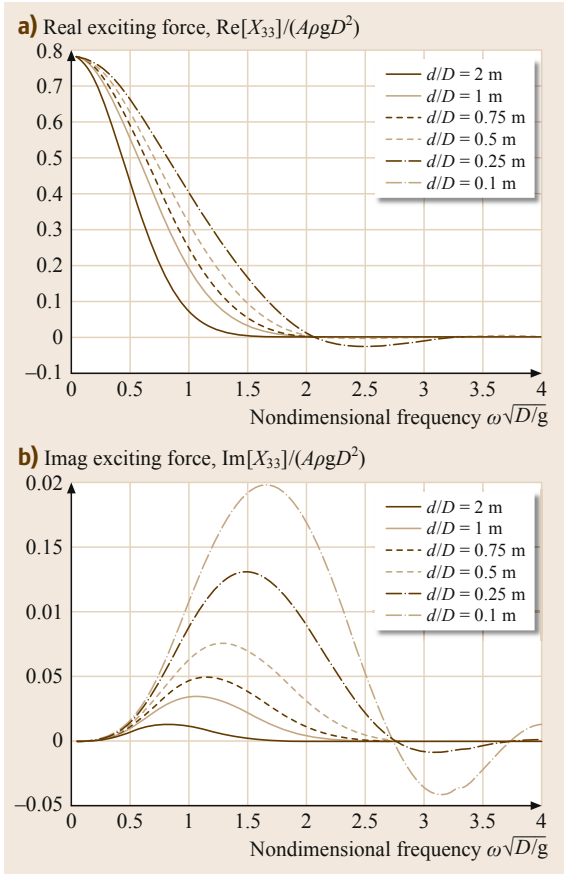

Fig. 40.10a,b Nondimensionalized heave wave-exciting forces for cylindrical buoys

For pitch motions, the hydrostatic restoring force is characterized by the metacentric height ($\overline{\mathrm{GM}}$).

If the hydrodynamic coefficients of the buoy are known, along with the mass and size of the buoy, the motions can be fully characterized using (40.7) and (40.8). The response amplitude operator is the magnitude of Z_3 per unit amplitude of the incoming waves A. For pitch, the RAO is typically defined as the magnitude of the pitch angle relative to the slope of the incoming waves ($\frac{|Z_5|}{A\omega^2}$).

Computing the hydrodynamic coefficients can be done analytically for simple shapes [40.37, 38] or numerically for more complicated shapes [40.39]. For cylindrical buoy shapes of various aspect ratios, the necessary hydrodynamic coefficients are presented in Figs. 40.9–40.12. In order to reduce the number of coefficients presented, frequency has been nondimensionalized by the buoy diameter and gravity ($\sqrt{D/g}$). For convenience, Fig. 40.13 can be used to relate nondimensional frequency to wave period for a range of buoy sizes.

These results are valid for freely floating bodies, but a first-order correction that includes the mean mooring tension is simple to generate by using hydrodynamic coefficients that represent the resulting deeper draft. For the pitch result the metacentric height also needs to be replaced with the modified metacentric height $\overline{\mathrm{GM}}'$ from (40.5). Note that in applying this correction, the buoy mass M and moment of inertia I are unchanged from the freely floating case, even though the buoy has a larger displacement.

Resonance

Resonance in heave and pitch occur when the denominator of (40.7) and (40.8) are at a minimum, for example,

$$\omega_{\mathrm{n}}^{\mathrm{H}} = \sqrt{\frac{\rho g A_{\mathrm{wp}}}{(M + a_{33})}} \qquad (40.9)$$

and,

$$\omega_{\mathrm{n}}^{\mathrm{P}} = \sqrt{\frac{mg\overline{\mathrm{GM}}}{(I_{55} + a_{55})}}\,. \qquad (40.10)$$

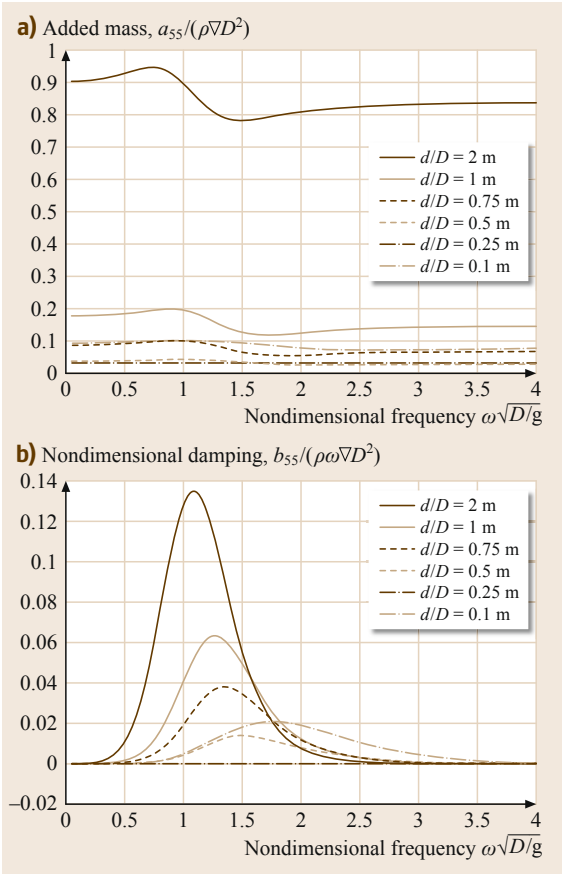

Fig. 40.11a,b Nondimensionalized pitch hydrodynamics for cylindrical buoys

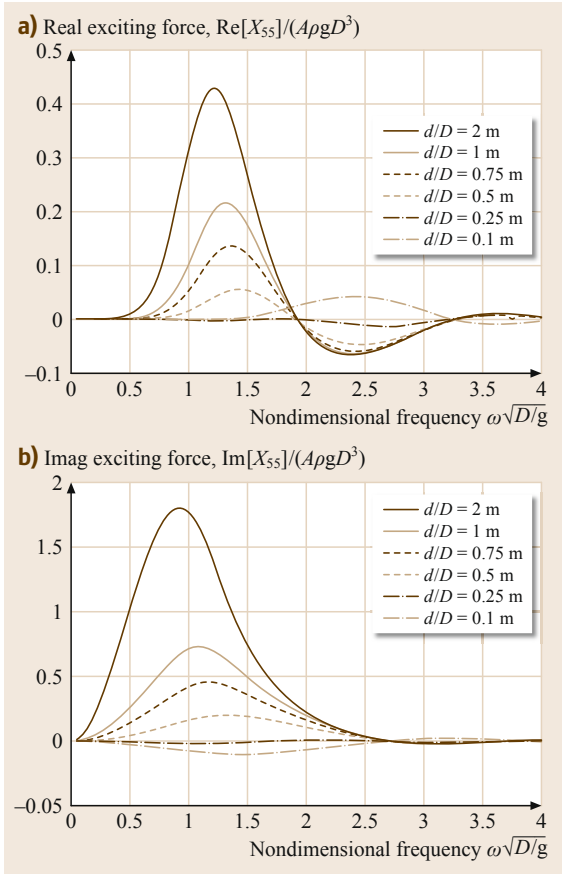

Fig. 40.12a,b Nondimensionalized pitch wave-exciting forces for cylindrical buoys

The magnitude of the resonance depends on the wave-exciting force and amount of damping at the resonance frequency.

$$\left|Z_3(\omega_n^H)\right| = \left|\frac{AX_3}{\omega_n^H b_{33}(\omega_n^H)}\right| , \tag{40.11}$$

$$\left|Z_5(\omega_n^P)\right| = \left|\frac{AX_5}{\omega_n^P b_{55}(\omega_n^P)}\right| . \tag{40.12}$$

The expressions for the natural frequency are implicit in frequency and depend on the hydrodynamic coefficients' dependence on frequency. Figure 40.14 presents the heave resonance frequency and amplitude for cylindrical buoy shapes of various aspect ratios, computed based on the hydrodynamic coefficients presented in Figs. 40.9 and 40.10.

40.3.4 Nonlinear Analysis

Although frequency-domain analysis provides some insight into the behavior of small buoy systems, the presence of the mooring generally cannot be ignored when predicting system behaviors in specific conditions. Figure 40.15 illustrates the system characteristics

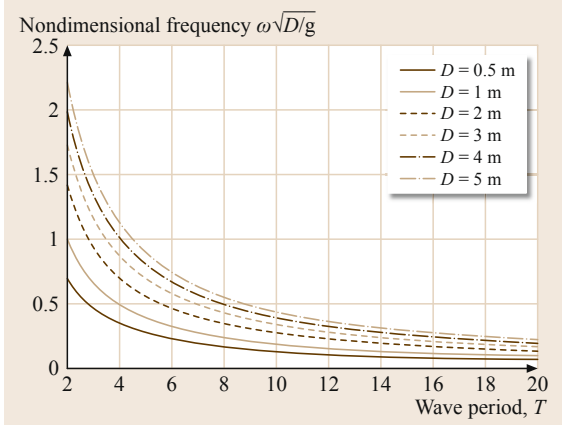

Fig. 40.13 Nondimensionalization wave frequency for different size buoy diameters

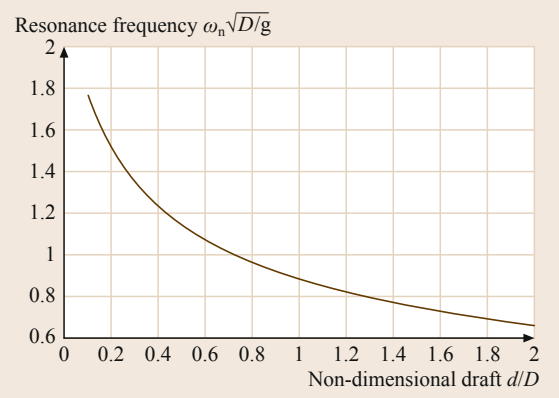

Fig. 40.14 Heave resonance-frequency of freely floating cylindrical buoys

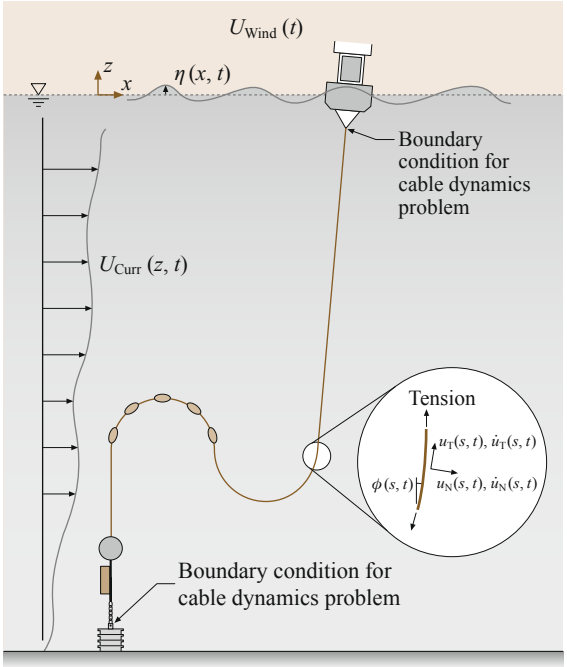

Fig. 40.15 Schematic of nonlinear mooring dynamics problem

and forcing inputs that are important. The three main environmental inputs are wind and wave forcing on the buoy and current forcing on the mooring. As in the frequency-domain analysis, the buoy is represented by its size, mass, and mass distribution. Additionally, a relation between the wind speed and resulting forces on the buoy is required (surface area and drag coefficient). The mooring characteristics that are required for this type of analysis are the mooring cable mass per unit length, hydrodynamic behavior, and constitutive relation that relates stress and strain. The hydrodynamic behavior is usually characterized as drag (force proportional to velocity squared) and added-mass (force proportional to acceleration) of the cable in the normal and tangential directions. The constitutive relations for the material are the stress/strain curve axially, and the moment/curvature relationship in bending. These are most simply represented as linear relations (EA and EI for linear constitutive relations axially and in bending). In some cases, such as the stretch hoses described above linear representation is inappropriate and the nonlinear relation such as those plotted in Fig. 40.7 should be used. Because the solution is being performed numerically, these nonlinearities (and the discontinuity that results when transitioning from material to another) does not introduce any fundamental problem.

The equations of motion governing the behavior of the mooring result from an application of Newton's second law ($F = ma$) in which the external forces are balanced with the inertial forces for each part of the system. A continuous representation of the equations of motion can be derived by applying this concept to each infinitesimal element of the system [40.40]. For solution, a discretized version of these equations is generated by utilizing finite difference techniques. In addition to providing a technique for numerical solution of the underlying continuous equations of motion, this approach can also accommodate lumped parameter representations of some elements. For instance, a common strategy is to represent the strength members as a finite-difference representation of the cable-dynamic equations, and then include the effect of items attached to the cable by simply increasing the mass, drag, weight, and buoyancy at appropriate nodes, such as where flotation or instruments are attached. In all cases, the unknowns that are solved for are the time histories along the cable of strain, shear force, inclination to vertical, and curvature. From these unknowns all quantities of interest can be found such as tension in the cable from the stress/strain relationship, and mooring line location from an integration of inclination, curvature and strain.

In the general problem the three main forces acting on the buoy and mooring (wind, wave, and currents) are time varying, requiring boundary conditions at the cables ends, and an initial condition for the state of the entire mooring. The boundary conditions can be simply provided as known points for each end versus time (such as at the anchor), or by coupling to the solution of the buoy dynamics equations of motion which are solved simultaneously. The initial condition is the solution of a version of the equations of motion in which the time-dependent terms are set to zero, and the wind, wave, and current forcing are constant (the only constant wave-forcing that is physically plausible is calm water). In addition to providing an initial condition for

the time-dependent solution, the static solution is very useful in its own right and provides the designer important information about the mooring geometry, static loads, and buoy draft as a function of currents and winds.

The mass, size, and hydrodynamic characteristics of all elements in the mooring system must be known or estimated. For cables and ropes, drag and added-mass coefficients equivalent to an infinitely long cylinder are appropriate for the normal motion. For the tangential direction the drag and added mass are much lower, but can be estimated to reflect the degree of smoothness the particular element possesses. For other components such as acoustic releases and flotation, tabulated data for drag coefficients of various items can be used [40.41].

Numerical Solution

The equations of motion described above can be reduced to a coupled set of nonlinear first-order differential equations. Solution of these equations can be performed in a number of ways, and all approaches are subject to the stability and accuracy concerns related to numerical analysis of such systems [40.42]. In some cases, discontinuities in the cable properties can cause problems due to limited precision in the numerical solution, so the computer codes must have strategies for dealing with these through adaptive grid or time-step refinement.

A variety of computer codes have been written to solve these problems, two examples are WHOI-Cable [40.40] and Orcaflex [40.43]. Although these two codes solve the cable dynamics equations motion in a similar way, the treatment of the buoy boundary condition differs.

WHOI-Cable focuses on the dynamics of the cable itself and simplifies the buoy-end boundary condition by assuming that the buoy is a pure wave-follower in heave, but is free to move laterally on the sea surface subject to the forces acting upon the buoy (mooring loads, hydrodynamic forces, and wind loading). For buoys of intermediate to low aspect ratio that have sufficient reserve buoyancy to always remain on the surface, this is a good assumption and simplifies the analysis. The user does not need to specify the mass distribution in the buoy, or determine the wave hydrodynamic coefficients for the floating body. The program does compute the buoy draft based upon the hydrostatic restoring force for the static solution, but then simply assigns the buoys vertical velocity to be the same as the wave's vertical velocity for the dynamic analysis. For this reason, this approach does not give a good idea of the time-varying buoy draft that results from wave forcing. While simple, this limitation precludes the accurate analysis of buoys with significant wave-hydrodynamic forces, or those that are designed to become submerged in large waves.

Orcaflex, on the other hand, has the capability to solve the coupled buoy/cable equations of motion. This requires the computation of the wave-hydrodynamic coefficients for the particular surface buoy under consideration. WAMIT is the tool most commonly used for this, although for simple shapes data from the literature is available (or Figs. 40.9–40.12 could be used for cylindrical buoys). The inclusion of the buoy equations of motion in the solution removes the assumption that the buoy is a wave-follower and more complicated situations including submerging buoys or wave-energy extracting buoys can be considered. In extreme cases of submerging buoys, the assumptions inherent in linearized wave hydrodynamics also break down and other (often heuristic) assumptions about the buoys behavior must be made.

These techniques typically do not have the capability to resolve vortex-induced vibrations and the resulting increase in drag on a mooring line. To do so would require solving for the local flow field around the rope or cable in conjunction with the cable motions. Although examining the Strouhal number for a given cable diameter and current speed does give some idea of the expected vortex-shedding frequency, it is not straightforward to identify the natural frequency of the cable in question. Practically speaking, vortex-induced vibration and the resulting *strumming* are commonly observed in high current regimes or during anchor-last deployment operations in which the mooring string is moving laterally through the water. The best that can be done for analysis is to include a multiplier on the drag coefficient of the cables.

40.4 Example Designs

As mentioned in the introduction, small buoy mooring systems have a long history and existing successful designs can provide an excellent starting point for designing new systems. This section provides descriptions of several systems that employ the components and features described above.

The literature also contains many examples of successful mooring design. In particular, the US Office of Naval Research/Marine Technology Society has initiated and sponsored a bi-annual Buoy Workshop, starting in 1996, intended to facilitate the exchange of technical information about small buoy/mooring sys-

tems. The proceedings from these meetings are an excellent source of solutions to the practical problems encountered in designing, building, and fielding these systems [40.44].

40.4.1 Chain-Catenary Mooring

Figure 40.16 illustrates a chain-catenary mooring design used in shallow water (72 m). The mooring has a scope of 1.5 and the section of chain that transitions off the seafloor is considerably heavier than the section which is connected to the anchor. The additional size in this section address increased wear and provides tension to the mooring string above. Instrumentation throughout the mooring string is battery operated and self-logging.

40.4.2 Auto-Detection Mooring

Figure 40.17 shows a semi-taut mooring design that utilizes a highly elastic element below the buoy to provide enough compliance in the design in relatively shallow water (144 m). A key requirement for this system is that it includes a quiet place to mount a hydrophone for passive acoustic applications such as the detection of whales in the area. Matching the inertia of the submerged sphere and the stretch-hose elasticity isolates much of the surface motion from the

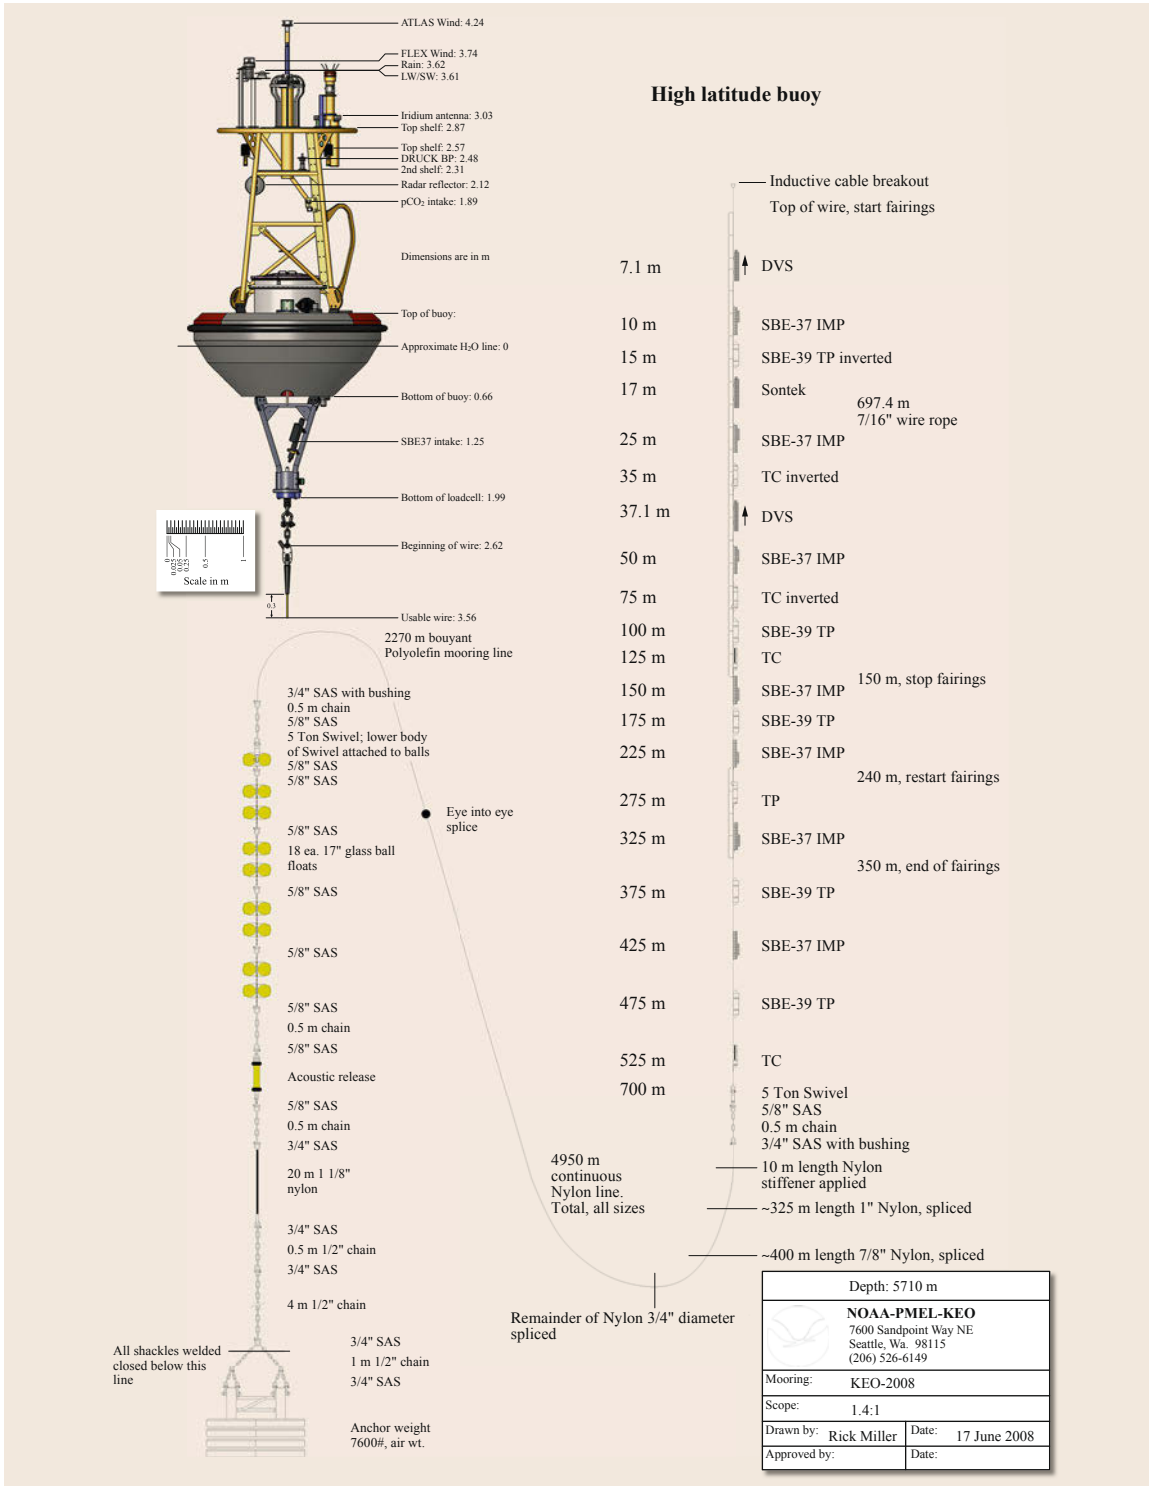

Fig. 40.18 Deep water inverse-catenary mooring utilizing nylon, polyolefin, and wire-rope strength materials (diagram courtesy of NOAA-PMEL)

lower part of the mooring, limiting flow-induced noise at the hydrophone. Additionally, the connections near the hydrophone and below the buoy are bolted flange connections, eliminating noise created by shackle connections in waves. Electrical conductors are helixed into the walls of the stretch hose at sufficient angle to reduce conductor strain to acceptable levels; these provide a power and data path between the buoy and the submerged hydrophone. This mooring was developed by WHOI [40.45, 46] and has been successfully deployed for many years; the stretch hoses have proven to be quite robust and are routinely reused for multiple year-long deployments without mechanical or electrical failure.

40.4.3 Deep-Water Mooring with Inductively Linked Instrumentation

Figure 40.18 illustrates a common oceanographic mooring design in deep water (5710 m). The inverse-catenary behavior is achieved by utilizing alternating sections of polyolefin and nylon rope and the mooring has a scope of 1.4. The buoy is a toroidal design, the behavior of this geometry is similar to that of a discus buoy due to its relatively large water-plane second moment of area to displacement ratio. The upper section of the mooring is jacketed wire-rope and includes inductively coupled instrumentation to monitor conditions throughout the water column. This system uses the seawater as a return-path for an conductive loop through the wire-rope. Data is inductively coupled onto the wire-rope at the top and at each instrument. Acoustic releases above the anchor facility recovery of this mooring which is deployed in an *anchor-last* fashion. Seventeen inch glass spheres above the release provide recovery buoyancy.

This mooring design is the result of iteration in which a failure of the nylon-rope section in a previous deployment of a similar system was addressed. A detailed report on the failure analysis and mitigation can be found in [40.29].

41. Liquefied Natural Gas Carriers

Krish P. Thiagarajan, Robert Seah

Global energy demand is rising as the world's population is growing. Various forecasts predict that by 2050, there could be 2.5 billion more humans than today, who would use twice the energy consumed today. Energy companies are examining all possible sources of energy as part of their widening portfolio.

Natural gas (NG) is an abundant resource that is still relatively a newer source for exploitation. With improving technology, NG can be an alternative fuel to generate electricity with operating costs comparable to coal or nuclear energy sources. Liquefaction of NG is an important part of the process, as liquefied natural gas (LNG) is compact and can be transported with special-purpose carrier vessels. Large offshore gas fields call for floating LNG (FLNG) terminals, which are capital and technology intensive. Various aspects of FLNG technology are being researched and developed currently. Notwithstanding this, companies are developing and deploying FLNG solutions based on past experience and proprietary technology. This chapter of the handbook deals with various aspects of LNG, design of carriers and especially the cargo holds, environmental and design challenges of these carriers and FLNG.

41.1 Types of LNG Carriers

Liquefied natural gas (LNG) is transported at a cryogenic temperature of −163 °C with an ullage pressure slightly above atmospheric. This requires that the vessel's LNG containment system should be designed to provide thermal isolation of the cargo to restrict boil-off and to provide thermal protection for hull steel against embrittlement by the cargo. Of course, with the cargo being a flammable product, the containment system also needs to isolate the contents from the atmosphere. These basic requirements make the maritime transport of LNG not a straightforward matter.

The first LNG vessel carried cargo from Lake Charles, Louisiana, to the Canvey Island, United Kingdom, in 1959, demonstrating the viability of maritime transport of LNG. This vessel, *The Methane Pioneer*, was a converted diesel powered cargo vessel and at 103 m (338 ft) length overall (LOA), had a capacity of just 5000 (5 K) m^3 of LNG carried in five independent aluminum prismatic tanks. As a prototype vessel, she made just seven trips and was renamed as the Aristotle in 1967. Interestingly, this vessel is noted to have imported LNG back into the United States when its cargo was offloaded in Boston in 1969. Based on the experience garnered by the Methane Pioneer, the first true purpose built commercial LNG carrier (LNGC), the Methane Princess and its sister vessel, the Methane

Fig. 41.1 Moss-type LNG carrier and portside ship-to-ship (STS) cargo transfer operations (courtesy of Hoegh LNG)

Progress, were constructed. These vessels gave birth to the LNG trade industry by delivering the first shipments from Algeria to UK in 1964. In contrast to the Methane Pioneer, the Methane Princess had a capacity of $27.4 \times 10^3\,m^3$ of LNG in nine Conch-type independent prismatic aluminum tanks.

Today, the largest LNG carriers are of the Qmax class, by Qatargas, with LOA of 345 m and a capacity of $266 \times 10^3\,m^3$. This is followed by the Qflex class of vessels with a LOA of 315 m and a capacity of $216 \times 10^3\,m^3$ of LNG at 100% fill. Standard LNG carriers have an average capacity of about $160 \times 10^3\,m^3$ and are likely to utilize a membrane containment system from Gaztransport and Technigaz (GTT). While there have been many developments and designs for the containment system in the prior decades since the Methane Pioneer, the vast majority of new and operating vessels use one of the following four containment system types: IHI-SPB self-supporting prismatic tanks, Kvaerner–Moss self-supporting spherical tanks (e.g., Fig.41.1), GTT's Technigaz Mark III membrane tanks, and GTT's Gaz Transport NO96 membrane tanks.

41.1.1 LNG Carrier Containment Systems

The purpose of the containment system is to prevent release of the cargo into the environment, minimize thermal ingress to reduce cargo boil-off as well as to protect the hull from the cryogenic temperatures of the cargo. All LNG carriers built on or after July 1986 are subject to the International Maritime Organization (IMO), international code for the construction, and equipment of ships carrying liquefied gases in bulk (IGC code). The code has several tank type definitions but categorizes the majority of LNG containment systems into just two main categories: membrane tank systems and independent self-supporting tanks.

Membrane Tank Systems

Membrane tank systems such as shown in Fig. 41.2 consist of two containment barriers, each formed by a metal membrane backed by an insulation layer. The ullage pressure in the tanks is maintained slightly above atmospheric pressure with the LNG at its phase-change temperature at this pressure. Boil-off is controlled by the thermal insulation and thus penetrations through the insulation have to be minimized. The two insulation spaces are maintained with a nitrogen gas environment which is monitored for the presence of natural gas as an indicator for loss of containment. In contrast to the self-supporting type, the membrane systems rely on the inner hull to provide structural strength and support to the primary and secondary barriers.

The popular NO96 system (Fig. 41.3) utilizes a 0.7 mm thick Invar film, a nickel alloy with very low thermal expansion rate, as the containment membrane. Plywood boxes, typically filled with perlite, act as the thermal insulation component as well as to provide support for the membrane and to transfer membrane stresses to the hull. The plywood boxes are reinforced with internal ribs to provide additional strength. Total insulation thickness is approximately 0.5 m. Two layers of the membrane–insulation combination are used to provide the primary and secondary containment required by the IGC code.

The Mark III system (Fig. 41.4) is similar to the NO96 system but uses a 1.2 mm thick stainless steel membrane atop a reinforced polyurethane (PU) foam insulation layer. Due to the thermal expansion properties of stainless steel, the Mark III primary barrier

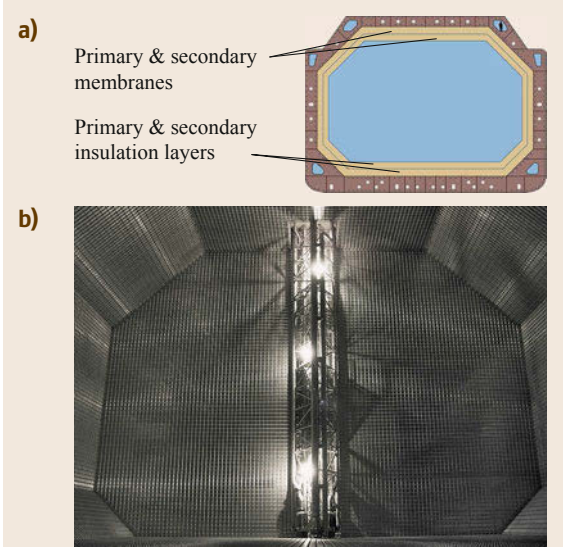

Fig. 41.2 (a) Membrane schematic and (b) pump tower @ GTT

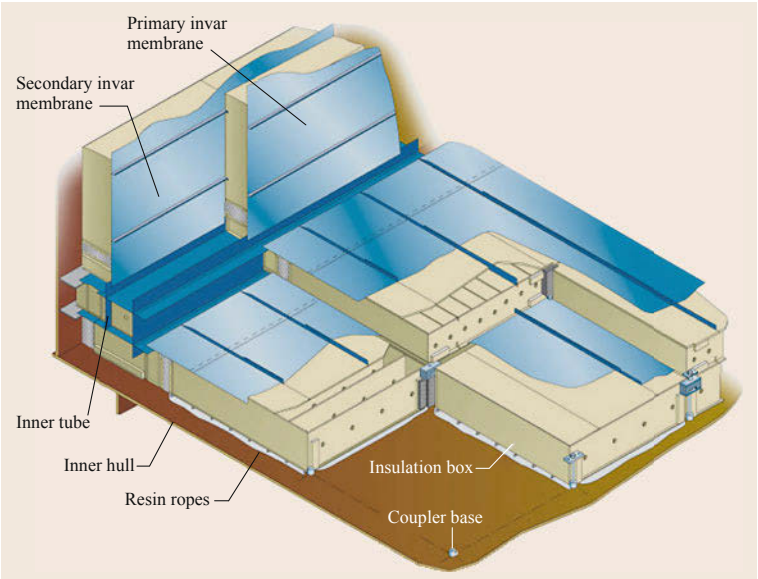

Fig. 41.3 NO96 containment system schematic (after [41.1])

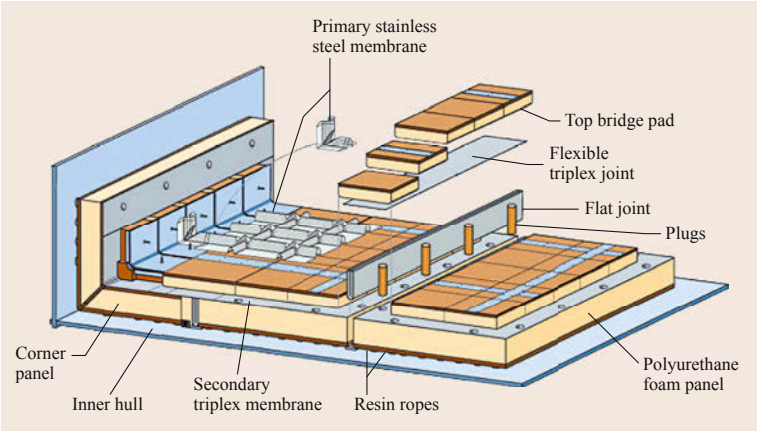

Fig. 41.4 Mark III containment system schematic (after [41.1])

incorporates a *waffle-like* system of corrugations to absorb the thermal expansion stresses. Insulation thickness for the Mark III system is approximately 0.3 m. For secondary containment, a different membrane, atop PU foam, composed of a composite laminate called Triplex is used instead.

GTT France also offers the CS1 membrane system (Fig. 41.5) which combines the features of the NO96 and Mark III system. The CS1 uses a primary membrane of Invar and the Triplex secondary composite membrane. Reinforced PU foam is used as the insulation layer with a total thickness of approximately 0.3 m.

Advantages. GTT's membrane containment systems, mostly NO96, have experienced a rapid rise in market share to become the dominant containment system deployed in new build carriers. One major advantage over competing designs is its cost efficiency. As the membrane systems rely on the hull for the structural strength, coupled with their compact design, they are able to maximize the storage capacity available for a given hull form. In addition, the costs of the membrane systems are relatively inexpensive, making the membrane systems the most cost-efficient containment system thus far. These systems also have a modular construction methodology enabling flexibility in construction and design. The low main deck profile not only reduces the windage area but also makes the membrane systems particular appealing for FLNG that require deck space for topside equipment.

Other operational advantages of the membrane design include quick cool down periods (low thermal capacity) during loading and hence quicker turnaround. Finally, GTT have licensed their design to a large

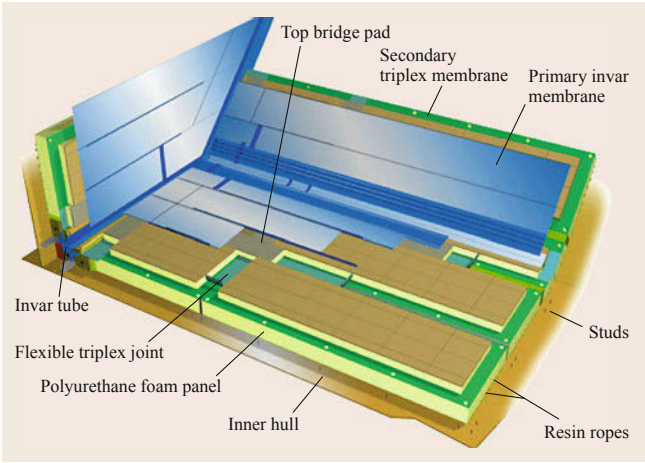

Fig. 41.5 CS1 containment system schematic (after [41.1])

number of shipyards, which has commercial flexibility advantages.

Disadvantages. The primary disadvantage of the membrane system is its apparent vulnerability to LNG sloshing induced damage. As the main load-bearing component is the hull itself, it is theoretically possible for the high-impact pressures induced by sloshing to locally damage the insulation or even breach the containment barrier. To mitigate this, the membrane tanks incorporate several design features. In Fig. 41.2, there are corner chamfers in the top 30% and bottom 10% of the tank height. The chamfering mitigates the impact of the LNG on the walls of the tanks at fill levels above 70% and below 10%. Consequently, the capacity of the tanks is reduced and most class societies require that the cargo level be either above 70% or below 10%. This fill restriction places limits on the ability of the LNG carrier to support spot market demands although this is somewhat mitigated by being able to shift cargo from tank to tank. The vulnerability to sloshing also places environmental limits on the vessels. Another mitigation measure is to reinforce the plywood insulation boxes for the NO96 system by increasing the number of internal plywood ribs in each box. This can be done selectively at tank locations most prone to sloshing impact damage, such as the tank ceiling for cost efficiency.

As the membrane system is attached to the inner hull of the vessel, the installation of the containment system is serialized with respect to the construction of the hull, that is, the installation of the containment systems can only commence after the inner hull is completed. Also, as a consequence of not having a void space between the tanks and the hull, inspection, and maintenance are inhibited.

Independent Self-Supporting Tanks

Independent self-supporting tanks, as the category name implies, are containment systems which are not part of the ship's hull and thus do not contribute to the strength of the hull. This category is further subdivided into types A, B, and C. Type A tanks are designed according to recognized standards or class rules and require a full secondary barrier. Examples of a type A tank are the aforementioned conch tanks. Type B tanks are designed using model tests and refined analysis methods and only require a partial secondary barrier. IHI-SPB and Kvaerner–Moss tanks are examples of type B tanks. Both type A and type B tanks have a design vapor pressure of less than 0.7 bar. In contrast, type C tanks are generally pressure vessels which require no additional secondary barriers.

The Moss–Rosenberg spherical LNG containment system (Fig. 41.6) was developed by Kvaerner in 1971. It consists of a steel tank cover, a PU foam insulated spherical aluminum (or 9% Ni steel) tank shell structure (primary barrier), a steel support skirt just below the equator of the sphere, a pipe tower, and a drip pan with splash walls (partial secondary barrier) below the shell. The tank loads, including weight, thermal and contraction stresses are transferred to the ship hull via the support skirt and hence the hull supports which the tanks sit on. The carrier is dual hulled and equipped with side ballast tanks. LNG leak detection is enabled by monitoring the atmosphere in the void space between the tank and hull as well as by temperature sensors monitoring the drip pan.

Advantages – Spherical

One significant advantage of the spherical tanks over the membrane tanks is the relatively low level of sloshing loads and hence do not have fill level restrictions or sloshing-related environmental restrictions that the membrane tanks are subjected to. It is hence favorable

Fig. 41.6 Moss–Rosenberg spherical LNG tank

for spot market LNG transactions. Also, in contrast to the membrane tanks, the spherical tanks can be built independently and later integrated with the hull resulting in flexibility in construction scheduling. As mentioned above, the resulting void space between the hull and tanks is monitored for the presence of methane for leak detection but also serves to provide access to the tank exterior (and hull interior) for inspection and repair, providing a greater sense of integrity. In the event of major damage, individual tanks can be replaced. Finally, due to the separation between the tank and hull, the tanks have a measure of protection in the event of a collision or grounding.

Disadvantages – Spherical

The disadvantage of the spherical tank is its space efficiency compared to prismatic tank forms. Further, due to the additional structural steel required for spherical tanks, these tanks are relatively heavy and costly when compared to membrane tanks and are thought to have led to its marked decrease in market share from its dominant position for LNG carriers several decades ago. The relatively higher structural weight per unit of cargo not only implies a greater unit cost but also incurs higher toll fees at the Suez canal which calculate fees according to the vessel's gross tonnage. The spherical geometry also leads to higher tank heights with increased wind loading. This is exacerbated when trying to layout process equipment around or above the tanks, as in an FLNG application. An increase in wind loading may give rise to seakeeping and resistance issues for LNGCs and stability or process efficiency issues for FLNGs.

In 1983, Ishikawajima–Harima heavy industries (IHI) introduced their SPB LNG tanks, first installed in two 87 000 m^3 LNGCs in 1993. SPB stands for self-supporting, prismatic IMO type B independent tank containment system, and an example is shown in Fig. 41.7. Like the Moss–Rosenberg spherical tanks it does not rely on the ship structure for strength. Instead, SPB tanks are distinctive in that they are constructed of Al-alloy (or 9% Ni steel) stiffened plate structures and are subdivided by a centerline liquid-tight bulkhead and swash bulkhead, giving the containment system relative high strength compared to the other systems. Each tank is insulated by PU foam and transfers loads via reinforced plywood supports to the inner bottom hull. In contrast to both membrane and Moss–Rosenberg systems, there is no pump tower or column. Instead, fill and discharge lines are supported by the girders and bulkheads.

Advantages – SPB

The SPB tanks share many of the advantages with both prismatic tanks and spherical tanks. Since SPB tanks are independent, like the Moss–Rosenberg tanks, they can be constructed in parallel with the hull as well. Note that even though these tanks are commonly referred to as *prismatic*, in actuality they conform closely to the hull form and the first bow tank is usually wedge shaped. This makes them particularly space efficient. Further, due to their strength there is no requirement for chamfered tank tops, and SPB tanks are known for their flush deck profile and low wind loading. This also makes them particularly suitable to layout process equipment atop the tanks, especially for FLNG applications and advantageous for maneuvering. Sloshing is not a concern for SPB tanks due to their stiffened plate structure. The internal stiffeners act as baffles to limit the extent and coherence of sloshing loads within the tanks. Thus, SPB tanks do not have fill restrictions and the associated environmental limits, similar to the Moss–Rosenberg tanks, albeit for different reasons.

Disadvantages – SPB

The main drawback of the IHI-SPB containment system is its cost which is higher than both the Moss–Rosenberg and the membrane systems. Also, there are only two yards with the capability to build the SPB system as compared to 25 for membrane systems. These

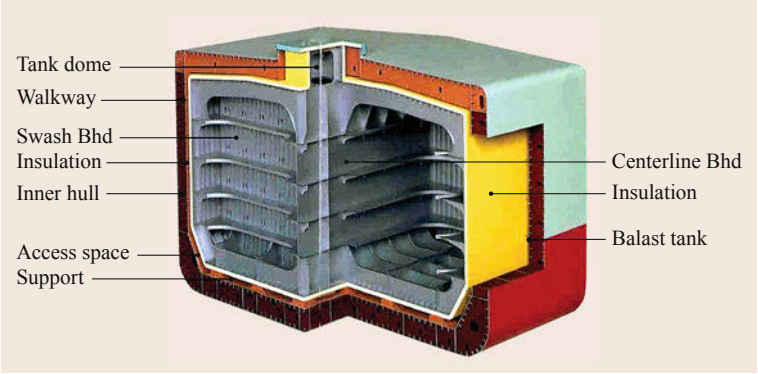

Fig. 41.7 IHI-SPB containment system

are likely the reasons that, at the time of this writing, there are only two LNG carriers in service using the IHI-SPB containment system. However, interest in the IHI-SPB containment system has recently grown as the industry moves toward floating LNG facilities. It turns out that the increased cost of the SPB system is relatively small compared to overall development cost for an FLNG facility, especially in light of the increased strength, reliability, and overall operability compared to the cheaper membrane systems. As mentioned previously, the SPB system also has the advantage of a flat deck to aid in the layout of LNG process trains.

41.2 Thermodynamics of LNG

The actual composition of LNG, while being predominantly methane (CH_4), varies based on its origins as well as the sales specifications it has to satisfy. Thus, there is variability in its properties and the values stated in the following sections are representative of a *typical* composition.

41.2.1 Properties of LNG

Once properly processed, LNG is a colorless, odorless, nontoxic, and noncorrosive liquid with a boiling point of −162 °C (111.15 K) at standard atmospheric pressure. It has a density of 450 kg m^{-3} and is approximately 1/600th the volume of the gaseous phase. The flammability limits are between 5% and 15%. The specific energy is approximately 50 MJ kg^{-1}, thus one reason for LNG's relative popularity is its efficient energy density being 22.5 kJ m^{-3} (22.5 MJ L^{-1}) in comparison to compressed natural gas (CNG) at 9 kJ m^{-3} (9 MJ L^{-1}). Heat of vaporization for regasification is 213 kJ kg^{-1} at standard atmospheric pressure.

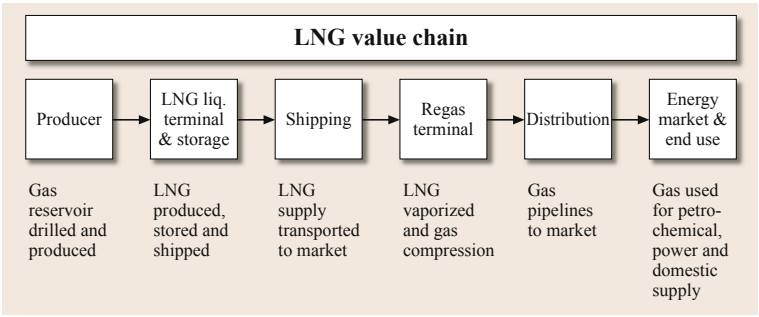

Fig. 41.8 LNG value chain

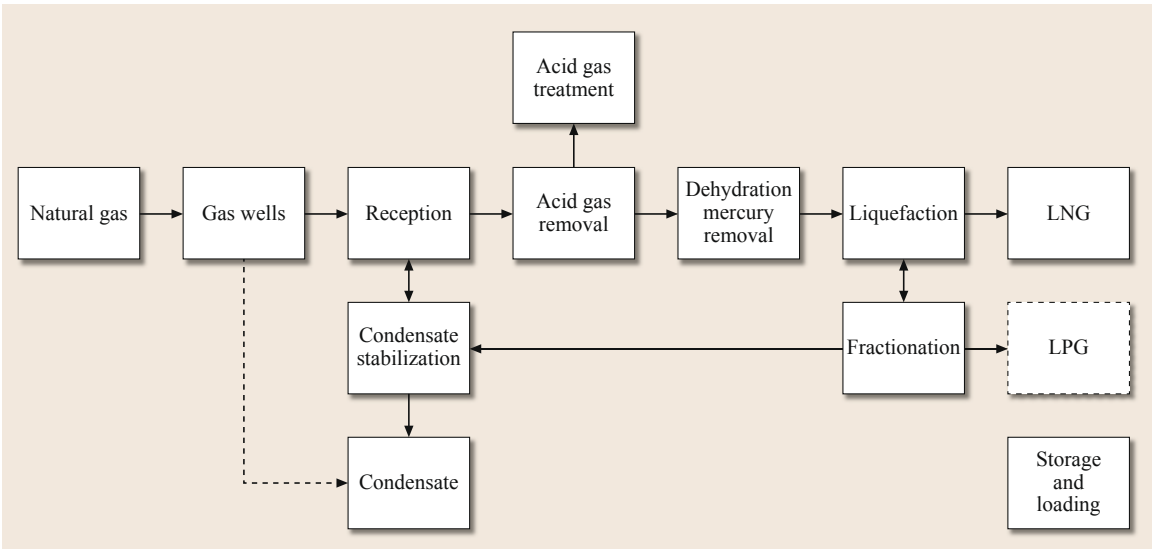

Fig. 41.9 Liquefied natural gas production (after [41.2])

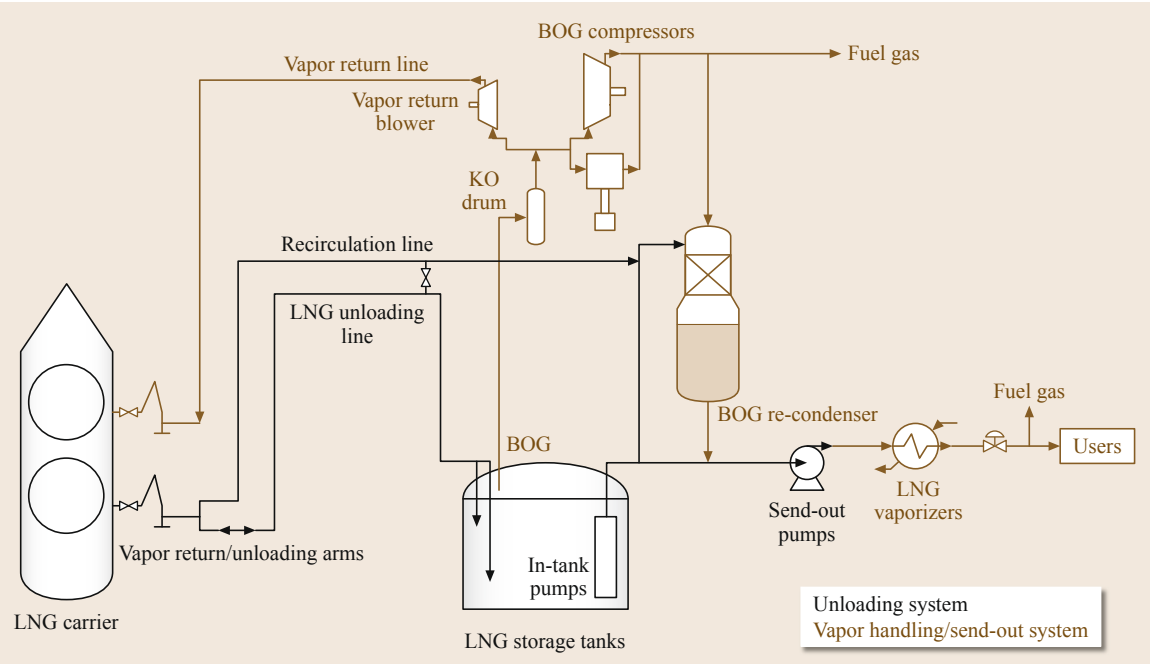

Fig. 41.10 LNG offloading line diagram

41.2.2 LNG Stages

The primary stages in the LNG value chain include gas treatment, liquefaction, storage, transport, offloading and regasification (Fig. 41.8).

During the gas treatment stage, the gas is brought to sales specification including heating value control by removal of natural gas liquids (NGL), dehydration, and CO_2 removal. A typical flow chart of the treatment and production process is shown in Fig. 41.9. Due to strict limits on toxic hydrogen sulfide (H_2S), sulfur, and mercury content, these contaminants have to be removed at this stage as well, lest they be released into the end user environment. Mercury, in particular, also has a corrosive effect on aluminum which is used extensively in the liquefaction (cryogenic) processes.

After processing, the sweet dry gas is ready for liquefaction. While there are numerous LNG liquefaction processes, the majority of the LNG plants use the Air Products propane precooled mixed refrigerant (C3MR) process, the ConocoPhilips' optimized cascade process (CoPOC) or the Linde multi fluid cascade (MFC) process, with C3MR being the most common.

Typically, the produced LNG is pumped into storage at this stage, either for transport or for later introduction into the retail gas pipeline. As most LNG plants are shore-based, the storage tanks are also onshore. Exceptions include floating LNG (FLNG) vessels and floating regasification and storage units (FSRU) which utilize the containment systems described above.

41.2.3 LNG Onshore Storage Considerations

The storage of LNG, being a cryogenic fluid, is by nature a complex but necessary function in the production of LNG. LNG is stored in specialty insulated tanks, either at the LNG plant prior to transport, during transport on LNGC or at the receiving terminal prior to regasification into a distribution pipeline. LNG is stored in a boiling state (162 °C) at close to atmospheric pressure. One particular feature of LNG storage and transfer is the handling of boil-off gas (BOG), (Fig. 41.10) As LNG is stored in a boiling state, heat ingress into the tanks causes a small proportion of the liquid LNG to boil off. The rate of BOG generation is determined by the rate of heat ingress into the tank through the insulation and tank penetrations such as the pump tower and tank supports. LNG is also used as the cryogenic agent to cool down the storage tanks prior to transfer of cargo, a process that may take more than 10 h. Additionally, LNG is continuously circulated through the transfer lines to maintain the cryogenic temperature. As a result, the LNG flashes to gaseous phase, generating BOG. BOG is generally recovered and either re-condensed or used as a local fuel source and its handling requires special consideration. BOG

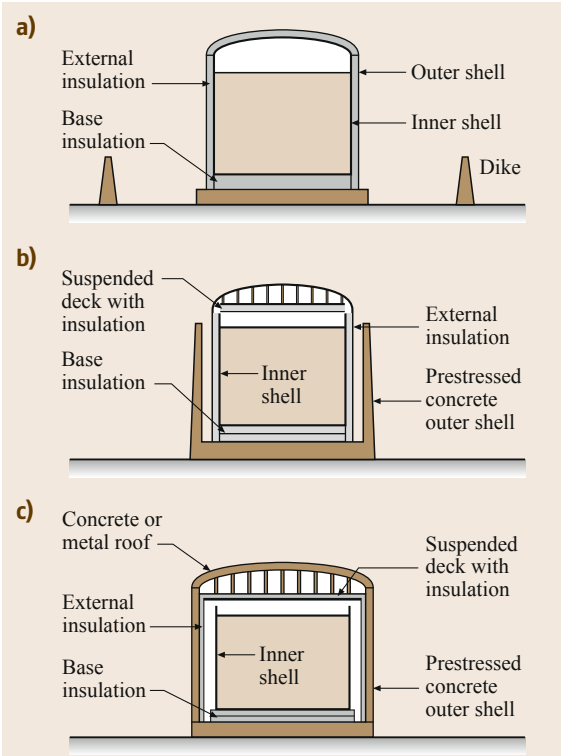

Fig. 41.11a–c Onshore LNG containment systems: **(a)** single containment; **(b)** double containment; **(c)** full containment

is also supplied via return lines to the storage tanks to maintain the near atmospheric pressure within the tanks.

Onshore LNG tanks (Fig. 41.11) feature both a primary and a secondary containment system. The latter is designed to contain the LNG liquid in the event of a failure in the primary containment system but may not always be designed to contain the vapor phase as well. The primary containment system (or inner tank) is generally constructed of a 9% nickel steel alloy and insulated using perlite. A greater degree of insulation is required on the base of the tank to insulate the tank from the ground. The base or slab may also contain heating elements to prevent the ground from freezing. The secondary containment system consists of a pre-stressed concrete outer shell or even an earthen wall.

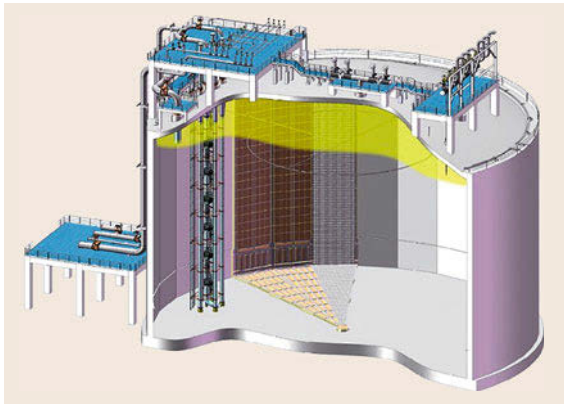

Fig. 41.12 Onshore LNG membrane containment system (after [41.1])

In contrast to the above where both primary and secondary containment systems are self-supported, membrane tanks (Fig. 41.12), similar to those used in LNG carriers, have a primary containment system which derives its structural strength from the prestressed concrete shell. Primary containment is provided by a stainless steel membrane mounted on a plywood-foam insulating panel to transfer the loads to the concrete shell. A secondary membrane barrier is typically also included. This system is typical of in-ground LNG tanks.

41.3 Environmental Challenges

41.3.1 Open Ocean Voyages

An LNGC during voyage in an open ocean encounters various sea-state conditions that can affect its motion response and maneuverability. Traditionally, LNGC were planned for port to port voyages and hence the tanks were either full or empty. The potentially dangerous internal free surface condition was thus avoided. As is well known, internal free surfaces can compromise safety and reduce vessel stability. For example, *Halkyard* et al. [41.3] say that the metacentric height of a vessel is reduced by the net sum of the water plane stiffness lost due to internal surfaces. This is given by

$$\mathrm{GM(new)} = \mathrm{GM} - \sum \frac{\rho_c}{\rho} \frac{i_{xx}}{\nabla} \,. \qquad (41.1)$$

Here the original metacentric height GM is reduced by the net effect of water plane stiffness (i_{xx}) lost due to internal surfaces. ρ_c and ρ are the densities of the cargo and ambient sea water, respectively, and ∇ is the displaced volume of the vessel.

Recently, spot market trading of LNG has become advantageous and economically viable for operators. This however, requires an LNGC to ply from one location to another collecting liquid cargo, thus operating

with one or more of its tanks partially full. While this causes a decrease in stability as discussed above, it also can result in potentially large sloshing loads on internal panels of LNC cargo holds. The internal surface of these holds is not designed for large impact loads, and hence dents and possible damage to the insulation can occur. A leak in insulation can result in loss of liquid cargo being released as vapor. A rapid increase in temperature can result in rapid expansion of cargo leading to possibility of explosion.

While traveling in waves, it is important to recall that the waves seen by a ship is altered by its so-called encounter effect. The frequency of excitation for a ship is given by ω_e, and is related to the actual wave frequency ω, by the formula

$$\omega_e = \omega - \frac{U^2}{g} \sin\beta \,, \tag{41.2}$$

where U is the speed of the ship and β is the angle of approach of a wave system. Thus at various partially filled conditions, significant sloshing may be experienced if the natural sloshing frequencies are matched with the encounter frequency seen by the ship. Since the latter is a function of ship speed, sloshing motions may be experienced at certain portions of the voyage only.

When an LNGC is loading or offloading at an exposed terminal, potential for sloshing again exists if the LNGC encounters a changing wind or wave pattern. Standard operating practice normally includes provision for emergency operations in case of adverse weather. Another situation conducive for sloshing relates to emergency disconnect during loading/offloading of an LNGC with an offshore liquefaction plant. In all these cases, potential sloshing loads can arise.

Yet another structural consideration caused during offloading relates to low-cycle high-stress fatigue. *Wang* et al. [41.4] discuss the fatigue stresses caused on welded joints in bulkheads separating two tanks one of which is full while the other one is empty. Duty cycles associated with such operations can produce stresses that exceed the yield strength of the weld. The frequency of these loads is low and hence in the plastic range and not covered in a standard *S–N* curve. The article suggests a calculation procedure based on the so-called Neuber's rule.

41.3.2 Boil-Off

Typical fill conditions of LNG tanks are close to 98% of volume. The small amount of atmosphere allows for vapor accumulation from the LNG. As LNG is close to its boiling temperature, some amount of LNG is converted into vapor, causing a boil-off condition. The boil-off rate is quite an important safety concern and is stipulated among others by IMO at 0.12% for 125 000 m^3 storage. The boil-off rate ($\dot{B}$) can be simply characterized by the following equation

$$\dot{B} = \frac{q}{h\rho_c V} \,. \tag{41.3}$$

Here q denotes the heat influx into an LNG tank of volume V from the enclosure, h and ρ_c are the latent heat coefficient and density of the LNG, respectively. *Zakaria* et al. [41.5] use computational fluid dynamics (CFD) to simulate the heat transfer across a membrane tank. The tank is considered to be one of the four tanks that make up a 160 K m^3 ship. The boil-off is found to be approximately 0.155%/(kg day) when the ship is operating in seawater at 0 °C, and ambient air at 5 °C.

41.4 Fluid Structure Interaction of LNG Systems

41.4.1 Wave-Induced Motions

An LNG carrier, like any other ship with forward speed will encounter waves during its voyage and hence should have good seakeeping characteristics. This is even more important if any of the tanks is partially filled with liquid cargo. During the loading and unloading stages, the LNG carrier behaves like a moored vessel and here again wave-induced motions are important.

A floating vessel's response to oncoming waves is characterized by its response amplitude operator (RAO). The RAO is strictly a complex quantity, comprising of amplitude and phase information. One can define the amplitude of an RAO as [41.6]

$$|\mathrm{RAO}|_i = \frac{|\eta_i|}{A} \,, \tag{41.4}$$

where η_i denotes the motion being considered, with the subscript following standard notation, that is, $i = 1, 2, 3$ denoting the three translations surge, sway, and heave, respectively, and $i = 4, 5, 6$ denoting the three rotations, roll, pitch, and yaw, respectively, A is the wave amplitude. In typical offshore computations, numerical methods based on potential flow assumptions are used. Then viscous damping is artificially added, which alters the resonant peaks in the RAO.

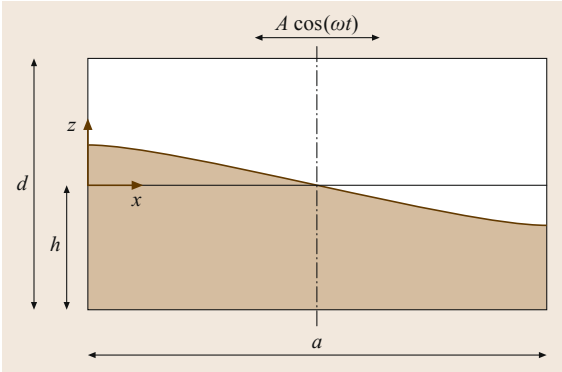

Fig. 41.13 Layout of rectangular tank subject to sloshing motions (after [41.7])

In a classical naval architectural sense, liquid cargo is treated hydrostatically and hence its effect on stability is evaluated. When tanks are partially filled then dynamic effects can be important. *Thiagarajan* et al. [41.7] suggest that in a linear diffraction problem, it is sufficient to consider the linear transfer function of sloshing, which introduces the first level of dynamics into the problem. For a tank of width a filled up to height h, subject to translational oscillation of frequency ω and amplitude A, the dynamic pressure on the walls is given in terms of vertical coordinate z ($z = 0$ is the free surface) by

$$p(z,t) = \sum_{n=1}^{\infty} \frac{2\rho a A(1-\cos n\pi)}{(n\pi)^2} \frac{\cosh\left(\frac{n\pi(z+h)}{a}\right)}{\cosh\left(\frac{n\pi h}{a}\right)} \times \frac{\omega^4}{(\omega^2-\omega_n^2)} \cos\omega t \,. \tag{41.5}$$

Here ω_n is the sloshing natural frequency, given for the n-th eigenmode by

$$\omega_n^2 = g\frac{n\pi}{a}\tanh\left(\frac{n\pi h}{a}\right) \,. \tag{41.6}$$

The pressure may be integrated to provide a force to be used in global response calculations.

A different linear computational approach to what was described above was used by *Chen* [41.8]. His computation employed the same Green's function to solve the flow inside the tanks as well as the flow external to the ship hull. A small amount of wall reflection was employed inside the tank, thus simulating damping. When motion was close to resonance then significant nonlinear effects occurred, requiring extra numerical treatment. *Chen* [41.8] presented numerical results at no damping ($\epsilon = 0$) and at 2% ($\epsilon = 0.02$) for an LNG carrier with two tanks, and compared it with model tests at 1 : 50 scale. The prototype LNGC (Fig. 41.14a) was 274 m long, 44.2 m wide, and was loaded to a draft of 11.58 m. The two tanks were of lengths ranging from 41 to 47 m, and width 39.1 m. The tanks were filled with cargo of 10 m in height. The motion RAO's of this LNGC are shown in Fig. 41.14b–d. The uncoupled fundamental natural frequency of sloshing in each tank is 0.72 rad s^{-1} based on (41.6). Resonant sloshing motion in the tank causes a dip in the sway RAO of the LNGC (Fig. 41.14b). The roll RAO of a floater is normally single peaked. However, in the presence of an internal surface, two peaks are visible, on either side of the sloshing frequency of the two tank system. This may be thought to be analogous to anti-roll tanks, which are designed to reduce the peak roll motion of a vessel. The effects of inertia of the vessel are offset by the restoring effect of the liquid movement resulting in a cancelation. On the other hand, the inertia of the vessel and the liquid cargo individually provide the two peaks on either side. The heave RAO shown in this figure is typical of floating vessels, and is unaffected by partially filled cargo tanks.

41.4.2 Sloshing Impact and Consequences

Sloshing is associated with uncontrollable motion of liquids within the walls of a containment structure. While normally sloshing loads are handled by structural elements supporting the inner walls, a membrane-type LNG tank encounters problems because structural members supporting the insulation material do not have sufficient strength. This has resulted in surface deformation [41.9] or for a chronology of sloshing related events one may refer to *Gavory* and *de Seze* [41.10]. The consequences of even a small failure of the insulation of an LNG system can be significant, if LNG is allowed to evaporate into NG which can escape to adjacent regions.

Impact loads due to sloshing are significant when the liquid is excited in and around its natural frequencies. These frequencies (41.6) are highly geometry and fill level dependent. Figure 41.15 shows the variation of first and third sloshing frequencies with fill level in the tank (shown as an aspect ratio of fill height to tank width). The even harmonics are not significant since there is cancellation of energy from both ends of the tank [41.7].

Considerable studies have focused on measuring and modeling sloshing impact pressures. For example, one can refer to the sloshing symposia organized as part of the international offshore and polar engineering (ISOPE) conferences from 2010 to 2014. Of note here is the SLOSHEL joint industry project [41.11], where significant experimental work has been con-

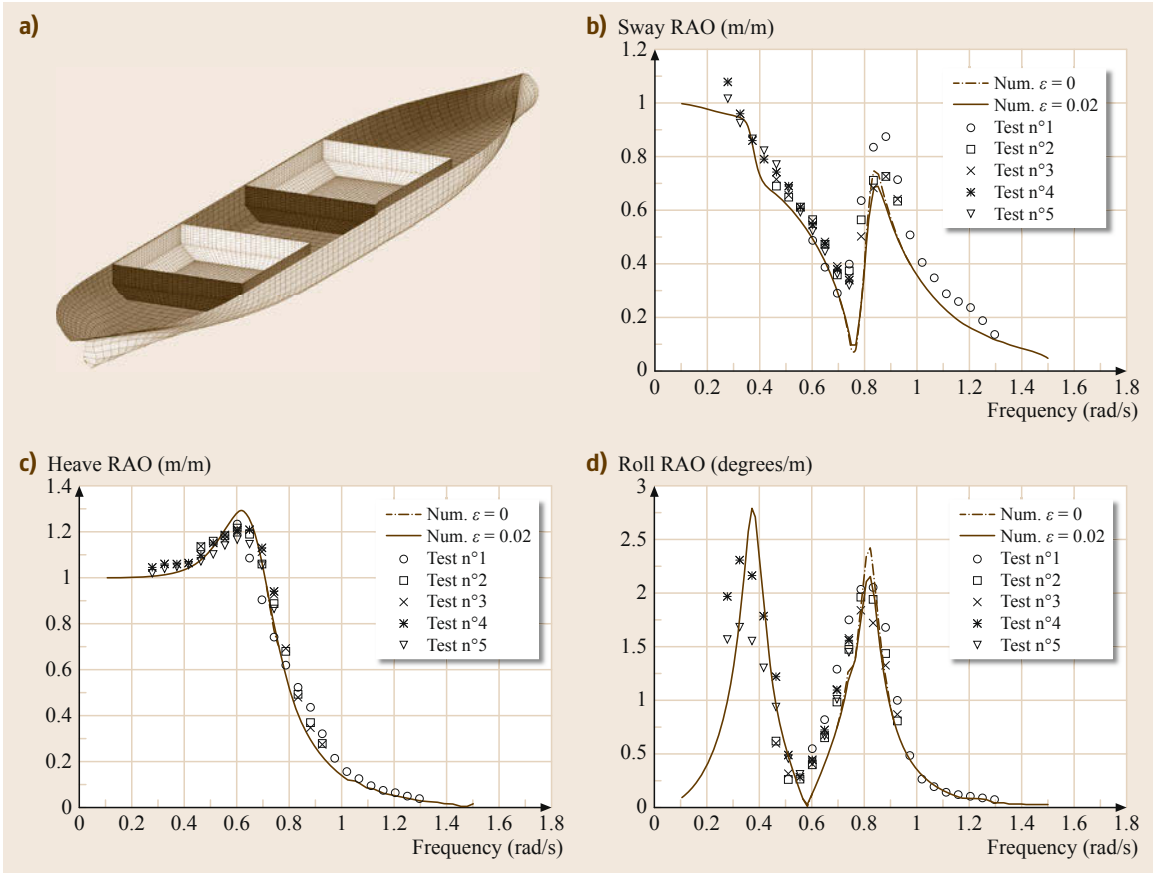

Fig. 41.14 **(a)** Mesh of LNGC and two tanks (after [41.8]), **(b)** sway RAO [$\mathrm{m\,m^{-1}}$] in beam sea, **(c)** heave RAO in beam sea, and **(d)** roll RAO in beam sea. All x-axes: frequency [$\mathrm{rad\,s^{-1}}$]

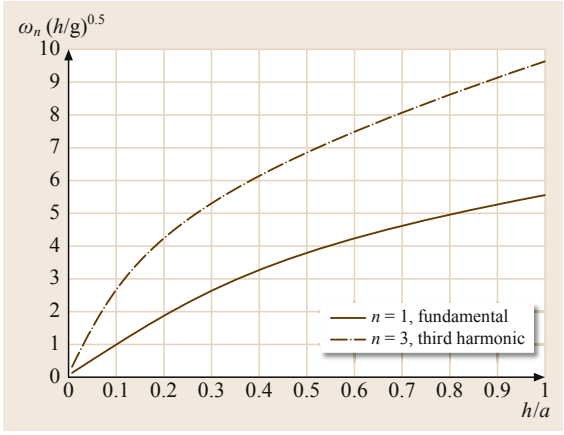

Fig. 41.15 Sloshing natural frequencies as functions of tank aspect ratio

ducted on the nature of the impact pressures. Sloshing pressures are highly stochastic. Even for systematic sway motion of the tank, there is significant variability of sloshing pressure from cycle to cycle. For example, Fig. 41.16 shows a time series of the pressure measured during an experiment. Such pressure signatures seen in this figure are typical of many reported papers.

While the magnitude of impact is of primary consideration, it is also important to note the time scale within which the impact occurs. Details of the formation and disintegration of the pressure peak is shown in Fig. 41.17 taken from *Pistani* and *Thiagarajan* [41.12]. The temporal quantities like rise time and decay time are also stochastic, however, with much smaller standard deviation than the impact magnitude.

High pressure is normally evidenced in the top corners of a rectangular tank, and hence it is common practice to provide a chamfer to the tanks (Fig. 41.2). Experiments show reduction in peak pressure when the corners are chamfered. For example, *Pistani* et al. [41.13] compare the pressures measured during an experiment at fill equal to 30% of tank height. There is notable decrease in pressure due to chamfer.

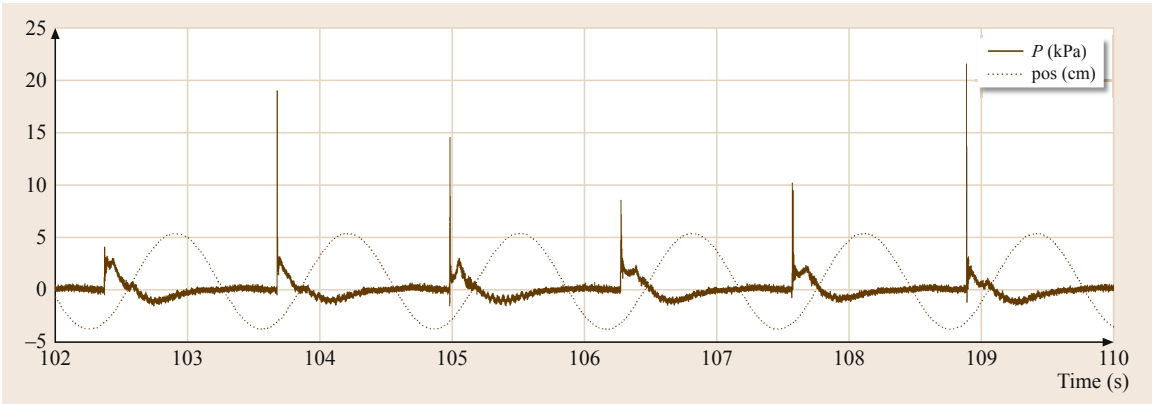

Fig. 41.16 Pressure trace from a transducer (in kPa) due to sloshing from a sway motion of a tank (pos in cm) (after [41.12])

Conventional wisdom [41.10] suggests that reducing the dimensions of the tank can reduce the effects of sloshing, and this principle has been adopted in SPB tanks (Sec. 41.1.1, *Independent Self-Supporting Tanks*) and in developments such as Shell's Prelude, where two rows of tanks are employed. Nevertheless, the accepted design practice [41.14] is to conduct model tests to ascertain the level of sloshing impact pressures and incorporate those in the design.

41.4.3 Scaling

An important pathway to developing robust full-scale design is via scaled model tests in a laboratory. Of various factors that affect design, three aspects have been tested quite rigorously in an ocean engineering laboratory:

1. Liquid sloshing
2. Coupled motions between a floater
3. Liquid cargo and vessels moored side by side.

The starting point of a scaling discussion is dimensional analysis. *Bass* et al. [41.15] have presented an excellent overview of the factors affecting the scaling of sloshing loads. Let us consider the sloshing base case – a rectangular tank in sway motion. The tank length is L, and its filling height is h. Table 41.1 summarizes all important parameters, and also points to the complexity of scaling all the parameters in a single experiment.

One can identify several nondimensional parameters from this list of parameters and some of them are expressed in Table 41.2. *Bass* et al. [41.15] have obtained the following relation for the impact pressure (P_w), which also shows resemblance to the list in Table 41.2:

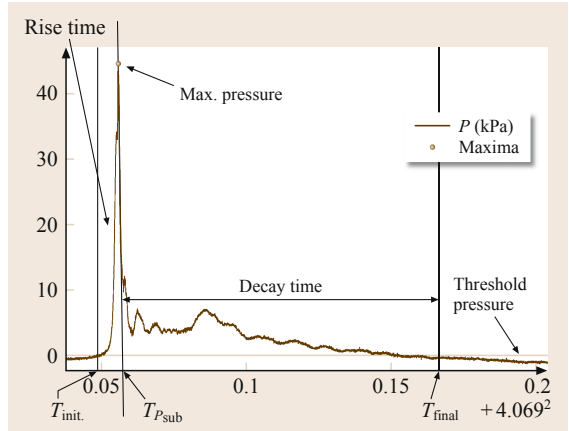

Fig. 41.17 Definitions of pressure impact during sloshing (after [41.12])

$$\frac{P_w}{\rho_l g L} = f'\left[\frac{\rho_l g^{\frac{1}{2}} L^{\frac{3}{2}}}{\mu_l}, \frac{P_u}{\rho g L}, \frac{E_l}{\rho g L}, \frac{P_u - P_v}{\rho_l g L}, \frac{\rho_g}{\rho_l}, m_0, \frac{\rho_l g L^2}{\sigma_l}, \frac{\rho_l C_l (t_w - t_{sat})}{\rho_v h_{fg}}, \text{wall properties, geometry}\right] . \tag{41.7}$$

Yung et al. [41.16] defined a parameter interaction index (Ψ), to characterize the effect of ambient vapor on the magnitude of impact. By introducing the pressure–density relationship for a polytropic process ($\frac{p}{\rho^\kappa}$ = constant) into the dimensionless unsteady Bernoulli equation, the interaction index is obtained as

$$\Psi = \frac{\rho_g}{\rho_l}\frac{\kappa - 1}{\kappa} . \tag{41.8}$$

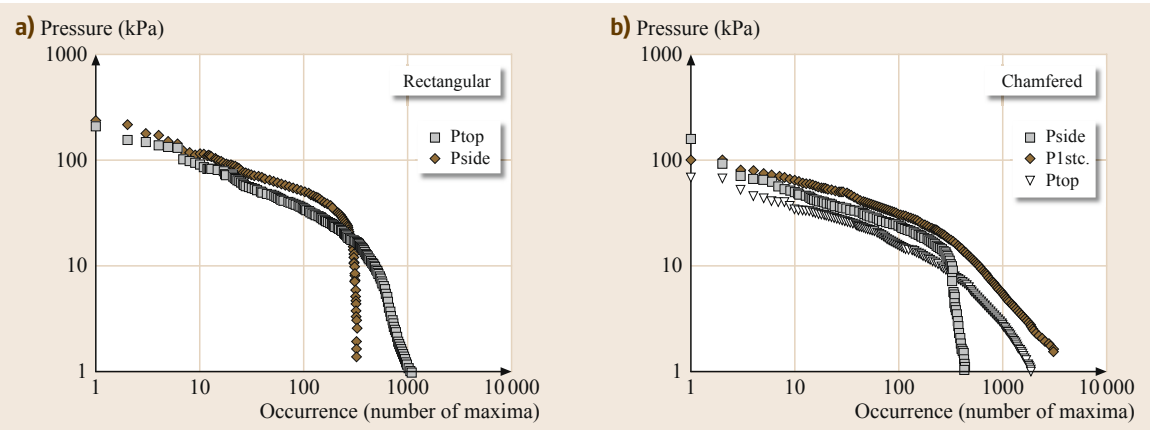

Fig. 41.18 Maximum of the pressures impacts for rectangular and chamfered tanks from *Pistani* et al. [41.13], using transducers on side wall, first corner of chamfer and top (ceiling) fill level here is 30% of tank height

Table 41.1 Key parameters affecting a sloshing experiment

Geometric parameters	**Symbol**	**SI units**
Length of the tank	L	m
Tank height	T	m
Water depth	h	m
Wall inclination	α	rad
Kinematic parameters		
Acceleration	g	$\mathrm{m\,s^2}$
Angular frequency	ω	$\mathrm{rad\,s^{-1}}$
Amplitude of oscillation	A	$\mathrm{m\,s^{-1}}$
Speed of sound	C	$\mathrm{m\,s^{-1}}$
Dynamic parameters		
Ullage pressure	P_u	$\mathrm{N\,m^{-2}}$
Bulk modulus of liquid	E_l	$\mathrm{N\,m^{-2}}$
Bulk modulus of vapor	E_v	$\mathrm{N\,m^{-2}}$
Ullage density	ρ_u	$\mathrm{kg\,m^{-3}}$
Liquid density	ρ_l	$\mathrm{kg\,m^{-3}}$
Viscosity of the liquid	μ_l	Pas
Wall pressure	P_w	$\mathrm{N\,m^{-2}}$
Wall elasticity	E	$\mathrm{N\,m^{-2}}$
Vapor pressure of liquid	P_l	$\mathrm{N\,m^{-2}}$
Thermodynamic parameters		
Ullage temperature	T_u	K
Liquid temperature	T_L	K
Thermal diffusivity of liquid	α_l	$\mathrm{m^2\,s^{-1}}$
Heat transfer coefficient of liquid	h_l	$\mathrm{W/(m^2\,K)}$
Thermal conductivity of liquid	k_l	$\mathrm{W/(m\,K)}$
Coefficient of expansion of liquid	β	$\mathrm{K^{-1}}$
Specific heat of liquid at constant pressure	C_p	$\mathrm{J/(kg\,K)}$
Specific heat of liquid at constant volume	C_v	$\mathrm{J/(kg\,K)}$
Surface tension	σ	$\mathrm{N\,m^{-1}}$

Table 41.2 Some important nondimensional numbers governing the physics of sloshing

Dimensionless number	**Definition**
Froude number	$\frac{A^2\omega^2}{gL}$
Euler number	$\frac{P_\mathrm{u}}{A^2\omega^2\rho_\mathrm{l}}$
Compressibility number of ullage gas	$\frac{\omega A}{\sqrt{\frac{E_\mathrm{v}}{\rho_\mathrm{v}}}}$
Density ratio	$\frac{\rho_\mathrm{l}}{\rho_\mathrm{u}}$
Reynolds number	$\frac{\rho_\mathrm{l}\omega AL}{\mu_\mathrm{l}}$
Prandtl number	$\frac{\mu C_\mathrm{p}}{K}$
Weber number	$\frac{\rho_\mathrm{l}A^2\omega^2L}{\sigma}$
Bond number	$\frac{(\rho_\mathrm{l}-\rho_\mathrm{u})L^2\mathrm{g}}{\sigma}$
Mach number	$\frac{L\omega}{C}$
Cavitation number	$\frac{P_\mathrm{u}-P_\mathrm{v}}{0.5A^2\omega^2\rho_\mathrm{l}}$

Here κ is the polytropic index of the ullage gas whose density is ρ_g. The liquid's density is given as ρ_l. The interaction index captures the condensation thermodynamics when gases are trapped in the flow causing entrapped pockets. Neglecting condensation can lead to exaggerated dynamics of entrapped air, such as springing oscillations. They argue that complete dynamic similitude is possible for the sloshing problem if the five parameters: Euler number, Froude number, Reynolds number, Weber number, and the interaction index are identical.

More commonly used tandem offloading method employs transfer from the stern of one vessel (e.g., FLNG) to the bow of a shuttle tanker. Hoses can be

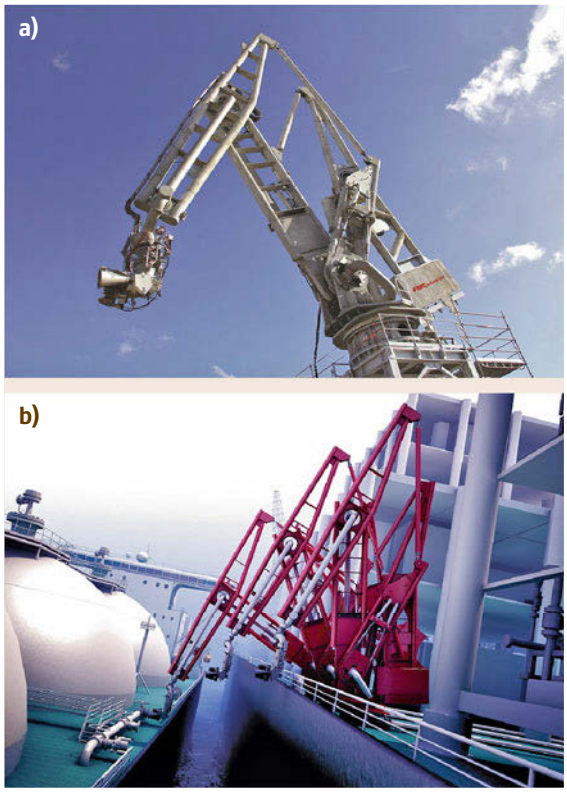

Fig. 41.19a,b Offshore loading arm (courtesy of FMC Technologies) **(a)** demonstrating flex joint technology, and **(b)** attached to an LNGC for cargo transfer

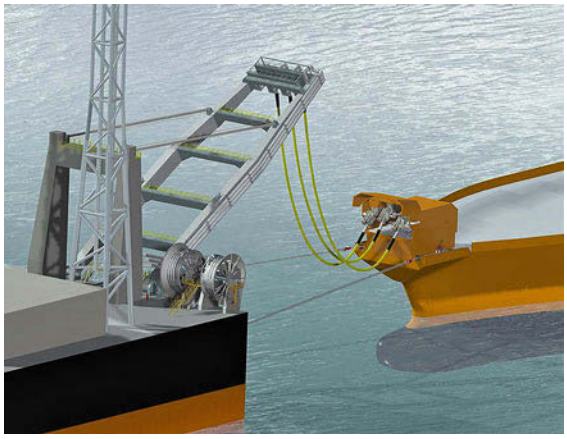

Fig. 41.20 Aerial hose tandem offloading, offshore cryogenic transfer system (courtesy of OneSubsea)

aerial, floating, submerged, or rigid arm arrangements (Fig. 41.20). For tandem offloading, relative motions can be large when conducted in diverse seastates. Recent Joint industry projects (JIP) have resulted in development of customized 8″ and 16″ cryogenic hoses

Table 41.3 Final dimensions and stiffness properties of a hose (after [41.17])

Inner diameter	16″ (406 mm)
External diameter	27″ (686 mm)
Weight – empty in air	88 kg m^{-1}
Weight – full of LNG	160 kg m^{-1}
Storage bending radius	4.5 m
Operational bending radius	10.0 m

for transfer of LNG. These are multi-sheathed pipes capable of handling fluids at −163 °C, large volumes at nominal pressures of 3–10 atm. Sample segments have been tested extensively in dynamic and load conditions. *Cox* et al. [41.17] provide the final dimensions and stiffness properties of a hose presented in Table 41.3.

One of the challenges with this hose is to balance the working weight with the length stipulated by the bending radius. Other JIPs have reported 16″ internal diameter (ID) pipe development with vacuum insulation technology to enable cryogenic transfer [41.18]. Several guides exist to assist with development of offloading system design and operation. *DNV* [41.19] lists the following:

- OCIMF/SIGTTO (Oil Companies Internatinal Marine Forum/Society of Interntional Gas Tanker and Terminal Operators):
  - Ship to ship transfer guide (liquefied gases)
  - LNG STS transfer guidelines
  - Standardization of manifold for refrigerated liquefied gas carriers (LNG).
- Euronorm:
  - EN1474-1 installation and equipment for liquefied natural gas. Design and testing of marine transfer systems. Design and testing of transfer arms.
  - EN1474-2 requirements for flexible hoses.
  - EN1474-3 risk-based qualification of offshore transfer systems.

Cryogenic cargo transfer poses challenges compared to conventional fuels. Some of the challenges [41.19] relate to safety of containment of cryogenic products, ramp-up and shut down operations, and ability to transfer LNG and vapor return within the limited time window of operation. Side by side offloading is currently applied to calm sea conditions, where relative motions between vessels are small. The vessels are separated by fenders, whose diameters are in the range of 5 m [41.19]. Common transfer hoses are aerial, or supported by rigid arms with swivel connections. An example of the flexjoint technology is the Chiksan loading arm developed by FMC, (Fig. 41.19) [41.20] is deployable. The arm uses a hydraulic quick connect

disconnect system, with a constant tension guide line connecting the arm and the manifold. The system can accommodate up to 4 m heave and 30 m drift between two vessels.

41.4.4 Multiple Body Interaction in Shallow Water

When two structures are floating in proximity, important hydrodynamic interactions can occur. Some of the more obvious ones are related to phase and magnitude difference in motions among the structures. When horizontal plane motions are out of phase, then station-keeping problems such as the structures drifting close to each other can arise. Alternatively, structures drifting apart can raise the tension in connecting hoses or guy lines to critical levels. In some cases, snap loads can occur. Phase difference in vertical plane motions such as heave and pitch can result in difficulties in cargo and personnel transfer.

Less obvious effects caused by proximal structures relate to changes in hydrodynamic pressure distributions, resulting in changes in added mass and damping coefficients. Furthermore, when structures are held close to each other *gap* problems such as resonant fluid motions can occur. Based on experimental observations, *Buchner* et al. [41.22] note that head sea waves can get amplified in the gap region. This can result in spikes in RAO and quadratic transfer function (QTF) of individual structures. Figure 41.21 from *Buchner* et al. [41.22] shows a large spike in heave RAO of a shuttle tanker when moored alongside a floating production storage and offloading (FPSO) (vessel). Due to motion coupling, a spike at the same frequency is noticed in pitch as well.

Simulations of gap problems can result in unrealistic free surface motions, which can be considered as inherent drawbacks of the state-of-the-art diffraction methods. These methods rely on discretized integral equation formulations that have limitations on the minimum spatial dimensions which can be handled without significantly increased discrete surface elements or panels. See [41.23] for an excellent overview of early works on this subject. Several authors have followed *Chen* [41.24] in imposing an artificial lid on the gap, which is equivalent to imposing an artificial damping on the free-surface motions at the gap. The boundary condition on the free surface at the gap is corrected by imposing a damping term (defined by ε).

$$-\omega^2\phi_s + g\frac{\partial\phi_s}{\partial z} - i\varepsilon\omega\phi_s = 0\,, \tag{41.9}$$

where φ_s is the scattering or radiation potential and ω is the wave frequency. The difficulty is in knowing the

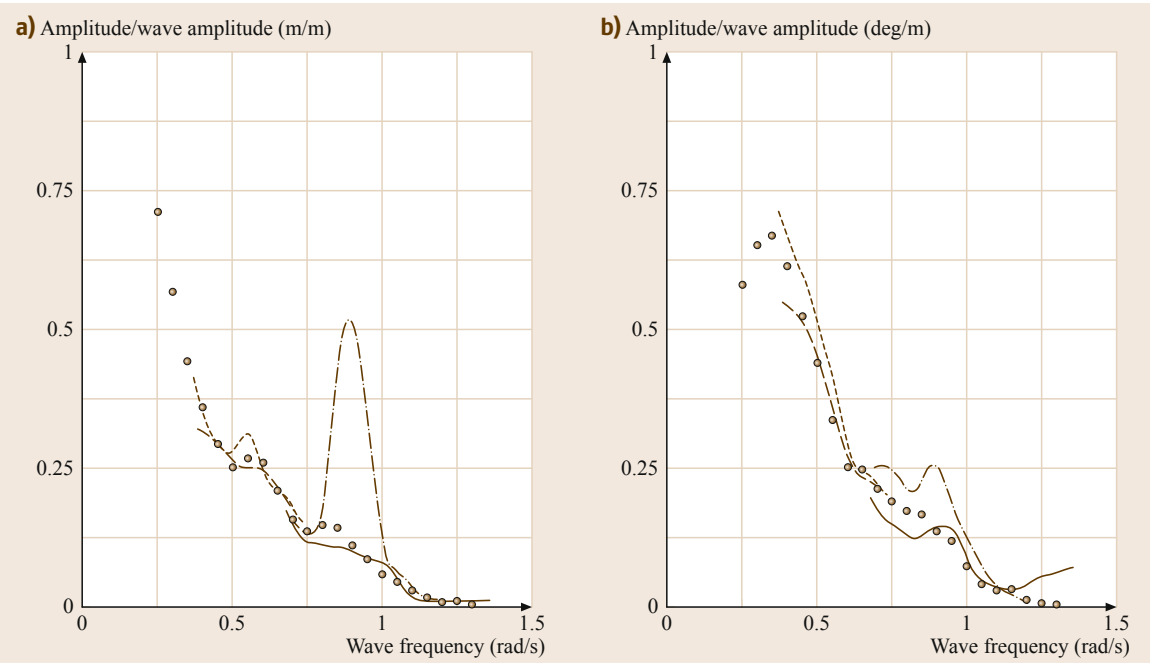

Fig. 41.21 Heave and pitch RAO for a shuttle tanker moored alongside a LNG FPSO (after [41.21]). Model test data at sea (*solid line*) and swell (*dashed line*) frequency domain analysis (*circles*), and time domain analysis in sea and swell (*dashed-dot line* and *long-dash line*)

exact value of damping to be imposed. In fact, *Pauw* et al. [41.25] show from comparison of experiments and simulations that no single value of damping can be universally applied. The optimal value has to be chosen based on the influence on the second-order drift forces. On the other hand, *Lu* and *Chen* [41.26] suggest that a damping value of 0.4 gives good agreement with linear transfer functions obtained from experiments and CFD.

The situation gets more complicated in shallow water, as the effect of the bottom further complicates the flow around the structures, resulting in changed viscous damping. For example *Buchner* et al. [41.22] show through experiments and simulations that the damping due to bilge keels of an LNGC is altered when placed in proximity to a concrete gravity structure, like a dock.

41.5 Design Methodologies of LNG Containment Systems

The design of LNG carriers and floating LNG facilities require additional unique analysis techniques that general cargo carriers are unencumbered by, due to the complex nonlinear physics involved in LNG sloshing. The crux of the issue, if not already clearly evident from the previous section, is the prediction of LNG sloshing loads from smaller scale model tests. Traditional scaling laws such as Froude, Reynolds, and Euler do not perform satisfactorily. In particular, if Froude scaling were to be applied, predicted prototype sloshing impact pressures would be extremely large and do not correlate to the rate of containment damage seen in the LNGC service histories. Such scaling laws taken in isolation obviously do not take into account thermodynamic and fluid–structure interactions. Further, micro and macro bubble dynamics play an important cushioning effect, an accounting of which cannot be complete without consideration of phase-change and cavitation, due to the fact that LNG is transported in a constant state of boiling.

In order to circumvent some of these complexities, the technique used to certify the design of new membrane LNG carriers by class societies is known as *comparative analysis* which relies on the past performance of a reference carrier to predict the performance of a new carrier based on tank sloshing tests. The method proved adequate but was not conducive to the progression of carrier size and thus the largest carriers that could be built for a while were roughly around 138 000 m^3 in capacity. More recent Qflex and Qmax carriers, with capacities of 216 and 260 k m^3, were designed using enabling research, performed by ExxonMobil corporation, which represents a significant leap forward in the fundamental understanding of the sloshing processes.

In contrast to the membrane LNG tanks, the design requirements for LNG carriers with independent tanks are much less onerous, largely due to the reduced sloshing risk or innate strength of the containment system. For instance, whereas ABS has several publications relating to the design guidance for membrane LNG carriers, in the case of their publication [41.14] on building and classing liquefied gas carriers with independent tanks, sloshing is briefly discussed in a subsection related to dynamic loading criteria. The remaining portion of this section will deal largely with assessment of the membrane type containment systems.

41.5.1 Comparative Analysis

Comparative analysis is a technique of assessing the performance of a new-build LNG carrier using membrane containment systems by scaling the sloshing loads from a reference carrier to the new design. The reference carrier is selected to have a known service history in which no damage to the containment systems is to have occurred. In essence, the new carrier is designed to have a higher load resistance than the reference carrier and since the reference carrier did not suffer any damage, it is assumed that the new carrier will be less likely to. Logically, this technique works best when the new design does not differ significantly from the reference design. Therefore, significant changes in geometry and/or capacity are impeded using this technique. The major classification societies have published guidance documents regarding this analysis methodology, such as *ABS* [41.27], *BV* [41.28], and *DNV* (Det norske Veritas) [41.19]. Figure 41.22 shows how comparative analysis is utilized in ABS' current strength assessment procedure for membrane-type LNG containment system.

The two main steps in comparative analysis are the determination of sloshing design loads and the containment strength assessment for both the new and reference carrier. Traditionally, the determination of sloshing design loads is performed solely via small-scale model testing. With modern advancements in computing, CFD is increasingly used to validate and augment the model tests. However, due to the statistical nature of sloshing loads, the computational burden to completely replace model testing makes this an impossibility at the time of this writing. In addition, while CFD is fairly accurate at predicting the spatial distribution of sloshing loads, the actual peak pressure is

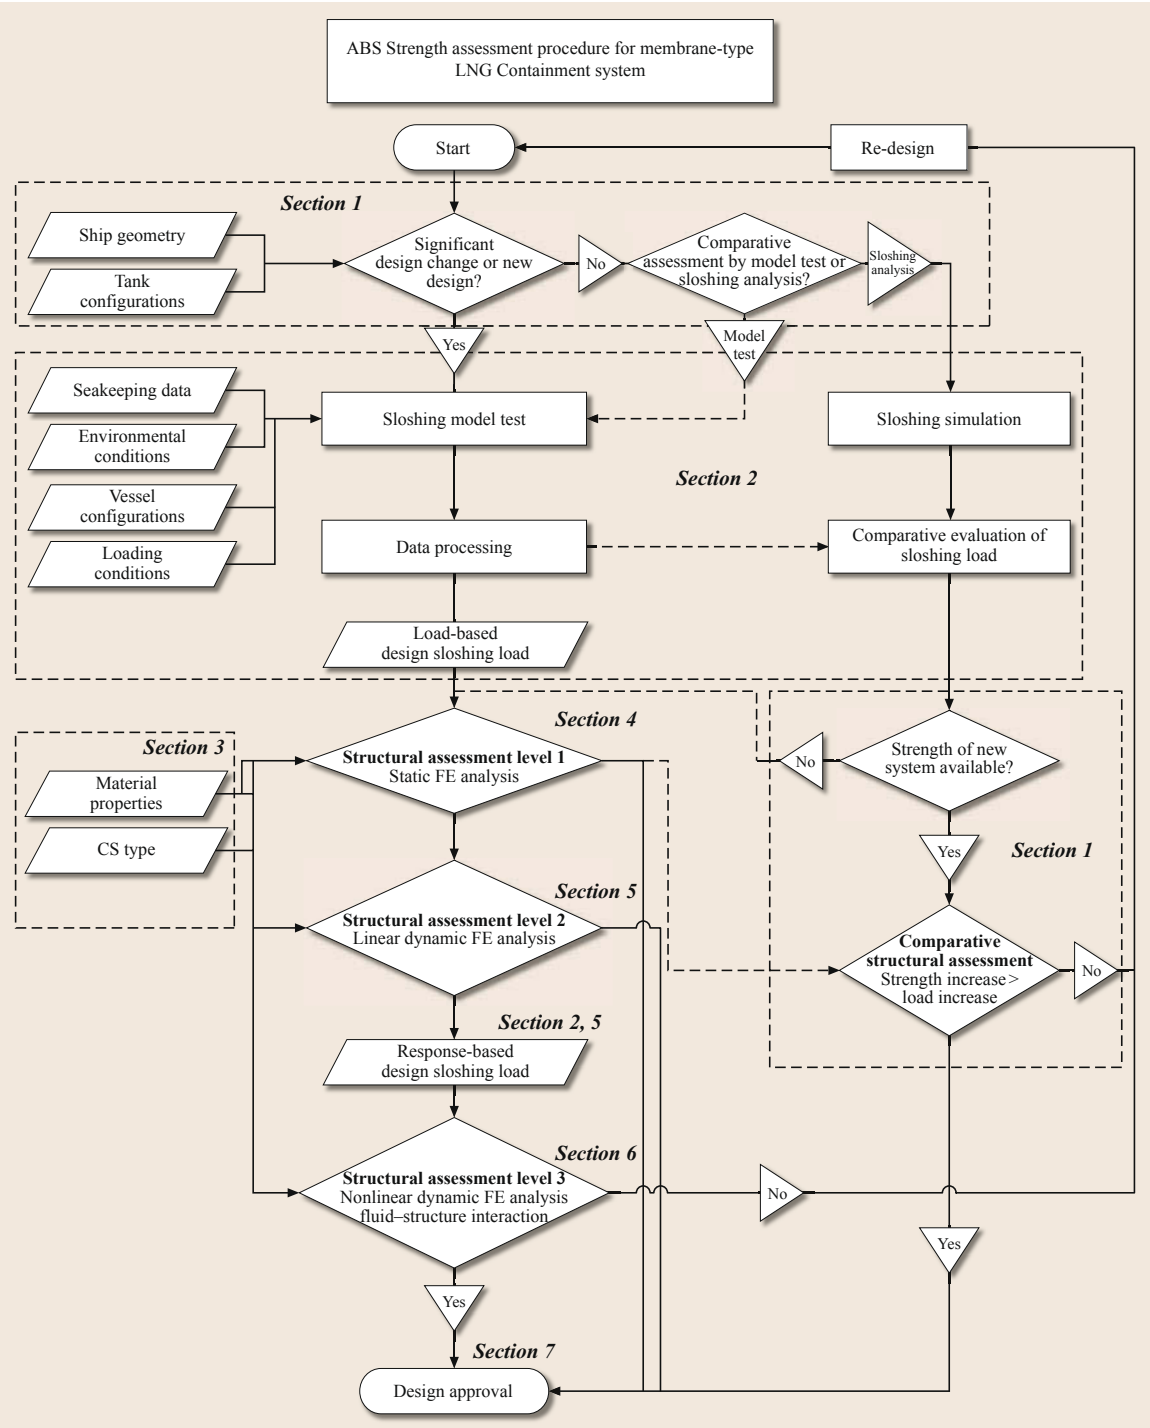

Fig. 41.22 American Bureau of Shipping (ABS) strength assessment procedure for membrane-type LNG containment system

difficult to capture accurately and depends largely on the knowledge of the CFD practitioner. Model testing too is not without its challenges with regard to the special requirements that sloshing testing imposes. This will be covered in a later section. At this point, it is important to note that the reference and new service history needs to be accounted for, including ship motion characteristics and service metocean environment, especially if comparative analysis is being used to qualify an older tanker for new service.

Sloshing impact is a dynamic process and thus the dynamic structural capacities for the different failure modes must be assessed, for the containment system on both the reference carrier and the new design. This is generally carried out using dynamic finite element analyses and needs to account for the different design features and material properties of the membrane CCS type (NO96, MkIII, CS1, etc.). Detailed procedures can be found in the guidance documents mentioned above, as well as simplified methods that may be applicable.

Once the sloshing design loads and the containment system capacities have been determined for both the systems, the comparative analysis can be performed. Here we examine the stated procedure from *BV* [41.28] which is carried out in two stages. In the first stage as shown in Fig. 41.23, a scaling factor λ for the sloshing loads is determined.

$$\lambda = \min\left(\frac{C_{\text{ref}}}{P_{\text{ref}}}\right) , \tag{41.10}$$

where C_{ref} is the full-scale dynamic capacity of the containment system (versus surface) used in the reference vessel and P_{ref} is the design sloshing loads for the reference vessel obtained from the model tests. λ is chosen such that the scaled design load curve is tangent to the capacity curve.

In step 2, the load-scaling factor λ is applied to the design sloshing load curve of the new design, P_{target}. The new design is deemed acceptable if the capacity exceeds the scaled sloshing loads after incorporating a safety factor (SF) (Fig. 41.24). That is, if

$$C_{\text{target}} \geq \text{SF}\lambda P_{\text{target}} . \tag{41.11}$$

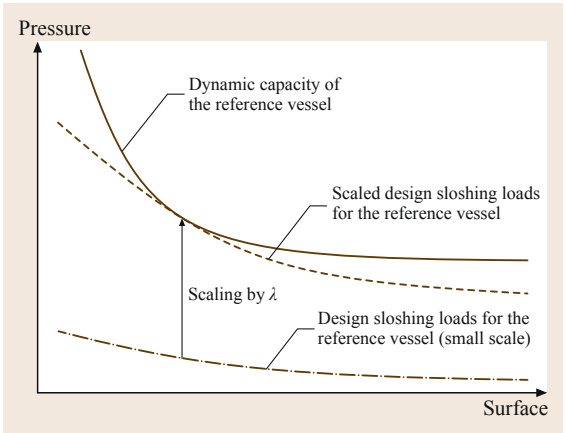

Fig. 41.23 Scaling of design sloshing loads for reference vessel

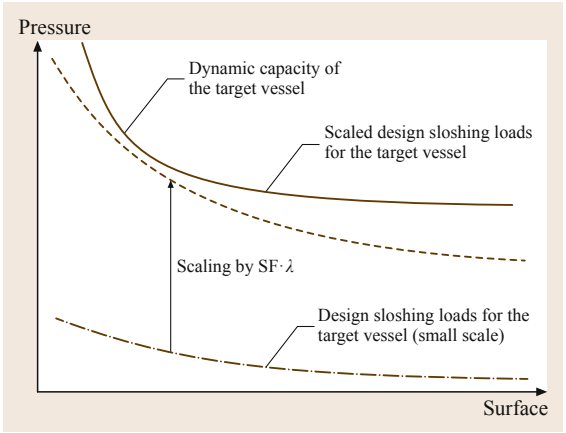

Fig. 41.24 Scaling of design sloshing loads for target vessel

41.5.2 Model Testing

Sloshing model tests are the favored technique to obtain sloshing loads. A tank geometrically similar to the specific cargo tank being studied is mounted atop a 6 degree of freedom platform like a hexapod or Stewart platform, (Fig. 41.25). The motion of the platform is a scaled synthetic time history of the vessel motion over an expected extreme seastate. Clusters of pressure sensors are located at positions where extreme pressures are expected. The traces from the pressure sensors are post processed to determine rise times, peak pressures, and decay times. A statistical model is built up of the sloshing impact pressures and used to determine the design sloshing impact loads for the containment system.

Tank

It is essential that the sloshing test tank should be an accurate representation of the actual cargo tank. A typical LNG carrier with a membrane containment system will have several prismatic tanks and a wedge-shape tank at the bow of the carrier. The sloshing impact types experienced by the latter are different from the prismatic tanks and are induced by a different mode of motion as well. Regarding the geometric scale of the test, it is

Fig. 41.25 Sloshing test using hexapod (courtesy of SYMETRIE)

recommended that the model scale should be as close as possible to the prototype scale in order to minimize scale effects. Obviously, there are practical limitations to the size of the model test tank such as the laboratory space available but more importantly the power required to excite the tank accurately according to the specified motion. Test tanks are generally designed to be transparent or with view ports to observe physical sloshing. However, steel or aluminium may be used to provide the necessary strength in the case of large tanks or a pressurized/depressurized tank.

Fluid Selection and Ullage Pressures

The typical gas–liquid combination used in sloshing tests is air–water. Further, the pressure in the tank ullage space is uncontrolled, that is, at atmospheric pressure. However, it is known that gas bubble cushioning has a significant effect on the impact pressures, with gas–liquid density ratio being an important parameter. The density ratio for air–water is significantly different from LNG–methane. Another phenomenon that may affect the cushioning effect is the bubble collapse as the methane condenses back into the bulk liquid. To try to account for some of these effects, various alternative gas–liquid combinations have suggested. Some combinations that can be found in the literature include SF_6-water, air-boiling water, and CO_2-carbonated water. Pressurized and depressurized ullage spaces have also been investigated.

Sensors, Sensor Distribution, and Data Acquisition

As Fig. 41.26 shows, a sloshing tank is generally outfitted with several arrays of pressure sensors. It is generally recommended that individual pressure sensors have as small a sensing surface as possible in order to capture a wide range of pressure versus loaded area. Depending on the geometric scale, even a sensor with a 3 mm diameter sensor may represent a large area in prototype scale. Sensors should also have an appropriate dynamic range and response, as model scale sloshing pressures increase in milliseconds and recorded peak pressures are at several bar which is typical. It is important that the sensor performance is prequalified prior to the sloshing test. For example, most off-the-shelf pressure sensors are designed for single-phase applications and the sensor might experience thermal shock each time it is wetted as a wave impacts it, leading to a spurious drop in pressure trace which is not physical in nature. Wedge drop tests are sometimes used to qualify the sensors. Special care should be paid in mounting the sensor flush with the inner surface of the tank as any protrusion or cavity will affect the fluid flow around the sensor and hence the pressure trace itself.

Peak sloshing pressures are generally expected at several locations within the tank, especially at corners and knuckle points. Peak pressures are also inversely proportional to the size of the loading area, that is, very high pressures can be recorded over a small area but are smaller when averaged over a larger area. It is important to investigate both area extremes as smaller areas

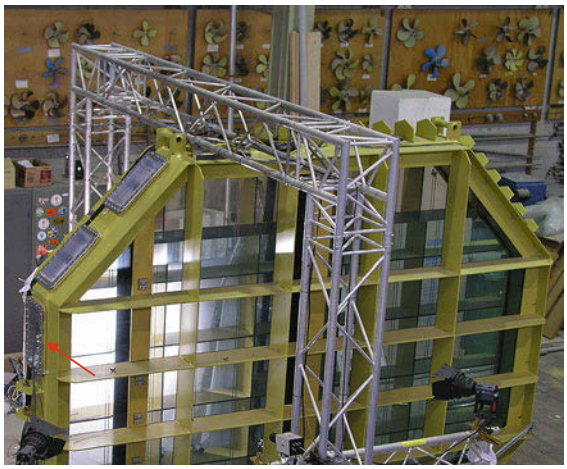

Fig. 41.26 Pressure sensor array on two-dimensional (2-D) sloshing tank (photo courtesy of MARIN)

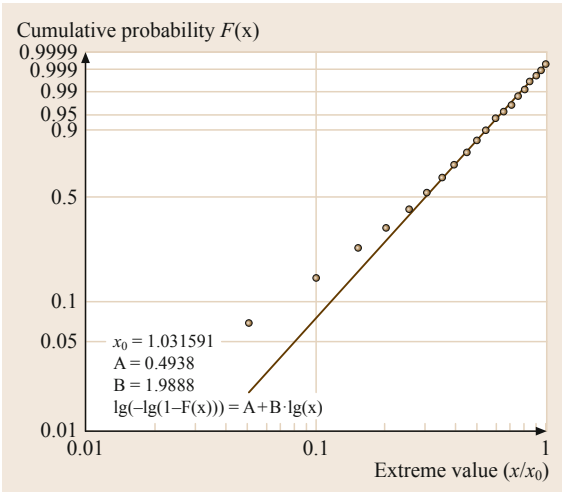

Fig. 41.27 Typical Weibull tail fitting

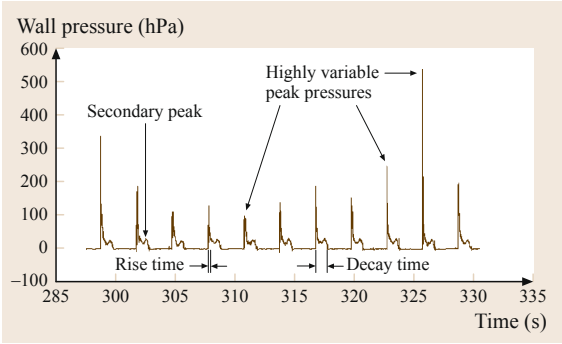

Fig. 41.28 Characteristic sloshing impact pressure trace

require a larger *local* pressure to induce a structural response and the converse is true for larger areas. For this reason the sensors are deployed in arrays of 3×3 or larger. The relationship between peak pressure and loaded area, such as that shown in the above section, can then be easily investigated by averaging over different combinations of pressure sensors.

As mentioned above, model scale sloshing impacts have rise-times in milliseconds, therefore the data sampling rate is recommended to be at least 20 kHz in order to accurately capture the peak of each sloshing impact. Such a high sampling rate in turn requires a specialized high-fidelity data acquisition system. Due to the large number of sensors and high sampling rate, the data storage strategy requires careful consideration. Some techniques that have been employed are to compute and store the data statistics only and to discard the actual pressure time trace. Triggering methods have also been used to store only data in a window centered around each impact. This is a very efficient method as much of the pressure trace show little sloshing activity. Of

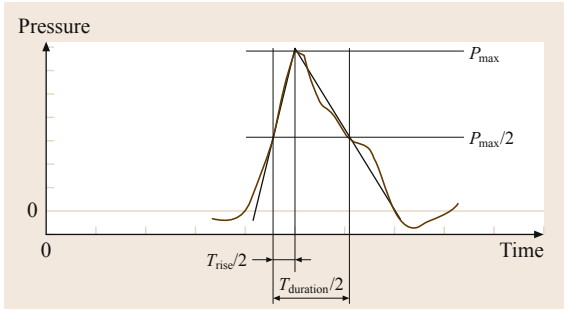

Fig. 41.29 Typical sloshing impact pressure trace with idealized form

course, if one wishes to correlate the pressure trace with the motion of the tank that is usually sampled at a much lower rate, a scheme to synchronize the low- and high-speed data acquisition has to be devised.

Post-Processing

Numerous individual runs are performed in a sloshing model test campaign. In general, the expected service environment of the carrier is examined to determine the conditions resulting in motions that will induce the most extreme sloshing loads. Each condition is repeated several times and at different fill levels to ensure that the sloshing loads for that condition can be appropriately modelled statistically. Typically, each sloshing run is conducted for 3–5 h prototype time to generate enough sloshing impacts in order to determine an appropriate fit using an extreme value statistical model for the impact pressures. The Weibull distribution (Fig. 41.27) is typically used, although other models such as the generalized Pareto may also be used. Once the extreme value distribution has been fitted, the distribution can be used to predict the expected maximum sloshing pressure for the tested condition at the appropriate probability level.

The individual sloshing traces (Fig. 41.28) may also be processed into an idealized representation for ease of data processing. The most common representation is the triangular impulse shape. The description described here is the *ABS* [41.27] formulation. Figure 41.29 shows a typical impact recorded in the pressure trace. The sloshing impact is characterized by a peak pressure P_{max}, a short rise time T_{rise}, typically only several milliseconds in model scale and the decay time which is measured in tens of milliseconds. As mentioned previously, the sampling rate needs to be sufficiently high to accurately capture the profile of the sloshing impact time history. For each sloshing impact the idealized triangular representation is thus determined from the P_{max} and the time it takes for the pressure to rise from $P_{max}/2$ to P_{max} and from the time it takes to decay from P_{max} to $P_{max}/2$.

42. Salvage Operations

Michael S. Dean

Salvage engineering is a broad-based, interdisciplinary field. Salvage engineers must have a firm grasp on the principles of naval architecture to be able to assess the strength and stability of a damaged vessel. A working knowledge of strength of materials, mechanics, dynamics, and structures is requisite, as is some understanding of soil mechanics, fluid dynamics, coastal processes, safety engineering, and the theory and practice associated with rigging systems design and operation, pumping operations, compressed air system design and operation, metals fabrication, industrial processes, and explosive use. An effective salvage engineer will also be familiar with ship operations, deck seamanship, machinery operation, diving, and oil-spill remediation. That said, an often quoted anecdote states that:

> *Ship salvage is a science of vague assumptions based on debatable figures from inconclusive instruments, performed with equipment of problematic accuracy by persons of doubtful reliability and of questionable mentality.*

The referenced publications contain thousands of pages of information developed from decades of experience and operations. Anyone undertaking marine salvage operations would be well advised to spend time within these publications to leverage the wealth of that knowledge. The material presented throughout this chapter is from a set of the United States Navy's Salvage Technical Manuals (Vol. 1–3) [42.1–3] published by Commander, Naval Sea Systems Command, Office of the Director of Ocean Engineering, Supervisor of Salvage and Diving.

42.1 The Casualty and Response

More often than not, initial assumptions must be made regarding the characterization of the casualty. Initial reports often contain conflicting information and the salvage team must initiate action for a rapid salvage assessment without having all the facts. Insurance coverage may very well frame the salvage response, affect the salvage contract type and therefore the composition of the salvage team. A cast

of characters: ship owners, underwriters, classification societies, salvage contractors, and regulators will all play a role in any significant salvage operation. Early salvage engineering assessments of structural integrity and stability can often determine the options available to the salvage team, the contract type preferred by the owners and underwriters and the actions of regulators in response to the developed salvage plan.

42.1.1 Contract Types

The type of contract can have a significant effect on the pace and success of the operation. Salvage and wreck removal operations invariably carry a degree of financial risk to the contractor and will affect the demands and expectations of the salvage officer/master on the personnel involved. There are several types of contracts used for salvage and wreck removal:

- *Open Form Contracts*: There are several open form contracts used in commercial salvage especially in cases of offshore casualties of flooding and towing to a port of refuge. These contracts are agreement that the salvor will undertake the salvage operation using his best endeavors with the compensation being settled by arbitration if the salvor is successful. If the salvors are not successful, they receive no compensation, thus the common term No Cure–No Pay for these types of contracts. This contract type will call on the salvage engineer to deliver the technical analysis very quickly and positively as time is of the essence. There is no room for second guessing in situations of emergency salvage and towing.
- *Fixed Price No Cure-No Pay Contracts*: This type of contract is frequently seen in salvage, particularly in wreck removals. Typically, wreck removal is a slower paced operation for the salvage engineer as there is generally time for planning trade-offs and survey opportunities.
- *Fixed Price Contracts*: Fixed price contracts are sometimes used in salvage and wreck removal. In this type of contract, the risk to the contractor is high, and it can be expected that a *risk factor* of up to 100% will be applied to the bid price. This type of contract can lead to significant pressures on the salvage engineer to expedite work and increase the pace of analysis if costs are becoming out of control and progress is not being made.
- *Time and Materials*: The time and materials contract is particularly applicable where there are a large number of unknowns that cannot be accounted for or estimated accurately in salvage planning. This type of contract has the disadvantage of not presenting much incentive to the contractor to finish his work expeditiously and cheaply. These contracts will typically provide the salvage engineer with a lot of analysis work sorting out the trade-offs in the salvage planning.
- *Cost Plus Fee*: Like time and materials contracts, costs plus fee contracts are useful when the salvor's costs are difficult to predict. Fees that are based on a percentage of the costs encourage the contractor to run his costs up, but incentive fees based on performance give the contractor an inducement to reduce costs and maximize his profits – advantageous to all. The salvage engineer can expect cost trade-off analyses.

42.1.2 Salvage Personnel

The salvage officer/master is typically the recognized leader of the salvage effort and the one on-scene person who directs the activity of the salvage team. Salvage team personnel include operations personnel who are expert in rigging and crane operations, fabrication and welding, mechanical and industrial repair and maintenance trades, boat operators, hydraulics and air systems technicians, remotely operated vehicle (ROV) operators and divers who along with the salvage engineering personnel must work together in a cohesive team that takes advantage of the strengths each discipline brings to the project. Shoreside there are expert facilitators and logistics personnel whose job is to procure and deliver equipment. Fitting the team together and getting the most out of each member requires skill on the part of the leadership, and maturity and cooperation from all the team members:

- *Salvage Officer/Salvage Master*: The salvage officer/master typically is a naval officer or master mariner (United States Coast Guard (USCG) licensed) who is fully at home in command of ships and tugs at sea. They must be expert in all of the operational skills required to conduct ship operations and towing. The salvage officer, if not himself a diver, should have a comprehensive knowledge of diving safety, the diving environment, environmental limitations on divers, and decompression practices. Salvage officers must keep the divers' safety paramount; diving safety must never be compromised. The job of salvage officer/master calls for extraordinary leadership skills.
- *Salvage Engineer*: Salvage engineers usually are technical advisors reporting directly to the salvage officer/master and are seldom in direct charge of working a salvage crew. The salvage engineer's

main role is to put numbers and dimensions to the emerging salvage plan and to analyze physical forces of ship buoyancy and stability, strength of material, pumping systems, flow rates, in fact everything involved with implementing salvage techniques. They must have excellent communication skills and an uncanny ability to guess what the salvage officer/master will need in the way of analysis and information to move from a plan concept to execution by the salvage crew. Ideally, they will combine the skills of seasoned naval architects and ocean engineers with that of marine engineers who are fully familiar with all shipboard systems. Salvage engineers are typically degreed Naval Architects, licensed Marine Engineers, and/or a P.E. with specialty training in ocean engineering. It is a great asset to the salvage engineer to have been to dive school.

Salvage teams are typically made up of personnel with years of experience in industrial trades including machinery operations, rigging and crane operations, hydraulics, pumping, and compressed air systems. They must be fully at home in a life at sea. Experience in fabrication and welding is essential on virtually every salvage operation. Salvage operations work around the clock when it is practical to do so and there must be sufficient people with the right skills to make multiple shifts effective. There must also be enough supervisors to supervise multiple shifts effectively. There must be strong supervision on all shifts. The strongest supervisors should be assigned to the night shifts.

- *Divers*: Divers and tenders are an integral and very special part of almost every salvage crew. They carry out a wide variety of mechanical work requiring fine judgment underwater – an environment that is hostile and hazardous. Because of the medium in which they work and the constraints it places on them, divers require much more time to carry out a task than surface workers require for the same task. A good salvage diver requires a high degree of patience, persistence, and a desire to see the job through.

42.1.3 The Salvage Engineer's Role

Salvage engineers bring to a salvage operation a deep technical background, often not balanced by a commensurate amount of experience. Other members of the team may have considerable experience and knowledge of what actions worked on other jobs, but may not have the technical depth to understand why and how they did work, how close they were to disaster, or how much overkill they had built in. Self-styled practical people with extensive experience, inherent common sense, and knowledge of how to do things, and theoretical engineers make a powerful team. They must take the time to listen to one another, understand one another's reasoning, and develop mutual respect.

Salvage engineers may be placed in various positions within a salvage response. They may be advisors to the owners or underwriters where they will analyze a salvage plan to assess its feasibility; they may be part of the salvors team where they will assist the salvage masters in plan development; they may be part of the regulators' team where their analysis will identify plan risk. Regardless of where they fit in the organization, engineers should take the time and make the effort to seek the advice and ideas of the people who will build and install their designs or implement a salvage plan. Minor design changes that do not affect the function of a design may make its construction and installation considerably more effective. Engineers who take the time to listen to and discuss the salvage crew's ideas will find the crew coming to them freely with valuable suggestions. The salvage engineer must not exhibit *pride of authorship* and must be prepared to absorb practical criticism to adapt salvage techniques to the particular job at hand.

A very real hazard exists when engineers and practical people develop a dichotomy and fail to communicate. Salvage operations have been severely disrupted when practical people have modified engineers' designs, unintentionally destroying their strength or integrity. Engineers must get out on deck and down in the holds, observe what is going on, see where the trouble spots are, and make an effort to understand the practical people.

42.2 Introduction to Salvage Engineering

There are no *standard* procedures or set plans in salvage operations; there are only well-known techniques that are employed in series or in parallel to accomplish the salvage goal. The salvage engineer and his team are expected to be conversant and analytically competent in the entire array of techniques used to effect salvage. The salvage operation will be incremental with the first steps generally taken to stabilize the situation (extinguish the fire, stop the flooding, pin the grounded ship, etc.), and then move on to gain control over the vessel by shifting weights, ballasting, patching, etc., and only then free the ship. A good salvage plan based on tried and true techniques will not ensure success, but an operation that is not well thought out and organized in the early

stages has little chance of success. Adequate planning is impossible without a thorough and detailed survey of the casualty and the salvage site. This is seldom accomplished before the initial salvage plan has met the reality of the operation. Often the second casualty of a salvage operation is the salvage plan (the first being the casualty itself). The salvage engineer must approach each casualty armed with a comprehensive knowledge of the general physical principles at play in the type of salvage casualty (grounding, stranding, capsize, flooding and list, collision, etc.) and in whatever setting (Offshore, Harbor, Coastal, etc.) and the best (if limited) information available. To demonstrate the workability of the salvage plan and the sequence of techniques involved, the salvage engineer must evaluate the position and condition of the ship, understand her difficulties, and conceptualize the work and methods to accomplish the aims of the operation.

Salvage is conducted to recover useable or valuable objects from the sea, or to eliminate a pollution hazard. A ship is salvaged because there is a reason for its recovery or removal – not simply because it is wrecked. The goals of a salvage operation influence virtually every decision throughout the operation. Military salvage is constrained by economy; yet, cost is only one of the several factors affecting the decision to undertake a given salvage operation. Tactical, strategic, political, environmental, and other factors also affect the decision. Although salvage engineers seldom decide whether a salvage operation will be undertaken, their evaluation of the technical requirements, difficulties, and probable cost strongly influence those decisions.

A number of authorities have attempted to expound definitive categorizations of salvage and related work, variously based on location, operational environment, or the type of casualty; no classification system can adequately describe all aspects of marine salvage. A brief examination of the different types of salvage work, however, can illustrate how varying conditions can constrain or facilitate operations.

42.2.1 Offshore and Coastal

Coastwise salvage is the refloating of ships stranded in exposed coastal waters. The fate of grounding casualties exposed to surf, swell, currents, and weather will deteriorate with time, often rapidly. A simple grounding on a coastal bar can lead to broaching and with the effects of wind and sea end up high and dry in a matter of hours, often before tug assistance can be brought to bear. Windows of opportunity created by abnormally high tides or fair weather may close abruptly and not reopen for weeks or months, while the casualty deteriorates. Often a simple grounding will evolve into a wreck in place operation. With offshore and ocean salvage, assistance must be prompt and effective to preserve the value of ship and cargo, making offshore salvage perhaps the most difficult type of salvage. Offshore salvage is undertaken from especially constructed and outfitted salvage vessels and tugs. Portable equipment must be relatively compact and lightweight, as it often must be transported by a helicopter or a small boat, and positioned by manual labor. Conditions are often not suitable for the employment of floating cranes, construction tenders, dredges, and similar floating plant which are usually designed for operation in sheltered waters. Furthermore, such equipment may not be immediately available, because of prior commitments or long transit time from the nearest port. Swift, but accurate and thorough surveys are required to ascertain the casualty's condition and to provide input for an engineering analysis to support a timely salvage plan.

A vessel damaged but still freely afloat may require many different services. The most useful service may be to assist the ship's own damage control effort. Measures taken to assist a damage control effort are, for the most part, planned responses to likely situations; any engineering or specific planning must be quick and extemporaneous. After the situation has stabilized, the salvage effort enters a phase where more detailed planning and engineering may be required.

42.2.2 Harbor and Inshore

Salvage of ships stranded or sunk in sheltered waters is termed as harbor or inshore salvage. Casualties in harbors or other sheltered waters are not usually subject to the rapid deterioration characteristic of offshore salvage; unless they obstruct important channels or facilities, time is not a driving factor. There is usually time for thorough surveys and planning, and to arrange for equipment and services from port facilities, widely dispersed salvage units, or contractors. As floating cranes can generally be employed, portable equipment is not as constrained by size and weight as in offshore salvage. Carpenters, stevedores, and general labor can be obtained from local labor pools.

42.2.3 Cargo and Equipment Recovery

In some cases, a casualty may not be worth saving, but her cargo or equipment may have a high priority for salvage, such as high-value cargos, critical war materials, sensitive military items, machinery, weapons mounts, etc. For example, the battleships ARIZONA and UTAH, sunk at Pearl Harbor, were never raised, but most of their guns were removed for use ashore or on new-construction combatants. When planning for cargo

and equipment removal, the integrity and stability of the hull must be evaluated to protect the environment. Machinery removal will often introduce machinery lubricants into the hull and or surrounding waters, which must be addressed in the salvage pollution plan. When there is no free communication with the sea, the hull can provide an excellent envelope to capture fuel and lubricant, and employing internal oil skimming equipment is a crude measure to take before attempting to move or section the hull for removal. There are often pressures to remove cargo prior to refloating a stranded ship. Generally, cargo removal for lightering is inefficient as compared to bunker or seawater ballast removal.

42.2.4 Pollution and Hazmat

Whereas early salvors' focus was entirely on the recovery of ship and cargo, today's environmental awareness dictates that all salvage is aimed at protecting the environment. There are an increasing number of salvage operations that do not involve the recovery of the vessel itself, either intact or in pieces. Many of these operations involve the recovery of oil, hazmat, and other materials that are a threat to the marine environment. Public and Government awareness of our environment has given way to the development of laws and obligations of the responsible party to clean remains of shipwrecks of all pollutants. In addition to the containment of pollutants, salvors must often work to protect sensitive marine ecosystems (e.g., coral reefs), where salvage work is often carried out.

Pollution Prevention and Control

Despite the time-critical nature of many salvage operations, in all but in some cases of military emergency the salvor's attention must be given to the prevention and control of pollution from the casualty. Pollution control and abatement efforts will affect the Salvage engineer's approach to vessel recovery and refloat tasks, for example, in cases where oil tanks have been holed and exposed to the sea it may be necessary to access the tank from the deck to strip the oil from the tank before attacking other operations. This type of action is fraught with hazards and the salvage engineer who is assisting in the planning (pumping flow rates, suction head, viscosity, etc.) the work must be cognizant of how risks of explosion are to be safely mitigated. The salvage engineer must be familiar with the applicable regional and local oil and hazardous substance (OHS) spill contingency plans; salvage plans must address control and cleanup of spills that have already occurred, as well as prevention of further pollution. The salvage engineer gets involved with pollution control in many salvage scenarios including cases where oil and hazardous materials (HAZMATs) are in free communication with the sea (ship is holed), or liquid cargos are being lightered or transferred from a casualty to an attending vessel.

Hazardous Materials

HAZMAT such as flammable or explosives, corrosive, reactive, or toxic cargos are an increasingly important part of any marine salvage operation. Operations involving chemical tankers, barges, or naval combatant vessels have inherent HAZMAT risks. Increasing amounts of HAZMAT are transported to treatment/disposal sites, leading directly to more HAZMAT salvage situations. Also, HAZMAT encountered in the salvage operation can stop or delay work for fear of hazarding workers or the environment. The presence of recognized HAZMAT may prohibit open ocean wreck disposal or scrap sale. In many cases, proper precautions by the salvage team can minimize the impact on the salvage effort. In such cases, HAZMAT removal contractors must be incorporated into the salvage plan.

Ecosystem Protection

Rapid removal of a vessel from its compromised position is generally the best method of mitigating environmental damage. The longer a vessel remains in extremis, the more likely the surrounding ecosystem will be adversely affected by leaking fuel and lubricants, hazardous cargos, or simply mechanical action of the hull on the bottom. The expediency of removal must however be weighed against the damage inflicted on the environment by the salvage process. In evaluating processes and equipment, engineers must consider the effects, for example, of excavators operating in sensitive marshlands or wire ropes and anchors abrading nearby corals.

42.2.5 Wreck Removal

Salvage forces may be called upon to remove hazardous or unsightly wrecks that have little salvage value. Wrecks are refloated or removed by the most feasible or suitable methods available to the salvors, without regard for the salvage value of the wreck. All that is desired is the wreck to be removed; salvors may cut the wreck into easily handled sections or refloat and remove the hulk in one piece, based only on their evaluation of which technique is easier. If the wreck is to be sunk in deep water, however, cast-in-place foam would be a poor choice as a refloating method.

42.2.6 Clearance

Harbor and waterway clearance involves the coordinated removal or salvage of a number of wrecks.

Obstructions may include vessels of all sizes and descriptions that have stranded or sunk with varying degrees of damage as a result of storm, collision, fire, combat, sabotage, or intentional wrecking by retreating enemy forces. In addition, vehicles, rail cars, port equipment, collapsed bridges and piers, and other materials may also require removal.

Clearance work is similar to wreck removal in that concerns over the preservation of the value of obstructing vessels or hardware generally give way to the requirement to restore the waterway to useful operation. Harbor clearance is often part of a larger port rehabilitation effort that may involve elements of the Army, Navy, or Marine Corps engineer branches; the Army Transportation Corps; the Coast Guard; Army and Navy Supply organizations; or civilian contractors. Mine, ordnance, or booby-trap clearance may be necessary in military harbors, combat-obstructed waterways, or ports intentionally wrecked by enemy forces. Various Federal, state, and local agencies will be involved in peacetime clearance operations.

42.3 Data, Surveys, and Planning

42.3.1 Essential Data and Ship Information

The conditions at a salvage site are seldom fully defined in the beginning and often are not ever fully defined during a salvage operation. Conditions change with time and weather. The salvage engineer's information gathering should begin immediately on the notice of involvement and well before the salvage team begins to arrive on scene, and should continue until the operation is complete.

Intact Ship Information

Intact ship information is available in the documents as follows:

Curves of form (displacement and other curves) and/or hydrostatic tables containing as much of the following as possible:

- Displacement in saltwater
- Vertical center of buoyancy (VCB or KB)
- Longitudinal position of the center of buoyancy (LCB)
- Tons per inch submersions (TPI)
- Moment to change trim one inch (MT1)
- Height of transverse metacenter above keel (KMt)
- Longitudinal metacentric radius (BML)
- Areas of waterplane (Awp).

Drawings and other reference material include:

- Trim and stability booklet
- Damage control manual
- Lines drawing, body plan and table of offsets
- Bonjean curves
- Booklet of general arrangements
- Capacity plan
- Docking plan
- Inboard and outboard profiles.

Structural drawings include:

- Midship section
- Shell expansion
- Scantling plans and sections
- Structural inertia and section modulus tables by frame or station
- Weight distribution curve.

Computer model of the vessel from ship owner, classification societies, etc.

Relevant information includes the ship's daily logs to include:

- Ship's log's – draft, trim, and list conditions
- Cargo loadout and tank soundings
- Speed and heading at the time of the casualty.
