Chapter 1 Engineering Thermodynamics 1

1.1 Fundamentals 3
Michael J. Moran
1.2 Control Volume Applications 15
Michael J. Moran
1.3 Property Relations and Data 23
Michael J. Moran
1.4 Combustion 56
Michael J. Moran
1.5 Exergy Analysis 67
Michael J. Moran
1.6 Vapor and Gas Power Cycles 76
Michael J. Moran
1.7 Guidelines for Improving Thermodynamic Effectiveness 84
Michael J. Moran
1.8 Exergoeconomics 86
George Tsatsaronis
1.9 Design Optimization 94
George Tsatsaronis
1.10 Economic Analysis of Thermal Systems 102
George Tsatsaronis
1.11 Exergoenvironmental Analysis 106
George Tsatsaronis
1.12 Advanced Exergy-Based Methods 107
George Tsatsaronis

Chapter 2 Fluid Mechanics 113

2.1 Fluid Statics 115
Stanley A. Berger
2.2 Equations of Motion and Potential Flow 123
Stanley A. Berger
2.3 Similitude: Dimensional Analysis and Data Correlation 139
Stuart W. Churchill
2.4 Hydraulics of Pipe Systems 154
J. Paul Tullis and Blake Paul Tullis
2.5 Open Channel Flow 170
Frank M. White
2.6 External Incompressible Flows 178
John C. Leylegian

2.7 Compressible Flow 190
John C. Leylegian
2.8 Multiphase Flow 209
John C. Chen
2.9 Non-Newtonian Flows 223
Anoop K. Gupta, Raj P. Chhabra, Thomas F. Irvine, Jr., and Massimo Capobianchi

Chapter 3 Heat and Mass Transfer 249

3.1 Conduction Heat Transfer 250
Robert F. Boehm
3.2 Convection Heat Transfer 263
3.2.1 Natural Convection 263
Swati A. Patel, Raj P. Chhabra, George D. Raithby, and K.G. Terry Hollands
3.2.2 Forced Convection: External Flows 283
Anoop K. Gupta, Raj P. Chhabra, and N.V. Suryanarayana
3.2.3 Forced Convection: Internal Flows 305
Anoop K. Gupta, Raj P. Chhabra, and N.V. Suryanarayana
3.2.4 Convection Heat Transfer in Non-Newtonian Fluids 315
Swati A. Patel, Raj P. Chhabra, Thomas F. Irvine, Jr., and Massimo Capobianchi
3.3 Radiative Heat Transfer 341
Michael F. Modest
3.4 Phase-Change 368
3.4.1 Boiling and Condensation 368
Van P. Carey
3.4.2 Particle Gas Convection 388
John C. Chen
3.4.3 Melting and Freezing 393
Vasilios Alexiades and Jan Kośny
3.5 Mass Transfer 417
Anthony F. Mills

Chapter 4 Applications 451

4.1 Heat Exchangers for the Process and Energy Industries 459
Joshua D. Ramsey, Ken Bell, and Ramesh K. Shah
4.2 Application of Nanofluids in Heat Exchangers: Performance and Challenges 545
Bengt Sundén and Zan Wu
4.3 Convection Heat Transfer in Conduits with Nanofluids 575
Clement Kleinstreuer and Zelin Xu
4.4 Fouling in Crude Oil and Food Related Heat-Transfer Equipment 603
D. Ian Wilson and Graham T. Polley
4.5 Bioheat Transfer 629
John A. Pearce, Kenneth R. Diller, and Jonathan W. Valvano
4.6 Thermal Insulation 716
David W. Yarbrough
4.7 Energy Audit for Buildings 728
Moncef Krarti

4.8 Advanced Energy-Efficient Building Envelope Systems 749
Moncef Krarti and John Zhai
4.9 Use of Phase Change Materials in Buildings 781
Jan Kośny and David W. Yarbrough
4.10 Thermal Bridges in Building Structures 800
Jan Kośny and David W. Yarbrough
4.11 Compressors 818
Christian K. Bach, Ian H. Bell, Craig R. Bradshaw, Eckhard A. Groll, Abhinav Krishna, Orkan Kurtulus, Margaret M. Mathison, Bryce Shaffer, Bin Yang, Xinye Zhang, and Davide Ziviani
4.12 Pumps and Fans 853
Robert F. Boehm
4.13 Cooling Towers 864
Anthony F. Mills
4.14 Pinch Technology 875
Santanu Bandyopadhyay and Shankar Narasimhan
4.15 Air-Conditioning Systems 897
Donald L. Fenton
4.16 Heat Transfer Enhancement 933
Raj M. Manglik
4.17 Heat Pipes 953
Sameer Khandekar
4.18 Liquid Atomization and Spraying 986
Mario F. Trujillo and *Rolf D. Reitz*
4.19 Heat Transfer in Plasma Sprays 1003
Milind A. Jog
4.20 Thermal Processing and Preservation of Foods 1017
Prabhat Kumar and K.P. Sandeep
4.21 Thermal Conduction in Electronic Microstructures and Nanostructures ... 1036
Sanjiv Sinha, Krishna Valavala and Jun Ma
4.22 Role of Cooling in Electronics Reliability 1078
Pradeep Lall
4.23 Direct Contact Heat Transfer 1131
Harold R. Jacobs
4.24 Heat Transfer in Presence of Synthetic Jets 1153
Mangesh Chaudhari and Amit Agrawal
4.25 Temperature and Heat Transfer Measurements 1162
Robert J. Moffat and Tadhg O'Donovan
4.26 Flow Measurement 1188
Jungho Kim, S.A. Sherif, and Alan T. McDonald
4.27 Applications of Artificial Neural Networks and Genetic Methods in Thermal Engineering 1217
Arturo Pacheco-Vega, Gerardo Diaz, Mihir Sen, and K.T. Yang
4.28 Thermal Aspects of Paper Making 1270
Martine Rueff and Evelyne Mauret
4.29 Drying of Materials 1306
Pawel Wawrzyniak, Ireneusz Zbicinski, and Mariia Sobulska
4.30 Heat Transfer in Rotary Kilns 1338
P.S. Ghoshdastidar
4.31 Heat Transfer in Glass Manufacturing Processes 1352
Naveen Tiwari and Rajappa Tadepalli

4.32 Solar Hydrogen as a "Renewable Reductant": Points and Counterpoints ... 1369
Raj Ganesh S. Pala
4.33 Passive and Active Solar Distillation ... 1386
Desh Bandhu Singh and G.N. Tiwari

Chapter 5 Numerical Methods and Computational Tools ... 1441

5.1 Computer Aided Engineering ... 1442
Atul Sharma
5.2 Finite Difference Methods ... 1445
Atul Sharma
5.3 Finite Volume Method ... 1454
Atul Sharma
5.4 Finite Element Method ... 1468
Salil S. Kulkarni
5.5 Lattice Boltzmann Method ... 1496
K. Hrisheekesh and Amit Agrawal
5.6 Immersed Boundary Method for Fluid-Structure Interaction Simulations ... 1507
Rajneesh Bhardwaj and Atul Sharma
5.7 Numerical Methods for Multiphase Flows ... 1524
Shyamprasad Karagadde and Atul Sharma
5.8 Large Eddy Simulation for Wall-Bounded Flows ... 1545
Amitabh Bhattacharya
5.9 Software and Computer Codes ... 1558
Atul Sharma

Appendix A: Properties of Gases and Vapors ... 1559
Paul Norton

Appendix B: Properties of Liquids ... 1597

Appendix C: Properties of Solids ... 1601

Appendix D: SI Units and Conversion Factors ... 1605

Index ... 1613

Acknowledgments

I would like to place on record my deep appreciation and gratitude to the many individuals who have facilitated the publication of this revised *Handbook*. First of all, I am grateful to the authors who have contributed to this Handbook. I have really enjoyed working with them all. Clearly, the high quality of the work included here demonstrates their passion, dedication, and high level of professionalism. Without them, this updated *Handbook* would not have been possible! Next, I wish to thank numerous reviewers for their timely and constructive reports on various sections, especially those in Chapter 4, which have led to significant improvements to the material on engineering applications included here. During the past two years, it has been a wonderful experience to work with many individuals at Taylor and Francis, the publishers of this *Handbook*. Each one of them has been extremely helpful, not only in keeping this project under a tight leash, but also coming to my rescue whenever I was in a difficult situation. Some of these individuals deserve to be singled out here. First and foremost, I would like to express my deep gratitude to Jonathan Plant, the commissioning editor for this project, who patiently answered my endless queries via e-mail and over the telephone and dealt with several unusual requests regarding the artwork, copyright issues, etc. Thank you, Jonathan! Similarly, Kyra Lindholm, Amber Donley, Hector Mojena III, and Laurie Oknowsky went out of their way, and much beyond the call of duty, to help with the issues related to obtaining the necessary permissions to reproduce the copyrighted material in this *Handbook*. Finally, Richard Tressider and Mathi Ganesan (of Codemantra) converted the material received from the individual contributors in a range of formats and styles into the finished product—the *Handbook*! I thank them all for their help during the course of this project.

Preface to the Second Edition

In order to put the field of thermal engineering—thermodynamics and heat transfer—in perspective, one only needs to walk down the aisles of a modern department or hardware store, and look at the range of manufactured goods, appliances, foodstuffs, integrated circuit boards, textiles, papers, televisions, air conditioners, cell phones, etc. now used in everyday life. Their manufacture and satisfactory performance are strongly influenced by various aspects of thermal engineering. Similarly, in the technological world, processes such as the fabrication of metallic and plastic components, fractionation of crude oil into valuable and usable products, desalination of water, and energy generation and management (to name only a few) are all heavily dependent on the application of thermal engineering principles.

Indeed, it is no exaggeration to say that thermal engineering is an inseparable part of the natural and man-made world we inhabit. This *Handbook* brings together current state-of-the-art-knowledge in many key application areas. The objectives and goals of the new edition of this *Handbook* remain the same as that of the first edition published in 2000 under the leadership of Frank Kreith: *The purpose here is not to compete with the available traditional Handbooks of heat transfer that emphasize fundamentals, analytical approaches to thermal problems and elegant solutions of traditional problems in thermal sciences! Instead, this Handbook endeavors to provide most up to date and reliable information on specific topics of interest in a convenient form that is accessible to the working professionals in industry.*

The first three chapters provide a quick refresher on the basic principles of thermodynamics (Chapter 1), fluid mechanics (Chapter 2), and heat transfer (Chapter 3) to understand the wide-ranging specific industrial applications presented in Chapter 4. In view of the growing importance of CFD (computational fluid dynamics) tools used in solving thermal engineering problems, Chapter 5 provides an overview of the range of computational techniques in use now, along with their relative merits and demerits and domains of application. This chapter has been put together by a completely new group of contributors to best address the latest developments across the range of computational methods.

So what is new in this edition? The first three chapters dealing with the fundamentals of thermodynamics, fluid mechanics, and heat transfer have been thoroughly reviewed and revised as deemed appropriate. In Chapter 4 on applications, many new application areas have been added that entail the application of thermal engineering principles, including the drying of wet solids and the role of drying in paper making, glass processing, rotary kilns, solar distillation, solar hydrogen as a renewable reductant, plasma sprays, thermal insulation and thermal bridging in buildings and structures, energy audit and management in buildings, bioheat transfer, to mention a few. Notwithstanding the dynamic and ever-changing nature of the field of thermal engineering, certain choices had to be made in the early planning stages to limit the scope of the *Handbook*. Likewise, a few chapters have been dropped from the first edition. Much of the new material in this *Handbook* has gone through a peer review process and been carefully proofread. However, in a project of this magnitude, with authors from diverse backgrounds, it is inevitable that some errors have gone unspotted. As the editor, I would like to invite the working professionals and other users of this *Handbook* to send me feedback regarding the applications included here, or the topics that should be added to the future editions of this volume, or simply to report the errors spotted so that these can be corrected at the first opportunity.

Raj P. Chhabra
Kanpur, India

Nomenclature

Symbol	Quantity	Unit		Dimensions (MLtT)
		SI	English	
a	Velocity of sound	m/s	ft/s	$L\,t^{-1}$
a	Acceleration	m/s^2	ft/s^2	$L\,t^{-2}$
A	Area: A_c, cross-sectional area; A_p, projected area of a body normal to the direction of flow; A_q, area through which rate of heat flow is q; A_g, surface area; A_o, outside surface area; A_i inside surface area; A_f, fin surface area	m^2	ft^2	L^2
b	Breadth or width	m	ft	L
c	Specific heat; c_p, specific heat at constant pressure; c_v, specific heat at constant volume	J/kg K	$Btu/lb_m\,°R$	$L^2\,t^{-2}\,T^{-1}$
C	Constant or Coefficient; C_D, total drag coefficient; C_f, skin friction coefficient; C_{fx}, local value of C_f at distance x, from leading edge; $\overline{C}_f$, average value of C_f	none	none	—
C	Thermal capacity	J/K	Btu/°F	$M\,L^2\,t^{-2}\,T^{-1}$
$\dot{C}$	Hourly heat capacity rate; $\dot{C}_c$, hourly heat capacity rate of colder fluid in a heat exchanger; $\dot{C}_h$, hourly heat capacity of hotter fluid; C*, ratio of heat capacity rates in heat exchangers	W/K	Btu/h°F	$M\,L^2\,t^{-1}\,T^{-1}$
D	Diameter, D_H, hydraulic diameter; D_o, outside diameter; D_i, inside diameter	m	ft	L
e	Base of natural or Napierian logarithm	none	none	—
e	Total energy per unit mass	J/kg	Btu/lb_m	$L^2\,t^{-2}$
E	Total energy	J	Btu	$M\,L^2\,t^{-2}$
E	Emissive power of a radiating body; E_b, emissive power of a blackbody	W/m^2	$Btu/h{\cdot}ft^2$	$M\,t^{-2}$
E_λ	Monochromatic emissive power per micron at wavelength λ	W/m μm	$Btu/h{\cdot}ft^2$ micron	$M\,t^{-2}\,L^{-1}$
f	Darcy or fanning friction factor for flow through a pipe or duct	none	none	—
f′	Friction coefficient for flow over banks of tubes	none	none	—
F	Force; F_B, buoyant force	N	lb	$M\,L\,t^{-2}$
F_T	Temperature factor	none	none	—
$F_{1\text{-}2}$	Geometric shape factor for radiation from one blackbody to another	none	none	—
g	Acceleration due to gravity	m/s^2	ft/s^2	$L\,t^{-2}$
g_c	Dimensional conversion factor	$1.0\ kg{\cdot}m/N{\cdot}s^2$	$32.2\ ft{\cdot}lb_m/lb{\cdot}s^2$	
G	Mass velocity or flow rate per unit area	$kg/s{\cdot}m^2$	$lb_m/h{\cdot}ft^2$	$M\,L^{-2}\,t^{-1}$
G	Irradiation incident on unit surface in unit time	W/m^2	$Btu/h{\cdot}ft^2$	$M\,L^{-2}\,t^{-1}$
h	Enthalpy per unit mass	J/kg	Btu/lb_m	$L^2\,t^{-2}$
h	Local heat transfer coefficient; $\bar{h}$, average heat transfer coefficient $\bar{h}=\bar{h}_c+\bar{h}_r$; $\bar{h}_b$, heat transfer coefficient of a boiling liquid; $\bar{h}_c$, local convection heat transfer coefficient; $\bar{h}_c$, average heat transfer coefficient; $\bar{h}_r$, average heat transfer coefficient for radiation	$W/m^2{\cdot}K$	$Btu/h{\cdot}ft^2{\cdot}°F$	$M\,t^{-3}\,T^{-1}$

h_{fg}	Latent heat of condensation or evaporation	J/kg	Btu/lb_m	$L^2 t^{-2}$
H	Head, elevation of hydraulic grade line	m	ft	L
i	Angle between sun direction and surface normal	rad	deg	—
I	Moment of inertia	m^4	ft^4	L^4
I	Intensity of radiation	W/sr	Btu/h unit solid angle	$M L^2 t^{-3}$
I_λ	Intensity per unit wavelength	W/sr·μm	Btu/h·sr micron	$M L t^{-3}$
J	Radiosity	W/m^2	$Btu/h·ft^2$	$M L^{-2} t^{-1}$
k	Thermal conductivity; k_s, thermal conductivity of a solid; k_f, thermal conductivity of a fluid; k_g, thermal conductivity of a gas	W/m·K	Btu/h·ft°F	$M L^{-2} t^{-1} T^{-1}$
K	Thermal conductance; k_k, thermal conductance for conduction heat transfer; k_c, thermal convection conductance; K_r, thermal conduction for radiation heat transfer	W/K	Btu/h·ft°F	$M t^{-1} T^{-1}$
K	Bulk modulus of elasticity	Pa	lb/ft^2	$M L^{-1} t^{-2}$
log	Logarithm to the base 10	none	none	—
ln	Logarithm to the base e	none	none	—
l	Length, general or characteristic length of a body	m	ft	L
L	Lift force	N	lb	$M L t^{-2}$
L_f	Latent heat of solidification	J/kg	Btu/lb_m	$L^2 t^{-2}$
$\dot{m}$	Mass flow rate	kg/s	lb_m/s	$M t^{-1}$
m	Mass	kg	lb_m	M
M	Molecular weight	gm/gm mole	lb_m/lb mole	—
$\dot{M}$	Momentum per unit time	N	lb	MLt^{-2}
n	Manning roughness factor	none	none	—
N	Number of moles	none	none	—
NPSH	Net positive suction head	m	ft	L
N	Number in general; number of tubes, etc.	none	none	—
P	Static pressure; p_c, critical pressure; p_A, partial pressure of component A	N/m^2	psi or lb/ft^2 or atm	$M L^{-1} t^{-2}$
P	Wetted perimeter or height of weir	m	ft	L
q	Discharge per unit width	m^2/s	ft^2/s	$L^2 t^{-1}$
q	Rate of heat flow; q_k, rate of heat flow by conduction; q_r, rate of heat flow by radiation; q_c, rate of heat flow by convection; q_b, rate of heat flow by nucleate boiling	W	Btu/h	$M L^2 t^{-3}$
q'''	Rate of heat generation per unit volume	W/m^3	$Btu/h·ft^3$	$M L^{-1} t^{-3}$
q''	Rate of heat generation per unit area (heat flux)	W/m^2	$Btu/h·ft^2$	$M t^{-3}$
Q	Quantity of heat	J	Btu	$M L^2 t^{-3}$
r	Radius; r_H, hydraulic radius; r_i, inner radius; r_o, outer radius	m	ft	L
R	Thermal resistance; R_c, thermal resistance to convection heat transfer; R_k, thermal resistance to conduction heat transfer; R_r, to radiation heat transfer	K/W	h°F/Btu	$L T M^{-1}$
R_e	Electrical resistance	ohm	ohm	—
R	Universal gas constant	8.314 J/K·kg mole	1545 $ft·lb_f$/lb·mole°F	$L^2 t^{-2} T^{-1}$
s	Entropy per unit mass	J/kg·K	$ft·lb/lb_m·°R$	$L^2t^{-2}T^{-1}$
S	Entropy	J/K	ft·lb/°R	$ML^2t^{-2}T^{-1}$

S_L	Distance between centerlines of tubes in adjacent longitudinal rows	m	ft	L
S_T	Distance between centerlines of tubes in adjacent transverse rows	m	ft	L
t	Time	s	h or s	t
T	Temperature; T_b, temperature of bulk of fluid; T_f, mean film temperature; T_s, surface temperature, T_o, temperature of fluid far removed from heat source or sink; T_m, mean bulk temperature of fluid flowing in a duct; T_M, temperature of saturated vapor; T_{sl}, temperature of a saturated liquid; T_{fr}, freezing temperature; T_t, liquid temperature; T_{as}, adiabatic wall temperature	K or °C	°F or R	T
u	Internal energy per unit mass	J/kg	Btu/lb_m	$L^2\ t^{-2}$
u	Velocity in x direction; u′, instantaneous fluctuating x component of velocity; ū, average velocity	m/s	ft/s or ft/h	$L\ t^{-1}$
u*	Shear stress velocity	m/s	ft/s	Lt^{-1}
U	Internal energy	J	Btu	ML^2t^{-2}
U	Overall heat transfer coefficient	W/m^2K	$Btu/h{\cdot}ft^{2\circ}F$	$M\ t^{-3}\ T^{-1}$
U_∞	Free-stream velocity	m/s	ft/s	$L\ t^{-1}$
v	Specific volume	m^3/kg	ft^3/lb_m	$L^3\ M^{-1}$
v	Velocity in y direction; v′, instantaneous fluctuating y component of velocity	m/s	ft/s or ft/h	$L\ t^{-1}$
V	Volume	m^3	ft^3	L^3
$\dot{V}$	Volumetric flow rate	m^3/s	ft^3/s	$L^3\ t^{-1}$
W_s	Shaft work	m·N	ft·lb	ML^2t^{-2}
$\dot{W}$	Rate of work output or power	W	Btu/h	$M\ L^2\ t^{-3}$
x	Coordinate or distance from the leading edge; x_c, critical distance from the leading edge where flow becomes turbulent	m	ft	L
x	Quality	percent	percent	none
y	Coordinate or distance from a solid boundary measured in direction normal to surface	m	ft	L
z	Coordinate	m	ft	L
Z	Ratio of hourly heat capacity rates in heat exchangers	none	none	—

Greek Symbols

α	Absorptivity for radiation, α_λ, monochromatic absorptivity at wavelength λ	none	none	—
α	Thermal diffusivity = k/ρc	m^2/s	ft^2/s	$L^2\ t^{-1}$
β	Temperature coefficient of volume expansion	l/K	1/R	T^{-1}
β_k	Temperature coefficient of thermal conductivity	l/K	1/R	T^{-1}
γ	Specific heat ratio, c_p/c_v	none	none	—
Γ	Circulation	m^2	ft^2	L^2t^{-1}
Γ	Body force per unit mass	N/kg	lb/lb_m	$L\ t^{-2}$
Γ_c	Mass rate of flow of condensate per unit breadth = $\dot{m}/\pi D$ for a vertical tube	kg/s·m	$lb_m/h{\cdot}ft$	$M\ L^{-2}\ t^1$
δ	Boundary-layer thickness; δ_h, hydrodynamic boundary-layer thickness; δ_{th}, thermal boundary-layer thickness	m	ft	L
Δ	Difference between values	none	none	—

ε	Heat exchanger effectiveness	none	none	—
ε	Roughness height	m	ft	L
ε	Emissivity for radiation; ε_λ, monochromatic emissivity at wavelength λ; ε_φ, emissivity in direction φ	none	none	—
ε_H	Thermal eddy diffusivity	m^2/s	ft^2/s	$L^2\,t^{-1}$
ε_M	Momentum eddy diffusivity	m^2/s	ft^2/s	$L^2\,t^{-1}$
ζ	Ratio of thermal to hydrodynamic boundary-layer thickness, δ_h/δ_{th}	—	—	—
η	Efficiency; η_f, fin efficiency	none	none	—
λ	Wavelength; λ_{max}, wavelength at which monochromatic emissive power $E_{b\lambda}$ is a maximum	μm	micron	L
μ	Absolute viscosity	$N{\cdot}s/m^2$	$lb/ft{\cdot}s$	$M\,L^{-1}\,t^{-1}$
ν	Kinematic viscosity, μ/ρ	m^2/s	ft^2/s	$L^2\,t^{-1}$
ν_f	Frequency of radiation	1/s	1/s	t^{-1}
Φ	Velocity potential	m^2/s	ft^2/s	$L^2\,t^{-1}$
ρ	Mass density, 1/v; ρ_l, density of liquid; ρ_v, density of vapor	kg/m^3	lb_m/ft^3	$M\,L^{-3}$
τ	Shearing stress, τ_s, shearing stress at surface; τ_w, shear at wall of a tube or a duct	N/m^2	lb/ft^2	$M\,L^{-1}\,t^{-2}$
τ	Transmissivity for radiation	none	none	—
σ	Stefan-Boltzmann constant	W/m^2K^4	$Btu/h\,ft^2R^4$	$M\,t^{-3}\,T^{-4}$
σ	Surface tension	N/m	lb/ft	$M\,t^{-2}$
φ	Angle	rad	rad	—
ψ	Stokes' stream function	m^3/s	ft^3/s	$L^3\,t^{-1}$
ω	Angular velocity	1/s	1/s	t^{-1}
ω	Solid angle	sr	steradian	—

Dimensionless Numbers

Bi	Biot number
Ec	Eckert number
Eu	Euler number
Fo	Fourier modulus
Fr	Froude number
Gz	Graetz number
Gr	Grahsof number
Ja	Jakob number
Kn	Knudsen number
M	Mach number
Nu	Average Nusselt number; Nu_D, average diameter Nusselt number; Nu_x, local Nusselt number
Pe	Peclet number
Pr	Prandtl number
Ra	Rayleigh number
Re	Reynolds number; Re_x, local value of Re at a distance x from leading edge; Re_D, diameter Reynolds number; Re_b, bubble Reynolds number
Θ	Boundary Fourier modulus or dimensionless time
St	Stanton number

We	Weber number

Miscellaneous

$a > b$	a greater than b
$a < b$	a smaller than b
$\propto$	Proportional sign
$\simeq$	Approximately equal sign
∞	Infinity sign
Σ	Summation sign

Subscripts

c	critical condition
i	inlet
f	fin
u	unit quantities
w	wall or properties at wall temperature
c.s.	control surface
c.v.	control volume
o	stagnation or standard state condition; outlet or outside
1,2	inlet and outlet, respectively, of control volume

Note: Those symbols and subscripts that are not included in the above list are defined in the text.

Editor

Dr. Raj P. Chhabra is a professor of chemical engineering at the Indian Institute of Technology Kanpur. He received his MS degree from the Indian Institute of Science, Bangalore, and his PhD from Monash University, both in chemical engineering. Dr. Chhabra is a fellow of the Indian Academy of Sciences, the National Academy of Science (India), and the Indian Academy of Engineering. His current research interests include hydrodynamics of non-Newtonian fluid particle systems, multiphase flow in pipes and packed beds, interaction between nonlinear properties of fluids and shapes of particles, and the modeling of Newtonian and non-Newtonian flow in fibrous media.

Although various aspects of what is now known as thermodynamics have been of interest since antiquity, formal study began only in the early 19th century through consideration of the motive power of *heat*: the capacity of hot bodies to produce *work*. Today, the scope is larger, dealing generally with *energy and entropy*, and with relationships among the *properties* of matter. Moreover, in recent decades, engineering thermodynamics has undergone a revolution, both in terms of the presentation of fundamentals and in the manner that it is applied. In particular, the second law of thermodynamics has emerged as an effective tool for engineering analysis and design.

1.1 FUNDAMENTALS

Michael J. Moran

Classical thermodynamics is concerned primarily with the macrostructure of matter. It addresses the gross characteristics of large aggregations of molecules and not the behavior of individual molecules. The microstructure of matter is studied in kinetic theory and statistical mechanics (including quantum thermodynamics). In this chapter, the classical approach to thermodynamics is featured.

Basic Concepts and Definitions

Thermodynamics is both a branch of physics and an engineering science. The scientist is normally interested in gaining a fundamental understanding of the physical and chemical behavior of fixed, quiescent quantities of matter and uses the principles of thermodynamics to relate the *properties* of matter. Engineers are generally interested in studying *systems* and how they interact with their *surroundings*. To facilitate this, engineers have extended the subject of thermodynamics to the study of systems through which matter flows.

System

In a thermodynamic analysis, the *system* is the subject of the investigation. Normally the system is a specified quantity of matter and/or a region that can be separated from everything else by a well-defined surface. The defining surface is known as the *control surface* or *system boundary.* The control surface may be movable or fixed. Everything external to the system is the *surroundings*. A system of fixed mass is referred to as a *control mass* or as a *closed system*. When there is flow of mass through the control surface, the system is called a *control volume*, or an *open system*. An *isolated* system is a closed system that does not interact in any way with its surroundings.

State, Property

The condition of a system at any instant of time is called its *state*. The state at a given instant of time is described by the properties of the system. A *property* is any quantity whose numerical value depends on the state but not the history of the system. The value of a property is determined in principle by some type of physical operation or test.

Extensive properties depend on the size or extent of the system. Volume, mass, energy, and entropy are examples of extensive properties. An extensive property is additive in the sense that its value for the whole system equals the sum of the values for its parts. *Intensive* properties are independent of the size or extent of the system. Pressure and temperature are examples of intensive properties.

A *mole* is a quantity of substance having a mass numerically equal to its molecular weight. Designating the molecular weight by M and the number of moles by n, the mass m of the substance is $m=nM$. One kilogram mole, designated kmol, of oxygen is 32.0 kg and one pound mole (lb mol) is 32.0 lb. When an extensive property is reported on a unit mass or a unit mole basis, it is called a *specific* property. An overbar is used to distinguish an extensive property written on a per mole basis

from its value expressed per unit mass. For example, the volume per mole is $\overline{v}$, whereas the volume per unit mass is v, and the two specific volumes are related by $\overline{v} = Mv$.

Process, Cycle

Two states are identical if, and only if, the properties of the two states are identical. When any property of a system changes in value, there is a change in state, and the system is said to undergo a *process*. When a system in a given initial state goes through a sequence of processes and finally returns to its initial state, it is said to have undergone a *cycle*.

Phase and Pure Substance

The term *phase* refers to a quantity of matter that is homogeneous throughout in both chemical composition and physical structure. Homogeneity in physical structure means that the matter is all *solid*, or all *liquid*, or all *vapor* (or, equivalently, all *gas*). *A* system can contain one or more phases. For example, a system of liquid water and water vapor (steam) contains *two* phases. A *pure substance* is one that is uniform and invariable in chemical composition. *A* pure substance can exist in more than one phase, but its chemical composition must be the same in each phase. For example, if liquid water and water vapor form a system with two phases, the system can be regarded as a pure substance because each phase has the same composition. The nature of phases that coexist in equilibrium is addressed by the *phase rule* (Section 1.3, Multicomponent Systems).

Equilibrium

Equilibrium means a condition of balance. In thermodynamics, the concept includes not only a balance of forces, but also a balance of other influences. Each kind of influence refers to a particular aspect of thermodynamic (complete) equilibrium. *Thermal* equilibrium refers to an equality of temperature, *mechanical* equilibrium to an equality of pressure, and *phase* equilibrium to an equality of chemical potentials (Section 1.3, Multicomponent Systems). *Chemical* equilibrium is also established in terms of chemical potentials (Section 1.4, Reaction Equilibrium). For complete equilibrium, the several types of equilibrium must exist individually.

To determine if a system is in thermodynamic equilibrium, one may think of testing it as follows: isolate the system from its surroundings and watch for changes in its observable properties. If there are no changes, it may be concluded that the system was in equilibrium at the moment it was isolated. The system can be said to be at an *equilibrium state*. When a system is *isolated*, it cannot interact with its surroundings; however, its state can change as a consequence of spontaneous events occurring internally as its intensive properties, such as temperature and pressure, tend toward uniform values. When all such changes cease, the system is in equilibrium. At equilibrium, temperature and pressure are uniform throughout. If gravity is significant, a pressure variation with height can exist, as in a vertical column of liquid.

Temperature

A scale of temperature independent of the *thermometric substance* is called a *thermodynamic* temperature scale. The Kelvin scale, a thermodynamic scale, can be elicited from the second law of thermodynamics (Section 1.1, The Second Law of Thermodynamics, Entropy). The definition of temperature following from the second law is valid over all temperature ranges and provides an essential connection between the several *empirical* measures of temperature. In particular, temperatures evaluated using a *constant volume gas thermometer* are identical to those of the Kelvin scale over the range of temperatures where gas thermometry can be used.

The empirical *gas scale* is based on the experimental observations that (1) at a given temperature level, all gases exhibit the same value of the product $p\bar{v}$ (p is pressure and $\bar{v}$ the specific volume on a molar basis) if the pressure is low enough and (2) the value of the product $p\bar{v}$ increases with the temperature level. On this basis, the gas temperature scale is defined by

$$T = \frac{1}{\bar{R}} \lim_{p \to 0} (p\bar{v}),$$

where T is temperature and $\bar{R}$ is the *universal gas constant*. The absolute temperature at the *triple point of water* (Section 1.3, *P–v–T* Relations) is fixed by international agreement to be 273.16 K on the *Kelvin* temperature scale. $\bar{R}$ is then evaluated experimentally as $\bar{R} = 8.314\ \text{kJ/kmol} \cdot \text{K}$ (1545 ft lbf/lbmol °R).

The *Celsius temperature scale* (also called the centigrade scale) uses the degree Celsius (°C), which has the same magnitude as the Kelvin. Thus, temperature *differences* are identical on both scales. However, the zero point on the Celsius scale is shifted to 273.15 K, as shown by the following relationship between the Celsius temperature and the Kelvin temperature:

$$T(^\circ\text{C}) = T(\text{K}) - 273.15. \tag{1.1.1}$$

On the Celsius scale, the triple point of water is 0.01°C and 0 K corresponds to –273.15°C.

Two other temperature scales are commonly used in engineering in the United States. By definition, the *Rankine scale*, the unit of which is the degree Rankine (°R), is proportional to the Kelvin temperature according to

$$T(^\circ\text{R}) = 1.8T(\text{K}). \tag{1.1.2}$$

The Rankine scale is also an absolute thermodynamic scale with an absolute zero that coincides with the absolute zero of the Kelvin scale. In thermodynamic relationships, temperature is always in terms of the Kelvin or Rankine scale unless specifically stated otherwise.

A degree of the same size as that on the Rankine scale is used in the *Fahrenheit scale*, but the zero point is shifted according to the relation

$$T(^\circ\text{F}) = T(^\circ\text{R}) - 459.67. \tag{1.1.3}$$

Substituting Equations 1.1.1 and 1.1.2 into Equation 1.1.3 gives

$$T(^\circ F) = 1.8T(^\circ C) + 32. \tag{1.1.4}$$

This equation shows that the Fahrenheit temperature of the *ice point* (0°C) is 32°F and of the *steam point* (100°C) is 212°F. The 100 Celsius or Kelvin degrees between the ice point and steam point corresponds to 180 Fahrenheit or Rankine degrees.

To provide a standard for temperature measurement taking into account both theoretical and practical considerations, the International Temperature Scale of 1990 (ITS-90) is defined in such a way that the temperature measured on it conforms with the thermodynamic temperature, the unit of which is the Kelvin, to within the limits of accuracy of measurement obtainable in 1990. Further discussion of ITS-90 is provided by Preston-Thomas (1990).

The First Law of Thermodynamics, Energy

Energy is a fundamental concept of thermodynamics and one of the most significant aspects of engineering analysis. Energy can be *stored* within systems in various macroscopic forms: kinetic energy, gravitational potential energy, and internal energy. Energy can also be *transformed* from

one form to another and *transferred* between systems. For closed systems, energy can be transferred by *work* and *heat transfer*. The total amount of energy is *conserved* in all transformations and transfers.

Work

In thermodynamics, the term *work* denotes a means for transferring energy. Work is an effect of one system on another that is identified and measured as follows: Work is done by a system on its surroundings if the *sole effect* on everything external to the system *could have been* the raising of a weight. The test of whether a work interaction has taken place is not that the elevation of a weight is actually changed, nor that a force actually acted through a distance, but that the sole effect *could be* the change in elevation of a weight. The magnitude of the work is measured by the number of standard weights that could have been raised. Since the raising of a weight is in effect a force acting through a distance, the work concept of mechanics is preserved. This definition includes work effects such as is associated with rotating shafts, displacement of the boundary, and the flow of electricity.

Work done *by* a system is considered positive: $W > 0$. Work done *on* a system is considered negative: $W < 0$. The time rate of doing work, or *power*, is symbolized by $\dot{W}$ and adheres to the same sign convention.

Energy

A closed system undergoing a process that involves only work interactions with its surroundings experiences an *adiabatic* process. On the basis of experimental evidence, it can be postulated that *when a closed system is altered adiabatically, the amount of work is fixed by the end states of the system and is independent of the details of the process*. This postulate, which is one way the *first law of thermodynamics* can be stated, can be made regardless of the type of work interaction involved, the type of process, or the nature of the system.

As the work in an adiabatic process of a closed system is fixed by the end states, an extensive property called *energy* can be defined for the system such that its change between two states is the work in an adiabatic process that has these as the end states. In engineering thermodynamics, the change in the energy of a system is considered to be made up of three macroscopic contributions: the change in *kinetic energy*, *KE*, associated with the motion of the system *as a whole* relative to an external coordinate frame, the change in gravitational *potential energy*, *PE*, associated with the position of the system *as a whole* in the Earth's gravitational field, and the change in *internal energy*, *U*, which accounts for all other energy associated with the system. Like kinetic energy and gravitational potential energy, internal energy is an extensive property.

In summary, the change in energy between two states of a closed system in terms of the work W_{ad} of an adiabatic process between these states is

$$\left(\mathrm{KE}_2 - \mathrm{KE}_1\right) + \left(\mathrm{PE}_2 - \mathrm{PE}_1\right) + \left(U_2 - U_1\right) = -W_{ad}, \tag{1.1.5}$$

where 1 and 2 denote the initial and final states, respectively, and the minus sign before the work term is in accordance with the previously stated sign convention for work. Since any arbitrary value can be assigned to the energy of a system at a given state 1, no particular significance can be attached to the value of the energy at state 1 or at *any* other state. Only *changes* in the energy of a system have significance.

The specific energy (energy per unit mass) is the sum of the specific internal energy, u, the specific kinetic energy, $v^2/2$, and the specific gravitational potential energy, gz, such that

$$\text{Specific energy} = u + \frac{v^2}{2} + gz, \tag{1.1.6}$$

where the velocity v and the elevation z are each relative to specified datums (often the Earth's surface) and g is the acceleration of gravity.

A property related to internal energy u, pressure p, and specific volume v is *enthalpy*, defined by

$$h = u + pv \tag{1.1.7a}$$

or on an extensive basis

$$H = U + pV \tag{1.1.7b}$$

Heat

Closed systems can also interact with their surroundings in a way that cannot be categorized as work, as, for example, a gas (or liquid) contained in a closed vessel undergoing a process while in contact with a flame. This type of interaction is called a *heat interaction*, and the process is referred to as *nonadiabatic*.

A fundamental aspect of the energy concept is that energy is conserved. Thus, since a closed system experiences precisely the same energy change during a nonadiabatic process as during an adiabatic process between the same end states, it can be concluded that the *net* energy transfer to the system in each of these processes must be the same. It follows that heat interactions also involve energy transfer. Denoting the amount of energy transferred *to* a closed system in heat interactions by Q, these considerations can be summarized by the *closed system energy balance*:

$$\left(U_2 - U_1\right) + \left(\mathrm{KE}_2 - \mathrm{KE}_1\right) + \left(\mathrm{PE}_2 - \mathrm{PE}_1\right) = Q - W. \tag{1.1.8}$$

The closed system energy balance expresses the conservation of energy principle for closed systems of all kinds.

The quantity denoted by Q in Equation 1.1.8 accounts for the amount of energy transferred to a closed system during a process by means other than work. On the basis of an experiment, it is known that such an energy transfer is induced only as a result of a temperature difference between the system and its surroundings and occurs only in the direction of decreasing temperature. This means of energy transfer is called an *energy transfer by heat*. The following sign convention applies:

$$Q > 0 : \text{heat transfer to the system}$$

$$Q < 0 : \text{heat transfer from the system}$$

The time rate of heat transfer, denoted by $\dot{Q}$, adheres to the same sign convention.

Methods based on experiment are available for evaluating energy transfer by heat. These methods recognize two basic transfer mechanisms: *conduction* and *thermal radiation*. In addition, theoretical and empirical relationships are available for evaluating energy transfer involving *combined* modes such as *convection*. Further discussion of heat-transfer fundamentals is provided in Chapter 3.

The quantities symbolized by W and Q account for *transfers* of energy. The terms *work* and *heat* denote different *means* whereby energy is transferred and not *what* is transferred. Work and heat are not properties, and it is improper to speak of work or heat "contained" in a system. However, to achieve economy of expression in subsequent discussions, W and Q are often referred to simply as work and heat transfer, respectively. This less formal approach is commonly used in engineering practice.

Power Cycles

Since energy is a property, over each cycle there is no net change in energy. Thus, Equation 1.1.8 reads for *any* cycle

$$Q_{\text{cycle}} = W_{\text{cycle}}.$$

That is, for *any* cycle the net amount of energy received through heat interactions is equal to the net energy transferred out in work interactions. A *power cycle*, or *heat* engine, is one for which a net amount of energy is transferred out by work: $W_{\text{cycle}} > 0$. This equals the net amount of energy transferred in by heat.

Power cycles are characterized both by addition of energy by heat transfer, Q_{A}, and inevitable rejections of energy by heat transfer, Q_{R}:

$$Q_{\text{cycle}} = Q_{\text{A}} - Q_{\text{R}}.$$

Combining the last two equations,

$$W_{\text{cycle}} = Q_{\text{A}} - Q_{\text{R}}.$$

The *thermal efficiency* of a heat engine is defined as the ratio of the net work developed to the total energy added by heat transfer:

$$\eta = \frac{W_{\text{cycle}}}{Q_{\text{A}}} = 1 - \frac{Q_{\text{R}}}{Q_{\text{A}}}. \tag{1.9}$$

The thermal efficiency is strictly less than 100%. That is, some portion of the energy Q_{A} supplied is invariably rejected $Q_{\text{R}} \neq 0$.

The Second Law of Thermodynamics, Entropy

Many statements of the second law of thermodynamics have been proposed. Each of these can be called a statement of the second law *or* a corollary of the second law since, if one is invalid, all are invalid. In every instance where a consequence of the second law has been tested directly or indirectly by experiment it has been verified. Accordingly, the basis of the second law, like every other physical law, is experimental evidence.

Kelvin–Planck Statement

The Kelvin–Planck statement of the second law of thermodynamics refers to a *thermal reservoir.* A thermal reservoir is a system that remains at a constant temperature even though energy is added or removed by heat transfer. A reservoir is an idealization, of course, but such a system can be approximated in a number of ways—by the Earth's atmosphere, large bodies of water (lakes, oceans), and so on. Extensive properties of thermal reservoirs, such as internal energy, can change in interactions with other systems even though the reservoir temperature remains constant, however.

The Kelvin–Planck statement of the second law can be given as follows: *It is impossible for any system to operate in a thermodynamic cycle and deliver a net amount of energy by work to its surroundings while receiving energy by heat transfer from a single thermal reservoir.* In other words, *a perpetual motion machine of the second kind* is impossible. Expressed analytically, the Kelvin–Planck statement is

$$W_{\text{cycle}} \leq 0 \left(\text{single reservoir}\right),$$

where the words *single reservoir* emphasize that the system communicates thermally only with a single reservoir as it executes the cycle. The "less than" sign applies when *internal irreversibilities* are present as the system of interest undergoes a cycle and the "equal to" sign applies only when no irreversibilities are present.

Irreversibilities

A process is said to be *reversible* if it is possible for its effects to be eradicated in the sense that there is some way by which *both* the system and its surroundings can be *exactly restored* to their respective initial states. A process is *irreversible* if there is no way to undo it. That is, there is no means by which the system and its surroundings can be exactly restored to their respective initial states. A system that has undergone an irreversible process is not necessarily precluded from being restored to its initial state. However, were the system restored to its initial state, it would not also be possible to return the surroundings to their initial state.

There are many effects whose presence during a process renders it irreversible. These include, but are not limited to, the following: heat transfer through a finite temperature difference; unrestrained expansion of a gas or liquid to a lower pressure; spontaneous chemical reaction; mixing of matter at different compositions or states; friction (sliding friction as well as friction in the flow of fluids); electric current flow through a resistance; magnetization or polarization with hysteresis; and inelastic deformation. The term *irreversibility* is used to identify effects such as these.

Irreversibilities can be divided into two classes, *internal* and *external*. Internal irreversibilities are those that occur within the system, while external irreversibilities are those that occur within the surroundings, normally the immediate surroundings. As this division depends on the location of the boundary there is some arbitrariness in the classification (by locating the boundary to take in the immediate surroundings, all irreversibilities are internal). Nonetheless, valuable insights can result when this distinction between irreversibilities is made. When internal irreversibilities are absent during a process, the process is said to be *internally reversible*. At every intermediate state of an internally reversible process of a closed system, all intensive properties are uniform throughout each phase present: the temperature, pressure, specific volume, and other intensive properties do not vary with position. The discussions to follow compare the actual and internally reversible process concepts for two cases of special interest.

For a gas as the system, the work of expansion arises from the force exerted by the system to move the boundary against the resistance offered by the surroundings:

$$W = \int_1^2 F\,\mathrm{d}x = \int_1^2 pA\,\mathrm{d}x,$$

where the force is the product of the moving area and the pressure exerted by the system there. Noting that $A\,\mathrm{d}x$ is the change in total volume of the system,

$$W = \int_1^2 p\,\mathrm{d}V.$$

This expression for work applies to both actual and internally reversible expansion processes. However, for an internally reversible process p is not only the pressure at the moving boundary but also the pressure of the entire system. Furthermore, for an internally reversible process the volume equals mv, where the specific volume v has a single value throughout the system at a given instant. Accordingly, the work of an internally reversible expansion (or compression) process is

$$W = m\int_1^2 p\,\mathrm{d}v. \tag{1.1.10}$$

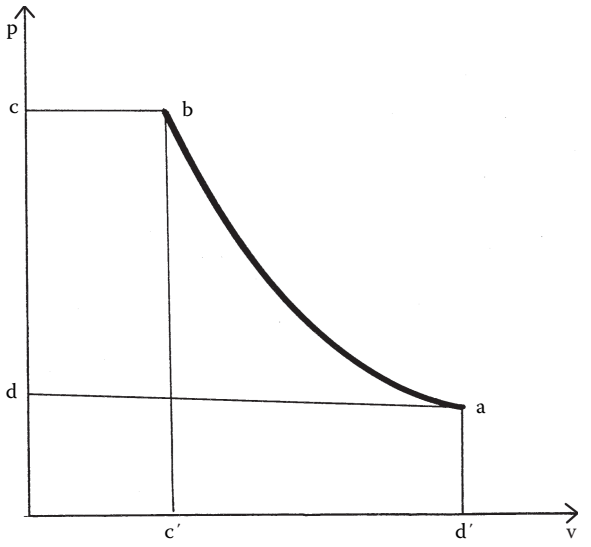

FIGURE 1.1.1 Internally reversible process on p–v coordinates.

When such a process of a closed system is represented by a continuous curve on a plot of pressure vs. specific volume, the area *under* the curve is the magnitude of the work per unit of system mass (area a–b–c'–d' of Figure 1.1.1, for example).

Although improved thermodynamic performance can accompany the reduction of irreversibilities, steps in this direction are normally constrained by a number of practical factors often related to costs. For example, consider two bodies able to communicate thermally. With a *finite* temperature difference between them, a spontaneous heat transfer would take place and, as noted previously, this would be a source of irreversibility. The importance of the heat-transfer irreversibility diminishes as the temperature difference narrows; and as the temperature difference between the bodies vanishes, the heat transfer approaches *ideality*. From the study of heat transfer it is known, however, that the transfer of a finite amount of energy by heat between bodies whose temperatures differ only slightly requires a considerable amount of time, a large heat-transfer surface area, or both. To approach *ideality*, therefore, a heat transfer would require an exceptionally long time and/or an exceptionally large area, each of which has cost implications constraining what can be achieved practically.

Carnot Corollaries

The two corollaries of the second law known as *Carnot* corollaries state: (1) the thermal efficiency of an irreversible power cycle is always less than the thermal efficiency of a reversible power cycle when each operates between the same two thermal reservoirs; (2) all reversible power cycles operating between the same two thermal reservoirs have the same thermal efficiency. A cycle is considered *reversible* when there are no irreversibilities within the system as it undergoes the cycle, and heat transfers between the system and reservoirs occur ideally (i.e., with a vanishingly small temperature difference).

Kelvin Temperature Scale

Carnot corollary 2 suggests that the thermal efficiency of a reversible power cycle operating between two thermal reservoirs depends only on the temperatures of the reservoirs and not on the nature of the substance making up the system executing the cycle or the series of processes. With Equation

1.1.9 it can be concluded that the ratio of the heat transfers is also related only to the temperatures, and is independent of the substance and processes:

$$\left(\frac{Q_C}{Q_H}\right)_{\text{rev cycle}} = \psi(T_C, T_H),$$

where Q_H *is* the energy transferred to the system by heat transfer from a *hot* reservoir at temperature T_H, and Q_C is the energy rejected from the system to a *cold* reservoir at temperature T_C. The words *rev cycle* emphasize that this expression applies only to systems undergoing reversible cycles while operating between the two reservoirs. Alternative temperature scales correspond to alternative specifications for the function ψ in this relation.

The Kelvin temperature scale is based on $\psi(T_C, T_H) = T_C / T_H$. Then

$$\left(\frac{Q_C}{Q_H}\right)_{\text{rev cycle}} = \frac{T_C}{T_H}. \tag{1.1.11}$$

This equation defines only a ratio of temperatures. The specification of the Kelvin scale is completed by assigning a numerical value to one standard reference state. The state selected is the same used to define the *gas scale*: at the triple point of water the temperature is specified to be 273.16 K. If a reversible cycle is operated between a reservoir at the reference state temperature and another reservoir at an unknown temperature T, then the latter temperature is related to the value at the reference state by

$$T = 273.16\left(\frac{Q}{Q'}\right)_{\text{rev cycle}},$$

where Q is the energy received by heat transfer from the reservoir at temperature T, and Q' is the energy rejected to the reservoir at the reference temperature. Accordingly, a temperature scale is defined that is valid over all ranges of temperature and that is independent of the thermometric substance.

Carnot Efficiency

For the special case of a reversible power cycle operating between thermal reservoirs at temperatures T_H and T_C on the Kelvin scale, combination of Equations 1.1.9 and 1.1.11 results in

$$\eta_{\max} = 1 - \frac{T_C}{T_H}, \tag{1.1.12}$$

called the *Carnot efficiency.* This is the efficiency of *all* reversible power cycles operating between thermal reservoirs at T_H and T_C. Moreover, it is the *maximum theoretical* efficiency that any power cycle, real or ideal, could have while operating between the same two reservoirs. As temperatures on the Rankine scale differ from Kelvin temperatures only by the factor 1.8, the above equation may be applied with either scale of temperature.

The Clausius Inequality

The Clausius inequality provides the basis for introducing two ideas instrumental for quantitative evaluations of processes of systems from a second law perspective: *entropy* and *entropy generation*. The Clausius inequality states that

$$\oint\left(\frac{\delta Q}{T}\right)_b \le 0, \tag{1.1.13a}$$

where δQ represents the heat transfer at a part of the system boundary during a portion of the cycle, and T is the absolute temperature at that part of the boundary. The symbol δ is used to distinguish

the differentials of *nonproperties*, such as heat and work, from the differentials of properties, written with the symbol *d*. The subscript b indicates that the integrand is evaluated at the boundary of the system executing the cycle. The symbol $\oint$ indicates that the integral is to be performed over all parts of the boundary and over the entire cycle. The Clausius inequality can be demonstrated using the Kelvin–Planck statement of the second law, and the significance of the inequality is the same: The equality applies when there are no internal irreversibilities as the system executes the cycle, and the inequality applies when internal irreversibilities are present.

The Clausius inequality can be expressed alternatively as

$$\oint \left(\frac{\delta Q}{T} \right)_b = -S_{\text{gen}}, \tag{1.1.13b}$$

where S_{gen} can be viewed as representing the *strength* of the inequality. The value of S_{gen} is positive when internal irreversibilities are present, zero when no internal irreversibilities are present, and can never be negative. Accordingly, S_{gen} is a measure of the irreversibilities present within the system executing the cycle. In the next section, S_{gen} is identified as the *entropy* generated (or *produced*) by internal irreversibilities during the cycle.

Entropy and Entropy Generation

Entropy

Consider two cycles executed by a closed system. One cycle consists of an internally reversible process A from state 1 to state 2, followed by an internally reversible process *C* from state 2 to state 1. The other cycle consists of an internally reversible process *B* from state 1 to state 2, followed by the same process *C* from state 2 to state 1 as in the first cycle. For these cycles, Equation 1.1.13b takes the form

$$\left(\int_1^2 \frac{\delta Q}{T} \right)_A + \left(\int_2^1 \frac{\delta Q}{T} \right)_C = -S_{\text{gen}} = 0$$

$$\left(\int_1^2 \frac{\delta Q}{T} \right)_B + \left(\int_2^1 \frac{\delta Q}{T} \right)_C = -S_{\text{gen}} = 0,$$

where S_{gen} has been set to zero since the cycles are composed of internally reversible processes. Subtracting these equations leaves

$$\left(\int_1^2 \frac{\delta Q}{T} \right)_A = \left(\int_1^2 \frac{\delta Q}{T} \right)_B.$$

Since A and B are arbitrary, it follows that the integral of $\delta Q/T$ has the same value for *any* internally reversible process between the two states: The value of the integral depends on the end states only. It can be concluded, therefore, that the integral defines the change in some property of the system. Selecting the symbol *S* to denote this property, its change is given by

$$S_2 - S_1 = \left(\int_1^2 \frac{\delta Q}{T} \right)_{\text{int rev}}, \tag{1.1.14a}$$

where the subscript *int rev* indicates that the integration is carried out for any internally reversible process linking the two states. This extensive property is called *entropy.*

Since entropy is a property, the change in entropy of a system in going from one state to another is the same for *all* processes, both internally reversible and irreversible, between these two states. In

other words, once the change in entropy between two states has been evaluated, this is the magnitude of the entropy change for *any* process of the system between these end states.

The definition of entropy change expressed on a differential basis is

$$dS = \left(\frac{\delta Q}{T} \right)_{\text{int rev}} . \tag{1.1.14b}$$

Equation 1.1.14b indicates that when a closed system undergoing an internally reversible process *receives* energy by heat transfer, the system experiences an *increase* in entropy. Conversely, when energy is *removed* from the system by heat transfer, the entropy of the system *decreases*. This can be interpreted to mean that an entropy transfer is *associated* with (or accompanies) heat transfer. The direction of the entropy transfer is the same as that of the heat transfer. In an *adiabatic* internally reversible process of a closed system, the entropy would remain constant. A constant entropy process is called an *isentropic* process.

On rearrangement, Equation 1.1.14b becomes

$$(\delta Q)_{\text{int rev}} = T \, \mathrm{d}S.$$

Then, for an internally reversible process of a closed system between states 1 and 2,

$$Q_{\text{int rev}} = m \int_1^2 T \, \mathrm{d}s. \tag{1.1.15}$$

When such a process is represented by a continuous curve on a plot of temperature vs. specific entropy, the area *under* the curve is the magnitude of the heat transfer per unit of system mass.

Entropy Balance

For a cycle consisting of an actual process from state 1 to state 2, during which internal irreversibilities are present, followed by an internally reversible process from state 2 to state 1, Equation 1.1.13b takes the form

$$\int_1^2 \left(\frac{\delta Q}{T} \right)_b + \int_2^1 \left(\frac{\delta Q}{T} \right)_{\text{int rev}} = -S_{\text{gen}},$$

where the first integral is for the actual process and the second integral is for the internally reversible process. Since no irreversibilities are associated with the internally reversible process, the term S_{gen} accounting for the effect of irreversibilities during the cycle can be identified with the actual process only.

Applying the definition of entropy change, the second integral of the foregoing equation can be expressed as

$$S_1 - S_2 = \int_2^1 \left(\frac{\delta Q}{T} \right)_{\text{int rev}}$$

Introducing this and rearranging the equation, the *closed system entropy balance* results

$$\underbrace{S_2 - S_1}_{\substack{\text{Entropy} \\ \text{change}}} = \underbrace{\int_1^2 \left(\frac{\delta Q}{T} \right)_b}_{\substack{\text{Entropy} \\ \text{transfer}}} + \underbrace{S_{\text{gen}}}_{\substack{\text{Entropy} \\ \text{generation.}}} \tag{1.1.16}$$

When the end states are fixed, the entropy change on the left side of Equation 1.1.16 can be evaluated independent of the details of the process from state 1 to state 2. However, the two terms on the right side depend explicitly on the nature of the process and cannot be determined solely from knowledge of the end states. The first term on the right side is associated with heat transfer to or from the system during the process. This term can be interpreted as the *entropy transfer associated with (or accompanying) heat transfer.* The direction of entropy transfer is the same as the direction of the heat transfer, and the same sign convention applies as for heat transfer: A positive value means that entropy is transferred into the system, and a negative value means that entropy is transferred out.

The entropy change of a system is not accounted for solely by entropy transfer, but is also due to the second term on the right side of Equation 1.1.16 denoted by S_{gen}. The term S_{gen} is positive when internal irreversibilities are present during the process and vanishes when internal irreversibilities are absent. This can be described by saying that entropy is *generated* (or produced) within the system by the action of irreversibilities. The second law of thermodynamics can be interpreted as specifying that entropy is generated by irreversibilities and conserved only in the limit as irreversibilities are reduced to zero. Since S_{gen} measures the effect of irreversibilities present within a system during a process, its value depends on the nature of the process and not solely on the end states. Entropy generation is *not* a property.

When applying the entropy balance, the objective is often to evaluate the entropy generation term. However, the value of the entropy generation for a given process of a system usually does not have much significance by itself. The significance is normally determined through comparison. For example, the entropy generation within a given component might be compared to the entropy generation values of the other components included in an overall system formed by these components. By comparing entropy generation values, the components where appreciable irreversibilities occur can be identified and rank ordered. This allows attention to be focused on the components that contribute most heavily to inefficient operation of the overall system.

To evaluate the entropy transfer term of the entropy balance requires information regarding both the heat transfer and the temperature on the boundary where the heat transfer occurs. The entropy transfer term is not always subject to direct evaluation, however, because the required information is either unknown or undefined, such as when the system passes through states sufficiently far from equilibrium. In practical applications, it is often convenient, therefore, to enlarge the system to include enough of the immediate surroundings that the temperature on the boundary of the *enlarged system* corresponds to the ambient temperature, T_{amb}. The entropy transfer term is then simply Q/T_{amb}. However, as the irreversibilities present would not be just those for the system of interest but those for the enlarged system, the entropy generation term would account for the effects of internal irreversibilities within the system *and* external irreversibilities present within that portion of the surroundings included within the enlarged system.

A form of the entropy balance convenient for particular analyses is the *rate form*:

$$\frac{\mathrm{d}S}{\mathrm{d}t} = \sum_j \frac{\dot{Q}_j}{T_j} + \dot{S}_{\text{gen}}, \tag{1.1.17}$$

where $\mathrm{d}S/\mathrm{d}t$ is the time rate of change of entropy of the system. The term $\dot{Q}_j/T_j$ represents the time rate of entropy transfer through the portion of the boundary whose instantaneous temperature is T_j. The term $\dot{S}_{\text{gen}}$ accounts for the time rate of entropy generation due to irreversibilities within the system.

For a system *isolated* from its surroundings, the entropy balance is

$$\left(S_2 - S_1\right)_{\text{isol}} = S_{\text{gen}}, \tag{1.1.18}$$

where S_{gen} is the total amount of entropy generated within the isolated system. Since entropy is generated in all actual processes, the only processes of an isolated system that actually can occur are those for which the entropy of the isolated system increases. This is known as the *increase of entropy principle*.

1.2 CONTROL VOLUME APPLICATIONS

Michael J. Moran

Since most applications of engineering thermodynamics are conducted on a control volume basis, the control volume formulations of the mass, energy, and entropy balances presented in this section are especially important. These are given here in the form of *overall* balances. Equations of change for mass, energy, and entropy in the form of differential equations are also available in the literature (see, e.g., Bird et al., 2002).

Conservation of Mass

When applied to a control volume, the principle of mass conservation states the time rate of accumulation of mass within the control volume equals the difference between the total rates of mass flow in and out across the boundary. An important case for engineering practice is one for which inward and outward flows occur, each through one or more ports. For this case, the conservation of mass principle takes the form

$$\frac{\mathrm{d}m_{\mathrm{cv}}}{\mathrm{d}t} = \sum_i \dot{m}_i - \sum_e \dot{m}_e . \tag{1.2.1}$$

The left side of this equation represents the time rate of change of mass contained within the control volume, $\dot{m}_i$ denotes the mass flow rate at an inlet, and $\dot{m}_e$ is the mass flow rate at an outlet.

The *volumetric flow rate* through a portion of the control surface with area dA is the product of the velocity component normal to the area, v_{n}, times the area: $v_{\mathrm{n}}\,\mathrm{d}A$. The *mass* flow rate through dA is $\rho(v_{\mathrm{n}}\,\mathrm{d}A)$. The mass rate of flow through a port of area A is then found by integration over the area

$$\dot{m} = \int_A \rho v_{\mathrm{n}}\,\mathrm{d}A.$$

For *one-dimensional* flow, the intensive properties are uniform with position over area A, and the last equation becomes

$$\dot{m} = \rho v A = \frac{vA}{v}, \tag{1.2.2}$$

where v denotes the specific volume and the subscript n has been dropped from velocity for simplicity.

Control Volume Energy Balance

When applied to a control volume, the principle of energy conservation states the time rate of accumulation of energy within the control volume equals the difference between the total incoming rate of energy transfer and the total outgoing rate of energy transfer. Energy can enter and exit a control volume by work and heat transfer. Energy also enters and exits with flowing streams of matter. Accordingly, for a control volume with one-dimensional flow at a single inlet and a single outlet,

$$\frac{\mathrm{d}(U + \mathrm{KE} + \mathrm{PE})_{\mathrm{cv}}}{\mathrm{d}t} = \dot{Q}_{\mathrm{cv}} - \dot{W} + \dot{m}\underline{\left(u_i + \frac{v_i^2}{2} + gz_i\right)} - \dot{m}\underline{\left(u_e + \frac{v_e^2}{2} + gz_e\right)}, \tag{1.2.3}$$

where the underlined terms account for the specific energy of the incoming and outgoing streams. The terms $\dot{Q}_{\mathrm{cv}}$ and $\dot{W}$ account, respectively, for the net rates of energy transfer by heat and work over the boundary (control surface) of the control volume.

Because work is always done on or by a control volume where matter flows across the boundary, the quantity $\dot{W}$ of Equation 1.2.3 can be expressed in terms of two contributions: one is the work associated with the force of the fluid pressure as mass is introduced at the inlet and removed at the exit. The other, denoted as $\dot{W}_{cv}$, includes *all other* work effects, such as those associated with rotating shafts, displacement of the boundary, and electrical effects. The work rate concept of mechanics allows the first of these contributions to be evaluated in terms of the product of the pressure force, pA, and velocity at the point of application of the force. To summarize, the work term $\dot{W}$ of Equation 1.2.3 can be expressed (with Equation 1.2.1) as

$$\begin{aligned}\dot{W} &= \dot{W}_{cv} + (p_e A_e)v_e - (p_i A_i)v_i \\ &= \dot{W}_{cv} + \dot{m}_e(p_e v_e) - \dot{m}_i(p_i v_i)\end{aligned} \tag{1.2.4}$$

The terms $\dot{m}_i\left(pv_i\right)$ and $\dot{m}_e\left(p_e v_e\right)$ account for the work associated with the pressure at the inlet and outlet, respectively, and are commonly referred to as *flow work*.

Substituting Equation 1.2.4 into Equation 1.2.3 and introducing the specific enthalpy h, the following form of the control volume energy rate balance results:

$$\frac{\mathrm{d}(U + \mathrm{KE} + \mathrm{PE})_{\mathrm{cv}}}{\mathrm{d}t} = \dot{Q}_{\mathrm{cv}} - \dot{W}_{\mathrm{cv}} + \dot{m}_i\left(h_i + \frac{v_i^2}{2} + gz_i\right) - \dot{m}_e\left(h_e + \frac{v_e^2}{2} + gz_e\right). \tag{1.2.5}$$

To allow for applications where there may be several locations on the boundary through which mass enters or exits, the following expression is appropriate:

$$\frac{\mathrm{d}(U + KE + PE)_{\mathrm{cv}}}{\mathrm{d}t} = \dot{Q}_{\mathrm{cv}} - \dot{W}_{\mathrm{cv}} + \sum_i \dot{m}_i\left(h_i + \frac{\mathrm{v}_i^2}{2} + \mathrm{gz}_i\right) - \sum_e \dot{m}_e\left(h_e + \frac{\mathrm{v}_e^2}{2} + \mathrm{gz}_e\right). \tag{1.2.6}$$

Equation 1.2.6 is an *accounting* rate balance for the energy of the control volume. It states that the time rate of accumulation of energy within the control volume equals the difference between the total rates of energy transfer in and out across the boundary. The mechanisms of energy transfer are heat and work, as for closed systems, and the energy accompanying the entering and exiting mass.

Control Volume Entropy Balance

Like mass and energy, entropy is an extensive property. And like mass and energy, entropy can be transferred into or out of a control volume by streams of matter. As this is the principal difference between the closed system and control volume forms, the control volume entropy rate balance is obtained by modifying Equation 1.1.17 to account for these entropy transfers. The result is

$$\underbrace{\frac{\mathrm{d}S_{\mathrm{cv}}}{\mathrm{d}t}}_{\substack{\text{Rate of}\\ \text{entropy}\\ \text{change}}} = \underbrace{\sum_j \frac{\dot{Q}_j}{T_j} + \sum_i \dot{m}_i s_i x}_{\substack{\text{Rate of}\\ \text{entropy}\\ \text{transfer}}} - \underbrace{\sum_e \dot{m}_e s_e + \dot{S}_{\mathrm{gen}}}_{\substack{\text{Rate of}\\ \text{entropy}\\ \text{generation}}} \tag{1.2.7}$$

where $\mathrm{d}S_{cv}/\mathrm{d}t$ represents the time rate of change of entropy within the control volume. The terms $\dot{m}_i s_i$ and $\dot{m}_e s_e$ account, respectively, for rates of entropy *transfer* into and out of the control volume associated with mass flow. One-dimensional flow is assumed at locations where mass enters and exits. $\dot{Q}_j$ represents the time rate of heat transfer at the location on the boundary where the

instantaneous temperature is T_j; and $\dot{Q}_j / T_j$ accounts for the associated rate of entropy *transfer*. $\dot{S}_{\text{gen}}$ denotes the time rate of entropy *generation* due to irreversibilities *within* the control volume. When a control volume comprises a number of components, $\dot{S}_{\text{gen}}$ is the sum of the rates of entropy generation of the components.

Control Volumes at Steady State

Engineering systems are often idealized as being at *steady state*, meaning that all properties are unchanging in time. For a control volume at steady state, the identity of the matter within the control volume changes continuously, but the total amount of mass remains constant. At steady state, Equation 1.2.1 reduces to

$$\sum_i \dot{m}_i = \sum_e \dot{m}_e . \tag{1.2.8a}$$

The energy rate balance of Equation 1.2.6 becomes, at steady state,

$$0 = \dot{Q}_{\text{cv}} - \dot{W}_{\text{cv}} + \sum_i \dot{m}_i \left(h_i + \frac{v_i^2}{2} + g z_i \right) - \sum_e \dot{m}_e \left(h_e + \frac{v_e^2}{2} + g z_e \right). \tag{1.2.8b}$$

At steady state, the entropy rate balance of Equation 1.2.7 reads

$$0 = \sum_j \frac{\dot{Q}_j}{T_j} + \sum_i \dot{m}_i s_i - \sum_e \dot{m}_e s_e + \dot{S}_{\text{gen}} . \tag{1.2.8c}$$

Mass and energy are conserved quantities, but entropy is not generally conserved. Equation 1.2.8a indicates that the total rate of mass flow into the control volume equals the total rate of mass flow out of the control volume. Similarly, Equation 1.2.8b states that the total rate of energy transfer into the control volume equals the total rate of energy transfer out of the control volume. However, Equation 1.2.8c shows that the rate at which entropy is transferred out *exceeds* the rate at which entropy enters, the difference being the rate of entropy generation within the control volume owing to irreversibilities.

Applications frequently involve control volumes having a single inlet and a single outlet, as, for example, the control volume of Figure 1.2.1 where heat transfer (if any) occurs at T_{b}: the temperature, or a suitable average temperature, on the boundary where heat transfer occurs. For this case

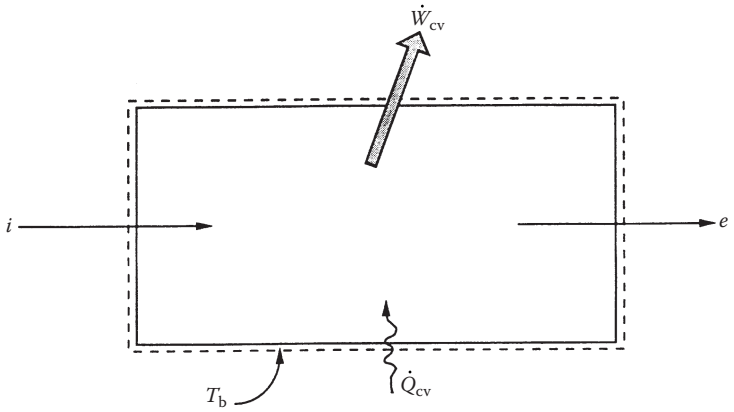

FIGURE 1.2.1 One-inlet, one-outlet control volume at steady state.

the mass rate balance, Equation 1.2.8a, reduces to $\dot{m}_i = \dot{m}_e$. Denoting the common mass flow rate by $\dot{m}$, Equations 1.2.8b and 1.2.8c read, respectively,

$$0 = \dot{Q}_{cv} - \dot{W}_{cv} + \dot{m}\left[(h_i - h_e) + \left(\frac{v_i^2 - v_e^2}{2}\right) + g(z_i - z_e)\right] \tag{1.2.9a}$$

$$0 = \frac{\dot{Q}_{cv}}{T_b} + \dot{m}(s_i - s_e) + \dot{S}_{gen}. \tag{1.2.10a}$$

When Equations 1.2.9a and 1.2.10a are applied to particular cases of interest, additional simplifications are usually made. The heat-transfer term Q_{cv} is dropped when it is insignificant relative to other energy transfers across the boundary. This may be the result of one or more of the following: (1) the outer surface of the control volume is insulated, (2) the outer surface area is too small for there to be effective heat transfer, (3) the temperature difference between the control volume and its surroundings is small enough that the heat transfer can be ignored, (4) the gas or liquid passes through the control volume so quickly that there is not enough time for significant heat transfer to occur. The work term $\dot{W}_{cv}$ drops out of the energy rate balance when there are no rotating shafts, displacements of the boundary, electrical effects, or other work mechanisms associated with the control volume being considered. The changes in kinetic and potential energy of Equation 1.2.9a are frequently negligible relative to other terms in the equation.

The special forms of Equations 1.2.9a and 1.2.10a listed in Table 1.2.1 are obtained as follows: When there is no heat transfer, Equation 1.2.10a gives

$$s_e - s_i = \frac{\dot{S}_{gen}}{\dot{m}} \geq 0 \quad \text{(no heat transfer)} \tag{1.2.10b}$$

Accordingly, when irreversibilities are present within the control volume, the specific entropy increases as mass flows from inlet to outlet. In the ideal case in which no internal irreversibilities are present, mass passes through the control volume with no change in its entropy—that is, *isentropically.*

For no heat transfer, Equation 1.2.9a gives

$$\dot{W}_{cv} = \dot{m}\left[(h_i - h_e) + \left(\frac{v_i^2 - v_e^2}{2}\right) + g(z_i - z_e)\right]. \tag{1.2.9b}$$

A special form that is applicable, at least approximately, to *compressors*, *pumps*, and *turbines* results from dropping the kinetic and potential energy terms of Equation 1.2.9b, leaving

$$\dot{W}_{cv} = \dot{m}(h_i - h_e) \quad \text{(compressors, pumps, and turbines)} \tag{1.2.9c}$$

In *throttling devices*, a significant reduction in pressure is achieved simply by introducing a restriction into a line through which a gas or liquid flows. For such devices $\dot{W}_{cv} = 0$ and Equation 1.2.9c reduces further to read

$$h_e \equiv h_i \quad \text{(throttling process)} \tag{1.2.9d}$$

TABLE 1.2.1
Energy and Entropy Balances for One-Inlet, One-Outlet Control Volumes at Steady State and No Heat Transfer

Energy balance

$$\dot{W}_{cv} = \dot{m}\left[(h_i - h_e) + \left(\frac{v_i^2 - v_e^2}{2}\right) + g(z_i - z_e)\right] \quad (1.2.9b)$$

Compressors, pumps, and turbines[a]

$$\dot{W}_{cv} = \dot{m}(h_i - h_e) \quad (1.2.9c)$$

Throttling

$$h_e \cong h_i \quad (1.2.9d)$$

Nozzles, diffusers[b]

$$v_e = \sqrt{v_i^2 + 2(h_i - h_e)} \quad (1.2.9f)$$

Entropy balance

$$s_e - s_i = \frac{\dot{S}_{gen}}{\dot{m}} \geq 0 \quad (1.2.10b)$$

[a] For an ideal gas with constant c_p, Equation 1′ of Table 1.3.6 allows Equation 1.2.9c to be written as

$$\dot{W}_{cv} = \dot{m}c_p(T_i - T_e) \quad (1.2.9c')$$

The power developed in an *isentropic process* is obtained with Equation 5′ of Table 1.3.6 as

$$\dot{W}_{cv} = \dot{m}c_pT_i\left[1 - (p_e/p_i)^{(k-1)/k}\right](s = c), \quad (1.2.9c'')$$

where $c_p = kR/(k-1)$.

[b] For an ideal gas with constant c_p, Equation 1′ of Table 1.3.6 allows Equation 1.2.9f to be written as

$$v_e = \sqrt{v_i^2 + 2c_p(T_i - T_e)} \quad (1.2.9f')$$

The exit velocity for an *isentropic process* is obtained with Equation 5′ of Table 1.3.6 as

$$v_e = \sqrt{v_i^2 + 2c_pT_i\left[1 - (p_e/p_i)^{(k-1)/k}\right]}\ (s = c) \quad (1.2.9f'')$$

where $c_p = kR/(k-1)$.

That is, in upstream and downstream of the throttling device, the specific enthalpies are equal.

A *nozzle* is a flow passage of varying cross-sectional area in which the velocity of a gas or liquid increases in the direction of flow. In a *diffuser*, the gas or liquid decelerates in the direction of flow. For such devices, $\dot{W}_{cv} = 0$. The heat transfer and potential energy change are also generally negligible. Then Equation 1.2.9b reduces to

$$0 = h_i - h_e + \frac{v_i^2 - v_e^2}{2}. \quad (1.2.9e)$$

Solving for the outlet velocity,

$$v_e = \sqrt{v_i^2 + 2(h_i - h_e)} \quad \text{(nozzle, diffuser)}. \quad (1.2.9f)$$

Further discussion of the flow-through nozzles and diffusers is provided in Chapter 2.

The mass, energy, and entropy rate balances, Equations 1.2.8, can be applied to control volumes with multiple inlets and/or outlets, as, for example, cases involving heat-recovery steam generators, feedwater heaters, and counterflow and crossflow heat exchangers. Transient (or unsteady) analyses can be conducted with Equations 1.2.1, 1.2.6, and 1.2.7. Illustrations of all such applications are provided by Moran et al. (2014).

Example 1.2.1

A turbine receives steam at 7 MPa, 440°C and exhausts at 0.2 MPa for subsequent process heating duty. If heat transfer and kinetic/potential energy effects are negligible, determine the steam mass flow rate, in kg/h, for a turbine power output of 30 MW when (1) the steam quality at the turbine outlet is 95%, (2) the turbine expansion is internally reversible.

***Solution*:** With the indicated idealizations, Equation 1.2.9c is appropriate. Solving, $\dot{m} = \dot{W}_{cv}/(h_i - h_e)$. Steam table data (Table A.5) at the inlet condition are $h_i = 3261.7$ kJ/kg, $s_i = 6.6022$ kJ/kg·K.

1. At 0.2 MPa and $x = 0.95$, $h_e = 2596.5$ kJ/kg. Then

$$\dot{m} = \frac{30\,\text{MW}}{(3261.7 - 2596.5)\text{kJ/kg}}\left(\frac{10^3\,\text{kJ/s}}{1\text{MW}}\right)\left(\frac{3600\,\text{s}}{1\text{h}}\right).$$
$$= 162{,}357\,\text{kg/h}$$

2. For an internally reversible expansion, Equation 1.2.10b reduces to give $s_e = s_i$. For this case, $h_e = 2499.6$ kJ/kg ($x = 0.906$), and $\dot{m} = 141{,}714$ kg/h.

Example 1.2.2

Air at 500°F, 150 lbf/in.^{2}, and 10 ft/s expands adiabatically through a nozzle and exits at 60°F, 15 lbf/in.^{2}. For a mass flow rate of 5 lb/s determine the exit area, in in.^{2}. Repeat for an isentropic expansion to 15 lbf/in.^{2}. Model the air as an ideal gas (Section 1.3, Ideal Gas Model) with specific heat $c_p = 0.24$ Btu/lb · °R ($k = 1.4$).

Solution: The nozzle exit area can be evaluated using Equation 1.2.2 together with the ideal gas equation, $v = RT/p$:

$$A_e = \frac{\dot{m}v_e}{v_e} = \frac{\dot{m}(RT_e/p_e)}{v_e}.$$

The exit velocity required by this expression is obtained using Equation 1.2.9f′ of Table 1.2.1:

$$v_e = \sqrt{v_i^2 + 2c_p(T_i - T_e)}$$
$$= \sqrt{\left(\frac{10\text{ ft}}{s}\right)^2 + 2\left(0.24\frac{\text{Btu}}{\text{lb}\cdot\text{R}}\right)\left(\frac{778.17\text{ ft}\cdot\text{lbf}}{1\,\text{Btu}}\right)(440°\text{R})\left(\frac{32.174\,\text{lb}\cdot\text{ft/s}^2}{1\text{lbf}}\right)}.$$
$$= 2299.5\,\text{ft/s}$$

Finally, with $R = \bar{R}/M = 53.33$ ft · lbf/lb · °R,

$$A_e = \frac{\left(5\text{lb/s}\right)\left(53.3\frac{\text{ft}\cdot\text{lbf}}{\text{lb}\cdot°\text{R}}\right)(520°\text{R})}{\left(2299.5\,\text{ft/s}\right)\left(15\text{ lbf/in.}^2\right)} = 4.02\text{ in.}^2$$

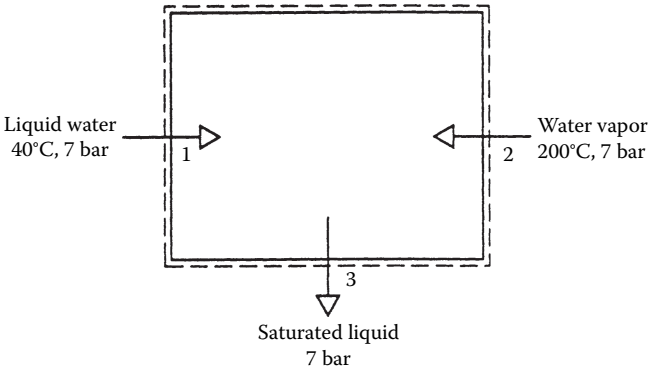

FIGURE 1.2.2 Open feed water heater.

Using Equation 1.2.9f″ in Table 1.2.1 for the isentropic expansion,

$$v_e = \sqrt{(10)^2 + 2(0.24)(778.17)(960)(32.174)\left[1-\left(\frac{15}{150}\right)^{0.4/1.4}\right]}.$$

$$= 2358.3\,\text{ft/s}$$

Then $A_e = 3.92$ in.^{2}.

Example 1.2.3

Figure 1.2.2 provides steady-state operating data for an open feedwater heater. Ignoring heat transfer and kinetic/potential energy effects, determine the ratio of mass flow rates, $\dot{m}_1/\dot{m}_2$.

Solution: For this case, Equations 1.2.8a and b reduce to read, respectively,

$$\dot{m}_1 + \dot{m}_2 = \dot{m}_3$$

$$0 = \dot{m}_1 h_1 + \dot{m}_2 h_2 - \dot{m}_3 h_3.$$

Combining and solving for the ratio $\dot{m}_1/\dot{m}_2$,

$$\frac{\dot{m}_1}{\dot{m}_2} = \frac{h_2 - h_3}{h_3 - h_1}.$$

Inserting steam table data, in kJ/kg, from Table A.5,

$$\frac{\dot{m}_1}{\dot{m}_2} = \frac{2844.8 - 697.2}{697.2 - 167.6} = 4.06.$$

Internally Reversible Heat Transfer and Work

For one-inlet, one-outlet control volumes at steady state, the following expressions give the heat-transfer rate and power in the absence of internal irreversibilities:

$$\left(\frac{\dot{Q}_{cv}}{\dot{m}}\right)_{\text{int rev}} = \int_1^2 T\,ds \tag{1.2.11}$$

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{\text{int rev}} = -\int_1^2 v\,\mathrm{d}p + \frac{v_1^2 - v_2^2}{2} + g(z_1 - z_2). \tag{1.2.12a}$$

(see, e.g., Moran et al. 2014).

If there is no significant change in kinetic or potential energy from inlet to outlet, Equation 1.2.12a reads

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{\text{int rev}} = -\int_1^2 v\,\mathrm{d}p \quad (\Delta ke = \Delta pe = 0). \tag{1.2.12b}$$

The specific volume remains approximately constant in many applications with liquids. Then Equation 1.2.12b becomes

$$\left(\frac{\dot{W}_{cv}}{\dot{m}}\right)_{\text{int rev}} = -v(p_2 - p_1) \quad (v = \text{constant}). \tag{1.2.12c}$$

When the states visited by a unit of mass flowing without irreversibilities from inlet to outlet are described by a continuous curve on a plot of temperature vs. specific entropy, Equation 1.2.11 implies that the area under the curve is the magnitude of the heat transfer per unit of mass flowing. When such an ideal process is described by a curve on a plot of pressure vs. specific volume, as shown in Figure 1.1.1, the magnitude of the integral $\int v\,\mathrm{d}p$ of Equation 1.2.12a and b is represented by the area *a–b–c–d behind* the curve. The area *a–b–c′–d′ under* the curve is identified with the magnitude of the integral $\int p\,\mathrm{d}v$ of Equation 1.1.10.

1.3 PROPERTY RELATIONS AND DATA

Michael J. Moran

Pressure, temperature, volume, and mass can be found experimentally. The relationships between the specific heats c_v and c_p and temperature at relatively low pressure are also accessible experimentally, as are certain other property data. Specific internal energy, enthalpy, and entropy are among those properties that are not so readily obtained in the laboratory. Values for such properties are calculated using experimental data of properties that are more amenable to measurement, together with appropriate property relations derived using the principles of thermodynamics. In this section, property relations and data sources are considered for *simple compressible systems*, which include a wide range of industrially important substances.

Property data are provided in the publications of the *National Institute of Standards and Technology* (formerly the U.S. Bureau of Standards), of professional groups such as the *American Society of Mechanical Engineering (ASME)*, the *American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE)*, and the *American Chemical Society*, and of corporate entities such as *Dupont* and *Dow Chemical*. Handbooks and property reference volumes such as those included in the list of references for this chapter are readily accessed sources of data. Property data are also retrievable from various commercial online data bases.

Basic Relations for Pure Substances

An energy balance in differential form for a closed system undergoing an internally reversible process in the absence of overall system motion and the effect of gravity reads

$$\mathrm{d}U = (\delta Q)_{\text{int rev}} - (\delta W)_{\text{int rev}}$$

From Equation 1.1.14b, $(\delta Q)_{\text{int rev}} = T\,\mathrm{d}s$. When consideration is limited to *simple compressible systems*: systems for which the only significant work in an internally reversible process is associated with volume change, $(\delta W)_{\text{int rev}} = p\,\mathrm{d}V$, the following equation is obtained:

$$\mathrm{d}U = T\,\mathrm{d}S - p\,\mathrm{d}V \tag{1.3.1a}$$

Introducing enthalpy, $H = U + pV$, the Helmholtz function, $\psi = U - TS$, and the Gibbs function, $G = H - TS$, three additional expressions are obtained:

$$\mathrm{d}H = T\,\mathrm{d}S + V\,\mathrm{d}p \tag{1.3.1b}$$

$$\mathrm{d}\psi = -p\,\mathrm{d}V - S\,\mathrm{d}T \tag{1.3.1c}$$

$$\mathrm{d}G = V\,\mathrm{d}p - S\,\mathrm{d}T \tag{1.3.1d}$$

Equations 1.3.1 can be expressed on a per-unit-mass basis as

$$\mathrm{d}u = T\,\mathrm{d}s - p\,\mathrm{d}v \tag{1.3.2a}$$

$$\mathrm{d}h = T\,\mathrm{d}s + v\,\mathrm{d}p \tag{1.3.2b}$$

$$\mathrm{d}\psi = -p\,\mathrm{d}v - s\,\mathrm{d}T \tag{1.3.2c}$$

$$\mathrm{d}g = v\,\mathrm{d}p - s\,\mathrm{d}T \tag{1.3.2d}$$

Similar expressions can be written on a per-mole basis.

TABLE 1.3.1
Relations from Exact Differentials

Function	Differential	Coefficients	Maxwell
General:			
$z = z(x, y)$	$dz = M(x, y)dx + N(x, y)dy$	$\left(\frac{\partial z}{\partial x}\right)_y = M$	$\left(\frac{\partial M}{\partial y}\right)_x = \left(\frac{\partial N}{\partial x}\right)_y$
		$\left(\frac{\partial z}{\partial y}\right)_x = N$	
Internal energy:			
$u(s, v)$	$du = Tds - pdv$	$\left(\frac{\partial u}{\partial s}\right)_v = T$	$\left(\frac{\partial T}{\partial v}\right)_s = -\left(\frac{\partial p}{\partial s}\right)_v$
		$\left(\frac{\partial u}{\partial v}\right)_s = -p$	
Enthalpy:			
$h(s, p)$	$dh = Tds + vdp$	$\left(\frac{\partial h}{\partial s}\right)_p = T$	$\left(\frac{\partial T}{\partial p}\right)_s = \left(\frac{\partial v}{\partial s}\right)_p$
		$\left(\frac{\partial h}{\partial p}\right)_s = v$	
Helmholtz function:			
$\psi(v, T)$	$d\psi = -pdv - sdT$	$\left(\frac{\partial \psi}{\partial v}\right)_T = -p$	$\left(\frac{\partial p}{\partial T}\right)_v = \left(\frac{\partial s}{\partial v}\right)_T$
		$\left(\frac{\partial \psi}{\partial T}\right)_v = -s$	
Gibbs function:			
$g(T, p)$	$dg = vdp - sdT$	$\left(\frac{\partial g}{\partial p}\right)_T = v$	$\left(\frac{\partial v}{\partial T}\right)_p = -\left(\frac{\partial s}{\partial p}\right)_T$
		$\left(\frac{\partial g}{\partial T}\right)_p = -s$	

Maxwell Relations

Since only properties are involved, each of the four differential expressions given by Equations 1.3.2 is an *exact* differential exhibiting the general form $dz = M(x, y)dx + N(x, y)dy$, where the second mixed partial derivatives are equal: $(\partial M/\partial y) = (\partial N/\partial x)$. Underlying these exact differentials are, respectively, functions of the form $u(s, v)$, $h(s, p)$, $\psi(v, T)$, and $g(T, p)$. From such considerations the *Maxwell relations* given in Table 1.3.1 can be established.

Example 1.3.1

Derive the Maxwell relation following from Equation 1.3.2a.

Solution: The differential of the function $u = u(s, v)$ is

$$du = \left(\frac{\partial u}{\partial s}\right)_v ds + \left(\frac{\partial u}{\partial v}\right)_s dv$$

By comparison with Equation 1.3.2a,

$$T = \left(\frac{\partial u}{\partial s}\right)_v, \quad -p = \left(\frac{\partial u}{\partial v}\right)_s$$

In Equation 1.3.2a, T plays the role of M, and $-p$ plays the role of N, so the equality of second mixed partial derivatives gives the Maxwell relation,

$$\left(\frac{\partial T}{\partial v}\right)_s = -\left(\frac{\partial p}{\partial s}\right)_v$$

Since each of the properties T, p, v, and s appears on the right side of two of the eight coefficients of Table 1.3.1, four additional property relations can be obtained by equating such expressions:

$$\left(\frac{\partial u}{\partial s}\right)_v = \left(\frac{\partial h}{\partial s}\right)_p, \quad \left(\frac{\partial u}{\partial v}\right)_s = \left(\frac{\partial \psi}{\partial v}\right)_T$$
$$\left(\frac{\partial h}{\partial p}\right)_s = \left(\frac{\partial g}{\partial p}\right)_T, \quad \left(\frac{\partial \psi}{\partial T}\right)_v = \left(\frac{\partial g}{\partial T}\right)_p$$

These four relations are identified in Table 1.3.1 by brackets. As any three of Equations 1.3.2 can be obtained from the fourth simply by manipulation, the 16 property relations in Table 1.3.1 can also be regarded as following from this single differential expression. Several additional first-derivative property relations can be derived (see, e.g., Zemansky, 1972).

Specific Heats and Other Properties

Engineering thermodynamics uses a wide assortment of thermodynamic properties and relations among these properties. Table 1.3.2 lists several commonly encountered properties.

Among the entries in Table 1.3.2 are the specific heats c_v and c_p. These intensive properties are often required for thermodynamic analysis and are defined as partial derivations of the functions $u(T, v)$ and $h(T, p)$, respectively,

TABLE 1.3.2
Symbols and Definitions for Selected Properties

Property	Symbol	Definition	Property	Symbol	Definition
Pressure	p		Specific heat, constant volume	c_v	$\left(\partial u/\partial T\right)_v$
Temperature	T		Specific heat, constant pressure	c_p	$\left(\partial h/\partial T\right)_p$
Specific volume	v		Volume expansivity	β	$\frac{1}{v}\left(\partial v/\partial T\right)_p$
Specific internal energy	u		Isothermal compressivity	κ	$-\frac{1}{v}\left(\partial v/\partial p\right)_T$
Specific entropy	s		Isentropic compressibility	α	$-\frac{1}{v}\left(\partial v/\partial p\right)_s$
Specific enthalpy	h	$u + pv$	Isothermal bulk modulus	B	$-v\left(\partial p/\partial v\right)_T$
Specific Helmholtz function	ψ	$u - Ts$	Isentropic bulk modulus	B_s	$-v\left(\partial p/\partial v\right)_s$
Specific Gibbs function	g	$h - Ts$	Joule–Thomson coefficient	μ_J	$\left(\partial T/\partial p\right)_h$
Compressibility factor	Z	pv/RT	Joule coefficient	η	$\left(\partial T/\partial v\right)_u$
Specific heat ratio	k	c_p/c_v	Velocity of sound	c	$\sqrt{-v^2\left(\partial p/\partial v\right)_s}$

$$c_v = \left(\frac{\partial u}{\partial T}\right)_v \tag{1.3.3}$$

$$c_p = \left(\frac{\partial h}{\partial T}\right)_p \tag{1.3.4}$$

Since u and h can be expressed either on a unit mass basis or a per-mole basis, values of the specific heats can be similarly expressed. Table 1.3.3 summarizes relations involving c_v and c_p. The property k, the specific heat ratio, is

$$k = \frac{c_p}{c_v} \tag{1.3.5}$$

TABLE 1.3.3
Specific Heat Relations

$$c_v = \left(\frac{\partial u}{\partial T}\right)_v = T\left(\frac{\partial s}{\partial T}\right)_v \tag{1}$$

$$= -T\left(\frac{\partial p}{\partial T}\right)_v \left(\frac{\partial v}{\partial T}\right)_s \tag{2}$$

$$c_p = \left(\frac{\partial h}{\partial T}\right)_p = T\left(\frac{\partial s}{\partial T}\right)_p \tag{3}$$

$$= T\left(\frac{\partial v}{\partial T}\right)_p \left(\frac{\partial p}{\partial T}\right)_s \tag{4}$$

$$c_p - c_v = T\left(\frac{\partial p}{\partial T}\right)_v \left(\frac{\partial v}{\partial T}\right)_p \tag{5}$$

$$= -T\left(\frac{\partial v}{\partial T}\right)_p^2 \left(\frac{\partial p}{\partial v}\right)_T \tag{6}$$

$$= \frac{Tv\beta^2}{\kappa} \tag{7}$$

$$c_p = \frac{1}{\mu_J}\left[T\left(\frac{\partial v}{\partial T}\right)_p - v\right] \tag{8}$$

$$c_v = \frac{1}{\eta}\left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right] \tag{9}$$

$$k = \frac{c_p}{c_v} = \left(\frac{\partial v}{\partial p}\right)_T \left(\frac{\partial p}{\partial v}\right)_s \tag{10}$$

$$\left(\frac{\partial c_v}{\partial v}\right)_T = T\left(\frac{\partial^2 p}{\partial T^2}\right)_v \tag{11}$$

$$\left(\frac{\partial c_p}{\partial p}\right)_T = -T\left(\frac{\partial^2 v}{\partial T^2}\right)_p \tag{12}$$

Note: See, for example, Moran, M.J. and Shapiro, H.N. *Fundamentals of Engineering Thermodynamics*, 4th ed., Wiley, New York, 2000.

Values for c_v and c_p can be obtained via statistical mechanics using *spectroscopic* measurements. They can also be determined macroscopically through exacting property measurements. Specific heat data for common gases, liquids, and solids are provided by the handbooks and property reference volumes listed among the Chapter 1 references. Specific heats are also considered in Section 1.3 as a part of the discussions of the *incompressible model* and the *ideal gas model*. Figure 1.3.1 shows how c_p for water vapor varies as a function of temperature and pressure. Other gases exhibit similar behavior. The figure also gives the variation of c_p with temperature in the limit as pressure tends to zero (the ideal gas limit). In this limit c_p increases with increasing temperature, which is a characteristic exhibited by other gases as well.

The following two equations are often convenient for establishing relations among properties:

$$\left(\frac{\partial x}{\partial y}\right)_z \left(\frac{\partial y}{\partial x}\right)_z = 1 \tag{1.3.6a}$$

$$\left(\frac{\partial y}{\partial z}\right)_x \left(\frac{\partial z}{\partial x}\right)_y \left(\frac{\partial x}{\partial y}\right)_z = -1 \tag{1.3.6b}$$

Their use is illustrated in Example 1.3.2.

Example 1.3.2

Obtain Equations 2 and 11 in Table 1.3.3 from Equation 1.

***Solution*:** Identifying *x*, *y*, *z* with *s*, *T*, and *v*, respectively, Equation 1.3.6b reads

$$\left(\frac{\partial T}{\partial v}\right)_s \left(\frac{\partial v}{\partial s}\right)_T \left(\frac{\partial s}{\partial T}\right)_v = -1$$

Applying Equation 1.3.6a to each of $(\partial T/\partial v)_s$ and $(\partial v/\partial s)_T$,

$$\left(\frac{\partial s}{\partial T}\right)_v = -\frac{1}{\left(\partial T/\partial v\right)_s \left(\partial v/\partial s\right)_T} = -\left(\frac{\partial v}{\partial T}\right)_s \left(\frac{\partial s}{\partial v}\right)_T$$

Introducing the Maxwell relation from Table 1.3.1 corresponding to $\psi(T, v)$,

$$\left(\frac{\partial s}{\partial T}\right)_v = -\left(\frac{\partial v}{\partial T}\right)_s \left(\frac{\partial p}{\partial T}\right)_v$$

With this, Equation 2 of Table 1.3.3 is obtained from Equation 1, which in turn is obtained in Example 1.3.3. Equation 11 of Table 1.3.3 can be obtained by differentiating Equation 1 with respect to specific volume at fixed temperature, and again using the Maxwell relation corresponding to ψ.

P–v–T Relations

Considerable pressure, specific volume, and temperature data have been accumulated for industrially important gases and liquids. These data can be represented in the form $p=f(v, T)$, called an *equation of state*. Equations of state can be expressed in tabular, graphical, and analytical forms.

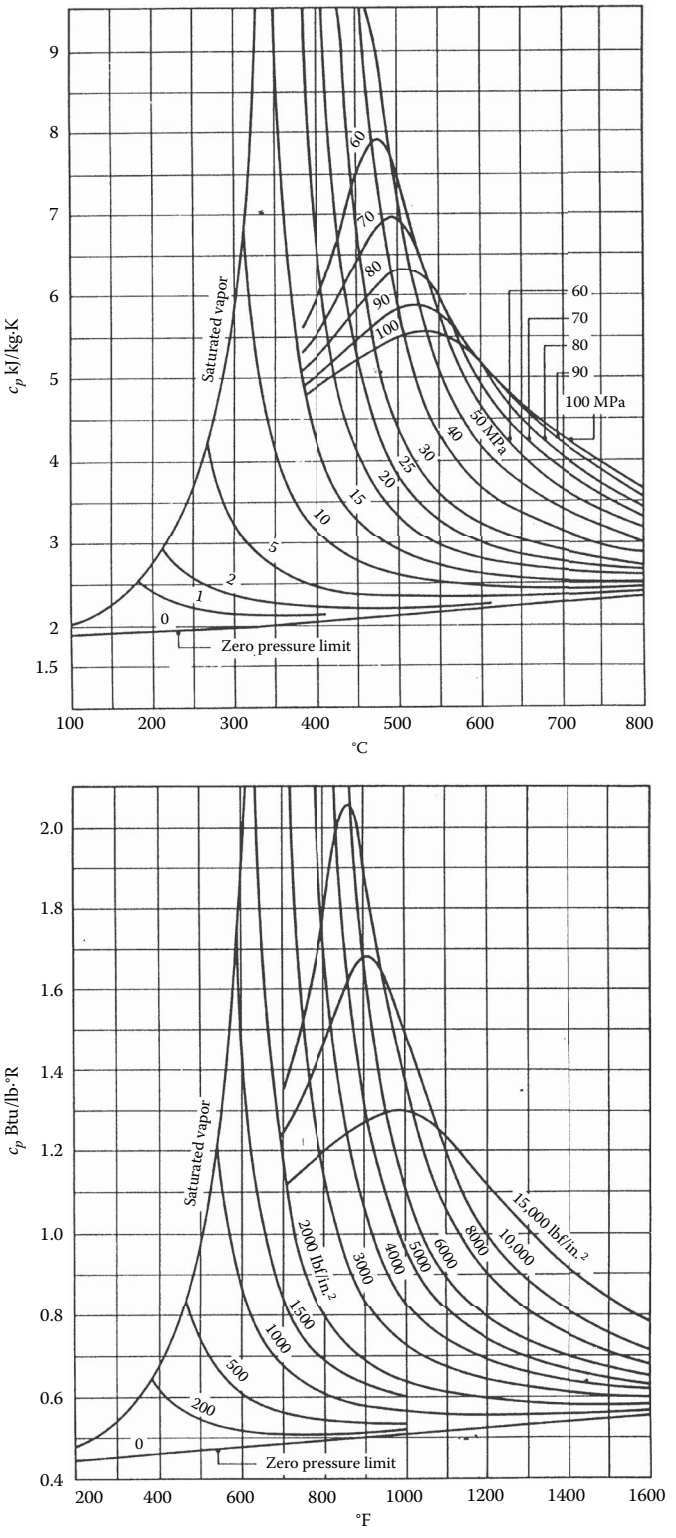

FIGURE 1.3.1 c_p of water vapor as a function of temperature and pressure. (Adapted from Keenan, J.H. et al., *Steam Tables—S.I. Units (English Units)*, John Wiley & Sons, New York, 1978.)

P–v–T Surface

The graph of a function $p=f(v, T)$ is a surface in three-dimensional space. Figure 1.3.2 shows the *p–v–T* relationship for water. Figure 1.3.2b shows the projection of the surface onto the pressure–temperature plane, called the *phase diagram*. The projection onto the *p–v* plane is shown in Figure 1.3.2c.

Figure 1.3.2 has three regions labeled solid, liquid, and vapor where the substance exists only in a single phase. Between the single-phase regions lie *two-phase* regions, where two phases coexist in equilibrium. The lines separating the single-phase regions from the two-phase regions are *saturation lines*. Any state represented by a point on a saturation line is a *saturation state*. The line separating the liquid phase and the two-phase liquid–vapor region is the saturated liquid line. The state denoted by *f* (Figure 1.3.2c) is a saturated liquid state. The saturated vapor line separates the vapor region and the two-phase liquid–vapor region. The state denoted by *g* is a saturated vapor state. The saturated liquid line and the saturated vapor line meet at the *critical point*. At the critical point, the pressure is the *critical pressure* p_c, and the temperature is the *critical temperature* T_c. Three phases can coexist in equilibrium along the line labeled *triple line*. The triple line projects onto a point on the phase diagram. The triple point of water is used in defining the Kelvin temperature scale (Section 1.1, Basic Concepts and Definitions; The Second Law of Thermodynamics, Entropy).

When a phase change occurs during constant pressure heating or cooling, the temperature remains constant as long as both phases are present. Accordingly, in the two-phase liquid–vapor region, a line of constant pressure is also a line of constant temperature. For a specified pressure, the corresponding temperature is called the *saturation temperature*. For a specified temperature,

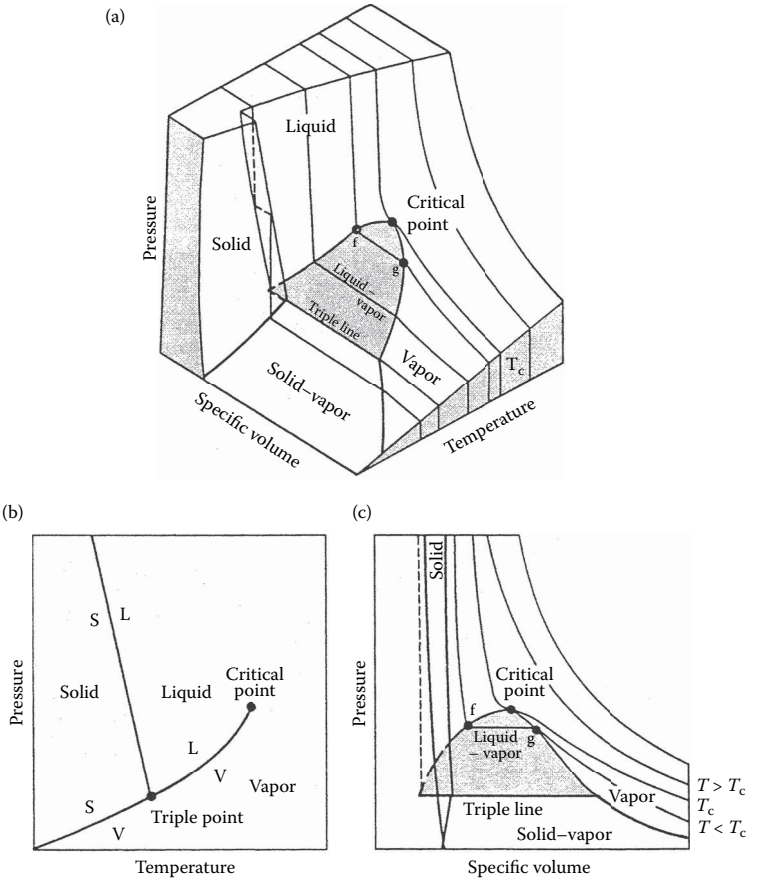

FIGURE 1.3.2 Pressure-specific volume–temperature surface and projections for water (not to scale).

the corresponding pressure is called the *saturation pressure*. The region to the right of the saturated vapor line is known as the *superheated vapor region* because the vapor exists at a temperature greater than the saturation temperature for its pressure. The region to the left of the saturated liquid line is known as the *compressed liquid region* because the liquid is at a pressure higher than the saturation pressure for its temperature.

When a mixture of liquid and vapor coexists in equilibrium, the liquid phase is a saturated liquid and the vapor phase is a saturated vapor. The total volume of any such mixture is $V = V_f + V_g$; or, alternatively, $mv = m_f v_f + m_g v_g$, where m and v denote mass and specific volume, respectively. Dividing by the total mass of the mixture m and letting the *mass fraction* of the vapor in the mixture, m_g/m, be symbolized by x, called the *quality*, the apparent specific volume v of the mixture is

$$\begin{aligned} v &= (1-x)v_f + xv_g \\ &= v_f + xv_{fg} \end{aligned} \tag{1.3.7a}$$

where $v_{fg} = v_g - v_f$. Expressions similar in form can be written for internal energy, enthalpy, and entropy:

$$\begin{aligned} u &= (1-x)u_f + xu_g \\ &= u_f + xu_{fg} \end{aligned} \tag{1.3.7b}$$

$$\begin{aligned} h &= (1-x)h_f + xh_g \\ &= h_f + xh_{fg} \end{aligned} \tag{1.3.7c}$$

$$\begin{aligned} s &= (1-x)s_f + xs_g \\ &= s_f + xs_{fg} \end{aligned} \tag{1.3.7d}$$

For the case of water, Figure 1.3.3 illustrates the phase change from solid to liquid (melting): *a*–*b*–*c*; from solid to vapor (sublimation): *a*′–*b*′–*c*′; and from liquid to vapor (vaporization): *a*″–*b*″–*c*″. During

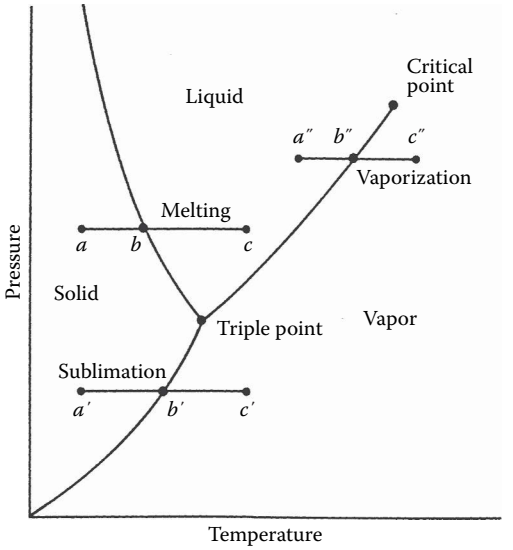

FIGURE 1.3.3 Phase diagram for water (not to scale).

any such phase change the temperature and pressure remain constant and thus are not independent properties. The *Clapeyron equation* allows the change in enthalpy during a phase change at fixed temperature to be evaluated from *p–v–T* data pertaining to the phase change. For vaporization, the Clapeyron equation reads

$$\left(\frac{\mathrm{d}p}{\mathrm{d}T}\right)_{\mathrm{sat}} = \frac{h_{\mathrm{g}} - h_{\mathrm{f}}}{T\left(v_{\mathrm{g}} - v_{\mathrm{f}}\right)} \tag{1.3.8}$$

where $(\mathrm{d}p/\mathrm{d}T)_{\mathrm{sat}}$ is the slope of the saturation pressure–temperature curve at the point determined by the temperature held constant during the phase change. Expressions similar in form to Equation 1.3.8 can be written for sublimation and melting.

The Clapeyron equation shows that the slope of a saturation line on a phase diagram depends on the signs of the specific volume and enthalpy changes accompanying the phase change. In most cases, when a phase change takes place with an increase in specific enthalpy, the specific volume also increases, and $(\mathrm{d}p/\mathrm{d}T)_{\mathrm{sat}}$ is positive. However, in the case of the melting of ice and a few other substances, the specific volume decreases on melting. The slope of the saturated solid–liquid curve for these few substances is negative, as illustrated for water in Figure 1.3.3.

Graphical Representations

The intensive states of a pure, simple compressible system can be represented graphically with any two independent intensive properties as the coordinates, excluding properties associated with motion and gravity. While any such pair may be used, there are several selections that are conventionally employed. These include the *p–T* and *p–v* diagrams in Figure 1.3.2, the *T–s* diagram in Figure 1.3.4, the *h–s* (Mollier) diagram in Figure 1.3.5, and the *p–h* diagram shown

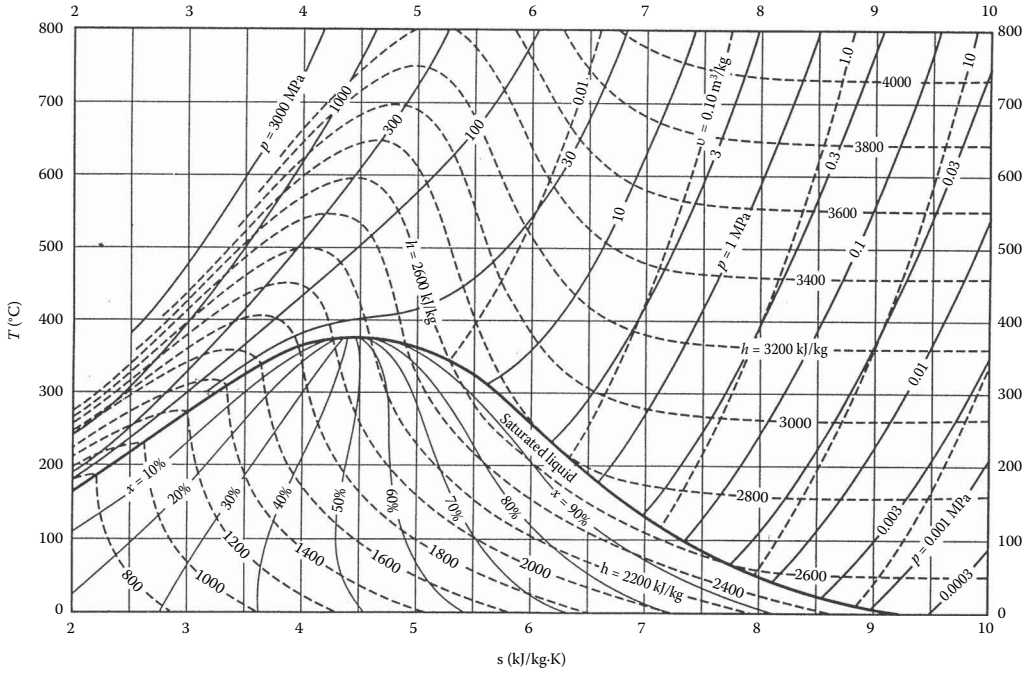

FIGURE 1.3.4 Temperature–entropy diagram for water. (From Jones, J.B. and Dugan, R.E., *Engineering Thermodynamics*, Prentice-Hall, Englewood Cliffs, NJ, 1996 based on data and formulations from Haar, L. et al., *NBS/NRC Steam Tables*. Hemisphere, Washington, DC, 1984.)

in Figure 1.3.6. The compressibility charts considered next use the compressibility factor as one of the coordinates.

Compressibility Charts

The p–v–T relation for a wide range of common gases is illustrated by the generalized compressibility chart shown in Figure 1.3.7. In this chart, the compressibility factor, Z, is plotted versus the *reduced* pressure, p_R, *reduced* temperature, T_R, and *pseudoreduced* specific volume, v'_R, where

$$Z = \frac{p\bar{v}}{\bar{R}T} \tag{1.3.9}$$

and

$$p_R = \frac{p}{p_c}, \quad T_R = \frac{T}{T_c}, \quad v'_R = \frac{\bar{v}}{\left(\bar{R}T_c/p_c\right)} \tag{1.3.10}$$

In these expressions, $\bar{R}$ is the universal gas constant, and p_c and T_c denote the critical pressure and temperature, respectively. Values of p_c and T_c are given for several substances in Table A.9. The

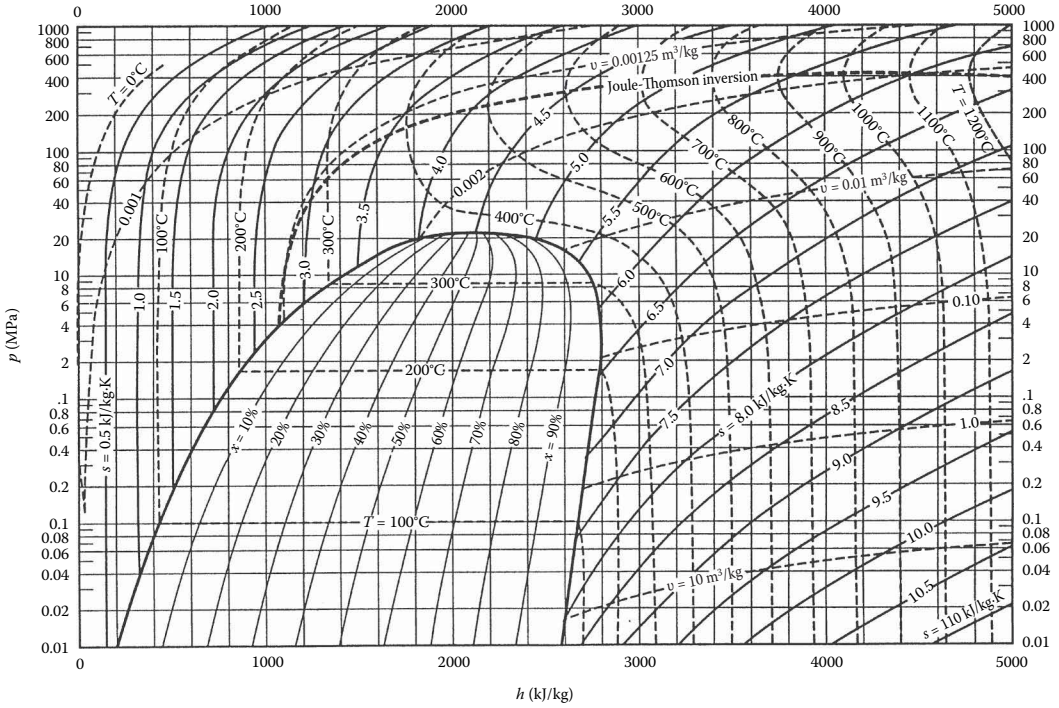

FIGURE 1.3.6 Pressure–enthalpy diagram for water. (From Jones, J.B. and Dugan, R.E., *Engineering Thermodynamics*, Prentice-Hall, Englewood Cliffs, NJ, 1996 based on data and formulations from Haar, L. et al., *NBS/NRC Steam Tables*, Hemisphere, Washington, DC, 1984.)

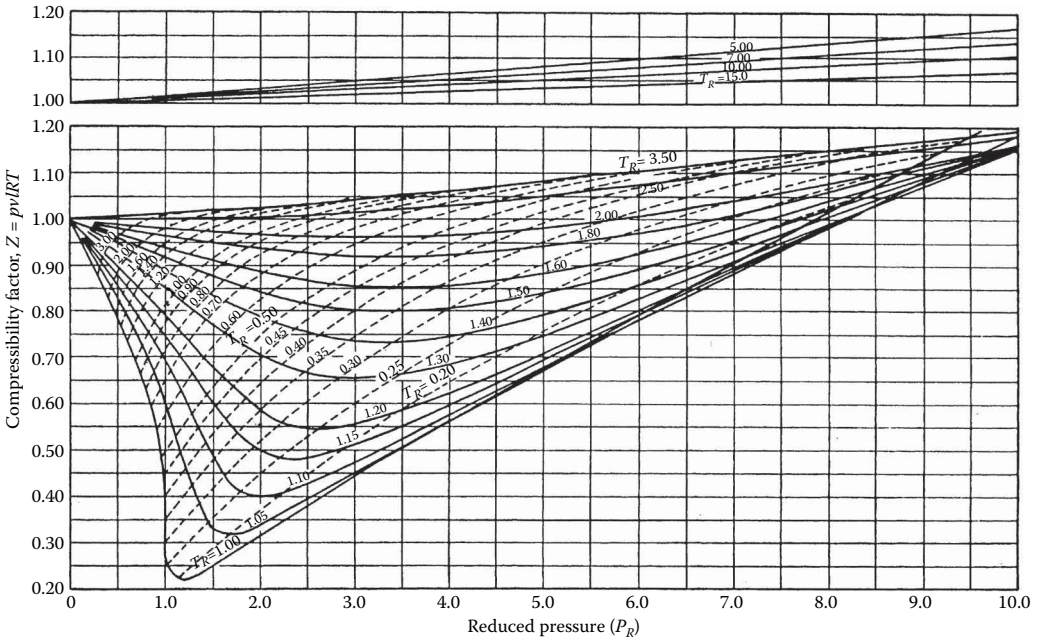

FIGURE 1.3.7 Generalized compressibility chart $\left(T_R = T/T_C,\ p_R = p/p_C,\ v'_R = \overline{v}p_C/RT_C\right)$ for $p_R \leq 10$. (From Obert, E.F. *Concepts of Thermodynamics*. McGraw-Hill, New York, 1960.)

reduced isotherms shown in Figure 1.3.7 represent the best curves fitted to the data of several gases. For the 30 gases used in developing the chart, the deviation of observed values from those of the chart is at most on the order of 5% and for most ranges is much less.*

Figure 1.3.7 gives a common value of about 0.27 for the compressibility factor at the critical point. As the critical compressibility factor for different substances actually varies from 0.23 to 0.33, the chart is inaccurate in the vicinity of the critical point. This source of inaccuracy can be removed by restricting the correlation to substances having essentially the same Z_c values, which is equivalent to including the critical compressibility factor as an independent variable: $Z=f(T_R, p_R, Z_c)$. To achieve greater accuracy, variables other than Z_c have been proposed as a third parameter—for example, the *acentric factor* (see, e.g., Reid and Sherwood, 1966).

Generalized compressibility data are also available in tabular form (see, e.g., Reid and Sherwood, 1966) and in equation form (see, e.g., Reynolds, 1979). The use of generalized data in any form (graphical, tabular, or equation) allows p, v, and T for gases to be evaluated simply and with reasonable accuracy. When accuracy is an essential consideration, generalized compressibility data should not be used as a substitute for p–v–T data for a given substance as provided by computer software, a table, or an equation of state.

Equations of State

Considering the isotherms shown in Figure 1.3.7, it is plausible that the variation of the compressibility factor might be expressed as an equation, at least for certain intervals of p and T. Two expressions can be written that enjoy a theoretical basis. One gives the compressibility factor as an infinite series expansion in pressure,

$$Z = 1 + \hat{B}(T)\,p + \hat{C}(T)\,p^2 + \hat{D}(T)\,p^3 + \cdots$$

and the other is a series in $1/\overline{v}$,

$$Z = 1 + \frac{B(T)}{\overline{v}} + \frac{C(T)}{\overline{v}^2} + \frac{D(T)}{\overline{v}^3} + \cdots$$

These expressions are known as *virial expansions*, and the coefficients $\hat{B}, \hat{C}, \hat{D}, \ldots$ and B, C, D, … are called *virial coefficients*. In principle, the virial coefficients can be calculated using expressions from statistical mechanics derived from consideration of the force fields around the molecules. Thus far only the first few coefficients have been calculated and only for gases consisting of relatively simple molecules. The coefficients also can be found, in principle, by fitting p–v–T data in particular realms of interest. Only the first few coefficients can be found accurately this way, however, and the result is a *truncated* equation valid only at certain states.

Over 100 equations of state have been developed in an attempt to portray accurately the p–v–T behavior of substances and yet avoid the complexities inherent in a full virial series. In general, these equations exhibit little in the way of fundamental physical significance and are mainly empirical in character. Most are developed for gases, but some describe the p–v–T behavior of the liquid phase, at least qualitatively. Every equation of state is restricted to particular states. The realm of applicability is often indicated by giving an interval of pressure, or density, where the equation can be expected to represent the p–v–T behavior faithfully. When it is not stated, the realm of applicability often may be approximated by expressing the equation in terms of the compressibility factor Z

* To determine Z for hydrogen, helium, and neon above a T_R of 5, the reduced temperature and pressure should be calculated using $T_R = T/(T_c + 8)$ and $P_R = p/(p_c + 8)$, where temperatures are in K and pressures are in atm.

and the reduced properties, and superimposing the result on a generalized compressibility chart or comparing with compressibility data from the literature.

Equations of state can be classified by the number of adjustable constants they involve. The Redlich–Kwong equation is considered by many to be the best of the two-constant equations of state. It gives pressure as a function of temperature and specific volume and thus is *explicit* in pressure:

$$p = \frac{\bar{R}T}{\bar{v} - b} - \frac{a}{\bar{v}\left(\bar{v} + b\right)T^{1/2}} \tag{1.3.11}$$

This equation is primarily empirical in nature, with no rigorous justification in terms of molecular arguments. Values for the Redlich–Kwong constants for several substances are provided in Table A.9. Modified forms of the equation have been proposed with the aim of achieving better accuracy.

Although the two-constant Redlich–Kwong equation performs better than some equations of state having several adjustable constants, two-constant equations tend to be limited in accuracy as pressure (or density) increases. Increased accuracy normally requires a greater number of adjustable constants. For example, the Benedict–Webb–Rubin equation, which involves eight adjustable constants, has been successful in predicting the *p–v–T* behavior of *light hydrocarbons*. The Benedict–Webb–Rubin equation is also explicit in pressure,

$$p = \frac{\bar{R}T}{\bar{v}} + \left(B\bar{R}T - A - \frac{C}{T^2}\right)\frac{1}{\bar{v}^2} + \frac{\left(b\bar{R}T - a\right)}{\bar{v}^3} + \frac{a\alpha}{\bar{v}^6} + \frac{c}{\bar{v}^3T^2}\left(1 + \frac{\gamma}{\bar{v}^2}\right)\exp\left(-\frac{\gamma}{\bar{v}^2}\right) \tag{1.3.12}$$

Values of the Benedict–Webb–Rubin constants for various gases are provided in the literature (see, e.g., Cooper and Goldfrank, 1967). A modification of the Benedict–Webb–Rubin equation involving 12 constants is discussed by Lee and Kessler (1975). Many multiconstant equations can be found in the engineering literature, and equations having 50 or more constants have been developed for representing the *p–v–T* behavior of different substances.

Gas Mixtures

Since an unlimited variety of mixtures can be formed from a given set of pure components by varying the relative amounts present, the properties of mixtures are reported only in special cases such as air. Means are available for predicting the properties of mixtures, however. Most techniques for predicting mixture properties are empirical in character and are not derived from fundamental physical principles. The realm of validity of any particular technique can be established by comparing predicted property values with empirical data. In this section, methods for evaluating the *p–v–T* relations for pure components are adapted to obtain plausible estimates for gas mixtures. The case of ideal gas mixtures is discussed in Section 1.3, Ideal Gas Model. In Section 1.3, Multicomponent Systems, some general aspects of property evaluation for multicomponent systems are presented.

The total number of moles of mixture, n, *is* the sum of the number of moles of the components, n_i:

$$n = n_1 + n_2 + \cdots + n_j = \sum_{i=1}^{j} n_i \tag{1.3.13}$$

The *relative* amounts of the components present can be described in terms of *mole fractions*. The mole fraction y_i of component i is $y_i = n_i/n$. The sum of the mole fractions of all components present is equal to unity. The apparent molecular weight M is the mole fraction average of the component molecular weights, such that

$$M = \sum_{i=1}^{j} y_i M_i \tag{1.3.14}$$

The *relative* amounts of the components present also can be described in terms of *mass fractions:* m_i/m, where m_i is the mass of component i and m is the total mass of mixture.

The p–v–T relation for a gas mixture can be estimated by applying an equation of state to the overall mixture. The constants appearing in the equation of state are *mixture values* determined with empirical combining rules developed for the equation. For example, mixture values of the constants a and b for use in the Redlich–Kwong equation are obtained using relations of the form

$$a = \left(\sum_{i=1}^{j} y_i a_i^{1/2} \right)^2, \quad b = \sum_{i=1}^{j} y_i b_i \tag{1.3.15}$$

where a_i and b_i are the values of the constants for component i. Combination rules for obtaining mixture values for the constants in other equations of state are also found in the literature.

Another approach is to regard the mixture as if it were a single pure component having critical properties calculated by one of several mixture rules. *Kay's rule* is perhaps the simplest of these, requiring only the determination of a mole fraction averaged critical temperature T_c and critical pressure p_c:

$$T_c = \sum_{i=1}^{j} y_i T_{c,i}, \quad p_c = \sum_{i=1}^{j} y_i p_{c,i} \tag{1.3.16}$$

where $T_{c,i}$ and $p_{c,i}$ are the critical temperature and critical pressure of component i, respectively. Using T_c and p_c, the mixture compressibility factor Z is obtained as for a single pure component. The unknown quantity from among the pressure p, volume V, temperature T, and total number of moles n of the gas mixture can then be obtained by solving $Z = pV/n\bar{R}T$.

Additional means for predicting the p–v–T relation of a mixture are provided by empirical mixture rules. Several are found in the engineering literature. According to the *additive pressure rule*, the pressure of a gas mixture is expressible as a sum of pressures exerted by the individual components:

$$p = p_1 + p_2 + p_3 \ldots]_{T,V} \tag{1.3.17a}$$

where the pressures p_1, p_2, etc., are evaluated by considering the respective components to be at the volume V and temperature T of the mixture. The additive pressure rule can be expressed alternatively as

$$Z = \sum_{i=1}^{j} y_i Z_i \Bigg]_{T,V} \tag{1.3.17b}$$

where Z is the compressibility factor of the mixture and the compressibility factors Z_i are determined assuming that component i occupies the entire volume of the mixture at the temperature T.

The *additive volume rule* postulates that the volume V of a gas mixture is expressible as the sum of volumes occupied by the individual components:

$$V = V_1 + V_2 + V_3 \ldots]_{p,T} \tag{1.3.18a}$$

where the volumes V_1, V_2, etc., are evaluated by considering the respective components to be at the pressure p and temperature T of the mixture. The additive volume rule can be expressed alternatively as

$$Z = \sum_{i=1}^{j} y_i Z_i \Bigg]_{p,T} \tag{1.3.18b}$$

where the compressibility factors Z_i are determined assuming that component i exists at the pressure p and temperature T of the mixture.

Evaluating Δh, Δu, and Δs

Using appropriate specific heat and p–v–T data, the changes in specific enthalpy, internal energy, and entropy can be determined between states of single-phase regions. Table 1.3.4 provides expressions for such property changes in terms of particular choices of the independent variables: temperature and pressure, and temperature and specific volume.

Taking Equation 1 of Table 1.3.4 as a representative case, the change in specific enthalpy between states 1 and 2 can be determined using the three steps shown in the accompanying property diagram. This requires knowledge of the variation of c_p with temperature at a fixed pressure p', and the variation of $[v - T(\partial v/\partial T)_p]$ with pressure at temperatures T_1 and T_2:

1-a: Since temperature is constant at T_1, the first integral of Equation 1 in Table 1.3.4 vanishes, and

$$h_a - h_1 = \int_{p_1}^{p'} \left[v - T\left(\partial v/\partial T\right)_p \right] \mathrm{d}p$$

a-b: Since pressure is constant at p', the second integral of Equation 1 vanishes, and

$$h_b - h_a = \int_{T_1}^{T_2} c_p\left(T, p'\right) \mathrm{d}T$$

b-2: Since temperature is constant at T_2, the first integral of Equation 1 vanishes, and

$$h_2 - h_b = \int_{p'}^{p_2} \left[v - T\left(\partial v/\partial T\right)_p \right] \mathrm{d}p$$

Adding these expressions, the result is $h_2 - h_1$. The required integrals may be performed numerically or analytically. The analytical approach is expedited when an equation of state explicit in specific volume is known.

Similar considerations apply to Equations 2 to 4 of Table 1.3.4. To evaluate $u_2 - u_1$ with Equation 3, for example, requires the variation of c_v with temperature at a fixed specific volume v', and the variation of $[T(\partial p/\partial T)_v - p]$ with specific volume at temperatures T_1 and T_2. An analytical approach to performing the integrals is expedited when an equation of state explicit in pressure is known.

As changes in specific enthalpy and internal energy are related through $h = u + pv$ by

$$h_2 - h_1 = \left(u_2 - u_1\right) + \left(p_2 v_2 - p_1 v_1\right) \tag{1.3.19}$$

only one of $h_2 - h_1$ and $u_2 - u_1$ need be found by integration. The other can be evaluated from Equation 1.3.19. The one found by integration depends on the information available: $h_2 - h_1$ would be found when an equation of state explicit in v and c_p as a function of temperature at some fixed pressure is known, $u_2 - u_1$ would be found when an equation of state explicit in p and c_v as a function of temperature at some specific volume is known.

Example 1.3.3

Obtain Equation 1 of Table 1.3.3 and Equations 3 and 4 of Table 1.3.4.

Solution. With Equation 1.3.3 and the Maxwell relation corresponding to $\psi(T, v)$ from Table 1.3.1, Equations 3′ and 4′ of Table 1.3.4 become, respectively,

TABLE 1.3.4
Δh, Δu, Δs Expressions

Independent Properties:	**Temperature and Pressure**	**Temperature and Specific Volume**
Preferred data:	$v(T, p)$, $c_p(T, p)$	$p(T, v)$, $c_v(T, v)$
Property diagram:		Property expressions:	$h(T, p)$:	$u(T, v)$:
	$$dh = \left(\frac{\partial h}{\partial T}\right)_p dT + \left(\frac{\partial h}{\partial p}\right)_T dp \quad (1')$$	$$du = \left(\frac{\partial u}{\partial T}\right)_v dT + \left(\frac{\partial u}{\partial v}\right)_T dv \quad (3')$$
	$c_p \qquad \left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right]$	$c_v \qquad \left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right]$
	$$\Delta h = \int c_p\, dT + \int \left[v - T\left(\frac{\partial v}{\partial T}\right)_p\right] dp \quad (1)$$	$$\Delta u = \int c_v\, dT + \int \left[T\left(\frac{\partial p}{\partial T}\right)_v - p\right] dv \quad (3)$$
	$s(T,p)$:	$s(T,v)$:
	$$ds = \left(\frac{\partial s}{\partial T}\right)_p dT + \left(\frac{\partial s}{\partial p}\right)_T dp \quad (2')$$	$$ds = \left(\frac{\partial s}{\partial T}\right)_v dT + \left(\frac{\partial s}{\partial v}\right)_T dv \quad (4')$$
	$\frac{c_p}{T} \qquad -\left(\frac{\partial v}{\partial T}\right)_p$	$\frac{c_v}{T} \qquad \left(\frac{\partial p}{\partial T}\right)_v$
	$$\Delta s = \int \frac{c_p}{T} dT - \int \left(\frac{\partial v}{\partial T}\right)_p dp \quad (2)$$	$$\Delta s = \int \frac{c_v}{T} dT + \int \left(\frac{\partial p}{\partial T}\right)_v dv \quad (4)$$

$$du = c_v\,dT + \left(\frac{\partial u}{\partial v}\right)_T dv$$

$$ds = \left(\frac{\partial s}{\partial T}\right)_v dT + \left(\frac{\partial p}{\partial T}\right)_v dv$$

Introducing these expressions for *du* and *ds* in Equation 1.3.2a, and collecting terms,

$$\left[T\left(\frac{\partial s}{\partial T}\right)_v - c_v\right]dT = \left[\left(\frac{\partial u}{\partial v}\right)_T + p - T\left(\frac{\partial p}{\partial T}\right)_v\right]dv$$

Since *T* and *v* are independent, the coefficients of d*T* and d*v* must vanish, giving, respectively,

$$\left(\frac{\partial s}{\partial T}\right)_v = \frac{c_v}{T}$$

$$\left(\frac{\partial u}{\partial v}\right)_T = T\left(\frac{\partial p}{\partial T}\right)_v - p$$

The first of these corresponds to Equation 1 of Table 1.3.3 and Equation 4 of Table 1.3.4. The second of the earlier expressions establishes Equation 3 of Table 1.3.4. With similar considerations, Equation 3 of Table 1.3.3 and Equations 1 and 2 of Table 1.3.4 may be obtained.

Fundamental Thermodynamic Functions

A fundamental thermodynamic function is one that provides a complete description of the thermodynamic state. The functions $u(s, v)$, $h(s, p)$, $\psi(T, v)$, and $g(T, p)$ listed in Table 1.3.1 are fundamental thermodynamic functions.

In principle, all properties of interest can be determined from a fundamental thermodynamic function by differentiation and combination. Taking the function $\psi(T, v)$ as a representative case, the properties *v* and *T*, being the independent variables, are specified to fix the state. The pressure *p* and specific entropy *s* at this state can be determined by differentiation of $\psi(T, v)$, as shown in Table 1.3.1. By definition, $\psi = u - Ts$, so specific internal energy is obtained as

$$u = \psi + Ts$$

with *u*, *p*, and *v* known, the specific enthalpy can be found from the definition $h = u + pv$. Similarly, the specific Gibbs function is found from the definition $g = h - Ts$. The specific heat c_v can be determined by further differentiation $c_v = (\partial u/\partial T)_v$.

The development of a fundamental function requires the selection of a functional form in terms of the appropriate pair of independent properties and a set of adjustable coefficients that may number 50 or more. The functional form is specified on the basis of both theoretical and practical considerations. The coefficients of the fundamental function are determined by requiring that a set of selected property values and/or observed conditions be satisfied in a least-squares sense. This generally involves property data requiring the assumed functional form to be differentiated one or more times, for example, *p–v–T* and specific heat data. When all coefficients have been evaluated, the function is tested for accuracy by using it to evaluate properties for which accepted values are known such as *velocity of sound* and *Joule–Thomson* data. Once a suitable fundamental function is established, extreme accuracy in and consistency among the thermodynamic properties are possible. The properties of water tabulated by Keenan et al. (1969) and Haar et al. (1984) have been calculated from representations of the Helmholtz function.

Thermodynamic Data Retrieval

Tabular presentations of pressure, specific volume, and temperature are available for practically important gases and liquids. The tables normally include other properties useful for thermodynamic analyses, such as internal energy, enthalpy, and entropy. The various *steam* table*s* included in the references of this chapter provide examples. Computer software for retrieving the properties of a wide range of substances is also available, as, for example, the ASME Steam Tables (1993) and Bornakke and Sonntag (1996).

The sample *steam table* data presented in Table 1.3.5 are representative of data available for substances commonly encountered in mechanical engineering practice. Table A.5 and Figures 1.3.4 to 1.3.6 provide *steam table* data for a greater range of states. The form of the tables and figures, and how they are used are assumed to be familiar. In particular, the use of *linear interpolation* with such tables is assumed known.

Specific internal energy, enthalpy, and entropy data are determined relative to arbitrary datums, and such datums vary from substance to substance. Referring to Table 1.3.5a, the datum state for the specific internal energy and specific entropy of water is seen to correspond to saturated liquid water at 0.01°C (32.02°F), the triple point temperature. The value of each of these properties is set to zero at this state. If calculations are performed involving only differences in a particular specific property, the datum cancels. When there are changes in chemical composition during the process, special care should be exercised. The approach followed when composition changes due to chemical reaction is considered in Section 1.4.

Liquid water data (see Table 1.3.5d) suggests that at fixed temperature the variation of specific volume, internal energy, and entropy with pressure is slight. The variation of specific enthalpy with pressure at fixed temperature is somewhat greater because pressure is explicit in the definition of enthalpy. This behavior for v, u, s, and h is exhibited generally by liquid data and provides the basis for the following set of equations for estimating property data at liquid states from saturated liquid data:

$$v(T,p) \approx v_f(T) \tag{1.3.20a}$$

$$u(T,p) \approx u_f(T) \tag{1.3.20b}$$

$$h(T,p) \approx h_f(T) + v_f\left[p - p_{\text{sat}}(T)\right] \tag{1.3.20c}$$

$$s(T,p) \approx s_f(T) \tag{1.3.20d}$$

As before, the subscript f denotes the saturated liquid state at the temperature T, and p_{sat} *is* the corresponding saturation pressure. The second term on the right hand side of Equation 1.3.20c is often negligible, giving $h(T, p) \approx h_f(T)$, which is used in Example 1.2.3 to evaluate h_1.

In the absence of saturated liquid data, or as an alternative to such data, the *incompressible model* can be employed:

$$\text{Incompressible model}: \begin{cases} v = \text{constant} \\ u = u(T) \end{cases} \tag{1.3.21}$$

This model is also applicable to solids. Since internal energy varies only with temperature, the specific heat c_v is also a function of only temperature: $c_v(T) = du/dT$. Although specific volume is constant, enthalpy varies with both temperature and pressure, such that

$$h(T,p) = u(T) + pv \tag{1.3.22}$$

Differentiation of Equation 1.3.22 with respect to temperature at fixed pressure gives $c_p = c_v$. The common specific heat is often shown simply as c. Specific heat data for several liquids and solids are

provided in Appendix tables B and C. As the variation of c with temperature is slight, c is frequently taken as constant.

When the incompressible model is applied, Equation 1.3.19 takes the form

$$\begin{aligned} h_2 - h_1 &= \int_{T_1}^{T_2} c(T)\,\mathrm{d}T + v(p_2 - p_1) \\ &= c_{\text{ave}}(T_2 - T_1) + v(p_2 - p_1) \end{aligned} \tag{1.3.23}$$

Also, as Equation 1.3.2a reduces to $\mathrm{d}u = T\,\mathrm{d}s$, and $\mathrm{d}u = c(T)\mathrm{d}T$, the change in specific entropy is

$$\begin{aligned} \Delta s &= \int_{T_1}^{T_2} \frac{c(T)}{T}\,\mathrm{d}T \\ &= c_{\text{ave}} \ln \frac{T_2}{T_1} \end{aligned} \tag{1.3.24}$$

Ideal Gas Model

Inspection of the generalized compressibility chart, Figure 1.3.7, shows that when p_R is small, and for many states when T_R is large, the value of the compressibility factor Z is close to 1. In other words, for pressures that are low relative to p_c, and for many states with temperatures high relative to T_c, the compressibility factor approaches a value of 1. Within the indicated limits, it may be assumed with reasonable accuracy that $Z = 1$, that is,

$$p\bar{v} = \bar{R}T \text{ or } pv = RT \tag{1.3.25a}$$

where $R = \bar{R}/M$ is the *specific* gas constant. Other forms of this expression in common use are

$$pV = n\bar{R}T, \quad pV = mRT \tag{1.3.25b}$$

Referring to Equation 3′ of Table 1.3.4, it can be concluded that $(\partial u/\partial v)_T$ vanishes identically for a gas whose equation of state is *exactly* given by Equation 1.3.25, and thus the specific internal energy depends only on temperature. This conclusion is supported by experimental observations beginning with the work of Joule, who showed that the internal energy of air at low density depends primarily on temperature.

These considerations allow for an *ideal gas model* of each real gas: (1) the equation of state is given by Equation 1.3.25 and (2) the internal energy and enthalpy are functions of temperature alone. The real gas approaches the model in the limit of low reduced pressure. At other states, the actual behavior may depart substantially from the predictions of the model. Accordingly, caution should be exercised when invoking the ideal gas model lest significant error is introduced.

Specific heat data for gases can be obtained by direct measurement. When extrapolated to zero pressure, ideal gas-specific heats result. Ideal gas-specific heats also can be calculated using molecular models of matter together with data from spectroscopic measurements. Table A.9 provides ideal gas-specific heat data for a number of substances. The following ideal gas-specific heat relations are frequently useful:

$$c_p(T) = c_v(T) + R \tag{1.3.26a}$$

$$c_p = \frac{kR}{k-1}, \quad c_v = \frac{R}{k-1} \tag{1.3.26b}$$

where $k = c_p/c_v$.

With the ideal gas model, Equations 1 through 4 of Table 1.3.4 give Equations 1 through 4 of Table 1.3.6, respectively. Equation 2 of Table 1.3.6 can be expressed alternatively using $s°(T)$ defined by

$$s^\circ(T) = \int_0^T \frac{c_p(T)}{T}\,dT \tag{1.3.27}$$

as

$$s(T_2, p_2) - s(T_1, p_1) = s^\circ(T_2) - s^\circ(T_1) - R\ln\frac{p_2}{p_1} \tag{1.3.28}$$

Expressions similar in form to Equations 1.3.26 through 1.3.38 can be written on a molar basis.

For processes of an ideal gas between states having the same specific entropy, $s_2 = s_1$, Equation 1.3.28 gives

$$\frac{p_2}{p_1} = \frac{\exp\left[s^\circ(T_2)/R\right]}{\exp\left[s^\circ(T_1)/R\right]}$$

or with $p_r = \exp[s°(T)/R]$

$$\frac{p_2}{p_1} = \frac{p_r(T_2)}{p_r(T_1)} \quad (s_2 = s_1) \tag{1.3.29a}$$

A relation between the specific volume and temperatures for two states of an ideal gas having the same specific entropy can also be developed:

$$\frac{v_2}{v_1} = \frac{v_r(T_2)}{v_r(T_1)} \quad (s_2 = s_1) \tag{1.3.29b}$$

TABLE 1.3.6
Ideal Gas Expressions for Δh, Δu, and Δs

Variable Specific Heats		Constant Specific Heats	
$h(T_2) - h(T_1) = \int_{T_1}^{T_2} c_p(T)\,dT$	(1)	$h(T_2) - h(T_1) = c_p(T_2 - T_1)$	(1′)
$s(T_2, p_2) - s(T_1, p_1) = \int_{T_1}^{T_2} \frac{c_p(T)}{T}\,dT - R\ln\frac{p_2}{p_1}$	(2)	$s(T_2, p_2) - s(T_1, p_1) = c_p\ln\frac{T_2}{T_1} - R\ln\frac{p_2}{p_1}$	(2′)
$u(T_2) - u(T_1) = \int_{T_1}^{T_2} c_v(T)\,dT$	(3)	$u(T_2) - u(T_1) = c_v(T_2 - T_1)$	(3′)
$s(T_2, v_2) - s(T_1, v_1) = \int_{T_1}^{T_2} \frac{c_v(T)}{T}\,dT + R\ln\frac{v_2}{v_1}$	(4)	$s(T_2, v_2) - s(T_1, v_1) = c_v\ln\frac{T_2}{T_1} + R\ln\frac{v_2}{v_1}$	(4′)
$s_2 = s_1$		$s_2 = s_1$	
$\frac{p_r(T_2)}{p_r(T_1)} = \frac{p_2}{p_1}$	(5)	$\frac{T_2}{T_1} = \left(\frac{p_2}{p_1}\right)^{(k-1)/k}$	(5′)
$\frac{v_r(T_2)}{v_r(T_1)} = \frac{v_2}{v_1}$	(6)	$\frac{T_2}{T_1} = \left(\frac{v_1}{v_2}\right)^{k-1}$	(6′)

Equations 1.3.29 are listed in Table 1.3.6 as Equations 5 and 6, respectively.

Table A.8 provides a tabular display of h, u, $s°$, p_r, and v_r versus temperature for air as an ideal gas. Tabulations of $\overline{h}$, $\overline{u}$, and $\overline{s}^\circ$ for several other common gases are provided in Table A.2. Property retrieval software also provides such data; see, e.g., Moran and Shapiro (2000). The use of data from Table A.8 for the nozzle of Example 1.2.2 is illustrated in Example 1.3.4.

When the ideal gas-specific heats are assumed constant, Equations 1 to 6 of Table 1.3.6 become Equations 1′ to 6′, respectively. The specific heat c_p is taken as constant in Example 1.2.2.

Example 1.3.4

Using data from Table A.8, evaluate the exit velocity for the nozzle of Example 1.2.2 and compare with the exit velocity for an isentropic expansion to 15 lbf/in.^{2}.

Solution: The exit velocity is given by Equation 1.2.9f

$$v_e = \sqrt{v_i^2 + 2\left(h_i - h_e\right)}$$

At 960 and 520°R, Table A.8 gives, respectively, h_i=231.06 Btu/lb and h_e=124.27 Btu/lb. Then

$$\mathrm{v}_e = \sqrt{\left(\frac{10\,\mathrm{ft}}{s}\right)^2 + 2\left(231.06 - 124.27\right)\left(\mathrm{Btu/lb}\right)\left(\frac{778.17\,\mathrm{ft\cdot lbf}}{1\mathrm{Btu}}\right)\left(\frac{32.174\,\mathrm{lb\cdot ft/s^2}}{1\mathrm{lbf}}\right)}$$

$$= 2312.5\,\mathrm{ft/s}$$

Using Equation 1.3.29a and p_r data from Table A.8, the specific enthalpy at the exit for an isentropic expansion is found as follows:

$$p_r\left(T_e\right) = p_r\left(T_i\right)\frac{p_e}{p_i} = 10.61\left(\frac{15}{150}\right) = 1.061$$

Interpolating with p_r data, h_e=119.54 Btu/lb. With this, the exit velocity is 2363.1 ft/s. The actual exit velocity is about 2% less than the velocity for an isentropic expansion, the maximum theoretical value. In this particular application, there is good agreement in each case between velocities calculated using Table A.8 data and, as in Example 1.2.2, assuming c_p constant. Such agreement cannot be expected generally, however. See, for example, the Brayton cycle data of Table 1.3.7.

Polytropic Processes

An internally reversible process described by the expression pv^n=constant is called a *polytropic process* and *n is* the *polytropic exponent*. Although this expression can be applied with real gas data, it most generally appears in practice together with the use of the ideal gas model. Table 1.3.7 provides several expressions applicable to polytropic processes and the special forms they take when the ideal gas model is assumed. The expressions for $\int p\,\mathrm{d}v$ and $\int v\,\mathrm{d}p$ have application to work evaluations with Equations 1.1.10 and 1.2.12, respectively. In some applications, it may be appropriate to determine n by fitting pressure-specific volume data.

Example 1.3.5 illustrates both the polytropic process and the reduction in the compressor work achievable by cooling a gas as it is compressed.

Example 1.3.5

A compressor operates at steady state with air entering at 1 bar, 20°C and exiting at 5 bar. (1) If the air undergoes a polytropic process with $n=1.3$, determine the work and heat transfer, each in kJ/kg of air flowing. Repeat for (2) an isothermal compression and (3) an isentropic compression.

Solution:

1. Using Equation 5′ of Table 1.3.7 together with Equation 1.2.12b,

$$\frac{\dot{W}_{cv}}{\dot{m}} = \frac{nRT_1}{n-1}\left[1-\left(\frac{p_2}{p_1}\right)^{(n-1)/n}\right]$$

$$= \left(\frac{1.3}{0.3}\right)\left(\frac{8.314}{28.97}\text{kJ/kg}\cdot\text{K}\right)(293\text{ K})\left[1-(5)^{0.3/1.3}\right]$$

$$= -163.9\text{kJ/kg}$$

(The area behind process 1–2 given in Figure 1.3.8, area 1–2–a–b, represents the magnitude of the work required, per unit mass of air flowing.) Also, Equation 1′ of Table 1.3.7 gives $T_2=425$ K. An energy rate balance at steady state and enthalpy data from Table A.8 gives

$$\frac{\dot{Q}_{cv}}{\dot{m}} = \frac{\dot{W}_{cv}}{\dot{m}} + h_2 - h_1$$

$$= -163.9 + (426.3 - 293.2) = -30.8\text{kJ/kg}$$

2. Using Equation 3′ of Table 1.3.7 together with Equation 1.2.12b,

$$\frac{\dot{W}_{cv}}{\dot{m}} = -RT\ln\frac{p_2}{p_1}$$

$$= -\left(\frac{8.314}{28.97}\right)(293)\ln 5$$

$$= -135.3\text{kJ/kg}$$

Area 1–2′–*a*–*b* in Figure 1.3.8 represents the magnitude of the work required, per unit of mass of air flowing. An energy balance reduces to give $\dot{Q}_{cv}/\dot{m} = \dot{W}_{cv}/\dot{m} = -135.3$kJ/kg.

3. For an isentropic compression, $\dot{Q}_{cv}=0$ and an energy rate balance reduces to give $\dot{W}_{cv}/\dot{m} = -(h_{2s} - h_1)$, where 2*s* denotes the exit state. With Equation 1.3.29a and p_r data, $h_{2s}=464.8$ kJ/kg ($T_{2s}=463$ K). Then $\dot{W}_{cv}/\dot{m} = -(464.8 - 293.2) = -171.6$ kJ/kg. Area 1–2*s*–*a*–*b* in Figure 1.3.8 represents the magnitude of the work required, per unit of mass of air flowing.

Ideal Gas Mixtures

When applied to an ideal gas mixture, the additive pressure rule (Section 1.3, *p*–*v*–*T* Relations) is known as the *Dalton model*. According to this model, each gas in the mixture acts as if it exists separately at the volume and temperature of the mixture. Applying the ideal gas equation of state to the mixture as a whole and to each component *i*, $pV = n\bar{R}T$, $p_iV = n_i\bar{R}T$, where p_i, the *partial pressure* of component *i*, is the pressure that component *i* would exert if n_i moles occupied the full volume *V* at the temperature *T*. Forming a ratio, the partial pressure of component *i* is

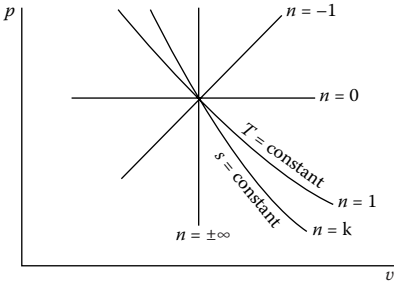
$$p_i = \frac{n_i}{n}p = y_i p \tag{1.3.30}$$

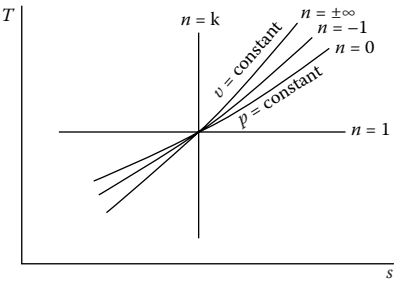
TABLE 1.3.7
Polytropic Processes: pv^n = Constant

General		Ideal Gas[a]	
$\frac{p_2}{p_1}=\left(\frac{v_1}{v_2}\right)^n$	(1)	$\frac{p_2}{p_1}=\left(\frac{v_1}{v_2}\right)^n=\left(\frac{T_2}{T_1}\right)^{n/(n-1)}$	(1′)
$n=0$: constant pressure $n=\pm\infty$: constant specific volume		$n=0$: constant pressure $n=\pm\infty$: constant specific volume $n=1$: constant temperature $n=k$: constant specific entropy when k is constant	
$n=1$		$n=1$	
$\int_1^2 p\,dv=p_1v_1\ln\frac{v_2}{v_1}$	(2)	$\int_1^2 p\,dv=RT\ln\frac{v_2}{v_1}$	(2′)
$-\int_1^2 v\,dp=-p_1v_1\ln\frac{p_2}{p_1}$	(3)	$-\int_1^2 v\,dp=-RT\ln\frac{p_2}{p_1}$	(3′)
$n\neq 1$		$n\neq 1$	
$\int_1^2 p\,dv=\frac{p_2v_2-p_1v_1}{1-n}=\frac{p_1v_1}{n-1}\left[1-\left(\frac{p_2}{p_1}\right)^{(n-1)/n}\right]$	(4)	$\int_1^2 p\,dv=\frac{R(T_2-T_1)}{1-n}=\frac{RT_1}{n-1}\left[1-\left(\frac{p_2}{p_1}\right)^{(n-1)/n}\right]$	(4′)
$-\int_1^2 v\,dp=\frac{n}{1-n}(p_2v_2-p_1v_1)=\frac{np_1v_1}{n-1}\left[1-\left(\frac{p_2}{p_1}\right)^{(n-1)/n}\right]$	(5)	$-\int_1^2 v\,dp=\frac{nR}{1-n}(T_2-T_1)=\frac{nRT_1}{n-1}\left[1-\left(\frac{p_2}{p_1}\right)^{(n-1)/n}\right]$	(5′)

Note: For polytropic processes of closed systems where volume change is the only work mode, Equations 2, 4, and 2′, 4′ are applicable with Equation 1.1.10 to evaluate the work. When each unit of mass passing through a one-inlet, one-exit control volume at steady state undergoes a polytropic process, Equations 3, 5, and 3′, 5′ are applicable with Equations 1.2.12a and b to evaluate the power. Also note that generally $-\int_1^2 v\,dp=n\int_1^2 p\,dv$.

[a]





where y_i is the mole fraction of component i. The sum of the partial pressures equals the mixture pressure.

The internal energy, enthalpy, and entropy of the mixture can be determined as the sum of the respective properties of the component gases, provided that the contribution from each gas is evaluated at the condition at which the gas exists in the mixture. On a *molar* basis,

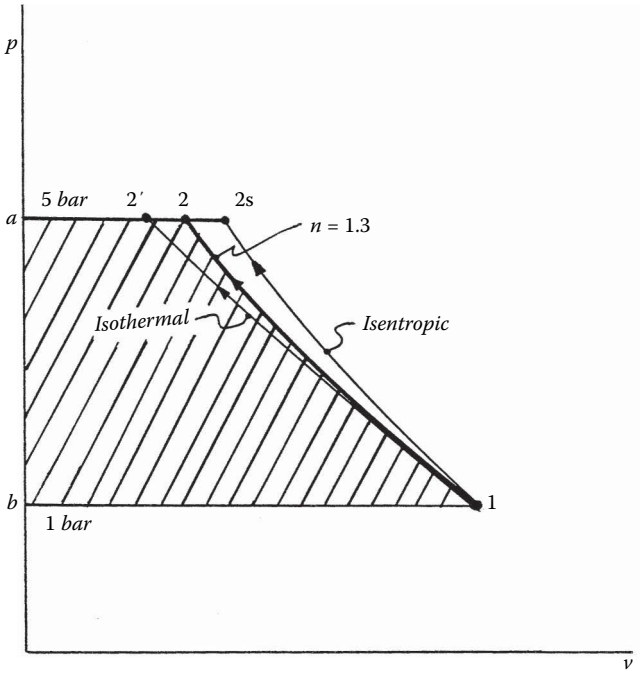


FIGURE 1.3.8 Internally reversible compression processes.

$$U = \sum_{i=1}^{j} n_i \overline{u}_i \text{ or } \overline{u} = \sum_{i=1}^{j} y_i \overline{u}_i \tag{1.3.31a}$$

$$H = \sum_{i=1}^{j} n_i \overline{h}_i \text{ or } \overline{h} = \sum_{i=1}^{j} y_i \overline{h}_i \tag{1.3.31b}$$

$$S = \sum_{i=1}^{j} n_i \overline{s}_i \text{ or } \overline{s} = \sum_{i=1}^{j} y_i \overline{s}_i \tag{1.3.31c}$$

The specific heats $\overline{c}_v$ and $\overline{c}_p$ for an ideal gas mixture in terms of the corresponding specific heats of the components are expressed similarly:

$$\overline{c}_v = \sum_{i=1}^{j} y_i \overline{c}_{vi} \tag{1.3.31d}$$

$$\overline{c}_p = \sum_{i=1}^{j} y_i \overline{c}_{pi} \tag{1.3.31e}$$

When working on a *mass* basis, expressions similar in form to Equations 1.3.31 can be written using *mass* and *mass fractions* in place of *moles* and *mole fractions*, respectively, and using u, h, s, c_p, and c_v in place of $\overline{u}$, $\overline{h}$, $\overline{s}$, $\overline{c}_p$, and $\overline{c}_v$, respectively.

The internal energy and enthalpy of an ideal gas depend only on temperature, and thus the $\overline{u}_i$ and $\overline{h}_i$ terms appearing in Equations 1.3.31 are evaluated at the temperature of the mixture. Since entropy depends on *two* independent properties, the $\overline{s}_i$ terms are evaluated either at the temperature

and the partial pressure p_i of component i, or at the temperature and volume of the mixture. In the former case,

$$S = \sum_{i=1}^{j} n_i \overline{s}_i \left(T, p_i\right)$$

$$= \sum_{i=1}^{j} n_i \overline{s}_i \left(T, x_i p\right) \tag{1.3.32}$$

Inserting the expressions for H and S given by Equations 1.3.31b and c into the Gibbs function, $G=H-TS$,

$$G = \sum_{i=1}^{j} n_i \overline{h}_i \left(T\right) - T \sum_{i=1}^{j} n_i \overline{s}_i \left(T, p_i\right)$$

$$= \sum_{i=1}^{j} n_i \overline{g}_i \left(T, p_i\right) \tag{1.3.33}$$

where the molar-specific Gibbs function of component i is $g_i(T, p_i)=h_i(T) - Ts_i(T, p_i)$. The Gibbs function of i can be expressed alternatively as

$$\overline{g}_i \left(T, p_i\right) = \overline{g}_i \left(T, p'\right) + \overline{R}T \ln\left(p_i / p'\right)$$

$$= \overline{g}_i \left(T, p'\right) + \overline{R}T \ln\left(x_i p / p'\right) \tag{1.3.34}$$

where p' is some specified pressure. Equation 1.3.34 is obtained by integrating Equation 1.3.2d at fixed temperature T from pressure p' to p_i.

Moist Air

An ideal gas mixture of particular interest for many practical applications is *moist air*. Moist air refers to a mixture of dry air and water vapor in which the dry air is treated as if it were a pure component. Ideal gas mixture principles usually apply to moist air. In particular, the *Dalton model* is applicable, and so the mixture pressure p is the sum of the partial pressures p_a and p_v of the dry air and water vapor, respectively.

Saturated air is a mixture of dry air and saturated water vapor. For saturated air, the partial pressure of the water vapor equals $p_{\text{sat}}(T)$, which is the saturation pressure of water corresponding to the dry-bulb (mixture) temperature T. The makeup of moist air can be described in terms of the *humidity ratio* (*specific humidity*) and the *relative humidity*. The bulb of a *wet-bulb thermometer* is covered with a wick saturated with liquid water, and the *wet-bulb* temperature of an air–water vapor mixture is the temperature indicated by such a thermometer exposed to the mixture.

When a sample of moist air is cooled at constant pressure, the temperature at which the sample becomes saturated is called the *dew point temperature*. Cooling below the dew point temperature results in the condensation of some of the water vapor initially present. When cooled to a final equilibrium state at a temperature below the dew point temperature, the original sample would consist of a gas phase of dry air and saturated water vapor in equilibrium with a liquid water phase.

Psychrometric charts are plotted with various moist air parameters, including the dry-bulb and wet-bulb temperatures, the humidity ratio, and the relative humidity, usually for a specified value of the mixture pressure such as 1 atm.

Generalized Charts for Enthalpy, Entropy, and Fugacity

The changes in enthalpy and entropy between two states can be determined in principle by correcting the respective property change determined using the ideal gas model. The corrections can be obtained, at least approximately, by inspection of the generalized enthalpy correction and entropy correction charts, Figures 1.3.9 and 1.3.10, respectively. Such data are also available in tabular form (see, e.g., Reid and Sherwood, 1966) and calculable using a generalized equation for the compressibility factor (Reynolds, 1979). Using the superscript * to identify ideal gas property values, the changes in specific enthalpy and specific entropy between states 1 and 2 are

$$\bar{h}_2 - \bar{h}_1 = \underline{\bar{h}_2^* - \bar{h}_1^*} - \underline{\bar{R}T_c\left[\left(\frac{\bar{h}^* - \bar{h}}{\bar{R}T_c}\right)_2 - \left(\frac{\bar{h}^* - \bar{h}}{\bar{R}T_c}\right)_1\right]} \tag{1.3.35a}$$

$$\bar{s}_2 - \bar{s}_1 = \underline{\bar{s}_2^* - \bar{s}_1^*} - \underline{\bar{R}\left[\left(\frac{\bar{s}^* - \bar{s}}{\bar{R}}\right)_2 - \left(\frac{\bar{s}^* - \bar{s}}{\bar{R}}\right)_1\right]} \tag{1.3.35b}$$

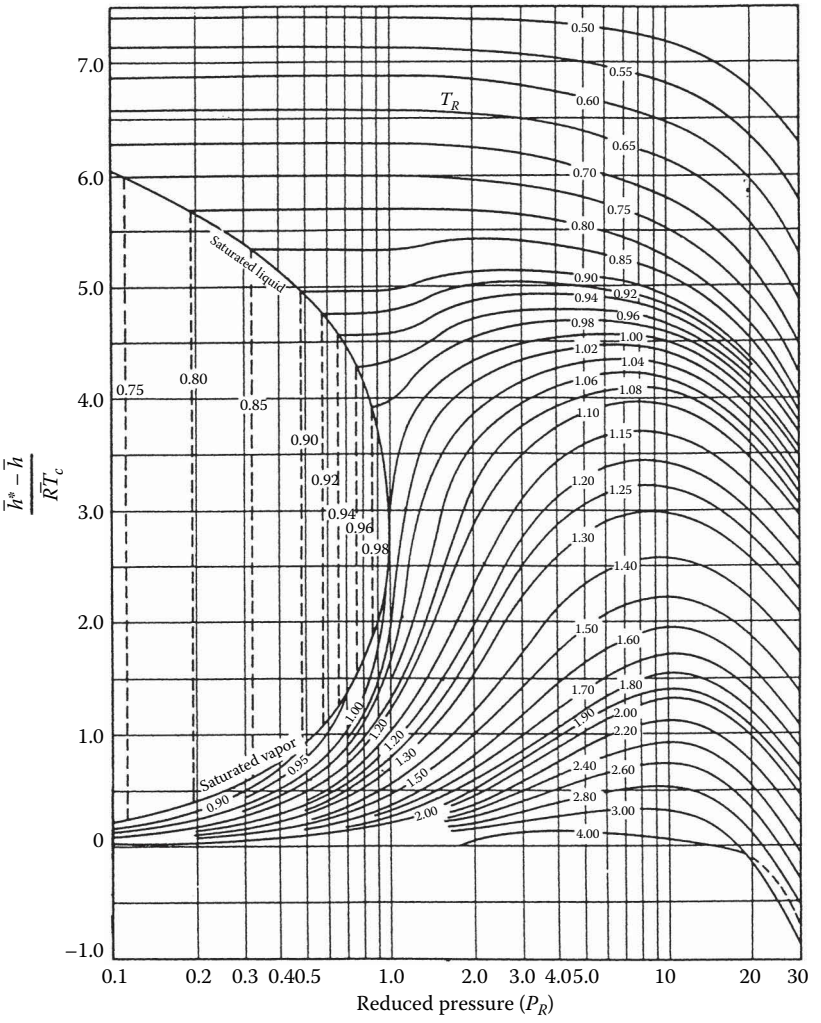

FIGURE 1.3.9 Generalized enthalpy correction chart. (Adapted from Van Wylen, G.J. and Sonntag, R.E., *Fundamentals of Classical Thermodynamics*, 3rd ed., English/SI., Wiley, New York, 1986.)

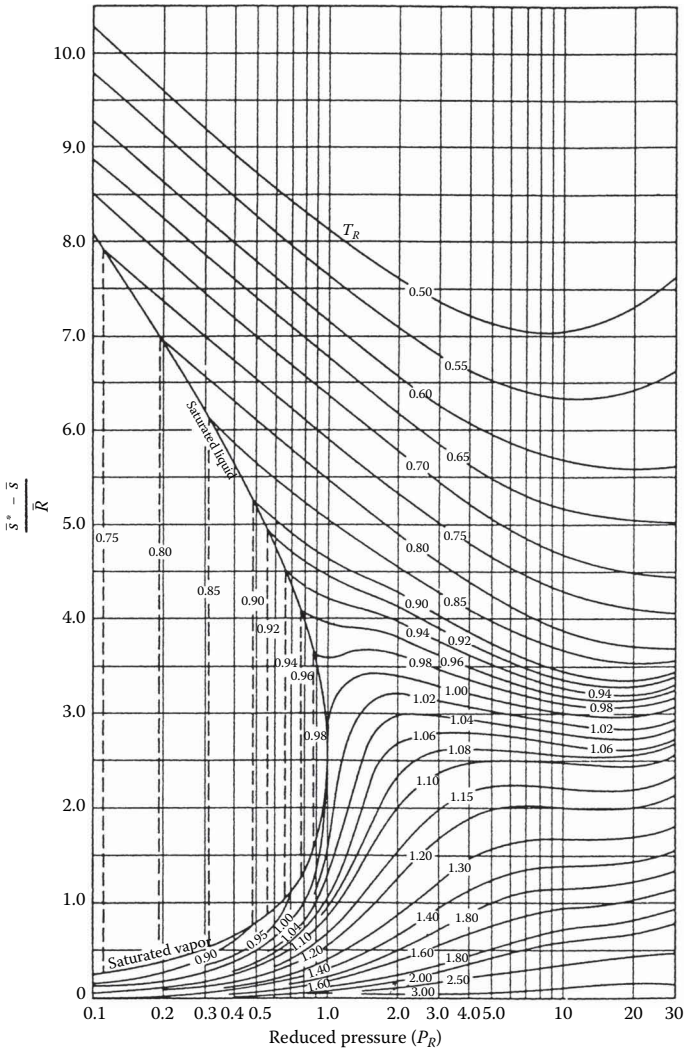

FIGURE 1.3.10 Generalized entropy correction chart. (Adapted from Van Wylen, G.J. and Sonntag, R.E., *Fundamentals of Classical Thermodynamics*, 3rd. ed., English/SI., Wiley, New York, 1986.)

The first underlined term on the right side of each expression represents the respective property change assuming ideal gas behavior. The second underlined term is the correction that must be applied to the ideal gas value to obtain the actual value. The quantities $\left(\overline{h}^* - \overline{h}\right)\Big/\overline{R}T_c$ and $\left(\overline{s}^* - \overline{s}\right)\Big/\overline{R}$ at state 1 would be read from the respective correction chart or table or calculated, using the reduced temperature T_{R1} and reduced pressure p_{R1} corresponding to the temperature T_1 and pressure p_1 at state 1, respectively. Similarly, $\left(\overline{h}^* - \overline{h}\right)\Big/\overline{R}T_c$ *and* $(\overline{s}^* - \overline{s})/\overline{R}$ at state 2 would be obtained using T_{R2} and p_{R2}. Mixture values for T_c and p_c determined by applying Kay's rule or some other mixture rule also can be used to enter the generalized enthalpy correction and entropy correction charts.

Figure 1.3.11 gives the *fugacity* coefficient, *f/p*, as a function of reduced pressure and reduced temperature. The fugacity *f* plays a similar role in determining the specific Gibbs function for a real gas as pressure plays for the ideal gas. To develop this, consider the variation of the specific Gibbs function with pressure at fixed temperature (from Table 1.3.1)

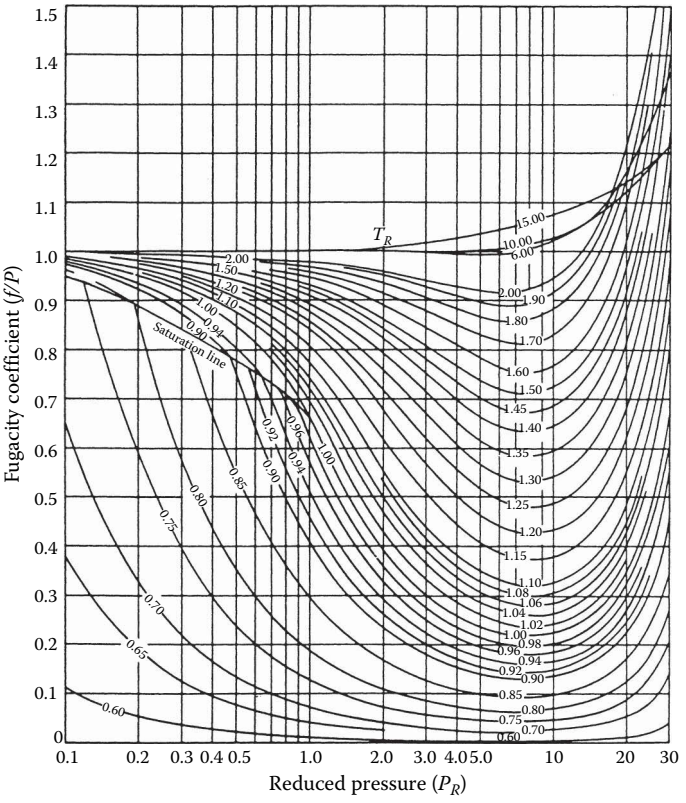

FIGURE 1.3.11 Generalized fugacity coefficient chart. (From Van Wylen, G.J. and Sonntag, R.E., *Fundamentals of Classical Thermodynamics*, 3rd ed., English/SI., Wiley, New York, 1986.)

$$\left(\frac{\partial g}{\partial p}\right)_T = v$$

For an ideal gas, integration at fixed temperature gives

$$g^* = RT \ln p + C(T)$$

where $C(T)$ is a function of integration. To evaluate g for a real gas, fugacity replaces pressure,

$$g = RT \ln f + C(T)$$

In terms of the fugacity coefficient, the departure of the real gas value from the ideal gas value at fixed temperature is then

$$g - g^* = RT \ln \frac{f}{p} \tag{1.3.36}$$

As pressure is reduced at fixed temperature, f/p tends to unity, and the specific Gibbs function is given by the ideal gas value.

Multicomponent Systems

In this section are presented some general aspects of the properties of multicomponent systems consisting of nonreacting mixtures. For a single-phase *multicomponent* system consisting of j

components, an extensive property X may be regarded as a function of temperature, pressure, and the number of moles of each component present in the mixture: $X=X(T, p, n_1, n_2,\ldots, n_j)$. Since X is mathematically *homogeneous of degree one* in the n's, the function is expressible as

$$X = \sum_{i=1}^{j} n_i \overline{X}_i \tag{1.3.37}$$

where the *partial molar property* $\overline{X}_i$ is by definition

$$\overline{X}_i = \left(\frac{\partial X}{\partial n_i} \right)_{T,p,n_l} \tag{1.3.38}$$

and the subscript n_l denotes that all n's except n_i are held fixed during differentiation. As $\overline{X}_i$ depends in general on temperature, pressure, and mixture composition: $\overline{X}_i\left(T, p, n_1, n_2, \ldots, n_j\right)$, the partial molal property $\overline{X}_i$ is an intensive property of the mixture and not simply a property of the ith component.

Selecting the extensive property X to be volume, internal energy, enthalpy, entropy, and the Gibbs function, respectively, gives

$$\begin{aligned} V &= \sum_{i=1}^{j} n_i \overline{V}_i, \quad U = \sum_{i=1}^{j} n_i \overline{U}_i \\ H &= \sum_{i=1}^{j} n_i \overline{H}_i, \quad S = \sum_{i=1}^{j} n_i \overline{S}_i \\ G &= \sum_{i=1}^{j} n_i \overline{G}_i \end{aligned} \tag{1.3.39}$$

where $\overline{V}_i$, $\overline{U}_i$, $\overline{H}_i$, $\overline{S}_i$, and $\overline{G}_i$ denote the respective partial molal properties.

When pure components, each initially at the same temperature and pressure, are mixed, the changes in volume, internal energy, enthalpy, and entropy on mixing are given by

$$\Delta V_{\text{mixing}} = \sum_{i=1}^{j} n_i \left(\overline{V}_i - \overline{v}_i \right) \tag{1.3.40a}$$

$$\Delta U_{\text{mixing}} = \sum_{i=1}^{j} n_i \left(\overline{U}_i - \overline{u}_i \right) \tag{1.3.40b}$$

$$\Delta H_{\text{mixing}} = \sum_{i=1}^{j} n_i \left(\overline{H}_i - \overline{h}_i \right) \tag{1.3.40c}$$

$$\Delta S_{\text{mixing}} = \sum_{i=1}^{j} n_i \left(\overline{S}_i - \overline{s}_i \right) \tag{1.3.40d}$$

where $\overline{v}_i$, $\overline{u}_i$, $\overline{h}_i$, and $\overline{s}_i$ denote the molar-specific volume, internal energy, enthalpy, and entropy of pure component i.

Chemical Potential

The partial molal Gibbs function of the *i*th component of a multicomponent system is the *chemical potential*, μ_i,

$$\mu_i = \overline{G}_i = \left(\frac{\partial G}{\partial n_i}\right)_{T,p,n_l} \tag{1.3.41}$$

Like temperature and pressure, the chemical potential, μ_i is an *intensive* property.

When written in terms of chemical potentials, Equation 1.3.37 for the Gibbs function reads

$$G = \sum_{i=1}^{j} n_i \mu_i \tag{1.3.42}$$

For a *single component system*, Equation 1.3.42 reduces to $G = n\mu$; that is, the chemical potential equals the molar Gibbs function. For an ideal gas mixture, comparison of Equations 1.3.33 and 1.3.42 suggests $\mu_i = \overline{g}_i(T, p_i)$; that is, the chemical potential of component *i* in an ideal gas mixture equals its Gibbs function per mole of gas *i* evaluated at the mixture temperature and the partial pressure of the *i*th gas of the mixture.

The chemical potential is a measure of the *escaping tendency* of a substance in a multiphase system: a substance tends to move from the phase having the higher chemical potential for that substance to the phase having a lower chemical potential. A necessary condition for *phase equilibrium is* that the chemical potential of each component has the same value in every phase.

The *Gibbs phase rule* gives the number *F* of independent intensive properties that may be arbitrarily specified to fix the intensive state of a system at equilibrium consisting of *N* nonreacting components present in *P* phases: $F = 2 + N - P$. *F* is called the *degrees of freedom* (or the *variance*). For water as a single component, for example, $N = 1$ and $F = 3 - P$.

- For a single phase, $P = 1$ and $F = 2$: Two intensive properties can be varied independently, say temperature *and* pressure, while maintaining a single phase.
- For two phases, $P = 2$ and $F = 1$: Only one intensive property can be varied independently if two phases are maintained—for example, temperature *or* pressure.
- For three phases, $P = 3$ and $F = 0$: There are no degrees of freedom; each intensive property of each phase is fixed. For a system consisting of ice, liquid water, and water vapor at equilibrium, there is a unique temperature: 0.01°C (32.02°F) and a unique pressure: 0.6113 kPa (0.006 atm).

The phase rule does not address the relative amounts that may be present in the various phases.

With $G = H - TS$ and $H = U + pV$, Equation 1.3.42 can be expressed as

$$U = TS - pV + \sum_{i=1}^{j} n_i \mu_i \tag{1.3.43}$$

from which can be derived

$$dU = T\,dS - p\,dV + \sum_{i=1}^{j} \mu_i\,dn_i \tag{1.3.44}$$

When the mixture composition is constant, Equation 1.3.44 reduces to Equation 1.3.1a.

Ideal Solution: The *Lewis–Randall rule* states that the fugacity $\overline{f}_i$ of each component *i* in an *ideal solution* is the product of its mole fraction and the fugacity of the pure component, f_i, at the same temperature, pressure, and state of aggregation (gas, liquid, or solid) as the mixture:

$$\overline{f}_i = y_i f_i \quad \text{(Lewis–Randall rule)} \tag{1.3.45}$$

The following characteristics are exhibited by an ideal solution: $\overline{V}_i = \overline{v}_i$, $\overline{U}_i = \overline{u}_i$, $\overline{H}_i = \overline{h}_i$. With these, Equations 1.3.40a, b, and c show that there is no change in volume, internal energy, or enthalpy on mixing pure components to form an ideal solution. The *adiabatic* mixing of different pure components would result in an increase in entropy, however, because such a process is irreversible.

The volume of an ideal solution is

$$V = \sum_{i=1}^{j} n_i \overline{v}_i = \sum_{i=1}^{j} V_i \quad \left(\text{ideal solution}\right) \tag{1.3.46}$$

where V_i is the volume that pure component i would occupy when at the temperature and pressure of the mixture. Comparing Equations 1.3.18a and 1.3.46, the *additive volume rule* is seen to be exact for ideal solutions. The internal energy and enthalpy of an ideal solution are

$$U = \sum_{i=1}^{j} n_i \overline{u}_i, \qquad H = \sum_{i=1}^{j} n_i \overline{h}_i \qquad \left(\text{ideal solution}\right) \tag{1.3.47}$$

where $\overline{u}_i$ and $\overline{h}_i$ denote, respectively, the molar internal energy and enthalpy of pure component i at the temperature and pressure of the mixture. Many gaseous mixtures at low to moderate pressures are adequately modeled by the Lewis-Randall rule. The ideal gas mixtures considered in Section 1.3, Ideal Gas Model, is an important special case. Some liquid solutions also can be modeled with the Lewis–Randall rule.

1.4 COMBUSTION

Michael J. Moran

The thermodynamic analysis of reactive systems is primarily an extension of principles presented in Sections 1.1 through 1.3. It is necessary, though, to modify the methods used to evaluate specific enthalpy and entropy.

Reaction Equations

In combustion reactions, rapid oxidation of combustible elements of the fuel results in energy release as combustion products are formed. The three major combustible chemical elements in most common fuels are carbon, hydrogen, and sulfur. Although sulfur is usually a relatively unimportant contributor to the energy released, it can be a significant cause of pollution and corrosion.

The emphasis in this section is on hydrocarbon fuels, which contain hydrogen, carbon, sulfur, and possibly other chemical substances. Hydrocarbon fuels may be liquids, gases, or solids such as coal. Liquid hydrocarbon fuels are commonly derived from crude oil through distillation and cracking processes. Examples are gasoline, diesel fuel, kerosene, and other types of fuel oils. The compositions of liquid fuels are commonly given in terms of mass fractions. For simplicity in combustion calculations, gasoline is often considered to be octane, C_8H_{18}, and diesel fuel is considered to be dodecane, $C_{12}H_{26}$. Gaseous hydrocarbon fuels are obtained from natural gas wells or are produced in certain chemical processes. Natural gas normally consists of several different hydrocarbons, with the major constituent being methane, CH_4. The compositions of gaseous fuels are commonly given in terms of mole fractions. Both gaseous and liquid hydrocarbon fuels can be synthesized from coal, oil shale, and tar sands. The composition of coal varies considerably with the location from which it is mined. For combustion calculations, the makeup of coal is usually expressed as an *ultimate analysis* giving the composition on a mass basis in terms of the relative amounts of chemical elements (carbon, sulfur, hydrogen, nitrogen, oxygen) and ash.

A fuel is said to have burned *completely* if all of the carbon present in the fuel is burned to carbon dioxide, all of the hydrogen is burned to water, and all of the sulfur is burned to sulfur dioxide. In practice, these conditions are usually not fulfilled and combustion is *incomplete*. The presence of carbon monoxide (CO) in the products indicates incomplete combustion. The products of combustion of *actual* combustion reactions and the relative amounts of the products can be determined with certainty only by experimental means. Among several devices for the experimental determination of the composition of products of combustion are the *Orsat analyzer, gas chromatograph, infrared analyzer*, and *flame ionization detector*. Data from these devices can be used to determine the makeup of the gaseous products of combustion. Analyses are frequently reported on a "dry" basis: Mole fractions are determined for all gaseous products as if no water vapor were present. Some experimental procedures give an analysis including the water vapor, however.

Since water is formed when hydrocarbon fuels are burned, the mole fraction of water vapor in the gaseous products of combustion can be significant. If the gaseous products of combustion are cooled at constant mixture pressure, the *dew point temperature* (Section 1.3, Ideal Gas Model) is reached when water vapor begins to condense. Corrosion of duct work, mufflers, and other metal parts can occur when water vapor in the combustion products condenses.

Oxygen is required in every combustion reaction. Pure oxygen is used only in special applications such as cutting and welding. In most combustion applications, air provides the needed oxygen. Idealizations are often used in combustion calculations involving air: (1) all components of air other than oxygen (O_2) *are* lumped with nitrogen (N_2). On a molar basis, air is then considered to be 21% oxygen and 79% nitrogen. With this idealization, the molar ratio of the nitrogen to the oxygen in combustion air is 3.76; (2) the water vapor present in air may be considered in writing the combustion equation or ignored. In the latter case, the combustion air is regarded as *dry*; (3) additional

simplicity results by regarding the nitrogen present in the combustion air as inert. However, if high-enough temperatures are attained, nitrogen can form compounds, often termed NO_X, such as nitric oxide and nitrogen dioxide. Even trace amounts of oxides of nitrogen appearing in the exhaust of internal combustion engines can be a source of air pollution.

The minimum amount of air that supplies sufficient oxygen for the complete combustion of all the combustible chemical elements is the *theoretical*, or *stoichiometric*, amount of air. In practice, the amount of air actually supplied may be greater than or less than the theoretical amount, depending on the application. The amount of air is commonly expressed as the *percent of theoretical air* or the *percent excess* (or *percent deficiency*) of air. The *air–fuel ratio* and its reciprocal *the fuel–air ratio*, each of which can be expressed on a mass or molar basis, are other ways that fuel–air mixtures are described. Another is the *equivalence ratio*: the ratio of the actual fuel–air ratio to the fuel–air ratio for complete combustion with the theoretical amount of air. The reactants form a *lean* mixture when the equivalence ratio is less than unity and a *rich* mixture when the ratio is greater than unity.

Example 1.4.1

Methane, CH_4, is burned with dry air. The molar analysis of the products on a dry basis is CO_2, 9.7%; CO, 0.5%; O_2, 2.95%; and N_2, 86.85%. Determine (1) the air–fuel ratio on both a molar and a mass basis, (2) the percent of theoretical air, (3) the equivalence ratio, and (4) the dew point temperature of the products, in °F, if the pressure is 1 atm.

***Solution*:**

1. The solution is conveniently conducted on the basis of 100 lbmol of dry products. The chemical equation then reads

$$a\mathrm{CH_4} + b(\mathrm{O_2} + 3.76\mathrm{N_2}) \rightarrow 9.7\mathrm{CO_2} + 0.5\mathrm{CO} + 2.95\mathrm{O_2} + 86.85\mathrm{N_2} + c\mathrm{H_2O},$$

   where N_2 is regarded as inert. Water is included in the products together with the assumed 100 lbmol of dry products. Balancing the carbon, hydrogen, and oxygen, the reaction equation is

$$10.2\mathrm{CH_4} + 23.1\left(\mathrm{O_2} + 3.76\mathrm{N_2}\right) \rightarrow 9.7\mathrm{CO_2} + 0.5\mathrm{CO} + 2.95\mathrm{O_2} + 86.85\mathrm{N_2} + 20.4\mathrm{H_2O}.$$

   The nitrogen also balances, as can be verified. This checks the accuracy of both the given product analysis and the calculations conducted to determine the unknown coefficients. Exact closure cannot be expected with measured data, however. On a molar basis, the air–fuel ratio is

$$\overline{\mathrm{AF}} = \frac{23.1(4.76)}{10.2} = 10.78 \frac{\text{lbmol (air)}}{\text{lbmol (fuel)}}.$$

   On a mass basis,

$$\mathrm{AF} = (10.78)\left(\frac{28.97}{16.04}\right) = 19.47 \frac{\text{lb (air)}}{\text{lb (fuel)}}.$$

2. The balanced chemical equation for the complete combustion of methane with the *theoretical* amount of air is

$$\mathrm{CH_4} + 2\left(\mathrm{O_2} + 3.76\mathrm{N_2}\right) \rightarrow \mathrm{CO_2} + 2\mathrm{H_2O} + 7.52\mathrm{N_2}.$$

The theoretical air–fuel ratio on a molar basis is

$$\left(\overline{AF}\right)_{theo} = \frac{2(4.76)}{1} = 9.52 \frac{\text{lbmol (air)}}{\text{lbmol (fuel)}}$$

The percent theoretical air is then

$$\% \text{ theoretical air} = \frac{\left(\overline{AF}\right)}{\left(\overline{AF}\right)_{theo}}$$

$$= \frac{10.78}{9.52} = 1.13(113\%).$$

3. Equivalence ratio $= (\overline{FA})/(\overline{FA})_{theo} = 9.52 / 10.78 = 0.88$. The reactants form a lean mixture.
4. To determine the dew point temperature requires the partial pressure p_v of the water vapor. The mole fraction of the water vapor is

$$y_v = \frac{20.4}{100 + 20.4} = 0.169.$$

Since $p = 1$ atm, $p_v = 0.169$ atm $= 2.48$ lbf/in.^{2}. With $p_{sat} = 2.48$ lbf/in.^{2}, the corresponding saturation temperature from the steam tables is 134°F. This is the dew point temperature.

Property Data for Reactive Systems

Tables of thermodynamic properties such as the steam tables provide values for the specific enthalpy and entropy relative to some arbitrary datum state where the enthalpy (or alternatively, the internal energy) and entropy are set to zero. When a chemical reaction occurs, however, reactants disappear and products are formed, and it is generally no longer possible to evaluate $\Delta\overline{h}$ and $\Delta\overline{s}$ so that these arbitrary datums cancel. Accordingly, special means are required to assign specific enthalpy and entropy for application to reacting systems.

Property data suited for the analysis of reactive systems are available from several sources. The encyclopedic *JANAF Thermochemical Tables* is commonly used. Data for a wide range of substances are retrievable from Knacke et al. (1991), which provides both tabular data and analytical expressions readily programmable for use with personal computers of the specific heat, enthalpy, entropy, and Gibbs function. Textbooks on engineering thermodynamics also provide selected data, as, for example, Moran et al. (2014).

Enthalpy of Formation

An enthalpy datum for reacting systems can be established by assigning arbitrarily a value of zero to the enthalpy of the *stable elements* at a *standard reference state* where the temperature is $T_{ref} = 298.15$ K (25°C) and the pressure is p_{ref}, which may be 1 bar or 1 atm depending on the data source. The term stable simply means that the particular element is chemically stable. For example, at the standard state, the stable forms of hydrogen, oxygen, and nitrogen are H_2, O_2, and N_2 and not the monatomic H, O, and N.

The molar enthalpy of a *compound* at the standard state equals its *enthalpy of formation*, symbolized here by $\overline{h}_f^\circ$. The enthalpy of formation is the energy released or absorbed when the compound is formed from its elements, the compound and elements all being at T_{ref} and p_{ref}. The enthalpy of formation may be determined by application of procedures from statistical thermodynamics using observed spectroscopic data. The enthalpy of formation also can be found in principle by measuring the heat transfer in a reaction in which the compound is formed from the elements. In this chapter, the superscript ° is used to denote p_{ref}. For the case of the enthalpy of formation, the reference temperature T_{ref} is also intended by this symbol. Table 1.4.1 gives the values of the enthalpy of formation of various substances at 298 K and 1 atm.

TABLE 1.4.1
Enthalpy of Formation, Gibbs Function of Formation, and Absolute Entropy of Various Substances at 298 K and 1 atm

Substance	Formula	$\bar{h}_f^\circ$ (kJ/kmol)	$\bar{g}_f^\circ$ (kJ/kmol)	$\bar{s}^\circ$ (kJ/kmol · K)
Carbon	C(s)	0	0	5.74
Hydrogen	H_2(g)	0	0	130.57
Nitrogen	N_2(g)	0	0	191.50
Oxygen	O_2(g)	0	0	205.03
Carbon monoxide	CO(g)	–110,530	–137,150	197.54
Carbon dioxide	CO_2(g)	–393,520	–394,380	213.69
Water	H_2O(g)	–241,820	–228,590	188.72
	H_2O(l)	–285,830	–237,180	69.95
Hydrogen peroxide	H_2O_2(g)	–136,310	–105,600	232.63
Ammonia	NH_3(g)	–46,190	–16,590	192.33

	CH_3OH(l)	–238,810	–166,290	126.80
Ethyl alcohol	C_2H_5OH(g)	–235,310	–168,570	282.59
	C_2H_5OH(l)	–277,690	174,890	160.70

Source: Wark, K., *Thermodynamics*, 4th ed., McGraw-Hill, New York, 1983 as based on JANAF Thermochemical Tables, NSRDS-NBS-37, 1971; *Selected Values of Chemical Thermodynamic Properties*, NBS Tech. Note 270-3, 1968; and *API Research Project 44*, Carnegie Press, 1953.

The molar enthalpy of a substance at a state other than the standard state is found by adding the molar enthalpy change $\Delta\bar{h}$ between the standard state and the state of interest to the molar enthalpy of formation:

$$\bar{h}(T,p) = \bar{h}_f^\circ + \left[\bar{h}(T,p) - \bar{h}\left(T_{ref}, p_{ref}\right)\right] = \bar{h}_f^\circ + \Delta\bar{h}. \tag{1.4.1}$$

That is, the enthalpy of a substance is composed of $\bar{h}_f^\circ$, associated with the formation of the substance from its elements, and $\Delta\bar{h}$, associated with a change of state at constant composition. An arbitrarily chosen datum can be used to determine $\Delta\bar{h}$, since it is a *difference* at constant composition. Accordingly, $\Delta\bar{h}$ can be evaluated from sources such as the steam tables and the ideal gas tables.

The *enthalpy of combustion*, $\bar{h}_{RP}$, is the difference between the enthalpy of the products and the enthalpy of the reactants, each on a per-mole-of-fuel basis, when complete combustion occurs and both reactants and products are at the same temperature and pressure. For hydrocarbon fuels, the

enthalpy of combustion is negative in value since chemical internal energy is liberated in the reaction. The *heating value* of a fuel is a positive number equal to the magnitude of the enthalpy of combustion. Two heating values are recognized: the *higher* heating value and the *lower* heating value. The higher heating value is obtained when all the water formed by combustion is a liquid; the lower heating value is obtained when all the water formed by combustion is a vapor. The higher heating value exceeds the lower heating value by the energy that would be required to vaporize the liquid water formed at the specified temperature. Heating values are typically reported at a temperature of 25°C (77°F) and a pressure of 1 bar (or 1 atm). These values also depend on whether the fuel is a liquid or a gas. A sampling is provided on a unit mass-of-fuel basis in Table 1.4.2.

In the absence of work $\dot{W}_{cv}$ and appreciable kinetic and potential energy effects, the energy liberated on combustion is transferred from a reactor at steady state in two ways: the energy accompanying the exiting combustion products and by heat transfer. The temperature that would be achieved by the products in the limit of adiabatic operation is the *adiabatic flame* or *adiabatic combustion* temperature.

For a specified fuel and specified temperature and pressure of the reactants, the *maximum* adiabatic flame temperature is realized for complete combustion with the theoretical amount of air. Example 1.4.2 provides an illustration. The measured value of the temperature of the combustion products may be several hundred degrees below the calculated maximum adiabatic flame temperature, however, for several reasons including the following: (1) heat loss can be reduced but not eliminated; (2) once adequate oxygen has been provided to permit complete combustion, bringing in more air dilutes the combustion products, lowering the temperature; (3) incomplete combustion tends to reduce the temperature of the products, and combustion is seldom complete; and (4) as result of the high temperatures achieved, some of the combustion products may dissociate. Endothermic dissociation reactions also lower the product temperature.

Absolute Entropy

A common datum for assigning entropy values to substances involved in chemical reactions is realized through the *third law* of thermodynamics, which is based on experimental observations obtained primarily from studies of chemical reactions at low temperatures and specific heat measurements at temperatures approaching absolute zero. The third law states that the entropy of a pure crystalline substance is zero at the absolute zero of temperature, 0 K or 0°R. Substances not having a pure crystalline structure have a nonzero value of entropy at absolute zero.

TABLE 1.4.2
Heating Values in kJ/kg of Selected Hydrocarbons at 25°C

		Higher Value[a]		Lower Value[b]	
Hydrocarbon	**Formula**	**Liquid Fuel**	**Gas. Fuel**	**Liquid Fuel**	**Gas. Fuel**
Methane	CH_4	—	55,496	—	50,010
Ethane	C_2H_6	—	51,875	—	47,484
Propane	C_3H_8	49,973	50,343	45,982	46,352
n-Butane	C_4H_{10}	49,130	49,500	45,344	45,714
n-Octane	C_8H_{18}	47,893	48,256	44,425	44,788
n-Dodecane	$C_{12}H_{26}$	47,470	47,828	44,109	44,467
Methanol	CH_3OH	22,657	23,840	19,910	21,093
Ethanol	C_2H_5OH	29,676	30,596	26,811	27,731

[a] H_2O liquid in the products.
[b] H_2O vapor in the products.

The third law provides a datum relative to which the entropy of each substance participating in a reaction can be evaluated. The entropy relative to this datum is called the *absolute* entropy. The change in entropy of a substance between absolute zero and any given state can be determined from measurements of energy transfers and specific heat data or from procedures based on statistical thermodynamics and observed molecular data. Tables 1.4.1, A.2, and A.8 provide absolute entropy data for various substances. In these tables, $p_{\text{ref}} = 1$ atm.

When the absolute entropy is known at pressure p_{ref} and temperature T, the absolute entropy at the same temperature and *any* pressure p can be found from

$$\overline{s}(T, p) = \overline{s}(T, p_{\text{ref}}) + \left[\overline{s}(T, p) - \overline{s}(T, p_{\text{ref}})\right]. \tag{1.4.2}$$

For an ideal gas, the second term on the right side of Equation 1.4.2 can be evaluated by using Equation 1.3.28, giving

$$\overline{s}(T, p) = \overline{s}^{\circ}(T) - \overline{R} \ln \frac{p}{p_{\text{ref}}} \quad \text{(ideal gas)}. \tag{1.4.3}$$

In this expression, $\overline{s}^{\circ}(T)$ denotes the absolute entropy at temperature T and pressure p_{ref}.

The entropy of the ith component of an *ideal gas mixture* is evaluated at the mixture temperature T and the *partial* pressure p_i : $\overline{s}_i(T, p_i)$. For the ith component, Equation 1.4.3 takes the form

$$\begin{aligned} \overline{s}_i(T, p_i) &= \overline{s}_i^{\circ}(T) - \overline{R} \ln \frac{p_i}{p_{\text{ref}}} \\ &= \overline{s}_i^{\circ}(T) - \overline{R} \ln \frac{y_i p}{p_{\text{ref}}} \quad \text{(ideal gas)}, \end{aligned} \tag{1.4.4}$$

where $\overline{s}_i^{\circ}(T)$ is the absolute entropy of component i at temperature T and p_{ref}.

Example 1.4.2

Liquid octane at 25°C, 1 atm enters a well-insulated reactor and reacts with dry air entering at the same temperature and pressure. For steady-state operation and negligible effects of kinetic and potential energy, (1) determine the temperature of the combustion products for complete combustion with the theoretical amount of air, and (2) the rates of entropy generation and exergy destruction, each per kmol of fuel.

***Solution*:** For combustion of liquid octane with the theoretical amount of air, the chemical equation is

$$C_8H_{18}(\text{l}) + 12.5O_2 + 47N_2 \rightarrow 8CO_2 + 9H_2O(\text{g}) + 47N_2.$$

1. At steady state, the control volume energy rate balance reduces to read

$$0 = \frac{\dot{Q}_{cv}}{\dot{n}_F}^{0} - \frac{\dot{W}_{cv}}{\dot{n}_F}^{0} + \sum_{R} n_i \left(\overline{h}_f^{\circ} + \Delta\overline{h}\right)_i - \sum_{P} n_e \left(\overline{h}_f^{\circ} + \Delta\overline{h}\right)_e,$$

where R denotes reactants, P denotes products, and the symbols for enthalpy have the same significance as in Equation 1.4.1. Since the reactants enter at 25°C, the corresponding $(\Delta\overline{h})_i$ terms vanish, and the energy rate equation becomes

$$\sum_{P} n_e \left(\Delta\overline{h}\right)_e = \sum_{R} n_i \overline{h}_{fi}^{\circ} - \sum_{P} n_e \overline{h}_{fe}^{\circ}.$$

Introducing coefficients from the reaction equation, this takes the form

$$8\left(\Delta\overline{h}\right)_{CO_2} + 9\left(\Delta\overline{h}\right)_{H_2O(g)} + 47\left(\Delta\overline{h}\right)_{N_2} = \left[\left(\overline{h}_f^\circ\right)_{C_8H_{18}(l)} + 12.5\left(\overline{h}_f^\circ\right)_{O_2} + 47\left(\overline{h}_f^\circ\right)_{N_2}\right] - \left[8\left(\overline{h}_f^\circ\right)_{CO_2} + 9\left(\overline{h}_f^\circ\right)_{H_2O(g)} + 47\left(\overline{h}_f^\circ\right)_{N_2}\right].$$

Using data from Table 1.4.1 to evaluate the right side,

$$8\left(\Delta\overline{h}\right)_{CO_2} + 9\left(\Delta\overline{h}\right)_{H_2O(g)} + 47\left(\Delta\overline{h}\right)_{N_2} = 5{,}074{,}630 \text{ kJ/kmol (fuel)}.$$

Each $\Delta\overline{h}$ term on the left side of this equation depends on the temperature of the products, T_p, which can be solved for iteratively as $T_p = 2395$ K.

2. The entropy rate balance on a per-mole-of-fuel basis takes the form

$$0 = \sum_j \frac{\dot{Q}_j}{\dot{n}_F}\cancel{\frac{T_j}{T_j}}^{0} + \overline{s}_F + \left(12.5\overline{s}_{O_2} + 47\overline{s}_{N_2}\right) - \left(8\overline{s}_{CO_2} + 9\overline{s}_{H_2O(g)} + 47\overline{s}_{N_2}\right) + \frac{\dot{S}_{gen}}{\dot{n}_F}$$

or on rearrangement,

$$\frac{\dot{S}_{gen}}{\dot{n}_F} = \left(8\overline{s}_{CO_2} + 9\overline{s}_{H_2O(g)} + 47\overline{s}_{N_2}\right) - \overline{s}_F - \left(12.5\overline{s}_{O_2} + 47\overline{s}_{N_2}\right).$$

The absolute entropy of liquid octane from Table 1.4.1 is 360.79 kJ/kmol·K. The oxygen and nitrogen in the combustion air enter the reactor as components of an ideal gas mixture at T_{ref}, p_{ref}, With Equation 1.4.4, where $p = p_{ref}$, and absolute entropy data from Table 1.4.1,

$$\begin{aligned}\overline{s}_{O_2} &= \overline{s}_{O_2}^\circ\left(T_{ref}\right) - \overline{R}\ln y_{O_2}\\ &= 205.03 - 8.314\ln 0.21 = 218.01 \text{kJ/kmol}\cdot\text{K},\\ \overline{s}_{N_2} &= \overline{s}_{N_2}^\circ\left(T_{ref}\right) - \overline{R}\ln y_{N_2}\\ &= 191.5 - 8.314\ln 0.79 = 193.46 \text{kJ/kmol}\cdot\text{K}.\end{aligned}$$

The product gas exits as a gas mixture at 1 atm, 2395 K with the following composition: $y_{CO_2} = 8/64 = 0.125$, $y_{H_2O(g)} = 9/64 = 0.1406$, and $y_{N_2} = 47/64 = 0.7344$. With Equation 1.4.4, where $p = p_{ref}$, *and* absolute entropy data at 2395 K from Table A-23 of Moran et al. (2014),

$$\overline{s}_{CO_2} = 320.173 - 8.314\ln(0.125) = 337.46 \text{kJ/kmol}\cdot\text{K},$$

$$\overline{s}_{H_2O} = 273.986 - 8.314\ln(0.1406) = 290.30 \text{kJ/kmol}\cdot\text{K},$$

$$\overline{s}_{N_2} = 258.503 - 8.314\ln(0.7344) = 261.07 \text{kJ/kmol}\cdot\text{K}.$$

Inserting values, the rate of entropy generation is

$$\begin{aligned}\frac{\dot{S}_{gen}}{\dot{n}_F} &= 8(337.46) + 9(290.30) + 47(261.07) - 360.79 - 12.5(218.01) - 47(193.46)\\ &= 5404 \text{kJ/kmol}\cdot\text{K}.\end{aligned}$$

Using Equation 1.5.3 and assuming $T_0 = 298$ K, the rate of energy destruction is $\dot{E}_D/\dot{n}_F = 1.61\times10^6$ kJ/kmol.

Gibbs Function of Formation

Paralleling the approach used for enthalpy, a value of zero is assigned to the Gibbs function of each stable element at the standard state. The *Gibbs function of formation* of a compound equals the change in the Gibbs function for the reaction in which the compound is formed from its elements. Table 1.4.1 provides Gibbs function of formation data of various substances at 298 K and 1 atm.

The Gibbs function at a state other than the standard state is found by adding to the Gibbs function of formation the change in the specific Gibbs function $\Delta\overline{g}$ between the standard state and the state of interest:

$$\overline{g}(T,p) = \overline{g}_f^\circ + \left[\overline{g}(T,p) - \overline{g}\left(T_{\text{ref}}, p_{\text{ref}}\right)\right] = \overline{g}_f^\circ + \Delta\overline{g}, \tag{1.4.5a}$$

where

$$\Delta\overline{g} = \left[\overline{h}(T,p) - \overline{h}\left(T_{\text{ref}}, p_{\text{ref}}\right)\right] - \left[T\overline{s}(T,p) - T_{\text{ref}}\overline{s}\left(T_{\text{ref}}, p_{\text{ref}}\right)\right]. \tag{1.4.5b}$$

The Gibbs function of component i in an ideal gas mixture is evaluated at the partial pressure of component i and the mixture temperature.

As an application, the maximum theoretical work that can be developed, per mole of fuel consumed, is evaluated for the control volume of Figure 1.4.1, where the fuel and oxygen each enter in separate streams and carbon dioxide and water each exit separately. All entering and exiting streams are at the same temperature T and pressure p. The reaction is complete:

$$C_aH_b + \left(a + \frac{b}{4}\right)O_2 \rightarrow aCO_2 + \frac{b}{2}H_2O.$$

This control volume is similar to idealized devices such as a reversible fuel *cell* or a *van't Hoff equilibrium box*.

For steady-state operation, the energy rate balance reduces to give

$$\frac{\dot{W}_{cv}}{\dot{n}_F} = \frac{\dot{Q}_{cv}}{\dot{n}_F} + \overline{h}_F + \left(a + \frac{b}{4}\right)\overline{h}_{O_2} - a\overline{h}_{CO_2} - \frac{b}{2}\overline{h}_{H_2O},$$

where $\dot{n}_F$ denotes the molar flow rate of the fuel. Kinetic and potential energy effects are regarded as negligible. If heat transfer occurs only at the temperature T, an entropy balance for the control volume takes the form

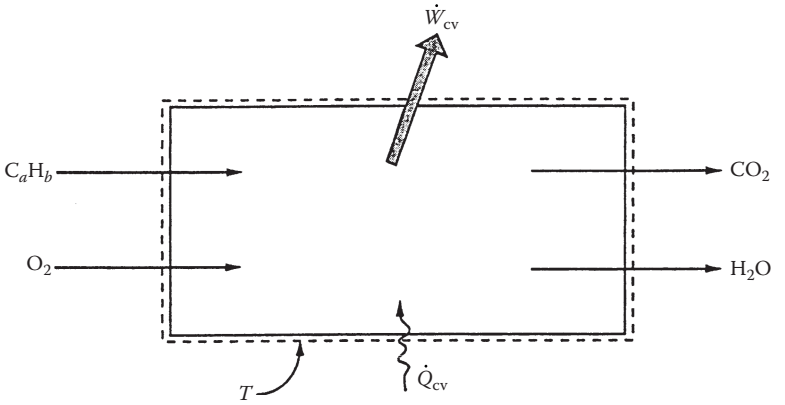

FIGURE 1.4.1 Device for evaluating maximum work.

$$0 = \frac{\dot{Q}_{cv}/\dot{n}_F}{T} + \bar{s}_F + \left(a + \frac{b}{4}\right)\bar{s}_{O_2} - a\bar{s}_{CO_2} - \frac{b}{2}\bar{s}_{H_2O} + \frac{\dot{S}_{gen}}{\dot{n}_F}.$$

Eliminating the heat transfer term from these expressions, an expression for the maximum theoretical value of the work developed per mole of fuel is obtained when the entropy generation term is set to zero:

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{\text{int rev}} = \left[\bar{h}_F + \left(a + \frac{b}{4}\right)\bar{h}_{O_2} - a\bar{h}_{CO_2} - \frac{b}{2}\bar{h}_{H_2O}\right](T,p) - T\left[\bar{s}_F + \left(a + \frac{b}{4}\right)\bar{s}_{O_2} - a\bar{s}_{CO_2} - \frac{b}{2}\bar{s}_{H_2O}\right](T,p).$$

This can be written alternatively in terms of the enthalpy of combustion as

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{\text{int rev}} = -\bar{h}_{RP}(T,p) - T\left[\bar{s}_F + \left(a + \frac{b}{4}\right)\bar{s}_{O_2} - a\bar{s}_{CO_2} - \frac{b}{2}\bar{s}_{H_2O}\right](T,p) \tag{1.4.6a}$$

or in terms of Gibbs functions as

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{\text{int rev}} = \left[\bar{g}_F + \left(a + \frac{b}{4}\right)\bar{g}_{O_2} - a\bar{g}_{CO_2} - \frac{b}{2}\bar{g}_{H_2O}\right](T,p). \tag{1.4.6b}$$

Equation 1.4.6b is used in the solution to Example 1.4.3.

Example 1.4.3

Hydrogen (H_2) and oxygen (O_2), each at 25°C, 1 atm, enter a fuel cell operating at steady state, and liquid water exits at the same temperature and pressure. The hydrogen flow rate is 2×10^{-4} kmol/s and the fuel cell operates isothermally at 25°C. Determine the maximum theoretical power the cell can develop, in kW.

***Solution*:** The overall cell reaction is $H_2 + 1/2\ O_2 \rightarrow H_2O(\ell)$, and Equations 1.4.6 are applicable. Selecting Equation 1.4.6b, and using Gibbs function data from Table 1.4.1,

$$\left(\frac{\dot{W}_{cv}}{\dot{n}_F}\right)_{\text{int rev}} = \left(\bar{g}_{H_2} + \frac{1}{2}\bar{g}_{O_2} - \bar{g}_{H_2O(l)}\right)(25°C, 1\text{atm})$$

$$= 0 + \frac{1}{2}(0) - (-237{,}180) = 237{,}180\ \text{kJ/kmol}.$$

Then,

$$\left(\dot{W}_{cv}\right)_{\text{int rev}} = \left(237{,}180\ \text{kJ/kmol}\right)\left(2\times10^{-4}\ \text{kmol/s}\right)\left(\frac{\text{kW}}{1\ \text{kJ/s}}\right) = 47.4\ \text{kW}.$$

Reaction Equilibrium

Let the objective be to determine the equilibrium composition of a system consisting of five gases A, B, C, D, and E, at a temperature T and pressure p, subject to a chemical reaction of the form

$$\nu_A A + \nu_B B \leftrightarrow \nu_C C + \nu_D D,$$

where the v's are stoichiometric coefficients. Component E is assumed to be inert and thus does not appear in the reaction equation. The equation suggests that at equilibrium the tendency of A and B to form C and D is just balanced by the tendency of C and D to form A and B.

At equilibrium, the temperature and pressure would be uniform throughout the system. Additionally, the *equation of reaction equilibrium* must be satisfied:

$$v_A\mu_A + v_B\mu_B = v_C\mu_C + v_D\mu_D, \tag{1.4.7a}$$

where the μ's are the chemical potentials (Section 1.3, Multicomponent Systems) of A, B, C, and D in the equilibrium mixture. In principle, the composition that would be present at equilibrium for a given temperature and pressure can be determined by solving this equation.

For ideal gas mixtures, the solution procedure is simplified by using the *equilibrium constant* $K(T)$ and the following equation:

$$\begin{aligned} K(T) &= \frac{y_C^{v_C} y_D^{v_D}}{y_A^{v_A} y_B^{v_B}} \left(\frac{p}{p_{ref}}\right)^{v_C+v_D-v_A-v_B} \\ &= \frac{n_C^{v_C} n_D^{v_D}}{n_A^{v_A} n_B^{v_B}} \left(\frac{p/p_{ref}}{n}\right)^{v_C+v_D-v_A-v_B}, \end{aligned} \tag{1.4.7b}$$

where y_A, y_B, y_C, and y_D denote the mole fractions of A, B, C, and D in the equilibrium mixture and $n=n_A+n_B+n_C+n_D+n_E$, where the n's denote the molar amounts of the gases in the mixture. Tabulations of $K(T)$ for each of several reactions of the form Equation 1.4.7a are provided in Table 1.4.3. An application of Equation 1.4.7b is provided in Example 1.4.4.

Example 1.4.4

One kmol of CO reacts with the theoretical amount of dry air to form an equilibrium mixture of CO_2, CO, O_2, and N_2 at 2500 K, 1 atm. Determine the amount of CO in the equilibrium mixture, in kmol.

***Solution*:** The reaction of CO with the theoretical amount of dry air to form CO_2, CO, O_2, and N_2 is

$$CO + \frac{1}{2}O_2 + 1.88N_2 \rightarrow zCO + \frac{z}{2}O_2 + (1-z)CO_2 + 1.88N_2,$$

where z is the amount of CO, in kmol, present in the equilibrium mixture. The total number of moles n is

$$n = z + \frac{z}{2} + (1-z) + 1.88 = \frac{5.76+z}{2}.$$

At equilibrium $CO_2 \leftrightarrow CO + 1/2O_2$; and Equation 1.4.7b takes the form

$$K = \frac{z\left(z/2\right)^{1/2}}{1-z}\left[\frac{p/p_{ref}}{(5.76+z)/2}\right]^{1/2},$$

where $p/p_{ref}=1$. At 2500 K, Table 1.4.3 gives $K=0.0363$. Solving iteratively, $z=0.175$.

1.5 EXERGY ANALYSIS

Michael J. Moran

The method of *exergy analysis* presented in this section enables the location, cause, and true magnitude of energy resource waste and loss to be determined. Such information can be used in the design of new energy-efficient systems and for improving the performance of existing systems. Exergy analysis also provides insights that elude a purely first-law approach. For example, on the basis of first-law reasoning alone, the condenser of a power plant may be mistakenly identified as the component primarily responsible for the plant's seemingly low overall performance. An exergy analysis correctly reveals not only that the condenser loss is relatively unimportant (see the last two rows of the Rankine cycle values of Table 1.6.2), but also that the steam generator is the principal site of thermodynamic inefficiency owing to combustion and heat-transfer irreversibilities within it.

When exergy concepts are combined with principles of engineering economy, the result is known as *thermoeconomics* or *exergoeconomics*. Thermoeconomics allows the real cost sources at the component level to be identified: capital investment costs, operating and maintenance costs, and the costs associated with the destruction and loss of exergy. Optimization of thermal systems can be achieved by a careful consideration of such cost sources. From this perspective, thermoeconomics is *exergy-aided cost minimization*.

Discussions of exergy analysis and thermoeconomics are provided by Bejan et al. (1996), Moran (1989), and Moran et al. (2014). The present section provides an introduction.

Defining Exergy

An opportunity for doing work exists whenever two systems at different states are placed in communication because, in principle, work can be developed as the two are allowed to come into equilibrium. When one of the two systems is a suitably idealized system called an *environment* and the other is some system of interest, *exergy* is the maximum theoretical useful work (shaft work or electrical work) obtainable as the systems interact to equilibrium, heat transfer occurring with the environment only. (Alternatively, exergy is the minimum theoretical useful work required to form a quantity of matter from substances present in the environment and to bring the matter to a specified state.) Exergy is a measure of the *departure* of the state of the system from that of the environment, and is therefore an attribute of the system and environment together. Once the environment is specified, however, a value can be assigned to exergy in terms of property values for the system only, so exergy can be regarded as an extensive property of the system.

Exergy can be destroyed and generally is not conserved. A limiting case is when exergy would be completely destroyed, as would occur if a system were to come into equilibrium with the environment *spontaneously* with no provision to obtain work. The capability to develop work that existed initially would be completely wasted in the spontaneous process. Moreover, since no work needs to be done to effect such a spontaneous change, the value of exergy can never be negative.

Environment

Models with various levels of specificity are employed for describing the environment used to evaluate exergy. Models of the environment typically refer to some portion of a system's surroundings, the intensive properties of each phase of which are uniform and do not change significantly as a result of any process under consideration. The environment is regarded as composed of common substances existing in abundance within the Earth's atmosphere, oceans, and crust. The substances are in their stable forms as they exist naturally, and there is no possibility of developing work from interactions—physical or chemical—between parts of the environment. Although the intensive properties of the environment are assumed to be unchanging, the extensive properties can change as a result of interactions with other systems. Kinetic and potential energies are

evaluated relative to coordinates in the environment, all parts of which are considered to be at rest with respect to one another.

For computational ease, the temperature T_0 and pressure p_0 of the environment are often taken as standard-state values, such as 1 atm and 25°C (77°F). However, these properties may be specified differently depending on the application. T_0 and p_0 might be taken as the average ambient temperature and pressure, respectively, for the location at which the system under consideration operates. Or, if the system uses atmospheric air, T_0 might be specified as the average air temperature. If both air and water from the natural surroundings are used, T_0 would be specified as the lower of the average temperatures for air and water.

Dead States

When a system is in equilibrium with the environment, the state of the system is called the *dead state*. At the dead state, the conditions of mechanical, thermal, and chemical equilibrium between the system and the environment are satisfied: the pressure, temperature, and chemical potentials of the system equal those of the environment, respectively. In addition, the system has no motion or elevation relative to coordinates in the environment. Under these conditions, there is no possibility of a spontaneous change within the system or the environment, nor can there be an interaction between them. The value of exergy is zero.

Another type of equilibrium between the system and environment can be identified. This is a restricted form of equilibrium where only the conditions of mechanical and thermal equilibrium must be satisfied. This state of the system is called the *restricted dead state*. At the restricted dead state, the fixed quantity of matter under consideration is imagined to be sealed in an envelope impervious to mass flow, at zero velocity and elevation relative to coordinates in the environment, and at the temperature T_0 and pressure p_0.

Exergy Balances

Exergy can be transferred by three means: exergy transfer associated with work, exergy transfer associated with heat transfer, and exergy transfer associated with the matter entering and exiting a control volume. All such exergy transfers are evaluated relative to the environment used to define exergy. Exergy is also destroyed by irreversibilities within the system or control volume.

Exergy balances can be written in various forms, depending on whether a closed system or control volume is under consideration and whether steady-state or transient operation is of interest. Owing to its importance for a wide range of applications, an exergy rate balance for control volumes at steady state is presented next.

Control Volume Exergy Rate Balance

At steady state, the control volume exergy rate balance takes the form

$$0 = \underbrace{\sum_j \dot{E}_{q\cdot j} - \dot{W}_{\mathrm{cv}} + \sum_i \dot{E}_i - \sum_e \dot{E}_e}_{\text{rates of exergy transfer}} - \underbrace{\dot{E}_{\mathrm{D}}}_{\text{rates of exergy destruction}} \tag{1.5.1a}$$

or

$$0 = \sum_j \left(1 - \frac{T_0}{T_j}\right)\dot{Q}_j - \dot{W}_{\mathrm{cv}} + \sum_i \dot{m}_i e_i - \sum_e \dot{m}_e e_e - \dot{E}_{\mathrm{D}}\,. \tag{1.5.1b}$$

$\dot{W}_{cv}$ has the same significance as in Equation 1.2.4: the work rate excluding the flow work. $\dot{Q}_j$ is the time rate of heat transfer at the location on the boundary of the control volume where the instantaneous temperature is T_j. The associated rate of exergy transfer is

$$\dot{E}_{q,j} = \left(1 - \frac{T_0}{T_j}\right)\dot{Q}_j. \tag{1.5.2}$$

As for other control volume rate balances, the subscripts i and e denote inlets and outlets, respectively. The exergy transfer rates at control volume inlets and outlets are denoted, respectively, as $\dot{E}_i = \dot{m}_i e_i$ and $\dot{E}_e = \dot{m}_e e_e$. Finally, $\dot{E}_D$ accounts for the time rate of exergy destruction due to irreversibilities within the control volume. The exergy destruction rate is related to the entropy generation rate by

$$\dot{E}_D = T_0 S_{gen}. \tag{1.5.3}$$

The specific exergy transfer terms e_i and e_e are expressible in terms of four components: physical exergy e^{PH}, kinetic exergy e^{KN}, potential exergy e^{PT}, and chemical exergy e^{CH}:

$$e = e^{PH} + e^{KN} + e^{PT} + e^{CH}. \tag{1.5.4}$$

The first three components are evaluated as follows:

$$e^{PH} = (h - h_0) - T_0(s - s_0), \tag{1.5.5a}$$

$$e^{KN} = \frac{1}{2}v^2, \tag{1.5.5b}$$

$$e^{PT} = gz. \tag{1.5.5c}$$

In Equation 1.5.5a, h_0 and s_0 denote, respectively, the specific enthalpy and specific entropy at the restricted dead state. In Equations 1.5.5b and 1.5.5c, v and z denote velocity and elevation relative to coordinates in the environment, respectively. The chemical exergy e^{CH} is considered next.

Chemical Exergy

To evaluate the chemical exergy, the exergy component associated with the departure of the chemical composition of a system from that of the environment, the substances comprising the system are referred to the properties of a suitably selected set of environmental substances. For this purpose, alternative models of the environment have been developed. For discussion, see, for example, Moran (1989) and Kotas (1995).

Exergy analysis is facilitated, however, by employing a *standard environment* and a corresponding table of *standard chemical exergies*. Standard chemical exergies are based on standard values of the environmental temperature T_0 and pressure p_0—for example, 298.15 K (25°C) and 1 atm, respectively. A standard environment is also regarded as consisting of a set of reference substances with standard concentrations reflecting as closely as possible the chemical makeup of the natural environment. The reference substances generally fall into three groups: gaseous components of the atmosphere, solid substances from the lithosphere, and ionic and nonionic substances from the oceans. The chemical exergy data of Table 1.5.1 correspond to two proposed standard exergy reference environments, called here model I and model II.

TABLE 1.5.1
Standard Molar Chemical Exergy, e^{CH} (kJ/kmol), of Various Substances at 298 K and p_0

Substance	Formula	Model I[a]	Model II[b]
Nitrogen	$N_2(g)$	640	720
Oxygen	$O_2(g)$	3,950	3,970
Carbon dioxide	$CO_2(g)$	14,175	19,870
Water	$H_2O(g)$	8,635	9,500
	$H_2O(l)$	45	900
Carbon (graphite)	C(s)	404,590	410,260
Hydrogen	$H_2(g)$	235,250	236,100
Sulfur	S(s)	598,160	609,600
Carbon monoxide	CO(g)	269,410	275,100
Sulfur dioxide	$SO_2(g)$	301,940	313,400
Nitrogen monoxide	NO(g)	88,850	88,900
Nitrogen dioxide	$NO_2(g)$	55,565	55,600
Hydrogen sulfide	$H_2S(g)$	799,890	812,000
Ammonia	$NH_3(g)$	336,685	337,900
Methane	$CH_4(g)$	824,350	831,650
Ethane	$C_2H_6(g)$	1,482,035	1,495,840
Methanol	$CH_3OH(g)$	715,070	722,300
	$CH_3OH(l)$	710,745	718,000
Ethyl alcohol	$C_2H_5OH(g)$	1,348,330	1,363,900
	$C_2H_5OH(l)$	1,342,085	1,357,700

[a] *Ahrendts, J. Die Exergie Chemisch Reaktionsfahiger Systeme, VDI-Forschungsheft. VDI-Verlag, Dusseldorf, 579, 1977.* Also see *Reference States, Energy—The International Journal*, *5:* 667–677, 1980. In Model I, $p_0 = 1.019$ atm. This model attempts to impose a criterion that the reference environment be in equilibrium. The reference substances are determined assuming restricted chemical equilibrium for nitric acid and nitrates and unrestricted thermodynamic equilibrium for all other chemical components of the atmosphere, the oceans, and a portion of the Earth's crust. The chemical composition of the gas phase of this model approximates the composition of the natural atmosphere.

[b] Szargut, J. et al., *Energy Analysis of Thermal, Chemical, and Metallurgical Processes*, Hemisphere, New York, 1988. In Model II, $p_0 = 1.0$ atm. In developing this model, a reference substance is selected for each chemical element from among substances that contain the element being considered and that are abundantly present in the natural environment, even though the substances are not in completely mutual stable equilibrium. An underlying rationale for this approach is that substances found abundantly in nature have little economic value. On an overall basis, the chemical composition of the exergy reference environment of Model II is closer than Model I to the composition of the natural environment, but the equilibrium criterion is not always satisfied.

Although the use of standard chemical exergies greatly facilitates the application of exergy principles, the term *standard* is somewhat misleading since there is no one specification of the environment that suffices for all applications. Still, chemical exergies calculated relative to alternative specifications of the environment are generally in good agreement. For a broad range of engineering applications, the simplicity and ease of use of standard chemical exergies generally outweigh any slight lack of accuracy that might result. In particular, the effect of slight variations in the values of T_0 and p_0 about the values used to determine the standard chemical exergies reported in Table 1.5.1 can be neglected.

The literature of exergy analysis provides several expressions allowing the chemical exergy to be evaluated in particular cases of interest. The molar chemical exergy of a gas mixture, for example, can be evaluated from

$$\overline{e}^{\mathrm{CH}} = \sum_{i=1}^{f} y_i \overline{e}_i^{\mathrm{CH}} + \overline{R}T_0 \sum_{i=1}^{f} y_i \ln y_i, \tag{1.5.6}$$

where $\overline{e}_i^{\mathrm{CH}}$ is the molar chemical exergy of the ith component.

Example 1.5.1

Ignoring the kinetic and potential exergies, determine the exergy rate, in kJ/kg, associated with each of the following streams of matter:

1. Saturated water vapor at 20 bar.
2. Methane at 5 bar, 25°C.

Let T_0=298 K, p_0=1.013 bar (1 atm).

Solution: Equation 1.5.4 reduces to read

$$e = \left(h - h_0\right) - T_0\left(s - s_0\right) + e^{\mathrm{CH}}$$

1. From Table A.5, h=2799.5 kJ/kg, s=6.3409 kJ/kg·K. At T_0=298 K (25°C), water would be a liquid; thus with Equations 1.3.20c and d, $h_0 \approx 104.9$ kJ/kg, $s_0 \approx 0.3674$ kJ/kg·K. Table 1.5.1 (model I) gives e^{CH}=45/18.02=2.5 kJ/kg. Then

$$\begin{aligned} e &= (2799.5 - 104.9) - 298(6.3409 - 0.3674) + 2.5 \\ &= 914.5 + 2.5 = 917.0 \text{ kJ/kg.} \end{aligned}$$

   Here the specific exergy is determined predominately by the physical component.
2. Assuming the ideal gas model for methane, $h - h_0 = 0$. Also, Equation 1.3.28 reduces to give $s - s_0 = -R \ln p/p_0$. Then, Equation 1.5.4 reads

$$e = RT_0 \ln p / p_0 + e^{\mathrm{CH}}.$$

   With e^{CH}=824,350/16.04=51,393.4 kJ/kg from Table 1.5.1 (model I),

$$\begin{aligned} e &= \left(\frac{8.314}{16.04}\text{kJ/kg}\cdot\text{K}\right)(298\text{K})\ln\frac{5}{1.013} + 51{,}393.4\text{kJ/kg} \\ &= 246.6 + 51{,}393.4 \\ &= 51{,}640\text{kJ/kg.} \end{aligned}$$

Here, the specific exergy is determined predominately by the chemical component.

The small difference between p_0=1.013 bar and the value of p_0 for model I has been ignored.

Exergetic Efficiency

The exergetic efficiency (second law efficiency, effectiveness, or rational efficiency) provides a true measure of the performance of a system from the thermodynamic viewpoint. To define the exergetic efficiency, both a *product* and a *fuel* for the system being analyzed are identified. The product represents the desired result of the system (power, steam, some combination of power and steam, etc.). Accordingly, the definition of the product must be consistent with the purpose of purchasing and using the system. The fuel represents the resources expended to generate the product and is not

TABLE 1.5.2
The Exergetic Efficiency for Selected Components at Steady State

Component	Turbine or Expander	Extraction Turbine	Compressor, Pump, or Fan	Heat Exchanger[a]	Mixing Unit[b]	Gasifier or Combustion Chamber	Boiler
							$\dot{E}_P$	$\dot{W}$	$\dot{W}$	$\dot{E}_2 - \dot{E}_1$	$\dot{E}_2 - \dot{E}_1$	$\dot{m}_1(e_3 - e_1)$	$\dot{E}_3 - \dot{E}_2$	$(\dot{E}_6 - \dot{E}_5) + (\dot{E}_8 - \dot{E}_7)$
$\dot{E}_F$	$\dot{E}_1 - \dot{E}_2$	$\dot{E}_1 - \dot{E}_2 - \dot{E}_3$	$\dot{W}$	$\dot{E}_3 - \dot{E}_4$	$\dot{m}_2(e_2 - e_3)$	$\dot{E}_1$	$(\dot{E}_1 + \dot{E}_2) + (\dot{E}_3 + \dot{E}_4)$
ε	$\dfrac{\dot{W}}{\dot{E}_1 - \dot{E}_2}$	$\dfrac{\dot{W}}{\dot{E}_1 - \dot{E}_2 - \dot{E}_3}$	$\dfrac{\dot{E}_2 - \dot{E}_1}{\dot{W}}$	$\dfrac{\dot{E}_2 - \dot{E}_1}{\dot{E}_3 - \dot{E}_4}$	$\dfrac{\dot{m}_1(e_3 - e_1)}{\dot{m}_2(e_2 - e_3)}$	$\dfrac{\dot{E}_3 - \dot{E}_2}{\dot{E}_1}$	$\dfrac{(\dot{E}_6 - \dot{E}_5) + (\dot{E}_8 - \dot{E}_7)}{(\dot{E}_1 - \dot{E}_2) - (\dot{E}_3 - \dot{E}_4)}$

Note: For discussion, see Bejan et al. (1996).

[a] This definition assumes that the purpose of the heat exchanger is to heat the cold stream ($T_1 \geq T_0$). If the purpose of the heat exchanger is to provide cooling ($T_3 \geq T_0$), then the following relations should be used: $\dot{E}_P = \dot{E}_4 - \dot{E}_3$ and $\dot{E}_F = \dot{E}_1 - \dot{E}_2$.

[b] The purpose of the mixing unit is to heat the cold stream; otherwise a mixing unit may be considered a dissipative component, i.e. a component for which no product can be defined.

necessarily restricted to being an actual fuel such as a natural gas, oil, or coal. Both the product and the fuel are expressed in terms of exergy.

For a control volume at steady state whose exergy rate balance reads

$$\dot{E}_F = \dot{E}_P + \dot{E}_D + \dot{E}_L .$$

The exergetic efficiency is

$$\varepsilon = \frac{\dot{E}_P}{\dot{E}_F} = 1 - \frac{\dot{E}_D + \dot{E}_L}{\dot{E}_F}, \tag{1.5.7}$$

where the rates at which the fuel is supplied and the product is generated are $\dot{E}_F$ and $\dot{E}_P$, respectively. $\dot{E}_D$ and $\dot{E}_L$ denote the rates of exergy destruction and exergy loss, respectively. Exergy is destroyed by irreversibilities within the control volume, and exergy is lost from the control volume via stray heat transfer, material streams vented to the surroundings, and so on. The exergetic efficiency shows the percentage of the fuel exergy provided to a control volume that is found in the product exergy. Moreover, the difference between 100% and the value of the exergetic efficiency, expressed as a percent, is the percentage of the fuel exergy wasted in this control volume as exergy destruction and exergy loss.

To apply Equation 1.5.7, decisions are required concerning what are considered as the fuel and the product. Table 1.5.2 provides illustrations for several common components. Similar considerations are used to write exergetic efficiencies for systems consisting of several such components, as, for example, a power plant.

Exergetic efficiencies can be used to assess the thermodynamic performance of a component, plant, or industry relative to the performance of *similar* components, plants, or industries. By this means the performance of a gas turbine, for instance, can be gauged relative to the typical present-day performance level of gas turbines. A comparison of exergetic efficiencies for *dissimilar* devices—gas turbines and heat exchangers, for example—is generally not significant, however.

The exergetic efficiency is generally more meaningful, objective, and useful than other efficiencies based on the first or second law of thermodynamics, including the thermal efficiency of a power plant, the isentropic efficiency of a compressor or turbine, and the effectiveness of a heat exchanger. The thermal efficiency of a cogeneration system, for instance, is misleading because it treats both work and heat transfer as having equal thermodynamic value. The isentropic turbine efficiency (Equation 1.6.2a) does not consider that the working fluid at the outlet of the turbine has a higher temperature (and consequently a higher exergy that may be used in the next component) in the actual process than in the isentropic process. The heat exchanger effectiveness fails, for example, to identify the exergy destruction associated with the pressure drops of the heat exchanger working fluids.

Example 1.5.2

Evaluate the exergetic efficiency of the turbine in part (1) of Example 1.2.1 for $T_0 = 298$ K.

Solution: The exergetic efficiency from Table 1.5.2 is

$$\varepsilon = \frac{\dot{W}}{\dot{E}_1 - \dot{E}_2} = \frac{\dot{W}}{\dot{m}(e_1 - e_2)}.$$

Using Equations 1.5.4 and 1.5.5a, and noting that the chemical exergy at 1 and 2 cancels,

$$\varepsilon = \frac{\dot{W}}{\dot{m}\left[\left(h_1 - h_2\right) - T_0\left(s_1 - s_2\right)\right]}.$$

Since $\dot{W} = \dot{m}(h_1 - h_2)$,

$$\varepsilon = \frac{\dot{W}}{\dot{W} + \dot{m}T_0(s_2 - s_1)}.$$

Finally, using data from Example 1.2.1 and $s_2 = 6.8473$ kJ/kg·K,

$$\varepsilon = \frac{30\,\text{MW}}{30\,\text{MW} + \left(\frac{162{,}357}{3600}\text{kg/s}\right)(298\text{K})(6.8473 - 6.6022)\left(\text{kJ/kg}\cdot\text{K}\right)\left(\frac{1\,\text{MW}}{10^3\,\text{kJ/s}}\right)}$$

$$= \frac{30\,\text{MW}}{(30 + 3.29)\text{MW}} = 0.9(90\%).$$

Introduction to Exergy Costing

Since exergy measures the true thermodynamic values of the work, heat, and other interactions between the system and its surroundings as well as the effect of irreversibilities within the system, exergy is a rational basis for assigning costs. This aspect of thermoeconomics is called *exergy costing*. An introduction to exergy costing is given in the present discussion.

Referring to Figure 1.5.1 showing a steam turbine-electric generator at steady state, the total cost to produce the electricity and exiting steam equals the cost of the entering steam plus the cost of owning and operating the device. This is expressed by the *cost rate balance* for the turbine generator:

$$\dot{C}_e + \dot{C}_2 = \dot{C}_1 + \dot{Z}, \tag{1.5.8a}$$

where $\dot{C}_e$ is the cost rate associated with the electricity, $\dot{C}_1$ and $\dot{C}_2$ are the cost rates associated with the entering steam and exiting steam, respectively, and $\dot{Z}$ accounts for the cost rate associated with owning and operating the system, each *annualized* in $ per year.

With exergy costing, the cost rates $\dot{C}_1$, $\dot{C}_2$, and $\dot{C}_e$ are evaluated in terms of the associated rate of exergy transfer and a *unit cost*. Equation 1.5.8a then appears as

$$c_e\dot{W}_e + c_2\dot{E}_2 = c_1\dot{E}_1 + \dot{Z}. \tag{1.5.8b}$$

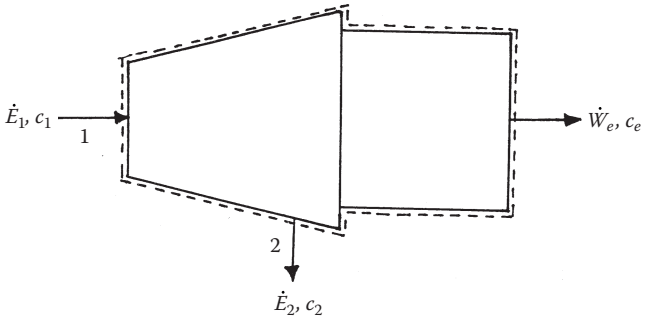

FIGURE 1.5.1 Steam turbine/electric generator used to discuss exergy costing.

The coefficients c_1, c_2, and c_e in Equation 1.5.8b denote the *average* cost per unit of exergy for the associated exergy rate. The unit cost c_1 of the entering steam would be obtained from exergy costing applied to the components upstream of the turbine. Assigning the same unit cost to the exiting steam: $c_2 = c_1$ on the basis that the purpose of the turbine generator is to generate electricity and thus all costs associated with owning and operating the system should be charged to the power, Equation 1.5.8b becomes

$$c_e \dot{W}_e = c_1(\dot{E}_1 - \dot{E}_2) + \dot{Z}. \tag{1.5.8c}$$

The first term on the right side accounts for the cost of the net exergy used, and the second term accounts for cost of the system itself. Introducing the exergetic efficiency from Table 1.5.2, the unit cost of the electricity is

$$c_e = \frac{c_1}{\varepsilon} + \frac{\dot{Z}}{\dot{W}_e}. \tag{1.5.9}$$

This equation shows, for example, that the unit cost of electricity would increase if the exergetic efficiency were to decrease owing to a deterioration of the turbine with use.

Example 1.5.3

A turbine generator with an exergetic efficiency of 90% develops 7×10^7 kW·h of electricity annually. The annual cost of owning and operating the system is $\$2.5 \times 10^5$. If the average unit cost of the steam entering the system is \$0.0165 $kW^{-1} \cdot h^{-1}$ of exergy, evaluate the unit cost of the electricity.

Solution: Substituting values into Equation 1.5.9,

$$c_e = \frac{\$0.0165/\text{kW} \cdot \text{h}}{0.9} + \frac{\$2.5 \times 10^5/\text{year}}{7 \times 10^7\,\text{kW} \cdot \text{h/year}}$$

$$= 0.0183 + 0.0036 = \$0.0219/\text{kW} \cdot \text{h}.$$

1.6 VAPOR AND GAS POWER CYCLES

Michael J. Moran

Vapor and gas power systems develop electrical or mechanical power from energy sources of chemical, solar, or nuclear origin. In *vapor* power systems, the *working fluid*, normally water, undergoes a phase change from liquid to vapor, and conversely. In *gas* power systems, the working fluid remains a gas throughout, although the composition normally varies owing to the introduction of a fuel and subsequent combustion. The present section introduces vapor and gas power systems.

The processes taking place in power systems are sufficiently complicated that idealizations are typically employed to develop tractable thermodynamic models. The *air-standard analysis* of gas power systems considered later in the present section is a noteworthy example. Depending on the degree of idealization, such models may provide only qualitative information about the performance of the corresponding real-world systems. Yet such information is frequently useful in gauging how changes in major operating parameters might affect actual performance. Elementary thermodynamic models can also provide simple settings to assess, at least approximately, the advantages and disadvantages of features proposed to improve thermodynamic performance.

Rankine and Brayton Cycles

In their simplest embodiments, vapor power and gas turbine power plants are represented conventionally in terms of four components in series, forming, respectively, the Rankine cycle and the Brayton cycle shown schematically in Table 1.6.1. The thermodynamically ideal counterparts of these cycles are composed of four internally reversible processes in series: two isentropic processes alternated with two constant pressure processes. Table 1.6.1 provides property diagrams of the actual and corresponding ideal cycles. Each actual cycle is denoted 1–2–3–4–1; the ideal cycle is 1–2*s*–3–4*s*–1. For simplicity, pressure drops through the boiler, condenser, and heat exchangers are not shown. Invoking Equation 1.2.11 for the ideal cycles, the heat added per unit of mass flowing is represented by the area *under* the isobar from state 2*s* to state 3: area *a*–2*s*–3–*b*–*a*. The heat rejected is the area *under* the isobar from state 4*s* to state 1: area *a*–1–4*s*–*b*–*a*. Enclosed area 1–2*s*–3–4*s*–1 represents the net heat added per unit of mass flowing. For any power cycle, the net heat added equals the net work done.

Expressions for the principal energy transfers are provided by Equations 1 through 4 shown on the schematics of Table 1.6.1. They are obtained by reducing Equation 1.2.9a with the assumptions of negligible heat loss and negligible changes in kinetic and potential energy from the inlet to the outlet of each component. All quantities are positive in the directions of the arrows on the figure. Using these expressions, the thermal efficiency is

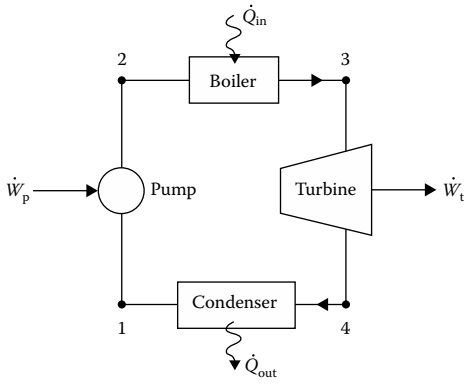
$$\eta = \frac{(h_3 - h_4) - (h_2 - h_1)}{h_3 - h_2}. \tag{1.6.1}$$

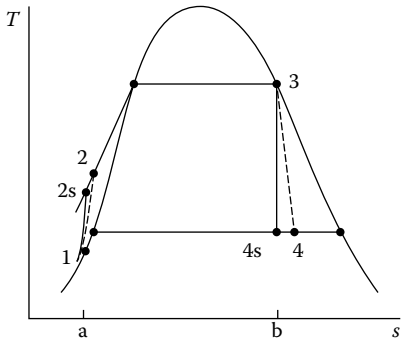
To obtain the thermal efficiency of the ideal cycle, h_{2_s} replaces h_2 and h_{4_s} replaces h_4 in Equation 1.6.1.

Decisions concerning cycle operating conditions normally recognize that the thermal efficiency tends to increase as the average temperature of heat addition increases and/or the temperature of heat rejection decreases. In the Rankine cycle, a high average temperature of heat addition can be achieved by superheating the vapor prior to entering the turbine, and/or by operating at an elevated steam generator pressure. In the Brayton cycle, an increase in the compressor pressure ratio p_2/p_1 tends to increase the average temperature of heat addition. Owing to materials limitations at elevated temperatures and pressures, the state of the working fluid at the turbine inlet must observe practical limits, however. The turbine inlet temperature of the Brayton cycle, for example, is controlled by providing air far in excess of what is required for combustion. In a Rankine cycle using water as the

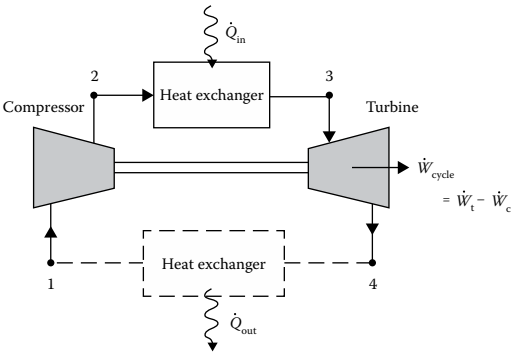
TABLE 1.6.1
Rankine and Brayton Cycles

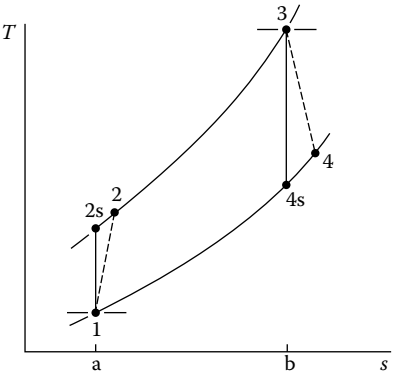
Rankine Cycle





Brayton Cycle





$$\left.\begin{matrix}\dot{W}_p \\ \dot{W}_c\end{matrix}\right\} = \dot{m}(h_2 - h_1) \quad (>0) \tag{1}$$

$$\dot{Q}_{in} = \dot{m}(h_3 - h_2) \quad (>0) \tag{2}$$

$$\dot{W}_t = \dot{m}(h_3 - h_4) \quad (>0) \tag{3}$$

$$\dot{Q}_{out} = \dot{m}(h_1 - h_4) \quad (>0) \tag{4}$$

working fluid, a low temperature of heat rejection is typically achieved by operating the condenser at a pressure below 1 atm. To reduce erosion and wear by liquid droplets on the blades of the Rankine cycle steam turbine, at least 90% quality should be maintained at the turbine exit: $x_4 > 0.9$.

The *back work ratio*, bwr, is the ratio of the work required by the pump or compressor to the work developed by the turbine:

$$\text{bwr} = \frac{h_2 - h_1}{h_3 - h_4}. \tag{1.6.2a}$$

As a relatively high specific volume vapor expands through the turbine of the Rankine cycle and a much lower specific volume liquid is pumped, the back work ratio is characteristically quite low in vapor power plants—in many cases on the order of 1% to 2%. In the Brayton cycle, however, both the turbine and compressor handle a relatively high specific volume gas, and the back ratio is much larger, typically 40% or more.

The effect of friction and other irreversibilities for flow through turbines, compressors, and pumps is commonly accounted for by an appropriate *isentropic efficiency*. The isentropic turbine efficiency is

$$\eta_t = \frac{h_3 - h_4}{h_3 - h_{4s}}. \tag{1.6.2b}$$

The isentropic compressor efficiency is

$$\eta_c = \frac{h_{2s} - h_1}{h_2 - h_1}. \tag{1.6.2c}$$

In the isentropic pump efficiency, η_p, which takes the same form as Equation 1.6.2c, the numerator is frequently approximated via Equation 1.2.12c *as* $h_{2s} - h_1 \approx v_1 \Delta p$, where Δp is the pressure rise across the pump.

Simple gas turbine power plants differ from the Brayton cycle model in significant respect. In actual operation, excess air is continuously drawn into the compressor, where it is compressed to a higher pressure; then fuel is introduced and combustion occurs; and finally the mixture of combustion products and air expands through the turbine and is subsequently discharged to the surroundings. Accordingly, the low-temperature heat exchanger shown by a dashed line in the Brayton cycle schematic of Table 1.6.1 is not an actual component, but included only to account formally for the cooling in the surroundings of the hot gas discharged from the turbine.

Another frequently employed idealization used with gas turbine power plants is that of an *air-standard analysis*. An air-standard analysis involves two major assumptions: (1) as shown by the Brayton cycle schematic of Table 1.6.1, the temperature rise that would be brought about by combustion is effected instead by a heat transfer from an external source and (2) the working fluid throughout the cycle is air, which behaves as an ideal gas. In a *cold* air-standard analysis, the specific heat ratio k for air is taken as constant. Equations 1 through 6 of Table 1.3.6 together with data from Table A.8 apply generally to air-standard analyses. Equations 1′ to 6′ of Table 1.3.6 apply to cold air-standard analyses, as does the following expression for the turbine power obtained from Table 1.2.1 (Equation 1.2.9c″):

$$\dot{W}_t = \dot{m} \frac{kRT_3}{k-1} \left[1 - \left(p_4 / p_3 \right)^{(k-1)/k} \right] \tag{1.6.3}$$

(Equation 1.6.3 also corresponds to Equation 5′ of Table 1.3.8 when $n = k$.) An expression similar in form can be written for the power required by the compressor.

For the simple Rankine and Brayton cycles of Table 1.6.1, the results of sample calculations are provided in Table 1.6.2. The Brayton cycle calculations are on an air-standard analysis basis.

Otto, Diesel, and Dual Cycles

Although most gas turbines are also internal combustion engines, the name is usually reserved to *reciprocating* internal combustion engines of the type commonly used in automobiles, trucks, and buses. Two principal types of reciprocating internal combustion engines are the *spark-ignition* engine and the *compression-ignition* engine. In a spark-ignition engine, a mixture of fuel and air is ignited by a spark plug. In a compression ignition engine, air is compressed to a high enough pressure and temperature that combustion occurs spontaneously when fuel is injected.

In a *four-stroke* internal combustion engine, a piston executes four distinct strokes within a cylinder for every two revolutions of the crankshaft. Figure 1.6.1 gives *a* pressure–displacement diagram as it might be displayed electronically. With the intake valve open, the piston makes an *intake stroke* to draw a fresh charge into the cylinder. Next, with both valves closed, the piston

undergoes a *compression stroke* raising the temperature and pressure of the charge. A combustion process is then initiated, resulting in a high-pressure, high-temperature gas mixture. A *power* stroke follows the compression stroke, during which the gas mixture expands and work is done on the piston. The piston then executes an *exhaust stroke* in which the burned gases are purged from the cylinder through the open exhaust valve. Smaller engines operate on *two-stroke* cycles. In two-stroke engines, the intake, compression, expansion, and exhaust operations are accomplished in one revolution of the crankshaft. Although internal combustion engines undergo *mechanical* cycles, the cylinder contents do not execute a *thermodynamic* cycle, since matter is introduced with one composition and is later discharged at a different composition.

A parameter used to describe the performance of reciprocating piston engines is the *mean effective pressure* or mep. The mean effective pressure is the theoretical constant pressure that, if it acted on the piston during the power stroke, would produce the same *net* work as actually developed in one cycle. That is,

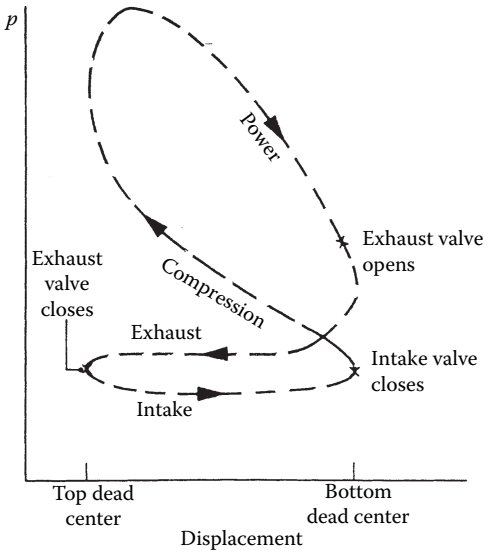

FIGURE 1.6.1 Pressure–displacement diagram for a reciprocating internal combustion engine.

$$\text{mep} = \frac{\text{Net work for one cycle}}{\text{Displacement volume}},$$

where the displacement volume is the volume swept out by the piston as it moves from the top dead center to the bottom dead center. For two engines of equal displacement volume, the one with a higher mean effective pressure would produce the greater net work and, if the engines run at the same speed, greater power.

Detailed studies of the performance of reciprocating internal combustion engines may take into account many features, including the combustion process occurring within the cylinder and the effects of irreversibilities associated with friction and with pressure and temperature gradients. Heat transfer between the gases in the cylinder and the cylinder walls, and the work required to charge the cylinder and exhaust the products of combustion also might be considered. Owing to these complexities, accurate modeling of reciprocating internal combustion engines normally involves computer simulation.

To conduct *elementary* thermodynamic analyses of internal combustion engines, considerable simplification is required. A procedure that allows engines to be studied *qualitatively* is to employ an *air-standard analysis* having the following elements: (1) a fixed amount of air modeled as an ideal gas is the system, (2) the combustion process is replaced by a heat transfer from an external source and generally represented in terms of elementary thermodynamic processes, (3) there are no exhaust and intake processes as in an actual engine; the cycle is completed by a constant volume heat rejection process, and (4) all processes are internally reversible.

The processes employed in air-standard analyses of internal combustion engines are selected to represent the events taking place within the engine simply and mimic the appearance of observed pressure–displacement diagrams. In addition to the constant volume heat rejection noted previously, the compression stroke and at least a portion of the power stroke are conventionally taken as isentropic. The heat addition is normally considered to occur at constant volume, constant pressure, or constant volume followed by a constant pressure process, yielding, respectively, the Otto, Diesel, and Dual cycles shown in Table 1.6.3. Referring to Table 1.6.3, the ratio v_1/v_2 is the *compression ratio, r.* For the Diesel cycle, the ratio v_3/v_2 is the *cutoff ratio,* r_c.

TABLE 1.6.3
Otto, Diesel, and Dual Cycles

(a) Otto Cycle	(b) Diesel Cycle	(c) Dual Cycle
				$\frac{W_{23}}{m} = 0$	$\frac{W_{23}}{m} = p_2(v_3 - v_2)$	$\frac{W_{23}}{m} = 0, \frac{Q_{2x}}{m} = u_x - u_2$
$\frac{Q_{23}}{m} = u_3 - u_2$	$\frac{Q_{23}}{m} = h_3 - h_2$	$\frac{W_{x3}}{m} = p_3(v_3 - v_2), \frac{Q_{x3}}{m} = h_3 - h_x$
$\eta = 1 - \frac{u_4 - u_1}{u_3 - u_2}$	$\eta = 1 - \frac{u_4 - u_1}{h_3 - h_2}$	$\eta = 1 - \frac{u_4 - u_1}{(u_x - u_2) + (h_3 - h_x)}$

Reducing the closed system energy balance, Equation 1.1.8, gives the following expressions for heat and work applicable in each case shown in Table 1.6.3:

$$\frac{W_{12}}{m} = u_1 - u_2 \quad (< 0)$$

$$\frac{W_{34}}{m} = u_3 - u_4 \quad (> 0)$$

$$\frac{Q_{41}}{m} = u_1 - u_4 \quad (< 0).$$

Table 1.6.3 provides additional expressions for work, heat transfer, and thermal efficiency identified with each case individually. The thermal efficiency, evaluated from Equation 1.1.9, takes the form

$$\eta = 1 - \frac{|Q_{41}/m|}{Q_A/m}.$$

Equations 1 through 6 of Table 1.3.6 together with data from Table A.8 apply generally to air-standard analyses. In a *cold* air-standard analysis, the specific heat ratio k for air is taken as constant. Equations 1′ through 6′ of Table 1.3.6 apply to cold air-standard analyses, as does Equation 4′ of Table 1.3.8, with $n = k$ for the isentropic processes of these cycles.

As all processes are internally reversible, areas on the p–v and T–s diagrams of Table 1.6.3 can be interpreted, respectively, as work and heat transfer. Invoking Equation 1.1.10 and referring to the p–v diagrams, the areas under process 3–4 of the Otto cycle, process 2–3–4 of the Diesel cycle, and process x–3–4 of the Dual cycle represent the work done by the gas during the power stroke, per unit of mass. For each cycle, the area under the isentropic process 1–2 represents the work done on the gas during the compression stroke, per unit of mass. The enclosed area of each cycle represents the net work done per unit mass. With Equation 1.1.15 and referring to the T–s diagrams, the areas under process 2–3 of the Otto and Diesel cycles and under process 2–x–3 of the Dual cycle represent the heat added per unit of mass. For each cycle, the area under the process 4–1 represents the heat rejected per unit of mass. The enclosed area of each cycle represents the net heat added, which equals the net work done, each per unit of mass.

Carnot, Ericsson, and Stirling Cycles

Three thermodynamic cycles that exhibit the Carnot efficiency (Equation 1.1.12) are the Carnot, Ericsson, and Stirling cycles shown in Figure 1.6.2. Each case represents a reversible power cycle in which heat is added from an external source at a constant temperature T_H (process 2–3) and rejected to the surroundings at a constant temperature T_C (process 4–1). Carnot cycles can be configured both as vapor power cycles and as cycles executed by a gas in a piston-cylinder assembly (see Moran et al., 2014). Carnot cycles also can be executed in systems where a capacitor is charged and discharged, a paramagnetic substance is magnetized and demagnetized, and in other ways. Regardless of the type of device and the working substance used, the Carnot cycle always has the same four internally reversible processes in series: two isentropic processes alternated with two isothermal processes.

The Ericsson and Stirling cycles also consist of four internally reversible processes in series: heating from state 1 to state 2 (at constant pressure in the Ericsson cycle and at constant volume in the Stirling cycle), isothermal heating from state 2 to state 3 at temperature T_H, cooling from state 3 to state 4 (at constant pressure in the Ericsson cycle and at constant volume in the Stirling cycle), and isothermal cooling from state 4 to state 1 at temperature T_C. An ideal regenerator allows the heat

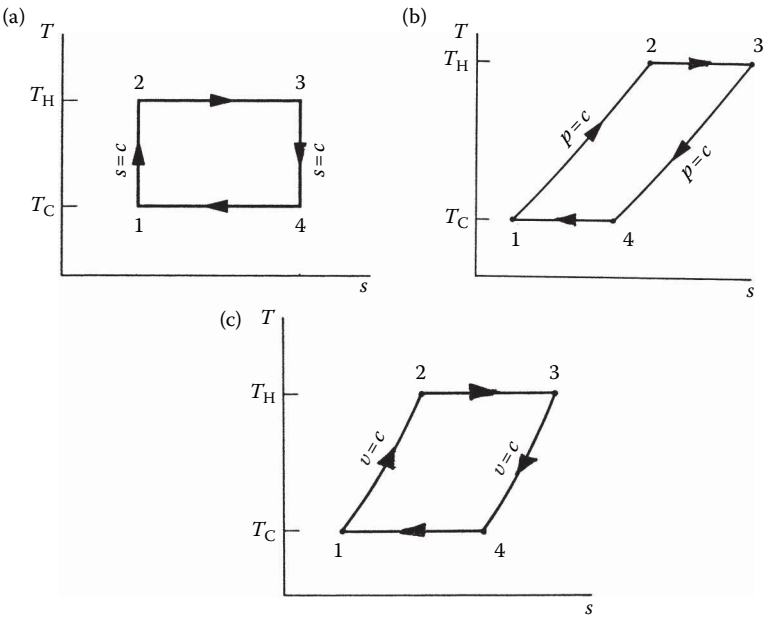

FIGURE 1.6.2 (a) Carnot, (b) Ericsson, and (c) Stirling cycles.

input required for process 1–2 to be obtained from the heat rejected in process 3–4. Accordingly, as in the Carnot cycle all the heat added externally occurs at T_H and all of the heat rejected to the surroundings occurs at T_C.

The Ericsson and Stirling cycles are principally of theoretical interest as examples of cycles that exhibit the same thermal efficiency as the Carnot cycle (Equation 1.1.12). However, a practical engine of the piston-cylinder type that operates on a closed regenerative cycle having features in common with the Stirling cycle has been under study in recent years. This engine, known as the *Stirling engine*, offers the opportunity for high efficiency together with reduced emissions from combustion products because the combustion takes place externally and not within the cylinder as in internal combustion engines. In the Stirling engine, energy is transferred to the working fluid from products of combustion, which are kept separate. It is an *external* combustion engine.

1.7 GUIDELINES FOR IMPROVING THERMODYNAMIC EFFECTIVENESS

Michael J. Moran

Thermal design frequently aims at the most effective system from the cost viewpoint. Still, in the cost optimization process, particularly of complex energy systems, it is often expedient to begin by identifying a design that is nearly optimal thermodynamically; such a design can then be used as a point of departure for cost optimization. Presented in this section are guidelines for improving the use of fuels (natural gas, oil, and coal) by reducing sources of thermodynamic inefficiency in thermal systems. Further discussion is provided by Bejan et al. (1996).

To improve thermodynamic effectiveness, it is necessary to deal directly with inefficiencies related to exergy destruction and exergy loss. The primary contributors to exergy destruction are chemical reaction, heat transfer, mixing, and friction, including unrestrained expansions of gases and liquids. To deal with them effectively, the principal sources of inefficiency not only should be understood qualitatively but also determined quantitatively, at least approximately. Design changes to improve effectiveness must be done judiciously, however, for the cost associated with different sources of inefficiency can be different. For example, the unit cost of the electrical or mechanical power required to provide for the exergy destroyed owing to a pressure drop is generally higher than the unit cost of the fuel required for the exergy destruction caused by combustion or heat transfer.

Since chemical reaction is a significant source of thermodynamic inefficiency, it is generally good practice to minimize the use of combustion. In many applications, the use of combustion equipment such as boilers is unavoidable, however. In these cases, a significant reduction in the combustion irreversibility by conventional means simply cannot be expected, for the major part of the exergy destruction introduced by combustion is an inevitable consequence of incorporating such equipment. Still, the exergy destruction in practical combustion systems can be reduced by minimizing the use of excess air and by preheating the reactants. In most cases, only a small part of the exergy destruction in a combustion chamber can be avoided by these means. Consequently, after considering such options for reducing the exergy destruction related to combustion, efforts to improve thermodynamic performance should focus on components of the overall system that are more amenable to betterment by cost-effective conventional measures. In other words, *some exergy destructions and energy losses can be avoided, others cannot. Efforts should be centered on those that can be avoided.*

Nonidealities associated with heat transfer also typically contribute heavily to inefficiency. Accordingly, unnecessary or cost-ineffective heat transfer must be avoided. Additional guidelines follow:

- The higher the temperature T at which a heat transfer occurs in cases where $T > T_0$, where T_0 denotes the temperature of the environment (Section 1.5), the more valuable the heat transfer and, consequently, the greater the need to avoid heat transfer to the ambient, to cooling water, or to a refrigerated stream. Heat transfer across T_0 should be avoided.
- The lower the temperature T at which a heat transfer occurs in cases where $T < T_0$, the more valuable the heat transfer and, consequently, the greater the need to avoid direct heat transfer to the ambient or a heated stream.
- Since exergy destruction associated with heat transfer between streams varies inversely with the temperature level, the lower the temperature level, the greater the need to minimize the stream-to-stream temperature difference.
- Avoid the use of intermediate heat-transfer fluids when exchanging energy by heat transfer between two streams.

Although irreversibilities related to friction, unrestrained expansion, and mixing are often secondary in importance to those of combustion and heat transfer, they should not be overlooked, and the following guidelines apply:

- Relatively more attention should be paid to the design of the lower temperature stages of turbines and compressors (the last stages of turbines and the first stages of compressors) than to the remaining stages of these devices.
- For turbines, compressors, and motors, consider the most thermodynamically efficient options.
- Minimize the use of throttling; check whether power recovery expanders are a cost-effective alternative for pressure reduction.
- Avoid processes using excessively large thermodynamic driving forces (differences in temperature, pressure, and chemical composition). In particular, minimize the mixing of streams differing significantly in temperature, pressure, or chemical composition.
- The greater the mass rate of flow, the greater the need to use the exergy of the stream effectively.
- The lower the temperature level, the greater the need to minimize friction.

Flowsheeting or *process simulation* softwares can assist efforts aimed at improving thermodynamic effectiveness by allowing engineers to readily model the behavior of an overall system, or system components, under specified conditions and do the required thermal analysis, sizing, costing, and optimization. Since process simulation is a rapidly evolving field, vendors should be contacted for up-to-date information concerning the features of flowsheeting software, including optimization capabilities (if any).

1.8 EXERGOECONOMICS

George Tsatsaronis

Exergoeconomics is an exergy-aided cost reduction method that combines exergy and cost analyses to provide the designer or operator of an energy conversion plant with information not available through conventional energy, exergy, or cost analyses. Exergoeconomics is also a powerful tool for understanding the interconnections between thermodynamics and economics and, thus, the behavior of an energy conversion plant from the cost viewpoint. For a more detailed presentation of exergoeconomics, readers may refer to the following references: Bejan et al. (1996), Lazzaretto and Tsatsaronis (2006), Tsatsaronis (1984, 1993, 1994, 1999a, 2007, 2011), and Tsatsaronis et al. (1985, 1986). Sections 1.2 through 1.5 outline the principles for conducting detailed thermodynamic evaluations of thermal systems. In particular, techniques have been developed for evaluating the thermodynamic inefficiencies of these systems: exergy destructions and exergy losses. However, we often need to know the costs (and the environmental impacts) associated with such inefficiencies. This information is very useful for improving the overall effectiveness of the system—that is, for reducing the costs (and the environmental impacts) associated with the final products produced by the system.

In addition, if a system has more than one product, as for example the net power and saturated vapor of the cogeneration system shown in Figure 1.8.1, we would want to know the production cost for each product. This is a common problem in chemical plants where electrical power, chilled water, compressed air, and steam at various pressure levels are generated in one department and sold to another. The plant operator wants to know the true cost at which each of the utilities is generated; these costs are then charged to the appropriate final products according to the type and amount of each utility used to generate a final product. In the design of a thermal system, such cost allocation assists in pinpointing cost-ineffective processes and operations and in identifying technical options that might improve the cost-effectiveness of the system.

Accordingly, the objective of an exergoeconomic analysis might be to (1) calculate separately the cost of each product generated by a system having more than one product, (2) estimate the cost associated with each inefficiency within the system, (3) understand the cost formation process and the flow of costs in the system, (4) optimize specific variables in a single component, or (5) minimize the costs associated with the overall system.

An exergoeconomic analysis must be preceded by an exergy analysis (see Section 1.5) and an economic analysis [see Bejan et al. (1996), Tsatsaronis and Winhold (1984), and Section 1.10]. Because of the variation of costs from year to year, we must use the cost levelization approach when we evaluate the design of a thermal system from the cost viewpoint. Therefore, the cost values used throughout the following discussion are levelized costs. For conciseness, the term levelized is omitted, however.

Cost accounting in exergoeconomics calls for the use of cost balances. Cost balances can be formulated for an overall system (subscript tot) operating at steady state

$$\dot{C}_{\mathrm{P,tot}} = \dot{C}_{\mathrm{F,tot}} + \dot{Z}^{\mathrm{Cl}}_{\mathrm{tot}} + \dot{Z}^{\mathrm{OM}}_{\mathrm{tot}} \tag{1.8.1}$$

and for each component (see Equations 1.8.6 and 1.8.7). Equation 1.8.1 indicates that the cost rate associated with the product of the system ($\dot{C}_{\mathrm{P}}$) equals the total rate of expenditures made to generate the product, namely, the fuel cost rate ($\dot{C}_{\mathrm{F}}$) and the cost rates associated with capital investment ($\dot{Z}^{\mathrm{CI}}$) and operating and maintenance (O&M) ($\dot{Z}^{\mathrm{OM}}$). Here, and throughout Sections 1.8, 1.9, and 1.10, the terms *fuel* and *product* are used in the sense introduced in Section 1.5. When referring to a single stream associated with a fuel or product, the expression *fuel stream* or *product stream* is used. The rates $\dot{Z}^{\mathrm{CI}}$ and $\dot{Z}^{\mathrm{OM}}$ are calculated by dividing the annual contribution of capital investment and the annual operating and maintenance costs, respectively, by the

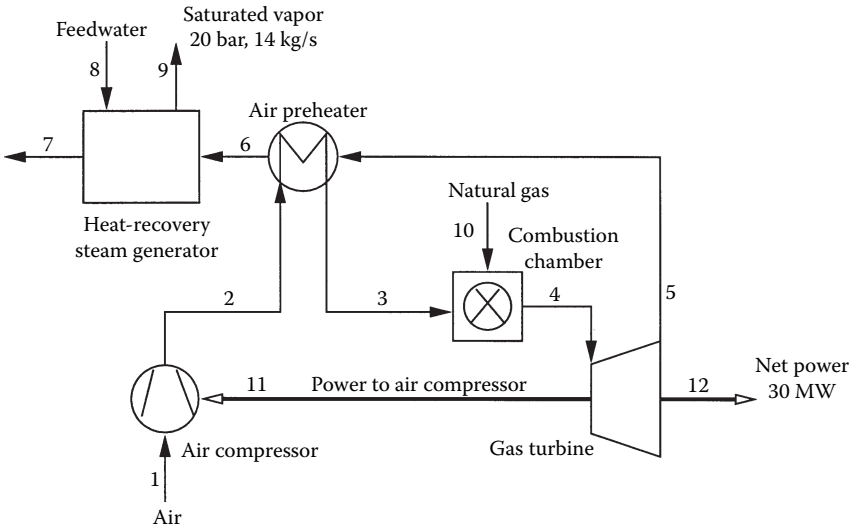

FIGURE 1.8.1 Cogeneration system.

number of time units (usually hours or seconds) of system operation per year. The sum of these two variables is denoted by $\dot{Z}$:

$$\dot{Z} = \dot{Z}^{\mathrm{CI}} + \dot{Z}^{\mathrm{OM}}. \tag{1.8.2}$$

In this section, we discuss the basic elements of exergoeconomics, which include exergy costing, cost balances, and means for costing various exergy transfers. The exergoeconomic variables defined later are used in the evaluation and optimization of the design and operation of thermal systems.

Exergy Costing

For a system operating at steady state, there may be a number of entering and exiting streams as well as both heat and work interactions with the surroundings. Associated with these transfers of matter and energy are exergy transfers into and out of the system and exergy destructions caused by the irreversibilities within the system. Since exergy measures the *true* thermodynamic value of such effects, and costs should only be assigned to commodities of value, it is meaningful to use exergy as a basis for assigning costs in thermal systems. Indeed, exergoeconomics rests on the notion that exergy is the *only* rational basis for assigning costs to the interactions a thermal system experiences with its surroundings and to the sources of inefficiencies within it. We refer to this approach as *exergy costing.*

In exergy costing, a cost rate is associated with each exergy transfer. Thus, for entering and exiting streams of matter with exergy transfers $\dot{E}_i$ and $\dot{E}_e$, respectively, power $\dot{W}$, and exergy transfer associated with heat transfer $\dot{E}_q$, we write, respectively,

$$\dot{C}_i = c_i \dot{E}_i,\ \dot{C}_e = c_e \dot{E}_e \tag{1.8.3}$$

$$\dot{C}_w = c_w \dot{W},\ \dot{C}_q = c_q \dot{E}_q, \tag{1.8.4}$$

where c_i, c_e, c_w, and c_q denote *average* costs per unit of exergy, for example, in dollars per gigajoule ($/GJ).

Exergy costing does not necessarily imply that costs associated with streams of matter are related *only* to the exergy rate of each respective stream. Nonexergy-related costs also can affect the total cost rate associated with material streams. Examples include the cost rates associated with a treated water stream at the outlet of a water treatment unit, an oxygen or nitrogen stream at the outlet of an air separation unit, a limestone stream supplied to a gasifier or fluidized-bed reactor, iron feedstock supplied to a metallurgical process, and an inorganic chemical fed to a chemical reactor. Accordingly, when significant nonexergy-related costs occur, the total cost rate associated with the material stream j, denoted by $\dot{C}_j^{\mathrm{TOT}}$, is given by

$$\dot{C}_j^{\mathrm{TOT}} = \dot{C}_j + \dot{C}_j^{\mathrm{NE}}, \tag{1.8.5}$$

where $\dot{C}_j$ is the cost rate directly related to the exergy of stream j (e.g., Equation 1.8.3), and $\dot{C}_j^{\mathrm{NE}}$ is the cost rate due to nonexergetic effects. The term $\dot{C}_j^{\mathrm{NE}}$ represents a convenient way for charging nonexergy-related costs from one component to other components that should bear such costs. More details about $\dot{C}_j^{\mathrm{NE}}$ are given in Bejan et al. (1996) and Tsatsaronis et al. (1986).

Cost Balance

Exergy costing usually involves cost balances formulated for each component separately. A cost balance applied to the kth system component indicates that the sum of cost rates associated with all exiting exergy transfers equals the sum of cost rates of all entering exergy transfers plus the appropriate charges due to capital investment ($\dot{Z}_k^{\mathrm{CL}}$) and operating and maintenance expenses ($\dot{Z}_k^{\mathrm{OM}}$). The sum of the last two terms is denoted by ($\dot{Z}_k$). For example, for a component receiving heat transfer (subscript q) and generating power (subscript w), we write

$$\sum_e \dot{C}_{e,k} + \dot{C}_{w,k} = \dot{C}_{q,k} + \sum_i \dot{C}_{i,k} + \dot{Z}_k. \tag{1.8.6}$$

This equation simply states that the total cost of the exiting exergy transfers equals the total expenditure to obtain them: the cost of the entering exergy streams plus the capital and other costs. When a component receives power (as in a compressor or a pump) the term $\dot{C}_{w,k}$ would move with its positive sign to the right side of this expression. The term $\dot{C}_{q,k}$ would appear with its positive sign on the left side if there is a heat transfer *from* the component. Cost balances are generally written so that all terms are positive.

Introducing the cost rate expressions of Equations 1.8.3 and 1.8.4, Equation 1.8.6 becomes

$$\sum_e (c_e \dot{E}_e)_k + c_{w,k}\dot{W}_k = c_{q,k}\dot{E}_{q,k} + \sum_i (c_i \dot{E}_i)_k + \dot{Z}_k. \tag{1.8.7}$$

The exergy rates exiting and entering the kth component denoted by $\dot{E}_{e,k}, \dot{W}_k, \dot{E}_{q,k}$, and $\dot{E}_{i,k}$ are calculated in an exergy analysis conducted at a previous stage. The term $\dot{Z}_k$ is obtained by first calculating the capital investment and O&M costs associated with the kth component and then computing the levelized values of these costs per unit of time (year, hour, or second) of system operation [see Bejan et al. (1996) and Tsatsaronis et al. (1984, 1986)].

The variables in Equation 1.8.7 are the levelized costs per unit of exergy for the exergy transfers associated with the kth component: $c_{e,k}$, $c_{w,k}$, $c_{q,k}$, and $c_{i,k}$. In analyzing a component, we may assume that the costs per exergy unit are known for all entering streams. These costs are known from the components they exit or, if a stream enters the overall system consisting of all components under consideration, from the purchase cost of this stream. Consequently, the unknown variables to be calculated with the aid of the cost balance for the kth component are the costs per exergy unit of the

exiting streams $c_{e,k}$ and, if power or useful heat are generated in that component, the cost per unit of exergy associated with the transfer of power $c_{w,k}$ or heat $c_{q,k}$. Some auxiliary equations are usually necessary to calculate these costs, as discussed next.

Auxiliary Costing Equations

Various approaches for formulating the auxiliary equations are suggested in the literature. However, the method recommended for obtaining an objective set of auxiliary equations consistent with the definitions of fuel and product is detailed by Lazzaretto and Tsatsaronis (2006) and summarized in the following three steps:

Step 1: Exergy Streams

All material and energy streams crossing the boundaries of the component being considered should be first identified, and the exergy values associated with these streams should be calculated.

Step 2: Definition of Fuel and Product

In evaluating the performance of a component, it is generally meaningful and appropriate to operate with exergy differences associated with each material stream between the inlet and outlet of the component. For example, in defining the product of a heat exchanger operating above ambient temperature, we consider only the exergy addition to the cold stream and not the sum of the exergies associated with the material streams at the outlet. Similarly, for defining the fuel of the heat exchanger, we consider only the exergy removal from the hot stream and not the sum of the exergies associated with the material streams at the inlet. Exergy differences (exergy additions to or removals from a stream) should be applied to all material streams undergoing a change of physical exergy (Equation 1.5.5a) and to some material streams undergoing a chemical exergy (Equation 1.5.6) conversion. This approach has been used in developing Table 1.5.1 for all cases except the gasifier/combustion chamber, which is considered next.

In many cases involving conversion of chemical exergy (e.g., conversion of chemical exergy of a solid fuel in chemical and thermal exergy through a gasification process), the purpose of owning and operating the component dictates that the chemical exergy at the outlet is considered on the product side and the chemical exergy of the fuel stream at the inlet on the fuel side. Thus, in the definition of the exergetic efficiency of a gasifier or combustion chamber in Table 1.5.1, the exergy of the "fuel" for the component equals the value of the exergy of the entering fuel stream.

Accordingly, when considering the fuel and product of a component, a decision must be made for each exergy stream with respect to whether an exergy difference or just the exergy values at the inlet or outlet should be included in the definitions of fuel and product. Then, the product consists of all the exergy values to be considered at the outlet plus all the exergy increases between inlet and outlet (i.e., the exergy additions to the respective material streams). Similarly, the fuel consists of the sum of all exergy rates to be considered at the inlet and all the exergy decreases between inlet and outlet (i.e. the exergy removals from the respective material streams).

Step 3: Auxiliary Equations

In general, if there are N_e exergy streams exiting the component being considered, we have N_e unknowns and only one equation, the costs balance (Equation 1.8.7). Therefore, we need to formulate $N_e - 1$ auxiliary equations. This is accomplished with the aid of the F and P rules presented next:

- The F rule refers to the *removal of exergy* from an exergy stream within the component being considered. The F rule states that the total cost associated with this removal of exergy must be equal to the average cost at which the removed exergy was supplied to the same stream in upstream components. The number of auxiliary equations provided by the

F rule is always equal to the number ($N_{e,\mathrm{F}}$) of exiting exergy streams that are considered in the definition of the fuel for the component.

- The P rule refers to the *supply of exergy* to an exergy stream within the component being considered and to the costing of streams associated with the product. The P rule states that each exergy unit is supplied to any stream associated with the product at the *same average cost,* c_{P}. This cost is calculated from the cost balance and the equations obtained by applying the F rule. The number of auxiliary equations provided by the P rule is always equal to $N_{e,\mathrm{P}} - 1$, where $N_{e,\mathrm{P}}$ is the number of exiting exergy streams that are included in the product definition.

Since the total number of exiting streams (N_c) is equal to the sum ($N_{e,\mathrm{F}}+N_{e,\mathrm{P}}$), the F and P rules together provide the required $N_e - 1$ auxiliary equations.

General Example

The general application of these steps may be demonstrated with the aid of Figure 1.8.2.

Step 1: Referring to Figure 1.8.2, there are seven exergy streams (1, 2, and 5 through 9) entering the component (subscript *i*) and seven exergy streams (3 through 8 and 10) exiting the component (subscript *e*). The streams shown in this figure are selected to cover all situations that might be encountered. In an actual component, however, not all of the streams shown in Figure 1.8.2 exist.

Step 2: The exergy streams 1 through 4 are associated with the chemical exergy or the total exergy of the corresponding material streams. The purpose of owning and operating the component dictates that the entering streams 1 and 2 should be part of the fuel, whereas the exiting streams 3 and 4 should be part of the product. For the exergy streams with the numbers 5, 6, 7, and 8, the purpose of the component dictates the consideration of the respective exergy differences between outlet and inlet. These are positive for streams 7 and 8 and negative for streams 5 and 6. Streams 9 at the inlet and 10 at the outlet represent exergy streams associated with the transport of mechanical, electrical, or thermal energy. We conclude that exergy streams 1, 2, 5, 6, and 9 are associated with the fuel, whereas streams 3, 4, 7, 8, and 10 are associated with the product of the component. Thus, the fuel and product of the component, respectively, are

$$\dot{E}_{\mathrm{F}} = \dot{E}_1 + \dot{E}_2 + \left(\dot{E}_{5i} - \dot{E}_{5e}\right) + \left(\dot{E}_{6i} - \dot{E}_{6e}\right) + \dot{E}_9 \tag{1.8.8}$$

$$\dot{E}_{\mathrm{P}} = \dot{E}_3 + \dot{E}_4 + \left(\dot{E}_{7e} - \dot{E}_{7i}\right) + \left(\dot{E}_{8e} - \dot{E}_{8i}\right) + \dot{E}_{10}. \tag{1.8.9}$$

Step 3: In accordance with Equation 1.8.7, the cost balance for the component is

$$\dot{C}_3 + \dot{C}_4 + \dot{C}_{5e} + \dot{C}_{6e} + \dot{C}_{7e} + \dot{C}_{8e} + \dot{C}_{10} = \dot{C}_1 + \dot{C}_2 + \dot{C}_{5i} + \dot{C}_{6i} + \dot{C}_{7i} + C_{8i} + \dot{C}_9 + \dot{Z}. \tag{1.8.10}$$

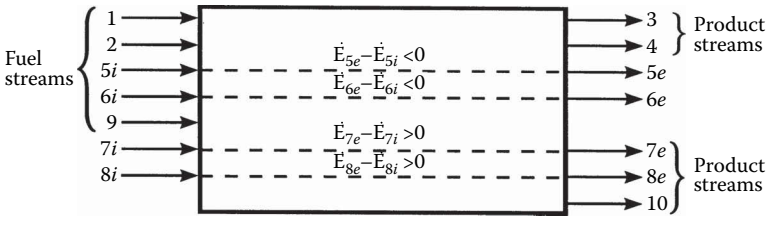

FIGURE 1.8.2 Schematic of a component in a thermal system to define fuel, product, and auxiliary equations.

By grouping the terms associated with fuel and product, we obtain

$$\dot{C}_3+\dot{C}_4+(\dot{C}_{7e}-\dot{C}_{7i})+(\dot{C}_{8e}-\dot{C}_{8i})+\dot{C}_{10}=\dot{C}_1+\dot{C}_2(\dot{C}_{5e}-\dot{C}_{5i})+(\dot{C}_{6e}-\dot{C}_{6i})+\dot{C}_9+\dot{Z}. \quad (1.8.11)$$

The F rule states that the total cost rate associated with the removal of exergy from stream 5 ($\dot{C}_{5i}-\dot{C}_{5e}$) must be equal to the *average* cost at which the removed exergy ($\dot{E}_{5i}-\dot{E}_{5e}$) was supplied to that stream in upstream components. Since each exergy unit was supplied to stream 5 at the average cost of c_{5i}, the F rule for stream 5 becomes

$$\dot{C}_{5i}-\dot{C}_{5e}=c_{5i}(\dot{E}_{5i}-\dot{E}_{5e}). \quad (1.8.12)$$

From this equation we obtain

$$c_{5e}=c_{5i}. \quad (1.8.13)$$

Similarly, for stream 6

$$c_{6e}=c_{6i}. \quad (1.8.14)$$

The P rule states that each exergy unit is *supplied* to all streams associated with the product at the *same* average cost, c_P. This rule leads to the following equation:

$$c_3=c_4=\frac{\dot{C}_{7e}-\dot{C}_{7i}}{\dot{E}_{7e}-\dot{E}_{7i}}=\frac{\dot{C}_{8e}-\dot{C}_{8i}}{\dot{E}_{8e}-\dot{E}_{8i}}=c_{10}=c_P. \quad (1.8.15)$$

Since we assume that the cost rate $\dot{Z}$ and all costs associated with all entering streams are known, we can calculate the unknowns, $\dot{C}_3$, $\dot{C}_4$, $\dot{C}_{5e}$, $\dot{C}_{6e}$, $\dot{C}_{7e}$, $\dot{C}_{8e}$, and $\dot{C}_{10}$, by solving the system of Equations 1.8.11, 1.8.13, 1.8.14, and 1.8.15.

Note that Equation 1.8.11 can be written as

$$c_P\dot{E}_P=\dot{C}_1+\dot{C}_2+(\dot{C}_{5i}-\dot{C}_{5e})+(\dot{C}_{6i}-\dot{C}_{6e})+\dot{C}_9+\dot{Z} \quad (1.8.16)$$

or

$$c_P\dot{E}_P=c_F\dot{E}_F+\dot{Z}, \quad (1.8.17)$$

where $\dot{E}_F$ $\dot{E}_P$, and c_P are given in Equations 1.8.8, 1.8.9, and 1.8.15, respectively. The variable c_F denotes the average cost at which each exergy unit of $\dot{E}_F$ is supplied to the component. Equation 1.8.16 demonstrates that the average cost (c_P) at which each exergy unit is supplied to all streams associated with the product can be calculated by combining the cost balance (Equation 1.8.16) with the equations obtained from the F rule (Equations 1.8.13 and 1.8.14).

After calculating the value of c_P, Equation 1.8.15 can be used to calculate the cost associated with each exiting stream included in the definition of the product. This suggests that the cost balance (Equation 1.8.16) should always be used to calculate the value of c_P with the aid of the auxiliary equations obtained from the F rule.

Exergoeconomic Variables and Evaluation

The cost balances together with the auxiliary equations formulated for each plant component form a system of linear equations, the solution of which provides the cost per exergy unit and the cost rates associated with all exergy streams in the system. The remaining exergoeconomic variables

are calculated from these cost rates and the known exergy rates using the equations for defining the respective exergoeconomic variables, as discussed next.

The exergoeconomic evaluation is conducted at the system component level using the following variables for the kth component. From the exergy analysis we know the

- Rate of exergy destruction $\dot{E}_{\mathrm{D},k}$:

$$\dot{E}_{\mathrm{D},k} = \dot{E}_{\mathrm{F},k} - \dot{E}_{\mathrm{P},k} - \dot{E}_{\mathrm{L},k} \tag{1.8.18}$$

- Exergetic efficiency ε_k:

$$\varepsilon_k = \dot{E}_{\mathrm{P},k} / \dot{E}_{\mathrm{F},k} = 1 - \left(\dot{E}_{\mathrm{D},k} + \dot{E}_{\mathrm{L},k}\right) / \dot{E}_{\mathrm{F},k} \tag{1.8.19}$$

- Exergy destruction ratio y_k:

$$y_{\mathrm{D},k} = \dot{E}_{\mathrm{D},k} / \dot{E}_{\mathrm{F,tot}} \tag{1.8.20}$$

In addition, we calculate the following variables from the exergoeconomic analysis:

- Cost per unit of fuel exergy $c_{\mathrm{F},k}$:

$$c_{\mathrm{F},k} = \dot{C}_{\mathrm{F},k} / \dot{E}_{\mathrm{F},k} \tag{1.8.21}$$

- Cost per unit of product exergy $c_{\mathrm{P},k}$:

$$c_{\mathrm{P},k} = \dot{C}_{\mathrm{P},k} / \dot{E}_{\mathrm{P},k} \tag{1.8.22}$$

- Cost rate associated with exergy destruction $\dot{C}_{\mathrm{D},k}$:

$$\dot{C}_{\mathrm{D},k} = c_{\mathrm{F},k} \dot{E}_{\mathrm{D},k} \tag{1.8.23}$$

- Cost rate associated with exergy losses $\dot{C}_{\mathrm{L},k}$

$$\dot{C}_{\mathrm{L},k} = c_{\mathrm{F},k}\, \dot{E}_{\mathrm{L},k} \tag{1.8.24}$$

- Cost rate associated with capital investment $\dot{Z}_k^{\mathrm{CI}}$
- Cost rate associated with operating and maintenance expenses $\dot{Z}_k^{\mathrm{OM}}$
- Sum $\dot{Z}_k$ of the cost rates associated with capital investment and O&M expenses:

$$\dot{Z}_k = \dot{Z}_k^{\mathrm{CI}} + \dot{Z}_k^{\mathrm{OM}} \tag{1.8.25}$$

- Relative cost difference r_k:

$$r_k = \frac{c_{\mathrm{P},k} - c_{\mathrm{F},k}}{c_{\mathrm{F},k}} = \frac{1-\varepsilon_k}{\varepsilon_k} + \frac{\dot{Z}_k}{c_{\mathrm{F},k}\dot{E}_{\mathrm{P},k}} \tag{1.8.26}$$

- Exergoeconomic factor f:

$$f_k = \frac{\dot{Z}_k}{\dot{Z}_k + c_{\mathrm{F},k}(\dot{E}_{\mathrm{D},k} + \dot{E}_{\mathrm{L},k})} \tag{1.8.27}$$

The value of $c_{F,k}$ depends on the relative position of the kth component in the system and on the interconnections among the kth component and the remaining components. As a general rule, the closer the kth component to the product (fuel) stream of the overall system, the larger (smaller) the value of $c_{F,k}$.

An exergoeconomic analysis

1. Identifies and compares the real cost sources in a system: Equations 1.8.23 through 1.8.25.
2. Illustrates the cost formation process within a system.
3. Calculates separately the cost at which each product stream is generated.
4. Most importantly, assists in the effective cost minimization in a thermal system, particularly its design.

Examples of design optimization (improvement) are given in Bejan et al. (1996), Lin and Tsatsaronis (1993), Tsatsaronis (1993, 2015), and Tsatsaronis et al. (1984, 1985, 1986, 1991, 1992, 1994). This point is discussed in Section 1.9.

1.9 DESIGN OPTIMIZATION

George Tsatsaronis

Design optimization of a thermal system means the modification of the structure and the design parameters of a system to minimize the total levelized cost of the system products under boundary conditions associated with available materials, financial resources, protection of the environment, and government regulation, together with the safety, reliability, operability, availability, and maintainability of the system. A truly optimized system is one for which the magnitude of every significant thermodynamic inefficiency (exergy destruction and exergy loss) is justified by considerations related to costs or is imposed by at least one of the above-mentioned boundary conditions. A *thermodynamic* optimization, which aims only at minimizing the thermodynamic inefficiencies, may be considered as a subcase of design optimization based on cost minimization.

An appropriate formulation of the optimization problem is usually the most important and sometimes the most difficult step of a successful optimization study. In optimization problems, we separate the independent variables into *decision variables* and *parameters*. The values of the decision variables are amenable to change. The values of the parameters are fixed by the particular application. In optimization studies, only the decision variables may be varied. The parameters are independent variables that are each given one specific and unchanging value in any particular model statement. The variables whose values are calculated from the independent variables using a mathematical model are the dependent variables.

However, the optimization of thermal systems involves complexities that render conventional mathematical optimization approaches ineffective. The reasons include the following:

- Some of the input data and functions required for the thermodynamic and, particularly, the economic model might not be available or might not be in the required form. For example, it is not always possible to express the purchased-equipment costs (PEC) as a function of the appropriate thermodynamic decision variables.
- A significant decrease in the product costs may be achievable only through changes in the structure of the system, but such changes are seldom elicited from conventional optimization techniques focusing on the optimization of a particular structure. Moreover, it is not always practical to develop a mathematical optimization model for every promising system structure.
- Even if all the required information is available, the complexity of the system might not allow a satisfactory mathematical model to be formulated and solved in a reasonable time. Very often developing an appropriate superstructure for the problem under consideration (to simultaneously optimize the structure of the system and the decision variables) results in a very complex optimization problem that cannot be handled by the available mathematical tools (e.g., mixed integer nonlinear programing).

In such cases, the application of exergoeconomic techniques may provide significant benefits for the optimization process. The more complex the thermal system, the larger the expected benefits, particularly when chemical reactions are involved. The interactions of exergoeconomics with several other areas during the optimization procedure are shown schematically in Figure 1.9.1. Exergoeconomics uses results from the synthesis, cost analysis, and simulation of thermal systems and provides useful information for the evaluation and optimization of these systems as well as for the application of expert systems to improve the design and operation of such systems.

The following section presents the main features of a general methodology that can be used to evaluate and iteratively optimize the design of a thermal system.

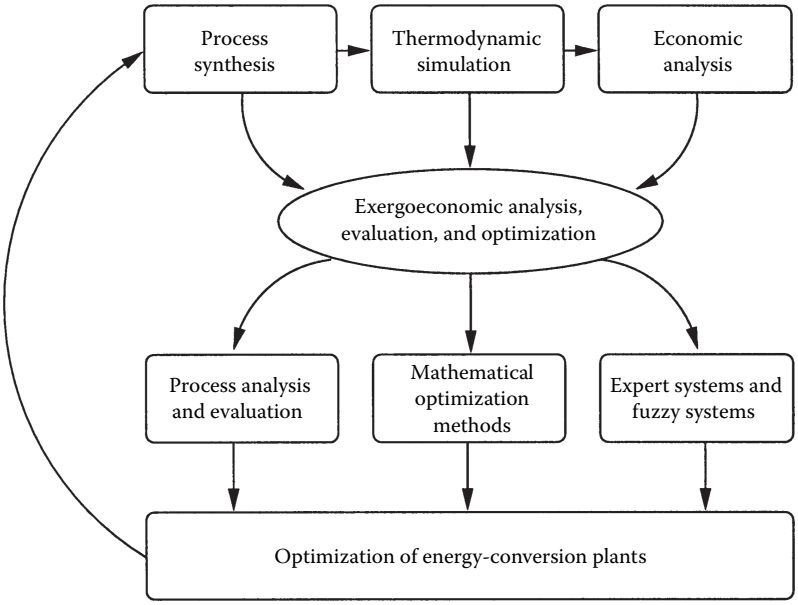

FIGURE 1.9.1 Interactions of exergoeconomics with other areas of engineering and optimization procedure.

An Iterative Exergoeconomic Procedure for Optimizing the Design of a Thermal System

The conventional approach to optimization is to iteratively optimize subsystems and/or ignore the influence of some structural changes and decision variables. An effective alternative approach for the optimization of complex systems is the following iterative exergoeconomic optimization technique that consists of seven steps:

1. In the first step, a workable design is developed. The guidelines presented in Section 1.7 and in Bejan et al. (1996), Lin and Tsatsaronis (1993), Linnhoff et al. (1982), Sama (1993), Tsatsaronis (1993), and Tsatsaronis and Pisa (1994) may assist in developing a workable design that is relatively close to the optimal design. Thus, the use of these guidelines can reduce the total number of required iterations.
2. A detailed exergoeconomic analysis and, if necessary, a pinch analysis are conducted for the design configuration developed in the previous step. The results are used to determine design changes that are expected to improve the design being considered. In this step, and in steps 3 through 7, we consider only changes in the decision variables that affect both the exergetic efficiency and the investment costs. The remaining decision variables are optimized in step 8.
3. A component optimization may be conducted for one or two components in isolation when in these components the sum of the cost rates $(\dot{Z}_k + \dot{C}_{D,k})$ is *significantly* higher than the same sum for the remaining components. For this, we assume that the costs per exergy unit remain constant for all inlet streams. Step 3 is meaningful only for components in which each of the terms $\dot{Z}_k$ and $\dot{C}_{D,k}$ has a significant contribution to the costs associated with the respective component. If not, step 3 should either be omitted or, preferably, replaced by (1) an efficiency maximization procedure when $\dot{C}_{D,k}$ is the dominating cost rate, or (2) an investment cost minimization procedure when $\dot{Z}_k$ is the dominating cost rate. A different approach is discussed by Tsatsaronis et al. (1991, 1994). The sum $(\dot{Z}_k + \dot{C}_{D,k})$ is a measure

of the economic importance of the kth component. Therefore, the components should be considered in order of descending value of this sum. The quality of this information is significantly improved when we consider only *avoidable* costs (see also Section 1.12) associated with both the capital investment and the cost of exergy destruction in the kth component (Tsatsaronis and Park, 2002).

4. The exergoeconomic factor f_k is used to identify the major cost source (capital investment or cost of exergy destruction).
   a. When the f_k value is high, investigate whether it is cost-effective to reduce the capital investment of the kth component, usually at the expense of the component efficiency.
   b. When the f_k value is low, try to improve the component efficiency by accepting an increase in the capital investment.
5. Eliminate any subprocesses that increase the exergy destruction or exergy loss without contributing to the reduction of capital investment or of fuel costs for other components.
6. Consider improving the exergetic efficiency of a component if it has a relatively low exergetic efficiency or relatively large values for the rate of exergy destruction, the exergy destruction ratio, or the exergy loss ratio.
7. Based on the results from steps 2 through 6, a new design is developed and the value of the objective function for this design is calculated. In comparison with the previous design, if the value of the objective function has been improved, we may decide to proceed with another iteration that involves steps 2 through 7. If, however, the value of the objective function is not better in the new design than in the previous one, we may either revise some design changes and repeat steps 2 through 7 or proceed with step 8.
8. In this step, we use an appropriate mathematical optimization technique to optimize the decision variables that affect the investment costs but not the exergetic efficiency. At the end of this step, a cost-optimal design is obtained.
9. Finally, a parametric study may be conducted to investigate the effect on the optimization results of some parameters used and/or assumptions made in the optimization procedure.

When applying this methodology, it is important to recognize that the values of all thermoeconomic variables depend on the component types: heat exchanger, compressor, turbine, pump, chemical reactor, and so forth. Accordingly, whether a particular value is judged to be high or low can be determined only with reference to a particular class of components. Application of fuzzy inference systems could also be useful in making such judgments (Cziesla and Tsatsaronis, 1999).

It is also important to consider the effects of contemplated design changes in one component on the performance of the remaining components. These effects may be determined either by inspection of the system flowsheets or by using a simulation program.

A cogeneration system studied by Frangopoulos (1994), Tsatsaronis and Pisa (1994), Valero et al. (1994), and von Spakovsky (1994) is used in the following case to demonstrate the application of steps 1, 2, 4, and 7. Examples of exergoeconomic evaluations and improvements of complex thermal systems are discussed by Tsatsaronis et al. (1991, 1992, 1994).

Case Study

Figure 1.8.1 presents the base-case design of a cogeneration system that develops a net power output of 30 MW and provides 14 kg/s of saturated water vapor at 20 bar. Not all data assumed for this system are realistic. The investment costs have been artificially increased to demonstrate the application of the exergoeconomic methodology to a variety of components. The optimization of a similar cogeneration system would in reality be significantly easier because the components of a gas turbine system would not be optimized individually, as done here.

The first five columns of Table 1.9.1 show relevant thermodynamic and economic data. The second column of Table 1.9.2 shows the assumed PEC for each component in the base-case design.

[a] For the overall plant, we have $\dot{C}_{P,tot} = \$3617/h$ and $\dot{C}_{L,tot} = \dot{C}_7 = \$145/h$.

These costs are obtained from the cost equations given in Appendix B of Bejan et al. (1996). The remaining direct costs, as well as the indirect costs, are estimated. The total capital investment of the cogeneration system in the base case is approximately $46 million in mid-1994 dollars. Table 7.9 in Bejan et al. (1996) summarizes the parameters and assumptions used in the economic analysis, which is based on the total revenue-requirement method (EPRI Technical Assessment Guide, 1991).

The year-by-year economic analysis results in the levelized annual costs for fuel ($\$10.4 \times 10^6$), operation and maintenance ($\$6.0 \times 10^6$), and carrying charges ($\$10.5 \times 10^6$) for a levelization time period of 10 years. These values are the corresponding levelized current-dollar costs obtained for the base case. The levelized costs are used as input data for the thermoeconomic analysis and optimization. The cost flow rates in the system are obtained by dividing the levelized annual costs by the number of hours of system operation per year.

The methodology introduced earlier will now be applied to the case study cogeneration system. The objectives are to identify the effects of the design variables on the costs and suggest values of

the design variables that would make the system more cost-effective. The key design variables—the decision variables—for the cogeneration system are the compressor pressure ratio p_2/p_1, the isentropic compressor efficiency η_{sc}, the isentropic turbine efficiency η_{st}, the temperature of the air entering the combustion chamber T_3, and the temperature of the combustion products entering the gas turbine T_4.

First Design Case

The following nominal values of the decision variables correspond to the first workable design (base-case design) developed for the cogeneration system of Figure 1.8.1 and Tables 1.9.1 and 1.9.2:

$$p_2/p_1 = 10,\ \eta_{sc} = \eta_{st} = 0.86,\ T_3 = 850\,\text{K},\ T_4 = 1520\,\text{K}.$$

The last two columns of Table 1.9.1 and the last 10 columns of Table 1.9.2 summarize the values of the thermoeconomic variables calculated for each component of the cogeneration system for the base-case design. In accordance with the methodology presented, the components are listed in order of descending value of the sum $(\dot{C}_D + \dot{Z})$.

The combustion chamber, the gas turbine, and the air compressor have the highest values of the sum $(\dot{Z} + \dot{C}_D)$ and are, therefore, the most important components from the thermoeconomic viewpoint. The low value of the exergoeconomic factor f for the combustion chamber shows that the costs associated with the combustion chamber are almost exclusively due to exergy destruction. A part of the exergy destruction in a combustion chamber can be avoided by preheating the reactants and by reducing the heat loss and the excess air, but this usually leads only to a small reduction in the cost of exergy destruction. For simplicity, we assume here that the heat loss cannot be further reduced. The excess air is determined by the desired temperature T_4 at the inlet to the gas turbine. The temperature T_4 is a key design variable for it affects both the thermodynamic performance and the investment costs of the overall system (exergy destruction and investment cost of the combustion chamber, gas turbine, air preheater, and heat-recovery steam generator (HRSG), as well as exergy loss associated with stream 7).

An increase in the heat-transfer rate within the air preheater, achieved through an increase in temperature T_3, also results in a decrease of the exergy destruction in the combustion chamber. Thus, the temperature T_3 is also a key design variable because, in addition to the combustion chamber, it affects the exergy loss associated with stream 7 as well as the performance and investment costs of the air preheater and the HRSG. Holding all other decision variables constant, the higher the temperature T_3, the smaller the average temperature difference in the air preheater and the HRSG. A decrease in the average temperature difference in these heat exchangers results in an increase in both the exergetic efficiency and the capital investment for each heat exchanger. In summary, by considering measures for reducing the high cost rate associated with the exergy destruction in the combustion chamber of the cogeneration system, two key design variables have been identified: temperatures T_3 and T_4. An increase in these temperatures reduces the $\dot{C}_D$ value for the combustion chamber and other components but increases their capital investment costs.

Turning next to the gas turbine, which has the second highest value of the sum $(\dot{Z} + \dot{C}_D)$, the relatively large value of the factor f suggests that the capital investment and O&M costs dominate. The capital investment cost of the gas turbine depends on temperature T_4, pressure ratio p_2/p_1, and isentropic efficiency η_{st}. To reduce the high $\dot{Z}$ value associated with the gas turbine, a reduction in the values of these variables should be considered.

The air compressor has the highest f value and the second highest relative cost difference r among all components. Thus, we would expect the cost-effectiveness of the entire system to improve if the $\dot{Z}$ value for the air compressor is reduced. This may be achieved by reducing the pressure ratio p_2/p_1 and/or the isentropic compressor efficiency η_{sc}.

The HRSG has the lowest exergetic efficiency and the highest r value among all the components. As the f value indicates, almost 45% of the relative cost difference is caused by the $\dot{Z}$ value in this component, with the remaining 55% caused by exergy destruction. Thus, we might conclude that a decrease of the exergy destruction in the HRSG could be cost-effective for the entire system, even if this would increase the investment cost associated with this component. The exergy destruction in the HRSG can be reduced by decreasing the values of T_6 and T_7. A decrease in the value of T_7 also results in a decrease in the exergy loss from the total system. In terms of the decision variables, increasing T_3 and/or decreasing T_4 at fixed values of the remaining decision variables would reduce temperatures T_6 and T_7.

The relatively high value of f in the air preheater suggests a reduction in the investment cost of this component. This can be achieved by decreasing T_3. It should be noted, however, that changes suggested by the evaluation of this component should only be considered if they do not contradict changes suggested by components with a larger value of $(\dot{C}_D + \dot{Z})$.

Summarizing the foregoing conclusions, the following changes in the design variables are expected to improve the cost-effectiveness of the system:

- Increase the value of T_3 as suggested by the evaluation of the combustion chamber and HRSG.
- Decrease the pressure ratio p_2/p_1 (and thus p_4/p_5) and the isentropic efficiencies η_{sc} and η_{st}, as suggested by the evaluation of the air compressor and gas turbine.
- Maintain T_4 fixed, since we get contradictory indications from the evaluation of the combustion chamber on one side and the gas turbine and HRSG on the other side.

Second Design Case

Contemplating the effects of changes made in accordance with the previous list in the values of the design variables used in the first iteration, the following new values are selected for the second design case:

$$T_3 = 870\,\text{K},\ T_4 = 1520\,\text{K}\,(\text{unchanged}),\ p_2/p_1 = 9,\ \eta_{sc} = 85\%,\ \eta_{st} = 85\%.$$

The new values of the thermoeconomic variables for each component are summarized in Table 1.9.3. In the new design, the combustion chamber, the gas turbine, and the air compressor also have the highest values of the sum $(\dot{C}_D + \dot{Z})$ and, therefore, are still the most important components from the thermoeconomic viewpoint. The high cost rate associated with the combustion chamber can be reduced by increasing the values of T_3 and T_4. In the evaluation of the cogeneration system, we should, however, consider that the value of the combustion chamber would always be the highest among the $(\dot{C}_D + \dot{Z})$ values for the components of the cogeneration system.

The gas turbine now has the highest f value. The reduction in this value from 82.7% in the base design to 81.0% in the new design is relatively small compared with a target value of below 75%. This observation suggests (1) a significant decrease in the values of η_{st} and/or p_2/p_1—that is, a decrease greater than the decrease in these variables in the previous step: from 86 to 85% and from 10% to 9%, respectively, and (2) a reduction in the value of T_4. Note that the decrease in the T_4 value contradicts the corresponding suggestion from the combustion chamber.

The high values of the exergoeconomic factor f and the relative cost difference r for the air compressor suggest a decrease in the values of the decision variables p_2/p_1 and η_{sc}.

The anticipated increase in the exergetic efficiency of the HRSG (see first iteration) was not realized because of the interdependence of the components. The reduction in the values of p_2/p_1, η_{sc}, and η_{st} for the compressor and the turbine leads to an increase in the temperature differences (and, therefore, a decrease in the exergetic efficiency) of the HRSG. Thus, the thermoeconomic evaluation of the HRSG suggests that the T_3 value increases and the T_4 value decreases.

TABLE 1.9.3

	(94.3)	(3.69)	(4.01)	(11.71)	(13.75)	(155)	(296)	(451)	(17.5)	(65.6)
Air compressor	92.1	2.34	2.69	16.97	23.96	143	546	689	41.2	79.2
	(90.5)	(2.99)	(3.25)	(13.75)	(18.38)	(148)	(324)	(472)	(33.6)	(68.7)
HRSG	66.6	6.40	7.35	13.26	25.60	305	261	566	93.1	46.1
	(67.6)	(6.10)	(6.65)	(11.71)	(23.51)	(257)	(284)	(541)	(100.7)	(52.5)
Air preheater	84.7	3.15	3.62	13.26	18.94	150	206	356	42.9	57.8
	(85.6)	(4.97)	(4.90)	(11.71)	(16.53)	(190)	(275)	(464)	(41.2)	(59.2)
Overall plant	49.1	41.01	47.09	4.57	21.80	675	1922	2597	377.0	74.0
	(46.6)	(44.79)	(48.79)	(4.57)	(19.06)	(736)	(1424)	(2160)	(317.2)	(65.9)

Note: For the overall plant in the new design case, we have $\dot{C}_{P,tot}$=$3355/h and $\dot{C}_{L,tot}=\dot{C}_7$=$157/h. The values given in parentheses refer to the third iteration case considered here (T_3=910 K; T_4=1480 K; p_2/p_1=7; η_{sc}=0.83). For the overall plant in this design case, we have $\dot{C}_{P,tot}$=$2934/h and $\dot{C}_{L,tot}=\dot{C}_7$=$167/h.

The relatively high value of f in the air preheater suggests a reduction in the T_3 value. As noted in the first iteration, however, changes suggested by the evaluation of this component should only be considered if they do not contradict changes suggested by components with a higher value of the sum $(\dot{C}_D+\dot{Z})$.

Summarizing the foregoing suggestions from the thermoeconomic evaluation of each component, the following changes in the decision variables are expected to improve the cost-effectiveness of the cogeneration system:

- Increase the value of T_3, as suggested by the evaluation of the combustion chamber and HRSG.
- Decrease the pressure ratio p_2/p_1 and the isentropic efficiencies η_{sc} and η_{st} as suggested by the evaluations of the air compressor and gas turbine.
- Decrease the temperature T_4, as suggested from the evaluations of the gas turbine and the HRSG.

Third Design Case

To illustrate the effect of the suggested changes in the decision variables on the overall costs, we use the following new set of values for the design variables:

$$T_3 = 910\,\text{K},\ T_4 = 1480\,\text{K},\ p_2/p_1 = 7,\ \eta_{sc} = 0.83,\ \text{and}\ \eta_{st} = 0.83.$$

The results from the thermoeconomic analysis for the last set of values are summarized in Table 1.9.3 by the values given in parentheses. A comparison of the corresponding values shown in Table 1.9.3 demonstrates the improvement in the cost-effectiveness of the last design case. As a result of these changes, the value of the objective function $\dot{C}_{P,tot}$ is reduced from $3355/h to $2934/h. The $\dot{C}_7$ value has increased from $157/h in the new case to $167/h in the last case. This increase, however, is outweighed by the decreases in the values of $(\dot{C}_{D,k}+\dot{Z}_k)$.

Additional Iterations

Additional iterations conducted in a similar way may be necessary to further decrease the value of the objective function and/or establish a nearly optimal design case. The cost-optimal values of the decision variables (Bejan et al., 1996) are

$$T_3 = 910\,\mathrm{K},\ T_4 = 1463.0\,\mathrm{K},\ p_2/p_1 = 5.77,\ \eta_{sc} = 0.811,\ \text{and}\ \eta_{st} = 0.845.$$

With these values, we obtain the objective function $\dot{C}_{P,tot} = \$2870/\mathrm{h}$. For the cost-optimal case, the exergetic efficiency of the overall system is 45.0%, the cost rate associated with the exergy loss is \$205/h, and the pinch temperature difference in the HRSG is 49.7 K.

1.10 ECONOMIC ANALYSIS OF THERMAL SYSTEMS

George Tsatsaronis

Generally, each company has a preferred approach for conducting an economic analysis and calculating the costs associated with the products generated in a thermal system. Here only a few general introductory comments are made. A detailed discussion of an economic analysis is given in Bejan et al. (1996).

A complete economic analysis consists of the following three steps:

Step 1: Estimate the required total capital investment.

Step 2: Determine the economic, financial, operating, and market-associated parameters for the detailed cost calculation.

Step 3: Calculate the cost of all products generated by the system.

These steps are now discussed in turn.

Estimation of Total Capital Investment

The capital needed to purchase the land, build all the necessary facilities, and purchase and install the required machinery and equipment for a system is called *fixed-capital investment*. The fixed-capital investment represents the total system cost, assuming a zero-time design, and construction period (overnight construction). The *total capital investment* is the sum of the fixed-capital investment and other outlays (e.g., startup costs, working capital, costs of licensing, research and development, as well as interest during construction).

The costs of all permanent equipment, materials, labor, and other resources involved in the fabrication, erection, and installation of the permanent facilities are the *direct costs*. The *indirect costs* (e.g., costs associated with engineering, supervision, and construction, including contractor's profit and contingencies) do not become a permanent part of the facilities but are required for the orderly completion of the project. The fixed-capital investment is the sum of all direct and indirect costs.

The *purchased equipment costs* are estimated with the aid of vendors' quotations, quotations from experienced professional cost estimators, calculations using extensive cost databases, or estimation charts. If necessary, the cost estimates of purchased equipment must be adjusted for size (with the aid of scaling exponents) and for time (with the aid of cost indices). The remaining direct costs are associated with equipment installation, piping, instrumentation, controls, electrical equipment and materials, land, civil structural and architectural work, and service facilities. These direct costs, indirect costs, and other outlays, if they cannot be estimated directly, are calculated as a percentage of the purchased equipment costs or alternatively as a percentage of the fixed-capital investment.

For more detailed information on the estimation of the total capital investment, readers should consult the references by Bejan et al. (1996), Chauvel et al. (1976), Douglas (1988), Garrett (1989), Guthrie (1969, 1970, 1974), Humphreys (1991), Perry and Chilton (1973), Peters and Timmerhaus (1991), Ulrich (1984), and Valle-Riestra (1983).

Principles of Economic Evaluation

Decisions about expenditures generally require consideration of the *time value of money*: If an amount of money P (*present value*) is deposited in an account earning i percent interest per time period, and the interest is compounded at the end of each of n time periods, the amount will grow to a *future value* (F):

$$F = P(1 + i)^n . \tag{1.10.1}$$

In engineering economy, the unit of time is usually taken as the year. If compounding occurs p times per year ($p \geq 1$) for a total number of n years ($n \geq 1$) and i is the *annual rate of return* (or *cost-of- money rate*), Equation 1.10.1 becomes

$$F = P\left(1 + \frac{i}{p}\right)^{np}. \tag{1.10.2}$$

Then the annual effective rate of return is

$$i_{\text{eff}} = \left(1 + \frac{i}{p}\right)^{p} - 1, \tag{1.10.3}$$

and the general equation for calculating the future value becomes

$$F = P(1 + i_{\text{eff}})^{n}. \tag{1.10.4}$$

When Equation 1.10.4 is used to calculate the present value (P) of a future amount (F), the term i_{eff} is called effective *discount rate*. Table 1.10.1 summarizes some basic formulas and factors used in economic analysis.

TABLE 1.10.1
Summary of Basic Formulas and Factors Used in Economic Analysis

Formula[a]	Factor
$\frac{F}{P} = \left(1 + i_{\text{eff}}\right)^{n}$	Single-payment compound-amount factor (SPCAF)
$\frac{P}{F} = \frac{1}{\left(1 + i_{\text{eff}}\right)^{n}}$	Single-payment present-worth factor or single-payment discount factor (SPDF)
$\frac{F}{A} = \frac{\left(1 + i_{\text{eff}}\right)^{n} - 1}{i_{\text{eff}}}$	Uniform-series compound-amount factor (USCAF)
$\frac{A}{F} = \frac{i_{\text{eff}}}{\left(1 + i_{\text{eff}}\right)^{n} - 1}$	Uniform-series sinking fund factor (USSFF)
$\frac{P}{A} = \frac{\left(1 + i_{\text{eff}}\right)^{n} - 1}{i_{\text{eff}}\left(1 + i_{\text{eff}}\right)^{n}}$	Uniform-series present-worth factor (USPWF)
$\frac{A}{P} = \frac{i_{\text{eff}}\left(1 + i_{\text{eff}}\right)^{n}}{\left(1 + i_{\text{eff}}\right)^{n} - 1}$	Capital-recovery factor (CRF)
$\frac{C_k}{P_0} = \frac{\left(1 + i_{\text{eff}}\right)^{n}}{\left(1 + i_{\text{eff}}\right)^{n} - 1}$	Capitalized-cost factor (CCF)
$\frac{A}{P_0} = \frac{k\left(1 - k^{n}\right)}{1 - k}\text{CRF}$	Constant-escalation levelization factor (CELF)

[a] In these expressions, cost-of-money compounding and ordinary annuities are assumed. The exponent n denotes the number of years and i_{eff} is the effective rate of return. The factor k is defined by Equation 1.10.9.

Annuities

An annuity is a series of *equal-amount* money transactions occurring at equal time intervals or periods (usually years). The most common type of annuity is the *ordinary annuity*, which involves money transactions occurring at the end of each period.

If an amount A is deposited at the end of each period in an account earning i_{eff} percent per period, the future sum F (*amount of the annuity*) accrued at the end of the nth period is

$$F = A\frac{(1+i_{\text{eff}})^n - 1}{i_{\text{eff}}}. \tag{1.10.5}$$

The term $[(1+i_{\text{eff}})^n - 1]/i_{\text{eff}}$ is called the *uniform-series compound amount factor* and the reciprocal $i_{\text{eff}} / [(1+i_{\text{eff}})^n - 1]$ is called the *uniform-series sinking fund factor.* These terms are also listed in Table 1.10.1.

The *present value* or *present worth of an annuity* (P) is defined as the amount of money that would have to be invested at the beginning of the first time interval at an effective compound rate of return per period i_{eff} to yield a total amount at the end of the last time interval equal to the amount of the annuity:

$$\frac{P}{A} = \frac{(1+i_{\text{eff}})^n - 1}{i_{\text{eff}}(1+i_{\text{eff}})^n}. \tag{1.10.6}$$

The expression on the right side of this equation is called *uniform-series present-worth factor.* The reciprocal of this factor is the *capital-recovery factor* (CRF, see Table 1.10.1), which may be used to convert the expenditures associated with capital investment into an annuity.

Cost Escalation

The *real escalation rate* of an expenditure is the annual rate of expenditure change caused by factors such as resource depletion, increased demand, and technological advances. The *nominal* (or *apparent*) *escalation rate* (r_{n}) is the total annual rate of change in an expenditure and includes the effects of both the real escalation rate (r_{r}) and the *inflation rate* (r_{i}):

$$(1+r_{\mathbf{n}}) = (1+r_{\mathbf{n}})(1+r_{\mathbf{r}}). \tag{1.10.7}$$

In the analysis of thermal systems, we often assume that all costs except fuel costs and the prices of byproducts change annually with the average inflation rate (i.e., $r_{\text{r}} = 0$). When fossil-fuel costs are expected over a long period of future years to increase on the average faster than the predicted inflation rate, a positive real escalation rate for fuel costs may be appropriate for the economic analysis of the thermal system being studied.

Levelization

Cost escalation applied to an expenditure over an n-year period results in a nonuniform cost schedule in which the expenditure at any year is equal to the previous year expenditure multiplied by $(1+r_{\text{n}})$. The *constant-escalation levelization factor* (CELF, see Table 1.10.1) is used to express the relationship between the value of the expenditure at the beginning of the first year (P_0) and an equivalent annuity (A), which is now called a *levelized value*. This levelization factor depends on

the effective annual cost-of-money rate i_{eff}, the number of time periods n, and the nominal escalation rate r_{n}:

$$\frac{A}{P_0} = \text{CELF} = \frac{k(1-k^n)}{1-k}\text{CRF}, \tag{1.10.8}$$

where

$$k = \frac{1+r_{\text{n}}}{1+i_{\text{eff}}}. \tag{1.10.9}$$

The concept of levelization is general and is defined as the use of time-value-of-money arithmetic to convert a series of varying quantities to a financially equivalent constant quantity (annuity) over a specified time interval. In exergoeconomics, the concept of levelization is applied to calculate representative values for all considered time periods: the levelized annual fuel costs, the levelized annual operating and maintenance expenses, and the levelized total cost associated with the capital investment. Among all available approaches, the *total revenue requirement method* (Bejan et al., 1996; Tsatsaronis et al., 1984, 1986) is the most detailed and most appropriate method for that purpose.

Parameters and Assumptions

To conduct a detailed economic analysis, several parameters must be specified and assumptions must be made for the entire life of the system being analyzed. These include

- The estimated total capital investment
- Current fuel cost and operating and maintenance expenditures
- Average capacity factors, average general inflation rate, and average nominal escalation rate of each expenditure
- Beginning and length of the design and construction period and of the operation period
- Allocation of investment expenditures to the individual years of design and construction
- Plant financing sources and associated required returns on capital
- Tax rates
- Depreciation method used for tax purposes
- Insurance cost

These parameters and assumptions are discussed in Bejan et al. (1996) and the EPRI Technical Assessment Guide (1991).

Calculation of the Product Costs

In a conventional economic analysis, we must identify among all product streams of a thermal system the *main product* stream; its cost is calculated from the overall cost balance. To proceed in this way, it is necessary to make assumptions with respect to the *selling prices* of all the remaining product streams, which are now *byproduct* streams.

However, when exergoeconomics is applied to a thermal system, the *total* annual levelized costs associated with owning and operating the system are apportioned among the product streams using the exergy costing approach and the auxiliary costing equations as discussed in Section 1.8. Thus, the cost associated with each product stream is calculated directly, and there is no need to use the prices of the byproducts.

1.11 EXERGOENVIRONMENTAL ANALYSIS

George Tsatsaronis

To improve the performance of an energy conversion system from the environmental point of view, we must understand the formation of environmental impact within the system. The term environment here refers to the physical environment, which is different from the thermodynamic environment used in exergy analysis. A so-called exergoenvironmental analysis rests on the notion that exergy, being the commodity of value, is the only rational basis for assigning not only monetary values but also environmental impact values to the transport of exergy and to the inefficiencies within a system (Meyer et al, 2009). We refer to this approach as *exergoenvironmental costing*.

The exergoenvironmental analysis consists of three steps: the first step is an exergetic analysis of the overall energy conversion system. In the second step, a life-cycle assessment (LCA) of (1) each relevant system component and (2) all relevant input streams to the overall system is carried out. In the third step, the environmental impact obtained from the LCA is assigned to the exergy streams in the system, *exergoenvironmental variables* are calculated, and an *exergoenvironmental evaluation* is conducted. With the aid of an exergoenvironmental analysis, the most important components with the highest environmental impact and the sources of this impact are identified. In the following the last two steps of an exergoenvironmental analysis are discussed.

An LCA is conducted for the input streams, supplied to the overall system, especially the fuel stream(s), and for the full life cycle of components. Inventories of elementary flows (i.e., consumption of natural resources and energy as well as emissions) are calculated following the guidelines of standard approaches. The environmental impact assessment can be performed with an indicator, e.g., the Eco-Indicator 99 (Goedkoop and Spriensma, 2000). This is based on the definition of three damage categories: human health, ecosystem quality, and natural resources. The numbers obtained from the three categories are aggregated and the result is expressed as Eco-Indicator points (pts), where a higher damage corresponds to a higher Eco-Indicator value.

In analogy to the assignment of costs to exergy streams in exergoeconomics, an environmental impact rate and an environmental impact per unit of exergy are assigned to each exergy stream in an exergoenvironmental evaluation. The *environmental impact rate* is the environmental impact expressed, for example, in Eco-Indicator points per unit of time of system operation (Pts/s or mPts/s). The specific (exergy-based) environmental impact (also called the specific *environmental cost*) is the average environmental impact associated with the production of the stream per unit of exergy of the same stream [Pts/(kJ exergy) or mPts/(MJ exergy)].

The further procedure in an exergoenvironmental analysis is identical with that in an exergoeconomic analysis: We only need to replace the term cost (in the exergoeconomic analysis) by the term environmental impact (in the exergoenvironmental analysis). Thus, we formulate an environmental impact balance for each system component, we apply the same auxiliary equations as in exergoeconomics, and we calculate the average environmental impact associated with fuel, product, and exergy destruction within each system component.

Hence, the exergoenvironmental analysis is the only approach that allows engineers to calculate the environmental impact associated with the real thermodynamic inefficiencies (exergy destruction and exergy loss) in the same way as the exergoeconomic analysis provides the cost associated with the same inefficiencies. For a detailed presentation of exergoenvironmental analysis, readers may refer to the following references: Meyer et al. (2009), Petrakopoulou et al. (2011a,b), Tsatsaronis (2011), and Tsatsaronis and Morosuk (2015).

1.12 ADVANCED EXERGY-BASED METHODS

George Tsatsaronis

The exergetic, exergoeconomic, and exergoenvironmental analyses discussed so far provide very useful information (not obtainable by other means) for the improvement of an energy conversion system from the viewpoints of thermodynamics, economics, and ecology. However, these approaches do not fully consider (1) the mutual interdependencies among the system components and (2) the real potential for improving each component of the energy conversion system (Tsatsaronis, 1999b). Advanced exergy-based analyses enable these evaluations.

The interactions among the components of the same system can be estimated and the quality of the conclusions obtained from an exergoeconomic and exergoenvironmental evaluation can be improved by splitting

- The exergy destruction within each (important) system component, the cost of exergy destruction, and the environmental impact associated with exergy destruction
- The component-related investment cost, and the environmental impact associated with manufacturing and installing each important system component

into endogenous/exogenous and avoidable parts (e.g., Tsatsaronis, 2008; Tsatsaronis and Morosiuk, 2008; Tsatsaronis, 2011). We call the analyses based on such splitting *advanced* (*exergetic*, *exergoeconomic*, or *exergoenvironmental*) *analyses*.

Endogenous (exergy destruction, capital investment cost, and construction-of component-related environmental impact) is that part of the considered variable (associated with a system component) that is obtained when all other components operate ideally and the component being considered operates with the same efficiency as in the real system. The *exogenous* part of the variable is the difference between the total value of the variable for the same component and the endogenous part.

The *unavoidable* exergy destruction, cost, or environmental impact cannot be further reduced due to technological limitations such as availability and cost of materials and manufacturing methods. The difference between total and unavoidable values for a component is the *avoidable value*. In the improvement efforts, only the avoidable values should be considered.

By combining the two splitting approaches, we obtain the following:

- The *avoidable endogenous* part of a variable that can be reduced by improving the considered component from the exergetic, economic, and environmental points of view.
- The *avoidable exogenous* part of the same variable that can be reduced by a structural improvement of the overall system, or by improving the remaining components, and always, of course, by improving the component being considered.

These variables are used in the iterative improvement of the system and in establishing research priorities.

The advanced exergy-based methods significantly improve the quality of the obtained information and the optimization procedures. For a detailed presentation of the advanced exergy-based methods and for applications, readers may refer to Boyano et al. (2012), Morosuk and Tsatsaronis (2009a,b, 2011, 2012), Morosuk et al. (2012), Petrakopoulou et al. (2011a,b, 2012, 2014), Tsatsaronis (2008, 2011), Tsatsaronis and Morosuk (2008, 2009, 2015), and Tsatsaronis and Park (2002).

2.1 FLUID STATICS

Stanley A. Berger

Equilibrium of a Fluid Element

If the sum of the external forces acting on a fluid element is zero, the fluid will be either at rest or moving as a solid body—in either case, we say the fluid element is in equilibrium. In this section we consider fluids in such an equilibrium state. For fluids in equilibrium, the only internal stresses acting will be normal forces, since the shear stresses depend on velocity gradients, and all such gradients, by the definition of equilibrium, are zero. If one then carries out a balance between the normal surface stresses and the body forces, assumed proportional to volume or mass, such as gravity, acting on an elementary prismatic fluid volume, the resulting equilibrium equations, after shrinking the volume to zero, show that the normal stresses at a point are the same in all directions, and since they are known to be negative, this common value is denoted by $-p$, p being the pressure.

Hydrostatic Pressure

If we carry out an equilibrium of forces on an elementary volume element $dxdydz$, the forces being pressures acting on the faces of the element and gravity acting in the $-z$ direction, we obtain

$$\frac{\partial p}{\partial x} = \frac{\partial p}{\partial y} = 0, \quad \text{and} \quad \frac{\partial p}{\partial z} = -\rho g = -\gamma \tag{2.1.1}$$

The first two of these imply that the pressure is the same in all directions at the same vertical height in a gravitational field. The third, where γ is the specific weight, shows that the pressure increases with depth in a gravitational field, the variation depending on $\rho(z)$. For homogeneous fluids, for which ρ = constant, this last equation can be integrated immediately, yielding

$$p_2 - p_1 = -\rho g\left(z_2 - z_1\right) = -\rho g\left(h_2 - h_1\right) \tag{2.1.2}$$

or

$$p_2 + \rho g h_2 = p_1 + \rho g h_1 = \text{constant} \tag{2.1.3}$$

where h denotes the elevation. These are the equations for the hydrostatic pressure distribution.

When applied to problems where a liquid, such as the ocean, lies below the atmosphere, with a constant pressure p_{atm}, h is usually measured (positive) downward from the ocean/atmosphere interface and p at any distance h below this interface differs from p_{atm} by an amount

$$p - p_{\text{atm}} = \rho g h \tag{2.1.4}$$

Pressures may be given either as *absolute pressure*, pressure measured relative to absolute vacuum, or *gauge pressure*, pressure measured relative to atmospheric pressure.

Manometry

The hydrostatic pressure variation may be employed to measure pressure differences in terms of heights of liquid columns—such devices are called manometers and are commonly used in wind tunnels and a host of other applications and devices. Consider, for example the U-tube manometer shown in Figure 2.1.1 filled with liquid of specific weight γ, the left leg open to the atmosphere and the right to the region whose pressure p is to be determined. In terms of the quantities shown in the figure, in the left leg

$$p_0 - \rho g h_2 = p_{\text{atm}} \tag{2.1.5a}$$

and in the right leg

$$p_0 - \rho g h_1 = p \tag{2.1.5b}$$

the difference being

$$p - p_{\text{atm}} = -\rho g \left(h_1 - h_2\right) = -\rho g d = -\gamma d \tag{2.1.6}$$

which determines p in terms of the height difference $d = h_1 - h_2$ between the levels of the fluid in the two legs of the manometer.

Hydrostatic Forces on Submerged Objects

The force acting on a submerged object due to the hydrostatic pressure is given by

$$\boldsymbol{F} = \iint p \; \boldsymbol{dA} = \iint p \cdot n \; \boldsymbol{dA} = \iint \rho g h \; \boldsymbol{dA} + p_0 \iint \boldsymbol{dA} \tag{2.1.7}$$

where h is the variable vertical depth of the element $\boldsymbol{dA}$ and p_0 is the pressure at the surface. In turn we consider plane and nonplanar surfaces.

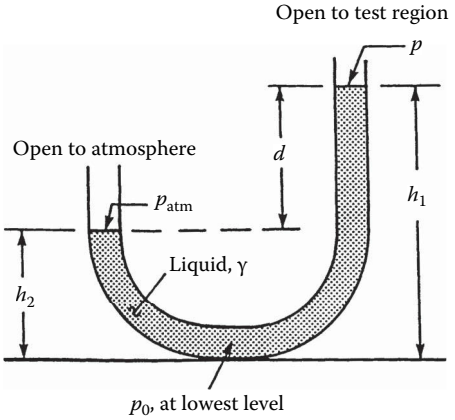

FIGURE 2.1.1 U-tube manometer.

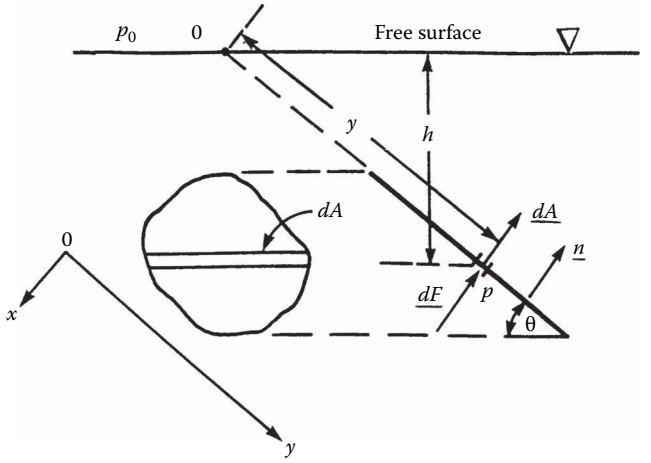

FIGURE 2.1.2 Hydrostatic force on a plane surface.

Forces on Plane Surfaces

Consider the planar surface A at an angle θ to a free surface shown in Figure 2.1.2. The force on one side of the planar surface, from Equation 2.1.7, is

$$\boldsymbol{F} = \rho g \boldsymbol{n} \iint_A h \; dA + p_0 A \boldsymbol{n} \tag{2.1.8}$$

but $h = y \sin\theta$, so

$$\iint_A h \; dA = \sin\theta \iint_A y \; dA = y_c A \sin\theta = h_c A \tag{2.1.9}$$

where the subscript c indicates the distance measured to the centroid of the area A. The total force (on one side) is then

$$\boldsymbol{F} = \gamma h_c \boldsymbol{A} + p_0 \boldsymbol{A} \tag{2.1.10}$$

Hence, the magnitude of the force is independent of the angle θ and is equal to the pressure at the centroid, $\gamma h_c + p_0$, times the area. If we use gauge pressure, the term $p_0 A$ in Equation 2.1.10 is dropped.

Since p is not evenly distributed over A, but varies with depth, F does not act through the centroid. The point of action of $\boldsymbol{F}$, called the *center of pressure*, can be determined by considering moments in Figure 2.1.2. The moment of the hydrostatic force acting on the elementary area dA about the axis perpendicular to the page passing through the point 0 on the free surface is

$$y \; dF = y(\gamma \, y \sin\theta \, dA) \; = \gamma \; y^2 \sin\theta \, dA \tag{2.1.11}$$

so if y_{cp} denotes the distance to the center of pressure,

$$y_{cp} F = \gamma \sin\theta \iint y^2 dA = \gamma \sin\theta I_x \tag{2.1.12}$$

where I_x is the moment of inertia of the plane area with respect to the axis formed by the intersection of the plane containing the planar surface and the free surface (say $0x$). Dividing by $F = \gamma h_c A = \gamma \; y_c \sin\theta A$ gives

$$y_{\text{cp}} = \frac{I_x}{y_c A} \tag{2.1.13}$$

By using the parallel axis theorem, $I_x = I_{xc} + Ay_c^2$, where I_{xc} is the moment of inertia with respect to an axis parallel to $0x$ passing through the centroid, Equation 2.1.13 becomes

$$y_{\text{cp}} = y_c + \frac{I_{xc}}{y_c A} \tag{2.1.14}$$

which shows that, in general, the center of pressure lies below the centroid.

Similarly, we find x_{cp} by taking moments about the y axis, specifically

$$x_{\text{cp}} F = \gamma \sin\theta \iint xy \; dA = \gamma \sin\theta \, I_{xy} \tag{2.1.15}$$

or

$$x_{\text{cp}} = \frac{I_{xy}}{y_c A} \tag{2.1.16}$$

where I_{xy} is the product of inertia with respect to the x and y axes. Again, by the parallel axis theorem, $I_{xy}=I_{xyc}+Ax_cy_c$, where the subscript c denotes the value at the centroid, so Equation 2.1.16 can be written

$$x_{\text{cp}} = x_c + \frac{I_{xyc}}{y_c A} \tag{2.1.17}$$

This completes the determination of the center of pressure (x_{cp}, y_{cp}). Note that if the submerged area is symmetrical with respect to an axis passing through the centroid and parallel to either the x or y axes that $I_{xyc}=0$ and $x_{\text{cp}}=x_c$; also that as y_c increases, $y_{\text{cp}} \to y_c$.

Centroidal moments of inertia and centroidal coordinates for some common areas are shown in Figure 2.1.3.

Forces on Curved Surfaces

On a curved surface the forces on individual elements of area differ in direction so a simple summation of them is not generally possible, and the most convenient approach to calculating the pressure force on the surface is by separating it into its horizontal and vertical components.

A free-body diagram of the forces acting on the volume of fluid lying above a curved surface together with the conditions of static equilibrium of such a fluid column leads to the results that:

1. The horizontal components of force on a curved submerged surface are equal to the forces exerted on the planar areas formed by the projections of the curved surface onto vertical planes normal to the directions of these components, the lines of action of these forces being calculated as described earlier for planar surfaces; and
2. The vertical component of force on a curved submerged surface is equal in magnitude to the weight of the entire column of fluid lying above the curved surface, and acts through the center of mass of this volume of fluid.

Since the three components of force, two horizontal and one vertical, calculated as above, need not meet at a single point, there is, in general, no single resultant force. They can, however, be combined and considered to be equivalent to a single force at any arbitrary point of application together with a moment about that point.

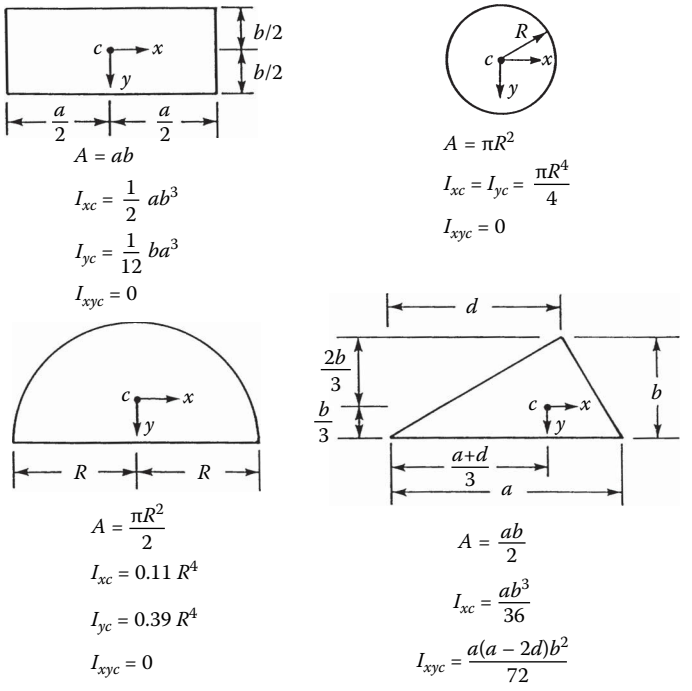

FIGURE 2.1.3 Centroidal moments of inertia and coordinates for some common areas.

Hydrostatic Forces in Layered Fluids

All of the above results which employ the linear hydrostatic variation of pressure are valid only for homogeneous fluids. If the fluid is heterogeneous, consisting of individual layers each of constant density, then the pressure varies linearly with a different slope in each layer and the preceding analyses must be remedied by computing and summing their separate contributions to the forces and moments.

Buoyancy

The same principles used above to compute hydrostatic forces can be used to calculate the net pressure force acting on completely submerged or floating bodies. These laws of buoyancy, the principles of Archimedes, are that:

1. A completely submerged body experiences a vertical upward force equal to the weight of the displaced fluid; and
2. A floating or partially submerged body displaces its own weight in the fluid in which it floats (i.e., the vertical upward force is equal to the body weight).

The line of action of the buoyancy force in both (1) and (2) passes through the centroid of the displaced volume of fluid; this point is called the *center of buoyancy*. (This point need not correspond to the center of mass of the body, which could have nonuniform density. In the above it has been assumed that the displaced fluid has a constant γ. If this is not the case, such as in a layered fluid, the magnitude of the buoyant force is still equal to the weight of the displaced fluid, but the line of action of this force passes through the center of gravity of the displaced volume, not the centroid.)

If a body has a weight exactly equal to that of the volume of fluid it displaces, it is said to be *neutrally buoyant* and will remain at rest at any point where it is immersed in a (homogeneous) fluid.

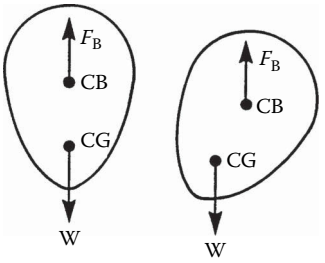

FIGURE 2.1.4 Stability for a submerged body: (left) equilibrium position and (right) slightly rotated.

Stability of Submerged and Floating Bodies

Submerged Body

A body is said to be in stable equilibrium if when given a slight displacement from the equilibrium position the forces thereby created tend to restore it back to its original position. The forces acting on a submerged body are the buoyancy force, F_B, acting through the center of buoyancy, denoted by CB, and the weight of the body, W, acting through the center of gravity denoted by CG (see Figure 2.1.4). We see from Figure 2.1.4 that if the CB lies above the CG, a rotation from the equilibrium position creates a restoring couple which will rotate the body back to its original position—thus, this is a *stable* equilibrium situation. The reader will readily verify that when the CB lies below the CG, the couple that results from a rotation from the vertical increases the displacement from the equilibrium position—thus, this is an *unstable* equilibrium situation.

Partially Submerged Body

The stability problem is more complicated for floating bodies because as the body rotates the location of the center of buoyancy may change. To determine stability in these problems requires that we determine the location of the *metacenter*. This is done for a symmetric body by tilting the body through a small angle $\Delta\theta$ from its equilibrium position and calculating the new location of the center of buoyancy CB′; the point of intersection of a vertical line drawn upward from CB′ with the line of symmetry of the floating body is the metacenter, denoted by M in Figure 2.1.5, and it is independent of $\Delta\theta$ for small angles. If M lies above the CG of the body, we see from Figure 2.1.5 that rotation of the body leads to a restoring couple, whereas M lying below the CG leads to a couple

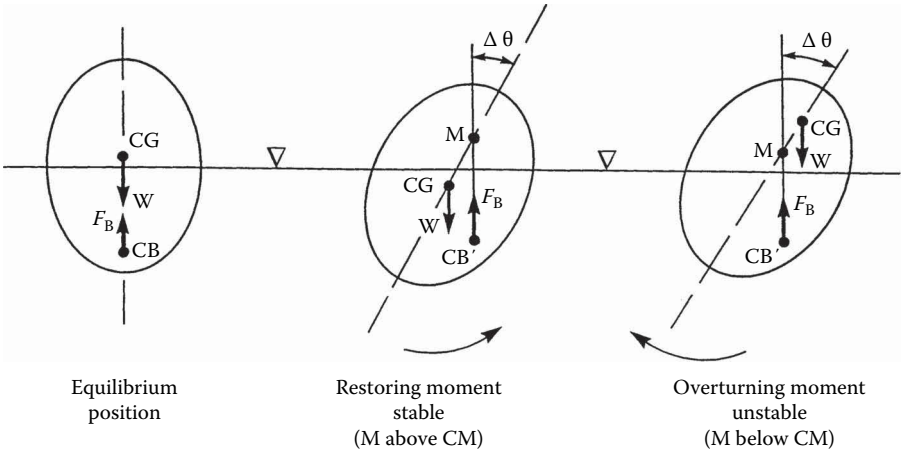

FIGURE 2.1.5 Stability for a partially submerged body.

which will increase the displacement. Thus, the stability of the equilibrium depends on whether M lies above or below the CG. The directed distance from CG to M is called the *metacentric height*, so equivalently the equilibrium is stable if this vector is positive and unstable if it is negative; stability increases as the metacentric height increases. For geometrically complex bodies, such as ships, the computation of the metacenter can be quite complicated.

Pressure Variation in Rigid-Body Motion of a Fluid

In rigid-body motion of a fluid all the particles translate and rotate as a whole, there is no relative motion between particles, and hence no viscous stresses since these are proportional to velocity gradients. The equation of motion is then a balance among pressure, gravity, and the fluid acceleration, specifically,

$$\nabla p = \rho(g - a) \tag{2.1.18}$$

where a is the uniform acceleration of the body. Equation 2.1.18 shows that the lines of constant pressure, including a free surface if any, are perpendicular to the direction $g-a$. Two important applications of this are to a fluid in uniform linear translation and rigid-body rotation. While such problems are not, strictly speaking, fluid statics problems, their analysis and the resulting pressure variation results are similar to those for static fluids.

Uniform Linear Acceleration

For a fluid partially filling a large container moving to the right with constant acceleration $\boldsymbol{a}=(a_x, a_y)$ the geometry of Figure 2.1.6 shows that the magnitude of the pressure gradient in the direction $\boldsymbol{n}$ normal to the accelerating free surface, in the direction $g-a$, is

$$\frac{dp}{dn} = \rho\left[a_x^2 + (g + a_y)^2\right]^{1/2} \tag{2.1.19}$$

and the free surface is oriented at an angle to the horizontal

$$\theta = \tan^{-1}\left(\frac{a_x}{g + a_y}\right) \tag{2.1.20}$$

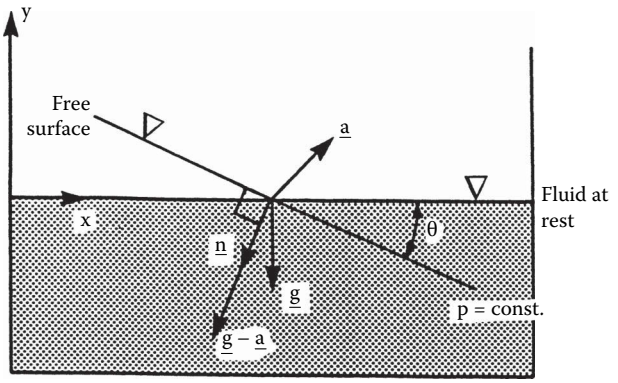

FIGURE 2.1.6 A fluid with a free surface in uniform linear acceleration.

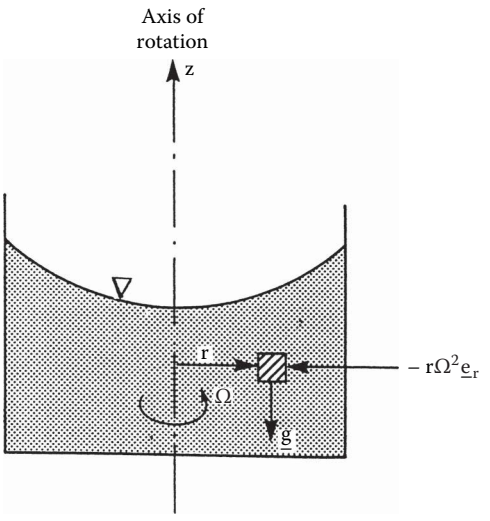

FIGURE 2.1.7 A fluid with a free surface in rigid-body rotation.

Rigid-Body Rotation

Consider the fluid-filled circilar cylinder rotating uniformly with angular velocity $\Omega=\Omega\boldsymbol{e}_z$ (Figure 2.1.7).

The only acceleration is the centripetal acceleration $\Omega\times(\Omega\times\boldsymbol{r})=-r\Omega^2\boldsymbol{e}_r$ so Equation 2.1.18 becomes

$$\nabla p=\frac{\partial p}{\partial r}\boldsymbol{e}_r+\frac{\partial p}{\partial z}\boldsymbol{e}_z=\rho(\boldsymbol{g}-\boldsymbol{a})=\rho(r\Omega^2\boldsymbol{e}_r-g\boldsymbol{e}_z) \tag{2.1.21}$$

or

$$\frac{\partial p}{\partial r}=\rho r\Omega^2,\qquad \frac{\partial p}{\partial z}=-\rho g=-\gamma \tag{2.1.22}$$

Integration of these equations leads to

$$p=p_0-\gamma z+\frac{1}{2}\rho r^2\Omega^2 \tag{2.1.23}$$

where p_0 is the reference pressure (at $r=z=0$). This result shows that at any fixed r the pressure varies hydrostatically in the vertical direction, while the constant pressure surfaces, including the free surface, are paraboloids of revolution.

FURTHER INFORMATION

The reader may find more detail and additional information on the topics in this section in any one of the many excellent introductory texts on fluid mechanics, such as

Munson, B.R., Young, D.F., and Okiishi, T.H. 1998. *Fundamentals of Fluid Mechanics*, 3rd ed., John Wiley & Sons, New York.

White, F.M. 1999. *Fluid Mechanics*, 4th ed., McGraw-Hill, New York.

2.2 EQUATIONS OF MOTION AND POTENTIAL FLOW

Stanley A. Berger

Integral Relations for a Control Volume

Like most physical conservation laws those governing the motion of a fluid apply to material particles or systems of such particles. This so-called Lagrangian viewpoint is generally not as useful in practical fluid flows as an analysis based on the flow through fixed (or deformable) control volumes (CV)—the Eulerian viewpoint. The relationship between these two viewpoints can be deduced from the Reynolds transport theorem, from which we also most readily derive the governing integral and differential equations of motion.

Reynolds Transport Theorem

The *extensive* quantity B, a scalar, vector, or tensor, is defined as any property of a given quantity of fluid (e.g., momentum, energy) and b as the corresponding value per unit mass (the *intensive* value). The Reynolds transport theorem for a moving and arbitrarily deforming control volume CV, with boundary CS (see Figure 2.2.1), states that

$$\frac{d}{dt}\left(B_{\text{system}}\right) = \frac{d}{dt}\left(\iiint_{\text{CV}} \rho b \; d\upsilon\right) + \iint_{\text{CS}} \rho b(\boldsymbol{V}_r \cdot \boldsymbol{n})\, dA \tag{2.2.1}$$

where B_{system} is the total quantity of B in the system (any mass of fixed identity), $\boldsymbol{n}$ is the outward normal to the CS, $\boldsymbol{V}_r = \boldsymbol{V}(\boldsymbol{r}, t) - \boldsymbol{V}_{\text{CS}}(\boldsymbol{r}, t)$, the velocity of the fluid particle, $\boldsymbol{V}(\boldsymbol{r}, t)$, relative to that of the CS, $\boldsymbol{V}_{\text{CS}}(\boldsymbol{r}, t)$, and d/dt on the left-hand side is the derivative following the fluid particles, i.e., the fluid mass comprising the system. The theorem states that the time rate of change of the total B in the system is equal to the rate of change within the CV plus the net flux of B through the CS. To distinguish between the d/dt which appears on the two sides of Equation 2.2.1 but which have different interpretations, the derivative on the left-hand side, following the system, is denoted by D/Dt and is called the material derivative. This notation is used in what follows. For any function $f(x, y, z, t)$,

$$\frac{Df}{Dt} = \frac{\partial f}{\partial t} + (\boldsymbol{V} \cdot \nabla) f$$

For a CV fixed with respect to the reference frame, Equation 2.2.1 reduces to

$$\frac{D}{Dt}\left(B_{\text{system}}\right) = \frac{d}{dt}\iiint_{\substack{\text{CV} \\ \text{(fixed)}}} (\rho b)\, d\upsilon + \iint_{\text{CS}} \rho b(\boldsymbol{V} \cdot \boldsymbol{n})\, dA \tag{2.2.2}$$

(The time derivative operator in the first term on the right-hand side may be moved inside the integral, in which case it is then to be interpreted as the partial derivative $\partial/\partial t$.)

Conservation of Mass

If we apply Equation 2.2.2 for a fixed control volume, with B_{system} the total mass in the system, then since conservation of mass requires that $DB_{\text{system}}/Dt = 0$ there follows, since $b = B_{\text{system}}/m = 1$,

$$\iiint_{\substack{\text{CV} \\ \text{(fixed)}}} \frac{\partial \rho}{\partial t}\, d\upsilon + \iint_{\text{CS}} \rho(\boldsymbol{V} \cdot \boldsymbol{n})\, dA = 0 \tag{2.2.3}$$

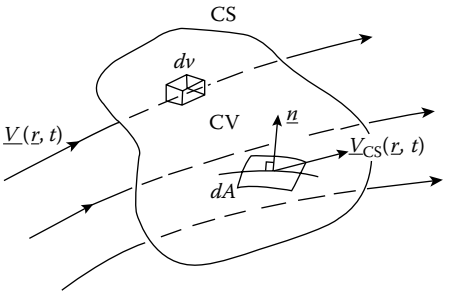

FIGURE 2.2.1 Control volume.

This is the integral form of the conservation of mass law for a fixed control volume. For a steady flow, Equation 2.2.3 reduces to

$$\iint_{CS} \rho(\boldsymbol{V} \cdot \boldsymbol{n}) dA = 0 \tag{2.2.4}$$

whether compressible or incompressible. For an incompressible flow, ρ=constant, so

$$\iint_{CS} (\boldsymbol{V} \cdot \boldsymbol{n}) dA = 0 \tag{2.2.5}$$

whether the flow is steady or unsteady.

Conservation of Momentum

The conservation of (linear) momentum states that

$$\boldsymbol{F}_{\text{total}} \equiv \sum (\text{external forces acting on the fluid system}) = \frac{D\boldsymbol{M}}{Dt} \equiv \frac{D}{Dt}\left(\iiint_{\text{system}} \rho \boldsymbol{V} \, d\upsilon \right) \tag{2.2.6}$$

where $\boldsymbol{M}$ is the total system momentum. For an arbitrarily moving, deformable control volume it then follows from Equation 2.2.1 with b set to V,

$$\boldsymbol{F}_{\text{total}} = \frac{d}{dt}\left(\iiint_{cv} \rho \boldsymbol{V} \, d\upsilon \right) + \iint_{CS} \rho \boldsymbol{V} (\boldsymbol{V}_r \cdot \boldsymbol{n}) dA \tag{2.2.7}$$

This expression is only valid in an inertial coordinate frame. To write the equivalent expression for a noninertial frame, we must use the relationship between the acceleration a_1 in an inertial frame and the acceleration a_R in a noninertial frame,

$$\boldsymbol{a}_1 = \boldsymbol{a}_R + \frac{d^2 \boldsymbol{R}}{dt^2} + 2\Omega \times \boldsymbol{V} + \Omega \times (\Omega \times r) + \frac{d\Omega}{dt} \times r \tag{2.2.8}$$

where $\boldsymbol{R}$ is the position vector of the origin of the noninertial frame with respect to that of the inertial frame, Ω is the angular velocity of the noninertial frame, and $\boldsymbol{r}$ and $\boldsymbol{V}$ the position and velocity vectors in the noninertial frame. The third term on the right-hand side of Equation 2.2.8 is the Coriolis acceleration, and the fourth term is the centripetal acceleration. For a noninertial frame Equation 2.2.7 is then

$$\boldsymbol{F}_{\text{total}} - \iiint_{\text{system}} \left[\frac{d^2\boldsymbol{R}}{dt^2} + 2\Omega \times V + \Omega \times (\Omega \times r) + \frac{d\Omega}{dt} \times r \right] \rho \, d\upsilon = \frac{D}{Dt} \left(\iiint_{\text{system}} \rho \boldsymbol{V} \, d\upsilon \right)$$

$$= \frac{d}{dt} \left(\iiint_{\text{CV}} \rho \boldsymbol{V} \, d\upsilon \right) + \iint_{\text{CS}} \rho \boldsymbol{V} \cdot (\boldsymbol{V}_r \cdot \boldsymbol{n}) dA \tag{2.2.9}$$

where the frame acceleration terms of Equation 2.2.8 have been brought to the left-hand side because to an observer in the noninertial frame they act as "apparent" body forces.

For a fixed control volume in an inertial frame for steady flow, it follows from the above that

$$\boldsymbol{F}_{\text{total}} = \iint_{\text{CS}} \rho \boldsymbol{V} (\boldsymbol{V} \cdot \boldsymbol{n}) dA \tag{2.2.10}$$

This expression is the basis of many control volume analyses for fluid flow problems.

The cross product of $\boldsymbol{r}$, the position vector with respect to a convenient origin, with the momentum Equation 2.2.6 written for an elementary particle of mass dm, noting that $(d\boldsymbol{r}/dt) \times \boldsymbol{V} = 0$, leads to the integral moment of momentum equation

$$\sum \boldsymbol{M} - \boldsymbol{M}_I = \frac{D}{Dt} \iiint_{\text{system}} \rho (\boldsymbol{r} \times \boldsymbol{V}) d\upsilon \tag{2.2.11}$$

where ΣM is the sum of the moments of all the external forces acting on the system about the origin of $\boldsymbol{r}$, and $\boldsymbol{M}_1$ is the moment of the apparent body forces (see Equation 2.2.9). The right-hand side can be written for a control volume using the appropriate form of the Reynolds transport theorem.

Conservation of Energy

The conservation of energy law follows from the first law of thermodynamics for a moving system

$$\dot{Q} - \dot{W} = \frac{D}{Dt} \left(\iiint_{\text{system}} \rho e \, d\upsilon \right) \tag{2.2.12}$$

where $\dot{Q}$ is the rate at which heat is added to the system, $\dot{W}$ the rate at which the system works on its surroundings, and e is the total energy per unit mass. For a particle of mass dm the contributions to the specific energy e are the internal energy u, the kinetic energy $V^2/2$, and the potential energy, which in the case of gravity, the only body force we shall consider, is gz, where z is the vertical displacement opposite to the direction of gravity. (We assume no energy transfer owing to chemical reaction as well as no magnetic or electric fields.) For a fixed control volume it then follows from Equation 2.2.2 [with $b = e = u + (V^2/2) + gz$] that

$$\dot{Q} - \dot{W} = \frac{d}{dt} \left(\iiint_{\text{CV}} \rho \left(u + \frac{1}{2} V^2 + gz \right) d\upsilon \right) + \iint_{\text{CS}} \rho \left(u + \frac{1}{2} V^2 + gz \right) (\boldsymbol{V} \cdot \boldsymbol{n}) \, dA \tag{2.2.13}$$

Example 2.2.1

An incompressible fluid flows through a pump at a volumetric flow rate $\hat{Q}$. The (head) loss between Sections 1 and 2 (see Figure 2.2.2) is equal to $\beta \rho V_1^2/2$ (V is the average velocity at the section). Calculate the power that must be delivered by the pump to the fluid to produce a given increase in pressure, $\Delta p = p_2 - p_1$.

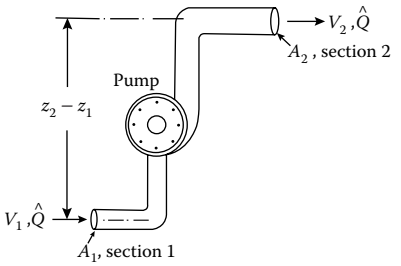

FIGURE 2.2.2 Pump producing pressure increase.

Solution: The principal equation needed is the energy Equation 2.2.13. The term $\dot{W}$, the rate at which the system does work on its surroundings, for such problems has the form

$$\dot{W} = -\dot{W}_{\text{shaft}} + \iint_{\text{CS}} p\boldsymbol{V}\cdot\boldsymbol{n}\ dA \tag{P.2.2.1}$$

where $\dot{W}_{\text{shaft}}$ represents the work done on the fluid by a moving shaft, such as by turbines, propellers, fans, etc., and the second term on the right side represents the rate of working by the normal stress, the pressure, at the boundary. For a steady flow in a control volume coincident with the physical system boundaries and bounded at its ends by Sections 1 and 2, Equation 2.2.13 reduces to ($u \equiv 0$),

$$\dot{Q} + \dot{W}_{\text{shaft}} - \iint_{\text{CS}} p\boldsymbol{V}\cdot\boldsymbol{n}\,dA = \iint_{\text{CS}} \left(\frac{1}{2}\rho V^2 + \gamma z\right)(\boldsymbol{V}\cdot\boldsymbol{n})\ dA \tag{P.2.2.2}$$

Using average quantities at Sections 1 and 2, and the continuity Equation 2.2.5, which reduces in this case to

$$V_1A_1 = V_2A_2 = \hat{Q} \tag{P.2.2.3}$$

we can write Equation P.2.2.2 as

$$\dot{Q} + \dot{W}_{\text{shaft}} - (p_2 - p_1)\hat{Q} = \left[\frac{1}{2}\rho\left(V_2^2 - V_1^2\right) + \gamma\left(z_2 - z_1\right)\right]\hat{Q} \tag{P.2.2.4}$$

$\dot{Q}$, the rate at which heat is added to the system, is here equal to $-\beta\rho V_1^2/2$, the head loss between Sections 1 and 2. Equation P.2.2.4 then can be rewritten

$$\dot{W}_{\text{shaft}} = \beta\rho\frac{V_1^2}{2} + (\Delta p)\hat{Q} + \frac{1}{2}\rho\left(V_2^2 - V_1^2\right)\hat{Q} + \gamma\left(z_2 - z_1\right)\hat{Q}$$

or, in terms of the given quantities,

$$\dot{W}_{\text{shaft}} = \frac{\beta\rho\hat{Q}^2}{A_1^2} + \left(\Delta p\right)\hat{Q} + \frac{1}{2}\rho\frac{\hat{Q}^3}{A_2^2}\left(1 - \frac{A_2^2}{A_1^2}\right) + \gamma\left(z_2 - z_1\right)\hat{Q} \tag{P.2.2.5}$$

Thus, for example, if the fluid is water ($\rho \approx 1000\,\text{kg/m}^3$, $\gamma = 9.8\,\text{kN/m}^3$), $\hat{Q} = 0.5\,\text{m}^3/\text{s}$, the heat loss is $0.2\rho V_1^2/2$, and $\Delta p = p_2 - p_1 = 2\times10^5\,\text{N/m}^2 = 200\,\text{kPa}$, $A_1 = 0.1\,\text{m}^2 = A_2/2$, $(z_2 - z_1) = 2\,\text{m}$, we find, using Equation P.2.2.5

$$\dot{W}_{\text{shaft}} = \frac{0.2(1000)(0.5)^2}{(0.1)^2} + \left(2\times10^5\right)(0.5) + \frac{1}{2}(1000)\frac{(0.5)^3}{(0.2)^2}(1-4) + \left(9.8\times10^3\right)(2)(0.5)$$
$$= 5{,}000 + 10{,}000 - 4{,}688 + 9{,}800 = 20{,}112 \text{ W}$$
$$= \frac{20{,}112}{745.7}\text{hp} = 27 \text{ hp}$$

Differential Relations for Fluid Motion

In the previous section the conservation laws were derived in integral form. These forms are useful in calculating, generally using a control volume analysis, gross features of a flow. Such analyses usually require some *a priori* knowledge or assumptions about the flow. In any case, an approach based on integral conservation laws cannot be used to determine the point-by-point variation of the dependent variables, such as velocity, pressure, temperature, etc. To do this requires the use of the differential forms of the conservation laws, which are presented below.

Mass Conservation–Continuity Equation

Applying Gauss's theorem (the divergence theorem) to Equation 2.2.3 we obtain

$$\iiint_{\substack{\text{CV}\\(\text{fixed})}}\left[\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho V)\right]d\upsilon = 0 \tag{2.2.14}$$

which, because the control volume is arbitrary, immediately yields

$$\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho\boldsymbol{V}) = 0 \tag{2.2.15}$$

This can also be written as

$$\frac{D\rho}{Dt} + \rho\nabla\cdot\boldsymbol{V} = 0 \tag{2.2.16}$$

using the fact that

$$\frac{D\rho}{Dt} = \frac{\partial\rho}{\partial t} + \boldsymbol{V}\cdot\nabla\rho \tag{2.2.17}$$

Special cases:

1. Steady flow $[(\partial/\partial t)\,() \equiv 0]$

$$\nabla.(\rho\boldsymbol{V}) = 0 \tag{2.2.18}$$

2. Incompressible flow ($D\rho/D\text{t}=0$)

$$\nabla\cdot V = 0 \tag{2.2.19}$$

Momentum Conservation

We note first, as a consequence of mass conservation for a system, that the right-hand side of Equation 2.2.6 can be written as

$$\frac{D}{Dt}\left(\iiint_{\text{system}} \rho V \; d\upsilon\right) \equiv \iiint_{\text{system}} \rho \frac{DV}{Dt} d\upsilon \tag{2.2.20}$$

The total force acting on the system which appears on the left-hand side of Equation 2.2.6 is the sum of body forces $\boldsymbol{F}_b$ and surface forces $\boldsymbol{F}_s$. The body forces are often given as forces per unit mass (e.g., gravity), and so can be written as

$$F_b = \iiint_{\text{system}} \rho f \; d\upsilon \tag{2.2.21}$$

The surface forces are represented in terms of the second-order stress tensor* $\underline{\sigma} = \{\sigma_{ij}\}$, where σ_{ij} is defined as the force per unit area in the i direction on a planar element whose normal lies in the j direction.† From elementary angular momentum considerations for an infinitesimal volume it can be shown that σ_{ij} is a symmetric tensor, and therefore has only six independent components. The total surface force exerted on the system by its surroundings is given by

$$F_s = \iint_{\substack{\text{system} \\ \text{surface}}} \underline{\sigma} \cdot \boldsymbol{n} \; dA, \text{ with } i - \text{component } F_{s_i} = \iint \sigma_{ij} n_j \; dA \tag{2.2.22}$$

The integral momentum conservation law Equation 2.2.6 can then be written

$$\iiint_{\text{system}} \rho \frac{DV}{Dt} d\upsilon = \iiint_{\text{system}} \rho f \; d\upsilon + \iint_{\substack{\text{system} \\ \text{surface}}} \underline{\sigma} \cdot \boldsymbol{n} \; dA \tag{2.2.23}$$

The application of the divergence theorem to the last term on the right-side of Equation 2.2.23 leads to

$$\iiint_{\text{system}} \rho \frac{DV}{Dt} d\upsilon = \iiint_{\text{system}} \rho f \; d\upsilon + \iiint_{\text{system}} \nabla \cdot \underline{\sigma} \; d\upsilon \tag{2.2.24}$$

where $\nabla \cdot \sigma \equiv \{\partial \sigma_{ij} / x_j\}$. Since Equation 2.2.24 holds for any material volume, it follows that

$$\rho \frac{DV}{Dt} = \rho \boldsymbol{f} + \nabla \cdot \underline{\sigma} \tag{2.2.25}$$

With the decomposition of $\boldsymbol{F}_{\text{total}}$ above, Equation 2.2.10 can be written as

$$\iiint_{\text{CV}} \rho f \; d\upsilon + \iint_{\text{CS}} \underline{\sigma} \cdot \boldsymbol{n} \; dA = \iint_{\text{CS}} \rho \boldsymbol{V} (\boldsymbol{V} \cdot \boldsymbol{n}) dA \tag{2.2.26}$$

If ρ is uniform and $\boldsymbol{f}$ is a conservative body force, i.e., $\boldsymbol{f} = -\nabla \Psi$, where Ψ is the force potential, then Equation 2.2.26, after application of the divergence theorem to the body force term, can be written

---

* We shall assume the reader is familiar with elementary Cartesian tensor analysis and the associated subscript notation and conventions. The reader for whom this is not true should skip the details and concentrate on the final principal results and equations given at the ends of the next few subsections.

† This assignment of roles to the first and second subscripts of the stress tensor is a convention and is far from universal. Frequently, their roles are reversed, the first subscript denoting the direction of the normal to the planar element, the second the direction of the force.

$$\iint_{CS}\left(-\rho\Psi n+\underline{\sigma}\cdot\boldsymbol{n}\right)dA=\iint_{CS}\rho V(\boldsymbol{V}\cdot\boldsymbol{n})\,dA \tag{2.2.27}$$

It is in this form, involving only integrals over the surface of the control volume, that the integral form of the momentum equation is used in control volume analyses, particularly in the case when the body force term is absent.

Analysis of Rate of Deformation

The principal aim of the following two subsections is to derive a relationship between the stress and the rate of strain to be used in the momentum Equation 2.2.25. The reader less familiar with tensor notation may skip these sections, apart from noting some of the terms and quantities defined therein, and proceed directly to Equations 2.2.38 or 2.2.39.

The relative motion of two neighboring points P and Q, separated by a distance η, can be written (using $\boldsymbol{u}$ for the local velocity)

$$\boldsymbol{u}(Q)=\boldsymbol{u}(P)+(\nabla\boldsymbol{u})\eta$$

or, equivalently, writing $\nabla\boldsymbol{u}$ as the sum of antisymmetric and symmetric tensors,

$$\boldsymbol{u}(Q)=\boldsymbol{u}(P)+\frac{1}{2}\left((\nabla\boldsymbol{u})-(\nabla\boldsymbol{u})^{*}\right)\eta+\frac{1}{2}\left((\nabla\boldsymbol{u})+(\nabla\boldsymbol{u})^{*}\right)\eta \tag{2.2.28}$$

where $\nabla\boldsymbol{u}=\{\partial u_i/\partial x_j\}$, and the superscript * denotes transpose, so $(\nabla\boldsymbol{u})^{*}=\{\partial u_j/\partial x_i\}$. The second term on the right-hand side of Equation 2.2.28 can be rewritten in terms of the *vorticity*, $\nabla\times\boldsymbol{u}$, so Equation 2.2.28 becomes

$$\boldsymbol{u}(Q)=\boldsymbol{u}(P)+\frac{1}{2}(\nabla\times\boldsymbol{u})\times\eta+\frac{1}{2}\left((\nabla\boldsymbol{u})+(\nabla\boldsymbol{u})^{*}\right)\eta \tag{2.2.29}$$

which shows that the local velocity field consists of a rigid-body translation, a rigid-body rotation with angular velocity 1/2 ($\nabla\times\boldsymbol{u}$), and a velocity or rate of deformation. The coefficient of $\boldsymbol{\eta}$ in the last term in Equation 2.2.29 is defined as the rate-of-strain tensor and is denoted by $\underline{e}$, in subscript form

$$e_{ij}=\frac{1}{2}\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right) \tag{2.2.30}$$

From $\underline{e}$ we can define a rate-of-strain central quadric, along the principal axes of which the deforming motion consists of a pure straining extension or contraction.

Relationship between Forces and Rate of Deformation

We are now in a position to determine the required relationship between the stress tensor $\underline{\sigma}$ and the rate of deformation. Assuming that in a static fluid the stress reduces to a (negative) hydrostatic or thermodynamic pressure, equal in all directions, we can write

$$\underline{\sigma}=-p\underline{I}+\underline{\tau}\qquad\text{or}\qquad\sigma_{ij}=-p\delta_{ij}+\tau_{ij} \tag{2.2.31}$$

where $\underline{\tau}$ is the viscous part of the total stress and is called the deviatoric stress tensor, $\underline{I}$ is the identity tensor, and δ_{ij} is the corresponding Kronecker delta ($\delta_{ij}=0$ if $i\neq j$; $\delta_{ij}=1$ if $i=j$). We make further assumptions that (1) the fluid exhibits no preferred directions; (2) the stress is independent of any previous history of distortion; and (3) that the stress depends only on the

local thermodynamic state and the kinematic state of the immediate neighborhood. Precisely, we assume that $\underline{\tau}$ is linearly proportional to the first spatial derivatives of $\boldsymbol{u}$, the coefficient of proportionality depending only on the local thermodynamic state. These assumptions and the relations below which follow from them are appropriate for a Newtonian fluid. Most common fluids, such as air and water under most conditions, are Newtonian, but there are many other fluids, including many which arise in industrial applications, which exhibit so-called non-Newtonian properties. The study of such non-Newtonian fluids, such as viscoelastic fluids, is the subject of the field of rheology (See Section 2.9 in this chapter).

With the Newtonian fluid assumptions above, and the symmetry of $\underline{\tau}$ which follows from the symmetry of $\underline{\sigma}$, one can show that the viscous part $\underline{\tau}$ of the total stress can be written as

$$\underline{\tau} = \lambda(\nabla \cdot \boldsymbol{u})\underline{I} + 2\mu\underline{e} \tag{2.2.32}$$

so the total stress for a Newtonian fluid is

$$\underline{\sigma} = -p\underline{I} + \lambda(\nabla \cdot \boldsymbol{u})\underline{I} + 2\mu\underline{e} \tag{2.2.33}$$

or, in subscript notation

$$\sigma_{ij} = -p\delta_{ij} + \lambda\left(\frac{\partial u_k}{\partial x_k}\right)\delta_{ij} + \mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{2.2.34}$$

(the Einstein summation convention is assumed here, namely, that a repeated subscript, such as in the second term on the right-hand side above, is summed over; note also that $\nabla \cdot \boldsymbol{u} = \partial u_k/\partial x_k = e_{kk}$). The coefficient λ is called the "second viscosity" and μ the "absolute viscosity," or more commonly the "dynamic viscosity," or simply the "viscosity." For a Newtonian fluid λ and μ depend only on local thermodynamic state, primarily on the temperature.

We note, from Equation 2.2.34, that whereas in a fluid at rest the stress is an isotropic normal stress (equal to p in all directions), this is not the case for a moving fluid, since in general $\sigma_{11} \neq \sigma_{22} \neq \sigma_{33}$. To have an analogous quantity to p for a moving fluid, the values of we define the pressure in a moving fluid as the negative mean normal stress, denoted, say, by $\overline{p}$

$$\overline{p} = -\frac{1}{3}\sigma_{ij} \tag{2.2.35}$$

(σ_{ii} is the trace of $\underline{\sigma}$ and an invariant of $\underline{\sigma}$, independent of the orientation of the axes). From Equation 2.2.34

$$\overline{p} = -\frac{1}{3}\sigma_{ii} = p - \left(\lambda + \frac{2}{3}\mu\right)\nabla \cdot \boldsymbol{u} \tag{2.2.36}$$

For an incompressible fluid $\nabla \cdot \boldsymbol{u} = 0$ and hence $\overline{p} \equiv p$. The quantity $(\lambda + 2/3\mu)$ is called the bulk viscosity. If one assumes that the deviatoric stress tensor τ_{ij} makes no contribution to the mean normal stress, it follows that $\lambda + (2/3)\mu = 0$, so again $\overline{p} = p$. This condition, $\lambda = -(2/3)\mu$, is called the Stokes assumption or hypothesis. If neither the incompressibility nor the Stokes assumptions are made, the difference between $\overline{p}$ and p is usually still negligibly small because $(\lambda + 2/3\mu)\,\nabla u \ll p$ in most fluid flow problems. If the Stokes hypothesis is made, as is often the case in fluid mechanics, Equation 2.2.34 becomes

$$\sigma_{ij} = -p\delta_{ij} + 2\mu\left(e_{ij} - \frac{1}{3}e_{kk}\delta_{ij}\right) \tag{2.2.37}$$

The Navier–Stokes Equations

Substitution of Equation 2.2.33 into 2.2.25, since $\nabla\cdot(\phi\underline{I})=\nabla\phi$, for any scalar function ϕ, yields (replacing $\boldsymbol{u}$ in Equation 2.2.33 by $\boldsymbol{V}$)

$$\rho\frac{D\boldsymbol{V}}{Dt}=\rho\boldsymbol{f}-\nabla p+\nabla(\lambda\nabla\cdot\boldsymbol{V})+\nabla\cdot(2\mu\underline{e}) \tag{2.2.38}$$

These equations are the Navier–Stokes equations (although the name is as often given to the full set of governing conservation equations). With the Stokes assumption ($\lambda=-2/3\mu$), Equation 2.2.38 becomes

$$\rho\frac{D\boldsymbol{V}}{Dt}=\rho\boldsymbol{f}-\nabla p+\nabla\cdot\left[2\mu\left(\underline{\underline{e}}-\frac{1}{3}e_{kk}\underline{\underline{I}}\right)\right] \tag{2.2.39}$$

If the Eulerian frame is not an inertial frame, then one must use the transformation to an inertial frame either using Equation 2.2.8 or the "apparent" body force formulation, Equation 2.2.9.

Energy Conservation: The Mechanical and Thermal Energy Equations

In deriving the differential form of the energy equation we begin by assuming that heat enters or leaves the material or control volume by heat conduction across the boundaries, the heat flux per unit area being $\boldsymbol{q}$. It then follows that

$$\dot{Q}=-\iint\boldsymbol{q}\cdot\boldsymbol{n}\;dA=-\iiint\nabla\cdot\boldsymbol{q}\;d\upsilon \tag{2.2.40}$$

The work-rate term $\dot{W}$ can be decomposed into the rate of work done against body forces, given by

$$-\iiint\rho\boldsymbol{f}\cdot\boldsymbol{V}\,d\upsilon \tag{2.2.41}$$

and the rate of work done against surface stresses, given by

$$-\iint_{\substack{\text{system}\\\text{surface}}}\boldsymbol{V}\cdot(\underline{\sigma}\boldsymbol{n})dA \tag{2.2.42}$$

Substitution of these expressions for $\dot{Q}$ and $\dot{W}$ into Equation 2.2.12, use of the divergence theorem, and conservation of mass lead to

$$\rho\frac{D}{Dt}\left(u+\frac{1}{2}V^2\right)=-\nabla\cdot\boldsymbol{q}+\rho\boldsymbol{f}\cdot\boldsymbol{V}+\nabla\cdot(\boldsymbol{V}\underline{\sigma}) \tag{2.2.43}$$

(note that a potential energy term is no longer included in e, the total specific energy, as it is accounted for by the body force rate-of-working term $\rho f\cdot V$).

Equation 2.2.43 is the total energy equation showing how the energy changes as a result of working by the body and surface forces and heat transfer. It is often useful to have a purely thermal energy equation. This is obtained by subtracting from Equation 2.2.43 the dot product of $\boldsymbol{V}$ with the momentum Equation 2.2.25, after expanding the last term in Equation 2.2.43, resulting in

$$\rho\frac{Du}{Dt}=\frac{\partial V_i}{\partial x_j}\sigma_{ij}-\nabla\cdot\boldsymbol{q} \tag{2.2.44}$$

With $\sigma_{ij}=-p\delta_{ij}+\tau_{ij}$, and the use of the continuity equation in the form of Equation 2.2.16, the first term on the right-hand side of Equation 2.2.44 may be written

$$\frac{\partial V_i}{\partial x_j}\sigma_{ij} = -\rho\frac{D\left(\frac{p}{\rho}\right)}{Dt}+\frac{Dp}{Dt}+\Phi \tag{2.2.45}$$

where Φ is the rate of dissipation of mechanical energy per unit mass due to viscosity, and is given by

$$\Phi \equiv \frac{\partial V_i}{\partial x_j}\tau_{ij} = 2\mu\left(e_{ij}e_{ij}-\frac{1}{3}e_{kk}^2\right)=2\mu\left(e_{ij}-\frac{1}{3}e_{kk}\delta_{ij}\right)^2 \tag{2.2.46}$$

With the introduction of Equation 2.2.45, Equation 2.2.44 becomes

$$\rho\frac{De}{Dt} = -p\nabla\cdot\boldsymbol{V}+\Phi-\nabla\cdot\boldsymbol{q} \tag{2.2.47}$$

or

$$\rho\frac{Dh}{Dt} = \frac{Dp}{Dt}+\Phi-\nabla\cdot\boldsymbol{q} \tag{2.2.48}$$

where $h=e+(p/\rho p)$ is the specific enthalpy. Unlike the other terms on the right-hand side of Equation 2.2.47, which can be negative or positive, Φ is always nonnegative and represents the increase in internal energy (or enthalpy) owing to irreversible degradation of mechanical energy. Finally, from elementary thermodynamic considerations

$$\frac{Dh}{Dt} = T\frac{DS}{Dt}+\frac{1}{\rho}\frac{Dp}{Dt}$$

where S is the entropy, so Equation 2.2.48 can be written as

$$\rho T\frac{DS}{Dt} = \Phi-\nabla\cdot\boldsymbol{q} \tag{2.2.49}$$

If the heat conduction is assumed to obey the Fourier heat conduction law, so $\boldsymbol{q}=-k\nabla T$, where k is the thermal conductivity, then in all of the above equations

$$-\nabla\cdot\boldsymbol{q} = \nabla\cdot(k\nabla T) = k\nabla^2 T \tag{2.2.50}$$

the last of these equalities holding only if $k=$constant.

In the event the thermodynamic quantities vary little, the coefficients of the constitutive relations for $\underline{\sigma}$ and $\boldsymbol{q}$ may be taken to be constant and the above equations simplified accordingly.

We note also that if the flow is incompressible, then the mass conservation, or continuity, equation simplifies to

$$\nabla\cdot\boldsymbol{V} = 0 \tag{2.2.51}$$

and the momentum Equation 2.2.38 to

$$\rho\frac{D\boldsymbol{V}}{Dt} = \rho\boldsymbol{f}-\nabla p+\mu\nabla^2\boldsymbol{V} \tag{2.2.52}$$

where ∇^2 is the Laplacian operator. The small temperature changes, compatible with the incompressibility assumption, are then determined, for a perfect gas with constant k and specific heats, by the energy equation rewritten for the temperature, in the form

$$\rho c_v \frac{DT}{Dt} = k\nabla^2 T + \Phi \tag{2.2.53}$$

Boundary Conditions

The appropriate boundary conditions to be applied at the boundary of a fluid in contact with another medium depends on the nature of this other medium—solid, liquid, or gas. We discuss a few of the more important cases here in turn:

1 *At a solid surface:* $\boldsymbol{V}$ and T are continuous. Contained in this boundary condition is the "no-slip" condition, namely, that the tangential velocity of the fluid in contact with the boundary of the solid is equal to that of the boundary. For an inviscid fluid, the no-slip condition does not apply, and only the normal component of velocity is continuous. If the wall is permeable, the tangential velocity is continuous and the normal velocity is arbitrary; the temperature boundary condition for this case depends on the nature of the injection or suction at the wall.

2. *At a liquid/gas interface*: For such cases the appropriate boundary conditions depend on what can be assumed about the gas the liquid is in contact with. In the classical liquid free-surface problem, the gas, generally atmospheric air, can be ignored and the necessary boundary conditions are that (1) the normal velocity in the liquid at the interface is equal to the normal velocity of the interface and (2) the pressure in the liquid at the interface exceeds the atmospheric pressure by an amount equal to

$$\Delta p = p_{\text{liquid}} - p_{\text{atm}} = \sigma\left(\frac{1}{R_1} + \frac{1}{R_2}\right) \tag{2.2.54}$$

where R_1 and R_2 are the radii of curvature of the intercepts of the interface by two orthogonal planes containing the vertical axis and σ is the interfacial tension. If the gas is a vapor which undergoes nonnegligible interaction and exchanges with the liquid in contact with it, the boundary conditions are more complex. Then, in addition to the above conditions on normal velocity and pressure, the shear stress (momentum flux) and heat flux must be continuous as well.

For interfaces in general the boundary conditions are derived from continuity conditions for each "transportable" quantity, namely continuity of the appropriate intensity across the interface and continuity of the normal component of the flux vector. Fluid momentum and heat are two such transportable quantities, the associated intensities are velocity and temperature, and the associated flux vectors are stress and heat flux. (The reader should be aware of circumstances where these simple criteria do not apply, for example, the velocity slip and temperature jump for a rarefied gas in contact with a solid surface.)

Vorticity in Incompressible Flow

With μ=constant, ρ=constant, and $\boldsymbol{f}=-\boldsymbol{g}=-g\boldsymbol{k}$ the momentum equation reduces to the form (see Equation 2.2.52)

$$\rho\frac{D\boldsymbol{V}}{Dt} = -\nabla p - \rho g\boldsymbol{k} + \mu\nabla^2 V \tag{2.2.55}$$

With the vector identities

$$(\boldsymbol{V}\cdot\nabla)\boldsymbol{V} = \nabla\left(\frac{V^2}{2}\right) - \boldsymbol{V}\times(\nabla\times\boldsymbol{V}) \tag{2.2.56}$$

and

$$\nabla^2 \boldsymbol{V} = \nabla(\nabla\cdot\boldsymbol{V}) \; - \nabla\times \; (\nabla\times\boldsymbol{V}) \tag{2.2.57}$$

and defining the *vorticity*

$$\zeta \equiv \nabla\times\boldsymbol{V} \tag{2.2.58}$$

Equation 2.2.55 can be written, noting that for incompressible flow $\nabla\cdot\boldsymbol{V}=0$,

$$\rho\frac{\partial \boldsymbol{V}}{\partial t} + \nabla\left(p + \frac{1}{2}\rho V^2 + \rho g z \right) = \rho \boldsymbol{V}\times\xi - \mu\nabla\times\xi \tag{2.2.59}$$

The flow is said to be *irrotational* if

$$\zeta \equiv \nabla\times\boldsymbol{V} = 0 \tag{2.2.60}$$

from which it follows that a *velocity potential* Φ can be defined

$$\boldsymbol{V} = \nabla\Phi \tag{2.2.61}$$

Setting $\zeta=0$ in Equation 2.2.59, using Equation 2.2.61, and then integrating with respect to all the spatial variables, leads to

$$\rho\frac{\partial \Phi}{\partial t} + \left(p + \frac{1}{2}\rho V^2 + \rho g z \right) = F(t) \tag{2.2.62}$$

(the arbitrary function $F(t)$ introduced by the integration can either be absorbed in Φ, or is determined by the boundary conditions). Equation 2.2.62 is the unsteady *Bernoulli equation* for irrotational, incompressible flow. (Irrotational flows are always potential flows, even if the flow is compressible. Because the viscous term in Equation 2.2.59 vanishes identically for $\zeta=0$, it would appear that the above Bernoulli equation is valid even for viscous flow. Potential solutions of hydrodynamics are in fact exact solutions of the full Navier–Stokes equations. Such solutions, however, are not valid near solid boundaries or bodies because the no-slip condition generates vorticity and causes nonzero ζ; the potential flow solution is invalid in all those parts of the flow field that have been "contaminated" by the spread of the vorticity by convection and diffusion. See below.)

The curl of Equation 2.2.59, noting that the curl of any gradient is zero, leads to

$$\rho\frac{\partial \zeta}{\partial t} = \rho\nabla\times(\boldsymbol{V}\times\zeta) - \mu\nabla\times\nabla\times\zeta \tag{2.2.63}$$

but

$$\begin{aligned} \nabla^2\zeta &= \nabla(\nabla\cdot\zeta) - \nabla\times\nabla\times\zeta \\ &= -\nabla\times\nabla\times\zeta \end{aligned} \tag{2.2.64}$$

since div curl () ≡ 0, and therefore also

$$\nabla\times\left(\boldsymbol{V}\times\zeta\right) \equiv \zeta(\nabla\boldsymbol{V}) + \boldsymbol{V}\nabla\cdot\zeta - \boldsymbol{V}\nabla\zeta - \zeta\nabla\cdot\boldsymbol{V} \tag{2.2.65}$$

$$= \zeta(\nabla\boldsymbol{V}) - \boldsymbol{V}\nabla\zeta \tag{2.2.66}$$

Equation 2.2.63 can then be written as

$$\frac{D\boldsymbol{\zeta}}{Dt} = (\boldsymbol{\zeta}\cdot\nabla)\boldsymbol{V} + \nu\nabla^2\boldsymbol{\zeta} \tag{2.2.67}$$

where $\nu=\mu/\rho$ is the kinematic viscosity. Equation 2.2.67 is the vorticity equation for incompressible flow. The first term on the right, an inviscid term, increases the vorticity by vortex stretching. In inviscid, two-dimensional flow both terms on the right-hand side of Equation 2.2.67 vanish, and the equation reduces to $D\zeta/Dt=0$, from which it follows that the vorticity of a fluid particle remains constant as it moves. This is Helmholtz's theorem. As a consequence it also follows that if $\zeta=0$ initially, $\zeta\equiv 0$ always; i.e., *initially irrotational flows remain irrotational* (for inviscid flow). Similarly, it can be proved that $D\Gamma/Dt=0$; i.e., the circulation around a material closed circuit remains constant, which is Kelvin's theorem.

If $\nu\neq 0$, Equation 2.2.67 shows that the vorticity generated, say, at solid boundaries, diffuses and stretches as it is convected.

We also note that for steady flow the Bernoulli equation reduces to

$$p+\frac{1}{2}\rho V^2+\rho g z = \text{constant} \tag{2.2.68}$$

valid for steady, irrotational, incompressible flow.

Stream Function

For two-dimensional planar, incompressible flows ($\boldsymbol{V}=(u,\nu)$), the continuity equation

$$\frac{\partial u}{\partial x}+\frac{\partial \nu}{\partial y}=0 \tag{2.2.69}$$

can be identically satisfied by introducing a stream function Ψ, defined by

$$u=\frac{\partial\psi}{\partial y}, \qquad \upsilon=-\frac{\partial\psi}{\partial x} \tag{2.2.70}$$

Physically Ψ is a measure of the flow between streamlines. (Stream functions can be similarly defined to satisfy identically the continuity equations for incompressible cylindrical and spherical axisymmetric flows; and for these flows, as well as the above planar flow, also when they are compressible, but only then if they are steady.) Continuing with the planar case, we note that in such flows there is only a single nonzero component of vorticity, given by

$$\boldsymbol{\zeta}=(0,0,\zeta_z)=\left(0,0,\frac{\partial\nu}{\partial x}-\frac{\partial u}{\partial y}\right) \tag{2.2.71}$$

With Equation 2.2.70

$$\zeta_z=-\frac{\partial^2\psi}{\partial x^2}-\frac{\partial^2\psi}{\partial y^2}=-\nabla^2\psi \tag{2.2.72}$$

For this two-dimensional flow, Equation 2.2.67 reduces to

$$\frac{\partial\zeta_z}{\partial t}+\nu\frac{\partial\zeta_z}{\partial x}+\nu\frac{\partial\zeta_z}{\partial y}=\nu\left(\frac{\partial^2\zeta_z}{\partial x^2}+\frac{\partial^2\zeta_z}{\partial y^2}\right)=\nu\nabla^2\zeta_z \tag{2.2.73}$$

Substitution of Equation 2.2.72 into Equation 2.2.73 yields an equation for the stream function

$$\frac{\partial\left(\nabla^2\psi\right)}{\partial t}+\frac{\partial\psi}{\partial y}\frac{\partial\left(\nabla^2\psi\right)}{\partial x}-\frac{\partial\psi}{\partial x}\frac{\partial}{\partial y}\left(\nabla^2\psi\right)=\nu\nabla^2\psi \tag{2.2.74}$$

where $\nabla^4=\nabla^2\,(\nabla^2)$. For uniform flow past a solid body, for example, this equation for Ψ would be solved subject to the boundary conditions:

$$\begin{aligned}&\frac{\partial\psi}{\partial x}=0,\quad \frac{\partial\psi}{\partial y}=V_\infty \qquad \text{at infinity}\\ &\frac{\partial\psi}{\partial x}=0,\quad \frac{\partial\psi}{\partial y}=0 \qquad \text{at the body (no-slip)}\end{aligned} \tag{2.2.75}$$

For the special case of irrotational flow, it follows immediately from Equations 2.2.70 and 2.2.71 with $\zeta_z=0$, that Ψ satisfies the Laplace equation

$$\nabla^2\psi=\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}=0 \tag{2.2.76}$$

Inviscid Irrotational Flow: Potential Flow

For irrotational flows, we have already noted that a velocity potential Φ can be defined such that $\boldsymbol{V}=\nabla\Phi$. If the flow is also incompressible, so $\nabla\cdot\boldsymbol{V}=0$, it then follows that

$$\nabla\cdot(\nabla\Phi)=\nabla^2\Phi=0 \tag{2.2.77}$$

so Φ satisfies Laplace's equation. (Note that unlike the stream function Ψ, which can only be defined for two-dimensional flows, the above considerations for Φ apply to flow in two and three dimensions. On the other hand, the existence of Ψ does not require the flow to be irrotational, whereas the existence of Φ does.)

Since Equation 2.2.77 with appropriate conditions on $\boldsymbol{V}$ at boundaries of the flow completely determines the velocity field, and the momentum equation has played no role in this determination, we see that inviscid irrotational flow—*potential theory*—is a purely kinematic theory. The momentum equation enters only after Φ is known in order to calculate the pressure field consistent with the velocity field $\boldsymbol{V}=\nabla\Phi$.

For both two-and three-dimensional flows the determination of Φ makes use of the powerful techniques of potential theory, well developed in the mathematical literature. For two-dimensional planar flows, the techniques of complex variable theory are available, since Φ may be considered as either the real or imaginary part of an analytic function (the same being true for Ψ, since for such two-dimensional flows Φ and Ψ are conjugate variables.)

Because the Laplace equation, obeyed by both Φ and Ψ, is linear, complex flows may be built up from the superposition of simple flows; this property of inviscid irrotational flows underlies nearly all solution techniques in this area of fluid mechanics.

Example 2.2.2

A two-dimensional inviscid irrotational flow has the velocity potential

$$\Phi = x^2-y^2 \tag{P.2.2.6}$$

What two-dimensional potential flow does this represent?

Solution: It follows from Equations 2.2.61 and 2.2.70 that for two-dimensional flows, in general

$$u = \frac{\partial \Phi}{\partial x} = \frac{\partial \psi}{\partial y}, \qquad \upsilon = \frac{\partial \Phi}{\partial y} = -\frac{\partial \psi}{\partial x} \tag{P.2.2.7}$$

It follows from Equation P.2.2.6 that

$$u = \frac{\partial \psi}{\partial y} = 2x, \qquad \upsilon = -\frac{\partial \psi}{\partial x} = -2y \tag{P.2.2.8}$$

Integration of Equation P.2.2.8 yields

$$\Psi = 2xy \tag{P.2.2.9}$$

The streamlines, Ψ=constant, and equipotential lines, Φ=constant, both families of hyperbolas and each family the orthogonal trajectory of the other, are shown in Figure 2.2.3. Because the x and y axes are streamlines, Equations P.2.2.6 and P.2.2.9 represent the inviscid irrotational flow in a right-angle corner. By symmetry, they also represent the planar flow in the upper half-plane directed toward a stagnation point at $x=y=0$ (see Figure 2.2.4). In polar coordinates (r, θ), with corresponding velocity components (u_r, u_θ), this flow is represented by

$$\Phi = r^2 \cos 2\theta, \qquad \psi = r^2 \sin 2\theta \tag{P.2.2.10}$$

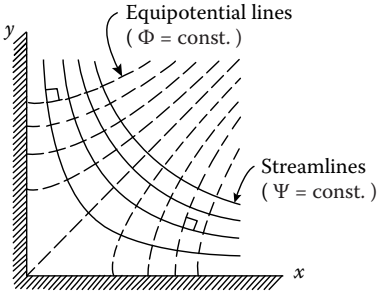

FIGURE 2.2.3 Potential flow in a 90° corner.

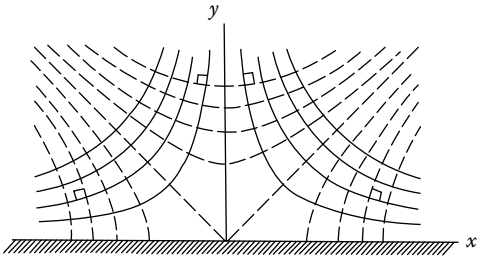

FIGURE 2.2.4 Potential flow impinging against a flat (180°) wall (plane stagnation-point flow).

with

$$u_r = \frac{\partial \Phi}{\partial r} = \frac{1}{r}\frac{\partial \psi}{\partial \theta} = 2r\cos 2\theta$$
$$u_\theta = \frac{1}{r}\frac{\partial \Phi}{\partial \theta} = -\frac{\partial \psi}{\partial r} = -2r\sin 2\theta \qquad \text{(P.2.2.11)}$$

For two-dimensional planar potential flows we may also use complex variables, writing the complex potential $f(z)=\Phi+i\Psi$ as a function of the complex variable $z=x+iy$, where the complex velocity is given by $f'(z)=w(z)=u-iv$. For the flow above,

$$f(z) = z^2 \qquad \text{(P.2.2.12)}$$

Expressions such as Equation P.2.2.12, where the right-hand side is an analytic function of z, may also be regarded as a conformal mapping, which makes available as an aid in solving two-dimensional potential problems all the tools of this branch of mathematics.

2.3 SIMILITUDE: DIMENSIONAL ANALYSIS AND DATA CORRELATION

Stuart W. Churchill

Dimensional Analysis

Similitude refers to the formulation of a description for physical behavior that is general and independent of the individual dimensions, physical properties, forces, etc. In this subsection, the treatment of similitude is restricted to *dimensional analysis*; for a more general treatment see Zlokarnik (1991, 2006). The full power and utility of dimensional analysis is often underestimated and underutilized by engineers. This technique may be applied to a complete mathematical model or to a simple listing of the variables that define the behavior. Only the latter application is described here. For a description of the application of dimensional analysis to a mathematical model see Hellums and Churchill (1964).

General Principles

Dimensional analysis is based on the principle that all additive or equated terms of a complete relationship between the variables must have the same net dimensions. The analysis starts with the preparation of a list of the individual dimensional variables (dependent, independent, and parametric) that are presumed to define the behavior of interest. The performance of dimensional analysis in this context is reasonably simple and straightforward; the principal difficulty and uncertainty arise from the identification of the variables to be included or excluded. If one or more important variables are inadvertently omitted, the reduced description achieved by dimensional analysis will be incomplete and inadequate as a guide for the correlation of a full range of experimental data or theoretical values. The familiar band of plotted values in many graphical correlations is more often a consequence of the omission of one or more variables than of inaccurate measurements. If, on the other hand, one or more irrelevant or unimportant variables are included in the listing, the consequently reduced description achieved by dimensional analysis will result in one or more unessential dimensionless groupings. Such excessive dimensionless groupings are generally less troublesome than missing ones because the redundancy will ordinarily be revealed by the process of correlation. Excessive groups may, however, suggest unnecessary experimental work or computations, or result in misleading correlations. For example, real experimental scatter may inadvertently and incorrectly be correlated in all or in part with the variance of the excessive grouping.

In consideration of the inherent uncertainty in selecting the appropriate variables for dimensional analysis, it is recommended that this process be interpreted as *speculative* and subject to correction on the basis of experimental data or other information. Speculation may also be utilized as a formal technique to identify the effect of eliminating a variable or of combining two or more. The latter aspect of speculation, which may be applied either to the original listing of dimensional variables or to the resulting set of dimensionless groups, is often of great utility in identifying possible limiting behavior or dimensionless groups of marginal significance. The systematic speculative elimination of all but the most certain variables, one at a time, followed by regrouping, is recommended as a general practice. The additional effort as compared with the original dimensional analysis is minimal, but the possible return is very high. A general discussion of this process may be found in Churchill (1981).

The minimum number of independent dimensionless groups i required to describe the fundamental and parametric behavior is (Buckingham, 1914)

$$i = n - m \tag{2.3.1}$$

where n is the number of variables and m is the number of fundamental dimensions such as mass M, length L, time θ, and temperature T that are introduced by the variables. The inclusion of redundant dimensions such as force F and energy E that may be expressed in terms of mass, length, time, and temperature is at the expense of added complexity and is to be avoided. (Of course, mass could be replaced by force or temperature by energy as alternative fundamental dimensions.) In some rare cases i is actually greater than $n-m$. Then

$$i = n - k \tag{2.3.2}$$

where k is the maximum number of the chosen variables that cannot be combined to form a dimensionless group. Determination of the minimum number of dimensionless groups is helpful if the groups are to be chosen by inspection, but is unessential if the algebraic procedure described below is utilized to determine the groups themselves since the number is then obvious from the final result.

The *particular* minimal set of dimensionless groups is arbitrary in the sense that two or more of the groups may be multiplied together to any positive, negative, or fractional power as long as the number of independent groups is unchanged. For example, if the result of a dimensional analysis is

$$\phi\{X, Y, Z\} = 0 \tag{2.3.3}$$

where X, Y, and Z are independent dimensionless groups, an equally valid expression is

$$\phi\{XY^{1/2}, Z/Y^2, Z\} = 0 \tag{2.3.4}$$

Dimensional analysis itself does not provide any insight as to the best choice of equivalent dimensionless groupings, such as between those of Equations 2.3.3 and 2.3.4. However, isolation of each of the variables that are presumed to be the most important in a separate group may be convenient in terms of interpretation and correlation. Another possible criterion in choosing between alternative groupings may be the relative invariance of a particular one. The functional relationship provided by Equation 2.3.3 may equally well be expressed as

$$X = \phi\{Y, Z\} \tag{2.3.5}$$

where X is implied to be the dependent grouping and Y and Z to be independent or parametric groupings.

Three primary methods of determining a minimal set of dimensionless variables are (1) by inspection; (2) by combination of the residual variables, one at a time, with a set of chosen variables that cannot be combined to obtain a dimensionless group; and (3) by an algebraic procedure. These methods are illustrated in the examples that follow.

Example 2.3.1: Fully Developed Flow of Water through a Smooth Round Pipe

Choice of Variables. The shear stress τ_w on the wall of the pipe may be postulated to be a function of the density ρ and the dynamic viscosity μ of the water, the inside diameter D of the pipe, and the space-mean of the time-mean velocity u_m. The limitation to fully developed flow is equivalent to a postulate of independence from distance x in the direction of flow, and the specification of a smooth pipe is equivalent to the postulate of independence from the roughness e of the wall. The choice of τ_w rather than the pressure drop per unit length $-dP/dx$ avoids the need to include the acceleration due to gravity g and the elevation z as variables. The choice of u_m rather than the volumetric rate of flow V, the mass rate of flow w, or the mass rate of flow per unit area G is arbitrary but has some important consequences as noted below. The postulated dependence may be expressed functionally as $\phi\{\tau_w, \rho, \mu, D, u_m\}=0$ or $\tau_w=\phi\{\rho, \mu, D, u_m\}$.

Tabulation. Next prepare a tabular listing of the variables and their dimensions:

	τ_w	ρ	μ	D	u_m
M	1	1	1	0	0
L	–1	–3	–1	1	1
θ	–2	0	–1	0	–1
T	0	0	0	0	0

Minimal Number of Groups. The number of postulated variables is 5. Since the temperature does not occur as a dimension for any of the variables, the number of fundamental dimensions is 3. From Equation 2.3.1, the minimal number of dimensionless groups is $5-3=2$. From inspection of the above tabulation, a dimensionless group cannot be formed from as many as three variables such as D, μ, and ρ. Hence, Equation 2.3.2 also indicates that $i=5-3=2$.

Method of Inspection. By inspection of the tabulation or by trial and error it is evident that only two independent dimensionless groups may be formed. One such set is

$$\phi\left\{\frac{\tau_w}{\rho u_m^2}, \frac{Du_m\rho}{\mu}\right\}=0$$

Method of Combination. The residual variables τ_w and μ may be combined in turn with the non-combining variables ρ, D, and u_m to obtain two groups such as those above.

Algebraic Method. The algebraic method makes formal use of the postulate that the functional relationship between the variables may in general be represented by a power series. In this example such a power series may be expressed as

$$\tau_w = \sum_{i=1}^{N} A_i \rho^{a_i} \mu^{b_i} D^{c_i} u_m^{d_i}$$

where the coefficients A_i are dimensionless. Each additive term on the right-hand side of this expression must have the same net dimensions as τ_w. Hence, for the purposes of dimensional analysis, only the first term need be considered and the indexes may be dropped. The resulting highly restricted expression is $\tau_w = A\varrho^a \mu^b D^c u_m^d$. Substituting the dimensions for the variables gives

$$\frac{M}{L\theta^2} = A\left(\frac{M}{L^3}\right)^a \left(\frac{M}{L\theta}\right)^b L^c \left(\frac{L}{\theta}\right)^d$$

Equating the sum of the exponents of M, L, and θ on the right-hand side of the above expression with those of the left-hand side produces the following three simultaneous linear algebraic equations: $1=a+b$; $-1=-3a-b+c+d$; and $-2=-b-d$, which may be solved for a, c, and d in terms of b to obtain $a=1-b$, $c=-b$, and $d=2-b$. Substitution then gives $\tau_w = A\rho^{1-b}\mu^b D^{-b} u_m^{2-b}$ which may be regrouped as

$$\frac{\tau_w}{\rho u_m^2} = A\left(\frac{\mu}{Du_m\rho}\right)^b$$

Since this expression is only the first term of a power series, it should *not* be interpreted to imply that $\tau_w/\varrho u_m^2$ necessarily proportional to some power at $\mu/Du_m\rho$ but instead only the equivalent of the expression derived by the method of inspection. The inference of a power dependence between the dimensionless groups is the most common and serious error in the use of the algebraic method of dimensional analysis.

Speculative Reductions. Eliminating ρ from the original list of variables on speculative grounds leads to

$$\phi\left\{\frac{\tau_w D}{\mu u_m}\right\} = 0$$

or its exact equivalent:

$$\frac{\tau_w D}{\mu u_m} = A$$

The latter expression with $A=8$ is actually the exact solution for the laminar regime ($Du_m\rho/\mu < 1800$). A relationship that does not include ρ may alternatively be derived directly from the solution by the method of inspection as follows. First, ρ is eliminated from one group, say $\tau_w/\rho u_m^2$, by multiplying it with $Du_m\rho/\mu$ to obtain

$$\phi\left\{\frac{\tau_w D}{\mu u_m}, \frac{Du_m\rho}{\mu}\right\} = 0$$

The remaining group containing ρ is now simply dropped. Had the original expression been composed of three independent groups each containing ρ, that variable would have to be eliminated from two of them before dropping the third one.

The relationships that are obtained by the speculative elimination of μ, D, and u_m, one at a time, do not appear to have any range of physical validity. Furthermore, if w or G had been chosen as the independent variable rather than u_m, the limiting relationship for the laminar regime would not have been obtained by the elimination of ρ.

Alternative Forms. The solution may also be expressed in an infinity of other forms such as

$$\phi\left\{\frac{\tau_w D^2\rho}{\mu^2}, \frac{Du_m\rho}{\mu}\right\} = 0$$

If τ_w is considered to be the principal dependent variable and u_m the principal independent variable, this latter form is preferable in that these two quantities do not then appear in the same grouping. On the other hand, if D is considered to be the principal independent variable, the original formulation is preferable. The variance of $\tau_w/\rho u_m^2$ is less than that of $\tau_w D/\mu u_m$ and $\tau_w D^2\rho/\mu^2$ in the turbulent regime while that of $\tau_w D/\mu u_m$ is zero in the laminar regime. Such considerations may be important in devising convenient graphical correlations.

Alternative Notations. The several solutions above are more commonly expressed as

$$\phi\left\{\frac{f}{2}, \mathrm{Re}\right\} = 0$$

$$\phi\left\{\frac{f\,\mathrm{Re}}{2}, \mathrm{Re}\right\} = 0$$

or

$$\phi\left\{\frac{f\,\mathrm{Re}^2}{2}, \mathrm{Re}\right\} = 0$$

where $f = 2\tau_w/\rho u_m^2$ is the *Fanning friction factor* and $Re = Du_m\rho/\mu$ is the *Reynolds number*.

The more detailed forms, however, are to be preferred for purposes of interpretation or correlation because of the explicit appearance of the individual, physically measurable variables.

Addition of a Variable. The above results may readily be extended to incorporate the roughness e of the pipe as a variable. If two variables have the same dimensions, they will always appear as

a dimensionless group in the form of a ratio, in this case e appears most simply as e/D. Thus, the solution becomes

$$\phi\left\{\frac{\tau_w}{\rho u_m^2}, \frac{Du_m\rho}{\mu}, \frac{e}{D}\right\} = 0$$

Surprisingly, as contrasted with the solution for a smooth pipe, the speculative elimination of μ and hence of the group $Du_m\rho/\mu$ now results in a valid asymptote for $Du_m\rho/\mu \to \infty$ and all finite values of e/D, namely,

$$\phi\left\{\frac{\tau_w}{\rho u_m^2}, \frac{e}{D}\right\} = 0$$

Example 2.3.2: Fully Developed Forced Convection in Fully Developed Flow in a Round Tube

It may be postulated for this process that $h=\phi\{D, u_m, \rho, \mu, k, c_p\}$, where here h is the local heat-transfer coefficient, and c_p and k are the specific heat capacity and thermal conductivity, respectively, of the fluid. The corresponding tabulation is

	h	D	u_m	ρ	μ	K	c_p
M	1	0	0	1	1	1	0
L	0	1	1	–3	–1	1	2
θ	–3	0	–1	0	–1	–3	–2
T	–1	0	0	0	0	–1	–1

The number of variables is 7 and the number of independent dimensions is 4, as is the number of variables such as D, u_m, ρ, and k that cannot be combined to obtain a dimensionless group. Hence, the minimal number of dimensionless groups is $7-4=3$. The following acceptable set of dimensionless groups may be derived by any of the procedures illustrated in Example 2.3.1:

$$\frac{hD}{k} = \phi\left\{\frac{Du_m\rho}{\mu}, \frac{c_p\mu}{k}\right\}$$

Speculative elimination of μ results in

$$\frac{hD}{k} = \phi\left\{\frac{Du_m\rho c_p}{k}\right\}$$

which has often erroneously been inferred to be a valid asymptote for $c_p\mu/k \to 0$. Speculative elimination of D, u_m, ρ, k, and c_p individually also does not appear to result in expressions with any physical validity. However, eliminating c_p and ρ or u_m gives a valid result for the laminar regime, namely,

$$\frac{hD}{k} = A$$

The general solutions for flow and convection in a smooth pipe may be combined to obtain

$$\frac{hD}{k} = \phi\left\{\frac{\tau_w D^2 \rho}{\mu^2}, \frac{c_p \mu}{k}\right\}$$

which would have been obtained directly had u_m been replaced by τ_w in the original tabulation. This latter expression proves to be superior in terms of speculative reductions. Eliminating D results in

$$\frac{h\mu}{k(\tau_w \rho)^{1/2}} = \phi\left\{\frac{c_p \mu}{k}\right\}$$

which may be expressed in the more conventional form of

$$\mathrm{Nu} = \mathrm{Re}\left(\frac{f}{2}\right)^{1/2} \phi\{\mathrm{Pr}\}$$

where $\mathrm{Nu} = hD/k$ is the *Nusselt number* and $\mathrm{Pr} = c_p\mu/k$ is the *Prandtl number*. This result appears to be a valid asymptote for $\mathrm{Re} \to \infty$ and a good approximation for even moderate values (Re >5000) for large values of Pr. Elimination of μ as well as D results in

$$\frac{h}{c_p(\tau_w \rho)^{1/2}} = A$$

or

$$\mathrm{Nu} = A\,\mathrm{Re}\,\mathrm{Pr}\left(\frac{f}{2}\right)^{1/2}$$

which appears to be an approximate asymptote for $\mathrm{Re} \to \infty$ and $\mathrm{Pr} \to 0$. Elimination of both c_p and ρ again yields the appropriate result for laminar flow, indicating that ρ rather than u_m is the meaningful variable to eliminate in this respect.

The numerical value of the coefficient A in the several expressions above depends on the mode of heating, a true variable, but one from which the purely functional expressions are independent. If j_w, the heat flux density at the wall, and $T_w - T_m$, the temperature difference between the wall and the bulk of the fluid, were introduced as variables in place of $h \equiv j_w/(T_w - T_m)$, another group such as $c_p(T_w - T_m)(D\rho/\mu)^2$ or $\rho c_p(T_w - T_m)/\tau_w$ or $c_p(T_w - T_m)/u_m^2$ which represents the effect of viscous dissipation, would be obtained. This effect is usually but not always negligible.

Example 2.3.3: Free Convection from a Vertical Isothermal Plate

The behavior for this process may be postulated to be represented by

$$h = \phi\{g, \beta, (T_w - T_\infty), x, \mu, \rho, c_p, k\}$$

where g is the acceleration due to gravity, β is the volumetric coefficient of expansion with temperature, T_∞ is the unperturbed temperature of the fluid, and x is the vertical distance along the plate. The corresponding tabulation is

	h	g	β	$T_w - T_\infty$	x	μ	ρ	c_p	k
M	1	0	0	0	0	1	1	0	1
L	0	1	0	0	1	–1	–3	2	1
θ	–3	–2	0	0	0	–1	0	–2	–3
T	–1	0	–1	1	0	0	0	–1	1

The minimal number of dimensionless groups indicated by both methods is $9-4=5$. A satisfactory set of dimensionless groups, as found by any of the methods illustrated in Example 2.3.1, is

$$\frac{hx}{k}=\phi\left\{\frac{\rho^2 g x^3}{\mu^2},\frac{c_p\mu}{k},\beta\left(T_w-T_\infty\right),c_p\left(T_w-T_\infty\right)\left(\frac{\rho x}{\mu}\right)^2\right\}$$

It may be reasoned that the buoyant force which generates the convective motion must be proportional to $\rho g\beta(T_w-T_\infty)$, thus, g in the first term on the right-hand side must be multiplied by $\beta(T_w-T_\infty)$, resulting in

$$\frac{hx}{k}=\phi\left\{\frac{\rho^2 g\beta\left(T_w-T_\infty\right)x^3}{\mu^2},\frac{c_p\mu}{k},\beta\left(T_w-T_\infty\right),c_p\left(T_w-T_\infty\right)\left(\frac{\rho x}{\mu}\right)^2\right\}$$

The effect of expansion other than on the buoyancy is now represented by $\beta(T_w-T_\infty)$, and the effect of viscous dissipation by $c_p(T_w-T_\infty)(\rho x/\mu)^2$. Both effects are negligible for all practical circumstances. Hence, this expression may be reduced to

$$\frac{hx}{k}=\phi\left\{\frac{\rho^2 g\beta\left(T_w-T_\infty\right)x^3}{\mu^2},\frac{c_p\mu}{k}\right\}$$

or

$$\mathrm{Nu}_x=\phi\left\{\mathrm{Gr}_x,\mathrm{Pr}\right\}$$

where $\mathrm{Nu}_x=hx/k$ and $\mathrm{Gr}_x=\rho^2 g\beta(T_w-T_\infty)x^3/\mu^2$ is the *Grashof number*.

Elimination of x speculatively now results in

$$\frac{hx}{k}=\left(\frac{\rho^2 g\beta\left(T_w-T_\infty\right)x^3}{\mu^2}\right)^{1/3}\phi\left\{\mathrm{Pr}\right\}$$

or

$$\mathrm{Nu}_x=\mathrm{Gr}_x^{1/3}\phi\{\mathrm{Pr}\}$$

This expression appears to be a valid asymptote for $\mathrm{Gr}_x\to\infty$ and a good approximation for the entire turbulent regime. Eliminating μ speculatively rather than x results in

$$\frac{hx}{k}=\phi\left\{\frac{\rho^2 c_p^2 g\beta\left(T_w-T_\infty\right)x^3}{k^2}\right\}$$

or

$$\mathrm{Nu}_x=\phi\left\{\mathrm{Gr}_x\mathrm{Pr}^2\right\}$$

The latter expression appears to be a valid asymptote for $\mathrm{Pr}\to 0$ for all Gr_x, that is, for both the laminar and the turbulent regimes. The development of a valid asymptote for large values of Pr requires more subtle reasoning. First $c_p\mu/k$ is rewritten as $\mu/\rho\alpha$ where $\alpha=k/\rho c_p$. Then ρ is eliminated speculatively except as it occurs in $\rho g\beta(T_w-T_\infty)$ and $k/\rho c_p$. The result is

$$\frac{hx}{k}=\phi\left\{\frac{c_p\rho^2 g\beta(T_w-T_\infty)x^3}{\mu k}\right\}$$

or

$$\mathrm{Nu}_x=\phi\left\{\mathrm{Ra}_x\right\}$$

where

$$\mathrm{Ra}_x = \frac{c_p \rho^2 g \beta (T_w - T_\infty) x^3}{\mu k} = \mathrm{Gr}_x \mathrm{Pr}$$

is the *Rayleigh number*. The above expression for Nu_x appears to be a valid asymptote for $\mathrm{Pr} \to \infty$ and a reasonable approximation for even moderate values of Pr for all Gr_x, that is, for both the laminar and the turbulent regimes.

Eliminating x speculatively from the above expressions for small and large values of Pr results in

$$\mathrm{Nu}_x = A\left(\mathrm{Gr}_x \mathrm{Pr}^2\right)^{1/3} = A\left(\mathrm{Ra}_x \mathrm{Pr}\right)^{1/3}$$

and

$$\mathrm{Nu}_x = B\left(\mathrm{Gr}_x \mathrm{Pr}\right)^{1/3} = B\left(\mathrm{Ra}_x\right)^{1/3}$$

The former appears to be a valid asymptote for $\mathrm{Pr} \to 0$ and $\mathrm{Gr}_x \to \infty$ and a reasonable approximation for very small values of Pr in the turbulent regime, while the latter is well confirmed as a valid asymptote for $\mathrm{Pr} \to \infty$ and $\mathrm{Gr}_x \to \infty$ and as a good approximation for moderate and large values of Pr over the entire turbulent regime. The expressions in terms of Gr_x are somewhat more complicated than those in terms of Ra_x, but are to be preferred since Gr_x is known to characterize the transition from laminar to turbulent motion in natural convection just as Re_D does in forced flow in a channel. The power of speculation combined with dimensional analysis is well demonstrated by this example in which valid asymptotes are thereby attained for several regimes.

Correlation of Experimental Data and Theoretical Values

Correlations of experimental data are generally developed in terms of dimensionless groups rather than in terms of the separate dimensional variables in the interests of compactness and in the hope of greater generality. For example, a complete set of graphical correlations for the heat-transfer coefficient h of Example 2.3.2 in terms of each of the six individual independent variables and physical properties might approach book length, whereas the dimensionless groupings both imply that a single plot with one parameter should be sufficient. Furthermore, the reduced expression for the turbulent regime implies that a plot of $\mathrm{Nu}/\mathrm{Re}\, f^{1/2}$ vs. Pr should demonstrate only a slight parametric dependence on Re or $\mathrm{Re}\, f^{1/2}$. Of course, the availability of a separate correlation for f as a function of Re is implied.

Theoretical values, that is, ones obtained by numerical solution of a mathematical model in terms of either dimensional variables or dimensionless groups, are presumably free from imprecision. Even so, because of their discrete form, the construction of a correlation or correlations for such values may be essential for the same reasons as for experimental data.

Graphical correlations have the merit of revealing general trends, of providing a basis for evaluation of the choice of coordinates, and most of all of displaying visually the scatter of the individual experimental values about a curve representing a correlation or their behavior on the mean. As mentioned in the previous subsection, the omission of a variable may, however give the false impression of experimental error in such a plot. On the other hand, correlating equations are far more convenient as an input to a computer than is a graphical correlation. These two formats thus have distinct and complementary roles; both should generally be utilized. The merits and demerits of various graphical forms of correlations are discussed in detail by Churchill (1979), while the use of logarithmic and arithmetic coordinates, the effects of the appearance of a variable in both coordinates, and the effects of the distribution of error between the dependent and independent variable are further illustrated by Wilkie (1985).

Churchill and Usagi (1972, 1974) proposed general usage of the following expression for the formulation of correlating equations:

$$y^n\{x\} = y_0^n\{x\} + y_\infty^n\{x\} \tag{2.3.6}$$

where $y_0\{x\}$ and $y_\infty\{x\}$ denote asymptotes for small and large values of x, respectively, and n is an arbitrary exponent. For convenience and simplicity, Equation 2.3.6 may be rearranged in either of the following two forms:

$$\left(Y(x)\right)^n = 1 + Z^n\{x\} \tag{2.3.7}$$

or

$$\left(\frac{Y\{x\}}{Z\{x\}}\right)^n = 1 + \frac{1}{Z^n\{x\}} \tag{2.3.8}$$

where $Y\{x\} \equiv y\{x\}/y_0\{x\}$ and $Z\{x\} \equiv y_\infty\{x\}/y_0\{x\}$. Equations 2.3.6, 2.3.7, and 2.3.8 are hereafter denoted collectively as the CUE (Churchill–Usagi equation). The principal merits of the CUE as a canonical expression for correlation are its simple form, generality, and minimal degree of explicit empiricism, namely, only that of the exponent n, since the asymptotes $y_0\{x\}$ and $y_\infty\{x\}$ are ordinarily known in advance from theoretical considerations or well-established correlations. Furthermore, as will be shown, the CUE is quite insensitive to the numerical value of n. Although the CUE is itself very simple in form, it is remarkably successful in representing closely very complex behavior, even including the dependence on secondary variables and parameters, by virtue of the introduction of such dependencies through $y_0\{x\}$ and $y_\infty\{x\}$. In the rare instances in which such dependencies are not represented in the asymptotes, n may be correlated as a function of the secondary variables and/or parameters. Although the CUE usually produces very close representations, it is empirical and not exact. In a few instances, numerical values of n have been derived or rationalized on theoretical grounds, but even then some degree of approximation is involved. Furthermore, the construction of a correlating expression in terms of the CUE is subject to the following severe limitations:

1. The asymptotes $y_0\{x\}$ and $y_\infty\{x\}$ must intersect once and only once;
2. The asymptotes $y_0\{x\}$ and $y_\infty\{x\}$ must be free of singularities. Even though a singularity occurs beyond the asserted range of the asymptote, it will persist and disrupt the prediction of the CUE, which is intended to encompass all values of the independent variable *x;* and
3. The asymptotes must both be upper or lower bounds.

In order to avoid or counter these limitations, it may be necessary to modify or replace the asymptotes with others. Examples of this process are provided below. A different choice for the dependent variable may be an option in this respect. The suitable asymptotes for use in Equation 2.3.6 may not exist in the literature and therefore may need to be devised or constructed. See, for example, Churchill (1988b) for guidance in this respect. Integrals and derivatives of the CUE are generally awkward and inaccurate, and may include singularities not present or troublesome in the CUE itself. It is almost always preferable to develop a separate correlating equation for such quantities using derivatives or integrals of $y_0\{x\}$ and $y_\infty\{x\}$, simplified or modified as appropriate.

The Evaluation of *n*

Equation 2.3.6 may be rearranged as

$$n = \frac{\ln\left\{1+\left(\dfrac{y_\infty\{x\}}{y_0\{x\}}\right)^n\right\}}{\ln\left\{\dfrac{y\{x\}}{y_0\{x\}}\right\}} \tag{2.3.9}$$

and solved for n by iteration for any known value of $y\{x\}$, presuming that $y_0\{x\}$ and $y_\infty\{x\}$ are known. If $y\{x^*\}$ is known, where x^* represents the value of x at the point of intersection of the asymptotes, that is, for $y_0\{x\} = y_\infty\{x\}$, Equation 2.3.9 reduces to

$$n = \frac{\ln\{2\}}{\ln\left\{\dfrac{y\{x^*\}}{y_0\{x^*\}}\right\}} \tag{2.3.10}$$

and iterative determination of n is unnecessary.

A graphical and visual method of evaluation of n is illustrated in Figure 2.3.1 in which $Y\{Z\}$ is plotted vs. Z for $0 \le Z \le 1$ and $Y\{Z\}/Z$ vs. $1/Z$ for $0 \le 1/Z \le 1$ in arithmetic coordinates with n as a parameter. Values of $y\{x\}$ may be plotted in this form and the best overall value of n selected visually (as illustrated in Figure 2.3.2). A logarithmic plot of $Y\{Z\}$ vs. Z would have less sensitivity relative to the dependence on n. (See, for example, Figure 1 of Churchill and Usagi, 1972.). Figure 2.3.1 explains in part the success of the CUE. Although y and x may both vary from 0 to ∞, the composite variables plotted in Figure 2.3.1 are highly constrained in that the compound independent variables Z and $1/Z$ vary only between 0 and 1, while for $n \ge 1$, the compound dependent variables $Y\{Z\}$ and $Y\{Z\}/Z$ vary only from 1 to 2.

Because of the relative insensitivity of the CUE to the numerical value of n, an integer or a ratio of two small integers may be chosen in the interest of simplicity and without significant loss of accuracy. For example, the maximum variance in Y (for $0 \le Z \le 1$) occurs at $Z = 1$ and increases only $100(2^{1/20} - 1) = 3.5\%$ if n is decreased from 5 to 4. If $y_0\{x\}$ and $y_\infty\{x\}$ are both lower bounds, n will be positive, and if they are both upper bounds, n will be negative. To avoid extending Figure 2.3.1 for negative values of n, $1/y\{x\}$ may simply be interpreted as the dependent variable.

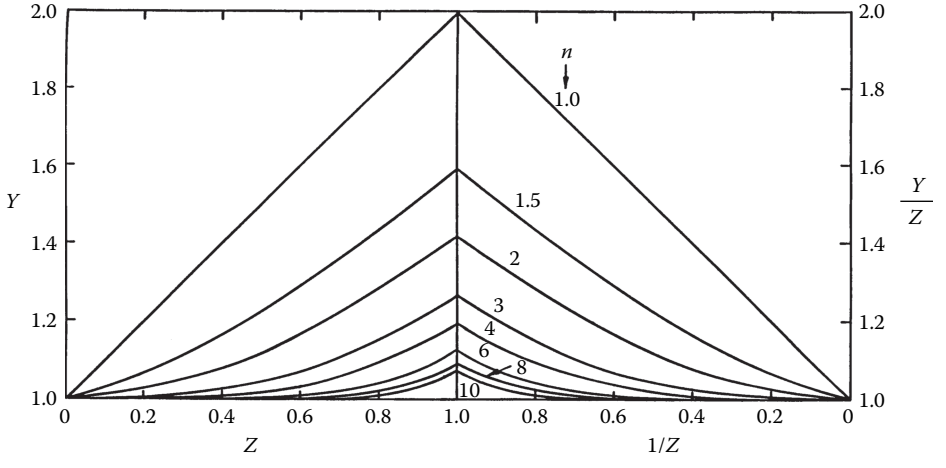

FIGURE 2.3.1 Arithmetic, split-coordinate plot of Equation 2.3.10. (From Churchill, S.W. and Usagi, R., *AIChE J.*, 18, 1123, 1972. With permission from the American Institute of Chemical Engineers.)

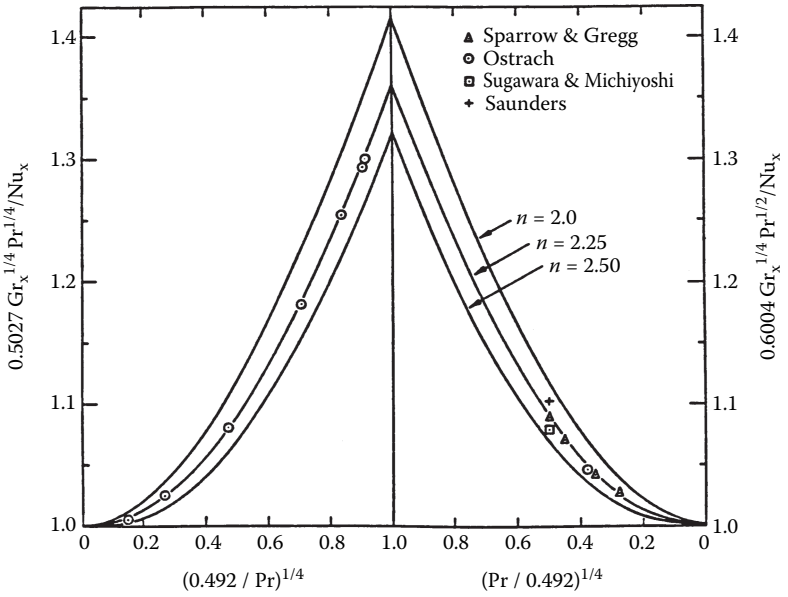

FIGURE 2.3.2 Arithmetic, split-coordinate plot of computed values and experimental data for laminar free convection from an isothermal vertical plate. (From Churchill, S.W. and Usagi, R., *AIChE J.*, 18, 1124, 1972. With permission from the American Institute of Chemical Engineers.)

Intermediate Regimes

Equations 2.3.6, 2.3.7, and 2.3.8 imply a slow, smooth transition between $y_0\{x\}$ and $y_\infty\{x\}$ and, moreover, one that is symmetrical with respect to $x^*(Z=1)$. Many physical systems demonstrate instead a relatively abrupt transition, as for example from laminar to turbulent flow in a channel or along a flat plate. The CUE may be applied serially as follows to represent such behavior if an expression $y_i\{x\}$ is postulated for the intermediate regime. First, the transition from the initial to the intermediate regime is represented by

$$y_1^n = y_0^n + y_i^n \tag{2.3.11}$$

Then the transition from this combined regime to the final regime by

$$y^m = y_1^m + y_\infty^m = \left(y_0^n + y_i^n\right)^{m/n} + y_\infty^m \tag{2.3.12}$$

Here, and throughout the balance of this subsection, in the interests of simplicity and clarity, the functional dependence of all the terms on x is implied rather than written out explicitly. If y_0 is a lower bound and y_i is implied to be one, y_1 and y_∞ must be upper bounds. Hence, n will then be positive and m negative. If y_0 and y_i are upper bounds, y_1 and y_∞ must be lower bounds; then n will be negative and m positive. The reverse formulation starting with y_∞ and y_1 leads by the same procedure to

$$y^n = y_0^n + \left(y_i^m + y_\infty^m\right)^{n/m} \tag{2.3.13}$$

If the intersections of y_i with y_0 and y_∞ are widely separated with respect to x, essentially the same pair of values for n and m will be determined for Equations 2.3.12 and 2.3.13, and the two representations for y will not differ significantly. On the other hand, if these intersections are close in terms of x, the pair of values of m and n may differ significantly and one representation may be quite superior to the other. In some instances a singularity in y_0 or y_∞ may be tolerable in either Equation

2.3.12 or 2.3.13 because it is overwhelmed by the other terms. Equations 2.3.12 and 2.3.13 have one hidden flaw. For $x \to 0$, Equation 2.3.12 reduces to

$$y \to y_0 \left[1 + \left(\frac{y_\infty}{y_0} \right)^m \right]^{1/m} \tag{2.3.14}$$

If y_0 is a lower bound, m is necessarily negative, and values of y less than y_0 are predicted. If y_0/y_∞ is sufficiently small or if m is sufficiently large in magnitude, this discrepancy may be tolerable. If not, the following alternative expression may be formulated, again starting from Equation 2.3.11:

$$\left(y^n - y_0^n \right)^m = y_i^{nm} + \left(y_\infty^n - y_0^n \right)^m \tag{2.3.15}$$

Equation 2.3.15 is free from the flaw identified by means of Equation 2.3.14 and invokes no additional empiricism, but a singularity may occur at $y_\infty = y_0$, depending on the juxtapositions of y_0, y_i, and y_∞. Similar anomalies occur for Equation 2.3.13 and the corresponding analog of Equation 2.3.14, as well as for behavior for which $n < 0$ and $m > 0$. The preferable form among these four is best chosen by trying each of them.

One other problem with the application of the CUE for a separate transitional regime is the formulation of an expression for $y_i\{x\}$, which is ordinarily not known from theoretical considerations. Illustrations of the empirical determination of such expressions for particular cases may be found in Churchill and Usagi (1974), Churchill and Churchill (1975), and Churchill (1976, 1977), as well as in Example 2.3.5 below.

Example 2.3.4: Pressure Gradient in Flow through a Packed Bed of Spheres

The pressure gradient at asymptotically low rates of flow (the creeping regime) can be represented by the Kozeny–Carman equation, $\Phi = 150\ \mathrm{Re}_p$, and at asymptotically high rates of flow (the inertial regime) by the Burke–Plummer equation, $\Phi = 1.75\ (\mathrm{Re}_p)^2$, where $\Phi = \rho\varepsilon^2 d_p(-\mathrm{d}P_f/\mathrm{d}x)\mu^2(1-\varepsilon)$, $\mathrm{Re}_p = d_p u_0 \rho/\mu(1-\varepsilon)$, d_p = diameter of spherical particles, m, ε = void fraction of bed of spheres, $\mathrm{d}P_f/\mathrm{d}x$ = dynamic pressure gradient (due to friction), Pa/m, and u_0 = superficial velocity (in absence of the spheres), m/s. For the origin of these two asymptotic expressions see Churchill (1988a). They both have a theoretical structure, but the numerical coefficients of 150 and 1.75 are basically empirical. These equations are both lower bounds and have one intersection. Experimental data are plotted in Figure 2.3.3, which has the form of Figure 2.3.1 with $\Upsilon = \Phi/150\ \mathrm{Re}_p$, $Y/Z = \Phi/(1.75\ \mathrm{Re}_p)^2$ and $Z = 1.75\mathrm{Re}_p^2/150\mathrm{Re}_p = \mathrm{Re}_p/85.7$. A value of $n = 1$ is seen to represent these data reasonably well on the mean, resulting in

$$\Phi = 150\mathrm{Re}_p + 1.75\left(\mathrm{Re}_p\right)^2$$

which was originally proposed as a correlating equation by Ergun (1952) on the conjecture that the volumetric fraction of the bed in "turbulent" flow is proportional to Re_p. The success of this expression in conventional coordinates is shown in Figure 2.3.4. The scatter, which is quite evident in the arithmetic split coordinates of Figure 2.3.3, is strongly suppressed in a visual sense in the logarithmic coordinates of Figure 2.3.4.

Example 2.3.5: Friction Factor for Commercial Pipes for All Conditions

The serial application of the CUE is illustrated here by the construction of a correlating equation for both smooth and rough pipes in the turbulent regime followed by combination of that expression with ones for the laminar and transitional regimes.

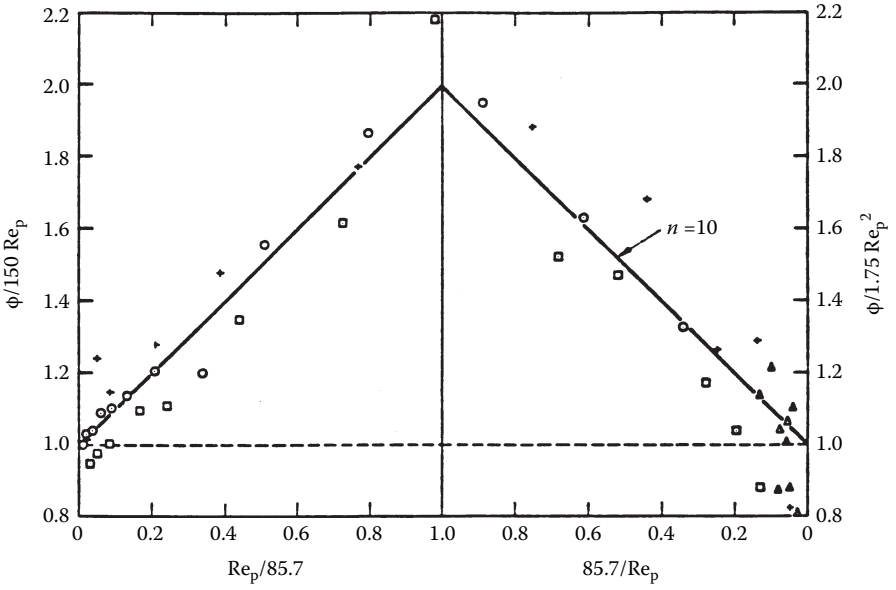

FIGURE 2.3.3 Arithmetic, split-coordinate plot of experimental data for the pressure drop in flow through a packed bed of spheres. (From Churchill, S.W. and Usagi, R., *AIChE J.*, 18, 1123, 1972. With permission from the American Institute of Chemical Engineers.)

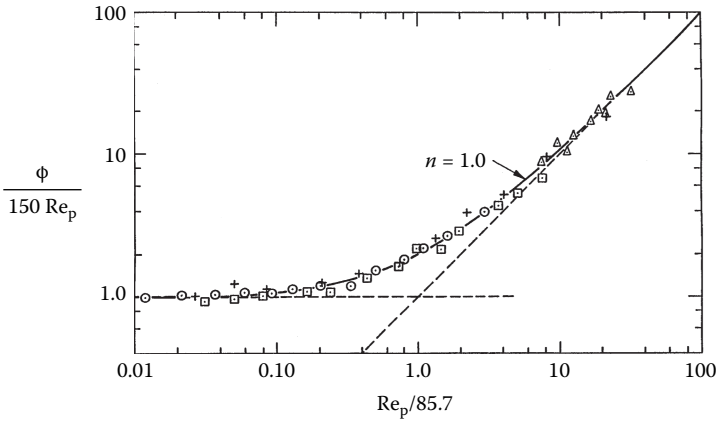

FIGURE 2.3.4 Logarithmic correlation of experimental data for the pressure drop in flow through a packed bed of spheres. (From Churchill, S.W. and Usagi, R., *AIChE J.*, 18, 1123, 1972. With permission from the American Institute of Chemical Engineers.)

The Turbulent Regime. The Fanning friction factor, f_F, for turbulent flow in a smooth round pipe for asymptotically large rates of flow (say $Re_D > 5000$) may be represented closely by the empirical expression:

$$\left(\frac{2}{f_F}\right)^{1/2} = 1.70 - \frac{310}{Re_D\left(\frac{f_F}{2}\right)^{1/2}} + \left(\frac{100}{Re_D\left(\frac{f_F}{2}\right)^{1/2}}\right)^2 + \frac{1}{0.436}\ln\left\{Re_D\left(\frac{f}{2}\right)^{1/2}\right\}$$

A corresponding empirical representation for naturally rough pipe is

$$\left(\frac{2}{f_F}\right)^{1/2} = 4.46 + \frac{1}{0.436}\ln\left\{\frac{D}{e}\right\}$$

Direct combination of these two expressions in the form of the CUE does not produce a satisfactory correlating equation, but their combination in the following rearranged forms:

$$e^{0.436(2/f_F)^{1/2}} = 2.10\,\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2} - e^{-135/\mathrm{Re}_D(f_F/2)^{1/2}} + e^{\left(43.6\Big/\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}\right)^2}$$

and

$$\dot{e}^{0.430}\left(2/f_F\right)^{1/2} = 6.69\left(\frac{D}{e}\right)$$

with $n=-1$ results in, after the reverse rearrangement,

$$\left(\frac{2}{f_F}\right)^{1/2} = 1.70 + \frac{310}{\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}} + \left(\frac{100}{\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}}\right)^2 + \frac{1}{0.436}\ln\left\{\frac{\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}}{1+0.301\left(\frac{e}{D}\right)\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}}\right\}$$

The exact equivalent of this expression in structure but with the slightly modified numerical coefficients of 0.300, 2.46, and 0.304 was postulated by Colebrook (1938–1939) to represent his own experimental data. The coefficients of the expression given here are presumed to be more accurate, but the difference in the predictions of f_F with the two sets of coefficients is within the band of uncertainty of the experimental data. The turbulent regime of the "friction-factor" plot in most textbooks and handbooks is simply a graphical representation of the Colebrook equation. Experimental values are not included in such plots since *e*, the effective roughness of commercial pipes, is simply a correlating factor that forces agreement with the Colebrook equation. Values of *e* for various types of pipe in various services are usually provided in an accompanying table, that thereby constitutes an integral part of the correlation.

The Laminar Region. The Fanning friction factor in the laminar regime of a round pipe ($\mathrm{Re}_d < 1800$) is represented exactly by the following theoretical expression known as Poiseuille's law: $f_F = 16/\mathrm{Re}_D$. This equation may be rearranged as follows for convenience in combination with that for turbulent flow:

$$\left(\frac{2}{f_F}\right)^{1/2} = \frac{\mathrm{Re}_D\left(f_F/2\right)^{1/2}}{8}$$

The Transitional Regime. Experimental data as well as semitheoretical computed values for the limiting behavior in the transition may be represented closely by $(f_F/2) = (\mathrm{Re}_D/37500)^2$. This expression may be rewritten, in terms of $(2/f_F)^{1/2}$, and $\mathrm{Re}_D(f_F/2)^{1/2}$, as follows:

$$\left(\frac{f_F}{2}\right)^{1/2} = \left(\frac{37500}{\mathrm{Re}_D\left(f_F/2\right)^{1/2}}\right)^{1/2}$$

Overall Correlation. The following correlating equation for all $\mathrm{Re}_D(f_F/2)^{1/2}$ and e/D may now be constructed by the combination of the expressions for the turbulent and transition regimes in the form of the CUE with $n=8$, and then that expression and that for the laminar regime with $n=-12$,

both components being chosen on the basis of experimental data and predicted values for the full regime of transition:

$$\left(\frac{2}{f_F}\right)^{1/2} = \left[\left(\frac{8}{\mathrm{Re}_D(f_F/2)^{1/2}}\right)^{12} + \left(\left[\frac{37500}{\mathrm{Re}_D(f_F/2)^{1/2}}\right]\right.\right.$$

$$\left.\left. + \left|1.706 - \frac{322.4}{\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}} + \left(\frac{95.2}{\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}}\right)^2 + \frac{1}{0.436}\ln\left\{\frac{\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}}{1+0.301\left(\frac{e}{D}\right)\mathrm{Re}_D\left(\frac{f_F}{2}\right)^{1/2}}\right\}\right|^8\right)^{-3/2}\right]^{-1/12}$$

The absolute value signs are only included for aesthetic reasons; the negative values of the logarithmic term for very small values of $\mathrm{Re}_D(f_F/2)^{1/2}$ do not affect the numerical value of $(2/f_F)^{1/2}$ in the regime in which they occur. This overall expression appears to have a complicated structure, but it may readily be recognized to reduce to its component parts when the corresponding term is large with respect to the other two. It is insensitive to the numerical values of the two arbitrary exponents. For example, doubling their values would have almost no effect on the predictions of $(f_F/2)^{1/2}$. The principal uncertainty is associated with the expression for the transition regime, but the overall effect of the corresponding term is very small. The uncertainties associated with this correlating equation are common to most graphical correlations and algebraic expressions for the friction factor, and are presumed to be fairly limited in magnitude and to be associated primarily with the postulated value of e. Although the overall expression is explicit in $\mathrm{Re}_D(f_F/2)^{1/2}$ rather than Re_D, the latter quantity may readily be obtained simply by multiplying the postulated value of $\mathrm{Re}_D(f_F/2)^{1/2}$ by the computed values of $(2/f_F)^{1/2}$.

2.4 HYDRAULICS OF PIPE SYSTEMS

J. Paul Tullis and Blake Paul Tullis

Basic Computations

Equations

Solving fluid flow problems involves the application of one or more of the three basic equations: continuity, momentum, and energy. These three basic tools are developed from the law of conservation of mass, Newton's second law of motion, and the first law of thermodynamics.

The simplest form of the continuity equation is for one-dimensional incompressible steady flow in a conduit. Applying continuity between any two sections gives

$$A_1V_1 = A_2V_2 = Q \tag{2.4.1}$$

For a variable density fluid, the equation can be written as

$$\rho_1A_1V_1 = \rho_2A_2V_2 = \dot{m} \tag{2.4.2}$$

where A is the cross-sectional area of the pipe, V is the mean flow velocity, Q is the flow rate, ρ is the fluid density, $\dot{m}$ is the mass flow rate, and the subscripts represent different system locations. The equations are valid for any rigid conduit as long as there is no addition or loss of liquid within the section.

For steady-state pipe flow, the momentum equation relates the net force in a given direction (F_x) acting on a control volume (a section of the fluid inside the pipe), to the net momentum flux through the control volume:

$$F_x = \rho_2A_2V_2V_{2x} - \rho_1A_1V_1V_{1x} \tag{2.4.3}$$

For incompressible flow, this equation can be reduced to

$$F_x = \rho Q\left(V_{2x} - V_{1x}\right) \tag{2.4.4}$$

These equations can easily be applied to a three-dimensional flow problem by adding equations for the y- and z-directions.

The following is a general form of the energy equation (see Chapter 1) applicable to incompressible pipe or duct flow:

$$\frac{P_1}{\gamma} + Z_1 + \frac{V_1^2}{2g} = \frac{p_2}{\gamma} + z_2 + \frac{V_2^2}{2g} - H_p + H_t + H_f \tag{2.4.5}$$

The units are energy per unit weight of liquid: ft·lb/lb or N·m/N, which reduce to ft or m. The first three terms are pressure head (P/γ), elevation head (Z) (relative to some datum), and velocity head ($V^2/2g$). The last three terms on the right side of the equation are the total dynamic head added by a pump (H_p) or removed by a turbine (H_t) and the friction plus minor head losses (H_f). The sum of the first three terms in Equation 2.4.5 is defined as the total head, and the sum of the pressure and elevation heads is referred to as the piezometric head.

The purpose of this section is to determine the pressure changes resulting from incompressible flow in pipe systems. Since pipes of circular cross-sections are most common in engineering application, the analysis in this section will be performed for circular geometry. However, the results can

be generalized for a pipe of noncircular geometry by substituting for the diameter D in any of the equations, the hydraulic diameter, D_h, defined as follows:

$$D_h = 4 \times \frac{\text{The cross-sectional area}}{\text{The wetted perimeter}}$$

The analysis in this section can also be applied to gases and vapors, provided the Mach number in the duct does not exceed 0.3. For greater values of the Mach number, the compressibility effect becomes significant and the reader is referred to Section 2.7 on compressible flow.

Fluid Friction

The method for calculating friction loss in pipes and ducts varies depending on whether the flow is laminar or turbulent. Most pipe flow is in the turbulent range.

The Reynolds number is the ratio of inertia forces to viscous forces and is a convenient parameter for predicting if a flow condition will be laminar or turbulent. It is defined as follows:

$$\text{Re} = \frac{\rho VD}{\mu} = \frac{VD}{\upsilon} \tag{2.4.6}$$

where V is the mean flow velocity, D is the diameter, ρ is the fluid density, μ is the dynamic viscosity, and ν is the kinematic viscosity.

Friction loss (H_f) depends on pipe diameter (D), length (L), roughness (e), fluid density (ρ) or specific weight (γ), viscosity (ν), and flow velocity (V). Dimensional analysis can be used to provide a functional relationship between the friction loss H_f, pipe dimensions, fluid properties, and flow parameters. The resulting equation is called the Darcy–Weisbach equation:

$$H_f = \frac{fLV^2}{2gd} = \frac{flQ^2}{1.23gD^5} \tag{2.4.7}$$

The friction factor f is a measure of pipe roughness. It has been evaluated experimentally for numerous pipes. The friction factor data were used to create the Moody diagram shown as in Figure 2.4.1. For $Re < 2000$, the flow in a pipe will be laminar and f, which is only a function of Re, is calculated as follows:

$$f = \frac{64}{\text{Re}} \tag{2.4.8}$$

For Reynolds numbers between 2000 and 4000, the flow is unstable as a result of the onset of turbulence (critical zone in Figure 2.4.1). In this range, friction loss calculations are difficult because it is impossible to determine a unique value of f. For $Re > 4000$, the flow becomes turbulent and f is a function of both Re and relative pipe roughness (e/D, e is the equivalent roughness height and D is the pipe diameter). At high Re, f eventually becomes independent of Re and depends only on e/d. This flow regime is referred to as fully turbulent flow and is represented in Figure 2.4.1 where family of friction factor curves become horizontal. The Re at which this occurs varies with e/D. Laminar flow in pipes is unusual. For example, for water flowing in a 0.3-m-diameter pipe, the velocity would have to be less than 0.02 m/s for laminar flow to exist. Therefore, most practical pipe flow problems are in the turbulent region.

Using the Moody diagram in Figure 2.4.1 to get f requires that Re and e/d be known. Calculating Re is direct if the water temperature, velocity, and pipe diameter are known. The problem is obtaining a good value for e. Typical values of e are listed in Figure 2.4.1. These values should be considered as guides only and not used if more exact values can be obtained from the pipe supplier.

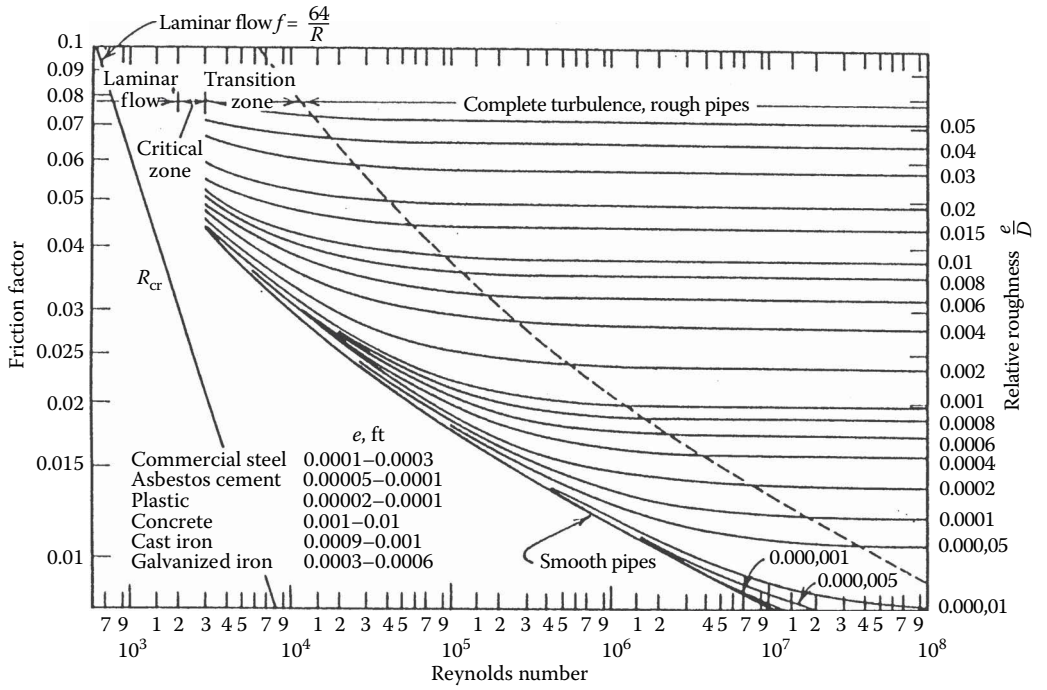

FIGURE 2.4.1 The Moody diagram.

Since roughness and inside pipe diameter may vary with time due to buildup of solid deposits or organic growths, f is also time dependent. Manufacturing tolerances also cause variations in the pipe diameter and surface roughness. Because of these factors, the friction factor for any pipe can only be approximated. A designer is required to use good engineering judgment in selecting a design value for f so that proper allowance is made for these uncertainties.

For noncircular pipes, the only change in the friction loss equation is the use of an equivalent diameter—based on the hydraulic radius (R_h), i.e., $D=4R_h$—in place of the circular pipe diameter D. R_h is the ratio of the flow area to the wetted perimeter.

Swamee and Jaine (1976), among others, have developed relationships that approximate the Moody diagram data. The Swamee–Jain equation is as follows:

$$f = 0.25\left[\mathrm{Ln}\left(\frac{e/D}{3.7}\right) + \frac{5.74}{\mathrm{Re}^{0.9}}\right]^{-2} \tag{2.4.9}$$

The practical problem of how to obtain a reliable value for e still remains. It cannot be directly measured but must be determined from friction loss pipe tests.

An exact solution using the Darcy–Weisbach equation for flow or pipe diameter requires a trial-and-error or iterative solution technique because of the dependency of f on Re [$\mathrm{Re}=f(V, D)$]. A typical approach to solving this problem is to estimate a reasonable fluid velocity to calculate Re and obtain f from the Moody diagram or Equation 2.4.9. Next, calculate a new velocity and Re value and repeat until the solution converges. The availability of solvers and programmable calculators has greatly simplified the solution to pipe flow and pipe sizing problems. The following is a visual basic program (Qswamee) that can be incorporated into a spreadsheet program to solve for the flow rate between two reservoirs via a single pipe when f is unknown.

```
Function Qswamee(dz,L,K,D,e,nu,g)
Dim f,Re,Q,A,Pi As Double
Pi=3.14159
A=Pi * D ^ 2 * 0.25
Qswamee=(dz * 2 * g * A ^ 2 / (0.018 * L / D+K)) ^ 0.5
Do
Q=Qswamee
Re=Q * D / (A * nu)
f=0.25 / (Log(e / (3.7 * D)+5.74 / (Re ^ 0.9))/Log(10)) ^ 2
Qswamee=(dz * 2 * g * A ^ 2 / (f * L / D+K)) ^ 0.5
Loop Until (Qswamee - Q) < 1e-06
End Function
```

The variables that follow the program name on the first line are values passed in through the function call at the spreadsheet level (dz is the change in elevation between the reservoirs, L is the pipe length, K is the sum of the minor loss coefficients, D is the pipe diameter, e is the pipe roughness, nu is the kinematic viscosity, and g is the gravitational constant). The second line defines additional variables used in the program. The initial flow rate (Qswamee) is approximated using an f value of 0.018. This value is stored as Q, Re, and f are calculated and an updated Qswamee is determined. This process continues until the difference between Q and Qswamee <1E-06 (user-defined accuracy limit). The Qswamee user-defined function returns the flow rate solution to the spreadsheet.

For long gravity flow pipelines, the general goal is to select the smallest pipe diameter that can pass the required flow without friction and minor losses exceeding the available head. For pumped systems, the pipe diameter selection must be based on an economic analysis that compares the pipe cost with the cost of building and operating the pumping facility.

Minor Losses

Flow through valves, orifices, elbows, transitions, etc., causes flow separation, which results in the generation and dissipation of turbulent eddies. For short systems containing many bends, valves, tees, etc., local or minor losses can exceed friction losses. The head loss h_l associated with the dissipation caused by a minor loss is proportional to the velocity head and can be accounted for as a minor or local loss using the following equation:

$$h_l = K_l \frac{Q^2}{(2gA_m^2)} \tag{2.4.10}$$

where K_l is the minor loss coefficient and A is the pipe area. The summation of the friction and minor losses in a pipe system can be expressed as follows:

$$H_f = h_f + h_l \tag{2.4.11}$$

$$H_f = \left[\Sigma\left(\frac{fL}{2gdA_p^2}\right) + \Sigma\left(\frac{K_l}{2gA_m^2}\right)\right]Q^2 = CQ^2 \tag{2.4.12}$$

where

$$C = \Sigma\left(\frac{fL}{2gdA_p^2}\right) + \Sigma\left(\frac{K_l}{2gA_m^2}\right) \tag{2.4.13}$$

A_p is the flow area of the pipe, and A_m is the flow area of the minor loss.

The challenging part of making minor loss calculations is obtaining reliable values of K_l. If the pipe is long, the friction losses may be large compared with the minor losses and approximate values of K_l will be sufficient. However, for short systems containing many pipefittings, the local losses can represent a significant portion of the total system losses, and they should be accurately determined. Numerous factors influence K_l. For example, for elbows, K_l is influenced by the shape of the conduit (rectangular vs. circular), by the radius of the bend, the bend angle, the Reynolds number, and the length of the outlet pipe. For dividing or combining tees or *Y*-branches, the percent division of flow and the change in pipe diameter must also be included when estimating K_l. Another important minor loss consideration is when local losses are installed close together. Depending on the type, orientation, and spacing of the components, the total loss coefficient may be greater or less than the simple sum of the individual K_l values.

Comparing the magnitude of $\sum\left(fL/2gdA_p^2\right)$ to $\sum(k_l/2gA_m^2)$ will determine how much care should be given to the selection of the K_l values. Typical values of K_l are listed in Table 2.4.1 (Tullis, 1989). When more comprehensive information on loss coefficients is needed, the reader is referred to Miller (1990).

Pressure Class Guidelines

Procedures for selecting the pressure class of pipe vary with the type of pipe material. Guidelines for different types of materials are available from professional societies and from the pipe manufacturers. These specifications should be obtained and studied for the pipe materials being considered.

The primary factors governing the selection of a pipe pressure class are (1) the maximum steady-state operating pressure, (2) surge/transient pressures, (3) external earth loads and live loads, (4) variation of pipe properties with temperature or long-time loading effects, and (5) damage that could result from handling, shipping, and installing or reduction in strength due to chemical attack or other aging factors. The influence of the first three items can be quantified, but the last two are subjective and are generally accounted for with a safety factor, which is the ratio of the burst pressure to the rated pressure. There is no single standard that specifies how large the safety factor should be or how many of the five preceding factors should be covered by the safety factor. Safety factor typically varies between 2 and 3.

When selecting a pipe pressure class, it is recommended that a transient computer analysis be included as part of that process. Such an analysis can determine the safe opening and closing times for valves, evaluate the influence of starting and stopping pumps on the maximum anticipated system pressure, and determine if surge protection devices are needed. Based on the results of computer simulations, select a pipe pressure class such that the rated pressure for the pipe is higher than the highest expected pressure caused by normal operation and by anticipated transient pressures. Be sure to select a safety factor large enough to account for the impact of earth and live loads and the effects of items 4 and 5 in the preceding list. Unusual or unexpected transient pressures are normally covered by the safety factor.

Selection of pressure class (or wall thickness) for larger pipes is sometimes more dependent on collapse pressure (due to an internal vacuum) or on handling loads than it is on operating pressure. A thin-wall, large-diameter pipe may be adequate for resisting relatively high internal pressures but may collapse under negative internal pressure.

External Loads

In some situations the external load is the controlling factor in determining if the pipe will collapse. The magnitude of the external load depends on the diameter and wall thickness of the pipe, the pipe material, the ovality (out of roundness) of the pipe cross section, the trench width, depth of cover, the specific weight of the soil, the degree of soil saturation, the type of backfill material, the method used to backfill, the degree of compaction, and live loads. The earth load increases with width

TABLE 2.4.1
Minor Loss Coefficients

Item	K_l Typical Value	Typical Range
Pipe inlets		
Inward projecting pipe	0.78	0.5–0.9
Sharp cornerflush	0.50	—
Slightly rounded	0.20	0.04–0.5
Bell mouth	0.04	0.03–0.1
Expansions[a]	$(1-A_1/A_2)^2$(based on V_1)	
Contractions[b]	$(1/C_c-1)^2$ (based on V_2)	

A_2/A_1	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
C_c	0.624	0.632	0.643	0.659	0.681	0.712	0.755	0.813	0.892

Bends[c]		
Short radius, $r/d=1$		
90	—	0.24
45	—	0.1
30	—	0.06
Long radius, $r/d=1.5$		
90	—	0.19
45	—	0.09
30	—	0.06
Mitered (1 m)		
90	1.1	—
60	0.50	0.40–0.59
45	0.3	0.35–0.44
30	0.15	0.11–0.19
Tees	c	—
Diffusers	[c]	—
Valves		
Check valves		
Swing check[d]	1.0	0.29–2.2
Tilt disk[d]	1.2	0.27–2.62

and depth of the trench, whereas the live load reduces as depth of cover increases. The cumulative effect of all these sources of external loading requires considerable study and analysis. As the pipe diameter increases, the need for a more thorough analysis of earth and live loads becomes more important.

There are no simple guidelines for evaluating external pipe loads. Because of the complexity of this analysis, one option is to simply use a higher pressure class of pipe in areas where there will be large external loads. One should consider the consequence of a pipe failure caused by external loads

compared with the cost of using a thicker pipe. Those interested in the details of performing calculations of earth loading can review Watkins and Anderson (2000) and Spranger and Handy (1973).

Limiting Velocities

Upper and lower velocity both present concerns. If the velocity is too low, problems may develop due to settling of suspended solids and air collecting at various locations in the pipe. The safe lower velocity limit to avoid collecting air and sediment depends on the amount and type of sediment and on the pipe diameter and pipe profile. Velocities greater than about 1 m/s (3 ft/s) are typically required to move air pockets to air release valves. Higher velocities are usually needed to keep sediment in suspension.

Potential problems associated with high velocities are (1) erosion of the pipe wall or liner (especially if coarse suspended sediment is present), (2) increased chance of cavitation at control valves, (3) increased pumping costs, (4) difficulty with trapping air in the pipeline and its removal at air release valves, and (5) increased risk of hydraulic transients. Each of these should be considered before making the final pipe diameter selection. A typical upper velocity for many applications is about 6 m/s (~20 ft/s).

Valves

Valves serve a variety of functions. Some function as isolation valves that are either full open or closed. Control valves are used to regulate flow or pressure and must operate over a wide range of valve openings and flow conditions. Check valves prevent reverse flow, and air valves release air during initial filling, release air that is collected during operation, and admit air when the pipe is drained.

Control Valves

Hydraulic criteria considered when selecting the proper type and size of flow or pressure control valve should include the following:

1. The valve should not produce excessive pressure drop when full open.
2. The valve should have the ability to control flow or pressure drop over at least 50% of its movement.
3. The valve should not be subjected to excessive cavitation.
4. Valve opening/closing times should be selected so pressure transients caused by valve operation will not exceed the safe limits of the system.
5. The system should be analyzed to ensure that the operating torque or thrust does not exceed the capacity of the operator or the safe limit of the valve shaft and connections for any anticipated flow condition.

Controllability. For many flow control applications, it is desirable to select a control valve that has linear control characteristics. This means that if you close the valve, say 10%, the flow reduces about 10%. Unfortunately, this is sometimes not possible because the ability of a valve to control flow depends as much on the system as it does on the design of the valve. The same valve that operates linearly in one system may not in another. To demonstrate the relationship between valve performance and system requirements, consider a valve that will be used to control the flow between two reservoirs with an elevation difference of ΔZ. System A is a short pipe (0.3 m diameter, 100 m long, $\Delta Z = 10$ m) where pipe friction is small ($fL/2gdA_p^2 = 46.9$), and System B is a long pipe (0.3 m diameter, 10,000 m long, $\Delta Z = 200$ m) with high friction ($fL/2gdA_p^2 = 4690$). Initially, assume that the same valve will be used in both pipes and it will be

the same size as the pipe. The flow can be calculated using the energy equation (Equation 2.4.5) and the system loss equation (Equation 2.4.12):

$$Q = \sqrt{\frac{\Delta Z}{\left[\Sigma\left(\frac{fL}{2gdA_p^2}\right)+\Sigma\left(\frac{k_l}{2gA_m^2}\right)\right]}} \tag{2.4.14}$$

For the full-open valve, assume $K_l = 0.2$, and at 50% open $K_l = 9.0$. Correspondingly, $k_l/2gA_m^2 = 1.905$ and 85.7. For System A (short pipe), the flow with the valve full open will be 0.453 m^3/s and at 50% open the flow will be 0.275 m^3/s; a reduction of 39%. Repeating these calculations over the full range of valve openings would show that the flow for System A reduces almost linearly as the valve closes.

For System B (long pipe), the flow with the valve full open will be 0.206 m^3/s and at 50% open 0.205 m^3/s, a reduction of less than 1%. Because the valve loss at 50% closed, expressed by $k_l/2gA_m^2$, is still small compared to the friction term (4690), the valve will not start to control the flow until it has closed considerably more than 50%. A line-size valve is obviously not a good choice for a control valve in System B. One solution to this problem is to use a smaller valve. If the valve installed in System B was half the pipe diameter, closing it 50% would reduce the flow by about 22%. Even though the valve is half the diameter of the pipe, the reduction in flow with the reduced sized valve wide open would be insignificant.

The range of opening over which the valve controls the flow also has a significant effect on the safe closure time for control valves. Transient pressures are created each time there is an incremental reduction in the flow. If the valve does not begin to control until it has closed more than 50% closed, the effective valve closure time will be less than half the total closing time. This will increase the magnitude of the transients that will be generated unless the closing time is increased.

Torque/Thrust. If a valve will be subjected to unusually high velocities or large pressure drops, it is advisable to analyze the system to determine the maximum torque or thrust that the valve will be subjected to in order to insure that the valve shaft, connections, and operator are properly sized. If the maximum operating force exceeds operator capacity, the valve may not be able to open and close all flow conditions. If the shaft and connectors are underdesigned, the valve may fail and slam shut causing a severe transient. Valve manufacturers are responsible for determining the maximum allowable torque or thrust that their valves can tolerate but the end user needs to evaluate their system to determine if those maximum conditions might be exceeded in their system.

One situation where one may overlook the condition causing maximum torque is with parallel pumps that have a discharge control valve. The maximum system flow occurs with all pumps operating. However, the maximum flow velocity and maximum torque for each pump-discharge valve will occur when only one pump is operating. One specific example (Tullis, 1989) showed that the torque on a pump-discharge butterfly valve was three times higher when one pump was operating compared with three pumps operating in parallel.

Cavitation. Cavitation is frequently an important consideration in selection and operation of control valves. It is necessary to determine if cavitation will exist, evaluate its intensity, and estimate its effect on the system and environment. Cavitation can cause noise, vibration, erosion damage and can decrease valve performance. A thorough system analysis should consider the full range of operation. Some valves cavitate worst at small openings and others cavitate heavily near full open. It depends on both the system and the valve design. If cavitation is ignored in the design and selection of the valves, repairs and replacement of the valves may be costly.

One step in a cavitation analysis is selecting the acceptable level of cavitation. Experimental data are available for four limits: incipient (light, intermittent noise), critical (light, steady noise), incipient damage (pitting damage begins), and choking (very heavy damage and performance drops off). Cavitation data are available for each of these limits for a number of different valve types (Tullis, 1989, 1993).

Choosing the appropriate cavitation limit depends on several factors related to the operating requirements, expected life, location of the device, details of the design, and economics. For long-term operation of a control valve in a system where noise can be tolerated, the valve should never operate at or beyond incipient damage. In systems where noise is objectionable, critical cavitation would be a better operating limit. For short-term operation, choking cavitation may be appropriate.

Choking cavitation is sometimes misunderstood. Some have erroneously taught that onset of choking cavitation represents onset of cavitation. In reality, choking is the point where the intensity of cavitation is near its maximum and significant noise, vibrations, and erosion damage may occur both within the valve and in the downstream pipe. Choking cavitation is generally appropriate as a design limit only for valves that operate for short periods of time, such as a pressure relief valve. The intensity of cavitation and the corresponding noise vibration and erosion damage at the valve are at their maximum just before a valve chokes. If the valve operates beyond choking (sometimes referred to as supercavitation), the collapse of the large vapor cavity can occur at a significant distance downstream from the valve where serious vibration and material erosion problems can occur.

If the cavitation analysis indicates that the valve, orifice, or other device will be operating at a cavitation level greater than can be tolerated, various techniques can be used to limit the level of cavitation. One option is to select a different type of valve. Recent developments in valve design have produced a new generation of valves that are more resistant to cavitation. Most of them operate on the principle of dropping the pressure in stages. They usually have multiple paths with numerous sharp turns or flow restrictions in series. Two drawbacks to these valves are that they often have high-pressure drops when full open, and they can only be used with clean fluids. An alternate approach is to use a conventional valve in series with a number of orifice plates.

For some applications, another way to suppress cavitation is to use a free-discharge valve that is vented so cavitation cannot occur. There are valves specifically designed for this application. Some conventional valves can also be used for free discharge, if they can be adequately vented.

Injecting air to suppress cavitation downstream from conventional valves is a technique that has been used for many years with varying degrees of success. The most common mistake is injecting the air in the wrong location so the air does not get to the cavitation zone. If an adequate amount of air is injected into the proper region, the noise, vibrations, and erosion damage can be significantly reduced. If the system can tolerate some air being injected, aeration is often the cheapest and best remedy for cavitation.

For additional information on predicting when a valve will cavitate and how to suppress the cavitation, see Tullis (1989, 1993).

Transients. Transient pressures can occur during filling and flushing air from the line, while operating valves, and when starting or stopping pumps. The basic cause of high transient pressures is rapid changes in velocity. The larger the incremental velocity change and the faster that change takes place, the greater the transient pressures. If adequate design provisions and operational procedures are not established, the transient pressure can easily exceed the safe operating pressure of the pipe.

In order to perform a thorough transient analysis and ensure that the system will function as required, it is necessary to establish written operating procedures, preferably before or during the design process. A transient computer program can then be used to evaluate each operating condition and determine the highest transient pressure for each section of the system. As part of the analysis, the program can vary the operating times for the valves, simulate starting and stopping pumps and it can evaluate the influence of adding protective measures—like surge towers or air chambers.

Transients caused by slow velocity changes, such as the rise and fall of the water level in a surge tank, are called surges. Surge analysis or "rigid column theory" involves mathematical or numerical solution of simple ordinary differential equations. The compressibility of the fluid and the elasticity of the conduit are ignored, and the entire column of fluid is assumed to move as a rigid body.

When changes in velocity occur rapidly, both the compressibility of the liquid and the elasticity of the pipe must be included in the analysis. This procedure is often called "elastic" or "water

hammer" analysis and involves tracking acoustic pressure waves through the pipe. The solution requires solving partial differential equations.

An equation predicting the head rise ΔH caused by a sudden change of velocity $\Delta V = V_2 - V_1$ can be derived by applying the unsteady momentum equation to a control volume of a section of the pipe where the change of flow is occurring. Consider a partial valve closure that instantly reduces the velocity by an amount ΔV. Reduction of the velocity results in an increase in the pressure upstream from the valve creating a pressure wave of magnitude ΔH which travels up the pipe at the acoustic velocity a. The increased pressure compresses the liquid and expands the pipe. The transient head rise due to an incremental change in velocity (ΔV) is

$$\Delta H = -a\Delta V / g \tag{2.4.15}$$

The derivation of Equation 2.4.15 is based on an assumption of an instant velocity change. For a valve closing at the end of the pipe, instant closure actually refers to a finite time. It is the longest time that a valve can be closed and still cause a pressure rise equal to that of an instant closure. Normally, instant closure time refers to any valve closure time $\leq 2L/a$ s (which is the time required for the pressure wave to travel to and from the other end of a pipe of length L traveling at wave speed a). When closing a valve at a time of $2L/a$, the maximum head rise at the valve will be the same as if the valve were closed instantly. The $2L/a$ time is therefore often defined as the instant closure time.

For a valve at the end of a long pipeline, the effective instant closure time can be considerably greater than $2L/a$. This is because when the friction loss coefficient fL/d is much greater than the loss coefficient for the valve K_1, the valve can be closed a considerable amount before the flow actually begins to change. This dead time must be added to the $2L/a$ time to identify the effective instant closure time. To avoid the maximum potential transient pressure rise, the valve must be closed much slower than the effective instant closure time.

Computational techniques for estimating transient pressures caused by unsteady flow in pipelines are too complex to be done with simple hand calculations. The solution involves solving partial differential equations based on the equations of motion and continuity. These equations are often solved by the method of characteristics. This technique transforms the equations into total differential equations. After integration, the equations can be solved numerically by finite differences. This analysis provides equations that can be used to predict the flow and head at any interior pipe section at any time (Tullis, 1989; Wiley and Streeter, 1993).

To complete the analysis, equations describing the boundary conditions are required. Typical boundary conditions are the connection of a pipe to a reservoir, a valve, a change in pipe diameter or material, pipe junctions, etc. Friction loss is included in the development of the basic equations, and minor losses are handled as boundary conditions. The analysis properly models friction and the propagation and reflections of multiple pressure waves. It can also be used for surge calculations.

It is recommended that every pipe system should have at least a cursory transient analysis performed to identify the possibility of serious transients and decide whether or not a detailed analysis is necessary. If an analysis indicates that transients are a problem, the types of solutions available to the engineer include

1. Increasing the closing time of control valves
2. Using a smaller valve to provide better control
3. Designing special facilities for filling, flushing, and removing air from pipelines
4. Increasing the pressure class of the pipeline
5. Limiting the flow velocity
6. Using pressure relief valves, surge tanks, air chambers, etc.

Check Valves

Check valves are most commonly installed on the discharge side of pumps to prevent reverse flow when the pump is stopped. Selecting the wrong type or size of check valve can result in poor performance, severe transients, and frequent repairs (Kalsi and Tullis, 1993). Proper check valve selection requires understanding the characteristics of the various types of check valves and analyzing how they will function as a part of the system in which they will be installed. A check valve that operates satisfactorily in one system may be inadequate in another. Each valve type has unique characteristics that give it advantages or disadvantages compared with the others. The characteristics of check valves that describe their hydraulic performance and that should be considered in the selection process include

1. Opening characteristics, i.e., velocity vs. disk position data
2. Velocity required to fully open and firmly backseat the disk
3. Pressure drop at maximum flow
4. Stability of the disk at partial openings
5. Sensitivity of disk flutter to upstream disturbances
6. Speed of valve closure compared with the rate of flow reversal of the system

Disk stability varies with valve design, flow rate, disk position, and upstream disturbances and is an important factor in determining the useful life of a check valve. For most applications, it is preferable to size the check valve so that the disk is fully open and firmly backseated at normal flow rates. One of the worst design errors is to oversize a check valve that is located just downstream from a disturbance such as a pump, elbow, or control valve. If the disk does not fully open, it may be subjected to severe motion that will accelerate wear. To avoid this problem, it may be necessary to select a check valve that is smaller than the pipe size.

The transient pressure rise generated at check valve closure is another important consideration. The pressure rise is a function of how fast the valve disk closes compared with how fast the flow in the system reverses. The speed that the flow in a system reverses depends on the system. If a check valve that closes relatively slowly is installed in a system where rapid flow reversals occur, the disk can slam shut causing a pressure transient (Thorley, 1989).

The closing speed of a check valve varies with valve design and is influenced by the mass of the disk, the forces closing the disk, and the distance of travel from full open to closed. Fast closing valves have the following properties: the disk (including all moving parts) is lightweight, closure is assisted by springs, and the full stroke of the disk is short. Swing check valves are the slowest closing valves because they violate all three of these criteria; i.e., they have heavy disks, no springs, and long disk travel. The nozzle check valve is one of the fastest closing valves because the closing element is light, is spring loaded, and has a short stroke. The silent, duo, double door, and lift check valves with springs are similar to nozzle valves in their closing times, mainly because of the closing force of the spring. For descriptions of these check valves, see (Tullis, 1989; Kalsi and Tullis, 1993).

Systems where rapid flow reversals occur include parallel pumps, where one pump is stopped while the others are still operating, and systems that have air chambers or surge tanks close to the check valve. For these systems, there is a high-energy source downstream from the check valve to cause a quick flow reversal. As the disk nears its seat, it starts to restrict the reverse flow. This builds up the pressure, accelerates the disk, and slams it into the seat. Results of laboratory experiments, field tests, and computer simulations show that dramatic reductions in the transient pressures at disk closure can be achieved by replacing a slow-closing swing check valve with a fast-acting check valve. For example, in a system containing parallel pumps where the transient was generated by stopping one of the pumps, the peak transient pressure was reduced from 745 to 76 kPa when a swing check was replaced with a nozzle check valve.

Air Valves

There are three types of automatic air valves: (1) air/vacuum valves, (2) air release valves, and (3) combination valves. The air/vacuum valve contains a large orifice that releases large quantities of air at near atmospheric pressure while the pipe is being filled and admits large quantities of air into the pipe when the pipe is being drained. These valves typically contain a float, which rises and closes the outlet orifice as the valve body fills with water. Once the pipeline is pressurized, this type of valve cannot reopen to remove air that may subsequently accumulate unless the pressure inside the pipe becomes negative. If the pressure becomes negative during a transient or while draining, the float drops and admits air into the line. For thin-walled pipes that can collapse under internal vacuums, the air/vacuum valves should be sized for a full pipe break at the lowest pipe elevation. The air/vacuum valve must have the ability to supply an airflow equal to the maximum drainage rate of the water from the pipe break and at an internal vacuum pressure that is above the pipe collapse pressure of the pipe. Air valve sizing charts are provided by manufacturers.

Air release valves contain a small orifice that is designed to release small quantities of pressurized air. The mechanism opening and closing the orifice is typically controlled by a plunger activated by a float at the end of a lever arm. As air accumulates in the valve body, the float drops and opens the orifice. As the air is expelled, the float rises and closes the orifice.

The combination valve is actually two valves in one: a large valve that functions as an air/vacuum valve and a small one that functions as an air release valve. The installation can either consist of an air/vacuum valve and an air release valve plumbed in parallel, or the two can be integrated into a single valve body. Most air valve installations require combination valves.

One caution is that large-diameter manual air release valves should be avoided because improper operation of them can cause pressure transients. If the system is filled and pressurized with the manual air valves closed, the trapped air will be pressurized to full system pressure. When the manual air valve is opened, the air will be released at sonic velocity. The rapid depressurization of the air can cause rapid acceleration of the liquid upstream from the air valve and a high-pressure rise can occur when the water hits the air valve and instantly decelerates. If manual air valves are installed, they should be small so the air release rate is controlled to a safe rate. The suggested definition of a "small" manual air valve is that the air valve is about 1/20 of the pipe diameter.

Locating air valves in a piping system depends on the pipe profile, pipe length, and flow rates. Preferably, pipes should be laid to grade with valves placed at prominent high points and at regular intervals between high points (not more than a few thousand feet apart). At the high point of the pipeline, be sure to install air/vacuum valves of sufficient size to protect the pipe from collapse in the event of a major pipe break.

Pump Selection

Optimizing the life of a water supply system requires proper selection, operation, and maintenance of the pumps. During the selection process, the designer must be concerned about matching the pump performance to the system requirements and must anticipate problems that will be encountered when the pumps are started or stopped and when the pipe is filled and drained.

Selecting a pump for a particular service requires matching the system requirements to the capabilities of the pump. The process consists of developing a system equation by applying the energy equation to evaluate the pumping head required to overcome the elevation difference, friction, and minor losses. For a pump supplying water between two reservoirs, the pump head required to produce a given discharge can be expressed as follows:

$$H_p = \Delta Z + H_f \tag{2.4.16}$$

or

$$H_p = \Delta Z + CQ^2 \tag{2.4.17}$$

in which the constant C is defined by Equation 2.4.13.

Figure 2.4.2 shows a system curve for a pipe having an 82-m elevation lift and moderate friction losses. If the elevation of either reservoir is a variable, then there is not a single curve but a family of curves corresponding to differential reservoir elevations.

The three pump curves (A, B, and C) shown in Figure 2.4.2 represent different impeller diameters installed in the same pump casing with the pump operating at full speed. The intersections of the system curve with the pump curves identify the flow that each pump will supply if installed in that system. For the system curve shown, a single A pump would supply a flow of about 550 lpm at a head of 104 m and an efficiency of about 85%. A single C pump would supply a flow of about 300 lpm at a head of 88 m and an efficiency of about 60%. The net positive suction head (NPSH) and brake horsepower (bhp) can be obtained from their respective curves.

The selection process for a fixed speed pump is more complex when the system demand varies, either due to variations in the water surface elevation or to changing flow requirements. If the system must operate over a range of reservoir elevations, the pump should be selected so that the system curve, based on the mean (or the most frequently encountered) water level, intersects the pump curve near the midpoint of the best efficiency range. If the water level variation is not too great, the pump may be able to operate efficiently over the complete flow range.

The problem of pump selection also becomes more difficult when planning for future demands or if the pumps are required to supply a varying flow. If the flow range is large, multiple pumps or a variable-speed drive may be needed. Selection of multiple pumps and the decision about installing them in parallel or in series depend on the discharge requirement and the amount of friction in the system. Parallel installations are most effective for low-friction systems. Series pumps work best in high-friction systems.

For parallel pump operation, the combined two-pump curve is constructed by adding the flow of each pump at a common total dynamic head (H_p). Such a curve for two C pumps in parallel is shown in Figure 2.4.3 (labeled two pumps). The intersection of the two-pump curve with the system curve identifies the combined flow for the two pumps. The efficiency for each pump is determined by projecting horizontally to the left to intersect the single-pump curve. For this

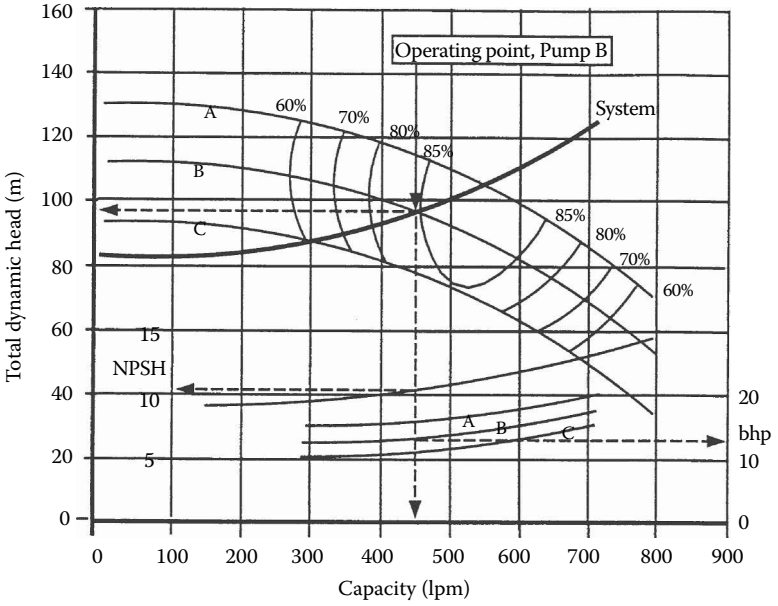

FIGURE 2.4.2 Pump selection for a single pump.

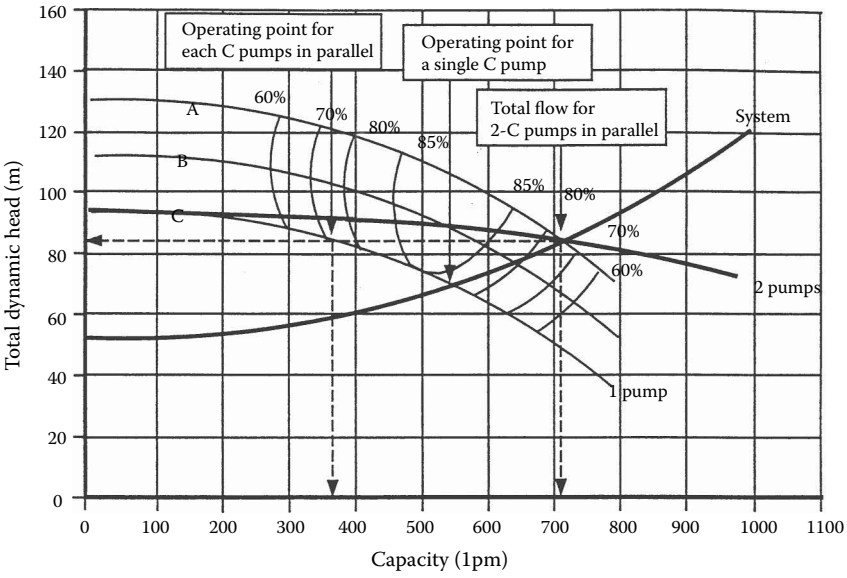

FIGURE 2.4.3 Selection of parallel pumps.

example with two C pumps operating in parallel, the flow will be 710 lpm at a head of 82 m and at an efficiency of each will be about 72%. For the two pumps to operate in the most efficient way, the selection should be made so the system curve intersects the single-pump curve to the right of its best efficiency point.

Starting a constant speed pump with the pipeline empty will result in filling at a very rapid rate because initially there is little friction to build backpressure. As a result, the pump will operate at a flow well above the design flow. This may cause the pump to cavitate, but the more serious problem is the possibility of high pressures generated by the rapid filling of the pipe. Provisions should be made to control the rate of filling to a safe rate. Start-up transients are often controlled by starting the pump against a partially open discharge valve located near the pump and using a bypass line around the pump. This allows the system to be filled slowly and safely. If the pipe remains full and no air is trapped, after the initial filling, subsequent start-up of the pumps generally does not create any serious problem. The preferred solution to avoiding rapid filling is to use variable speed pumps so the fill rate can be set at a safe rate.

For some systems, stopping the pump either intentionally or by a power failure can generate high pressures that can damage the pipe. If the design process does not consider these potential problems, the system may not function trouble free. Downtime and maintenance costs may be high. Not all systems will experience start-up and shutdown problems, but the design should at least consider the possibility. The problem is more severe for pipelines that have a large elevation change and multiple high points. The magnitude of the transient is related to the length and profile of the pipeline, the pump characteristics, the magnitude of the elevation change, and the type of check valve used. The downsurge caused by stopping the pump can cause column separation and high pressures due to flow reversals and closure of the check valves. Surge-protection equipment can be added to such systems to prevent damage and excessive maintenance.

Numerous mechanical devices and techniques have been used to suppress pump shutdown transients. These include increasing the rotational inertia of the pump, using surge tanks or air chambers near the pump, pressure relief valves, vacuum-breaking valves, and surge-anticipating valves. Selection of the proper transient control device will improve reliability, extend the economic life of the system, and reduce maintenance.

Filling and Flushing

If a piping system is short, the process of filling and flushing to remove trapped air poses little problem in either time or potential threat to the system. Simply fill slowly at a fill rate of about 0.25–0.5 mps (1–2 fps) and release the air either through automatic air valves or small manually opened bleed valves. Once the initial air is released, slowly increase the flow velocity to about 1–2 mps (3–6 fps) to flush any remaining air trapped to the air release valves.

When a pipeline is long, and especially if it has an undulating profile containing multiple high and low points, greater precaution is needed when filling and flushing. Few professional organizations publish guidelines for filling and flushing pipelines. The American Water Works Association (AWWA) is one organization that publishes limited guidelines for filling PVC pipe in their Standard: ANSI/AWWA C605-05. Their recommendations are conservative and incomplete. They simply suggest that pipelines be filled at a velocity of about 0.3 mps (1 fps) and then flushed at a velocity greater than 1 mps (3 fps). The 0.3 m/s fill limit is not the appropriate filling limit for all pipelines. It is simply a suggestion or a "rule of thumb," not a requirement and failing to strictly adhere to it does not automatically endanger a pipeline.

The appropriate rate to safely fill a pipeline depends on the length and profile of the pipeline and whether the pipeline is filled as a closed pipe (end valve closed) or an open pipe (end valve open). Consider a pipe that is lying on a flat surface connected to a pump with the end valve open. Or, alternately, consider the same pipe connected to a reservoir with a fill valve at the reservoir and no valve at the outlet end. Such a pipeline (short or long) can be safely filled by simply turning the pump on or opening the inlet valve. Because there is no closed or partially closed valve, and no high and low points in the line to restrict the movement of the air or water within the pipe, the pipe can be filled at a high velocity without endangering the pipe. The rapidly moving water simply forces the air to exit the end of the pipe as the water fills the pipe. The pipe gradually comes up to its normal operating pressure and no pressure surge is created. Using the suggested AWWA filling of 0.3 mps (1 fps) for such a pipe would be inappropriate and a waste of time because the pipe would never fill at such a low fill rate.

If it is necessary to fill a pipe as a closed system, the AWWA recommended 0.3 mps (1 fps) filling limit is a reasonable guideline because a closed pipe must be filled slowly to avoid the rapid pressurization of air that will be trapped in the pipe. This is not the preferred method of filling a long pipeline because it is inevitable that large air pockets will be trapped at high pressure. Once a closed pipe has been filled, pressurized and no more air can be vented, the trapped air must then be flushed to air release valves or out the end of the pipe by opening the end valve to establish flow. It is dangerous to flush high-pressure air pockets through the system and out of the end of the pipe. It is much safer to keep the pressure inside the pipe to a minimum while filling and flushing.

Another reason why it is best to avoid filling a pipe as a closed pipe is that it creates the possibility of subjecting the entire pipeline to the shutoff pressure of the upstream reservoir or pump, which may over-pressurize sections of the pipeline.

A safer way to fill a pipeline is to operate the system as an open pipe (end valve open). This keeps the pressure of the trapped air at a minimum while filling and flushing. Start filling at a rate of about 0.5–1 mps (1.5–3 fps). When liquid begins to flow out the end of the pipeline, increase the flow rate to about 2 mps (6 fps). Monitor flow and pressure in the pipeline and adjust the inflow rate and/or the opening of the valve at the end of the pipe to slowly bring the pipeline up to normal pressure.

System Monitoring and Control

Key elements such as flow rate, pressure, valve position, and pump operation should be continuously monitored and recorded by a System Control and Data Acquisition System (SCADA). Programmable Logic Controllers (PLCs) can be used to assist in operating the system and can provide warnings and take action when the flow or pressure is outside the safe or required operating limits.

Written operating instructions should be developed during the design phase and used after construction to safely operate the system. Such instructions should include normal operation and emergency shutdown procedures. Preparing the operating instructions during the design of the system and using them to perform computer simulations of the various operating scenarios will provide assurance that the system design will provide the required safety and flexibility so the system can meet all expectation. The operating instructions can be used to guide the steady-state and transient computer program simulations of system performance during the design phase.

2.5 OPEN CHANNEL FLOW

Frank M. White

Definition

The term *open channel flow* denotes the gravity-driven flow of a liquid with a free surface. Technically, we may study any flowing liquid and any gas interface. In practice, the vast majority of open channel flows concern water flowing beneath atmospheric air in artificial or natural channels. Excellent accounts of open channel flows are available in books by Brater (1976), Chow (1959), Henderson (1966) and Sellin (1970) for instance.

The geometry of an arbitrary channel is shown in Figure 2.5.1. The area A is for the water cross section only, and b is its top width. The wetted perimeter P covers only the bottom and sides, as shown, not the surface (whose air resistance is neglected). The water depth at any location is y, and the channel slope is θ, often denoted as $S_o = \sin\theta$. All of these parameters may vary with distance x along the channel. In unsteady flow (not discussed here), they may also vary with time.

Uniform Flow

A simple reference condition, called *uniform flow*, occurs in a long straight prismatic channel of constant slope S_o. There is no acceleration, and the water flows at constant depth with fluid weight exactly balancing the wetted wall shear force: $\rho g L A \sin\theta = \tau_w P L$, where L is the channel length. Thus, $\tau_w = \rho g R_h S_o$, where $R_h = A/P$ is called the *hydraulic radius* of the channel. If we relate wall shear stress to the Darcy friction factor f, $\tau_w = (f/8)\rho V^2$, we obtain the basic uniform flow open channel relation:

$$\text{Uniform flow}: V = \sqrt{\frac{8g}{f}}\sqrt{R_h S_o}, \text{ where} \sqrt{\frac{8g}{f}} = C = \text{Chézy coefficient} \tag{2.5.1}$$

Antoine Chézy first derived this formula in 1769. It is satisfactory to base f upon the pipe-flow Moody diagram (Figure 2.4.1) using the hydraulic diameter, $D_h = 4R_h$, as a length scale. That is, $f = fcn\,(VD_h/\nu, \varepsilon/D_h)$ from the Moody chart. In ordinary practice, however, engineers assume fully rough, high-Reynolds-number flow and use Robert Manning's century-old correlation:

$$C = \frac{\zeta}{n} R_h^{1/6}, \quad \text{or} \quad V_{\text{uniform}} \approx \frac{\zeta}{n} R_h^{2/3} S_o^{1/2} \quad \text{and} \quad Q = VA \tag{2.5.2}$$

where ζ is a conversion factor equal to 1.0 in SI units and 1.486 in English units. The quantity n is Manning's roughness parameter, with typical values, along with the associated roughness heights ε, listed in Table 2.5.1.

Critical Flow

Since the surface is always atmospheric, pressure head is not important in open channel flows. Total energy E relates only to velocity and elevation:

$$\text{Specific energy } E = y + \frac{V^2}{2g} = y + \frac{Q^2}{2gA^2}$$

At a given volume flow rate Q, the energy passes through a minimum at a condition called *critical flow*, where $dE/dy = 0$, or $dA/dy = b = gA^3/Q^2$:

$$A_{\text{crit}} = \left(\frac{bQ^2}{g}\right)^{1/3} \quad ; V_{\text{crit}} = \frac{Q}{A_{\text{crit}}} = \left(\frac{gA_{\text{crit}}}{b}\right)^{1/2} \tag{2.5.3}$$

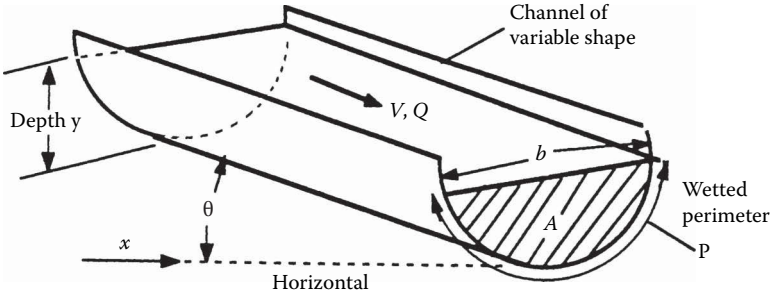

FIGURE 2.5.1 Definition sketch for an open channel.

where b is the top-surface width as shown in Figure 2.5.1. The velocity V_{crit} equals the speed of propagation of a surface wave along the channel. Thus, we may define the Froude number Fr of a channel flow, for any cross section, as $Fr = V/V_{crit}$. The three regimes of channel flow are

$$Fr < 1: \text{subcritical flow}; \quad Fr = 1: \text{critical flow}; \quad Fr > 1: \text{supercritical flow}$$

There are many similarities between Froude number in channel flow and Mach number in variable-area duct flow (see Section 2.6).

For a rectangular duct, $A = by$, we obtain the simplified formulas

$$V_{crit} = \sqrt{gy} \quad \text{and} \quad Fr = \frac{V}{\sqrt{gy}} \tag{2.5.4}$$

independent of the width of the channel.

Example 2.5.1

Water ($\rho = 998\,\text{kg/m}^3$, $\mu = 0.001$ kg/m·s) flows uniformly down a half-full brick 1-m-diameter circular channel sloping at 1°. Estimate (a) Q; and (b) the Froude number.

Solution 2.5.1 (a). First compute the geometric properties of a half-full circular channel:

$$A = \frac{\pi}{8}(1\,\text{m})^2 = 0.393\,\text{m}^2; \quad P = \frac{\pi}{2}(1\,\text{m}) = 1.57\,\text{m}; \quad R_h = \frac{A}{P} = \frac{0.393}{1.57} = 0.25$$

From Table 2.5.1, for brickwork, $n \approx 0.015$. Then, Manning's formula, Equation 2.5.2 predicts

$$V = \frac{\zeta}{n} R_h^{1/6} S R_o^{1/2} = \frac{1.0}{0.015}(0.25)^{1/6}(\sin 1°)^{1/2} \approx 3.49\,\frac{\text{m}}{\text{s}}; \quad Q = 3.49(0.393) \approx 1.37\,\frac{\text{m}^3}{\text{s}}$$

The uncertainty in this result is about ±10%. The flow rate is quite large (21,800 gal/min) because 1°, although seemingly small, is a substantial slope for a water channel.

One can also use the Moody chart. With $V \approx 3.49$ m/s, compute $\text{Re} = \rho V D_h/\mu \approx 3.49 \times 10^6$ and $\varepsilon/D_h \approx 0.0037$, then compute $f \approx 0.0278$ from the Moody chart. Equation 2.5.1 then predicts

$$V = \sqrt{\frac{8g}{f} R_h S_o} = \sqrt{\frac{8(9.81)}{0.0278}(0.25)(\sin 1°)} \approx 3.51\,\frac{\text{m}}{\text{s}}; \quad Q = VA \approx 1.38\,\frac{\text{m}^3}{\text{s}}$$

The two values of Q are remarkably close. With Q known from part (a), compute the critical conditions from Equation 2.5.3:

$$A_{crit} = \left(\frac{bQ^2}{g}\right)^{1/3} = \left[\frac{1.0(1.37)^2}{9.81}\right] = 0.576\ \text{m}^2, \quad V_{crit} = \frac{Q}{A_{crit}} = \frac{1.37}{0.576} = 2.38\,\frac{\text{m}}{\text{s}}$$

Hence

$$\text{Fr} = \frac{V}{V_{crit}} = \frac{3.49}{2.38} \approx 1.47 \ (\text{supercritical})$$

Again the uncertainty is approximately ±10%, primarily because of the need to estimate the brick roughness.

Hydraulic Jump

In gas dynamics (Section 2.6), a supersonic gas flow may pass through a thin normal shock and exit as a subsonic flow at higher pressure and temperature. By analogy, a supercritical open channel flow

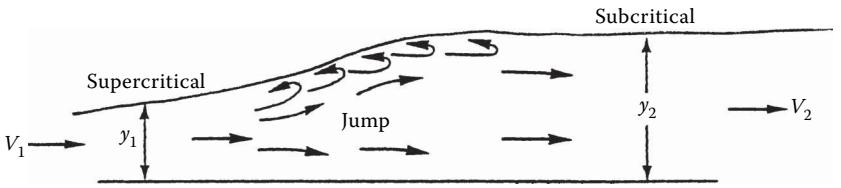

FIGURE 2.5.2 A two-dimensional hydraulic jump.

may pass through a *hydraulic jump* and exit as a subcritical flow at greater depth, as in Figure 2.5.2. Application of the continuity and momentum balances to a jump in a rectangular channel yields

$$V_2 = V_1 \frac{y_1}{y_2} \quad ; y_2 = \frac{y_1}{2}\left[-1+\sqrt{1+8\mathrm{Fr}_1^2}\right] \quad \text{where} \quad \mathrm{Fr}_1 = \frac{V}{\sqrt{g y_1}} > 1 \tag{2.5.5}$$

Both the normal shock and the hydraulic jump are dissipative processes: the entropy increases and the effective energy decreases. For a rectangular jump,

$$\Delta E = E_1 - E_2 = \frac{\left(y_2 - y_1\right)^3}{4 y_1 y_2} > 0 \tag{2.5.6}$$

For strong jumps, this loss in energy can be up to 85% of E_1. The second law of thermodynamics requires $\Delta E > 0$ and $y_2 > y_1$ or, equivalently, $\mathrm{Fr}_1 > 1$,

Note from Figure 2.5.2 that a hydraulic jump is not thin. Its total length is approximately four times the downstream depth. Jumps also occur in nonrectangular channels, and the theory is much more algebraically laborious.

Weirs

If an open channel flow encounters a significant obstruction, it will undergo rapidly varied changes which are difficult to model analytically but can be correlated with experiment. An example is the *weir* in Figure 2.5.3 (colloquially called a *dam*), which forces the flow to deflect over the top. If $L \ll Y$, the weir is termed *sharp-crested*; if $L = O(Y)$ it is *broad-crested*. Small details, such as the upper front corner radius or the crest roughness, may be significant. The crest is assumed level and of width b into the paper.

If there is a free overfall, as in Figure 2.5.3, the flow accelerates from subcritical upstream to critical over the crest to supercritical in the overfall. There is no flow when the excess upstream

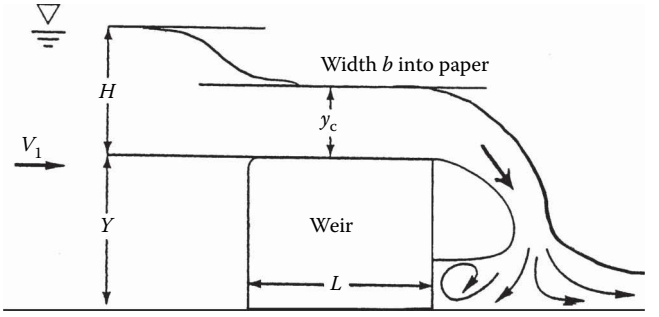

FIGURE 2.5.3 Geometry and notation for flow over a weir.

depth $H=0$. A simple Bernoulli-type analysis predicts that the flow rate Q over a wide weir is approximately proportional to $bg^{1/2}H^{3/2}$. An appropriate correlation is thus

$$Q_{\text{weir}} = C_{\text{d}} b g^{1/2} H^{3/2}, \quad \text{where } C_d = \text{dimensionless weir coefficient} \tag{2.5.7}$$

If the upstream flow is turbulent, the weir coefficient depends only upon geometry, and Reynolds number effects are negligible. If the weir has sidewalls and is narrow, replace width b by $(b-0.1H)$.

Two recommended empirical correlations for Equation 2.5.7 are as follows:

$$\begin{aligned} &\text{Sharp-crested:} \quad C_{\text{d}} \approx 0.564 + 0.0846\frac{H}{Y} \quad \text{for } \frac{L}{Y} < 0.07 \\ &\text{Broad-crested:} \quad C_{\text{d}} \approx 0.462 \quad \text{for } 0.08 < \frac{H}{L} < 0.33 \end{aligned} \tag{2.5.8}$$

These data are for wide weirs with a sharp upper corner in front. Many other weir geometries are discussed in the references for this section. Of particular interest is the sharp-edged vee-notch weir, which has no length scale b. If 2θ is the total included angle of the notch, the recommended correlation is

$$\text{Vee-notch, angle } 2\theta: \quad Q \approx 0.44 \tan\theta \; g^{1/2} H^{5/2} \quad \text{for} \quad 10^\circ < \theta \le 50^\circ \tag{2.5.9}$$

The vee-notch is more sensitive at low flow rates (large H for a small Q) and thus is popular in laboratory measurements of channel flow rates.

A weir in the field will tend to spring free and form a natural *nappe*, or air cavity, as in Figure 2.5.3. Narrow weirs, with sidewalls, may need to be aerated artificially to form a nappe and keep the flow from sliding down the face of the weir. The correlations above assume nappe formation. Further details can be found in Ackers et al. (1978), Boss and Coworkers (1984, 1985), Spitzer (1991), etc.

Gradually Varied Flow

Return to Figure 2.5.1 and suppose that (y, A, b, P, S_o) are all variable functions of horizontal position x. If these parameters are slowly changing, with no hydraulic jumps, the flow is termed *gradually varied* and satisfies a simple one-dimensional first-order differential equation if Q=constant:

$$\frac{dy}{dx} \approx \frac{S_o - S}{1 - \dfrac{V^2 b}{gA}}, \quad \text{where } V = \frac{Q}{A} \quad \text{and} \quad S = \frac{f}{D_h}\frac{V^2}{2g} = \frac{n^2 V^2}{\zeta^2 R_h^{4/3}} \tag{2.5.10}$$

The conversion factor $\zeta^2=1.0$ for SI units and 2.208 for English units. If flow rate, bottom slope $S_o(x)$, channel geometry, and surface roughness are known, we may solve for $y(x)$ for any given initial condition $y=y_0$ at $x=x_0$. The solution is computed by any common numerical method and is especially easy with a spreadsheet.

Recall from Equation 2.5.3 that the term $V^2b/(gA)=\text{Fr}^2$, so the sign of the denominator in Equation 2.5.10 depends upon whether the flow is sub- or supercritical. The mathematical behavior of Equation 2.5.10 differs also. If Fr is near unity, the change dy/dx will be very large, which probably violates the basic assumption of "gradual" variation.

For a given flow rate and local bottom slope, two reference depths are useful and may be computed in advance:

1. The *normal* depth y_n for which Equation 2.5.2 yields the flow rate.
2. The *critical* depth y_c for which Equation 2.5.3 yields the flow rate.

Comparison of these two, and their relation to the actual local depth y, specifies the type of solution curve being computed. The five bottom-slope regimes (mild M, critical C, steep S, horizontal H, and adverse A) create 12 different solution curves, as illustrated in Figure 2.5.4. All of these may be readily generated by a numerical solution of Equation 2.5.10. The following example illustrates a typical solution to a gradually varied flow problem.

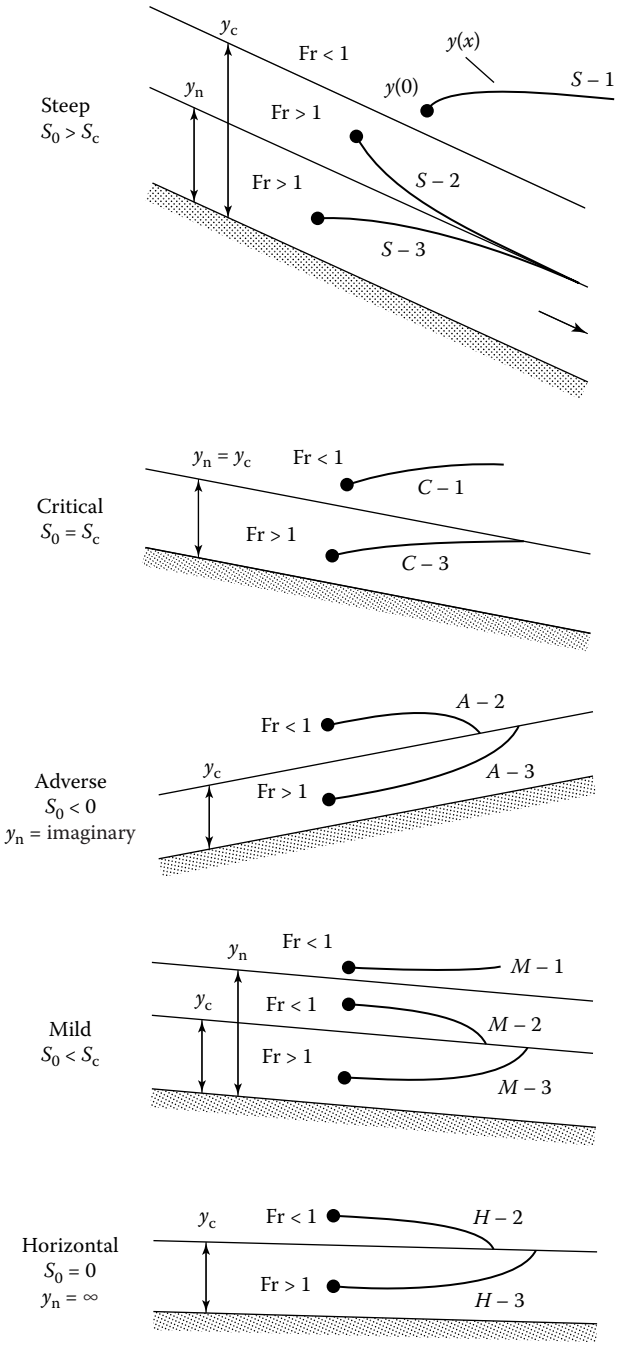

FIGURE 2.5.4 Classification of solution curves for gradually varied flow.

Example 2.5.2

Water, flowing at 2.5 m^3/s in a rectangular gravelly earth channel 2 m wide, encounters a broad-crested weir 1.5 m high. Using gradually varied theory, estimate the water depth profile back to 1 km upstream of the weir. The bottom slope is 0.1°.

Solution. We are given Q, $Y=1.5$ m, and $b=2$ m. We may calculate excess water level H at the weir (see Figure 2.5.3) from Equations 2.5.7 and 2.5.8:

$$Q = 2.5\frac{\text{m}^3}{\text{s}} = C_d b_{\text{eff}} g^{1/2} H^{3/2} = 0.462\left(2.0 - 0.1H\right)\left(9.81\right)^{1/2} H^{3/2}, \quad \text{solve for } H \approx 0.94 \text{ m}$$

Since the weir is not too wide, we have subtracted 0.1 H from b as recommended. The weir serves as a "control structure" which sets the water depth just upstream. This is our initial condition for gradually varied theory: $y(0)=Y+H=1.5+0.94\approx 2.44$ m at $x=0$. Before solving Equation 2.5.10, we find the normal and critical depths to get a feel for the problem:

$$\text{Normal depth:} \quad Q = 2.5\frac{\text{m}^3}{\text{s}} = \frac{1.0}{0.025}\left(2.0y_n\right)\left(\frac{2.0y_n}{2.0+2y_n}\right)^{2/3} \sqrt{\sin 0.1°}, \text{ solve } y_n \approx 1.14 \text{ m}$$

$$\text{Critical depth:} \quad A_c = 2.0y_c = \left(\frac{bQ^2}{g}\right)^{1/3} = \left[\frac{2.0\left(2.5\right)^2}{9.81}\right]^{1/3}, \quad \text{solve } y_c \approx 0.54 \text{ m}$$

We have taken $n\approx 0.025$ for gravelly earth, from Table 2.5.1. Since $y(0) > y_n > y_c$, we are on a mild slope $M-1$ "backwater" curve, as in Figure 2.5.4. For our data, Equation 2.5.10 becomes

$$\frac{dy}{dx} \approx \frac{S_o - n^2 Q^2 / \left(\zeta^2 A^2 R_h^{4/3}\right)}{1 - Q^2 b / \left(gA^3\right)}$$

where $Q=2.5$, $b=2$, $\zeta=1$, $A=2y$, $S_o=\sin 0.1°$, $R_h=2y/(2+2y)$, $g=9.81$, $y(0)=2.44$ at $x=0$.

Integrate numerically backward, that is, for $\Delta x < 0$, until $x=-1$ km$=-1000$ m. The complete solution curve is shown in Figure 2.5.5. The water depth decreases upstream and is approximately $y\approx 1.31$ m at $x=-1000$ m. If slope and channel width remain constant, the water depth asymptotically approaches the normal depth y_n far upstream.

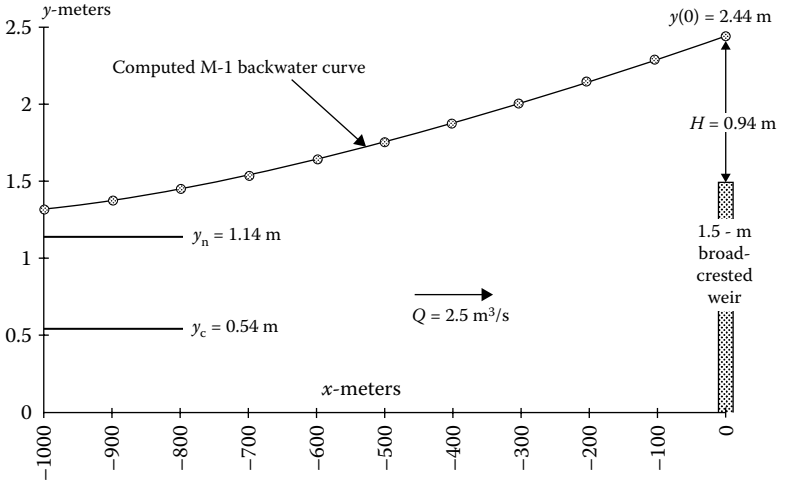

FIGURE 2.5.5 Backwater solution curve for Example 2.5.2.

2.6 EXTERNAL INCOMPRESSIBLE FLOWS

John C. Leylegian

Introduction and Scope

Potential flow theory (Section 2.2) assumes a fluid to be incompressible and inviscid. There are no shear stresses; pressure is the only stress acting on a fluid particle. Because of the assumption of zero viscosity, potential flow theory predicts no drag force when an object moves through a fluid, which obviously is not correct, because all real fluids are viscous and lead to drag forces (note that although viscosity is required for any object to experience drag, the drag itself will often be due to the resulting pressure field). The objective of this section is to consider the behavior of a viscous, incompressible fluid flowing over an object.

A number of phenomena that occur in external flow at high Reynolds number (for most of which viscous effects are negligible) over an object are shown in Figure 2.6.1. As the flow reaches the object, the streamlines are diverted around the object; the freestream flow divides at the stagnation point. Fluid at the object surface moves at the velocity of the body as a result of the *no-slip condition*. Boundary layers form on the surfaces of the body; flow in the boundary layers is initially laminar, then if conditions are favorable, a *transition* to turbulent flow may occur (points "T").

As the boundary layers develop, they will cause a slight displacement of the streamlines of the external flow (their thickness is greatly exaggerated in Figure 2.6.1). *Separation* may occur if the fluid enters a region of increasing pressure on the rear of the body (points "S"); at separation, the flow adjacent to the body surface reverses direction. Fluid that was in the boundary layers thickens and forms a *wake* behind the object.

The Bernoulli equation is valid for steady, incompressible, inviscid flow. It may be used to predict pressure variations outside the boundary layer. The stagnation pressure is constant in the uniform inviscid flow far from an object, and the Bernoulli equation reduces to

$$p_\infty + \frac{1}{2}\rho U_\infty^2 = p + \frac{1}{2}\rho U^2, \tag{2.6.1}$$

where p is the freestream pressure, ρ is the fluid density, U is the freestream velocity, and the subscript ∞ denotes freestream conditions far upstream of the body. Therefore, the local pressure can be determined if the local freestream velocity is known.

Boundary Layers

The Boundary Layer Concept

The *boundary layer* is the thin region near the surface of a body in which viscous effects are important. By recognizing that viscous effects are concentrated near the surface of an object, Prandtl showed that only the Euler equations for inviscid flow need be solved in the region outside the boundary layer. Inside the boundary layer, the elliptic Navier–Stokes equations are simplified to the boundary layer equations, which are of parabolic form, and are easier to solve. The thin boundary layer has negligible pressure variation across it; pressure from the freestream is impressed upon the boundary layer.

The development of a boundary layer over a flat plate in a semi-infinite fluid is shown in Figure 2.6.2. Because the boundary layer is thin, there is negligible disturbance of the inviscid flow outside the boundary layer, and for a flat plate the *pressure gradient* along the surface is close to zero. Transition from laminar to turbulent boundary layer flow on a flat plate occurs when Reynolds number based on x (the distance downstream of the leading edge of the plate) exceeds $Re_x = 500{,}000$. Transition may occur earlier if the surface is rough, pressure increases in the flow direction, or separation occurs. Transition

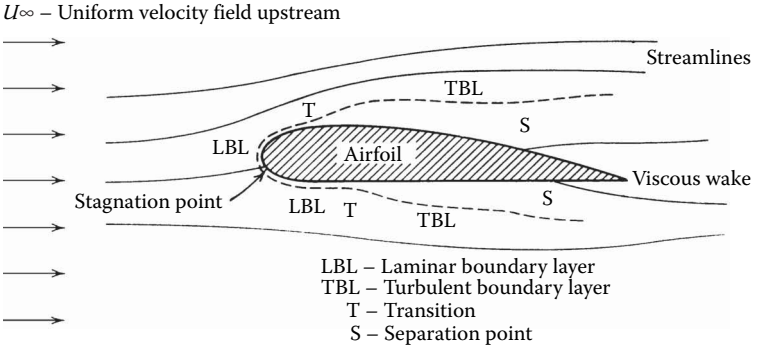

FIGURE 2.6.1 Viscous flow around an airfoil (boundary layer thickness exaggerated for clarity).

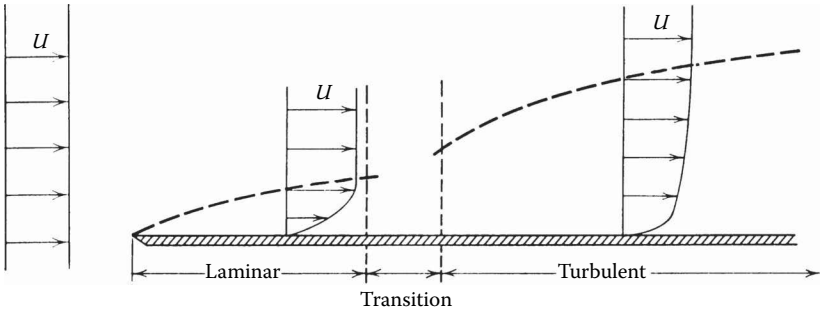

FIGURE 2.6.2 Boundary layer on a flat plate (vertical thickness exaggerated for clarity).

may also occur later if the surface is very smooth, if the pressure decreases in the flow direction, or if the flow has no disturbances. Following transition, the turbulent boundary layer thickens more rapidly than the laminar boundary layer as a result of increased shear stress at the body surface.

Boundary Layer Thickness Definitions

The boundary layer disturbance thickness, δ, is usually defined as the distance, y, from the surface to the point where the velocity within the boundary layer, u, is within 1% of the local freestream velocity, U. As shown in Figure 2.6.2, the boundary layer velocity profile merges smoothly and asymptotically into the freestream, making δ difficult to measure. For this reason and for their physical significance, we define two integral measures of boundary layer thickness. The displacement thickness, δ^*, is defined as

$$\frac{\delta^*}{\delta} = \int_0^\infty \left(1 - \frac{u}{U}\right) d\left(\frac{y}{\delta}\right) \tag{2.6.2}$$

The displacement thickness is the distance the solid boundary would have to be displaced into the freestream in a frictionless flow to produce the mass flow deficit caused by the presence of the boundary layer. The momentum thickness, θ, is defined as

$$\frac{\theta}{\delta} = \int_0^\infty \frac{u}{U}\left(1 - \frac{u}{U}\right) d\left(\frac{y}{\delta}\right) \tag{2.6.3}$$

The momentum thickness is the distance the solid boundary would have to be moved into the freestream to produce the same deficit in momentum flux as that caused by the boundary layer (momentum flux is momentum per unit time passing a cross section).

Because the displacement and momentum thicknesses are defined in terms of integrals for which the integrand vanishes in the freestream, they are easier to evaluate experimentally than disturbance thickness δ.

Exact Solution of the Laminar Flat-Plate Boundary Layer

Blasius obtained an exact solution for laminar boundary layer flow on a flat plate. He assumed a thin boundary layer to simplify the streamwise momentum equation. He also assumed *similar* velocity profiles in the boundary layer, so that when written as $u/U = f(y/\delta)$, velocity profiles do not vary with x. He used a similarity variable $\eta = y\,(U/\nu x)^{-1/2}$ to reduce the partial differential equations of motion and continuity to a single third-order ordinary differential equation.

Blasius used numerical methods to solve the ordinary differential equation; as a result, the velocity profile cannot be expressed as a function. The principal results of the Blasius solution may be expressed as

$$\frac{\delta}{x} = \frac{5}{\sqrt{Re_x}} \tag{2.6.4}$$

and

$$C_f = \frac{\tau_w}{\frac{1}{2}\rho U^2} = \frac{0.664}{\sqrt{Re_x}}, \tag{2.6.5}$$

where Re_x is the Reynolds number, C_f is the skin friction coefficient, and τ_w is the wall shear stress. These results show that the laminar boundary layer thickness on a flat plate varies as $x^{1/2}$ and wall shear stress varies as $1/x^{1/2}$.

Approximate Solutions

The Blasius solution cannot be expressed in closed form and is limited to laminar flow. Therefore, approximate methods that may give solutions for both laminar and turbulent flow in closed form are desirable. One such method is the *momentum integral equation* (MIE), which may be developed by integrating the boundary layer equation across the boundary layer or by applying the streamwise momentum equation to a differential control volume (Pritchard and Mitchell, 2015). The result is the ordinary differential equation:

$$\frac{d\theta}{dx} = \frac{\tau_w}{\rho U^2} - \left(\frac{\delta^*}{\theta} + 2\right)\frac{\theta}{U}\frac{dU}{dx}. \tag{2.6.6}$$

The first term on the right side of Equation 2.6.6 contains the influence of wall shear stress. Since τ_w is always positive in the direction of the flow, it always causes θ to increase with x. The second term on the right side contains the pressure gradient, which can have either sign. Therefore, the effect of the pressure gradient can be to either increase or decrease the rate of growth of boundary layer thickness.

Equation 2.6.6 is an ordinary differential equation that can be solved for θ as a function of x on a flat plate (zero pressure gradient), provided a reasonable shape is assumed for the boundary layer velocity profile and shear stress is expressed in terms of the other variables. Results for laminar and turbulent flat-plate boundary layer flows are discussed below.

TABLE 2.6.1
Exact and Approximate Solutions for Laminar Boundary Layer Flow over a Flat Plate at Zero Incidence

Velocity Distribution				
$\frac{u}{U}=f\left(\frac{y}{\delta}\right)=f(\eta)$	$\frac{\theta}{\delta}$	$\frac{\delta^*}{\delta}$	$a=\frac{\delta}{x}\sqrt{Re_x}$	$b=C_f\sqrt{Re_x}$
$f(\eta)=2\eta-\eta^2$	2/15	1/3	5.48	0.730
$f(\eta)=3/2\eta-1/2\eta^3$	39/280	3/8	4.64	0.647
$f(\eta)=\sin(\pi/2\eta)$	$(4-\pi)/2\pi$	$(\pi-2)/\pi$	4.80	0.654
Exact	0.133	0.344	5.00	0.664

Laminar Boundary Layers

A reasonable approximation to the laminar boundary layer velocity profile is to express u as a polynomial in y. The resulting solutions for δ and τ_w have the same dependence on x as the exact Blasius solution. Numerical results are presented in Table 2.6.1. Comparing the approximate and exact solutions shows remarkable agreement in view of the approximations used in the analysis. The trends are predicted correctly and the approximate values are within 10% of the exact values.

Turbulent Boundary Layers

The turbulent velocity profile may be expressed well using a power law, $u/U=(y/\delta)^{1/n}$, where n is an integer between 6 and 10 (frequently 7 is chosen). For turbulent flow, it is not possible to express shear stress directly in terms of a simple velocity profile; an empirical correlation is required. Using a pipe flow data correlation gives

$$\frac{\delta}{x}=\frac{0.382}{Re_x^{1/5}} \tag{2.6.7}$$

and

$$C_f=\frac{\tau_w}{\frac{1}{2}\rho U^2}=\frac{0.0594}{Re_x^{1/5}}. \tag{2.6.8}$$

These results characterize the turbulent boundary layer on a flat plate. They show that the turbulent boundary layer thickness varies as $x^{4/5}$ and wall shear stress varies as $1/x^{1/5}$.

Approximate results for laminar and turbulent boundary layers are compared in Table 2.6.2. At a Reynolds number of 1×10^6, wall shear stress for the turbulent boundary layer is nearly six times as large as for the laminar layer. For a turbulent boundary layer, thickness increases five times faster with distance along the surface than for a laminar layer. These approximate results give a physical feel for relative magnitudes in the two cases.

The MIE cannot be solved in closed form for flows with nonzero pressure gradients. However, the role of the pressure gradient can be understood qualitatively by studying the MIE.

Effect of Pressure Gradient

Boundary layer flow with favorable, zero, and adverse pressure gradients is depicted schematically in Figure 2.6.3. (Assume a thin boundary layer, so the flow on the lower surface behaves as external

TABLE 2.6.2

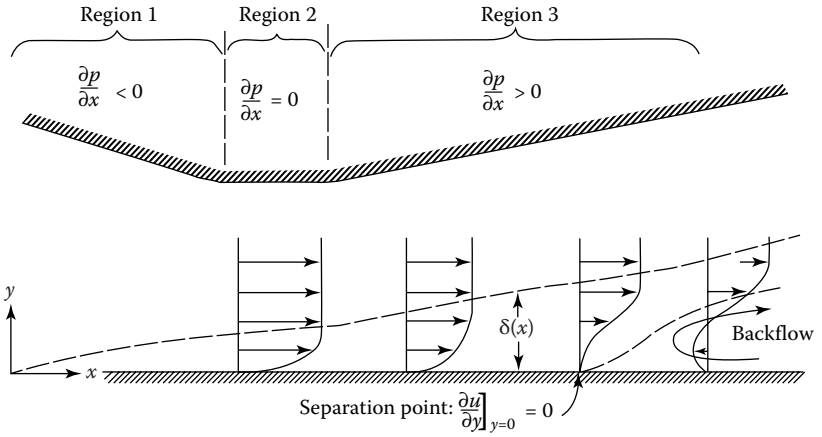

FIGURE 2.6.3 Boundary layer flow with pressure gradient (thickness exaggerated for clarity).

flow on a flat surface, with the pressure gradient generated by the upper surface geometry impressed on the boundary layer.) The pressure gradient is favorable when $\partial p/\partial x < 0$, zero when $\partial p/\partial x = 0$, and adverse when $\partial p/\partial x > 0$, as indicated for Regions 1, 2, and 3.

Viscous shear always causes a net retarding force on any fluid particle within the boundary layer. For zero pressure gradient, shear forces alone can never bring the particle to rest. (Recall that for laminar and turbulent boundary layers the shear stress varied as $1/x^{1/2}$ and $1/x^{1/5}$, respectively; shear stress never becomes zero for finite x.) Hence, since shear stress is given by $\tau_w = \mu\ \partial u/\partial y)_{y=0}$, the velocity gradient cannot be zero. Therefore, flow cannot separate in a zero pressure gradient; shear stresses alone can never cause flow separation.

In the favorable pressure gradient of Region 1, pressure forces tend to maintain the motion of the particle, so flow cannot separate. In the adverse pressure gradient of Region 3, pressure forces oppose the motion of a fluid particle. An adverse pressure gradient is a necessary condition for flow separation.

Velocity profiles for laminar and turbulent boundary layers are shown in Figure 2.6.2. It is easy to see that the turbulent velocity profile has much more momentum than the laminar profile. Therefore, the turbulent velocity profile can resist separation in an adverse pressure gradient better than the laminar profile.

The freestream velocity distribution must be known before the MIE can be applied. We obtain a first approximation by applying inviscid flow theory (e.g., potential flow) to calculate the flow field around the object. Much effort has been devoted to calculation of velocity distributions over objects of known shape (the "direct" problem) and to determine shapes to produce a desired pressure distribution (the "inverse" problem). Detailed discussion of such calculation schemes is beyond the scope of this section; the state-of-the art continues to progress.

Drag

Any object immersed in a viscous fluid flow experiences a net force from the shear stresses and pressure differences caused by the fluid motion. *Drag* is the force component parallel to the freestream velocity vector, while *lift* is the force component normal to the freestream velocity vector. *Streamlining* is the art of shaping a body to reduce fluid dynamic drag. Airfoils (and hydrofoils) are designed to produce lift in air (or water); they are streamlined to reduce drag and thus to attain high lift–drag ratios.

In general, lift and drag cannot be predicted analytically for flows with separation, but progress continues on computational fluid dynamics methods. For most engineering applications, aerodynamic bodies are designed based on a combination of past experience and theoretical/numerical work, and the resulting drag and lift forces are calculated from experimentally derived coefficients, discussed below.

The drag *coefficient* is defined as

$$C_D = \frac{F_D}{\frac{1}{2}\rho V^2 A}, \tag{2.6.9}$$

where $\frac{1}{2}\rho V^2$ is the dynamic pressure and A is a characteristic area upon which the coefficient is based. Common practice is to base the drag coefficient on the projected *frontal area* (Pritchard and Mitchell, 2015).

Similitude was treated in Section 2.3. In general, the drag coefficient may be expressed as a function of Reynolds number, Mach number, Froude number, relative roughness, depth of submergence divided by length, and so on. In this section, we consider neither high-speed flow nor free-surface effects, so we will consider only Reynolds number and roughness effects on drag coefficient.

Friction Drag

The total friction drag force acting on a plane surface aligned with the flow direction can be found by integrating the shear stress distribution along the surface. The drag coefficient for this case is defined as friction force divided by dynamic pressure and *wetted area* in contact with the fluid. Since shear stress is a function of Reynolds number, so is drag coefficient (see Figure 2.6.4). In Figure 2.6.4, transition occurs at $Re_x = 5 \times 10^5$; the dashed line represents the drag coefficient at larger Reynolds numbers. A number of empirical correlations may be used to model the variation in C_D shown in Figure 2.6.4 (Schlichting, 1979).

As seen in the figure, extending the laminar boundary layer line to higher Reynolds numbers shows that it is beneficial to delay transition to the highest possible Reynolds number. Some results are presented in Table 2.6.3; drag is reduced more than 50% by artificially extending laminar boundary layer flow to $Re_L = 10^6$.

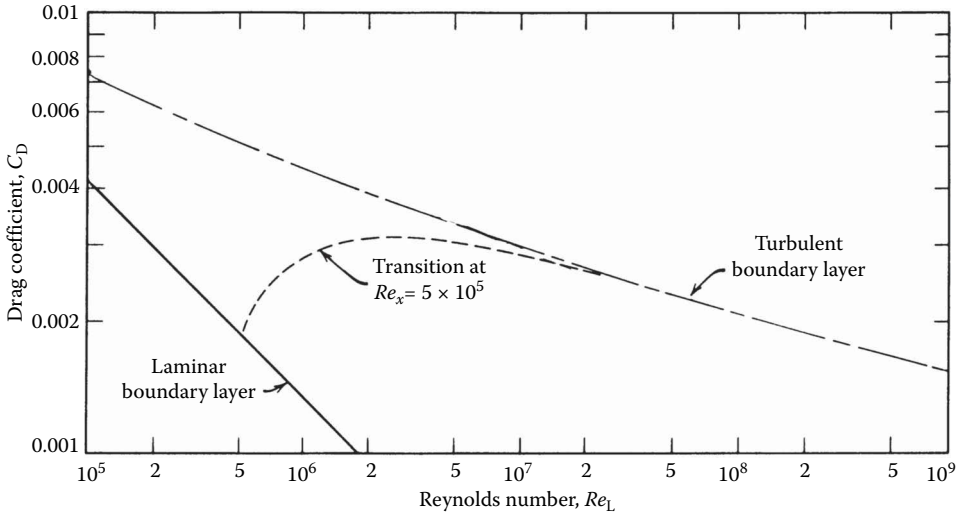

FIGURE 2.6.4 Drag coefficient vs. Reynolds number for a smooth flat plate parallel to the flow.

Pressure Drag

A thin flat surface normal to the flow has no area parallel to the flow direction. Therefore, there can be no friction force parallel to the flow; all drag is caused by pressure forces. Drag coefficients for objects with sharp edges tend to be independent of Reynolds number (for $Re > 1000$), because the separation points are fixed by the geometry of the object. Drag coefficients for selected objects are shown in Table 2.6.4.

Certain aspects of geometry have a significant effect on drag. For instance, rounding the edges that face the flow reduces drag markedly. This effect may be seen when comparing the drag coefficients for the hemisphere and C-section shapes facing into and away from the flow. It should also be noted that the drag coefficient for a two-dimensional object (long square cylinder) is about twice that for the corresponding three-dimensional object (square cylinder with $b/h = 1$).

TABLE 2.6.4
Drag Coefficient Data for Selected Objects ($Re > 1000$)[a]

Object	Diagram		$C_D(Re* \geq 10^3)$
Square prism		$b/h = \infty$	2.05
		$b/h = 1$	1.05
Disk			1.17
Ring			1.20[b]
Hemisphere (open end facing flow)			1.42
Hemisphere (open end facing downstream)			0.38
C-section (open side facing flow)			2.30

Friction and Pressure Drag: Bluff Bodies

Both friction and pressure forces contribute to the drag of *bluff bodies* (see Shapiro, 1960, for a good discussion of the mechanisms of drag). As an example, consider the drag coefficient for a smooth sphere shown in Figure 2.6.5. Transition from laminar to turbulent flow in the boundary layers on the forward portion of the sphere causes a dramatic dip in drag coefficient at the *critical Reynolds number* ($Re_D \approx 2 \times 10^5$). The turbulent boundary layer is better able to resist the adverse pressure gradient on the rear of the sphere, so separation is delayed and the wake is smaller, causing less pressure drag.

Surface roughness (or freestream disturbances) can reduce the critical Reynolds number. Many examples of this phenomenon may be seen. For example, dimples on a golf ball cause the boundary layer to become turbulent and, therefore, lower the drag coefficient in the range of speeds encountered in a drive. The stitches on a baseball or softball can have the same effect during a

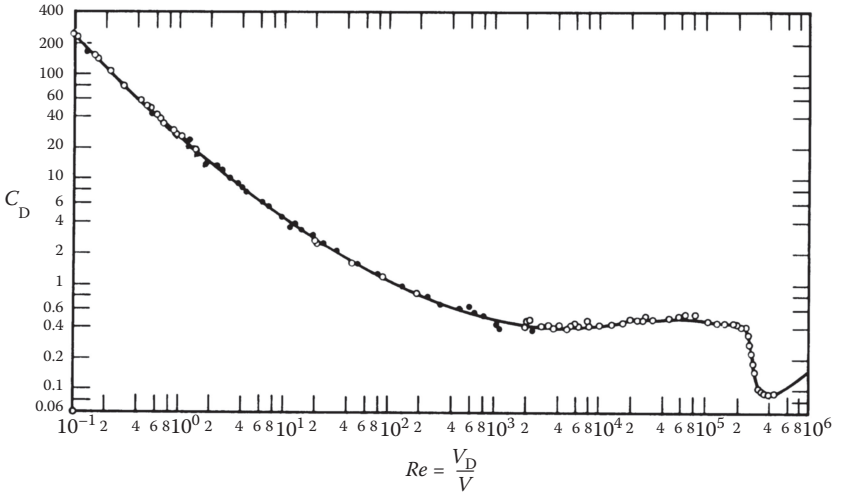

FIGURE 2.6.5 Drag coefficient vs. Reynolds number for a smooth sphere. (From Schlichting, H., *Boundary Layer Theory*, 7th ed., McGraw-Hill, New York, 1979. With permission.)

pitch. Roughness on race swimsuits and bicycle outfits also lower drag by causing transition to turbulent flow.

Streamlining

The most significant example of streamlining is adding a faired tail section to reduce the region of separated flow on the downstream portion of an object (at high Reynolds number, where pressure forces dominate drag). The pressure increase is taken over a longer distance, decreasing the magnitude of the adverse pressure gradient and delaying separation. However, adding a faired tail increases surface area, causing skin friction drag to increase. Thus, streamlining must be optimized for each shape.

Front contours are of principal importance in road vehicle design; the angle of the back glass also is important, but in most cases the entire rear end cannot be made long enough to control separation and reduce drag significantly.

Lift

Lift *coefficient* is defined as

$$C_L = \frac{F_L}{\frac{1}{2}\rho V^2 A}. \tag{2.6.10}$$

Note that lift coefficient is based on projected *planform area*.

Airfoils

Airfoils are shaped to produce lift primarily by accelerating flow over the upper surface to produce a low-pressure region. Because the flow must again decelerate, inevitably there must be a region of adverse pressure gradient near the rear of the upper surface (pressure distributions are shown clearly in Hazen, 1965).

Lift and drag coefficients for airfoil sections depend on Reynolds number and *angle of attack* between the chord line and the free stream flow direction. The *chord line* is the straight line joining the leading and trailing edges of the airfoil (Abbott and von Doenhoff, 1959).

As the angle of attack is increased, the minimum pressure point moves forward on the upper surface and the minimum pressure becomes lower. This change in the pressure profile increases the adverse pressure gradient. At some angle of attack, the adverse pressure gradient is strong enough to cause the boundary layer to separate completely from the upper surface, causing the airfoil to *stall*. The separated flow alters the pressure distribution, sharply reducing lift.

Increasing the angle of attack also causes the drag coefficient to increase. At some angle of attack below stall, the ratio of lift to drag, the *lift–drag* ratio, reaches a maximum, optimum, value.

Drag due to Lift

For wings (airfoils of finite span), lift and drag also are functions of aspect ratio. Lift is smaller and drag is larger for an airfoil of finite span compared with one of infinite span, because end effects cause the lift vector to rotate rearward. For a given geometric angle of attack, this rotation of the lift vector reduces the effective angle of attack, reducing lift. The additional component of lift acting in the flow direction increases drag; the increase in drag due to lift is called *induced drag.*

The effective aspect ratio includes the effect of planform shape. When written in terms of effective aspect ratio, the drag of a finite-span wing is

$$C_D = C_{D,\infty} + \frac{C_L^2}{\pi\,\mathrm{ar}} \tag{2.6.11}$$

where ar is the effective aspect ratio and the subscript ∞ refers to the infinite span section drag coefficient. The aspect ratio is defined as

$$\mathrm{ar} = \frac{b^2}{A}, \tag{2.6.12}$$

where b is the span of the wing and A is the planform area. In the case of a rectangular wing, the aspect ratio reduces to b/c, where c is the chord length. For further details, consult the references.

The lift coefficient must increase to support aircraft weight as speed is reduced. Therefore, induced drag can increase rapidly at low flight speeds. For this reason, minimum allowable flight speeds for commercial aircraft are closely controlled by the FAA.

Boundary Layer Control

The major part of the drag on an airfoil or wing is caused by skin friction. Therefore, it is important to maintain laminar flow in the boundary layers as far aft as possible; laminar flow sections are designed to do this. It also is important to prevent flow separation and to achieve high lift to reduce takeoff and landing speeds. These topics fall under the general heading of boundary layer control.

Profile Shaping

Boundary layer transition on a conventional airfoil section usually occurs almost immediately after the minimum pressure at about 25% chord aft of the leading edge. Transition can be delayed by shaping the profile to maintain a favorable pressure gradient over more of its length. The U.S. National Advisory Committee for Aeronautics (NACA) developed several series of profiles that delayed transition to 60% or 65% of chord, reducing drag coefficients (in the design range) 60% compared with conventional sections of the same thickness ratio (Abbott and von Doenhoff, 1959).

Flaps and Slats

Flaps are movable sections near the trailing edge of a wing. They extend and/or deflect to increase wing area and/or increase wing camber (curvature), to provide higher lift than the clean wing. Many aircraft also are fitted with leading edge slats which open to expose a slot from the pressure side

of the wing to the upper surface. The open slat increases the effective radius of the leading edge, improving maximum lift coefficient. The slot allows energized air from the pressure surface to flow into the low-pressure region atop the wing, energizing the boundary layers and delaying separation and stall.

Suction and Blowing

Suction removes low-energy fluid from the boundary layer, reducing the tendency for early separation. Blowing via high-speed jets directed along the surface reenergizes low-speed boundary layer fluid. The objective of both approaches is to delay separation, thus increasing the maximum lift coefficient the wing can achieve. Powered systems add weight and complexity; they also require bleed air from the engine compressor, reducing thrust or power output.

Moving Surfaces

Many schemes have been proposed to utilize moving surfaces for boundary layer control. Motion in the direction of flow reduces skin friction, and thus the tendency to separate; motion against the flow has the opposite effect. The aerodynamic behavior of sports balls—baseballs, golf balls, and tennis balls—depends significantly on aerodynamic side force (lift, down force, or side force) produced by spin. These effects are discussed at length in Pritchard and Mitchell (2015) and its references.

Computation vs. Experiment

Experiments cannot yet be replaced completely by analysis. Progress in modeling, numerical techniques, and computer power continues to be made, but the role of the experimentalist likely will remain important for the foreseeable future.

Computational Fluid Dynamics (CFD)

Computation of fluid flow requires accurate mathematical modeling of flow physics and accurate numerical procedures to solve the equations. The basic equations for laminar boundary layer flow are well known. For turbulent boundary layers, generally it is not possible to resolve the solution space into sufficiently small cells to allow direct numerical simulation. Instead, empirical models for the turbulent stresses must be used. Advances in computer memory storage capacity and speed (e.g., through use of massively parallel processing) continue to increase the resolution that can be achieved.

A second source of error in CFD work results from the numerical procedures required to solve the equations. Even if the equations are exact, approximations must be made to discretize and solve them using finite-difference or finite-volume methods. Whichever is chosen, the solver must guard against introducing numerical instability, round-off errors, and numerical diffusion (Zikanov, 2010). Because of the time and difficulty involved in developing CFD code, engineers resort to commercially available packages such as *ANSYS Fluent* or *STAR-CD.*

Role of the Wind Tunnel

Traditionally, wind tunnel experiments have been conducted to verify the design and performance of components and complete aircraft. Design verification of a modern aircraft may require expensive scale models, several thousand hours of wind tunnel time at many thousands of dollars an hour, and additional full-scale flight testing.

New wind tunnel facilities continue to be built and old ones refurbished. This trend of maintaining and improving experimental facilities indicates a need for continued experimental work in developing and optimizing aircraft configurations.

Many experiments are designed to produce baseline data to validate computer codes. Such systematic experimental data can help to identify the strengths and weaknesses of computational methods.

CFD tends to become only indicative of trends when massive zones of flow separation are present. Takeoff and landing configurations of conventional aircraft, with landing gear, high-lift devices, and flaps extended, tend to need final experimental confirmation and optimization. Many studies of vertical takeoff and vectored thrust aircraft require testing in wind tunnels.

ASME (American Society of Mechanical Engineers, New York, NY) publishes the *Journal of Fluids Engineering* quarterly. *JFE* contains fluid machinery and other engineering applications of fluid mechanics.

The monthly *AIAA Journal* and bimonthly *Journal of Aircraft* (American Institute for Aeronautics and Astronautics, New York) treat aerospace applications of fluid mechanics.

2.7 COMPRESSIBLE FLOW

John C. Leylegian

Introduction

This section deals with compressible flow. One- or two-dimensional steady, inviscid flows for which specific heats may be considered constant, i.e., calorically perfect gas behavior, are considered. Readers are referred to other sources of information for unsteady effects, viscous effects, and three-dimensional flows.

The term *compressible flow* is routinely used to define variable density flow. In many cases, these density variations are caused by the pressure changes from one point to another. *Compressibility* can be defined as the fractional change in volume of a fluid per unit change in pressure. It is a property of the fluid and is defined as follows:

$$\tau = \frac{1}{\rho}\frac{d\rho}{dp}$$

where τ is the compressibility of the fluid, ρ is the density, and p is the pressure being exerted on the fluid. A more precise definition of compressibility is obtained if we take into account the thermal and frictional losses. If during the compression, the temperature of the gas is held constant, it is called the isothermal compressibility and can be written as follows:

$$\tau_T = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial p}\right)_T$$

However, if the compression process is reversible and adiabatic, it is called the isentropic compressibility and can be written as follows:

$$\tau_s = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial p}\right)_s$$

Gases in general have high compressibility (τ_T for air is 10^{-5} m^2/N at 1 atm) as compared with liquids (τ_T for water is 5×10^{-10} m^2/N at 1 atm).

However, it can be seen that a large compressibility is not the only requirement for compressible flow; in fact, in many instances, air may be treated as incompressible. Based on the definition of compressibility, a large change in pressure arising with large changes in velocity would cause large changes in density. The change in velocity to cause a significant change in density may be found by comparing the flow velocity to the *speed of sound, a*, which is the speed of propagation of small pressure disturbances. The speed of sound for a gas is defined as follows:

$$a^2 = \left(\frac{\partial p}{\partial \rho}\right)_s \text{ or } a = \sqrt{\left(\frac{\partial p}{\partial \rho}\right)_s}$$

In an isentropic process for a perfect gas, the pressure and density are related through

$$\frac{p}{\rho^\gamma} = \text{constant}$$

Using this relation along with the ideal gas equation of state $p=\rho RT$, we can show that for a perfect gas

$$a=\sqrt{\gamma RT}=\sqrt{\frac{\gamma p}{\rho}}$$

where γ is the ratio of specific heats c_p/c_v, R is the gas constant, and T is the temperature. For air under normal conditions, γ is 1.4 and R is 287 $m^2/s^2{\cdot}K$, so that the speed of sound for air becomes $a=20.045\sqrt{T}$ m/s, where T is in Kelvin. The gas used has an effect on the speed of sound; e.g., helium has higher values of both γ and R so that the speed of sound for helium becomes $a=58.834\sqrt{T}$ m/s. This dependence of sound speed on the type of gas is employed in the design and use of shock tubes and shock tunnels.

Another important parameter in compressible flows is the *Mach number, M*, which is defined as the ratio of the gas velocity to the speed of sound or

$$M=\frac{V}{a}$$

where V is the velocity of gas. Depending upon the Mach number of the flow, we can define the following flow regimes:

$$M \ll 1 \text{ Incompressible flow}$$

$$M < 1 \text{ Subsonic flow}$$

$$M \approx 1 \text{ Transonic flow}$$

$$M > 1 \text{ Supersonic flow}$$

$$M \gg 1 \text{ Hypersonic flow}$$

Subsonic through hypersonic flows are compressible in nature. In these flows, the velocity is appreciable compared with the speed of sound, and the fractional changes in pressure, temperature, and density are all of significant magnitude. We will restrict ourselves in this section to subsonic through supersonic flows only.

Before we move on to study these flows, let us define one more term. Let us consider a gas with static pressure p and temperature T, traveling at some velocity V and corresponding Mach number M. If this gas is brought isentropically to rest, the resulting pressure and temperature of the gas are referred to as *stagnation pressure* p_0 and *stagnation temperature* T_0 (they are also called the total pressure and total temperature). The speed of sound at this stagnation state is called the *stagnation speed of sound* and is denoted as a_0.

One-Dimensional Flow

In one-dimensional flow, the flow properties vary only in one coordinate direction. In a steady, truly one-dimensional flow between two states 1 and 2, conservation of mass, momentum, and energy leads to the following equations:

$$\begin{aligned}
&\rho_1 u_1 = \rho_2 u_2 \\
&p_1 + \rho_1 u_1^2 = p_2 + \rho_2 u_2^2 \\
&h_1 + \frac{u_1^2}{2} + q = h_2 + \frac{u_2^2}{2}
\end{aligned} \tag{2.7.1}$$

where q is the heat added per unit mass of the gas. These equations neglect body forces, viscous stresses, and heat transfer due to thermal conduction and diffusion. The energy equation for a calorically perfect gas, for which $h=c_pT$, in the absence of external heat transfer, becomes

$$c_pT_1+\frac{u_1^2}{2}=c_pT_2+\frac{u_2^2}{2} \tag{2.7.2}$$

Using $c_p=\gamma R/(\gamma-1)$ and $a^2=\gamma RT$, the above equation can be written as follows:

$$\frac{a_1^2}{\gamma-1}+\frac{u_1^2}{2}=\frac{a_2^2}{\gamma-1}+\frac{u_2^2}{2} \tag{2.7.3}$$

Since Equation 2.7.3 is written for no heat addition, it holds for an adiabatic flow. If the energy equation is applied to the stagnation state, it can be written as follows:

$$\begin{aligned} c_pT+\frac{u^2}{2}&=c_pT_0\\ \frac{T_0}{T}&=1+\frac{\gamma-1}{2}M^2 \end{aligned} \tag{2.7.4}$$

It is worth mentioning that in arriving at Equation 2.7.4, only adiabatic flow is assumed, whereas the stagnation state is defined as that where the gas is brought to rest isentropically. Therefore, the definition of stagnation temperature is less restrictive than the general definition of the stagnation state. According to the general definition of isentropic flow, it is both adiabatic and reversible. For an isentropic flow

$$\frac{p_0}{p}=\left(\frac{\rho_0}{\rho}\right)^{\gamma}=\left(\frac{T_0}{T}\right)^{\gamma/(\gamma-1)} \tag{2.7.5}$$

From Equations 2.7.4 and 2.7.5, we can write

$$\frac{p_0}{p}=\left(1+\frac{\gamma-1}{2}M^2\right)^{\gamma/(\gamma-1)} \tag{2.7.6}$$

$$\frac{\rho_0}{\rho}=\left(1+\frac{\gamma-1}{2}M^2\right)^{1/(\gamma-1)} \tag{2.7.7}$$

Values of stagnation conditions are tabulated in Anderson (2003) as a function of M for $\gamma=1.4$.

Normal Shock Wave

A shock wave is a very thin region (of the order of a few molecular mean free paths) across which the static pressure, temperature, and density increase whereas the velocity decreases. If the shock wave is perpendicular to the flow, it is called a *normal shock wave*. The flow is supersonic ahead of the normal shock wave and subsonic behind it. Figure 2.7.1 shows the flow conditions across a normal shock wave which is treated as a discontinuity. Since there is no heat added or removed, the

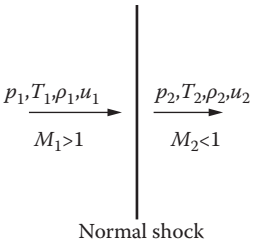

FIGURE 2.7.1 Flow conditions across a normal shock.

flow across the shock wave is adiabatic. By using Equation2.7.2, the normal shock equations can be written as follows:

$$\begin{aligned} \rho_1 u_1 &= \rho_2 u_2 \\ p_1 + \rho_1 u_1^2 &= p_2 + \rho_2 u_2^2 \\ h_1 + \frac{u_1^2}{2} &= h_2 + \frac{u_2^2}{2} \end{aligned} \tag{2.7.8}$$

Equation 2.7.8 is applicable to a general fluid; however, for a calorically perfect gas, we can use the relations $p = \rho RT$ and $h = c_p T$ to derive a number of equations relating flow conditions downstream of the normal shock to those upstream. These equations (also known as Rankine–Hugoniot relations) are

$$\begin{aligned} \frac{p_2}{p_1} &= 1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 - 1\right) \\ \frac{\rho_2}{\rho_1} &= \frac{u_1}{u_2} = \frac{(\gamma+1)M_1^2}{2 + (\gamma-1)M_1^2} \\ \frac{T_2}{T_1} &= \frac{h_2}{h_1} = \left[1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 - 1\right)\right]\left[\frac{2 + (\gamma-1)M_1^2}{(\gamma+1)M_1^2}\right] \\ M_2^2 &= \frac{1 + \frac{\gamma-1}{2}M_1^2}{\gamma M_1^2 - \frac{\gamma-1}{2}} \end{aligned} \tag{2.7.9}$$

Again, the values of p_2/p_1, ρ_2/ρ_1, T_2/T_1, etc. are tabulated in Anderson (2003) as a function of M_1 for $\gamma = 1.4$. Let us examine some limiting cases. As $M_1 \to 1$, Equation 2.7.9 yields $M_2 \to 1$, $p_2/p_1 \to 1$, $\rho_2/\rho_1 \to 1$, and $T_2/T_1 \to 1$. This is the case of an extremely weak normal shock across which no finite changes occur, i.e., a sound wave. On the other hand, as $M_1 \to \infty$, Equation 2.7.9 yields

$$M_2 \to \sqrt{\frac{\gamma-1}{2\gamma}} = 0.378; \quad \frac{\rho_2}{\rho_1} \to \frac{\gamma+1}{\gamma-1} = 6; \quad \frac{p_2}{p_1} \to \infty; \quad \frac{T_2}{T_1} \to \infty$$

However, the calorically perfect gas assumption no longer remains valid as $M_1 \to \infty$, since large changes in temperature result in significant changes to specific heat, as well as dissociation and ionization of gases. These phenomena are beyond the scope of this section.

Let us now examine why the flow ahead of a normal shock wave must be supersonic even though Equation 2.7.8 holds for $M_1 < 1$ as well as $M_1 > 1$. From the second law of thermodynamics, the entropy change across the normal shock can be written as follows:

$$s_2 - s_1 = c_p \ln \frac{T_2}{T_1} - R \ln \frac{p_2}{p_1}$$

By using Equation 2.7.9, it becomes

$$s_2 - s_1 = c_p \ln \left\{ \left[1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 - 1\right) \right] \left[\frac{2 + (\gamma-1)M_1^2}{(\gamma+1)M_1^2} \right] \right\} - R \ln \left[1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 - 1\right) \right] \tag{2.7.10}$$

Equation 2.7.10 shows that the entropy change across the normal shock is a function of M_1 only. Using Equation 2.7.10, it can be shown that

$$\begin{aligned} s_2 - s_1 &= 0 \quad \text{for } M_1 = 1 \\ &< 0 \quad \text{for } M_1 < 1 \\ &> 0 \quad \text{for } M_1 > 1 \end{aligned}$$

Since it is necessary that $s_2 - s_1 \geq 0$ from the second law, $M_1 \geq 1$. This, in turn, requires that $p_2/p_1 \geq 1$, $\rho_2/\rho_1 \geq 1$, $T_2/T_1 \geq 1$, and $M_2 \leq 1$.

We now examine how the stagnation conditions change across a normal shock wave. For a calorically perfect gas, the energy equation in Equation 2.7.9 gives

$$c_p T_{01} = c_p T_{02} \text{ or } T_{01} = T_{02}$$

In other words, the total temperature remains constant across a stationary normal shock wave.

Let us now apply the entropy change relation across the shock using the stagnation conditions.

$$s_2 - s_1 = c_p \ln \frac{T_{02}}{T_{01}} - R \ln \frac{p_{02}}{p_{01}}$$

Note that entropy at stagnation conditions is the same as at the static conditions since to arrive at stagnation conditions, the gas is brought to rest isentropically. Since $T_{02} = T_{01}$

$$\begin{aligned} s_2 - s_1 &= -R \ln \frac{p_{02}}{p_{01}} \\ \frac{p_{02}}{p_{01}} &= e^{-(s_2 - s_1)/R} \end{aligned} \tag{2.7.11}$$

Since $s_2 > s_1$ across the normal shockwave, Equation 2.7.11 gives $p_{02} < p_{01}$ or, in other words, the total pressure decreases across a shock wave.

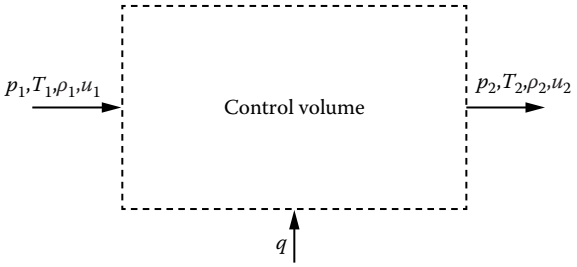

FIGURE 2.7.2 One-dimensional control volume with heat addition.

One-Dimensional Flow with Heat Addition

Consider one-dimensional flow through a control volume with inlet location 1 and exit at 2, as shown in Figure 2.7.2. A specified amount of heat per unit mass, q, is added to the control volume. The governing equations relating conditions 1 and 2 can be written as follows:

$$\begin{aligned} \rho_1 u_1 &= \rho_2 u_2 \\ p_1 + \rho_1 u_1^2 &= p_2 + \rho_2 u_2^2 \\ h_1 + \frac{u_1^2}{2} + q &= h_2 + \frac{u_2^2}{2} \end{aligned} \tag{2.7.12}$$

The following relations can be derived from Equation 2.7.12 for a calorically perfect gas:

$$q = c_p \left(T_{02} - T_{01} \right) \tag{2.7.13}$$

$$\frac{p_2}{p_1} = \frac{1 + \gamma M_1^2}{1 + \gamma M_2^2} \tag{2.7.14}$$

$$\frac{p_{02}}{p_{01}} = \frac{1 + \gamma M_1^2}{1 + \gamma M_2^2} \left(\frac{1 + \dfrac{\gamma - 1}{2} M_2^2}{1 + \dfrac{\gamma - 1}{2} M_1^2} \right)^{\gamma/(\gamma - 1)} \tag{2.7.15}$$

$$\frac{T_2}{T_1} = \left(\frac{1 + \gamma M_1^2}{1 + \gamma M_2^2} \right)^2 \left(\frac{M_2}{M_1} \right)^2 \tag{2.7.16}$$

$$\frac{T_{02}}{T_{01}} = \left(\frac{1 + \gamma M_1^2}{1 + \gamma M_2^2} \right)^2 \left(\frac{M_2}{M_1} \right)^2 \left(\frac{1 + \dfrac{\gamma - 1}{2} M_2^2}{1 + \dfrac{\gamma - 1}{2} M_1^2} \right) \tag{2.7.17}$$

$$\frac{\rho_2}{\rho_1} = \left(\frac{1 + \gamma M_2^2}{1 + \gamma M_1^2} \right)^2 \left(\frac{M_1}{M_2} \right)^2 \tag{2.7.18}$$

Equation 2.7.13 indicates that the effect of heat addition is to directly change the stagnation temperature T_0 of the flow. Table 2.7.1 shows some physical trends due to heat addition for subsonic and supersonic flows. With heat extraction, the trends in Table 2.7.1 are reversed.

Figure 2.7.3 shows a plot between enthalpy and entropy (known as the Mollier diagram) based on the earlier equations, for one-dimensional flow with heat addition. This curve is called the Rayleigh curve and is drawn for a set of given initial conditions. Each point on this curve corresponds to a different amount of heat added or removed. It is seen from this curve that heat addition always drives the Mach numbers toward 1. For a certain amount of heat addition, the flow will become sonic. For this condition, the flow is said to be *choked*. Any further increase in heat addition is not possible without adjustment in initial conditions. For example, if more heat is added in region 1, which is initially supersonic, than allowed for attaining Mach 1 in region 2, then a normal shock will form inside the control volume which will suddenly change the conditions in region 1 to subsonic. Similarly, in the case of an initially subsonic flow corresponding to region 1′, any heat addition beyond that is needed to attain Mach 1 in region 2, the conditions in region 1′ will adjust to a lower subsonic Mach number through a series of pressure waves.

Equations 2.7.13 through 2.7.18 may be used to determine the exit conditions for a flow with heat transfer. However, these equations are not easy to work with. Therefore, we establish a reference state for flow with heat transfer at Mach 1. We denote this sonic reference state using an asterisk (*):

TABLE 2.7.1
Effect of Heat Addition on Subsonic and Supersonic Flow

	$M_1<1$	$M_1>1$
M_2	Increases	Decreases
p_2	Decreases	Increases
T_2	Increases for $M_1 < \gamma^{-1/2}$ and decreases for $M_1 > \gamma^{-1/2}$	Increases
u_2	Increases	Decreases
T_{02}	Increases	Increases
p_{02}	Decreases	Decreases

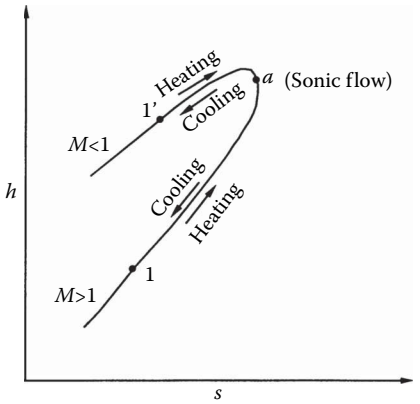

FIGURE 2.7.3 The Rayleigh curve.

$$\frac{p}{p^*} = \frac{1+\gamma}{1+\gamma M^2} \tag{2.7.19}$$

$$\frac{p_0}{p_0^*} = \frac{1+\gamma}{1+\gamma M^2}\left(\frac{2+(\gamma-1)M^2}{\gamma+1}\right)^{\gamma/(\gamma-1)} \tag{2.7.20}$$

$$\frac{T}{T^*} = M^2\left(\frac{1+\gamma}{1+\gamma M^2}\right)^2 \tag{2.7.21}$$

$$\frac{T_0}{T_0^*} = \frac{(\gamma+1)M^2}{\left(1+\gamma M^2\right)^2}\left[2+(\gamma-1)M^2\right] \tag{2.7.22}$$

$$\frac{\rho}{\rho^*} = \frac{1}{M^2}\left(\frac{1+\gamma M^2}{1+\gamma}\right) \tag{2.7.23}$$

Equations 2.7.13 and 2.7.19 through 2.7.23 are used to solve problems involving flow with heat transfer. The functions shown earlier are tabulated as a function of M for $\gamma = 1.4$ in Anderson (2003).

Similar to the preceding heat addition or extraction relationships, we can also develop relationships for one-dimensional steady, adiabatic flow but with frictional effects due to viscosity. In this case, the momentum equation is modified due to frictional shear stress. For details, readers are referred to Anderson (2003).

One-Dimensional Flow with Area Change

In one-dimensional flow with area change, in addition to flow conditions, the area of duct also changes with x. The governing equations for this flow can be written in a differential form as follows using an infinitesimal control volume shown in Figure 2.7.4:

$$\mathrm{d}(\rho u A) = 0 \tag{2.7.24}$$

$$\mathrm{d}p + \rho u\,\mathrm{d}u = 0 \tag{2.7.25}$$

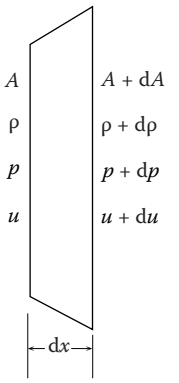

FIGURE 2.7.4 Control volume for one-dimensional flow with area change.

$$dh + u\,du = 0 \tag{2.7.26}$$

Equation 2.7.24 can be written as follows:

$$\frac{d\rho}{\rho} + \frac{du}{u} + \frac{dA}{A} = 0 \tag{2.7.27}$$

which can be further written as follows for an isentropic flow:

$$\frac{1}{M^2 - 1}\frac{du}{u} = \frac{dA}{A} \tag{2.7.28}$$

Some very useful physical insights can be obtained from this area–velocity relation.

- For subsonic flow ($0 \leq M < 1$), an increase in area results in decrease in velocity, and vice versa.
- For supersonic flow ($M > 1$), an increase in area results in increase in velocity, and vice versa.
- For sonic flow ($M = 1$), $dA/A = 0$, which corresponds to a minimum or maximum in the area distribution, but based on the area–velocity relationship for subsonic and supersonic flow, it can be seen that a minimum in area is the only physical solution.

Figure 2.7.5 shows the preceding results in a schematic form.

Based on this discussion, for a gas to accelerate isentropically from subsonic to supersonic conditions, or to decelerate from supersonic to subsonic conditions, it must flow through a convergent–divergent duct, also known as the de Laval nozzle. The minimum area of the nozzle at which the flow becomes sonic is called the throat. This physical observation forms the basis of designing supersonic wind tunnels shown schematically in Figure 2.7.6. In general, in a supersonic wind tunnel, a stagnant gas is first expanded to the desired supersonic Mach number. The supersonic flow enters the test section where it passes over a model being tested. The flow then is slowed down by compressing it through a second convergent–divergent duct, also known as a diffuser, before it is exhausted to the atmosphere.

Now, using the equations for one-dimensional flow with area change and the isentropic flow conditions, we can derive a relation for the area ratio that is needed to accelerate or decelerate the gas to sonic conditions. Denoting the sonic conditions by an asterisk, we can write $u^* = a^*$, but do not confuse this sonic reference state with the sonic reference state mentioned earlier for flow with heat transfer. The area is denoted as A^*, and would be the minimum area for the throat of the nozzle. From Equation 2.7.24, we have

$$\rho u A = \rho^* u^* A^*$$

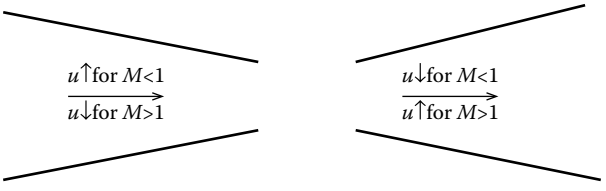

FIGURE 2.7.5 Compressible flow in converging and diverging ducts.

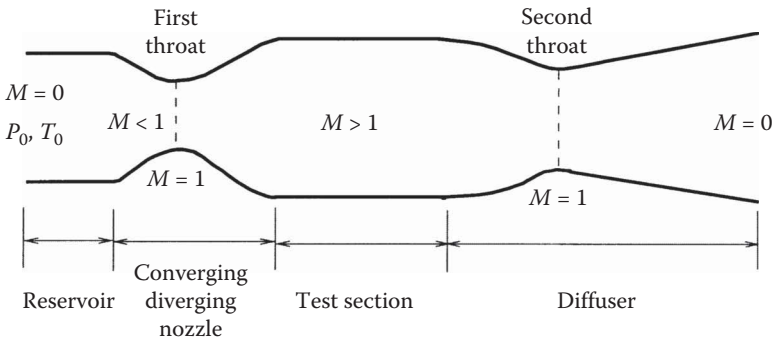

FIGURE 2.7.6 Schematic of a typical supersonic wind tunnel.

$$\frac{A}{A^*} = \frac{\rho^* u^*}{\rho u} = \frac{\rho^*}{\rho_0}\frac{\rho_0}{\rho}\frac{u^*}{u} \tag{2.7.29}$$

Under isentropic conditions

$$\frac{\rho_0}{\rho} = \left(1 + \frac{\gamma - 1}{2} M^2\right)^{1/(\gamma-1)} \tag{2.7.30}$$

$$\frac{\rho_0}{\rho^*} = \left(1 + \frac{\gamma - 1}{2}\right)^{1/(\gamma-1)} = \left(\frac{\gamma + 1}{2}\right)^{1/(\gamma-1)} \tag{2.7.31}$$

Also, $u^*/u = a^*/u$. Let us define a Mach number $M^* = u/a^*$. M^* is known as the *characteristic Mach number* and it is related to the local Mach number by the following relation:

$$M^{*2} = \frac{\frac{\gamma+1}{2} M^2}{1 + \frac{\gamma-1}{2} M^2} \tag{2.7.32}$$

Using Equations 2.7.30 through 2.7.32 in Equation 2.7.29, we can write

$$\left(\frac{A}{A^*}\right)^2 = \frac{1}{M^2}\left[\left(\frac{2}{\gamma+1}\right)\left(1 + \frac{\gamma-1}{2} M^2\right)\right]^{(\gamma+1)/(\gamma-1)} \tag{2.7.33}$$

Equation 2.7.26 is called the area Mach number relation. Figure 2.7.7 shows a plot of A/A^* against Mach number. A/A^* is always ≥1 for physically viable solutions.

The area Mach number relation indicates that for a given Mach number, there is only one area ratio A/A^*. This is a very useful relation and is frequently used to design convergent–divergent nozzles to produce a desired Mach number. Values of A/A^* are tabulated as a function of M in Anderson (2003).

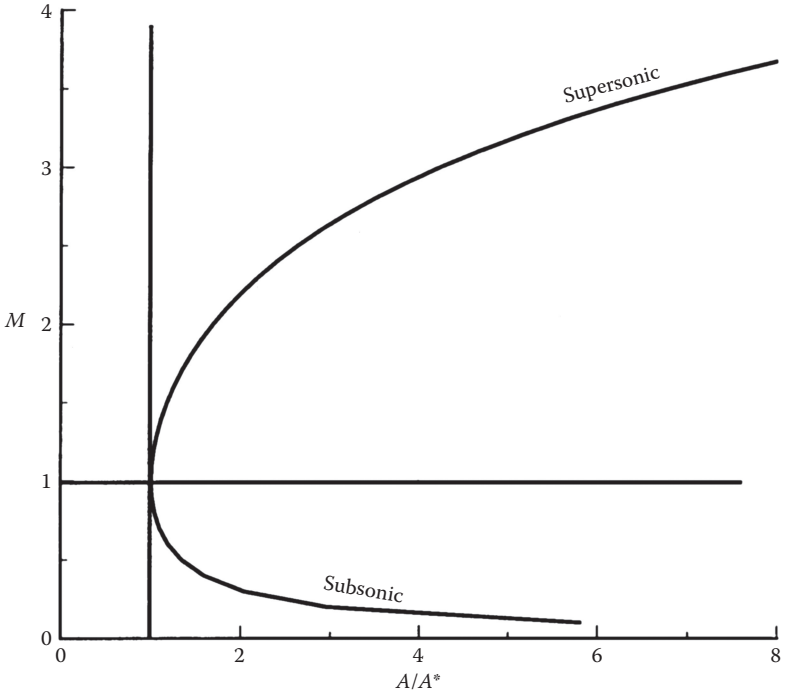

FIGURE 2.7.7 Variation of area ratio A/A^* as a function of Mach number for a one-dimensional flow with area change.

Equation 2.7.33 can also be written in terms of pressure as follows:

$$\frac{A}{A^*} - \frac{\left[1-\left(\frac{p}{p_0}\right)^{(\gamma-1)/\gamma}\right]^{1/2}\left(\frac{p}{p_0}\right)^{1/\gamma}}{\left(\frac{\gamma-1}{2}\right)^{1/2}\left(\frac{2}{\gamma+1}\right)^{(\gamma+1)/2(\gamma-1)}} \tag{2.7.34}$$

Nozzle Flow

Using the area relations, we can now plot the distributions of Mach number and pressure along a nozzle. Figure 2.7.8 shows pressure and Mach number distributions along a given nozzle and the wave configurations for several exit pressures. For curves *a* and *b*, the flow stays subsonic throughout and the exit pressure controls the flow in the entire nozzle. On curve *c*, the throat has just become sonic, and so the pressure at the throat, and upstream of it, can decrease no further. There is another exit pressure corresponding to curve *j* ($p_j < p_c$) for which a supersonic isentropic solution exists. But if the pressure lies between p_c and p_j, there is no isentropic solution possible. For example, for an exit pressure p_d, a shock will form in the nozzle at location *s* which will raise the pressure to p_d and turn the flow subsonic. The pressure will then rise to p_d as the subsonic flow goes through an increasing area duct. The location, *s*, depends on the exit pressure. Various possible situations are shown in Figure 2.7.8. It is clear that if the exit pressure is equal to or below p_f, the flow within the nozzle is fully supersonic. This is the principle used in designing supersonic wind tunnels by operating from a high-pressure reservoir or into a vacuum receiver, or both.

Diffuser

If a nozzle discharges directly into the receiver, the minimum pressure ratio for full supersonic flow in the test section is

$$\left(\frac{p_0}{p_E}\right)_{min} = \frac{p_0}{p_f}$$

where p_f is the value of p_E at which the normal shock stands right at the nozzle exit. However, by adding an additional diverging section, known as a diffuser, downstream of the test section as shown in Figure 2.7.9, it is possible to operate the tunnel at a lower pressure ratio than p_0/p_f. This change in operating conditions happens because the diffuser can now decelerate the subsonic flow downstream of the shock isentropically to a stagnation pressure p_0'. The pressure ratio required then is the ratio of stagnation pressures across a normal shock wave at the test section Mach number. In practice, the diffuser gives lower than expected recovery as a result of viscous losses caused by the interaction of shock wave and the boundary layer, which are neglected here.

The operation of supersonic wind tunnels can be made even more efficient; i.e., they can be operated at even lower pressure ratios than p_0/p_0', by using the approach shown in Figure 2.7.6 where the diffuser has a second throat. It can slow down the flow to subsonic Mach numbers isentropically and, ideally, can provide complete recovery, giving $p_0' = p_0$. However, due to other considerations, such as the starting process of the wind tunnel and viscous effects, it is not realized in real life. Rather, the tunnel must undergo a "starting" process. As the receiver pressure is decreased, the flow through the nozzle will accelerate, and as the pressure is dropped low enough to achieve sonic flow at the throat, a normal shock will sit in the diverging portion, as mentioned in the previous section. As the receiver pressure is decreased further, the shock will migrate through the diverging portion of the nozzle, until it sits at the nozzle exit. Further decrease in receiver pressure will make the shock jump to the diverging portion of the diffuser, and the wind tunnel test section will be at the proper conditions. The receiver pressure may be increased slightly, to move the shock closer to the diffuser

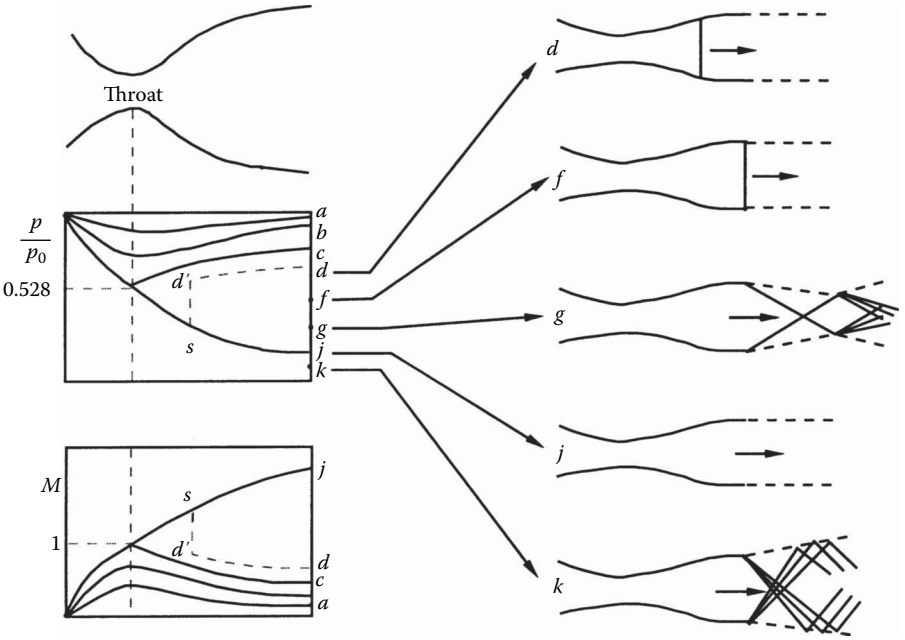

FIGURE 2.7.8 Effect of exit pressure on flow through a nozzle.

throat and decrease the stagnation pressure loss in the tunnel. At the end of the starting process, a weak normal shock wave sits just downstream of the diffuser throat. The area ratio (nozzle throat to diffuser throat) required to allow this configuration to operate is equal to the stagnation pressure ratio across a normal shock at the wind tunnel operation Mach number. If the diffuser throat is too small, the tunnel will not start properly. If the receiver pressure were to increase, the shock could jump back up to the nozzle, resulting in subsonic conditions in the test section. This phenomenon is known as unstart, and the starting process would have to be performed again.

Two-Dimensional Supersonic Flow

When supersonic flow goes over a wedge or an expansion corner, it goes through an oblique shock or expansion waves, respectively, to adjust to the change in surface geometry. Figure 2.7.10 shows the two flow situations. In Figure 2.7.10a, an oblique shock abruptly turns the flow parallel to the wedge surface. The Mach number after the shock is less than that ahead of it, and the pressure, temperature, and density all increase. In the case of an expansion corner, oblique expansion waves smoothly turn the flow to become parallel to the surface downstream of the expansion corner. In this case, the Mach number increases, and the pressure, temperature, and density decrease as the flow goes through the expansion corner. Oblique shocks and expansion waves occur in two- and

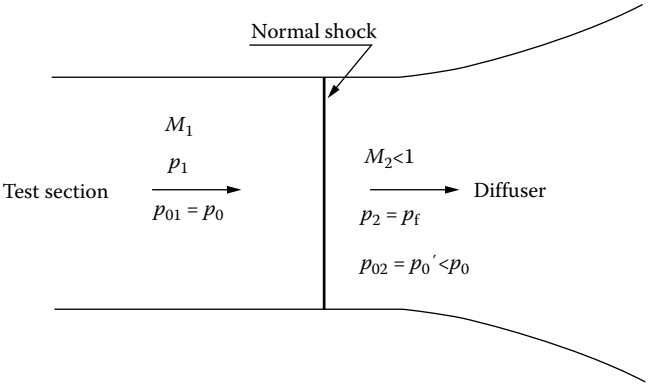

FIGURE 2.7.9 Normal shock diffuser.

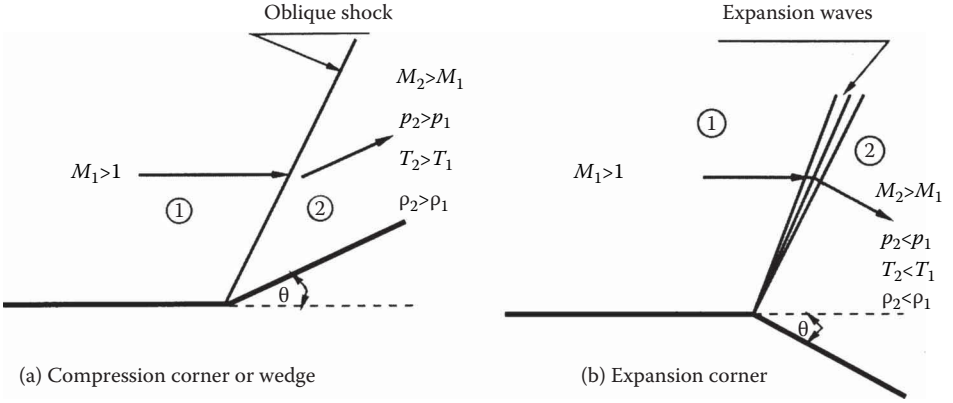

FIGURE 2.7.10 Supersonic flow over a corner.

three-dimensional supersonic flows. In this section, we will restrict ourselves to steady, two-dimensional supersonic flows.

Oblique Shock Waves

The oblique shock can be treated as the normal shock by superimposing a suitable uniform velocity v parallel to the wave. In this way, the resultant velocity before the shock can be adjusted to any desirable flow direction by adjusting the magnitude of v. As shown in Figure 2.7.11, the resultant velocity ahead of the shock is $w_1 = \sqrt{u_1^2 + v^2}$ and its direction relative to the shock is given by $\beta = \tan^{-1}(u_1/v)$. On the downstream side of the shock, since u_2 is always less than u_1, the flow always turns toward the shock. The magnitude of u_2 can be determined by the normal shock relations corresponding to velocity u_1 and the magnitude of v is such that the flow downstream of the shock turns parallel to the surface. Since imposition of a uniform velocity does not affect the pressure, temperature, etc., we can use normal shock relations with Mach number replaced in them to correspond to velocity u_1 or u_1/a_1, in other words $M_1 \sin\beta$. Thus, the oblique shock relations become

$$\frac{p_2}{p_1} = 1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 \sin^2\beta - 1\right) \tag{2.7.35}$$

$$\frac{\rho_2}{\rho_1} = \frac{(\gamma+1)M_1^2 \sin^2\beta}{(\gamma-1)M_1^2 \sin^2\beta + 2} \tag{2.7.36}$$

$$\frac{T_2}{T_1} = \frac{a_2^2}{a_1^2} = \left[1 + \frac{2\gamma}{\gamma+1}\left(M_1^2 \sin^2\beta - 1\right)\right]\left[\frac{2 + (\gamma-1)M_1^2 \sin^2\beta}{(\gamma+1)M_1^2 \sin^2\beta}\right] \tag{2.7.37}$$

The Mach number M_2 $(= w_2/a_2)$ can be obtained by using a Mach number corresponding to velocity u_2 $\left(= w_2 \sin(\beta - \theta)\right)$ in the normal shock relation for the Mach number. In other words

$$M_2^2 \sin^2(\beta - \theta) = \frac{1 + \frac{\gamma-1}{2} M_1^2 \sin^2\beta}{\gamma M_1^2 \sin^2\beta - \frac{\gamma-1}{2}} \tag{2.7.38}$$

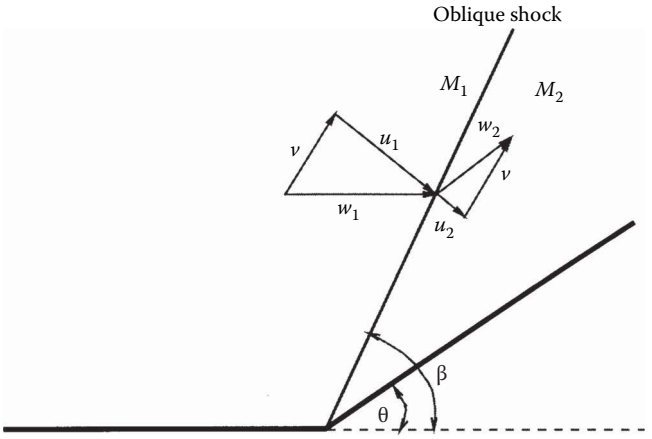

FIGURE 2.7.11 Oblique shock on a wedge.

To derive a relation between the wedge angle θ and the wave angle β, we have from Figure 2.7.11

$$\tan\beta = \frac{u_1}{v} \text{ and } \tan(\beta-\theta) = \frac{u_2}{v}$$

so that

$$\frac{\tan(\beta-\theta)}{\tan\beta} = \frac{u_2}{u_1} = \frac{\rho_1}{\rho_2} = \frac{(\gamma-1)M_1^2\sin^2\beta+2}{(\gamma+1)M_1^2\sin^2\beta}$$

This can be simplified to

$$\tan\theta = 2\cot\beta\frac{M_1^2\sin^2\beta-1}{M_1^2(\gamma+\cos 2\beta)+2} \tag{2.7.39}$$

Dennard and Spencer (1964) have tabulated oblique shock properties as a function of M_1. Let us now make some observations from the preceding relations.

From the normal shock relations, $M_1 \sin\beta \geq 1$. This condition defines a minimum wave angle for a given Mach number. The maximum wave angle, of course, corresponds to the normal shock or $\beta = \pi/2$. Therefore, the wave angle β has the following range:

$$\sin^{-1}\frac{1}{M} \leq \beta \leq \frac{\pi}{2} \tag{2.7.40}$$

Equation 2.7.39 becomes zero at the two limits of β. Figure 2.7.12 shows a plot of θ against β for various values of M_1. For each value of M_1, there is a maximum value of θ. For $\theta < \theta_{max}$, there are

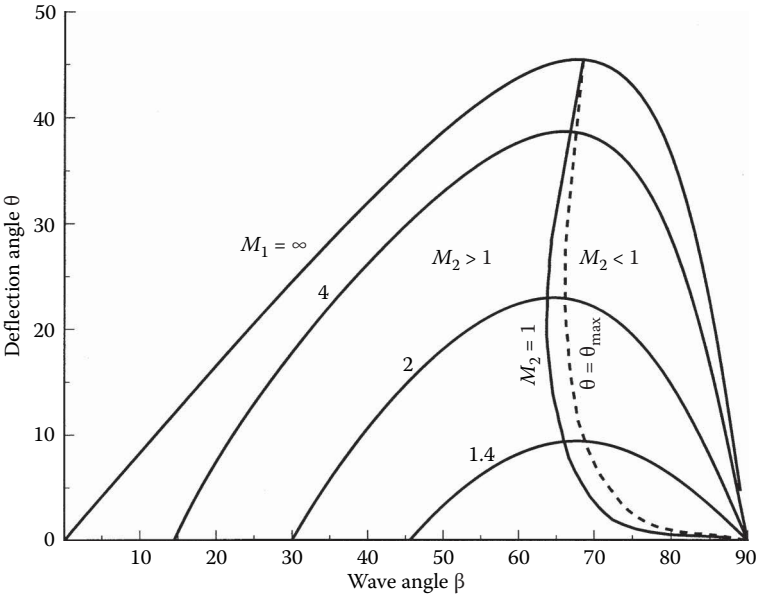

FIGURE 2.7.12 Oblique shock characteristics.

two possible solutions having different values of β. The larger value of β gives the stronger shock in which the flow becomes subsonic. A locus of solutions for which $M_2 = 1$ is also shown in the figure. It is seen from the figure that with weak shock solution, the flow remains supersonic except for a small range of θ slightly smaller than θ_{max}.

Let us now consider the limiting case of θ going to zero for the weak shock solution. As θ decreases to zero, β decreases to the limiting value μ, given by

$$M_1^2 \sin^2 \mu - 1 = 0$$
$$\mu = \sin^{-1} \frac{1}{M_1} \tag{2.7.41}$$

For this angle, the oblique shock relations show no jump in flow quantities across the wave or, in other words, there is no disturbance generated in the flow. This angle μ is called the *Mach angle* and the lines at inclination μ are called *Mach lines.*

Thin-Airfoil Theory

For a small deflection angle Δθ, it can be shown that the change in pressure in a supersonic flow at Mach M_1 between 1.2 and 5 is given approximately by

$$\frac{\Delta p}{p_1} \approx \frac{\gamma M_1^2}{\sqrt{M_1^2 - 1}} \Delta\theta \tag{2.7.42}$$

This expression holds for both compression and expansion. The Mach number range given here is based on the terms dropped in the linearization of the conservation equations. If Δp is measured with respect to the freestream pressure, p_1, and all deflections to the freestream direction, we can write Equation 2.7.35 as follows:

$$\frac{p - p_1}{p_1} = \frac{\gamma M_1^2}{\sqrt{M_1^2 - 1}} \theta \tag{2.7.43}$$

where θ is positive for a compression and negative for expansion. Let us define a pressure coefficient C_p, as follows:

$$C_p = \frac{p - p_1}{q_1}$$

where q_1 is the dynamic pressure and is equal to $\gamma p_1 M_1^2/2$. Equation 2.7.43 then gives

$$C_p = \frac{2\theta}{\sqrt{M_1^2 - 1}} \tag{2.7.44}$$

Equation 2.7.44 states that the pressure coefficient is proportional to the local flow deflection. This relation can be used to develop supersonic thin-airfoil theory. As an example, for a flat plate at angle of attack α_0 (shown in Figure 2.7.13), the pressure coefficients on the upper and lower surfaces are

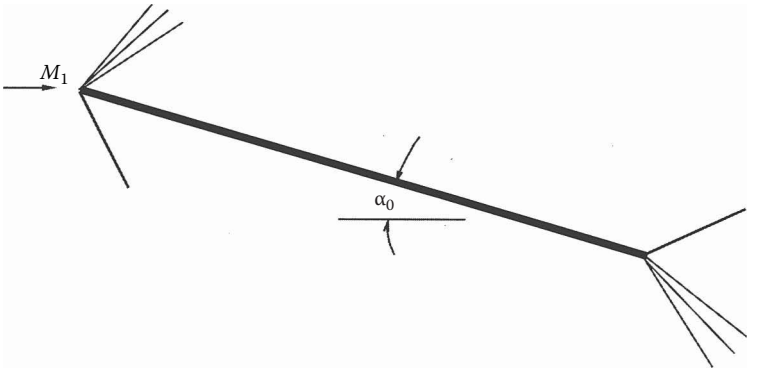

FIGURE 2.7.13 Lifting flat plate.

$$C_p = \mp \frac{2\alpha_0}{\sqrt{M_1^2 - 1}}$$

The lift and drag coefficients can be written as follows:

$$C_L = \frac{(p_L - p_U)c\cos\alpha_0}{q_1 c} = (C_{pL} - C_{pU})\cos\alpha_0$$

$$C_D = \frac{(p_L - p_U)c\sin\alpha_0}{q_1 c} = (C_{pL} - C_{pU})\sin\alpha_0$$

where c is the chord length of the plate. Since α_0 is small, we can write

$$C_L = \frac{4\alpha_0}{\sqrt{M_1^2 - 1}}, \quad C_D = \frac{4\alpha_0^2}{\sqrt{M_1^2 - 1}} \tag{2.7.45}$$

A similar type of expression can be obtained for an arbitrary thin airfoil that has thickness, camber, and angle of attack. Figure 2.7.14 shows such an airfoil. The pressure coefficients on the upper and lower surfaces can be written as follows:

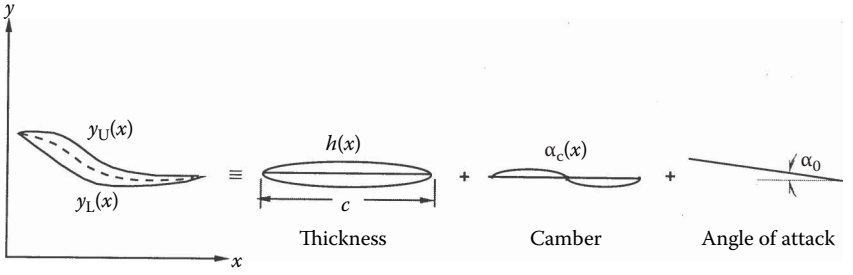

FIGURE 2.7.14 Arbitrary thin airfoil and its components.

$$C_{p_U} = \frac{2}{\sqrt{M_1^2 - 1}} \frac{dy_U}{dx}, \quad C_{p_L} = \frac{2}{\sqrt{M_1^2 - 1}} \left(\frac{dy_L}{dx} \right) \tag{2.7.46}$$

For the thin airfoil, the profile may be resolved into three separate components, as shown in Figure 2.7.14. The local slope of the airfoil can be obtained by superimposing the local slopes of the three components as follows:

$$\begin{aligned} \frac{dy_U}{dx} &= -\left(\alpha_0 + \alpha_c(x)\right) + \frac{dh}{dx} = -\alpha(x) + \frac{dh}{dx} \\ \frac{dy_L}{dx} &= -\left(\alpha_0 + \alpha_c(x)\right) - \frac{dh}{dx} = -\alpha(x) - \frac{dh}{dx} \end{aligned} \tag{2.7.47}$$

where $\alpha = \alpha_0 + \alpha_c(x)$ is the local total angle of attack of the camber line. The lift and drag for the thin airfoil are given by

$$L = q_1 \int_0^c \left(C_{p_L} - C_{p_U} \right) dx$$

$$D = q_1 \int_0^c \left[C_{p_L} \left(-\frac{dy_L}{dx} \right) + C_{p_U} \left(\frac{dy_U}{dx} \right) \right] dx$$

Let us define an average value of $\alpha(x)$ as follows:

$$\bar{\alpha} = \frac{1}{c} \int_0^c \alpha(x) dx$$

Using Equation 2.7.47 and the fact that $\bar{\alpha}_0 = \alpha$ and $\bar{\alpha}_c = 0$ by definition, the lift and drag coefficients for the thin airfoil can be written as follows:

$$\begin{aligned} C_L &= \frac{4\alpha_0}{\sqrt{M_1^2 - 1}} \\ C_D &= \frac{4}{\sqrt{M_1^2 - 1}} \left[\overline{\left(\frac{dh}{dx} \right)^2} + \overline{\alpha_C^2(x)} + \alpha_0^2 \right] \end{aligned} \tag{2.7.48}$$

Equation 2.7.48 shows that the lift coefficient depends only on the mean angle of attack whereas the drag coefficient is a linear combination of the drag due to thickness, drag due to camber, and drag due to lift (or mean angle of attack).

Further Information

As mentioned in the beginning, this section discussed only one- or two-dimensional steady, inviscid compressible flows and assumes ideal gas behavior. Even this discussion was quite brief because of space limitations. For more details on the subject as well as for compressible unsteady viscous flows, readers are referred to Anderson (2003) and Liepmann and Roshko (1966).

2.8 MULTIPHASE FLOW

John C. Chen

Introduction

Classic study of fluid mechanics concentrates on the flow of a single homogeneous phase, e.g., water, air, steam. However, many industrially important processes involve simultaneous flow of multiple phases, e.g., gas bubbles in oil, wet steam, dispersed particles in gas or liquid, foams, emulsions. Examples include vapor–liquid flow in refrigeration systems, steam–water flows in boilers and condensers, vapor–liquid flows in distillation columns, pneumatic hydraulic transport of solid particulates. In spite of their importance, multiphase flows are often neglected in standard textbooks. Fundamental understanding and engineering design procedures for multiphase flows are not nearly so well developed as those for single-phase flows. An added complexity is the need to predict the relative concentrations of the different phases in the multiphase flows, a need that doesn't exist for single-phase flows.

Inadequate understanding not withstanding, a significant amount of data have been collected and combinations of theoretical models and empirical correlations are used in engineering calculations. This knowledge base is briefly summarized in this section and references are provided for additional information. While discussions are provided of solid–gas flows and solid–liquid flows, primary emphasis is placed on multiphase flow of gas–liquids since this is the most often encountered class of multiphase flows in industrial applications.

A multiphase flow occurs whenever two or more of the following phases occur simultaneously: gas/vapor, solids, single-liquid phase, multiple (immiscible) liquid phases. Every possible combination has been encountered in some industrial process, the most common being the simultaneous flow of vapor/gas and liquid (as encountered in boilers and condensers). All multiphase flow problems have features which are characteristically different from those found in single-phase problems. First, the relative concentration of different phases is usually a dependent parameter of great importance in multiphase flows, while it is a parameter of no consequence in single-phase flows. Second, the spatial distribution of the various phases in the flow channel strongly affects the flow behavior, again a parameter that is of no concern in single-phase flows. Finally, since the density of various phases can differ by orders of magnitude, the influence of gravitational body force on multiphase flows is of much greater importance than in the case of single-phase flows. In any given flow situation, the possibility exists for the various phases to assume different velocities, leading to the phenomena of slip between phases and consequent interfacial momentum transfer. Of course, the complexity of laminar/turbulent characteristics occurs in multiphase flows as in single-phase flows, with the added complexity of interactions between phases altering the laminar/turbulent flow structures. These complexities increase exponentially with the number of phases encountered in the multiphase problem. Fortunately, a large number of applications occur with just two phase flows, or can be treated as pseudo-two-phase flows.

Two types of analysis are used to deal with two-phase flows. The simpler approach utilizes homogeneous models which assume that the separate phases flow with the same identical local velocity at all points in the fluid. The second approach recognizes the possibility that the two phases can flow at different velocities throughout the fluid, thereby requiring separate conservation equations for mass and momentum for each phase. Brief descriptions of both classes of models are given below.

Fundamentals

Consider n phases in concurrent flow through a duct with cross-sectional area A_c. Fundamental quantities that characterize this flow are

$\dot{m}_i$ = mass flow rate of *i*th phase
u_i = velocity of *i*th phase
α_i = volume fraction of *i*th phase in channel

Basic relationships between these and related parameters are

$$G_i = \text{mass flux of } i\text{th phase} = \frac{\dot{m}_i}{A_c} \tag{2.8.1}$$

$$v_i = \text{superficial velocity of } i\text{th phase} = \frac{G_i}{\rho_i} \tag{2.8.2}$$

$$u_i = \text{actual velocity of } i\text{th phase} = \frac{v_i}{\alpha_i} \tag{2.8.3}$$

$$x_i = \text{flow quality of } i\text{th phase} = \frac{\dot{m}_i}{\sum_i^n m_i} = \frac{G_i}{\sum_{i=1}^n G_i} \tag{2.8.4}$$

$$\alpha_i = \text{volume fraction of } i\text{th phase} = \frac{\left(\frac{x_i}{\rho_i u_i}\right)}{\sum_{i=1}^n \left(\frac{x_i}{\rho_i u_i}\right)} \tag{2.8.5}$$

In most engineering calculations, the above parameters are defined as average quantities across the entire flow area, A_c. It should be noted, however, that details of the multiphase flow could involve local variations across the flow area. In the latter situation, G_i, v_i, and α_i are often defined on a local basis, varying with transverse position across the flow area.

Pressure drop along the flow channel is associated with gravitational body force, acceleration forces, and frictional shear at the channel wall. The total pressure gradient along the flow axis can be represented as

$$\frac{dP}{dz} = \left(\frac{dP}{dz}\right)_g + \left(\frac{dP}{dz}\right)_a + \left(\frac{dP}{dz}\right)_f \tag{2.8.6}$$

where

$$\left(\frac{dP}{dz}\right)_g = -g\cos\theta \cdot \sum_{i=1}^n \alpha_i \rho_i \tag{2.8.7}$$

θ = angle of channel from vertical and the flow is in the upward direction.

and

$$\left(\frac{dP}{dz}\right)_a = -\sum_{i=1}^{n} G_i \frac{du_i}{dz} \tag{2.8.8}$$

$$\left(\frac{dP}{dz}\right)_f = -\frac{\rho u^2}{2D} f \tag{2.8.9}$$

ρ = density of multiphase mixture

$$= \sum_{i=1}^{n} \rho_i \alpha_i \tag{2.8.10}$$

u = an average mixture velocity

$$= \frac{1}{\rho} \sum_{i=1}^{n} G_i \tag{2.8.11}$$

f = equivalent Darcy friction factor for the multiphase flow

In applications, the usual requirement is to determine pressure gradient (dP/dz) and the volume fractions (α_i). The latter quantities are of particular importance since the volume fraction of individual phases affects all three components of the pressure gradient, as indicated in Equations 2.8.7 through 2.8.11. Correlations of various types have been developed for prediction of the volume fractions, all but the simplest of which utilize empirical parameters and functions.

The simplest flow model is known as the homogeneous equilibrium model (HEM), wherein all phases are assumed to be in neutral equilibrium. One consequence of this assumption is that individual phase velocities are equal for all phases everywhere in the flow system, i.e., there is no-slip between the phases:

$$u_i = u \text{ for all } i \tag{2.8.12}$$

This assumption permits direct calculation of the volume fractions from known mass qualities:

$$\alpha_i = \frac{x_i}{\rho_i \sum_{i=1}^{n} \left(\frac{x_i}{\rho_i}\right)} \tag{2.8.13}$$

The uniform velocity for all phases is the same as mixture velocity:

$$u = \frac{1}{\rho} \sum_{i=1}^{n} G_i \tag{2.8.14}$$

where

$$\frac{1}{\rho} = \sum_{i=1}^{n} \left(\frac{x_i}{\rho_i}\right) \tag{2.8.15}$$

This homogeneous model permits direct evaluation of all three components of axial pressure gradient, if flow qualities (x_i) are known:

$$\left(\frac{dP}{dz}\right)_g = -\frac{g\cos\theta}{\sum_{i=1}^{n}\left(\frac{x_i}{\rho_i}\right)} \tag{2.8.16}$$

$$\left(\frac{dP}{dz}\right)_a = -\left(\sum_{i=1}^{n} G_i\right)\cdot\frac{du}{dz} \tag{2.8.17}$$

$$\left(\frac{dP}{dz}\right)_f = -\frac{\rho u^2}{2D}\cdot f \tag{2.8.18}$$

where u and ρ are given by Equations 2.8.14 and 2.8.15.

Predicting the coefficient of friction, f, remains a problem, even in the homogeneous model. For cases of fully turbulent flows, experience has shown that a value of 0.02 may be used as a first-order approximation for f, i.e., $f = 0.02$. More-accurate estimates require empirical correlations, specific to particular classes of multiphase flows and subcategories of flow regimes.

The following parts of this section consider the more common situations of two-phase flows and describe improved design methodologies specific to individual situations.

Gas–Liquid Two-Phase Flow

The most common case of multiphase flow is two-phase flow of gas and liquid, as encountered in steam generators and refrigeration systems. A great deal has been learned about such flows, including delineation of flow patterns in different flow regimes, methods for estimating volume fractions (gas void fractions), and two-phase pressure drops.

Flow Regimes

A special feature of multiphase flows is their ability to assume different spatial distributions of the two phases. These different flow patterns have been classified in flow regimes, which are themselves altered by the direction of flow relative to gravitational acceleration. Figures 2.8.1 and 2.8.2 (Delhaye, 1981; Michaelides et al, 2016) show the flow patterns commonly observed for co-current flow of gas and liquid in vertical and horizontal channels, respectively. For a constant liquid flow rate, the gas phase tends to be distributed as small bubbles at low gas flow rates. Increasing gas flow rate causes agglomeration of bubbles into larger slugs and plugs. Further increasing gas flow rate causes separation of the phases into annular patterns wherein liquid concentrates at the channel wall and gas flows in the central core for vertical ducts. For horizontal ducts, gravitational force tends to drain the liquid annulus toward the bottom of the channel, resulting in stratified and stratified wavy flows. This downward segregation of the liquid phase can be overcome by kinetic forces at high flow rates, causing stratified flows to revert to annular flows. At high gas flow rates, more of the liquid tends to be entrained as dispersed drops; in the limit one obtains completely dispersed mist flow.

Flow pattern maps are utilized to predict flow regimes for specific applications. The first generally successful flow map was that of Baker (1954) for horizontal flow, reproduced here in Figure 2.8.3. For vertical flows, the map of Hewitt and Roberts (1969), duplicated in Figure 2.8.4, provides a simple method for determining flow regimes. Parameters used for the axial coordinates of these flow maps are defined as follows:

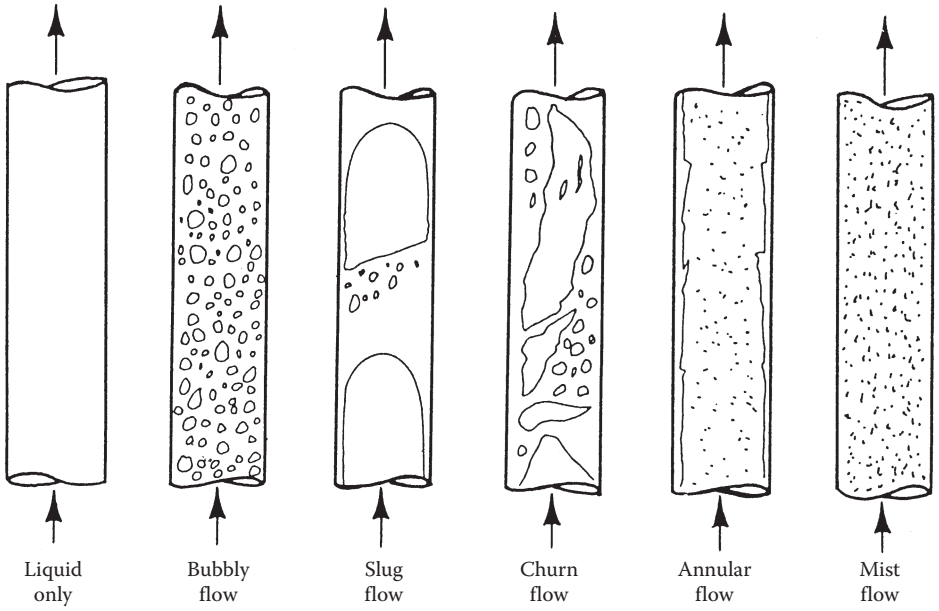

FIGURE 2.8.1 Flow patterns in gas–liquid vertical flow. (From Lahey, R.T., Jr. and Moody, F.I., 1977, *The Thermal Hydraulics of a Boiling Water Nuclear Reactor*, The American Nuclear Society, LaGrange, IL. With permission.)

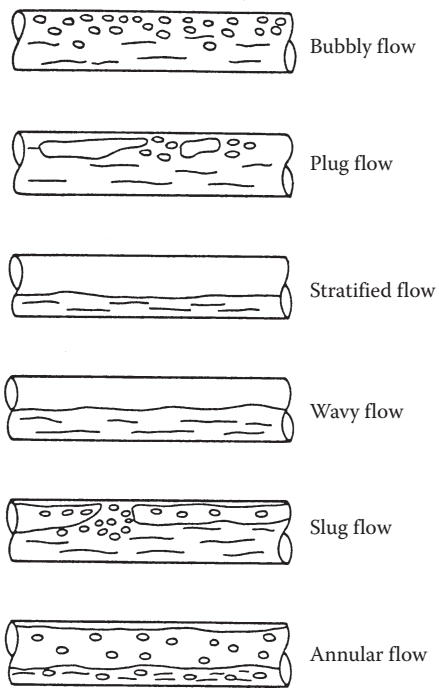

FIGURE 2.8.2 Flow patterns in gas–liquid horizontal flow.

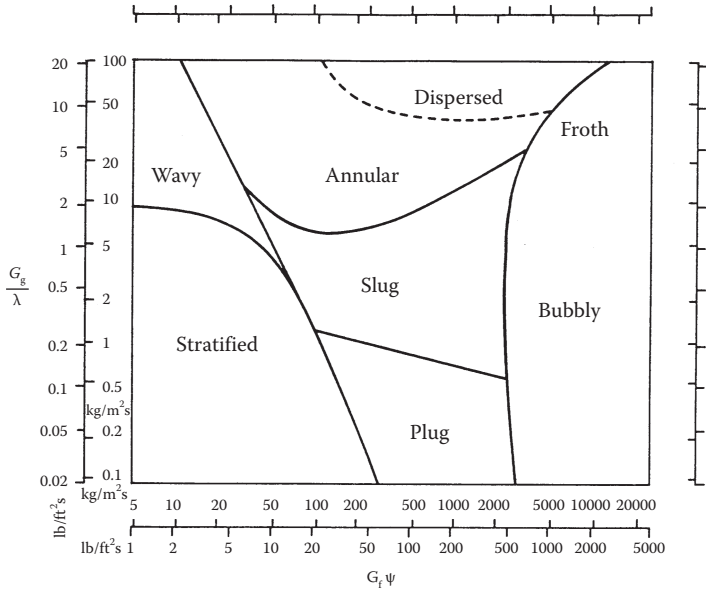

FIGURE 2.8.3 Flow pattern map for horizontal flow (Baker, 1954). (From Collier, J.G., 1972, *Convective Boiling and Condensation*, McGraw-Hill, London. With permission.)

$$\lambda = \left(\frac{\rho_g \rho_l}{\rho_a \rho_w}\right)^{1/2} \tag{2.8.19}$$

$$\psi = \left(\frac{\sigma_w}{\sigma}\right)\left[\left(\frac{\mu_l}{\mu_w}\right)\left(\frac{\rho_w}{\rho_l}\right)^2\right]^{1/3} \tag{2.8.20}$$

$$j = \text{volumetric flux}, \frac{G}{\rho} \tag{2.8.21}$$

Void Fractions

In applications of gas–liquid flows, the volume fraction of gas (α_g) is commonly called "void fraction" and is of particular interest. The simplest method to estimate void fraction is by the HEM. From Equation 2.8.13, the void fraction can be estimated as

$$\alpha_g = \frac{x_g}{x_g + (1 - x_g)\dfrac{\rho_g}{\rho_l}} \tag{2.8.22}$$

where α_g, x_g, ρ_g, ρ_ϵ are cross-sectional averaged quantities.

In most instances, the homogeneous model tends to overestimate the void fraction. Improved estimates are obtained by using separated-phase models which account for the possibility of slip between gas and liquid velocities. A classic separated-phase model is that of Lockhart and Martinelli (1949). The top portion of Figure 2.8.5 reproduces the Lockhart–Martinelli correlation for void fraction (shown as α) as a function of the parameter X which is defined as

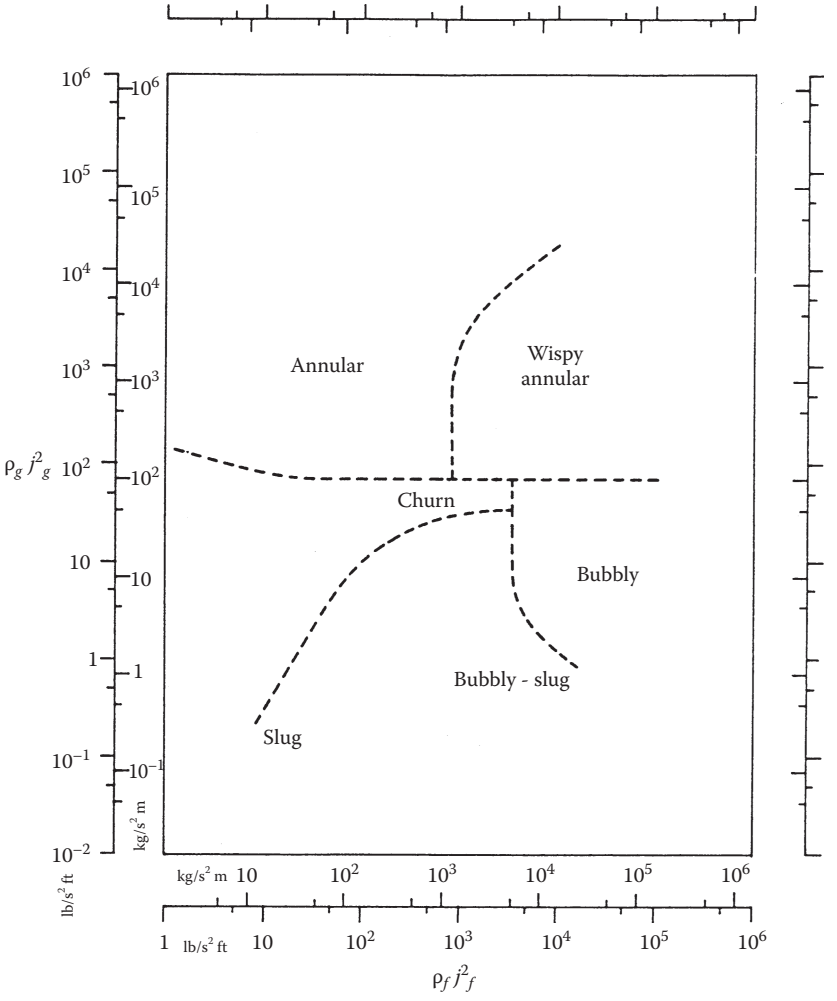

FIGURE 2.8.4 Flow pattern map for vertical flow (Hewitt and Roberts, 1969). (From Collier, J.G., 1972, *Convective Boiling and Condensation*, McGraw-Hill, London. With permission.)

$$X = \left[\left(\frac{dP}{dz} \right)_{fl} \Big/ \left(\frac{dP}{dz} \right)_{fg} \right]^{1/2} \tag{2.8.23}$$

where

$\left(\frac{dP}{dz} \right)_{fl}$ = frictional pressure gradient of liquid phase flowing alone in channel

$\left(\frac{dP}{dz} \right)_{fg}$ = frictional pressure gradient of gas phase flowing alone in channel

Often, flow rates are sufficiently high such that each phase if flowing alone in the channel would be turbulent. In this situation the parameter X can be shown to be

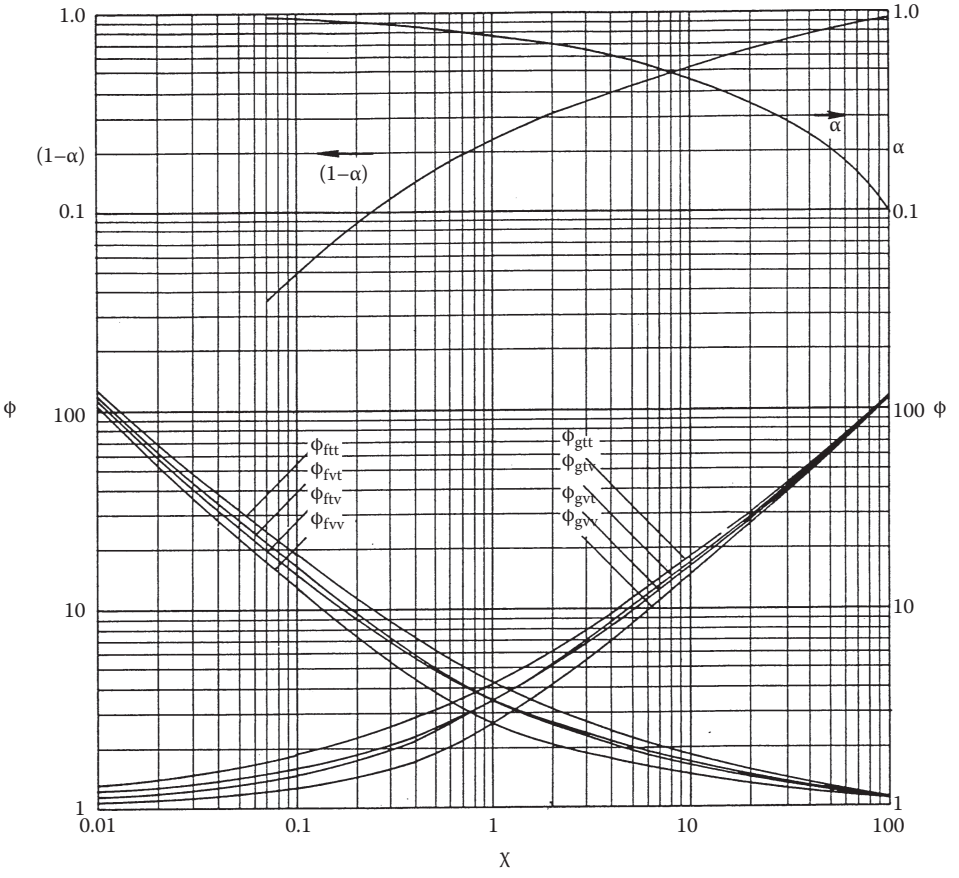

FIGURE 2.8.5 Correlations for void fraction and frictional pressure drop (Lockhart and Martinelli, 1949). (From Collier, J.G., 1972, *Convective Boiling and Condensation*, McGraw-Hill, London. With permission.)

$$X_{tt} = \left(\frac{1-x_g}{x_g}\right)^{0.9}\left(\frac{\rho_g}{\rho_l}\right)^{0.5}\left(\frac{\mu_l}{\mu_g}\right)^{0.1} \tag{2.8.24}$$

Another type of separated-phase model is the drift-flux formulation of Wallis (1969). This approach focuses attention on relative slip between phases and results in slightly different expressions depending on the flow regime. For co-current upflow in two of the more common regimes, the drift-flux model gives the following relationships between void fraction and flow quality:

Bubbly flow or churn-turbulent flow:

$$\alpha_g = \frac{x_g}{\left(\frac{u_o\rho_g}{G}\right) + C_o\left[x_g + (1-x_g)\frac{\rho_g}{\rho_l}\right]} \tag{2.8.25}$$

Dispersed drop (mist) flow:

$$x_g = \frac{1-(1-\alpha_g)\left(\frac{u_o\rho_l}{G}\alpha_g^2 + 1\right)}{1-(1-\alpha_g)\left(1-\frac{\rho_l}{\rho_g}\right)} \tag{2.8.26}$$

where u_o = terminal rise velocity of bubble, in bubbly flow, or terminal fall velocity of drop in churn-turbulent flow

C_o = an empirical distribution coefficient $\simeq 1.2$

Pressure Drop

Equations 2.8.16 through 2.8.18 permit calculation of the two-phase pressure drop by the homogeneous model, if the friction coefficient (f) is known. One useful method for estimating (f) is to treat the entire two-phase flow as if it were all liquid, except flowing at the two-phase mixture velocity. By this approach the frictional component of the two-phase pressure drop becomes

$$\left(\frac{dP}{dz}\right)_f = \left[1 + x_g\left(\frac{\rho_l}{\rho_g} - 1\right)\right] \cdot \left(\frac{dP}{dz}\right)_{flG} \tag{2.8.27}$$

where $(dP/dz)_{flG}$ = frictional pressure gradient if entire flow (of total mass flux G) flowed as liquid in the channel.

The equivalent frictional pressure drop for the entire flow as liquid, $(dP/dz)_{fl_g}$, can be calculated by standard procedures for single-phase flow. In using Equations 2.8.16 through 2.8.18, the void fraction would be calculated with the equivalent homogeneous expression Equation 2.8.13.

A more accurate method to calculate two-phase pressure drop is by the separated-phases model of Lockhart and Martinelli (1949). The bottom half of Figure 2.8.5 shows empirical curves for the Lockhart–Martinelli frictional multiplier, ϕ:

$$\phi_i = \left[\left(\frac{dP}{dz}\right)_f \Big/ \left(\frac{dP}{dz}\right)_{fi}\right]^{1/2} \tag{2.8.28}$$

where (i) denotes either the fluid liquid phase (f) or gas phase (g). The single-phase frictional gradient is based on the ith phase flowing alone in the channel, in either viscous laminar (v) or turbulent (t) modes. The most common case is where each phase flowing alone would be turbulent, whence one could use Figure 2.8.5 to obtain

$$\begin{aligned}\left(\frac{dP}{dz}\right)_f &= \text{frictional pressure gradient for two-phase flow} \\ &= \phi_{gtt}^2 \cdot \left(\frac{dP}{dz}\right)_{fg}\end{aligned} \tag{2.8.29}$$

where $(dP/dz)_{fg}$ is calculated for gas phase flowing alone and $X = X_{tt}$ as given by Equation 2.8.24.

The correlation of Lockhart–Martinelli has been found to be adequate for two-phase flows at low-to-moderate pressures, i.e., with reduced pressures less than 0.3. For applications at higher pressures, the revised models of Martinelli and Nelson (1984) and Thom (1964) are recommended.

Gas–Solid, Liquid–Solid Two-Phase Flows

Two-phase flows can occur with solid particles in gas or liquid. Such flows are found in handling of granular materials and heterogeneous reaction processing. Concurrent flow of solid particulates with a fluid phase can occur with various flow patterns, as summarized below.

Flow Regimes

Consider vertical upflow of a fluid (gas or liquid) with solid particles. Figure 2.8.6 illustrates the major flow regimes that have been identified for such two-phase flows. At low flow rates, the fluid phase percolates between stationary particles; this is termed flow through a fixed bed. At some higher velocity a point is reached when the particles are all suspended by the upward flowing fluid, the drag force between particles and fluid counterbalancing the gravitational force on the particles. This is the point of minimum fluidization, marking the transition from fixed to fluidized beds. Increase of fluid flow rate beyond minimum fluidization causes instabilities in the two-phase mixture, and macroscopic bubbles or channels of fluid are observed in the case of gaseous fluids. In the case of liquids, the two-phase mixture tends to expand, often without discrete bubbles or channels. Further increase of fluid velocity causes transition to turbulent fluidization wherein discrete regions of separated phases (fluid slugs or channels and disperse suspensions of particles) can coexist. Depending on specific operating conditions (e.g., superficial fluid velocity, particle size, particle density, etc.), net transport of solid particles with the flowing fluid can occur at any velocity equal to or greater than that associated with slug flow and turbulent flow. Further increases in fluid velocity increase the net transport of solid particles. This can occur with large-scale clusters of solid particles (as exemplified by the fast fluidization regime) or with dilute dispersions of solid particles (as often utilized in pneumatic conveying). For engineering application of fluid–solid two-phase flows, the important thresholds between flow regimes are marked by the fluid velocity for minimum fluidization, terminal slip, and saltation threshold.

Minimum Fluidization

The transition from flow through packed beds to the fluidization regime is marked by the minimum fluidization velocity of the fluid. On a plot pressure drop vs. superficial fluid velocity, the point of

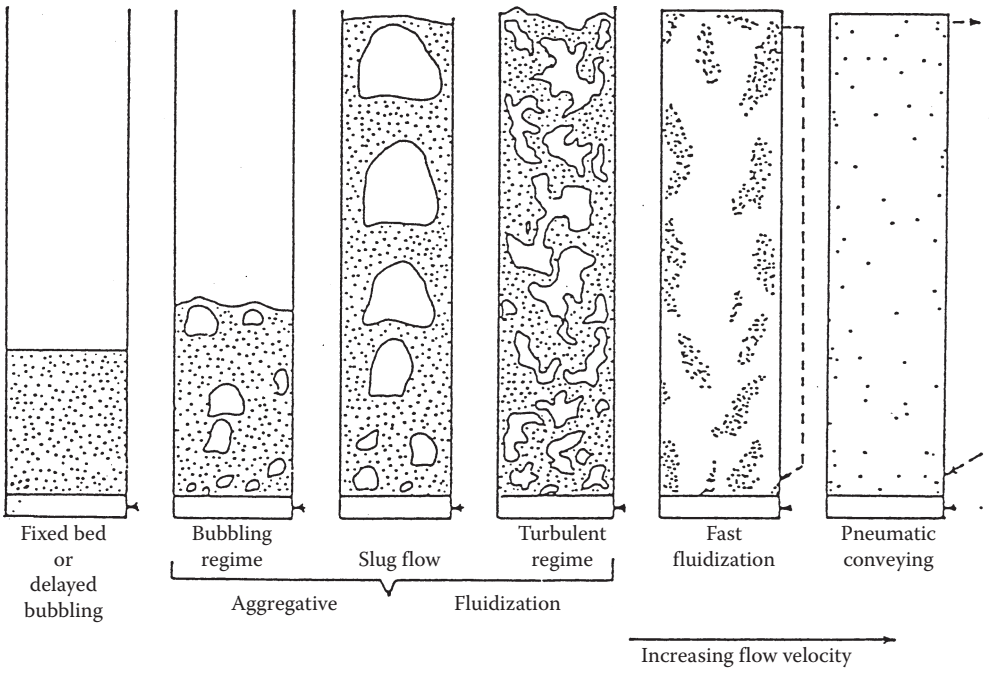

FIGURE 2.8.6 Flow patterns for vertical upflow of solid particles and gas or liquid. (From Chen, J.C., 1994, *Proc. Xth Int. Heat Transfer Conf.*, Brighton, UK, 1:369–386. With permission.)

minimum fluidization is marked by a transition from a linearly increasing pressure drop to a relatively constant pressure drop as shown in Figure 2.8.7 for typical data, for two-phase flow of gas with sand particles of 280 μm mean diameter (Chen, 1996). The threshold fluid velocity at minimum fluidization is traditionally derived from the Carman–Kozeny equation,

$$U_{mf} = \frac{(\rho_s - \rho_f)(\phi\, dp)^2\, g}{150\,\mu_f} \cdot \frac{\alpha_{mf}^2}{(1-\alpha_{mf})} \tag{2.8.30}$$

where ϕ = sphericity of particles (unity for spherical particles)

α_{mf} = volumetric fraction of fluid at minimum fluidization

Small, light particles have minimum fluidization voidage (α_{mf}) of the order 0.6, while larger particles such as sand have values closer to 0.4.

An alternative correlation for estimating the point of minimum fluidization is that of Wen and Yu (1966):

$$\frac{U_{mf} d_p \rho_f}{\mu_f} = (33.7 + 0.041 Ga)^{0.5} - 33.7 \tag{2.8.31}$$

where $Ga = \rho_f d_p^3 (\rho_s - \rho_f)\, g / \mu_f^2$.

When the fluid velocity exceeds U_{mf}, the two-phase mixture exists in the fluidized state in which the pressure gradient is essentially balanced by the gravitational force on the two-phase mixture:

$$\frac{dP}{dz} = g\left[\alpha_s \rho_s + \alpha_f \rho_f\right] \tag{2.8.32}$$

This fluidized state exists until the fluid velocity reaches a significant fraction of the terminal slip velocity, beyond which significant entrainment and transport of the solid particles occur.

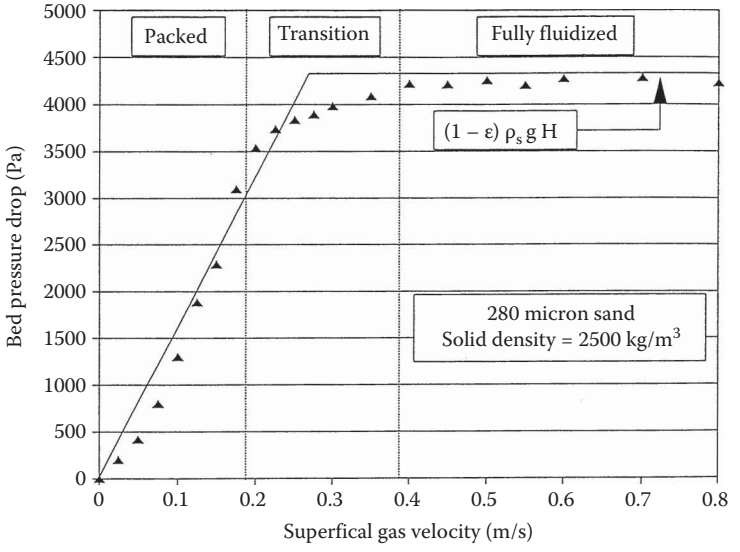

FIGURE 2.8.7 Transition at minimum fluidization. (From Chen, J.C., 1996, In *Annual Reviews of Heat Transfer*, Vol. VII, Begal House, Washington, DC With permission.)

Terminal Slip Velocity

For an isolated single particle, the maximum velocity relative to an upflowing fluid is the terminal slip velocity. At this condition, the interfacial drag of the fluid on the particle exactly balances the gravitational body force on the particle:

$$U_t = \left(U_f - U_s\right)_t = \left[\frac{4d_p\left(\rho_s - \rho_f\right)}{3\rho_f} \cdot \frac{1}{C_D}\right]^{1/2} \tag{2.8.33}$$

where C_D = coefficient of drag on the particle.

The coefficient of drag on the particle (C_D) depends on the particle Reynolds number:

$$\mathrm{Re}_p = \frac{\rho_f d_p\left(U_f - U_s\right)}{\mu_f} \tag{2.8.34}$$

The following expressions may be used to estimate C_D as appropriate:

$$\begin{aligned} C_D &= \frac{32}{\mathrm{Re}_p}, \qquad \mathrm{Re}_p \le 1 \\ C_D &= \frac{18.5}{\mathrm{Re}_p^{0.67}}, \qquad 1 \le \mathrm{Re}_p \le 10^3 \end{aligned} \tag{2.8.35}$$

Pneumatic Conveying

A desirable mode of pneumatic conveying is two-phase flow with solid particles dispersed in the concurrent flowing fluid. Such dispersed flows can be obtained if the fluid velocity is sufficiently high. For both horizontal and vertical flows, there are minimum fluid velocities below which saltation

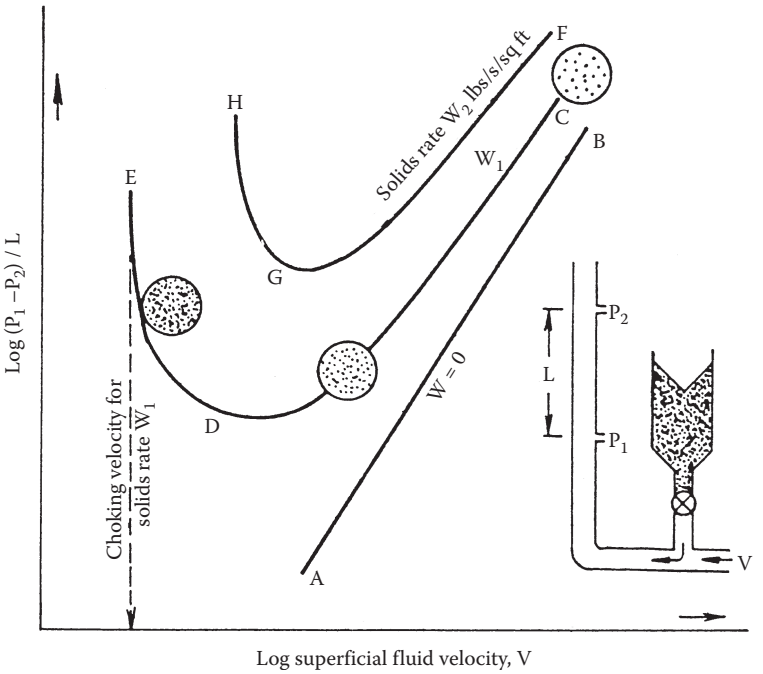

FIGURE 2.8.9 Flow characteristics in vertical pneumatic conveying. (From Zeng, F.A. and Othmer, D.F., 1960, *Fluidization and Fluid-Particle Systems*, Reinhold, New York. With permission.)

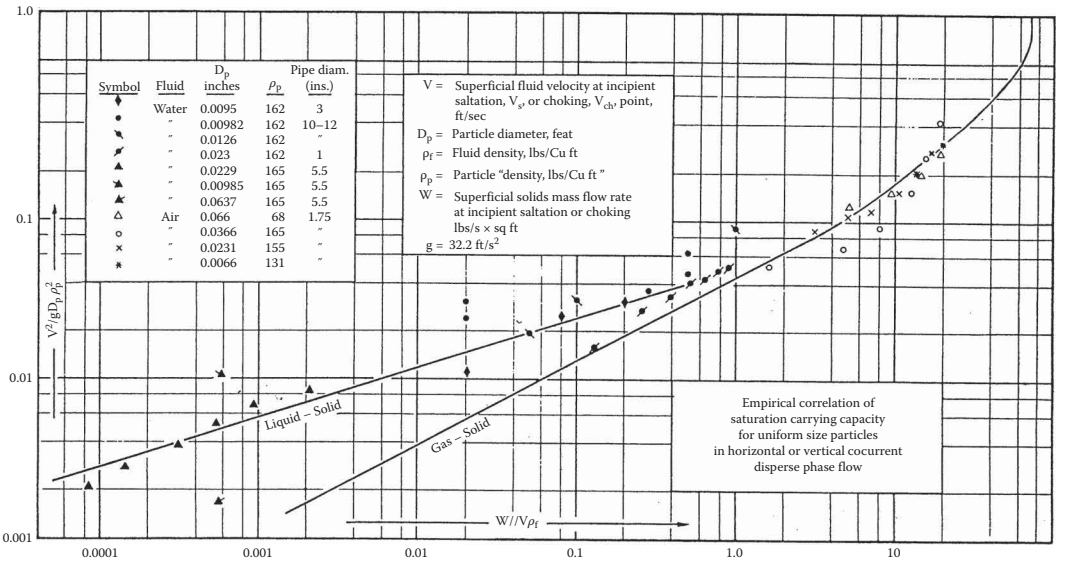

FIGURE 2.8.10 Correlations for limiting velocities in pneumatic conveying. (From Zeng, F.A. and Othmer, D.F., 1960, *Fluidization and Fluid-Particle Systems*, Reinhold, New York. With permission.)

of the solid particles due to gravitational force occurs, leading to settling of the solid particles in horizontal channels and choking of the particles in vertical channels. Figures 2.8.8 and 2.8.9, from Zenz and Othmer (1960), show these different regimes of pneumatic conveying for horizontal and vertical transport, respectively. Figure 2.8.8 shows that for a given rate of solids flow (W) there is a minimum superficial fluid velocity below which solid particles tend to settle into a dense layer at the

bottom of the horizontal channels. Above this saltation threshold, fully dispersed two-phase flow is obtained. In the case of vertical transport illustrated in Figure 2.8.9, there is a minimum fluid velocity below which solid particles tend to detrain from the two-phase suspension. This choking limit varies not only with particle properties but also with the actual rate of particle flow. Well-designed transport systems must operate with superficial fluid velocities greater than these limiting saltation and choking velocities.

Zenz and Othmer (1960) recommend the empirical correlations represented in Figure 2.8.10 estimating limiting superficial fluid velocities at incipient saltation or choking, for liquid or gas transport of uniformly sized particles. Note that these correlations are applicable for either horizontal or vertical concurrent flow. Figure 2.8.10 is duplicated from the original source and is based on parameters in engineering units, as noted in the figure. To operate successfully in dispersed pneumatic conveying of solid particles, the superficial fluid velocity must exceed that determined from the empirical correlations of Figure 2.8.10.

More detailed treatment of multiphase flows can be found in several books, e.g., see Wilson et al. (2006) for slurry flows, klinzing et al. (1997) for preumatic conveying and Michaelides et al. (2016) for gas-liquid and systems.

2.9 NON-NEWTONIAN FLOWS

Anoop K. Gupta, Raj P. Chhabra, Thomas F. Irvine, Jr., and Massimo Capobianchi

Introduction

It is now readily acknowledged that most structured fluids (polymer solutions and melts, gas–liquid dispersions, foams, slurries and suspensions, worm-like micellar solutions containing surfactant molecules, for instance) exhibit what is known as complex non-Newtonian behavior under the application of an external stress. Conversely, such fluids do not conform to Newton's law of viscosity and indeed even a small concentration of high molecular weight polymers in water gives rise to numerous spectacular phenomena like drag reduction in turbulent pipe flow, die swell, bouncing balls; see Boger and Walters (1992) for a range of unusual effects observed with such systems. Indeed, none of these effects can be explained even qualitatively using the postulate of Newtonian fluid behavior. While detailed listings of systems displaying the so-called non-Newtonian or complex rheological behavior are available in several books (Bird et al., 1987; Barnes, 1989; Darby, 1976; Chhabra and Richardson, 2008; Chhabra, 2016), typical examples include coal/water, clay/water slurries, processed foodstuffs (like jams, jellies, and marmalades), polymers and composites, shaving foams, personal care products, biological fluids (like blood, saliva, and semen), etc.

In the following sections, the definition and classification of non-Newtonian fluids and the prediction of pressure drops in both laminar and turbulent flow in ducts of various cross-sectional shapes for different classes of non-Newtonian fluids are discussed. The analogous information for boundary layer flows is provided in Section 3.2.4.

Classification of Non-Newtonian Behavior

Newtonian Fluid Behavior

It is convenient to first define the familiar Newtonian fluid behavior. For a one-dimensional steady shearing flow (with one component of velocity, V_x, which varies in the lateral direction, y), the Newtonian fluid behavior is characterized by the linear relationship between the shear stress (τ_{yx}) and the velocity gradient (also called the rate of strain or simply the shear rate, $\dot{\gamma}_{yx}$ or dV_x / dy) as

$$\tau_{yx} = \mu\dot{\gamma}_{yx} = \mu \frac{dV_x}{dy}. \tag{2.9.1}$$

The constant of proportionality, μ, variously known as the viscosity or dynamic viscosity, is a true material constant which is influenced by pressure and temperature for each substance, but it is independent of shear rate or shear stress for a Newtonian fluid. For instance, water has a viscosity of 10^{-3} Pa·s at room temperature and atmospheric pressure, whereas the corresponding value for air is of the order ~ 10^{-5} Pa·s. Other related terms are fluidity which is simply the reciprocal of viscosity, and kinematic viscosity which is defined as the viscosity divided by density; the latter is also known as the momentum diffusivity and it plays the same role in diffusive momentum transfer processes as the thermal diffusivity in heat transfer. Returning to Equation 2.9.1, at a given temperature and pressure, the flow behavior of a Newtonian fluid is thus characterized by a single flow property, μ, which is given by the slope of the shear stress–shear rate data (see Figure 2.9.1 for three different fluids). Most low molecular weight (<~10, 000 Daltons) substances such as organic liquids, molten salts and metals, gases, all conform to Equation 2.9.1 and are thus accordingly called Newtonian fluids. For most

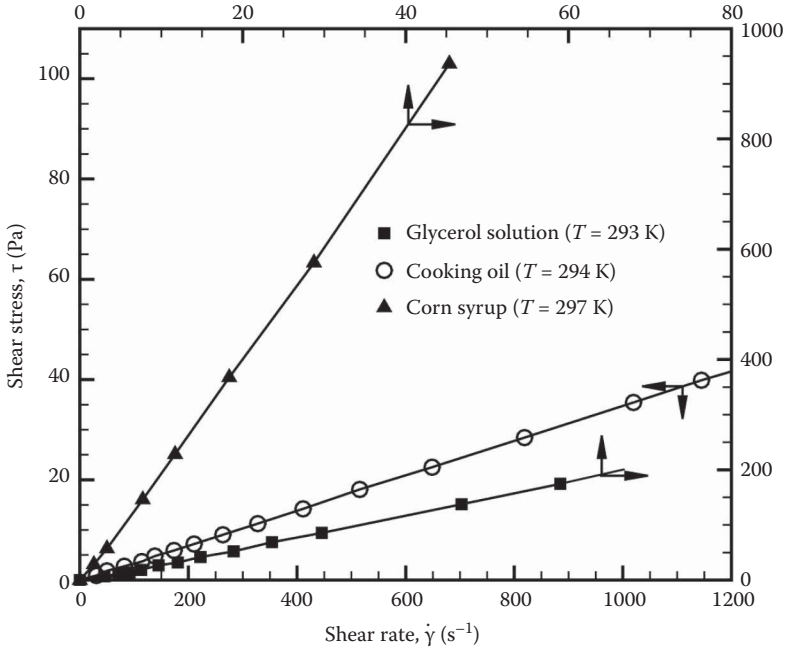

FIGURE 2.9.1 Typical shear stress–shear rate data for Newtonian fluids (glycerol solution, cooking oil, and corn syrup).

liquids, the value of viscosity decreases with temperature and increases with pressure. For gases, their viscosity increases with both temperature and pressure (Poling et al., 2000; Haynes, 2015).

It must be recognized here that Equation 2.9.1 relates to the simplest case of unidimensional and unidirectional flow situation. For the general case of 3D flows (Figure 2.9.2), it is easy to imagine that there will be two tangential stress components and one normal stress components corresponding to each coordinate direction thereby yielding a stress tensor ($\underline{\underline{S}}$) consisting of nine components altogether as follows:

$$\underline{\underline{S}} = \begin{pmatrix} -p+\tau_{xx} & \tau_{yx} & \tau_{zx} \\ \tau_{xy} & -p+\tau_{yy} & \tau_{zy} \\ \tau_{xz} & \tau_{yz} & -p+\tau_{zz} \end{pmatrix}. \tag{2.9.2}$$

In Equation 2.9.2, each row corresponds to the stress components acting in the same direction, whereas each column contains the stress components acting on the same surface.

The requirements of the tracelessness $\left(\sum(-p+\tau_{ii})=0\right)$ and of symmetry $\left(\tau_{ij}=\tau_{ji}\right)$ of the stress tensor imply that the state of stress at a point in a fluid can be described in terms of three independent shear components and two normal stress differences. For instance, in the Cartesian coordinate system, these are given as $\tau_{xy}(=\tau_{yx})$, $\tau_{yz}(=\tau_{zy})$, and $\tau_{zx}(=\tau_{xz})$, and the two normal stress differences are defined as

$$N_1 = \tau_{xx} - \tau_{yy};\ N_2 = \tau_{yy} - \tau_{zz}. \tag{2.9.3}$$

For a Newtonian substance, the tangential and normal stress components are related linearly to the components of the rate of deformation tensor via its viscosity; see Equations 2.2.32 through 2.2.37 in Chapter 2 of this handbook. For an incompressible Newtonian fluid subject to simple shearing

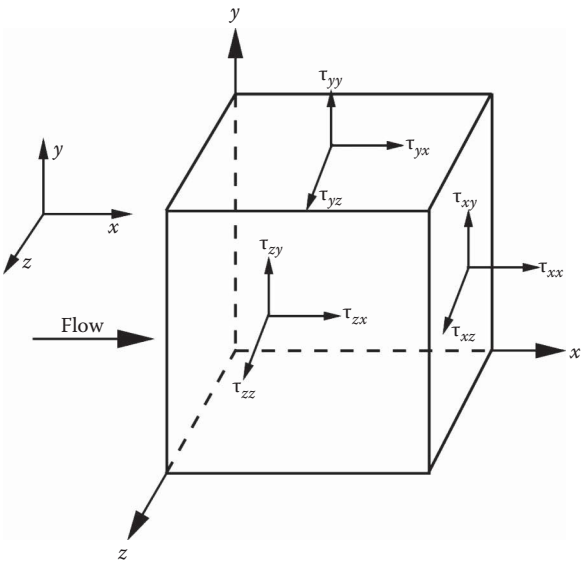

FIGURE 2.9.2 Stress components in a 3D flow.

motion, $\tau_{xx} = \tau_{yy} = \tau_{zz} = 0$; hence, the complete definition of a Newtonian fluid requires a fluid to satisfy the complete Navier–Stokes equations (see Equations 2.2.38 and 2.2.39) rather than simply exhibiting a constant viscosity in one-dimensional shear.

Non-Newtonian Fluid Behavior

In view of the preceding discussion, a non-Newtonian fluid is one which does not satisfy the Navier–Stokes equations, or in simple shear, it does not conform to Equation 2.9.1. Since the ensuing discussion is limited mainly to one-dimensional shearing, hereafter the relevant components of the stress and the rate-of-strain tensors are denoted simply as τ and $\dot{\gamma}$, respectively, without any subscripts. The simplest signature of non-Newtonian fluid behavior is when the shear stress (τ)–shear rate ($\dot{\gamma}$) data does not yield a linear relationship or does not pass through the origin or both, as shown in Figure 2.9.3. In spite of this complexity, it is still customary to define the so-called apparent viscosity, defined as, $|\tau|/|\dot{\gamma}|$, which is obviously not a constant. In fact, it may increase with shear rate (shear thickening or dilatant behavior, see Figure 2.9.4), or it may decrease with shear rate (shear thinning or pseudoplastic, see Figure 2.9.5). This is in stark contrast to the notion of constant viscosity in the context of Newtonian fluids for which the viscosity is an intrinsic property determined by the structure of the molecule. It is standard practice, though unscientific as well as arbitrary, to further categorize non-Newtonian flow behavior into three types:

1. Systems in which the value of the shear rate $\dot{\gamma}$ at a point within the fluid is determined solely by the current value of the stress at that point or vice versa. This category of fluid behavior is variously known as *purely viscous*, *generalized Newtonian fluids* (GNF), *time-independent* or *inelastic* fluids.
2. Systems in which the relationship between τ–$\dot{\gamma}$ also shows further dependence on the duration of shearing and/or the kinematic history of the sample. This type of fluid behavior is known as time-dependent. If the viscosity of a substance decreases with time at a fixed shear rate (see Figure 2.9.6 for instance), it is called thixotropy. The viscosity (or shear stress) may or may not approach an equilibrium value even after prolonged shearing. On the other hand, there are substances which exhibit the reverse trend, that is, their apparent viscosity increases with the duration of shearing (see Figure 2.9.7), though this behavior

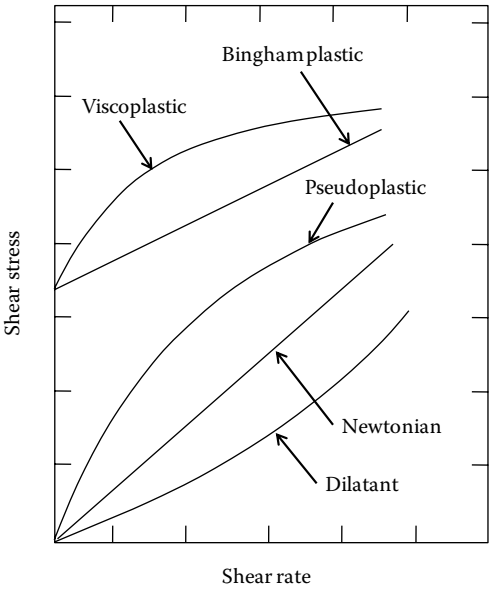

FIGURE 2.9.3 Qualitative flow curves for time-independent fluid behavior.

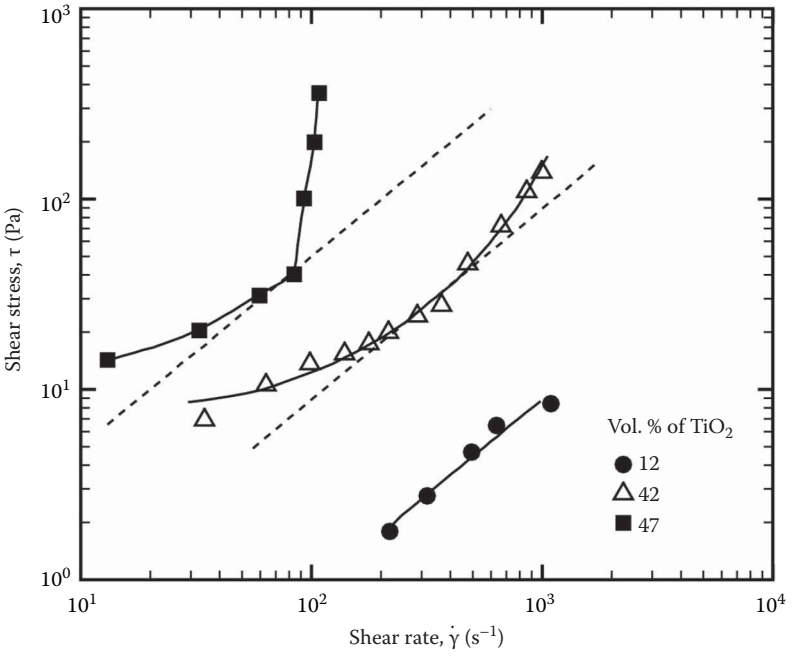

FIGURE 2.9.4 Typical shear stress–shear rate data for TiO_2 suspensions displaying shear-thickening behavior.

is less common. This phenomenon is known as anti-thixotropy, or negative thixotropy or rheopexy. More detailed discussion of this subclass of fluids and their constitutive modelling can be found in Barnes (1997), Mujumdar et al. (2002), Dullaert and Mewis (2005, 2006), and Mewis and Wagner (2012).

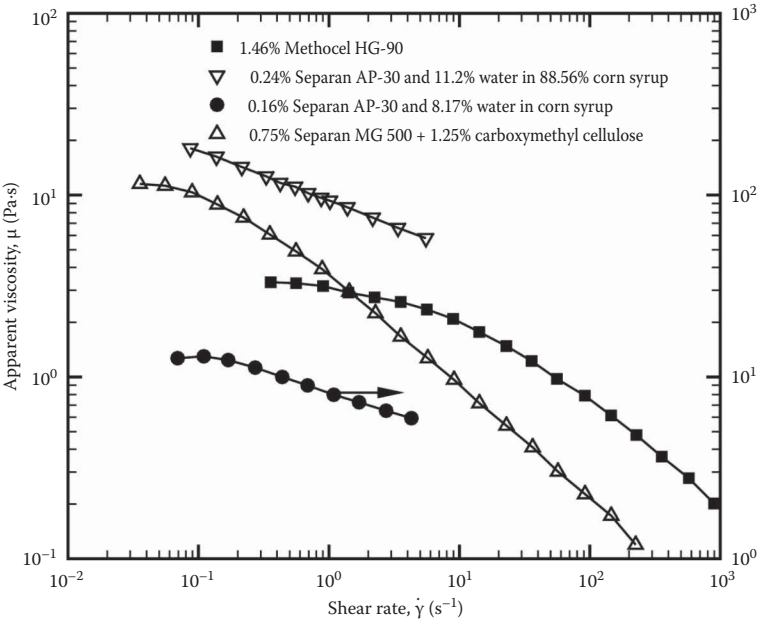

FIGURE 2.9.5 Representative plots for apparent viscosity vs. shear rate data for different pseudoplastic polymer solutions.

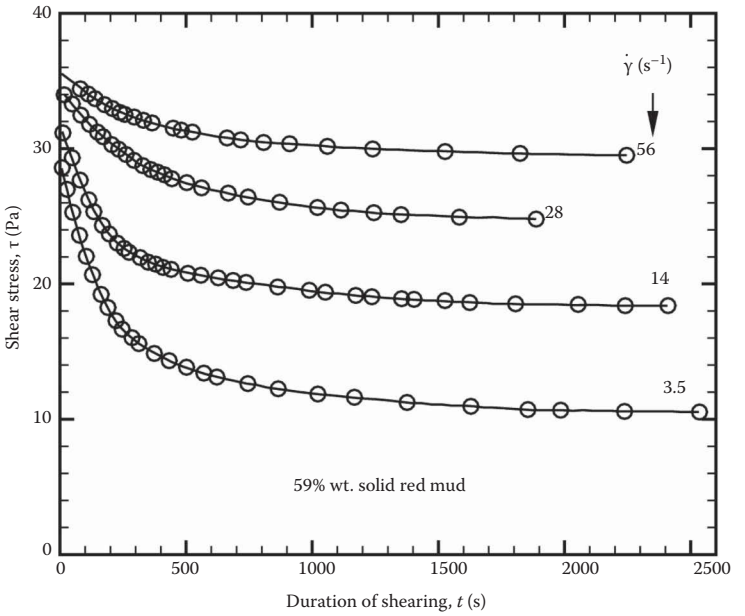

FIGURE 2.9.6 Typical experimental data showing thixotropic behavior in a red mud suspension. (From Ngugen, Q.D., Uhlherr, P.H.T., *Proceedings of 3rd National Conference Rheology*, Melbourne, Australia, 63–68, 1983. With permission.)

3. Finally, systems which display a blend of viscous fluid-like and elastic solid-like behavior. For example, these substances show partial elastic recovery recoil, creep, normal stress

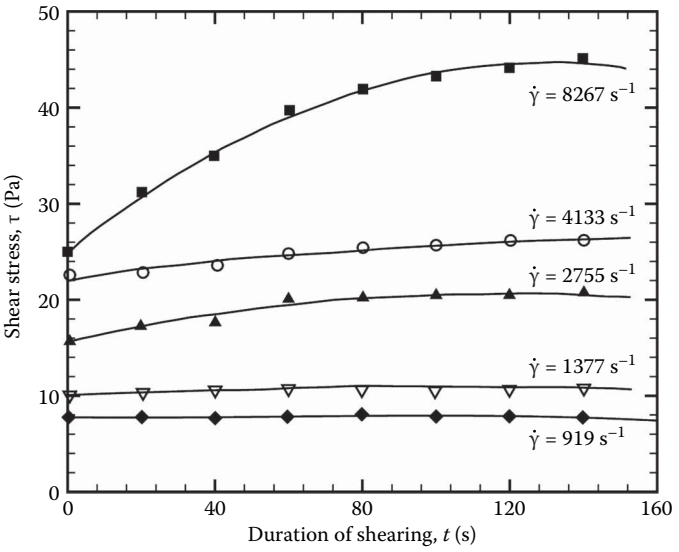

FIGURE 2.9.7 Rheopexy behavior in a saturated polyester. Replotted From Steg, I., Katz, D., J. *Appl. Polym. Sci.*, 9, 3177–3193, 1965.

effects, strain hardening, memory effects, etc. Accordingly, these are called viscoelastic or elastic-viscous. In a nutshell, the value of the shear rate ($\dot{\gamma}$) at a point in the fluid is determined by the current value of the stress as well as by the value of the stress in the past.

As noted earlier, while the foregoing classification is convenient, it is quite arbitrary because most real non-Newtonian fluids often display a combination of two or even all three types of characteristics under appropriate conditions, for example, most polymer solutions exhibit shear-dependent viscosity and viscoelastic behavior. Generally, it is, however, possible to identify the dominant non-Newtonian aspect and to use it as the basis for the process engineering design calculations. The ensuing discussion is mainly limited to the laminar and turbulent flow of time-independent fluids in ducts of circular and noncircular cross sections, followed by a short discussion about the viscoelastic effects in this flow situation. Detailed descriptions can be found in several books (Darby, 1976; Govier and Aziz, 1982; Bird et al., 1987; Chhabra and Richardson, 2008).

Types of Time-Independent Fluids and Constitutive Equations

For time-independent fluids, their steady shear behavior can evidently be described by a function, $g(\tau)$, of the form:

$$\dot{\gamma} = g(\tau). \tag{2.9.4}$$

Or, its inverse form,

$$\tau = g^{-1}(\dot{\gamma}). \tag{2.9.5}$$

Depending upon the form of these functions, three possibilities exist:

1. Shear-thinning or pseudoplastic behavior (Figure 2.9.5)
2. Shear-thickening or dilatant behavior (Figure 2.9.4)
3. Viscoplastic behavior with or without shear-thinning effects (Figure 2.9.8)

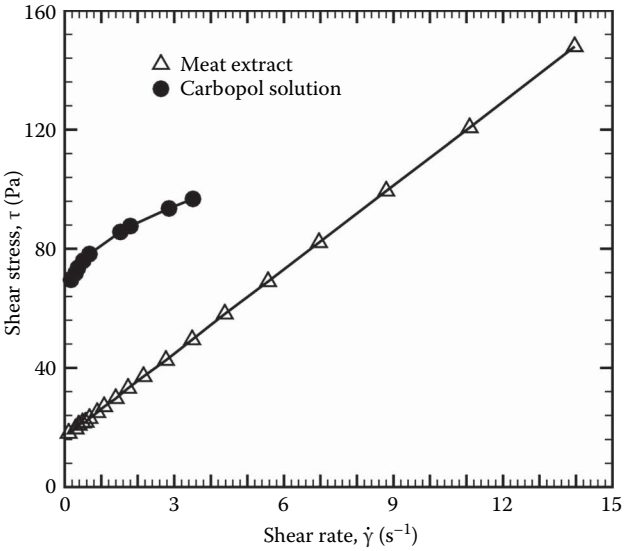

FIGURE 2.9.8 Representative shear stress–shear rate data showing viscoplastic behavior in a meat extract (Bingham plastic) and in an aqueous carbopol polymer solution (yield-pseudoplastic).

While these three possibilities are shown schematically in Figure 2.9.3, suffice it to add here that a viscoplastic substance deforms like an elastic solid for stress levels below its yield stress and it exhibits a constant (Bingham plastic) or shear-thinning (Herschel–Bulkley) viscosity for stress levels in excess of the fluid yield stress. Figure 2.9.8 shows viscoplastic behavior in a meat product and in an aqueous polymer solution. Though much confusion exists in the literature whether a true yield stress exists or not and/or about its measurement, the notion of an apparent yield stress has proved to be of value in approximating the flow behavior of many industrially important fluids (Barnes, 1999).

Rheological Equation of State

A constitutive equation (or the rheological equation of state) describes the response of a material to externally applied stress. Thus, Hooke's law of elasticity is a constitutive relation for an elastic solid, as is the ideal gas law for gases, or Equation 2.9.1 for a Newtonian fluid in unidirectional shearing flow. The literature abounds with many such relations for time-independent fluids entailing 2–6 (or even more) material constants.

From an engineering application standpoint, simpler (with fewer constants) constitutive relations are normally satisfactory as far as the prediction of pressure drop and pumping power for flow in pipes and conduits is concerned. In this context, four of the most popular models are considered here, namely, the power-law (or Ostwald de Waele) model and modifications thereof, and the Herschel–Bulkley model.

Power-Law Model

In simple shearing motion, the power-law fluid model is written as

$$\tau = K(\dot{\gamma})^n \tag{2.9.6}$$

or in terms of the apparent viscosity as

$$\mu = \frac{\tau}{\dot{\gamma}} = K(\dot{\gamma})^{n-1}, \tag{2.9.7}$$

where K and n are known as the power-law consistency coefficient (Pa·s^n) and the power-law behavior index, respectively. Naturally, $n = 1$ corresponds to Newtonian fluid behavior (Equation 2.9.1). For $n > 1$, Equation 2.9.7 predicts shear-thickening or dilatant behavior characterized by an increasing apparent viscosity with shear rate, as shown in Figure 2.9.4. Barnes (1989) has provided a thorough review of shear-thickening behavior in suspensions. For $n < 1$, Equation 2.9.6 predicts shear-thinning behavior, that is, decreasing apparent viscosity with shear rate. This is possibly the commonest type of time-independent fluid behavior exhibited by most polymeric fluids, suspensions and dispersions, as seen in Figure 2.9.5 (Chhabra and Richardson, 2008). Indeed, it is not uncommon to have the value of the power-law behavior index as small as $n = 0.15-0.2$ for some clay suspensions, for instance. At vanishingly small values of shear rate ($\dot{\gamma} \to 0.$), many polymer systems (solutions and melts) exhibit a constant viscosity (the so-called zero shear viscosity, μ_0) and clearly, the power-law model, given by Equation 2.9.6 or 2.9.7, leads to infinite viscosity in this limit for $n < 1$. For example, if one considers the flow of a pseudoplastic fluid ($n < 1$) through a circular duct, because of the symmetry, the shear rate (velocity gradient) becomes zero, and thus the apparent viscosity from Equation 2.9.6 becomes infinite, at the center of the pipe. This poses conceptual difficulties especially when performing numerical analyses on such systems. In this case, the power-law equation is not applicable and a more general constitutive equation is needed.

Modified Power-Law Constitutive Equation

Dunleavy and Middleman (1966) proposed a generalization of the power-law equation, which extends the shear rate range spanning the zero shear viscosity and onset of shear-thinning regimes, and is given by

$$\mu = \frac{\mu_0}{1 + \dfrac{\mu_0}{K}\dot{\gamma}^{1-n}}. \tag{2.9.8}$$

Examination of Equation 2.9.8 reveals that at low shear rates, the second term in the denominator becomes small compared with unity $\left(\text{i.e., } \mu_0 / K\dot{\gamma}^{n-1} << 1\right)$ and the apparent viscosity becomes constant equal to μ_0. This represents the Newtonian plateau at vanishingly low shear rates, as seen in Figure 2.9.5. On the other hand, as the second term in the denominator becomes large compared with unity, Equation 2.9.8 reduces to Equation 2.9.7 and represents the shear-thinning region or the power-law region.

An important advantage of the modified power-law equation is that it retains the rheological properties K and n of the power-law model plus the additional property μ_0. Thus, as will be shown later, in the flow and heat-transfer equations, the same dimensionless groups as in the power-law model will appear plus an additional dimensionless parameter which describes in which region (power-law or zero shear or both) a particular system is operating. Also, solutions using the modified power-law model will have Newtonian and power-law solutions as the limiting conditions.

Equation 2.9.8 describes the flow curve for a pseudoplastic fluid ($n < 1$). For a dilatant fluid, ($n > 1$), an appropriate modified power-law model is given by

$$\mu = \mu_0 \left[1 + \frac{K}{\mu_0}\dot{\gamma}^{n-1}\right] \tag{2.9.9}$$

Extended Modified Power-Law (EMPL) Constitutive Equation

For some non-Newtonian fluids, once the apparent viscosity transitions from Newtonian to power-law behavior, it follows the power-law model indefinitely as the shear rate increases. For such fluids, the modified power-law equation is appropriate. Other fluids at sufficiently high shear rates transition smoothly back to Newtonian behavior with a (constant) apparent viscosity, μ_∞, that is less than μ_0 for pseudoplastic fluids, and greater than μ_0 for dilatant fluids. Thus, constitutive equations for

such fluids necessarily require more parameters than μ_0, K, and n. A model that spans from the zero to the high shear rate Newtonian regions and that contains only one additional parameter, μ_∞, is the extended modified power-law constitutive equation. For pseudoplastic fluids, it is given by

$$\mu = \frac{\mu_0 - \mu_\infty}{1 + \frac{\mu_0}{K}\dot{\gamma}^{1-n}} + \mu_\infty . \tag{2.9.10}$$

This equation may be recognized as the Cross (1965) model except with the Cross parameters explicitly expressed in terms of K and n. An analogous equation for dilatant fluids is given by

$$\mu = \frac{\mu_\infty - \mu_0}{1 + \frac{\mu_\infty}{K}\dot{\gamma}^{1-n}} + \mu_0 . \tag{2.9.11}$$

It may be shown that from the zero shear rate Newtonian region through the power-law region, these equations follow the corresponding modified power-law models if μ_∞ differs sufficiently from μ_0 by four orders of magnitude or more. Otherwise, for more modest differences, the low and high shear rate transition regions merge to establish a smooth flow curve with a power-law region whose slope corresponds to an effective n that is closer to 1 than the physical value of n (Figure 2.9.9). The result is that flows of such fluids fail to reach power-law solutions even when all of the shear rates are in the power-law region.

Finally, it should be emphasized that when using analytical or numerical solutions, care needs to be exercised to ensure that the rheology model used in the solution matches the behavior of the fluid at hand. This is particularly true for dilatant fluids as their rheology may be more complicated

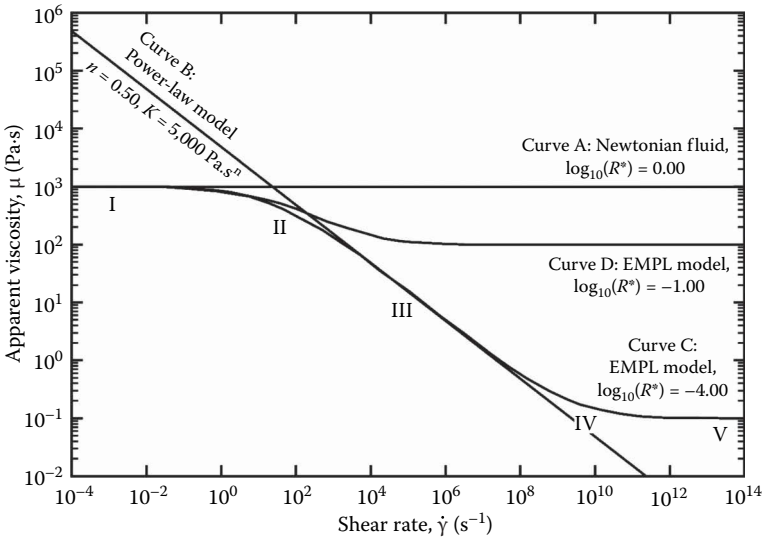

FIGURE 2.9.9 Flow curves of four related fluids. Curve A: a Newtonian fluid ($n=1$, $\log_{10} R^* = \log_{10}(\mu_\infty/\mu_0) = 0$) with a viscosity of 10^3 Pa·s. Curve B: a power-law model ($n=0.5$, $K = 5 \times 10^3$ Pa·s^n). Curve C: a strongly non-Newtonian pseudoplastic fluid ($n=0.5$, $K = 5 \times 10^3$ Pa·s^n, $\log_{10} R^* = -4.0$ and $\mu_0 = 10^3$ Pa·s) plotted using EMPL model, Equation 2.9.10. Also shown are the shear rate regimes: I-zero shear rate Newtonian region; II-low shear rate transition region; III-power-law region; IV-high shear rate transition region; V-high shear rate Newtonian region. Curve D: a weakly non-Newtonian pseudoplastic fluid ($n=0.5$, $K = 5 \times 10^3$ Pa·s^n, $\log_{10} R^* = -1.0$ and $\mu_0 = 10^3$ Pa·s). (From Capobianchi, M., Aziz, A., *ASME J. Heat Transfer*, 134, 122502, 2012. With permission.)

than what can be modeled by the above equations. For example, at low shear rates, dilatant fluids may first shear thin similar to a pseudoplastic fluid, then shear thicken as the shear rate increases and, after plateauing at a maximum apparent viscosity, begin to shear thin again as the shear rate increases further. Analytical and numerical solutions that use the above dilatant fluid equations would then be inapplicable or at best be only an approximation.

Viscoplastic Models

When a fluid exhibits both shear-thinning and yield stress characteristics, it is customary to use the Herschel–Bulkley viscosity model as

$$\tau = \tau_0 + K(\dot{\gamma})^n \quad |\tau| > |\tau_0|, \tag{2.9.12a}$$

$$\dot{\gamma} = 0 \quad |\tau| \le |\tau_0|, \tag{2.9.12b}$$

or, in terms of the apparent viscosity,

$$\mu = \frac{\tau}{\dot{\gamma}} = \frac{\tau_0}{\dot{\gamma}} + K(\dot{\gamma})^{n-1} \quad |\tau| > |\tau_0|, \tag{2.9.13a}$$

$$\mu \to \infty \quad |\tau| \le |\tau_0|. \tag{2.9.13b}$$

Though the Herschel–Bulkley fluid model, Equations 2.9.12 and 2.9.13, is a three parameter model similar to the modified power-law model, it contains several other viscosity equations as limiting cases. Firstly, for $n = 1$, it reduces to the familiar Bingham fluid model. For $\tau_0 = 0$, it reverts to the power-law model, Equation 2.9.7, and finally, for $n = 1$ and $\tau_0 = 0$, Newtonian fluid behavior is recovered.

These four models will now be used to study fully developed laminar and turbulent flow in circular and noncircular ducts in the following sections, especially with the objective of predicting the pressure drop in a given application.

Fully Developed Laminar Flow in a Tube

From a theoretical standpoint, one can combine Cauchy's momentum equation with a suitable constitutive equation for the extra stress tensor, τ, such as that given by Equation 2.9.6 or 2.9.12a, followed by an integration (and using the no-slip condition at the wall) to obtain the detailed velocity distribution across the pipe cross section. The resulting velocity distribution can be used to obtain expressions for the mean and maximum velocity, plug radius and velocity, etc., for a specific fluid model. A summary of the resulting expressions for a range of viscosity models is available in Skelland (1967), Govier and Aziz (1982), and Chhabra and Richardson (2008).

Herschel–Bulkley Fluids

It is useful to begin with the case of the Herschel–Bulkley fluid model, for it degenerates into various models under appropriate conditions. The volumetric flow rate, Q, for the Herschel–Bulkley model fluid is given by

$$Q = \pi R^3 n \left(\frac{\tau_w}{K}\right)^{1/n} (1-\phi)^{\frac{n+1}{n}} \left\{\frac{(1-\phi)^2}{(3n+1)} + \frac{2\phi(1-\phi)}{2n+1} + \frac{\phi^2}{n+1}\right\}, \tag{2.9.14}$$

where $\phi = (\tau_0 / \tau_w) < 1$ and $\tau_w = (\Delta p/L)(D/4)$ is the shear stress at the wall of the pipe. Evidently, for a given value of the pressure gradient $(\Delta p/L)$, one can readily calculate the corresponding flow

rate (Q). However, the reverse calculation (i.e., for a known value of Q) of ($\Delta p/L$) necessitates an iterative solution to Equation 2.9.14.

As noted above, Equation 2.9.14 can be reduced to the corresponding expression for power-law fluids by substituting $\phi = 0$ (i.e., $\tau_0 = 0$):

$$Q = \frac{\pi R^3 n}{(3n+1)}\left(\tau_w / K\right)^{1/n}. \tag{2.9.15}$$

It is customary to introduce the familiar Fanning friction factor, f as

$$f = \frac{\tau_w}{\left(1/2\right)\rho V^2} = \frac{\left(D\Delta p / 4L\right)}{\left(1/2\right)\rho V^2}. \tag{2.9.16}$$

Now, Equation 2.9.15 can be recast as

$$f = \frac{16}{Re_{PL}}, \tag{2.9.17}$$

where the corresponding Reynolds number, Re_{PL}, is defined as

$$Re_{PL} = \frac{\rho V^{2-n} D^n}{8^{n-1} K\left(\frac{3n+1}{4n}\right)^n}. \tag{2.9.18}$$

Equation 2.9.18 thus ensures that the friction factor values for power-law fluids coincide with the familiar expression of $f = (16/Re)$ for Newtonian fluids. In contrast, it is very cumbersome to organize Equation 2.9.14 in this form. However, for the case of the Bingham fluid ($n = 1$), Equation 2.9.14 reduces to

$$Q = \frac{\pi R^4}{8K}\left(\frac{-\Delta p}{L}\right)\left(1 - \frac{4}{3}\phi + \frac{1}{3}\phi^4\right). \tag{2.9.19}$$

This can be rearranged in terms of the friction factor f as

$$f = \frac{16}{Re_B}\left[1 + \frac{1}{6}\frac{He}{Re_B} - \frac{1}{3}\frac{He^4}{f^3 Re_B^7}\right], \tag{2.9.20}$$

where the Reynolds number, Re_B, and Hedstrom number, $He = Bi \cdot Re_B$, respectively, are defined as

$$Re_B = \frac{\rho VD}{K};\ He = \frac{\rho D^2 \tau_0}{K^2}. \tag{2.9.21}$$

A more convenient form of Equation 2.9.18 is given by

$$f \cdot Re_B = 16\left[1 + \frac{Bi}{6} - \frac{1}{3}\frac{Bi^4}{(fRe_B)^3}\right]. \tag{2.9.22}$$

Equation 2.9.22 suggests the product $f \cdot Re_B$ to be a function of the Bingham number, $Bi = \tau_0 D / KV$, only. Figure 2.9.10 shows a plot of Equation 2.9.22 where it is clearly seen that the value of $(f \cdot Re_B)$ veers away from the Newtonian value of 16 only for $Bi > 0.1$ or so. Evidently, the utility of Equation

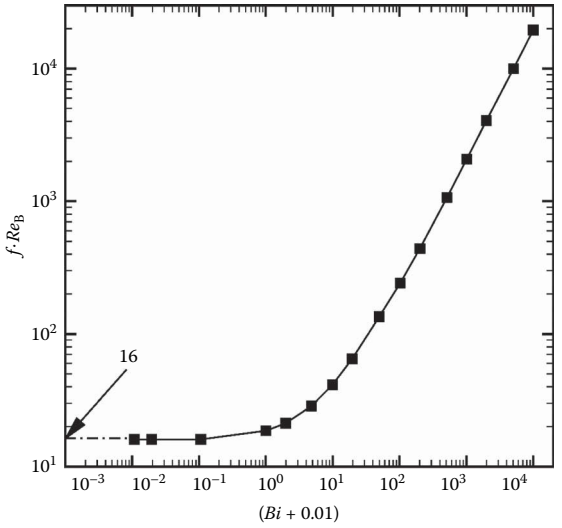

FIGURE 2.9.10 Effect of Bingham number on the value of $(f \cdot Re_B)$ as predicted by Equation 2.9.22.

(2.9.22) in practice is severely hampered due to the occurrence of the fourth order term. Ihle and Tamburrino (2012) have introduced the following two parameters to obtain appropriate explicit forms of Equation 2.9.22 as follows:

$$\alpha_1 = \frac{Bi}{Re_B};\ \alpha_2 = \frac{2}{Re_B}\left(\frac{Bi}{3} + 2\right). \tag{2.9.23}$$

The friction factor, f, is now given by

$$f = \alpha_2 + (\alpha_2^2 + \alpha_3)^{1/2} + \left[2\alpha_2^2\left\{1 + \left(1 + \frac{\alpha_3}{\alpha_2^2}\right)^{-1/2}\right\} - \alpha_3\right]^{1/2}, \tag{2.9.24}$$

where $\alpha_3 = \varepsilon_1 + \varepsilon_2$ when

$$\varepsilon_i = \frac{2}{3}\alpha_1^{4/3}\left\{\left(\frac{3}{2}\alpha_2\right)^2 + (-1)^i\left[\left(\frac{3}{2}\alpha_2\right)^4 - \alpha_1^4\right]^{1/2}\right\}^{1/3}. \tag{2.9.25}$$

Hence, ε_1 and ε_2 can be evaluated using Equation 2.9.25 by using $i=1$ and $i=2$, respectively. It needs to be emphasized here that for $\alpha_1=0$ (i.e., $Bi=0$), Equation 2.9.24 coincides with the expected limit of $f=16/\mathrm{Re}$ (Newtonian fluids). For a fixed value of the Reynolds number, Ihle and Tamburrino (2012) expanded Equation 2.9.24 around $Bi=0$ as

$$f \approx 4\alpha_2 - \frac{1}{12}\frac{\alpha_1^4}{\alpha_2^3} - \frac{1}{192}\frac{\alpha_1^8}{\alpha_2^7} - \cdots \tag{2.9.26}$$

Of course, Equation 2.9.26 is likely to work well for small values of Bingham number, but the error is only 10% at $Bi=10^4$. The main virtue of Equation 2.9.26 lies in its simplicity and the fact that one can calculate the value of the friction factor for given values of the Reynolds number and Bingham number without resorting to a trial-and-error procedure.

The corresponding development for the cases of the modified and extended modified power-law fluid models given by Equations 2.9.8 and 2.9.10 are presented next.

Modified Power-Law Model Fluids

For laminar fully developed flow of a modified power-law fluid in a circular duct, the product of the friction factor and a certain Reynolds number is a constant depending on the value of the flow index, n, and the shear rate parameter, β defined below, that is,

$$f \cdot Re_{\mathrm{m}} = \text{ constant } (n,\beta), \tag{2.9.27}$$

where f is the Fanning friction factor given by Equation 2.9.16, and Re_{m} is the modified power-law Reynolds number, that is,

$$Re_{\mathrm{m}} = \frac{\rho VD}{\mu^*}, \tag{2.9.28}$$

$$\mu^* = \frac{\mu_0}{1+\beta}, \tag{2.9.29}$$

$$\beta = \frac{\mu_0}{K}\left(\frac{V}{D}\right)^{1-n}. \tag{2.9.30}$$

β is the shear rate parameter mentioned previously which can be calculated by the designer for a given application (known values of V and D) and a certain pseudoplastic fluid (μ_0, K, n). The solution for a circular tube has been calculated by Brewster and Irvine (1987) and the results are shown in Figure 2.9.11 and in Table 2.9.1. Referring to Figure 2.9.11, we can see that when the values of $\log_{10}\beta$ is less than approximately –2, the duct is operating in the Newtonian ($\mu^* = \mu_0$) region. Note that in the Newtonian region, $\mathrm{Re_m}$ also reverts to the Newtonian Reynolds number.

When the value of $\log_{10}\beta$ is approximately in the range $-2 \le \log_{10}\beta \le 2$, the duct is operating in the transition region, that is, the Newtonian and shear-thinning region, and the values of $f \cdot Re_{\mathrm{m}}$ must be obtained from Figure 2.9.11 or from Table 2.9.1.

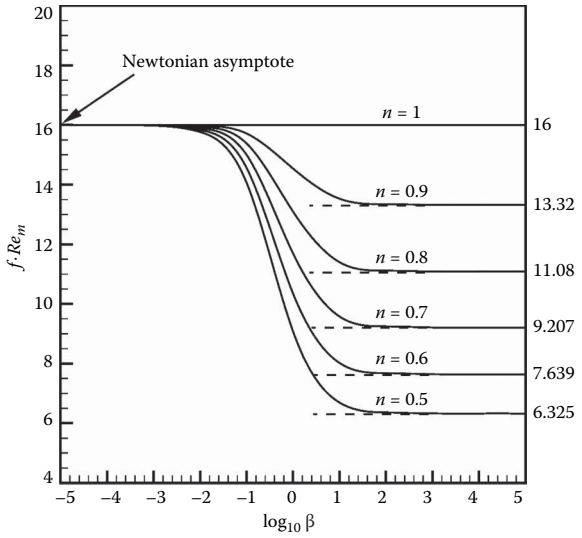

FIGURE 2.9.11 Product of friction factor and modified Reynolds number vs. $\log_{10}\beta$ for a circular duct. (Modified from Brewster, A.A. and Irvine, T.F., *Wärme und Stoffübertragung*, 21, 83–86, 1987.)

Source: Brewster, A.A. and Irvine, T.F., *Wärme und Stoffübertragung*, 21, 83–86, 1987.

For $\log_{10} \beta > \sim 2$, the duct is operating completely in the power-law region and in this case the power-law friction factor–Reynolds number relations can be used, given by Equations 2.9.17 and 2.9.18. In this region, Re_m becomes the power-law Reynolds number given by

$$Re_g = \frac{\rho V^{2-n} D^n}{K}. \tag{2.9.31}$$

For convenience, Brewster and Irvine (1987) have presented the following correlation which agrees within 0.1% with the results tabulated in Table 2.9.1:

$$f \cdot Re_m = \frac{4(1+\beta)}{\frac{1}{64} + \frac{\beta}{2^{2n+3}\left(\frac{3n+1}{4n}\right)^n}}. \tag{2.9.32}$$

Thus, Equation 2.9.32 contains all of the information required to calculate the circular tube laminar fully developed pressure drop for a pseudoplastic fluid depending upon the shear rate region(s) under consideration. Note that in scaling such non-Newtonian systems, both Re_m and β must be held constant. Modified power-law solutions have been reported for two other duct shapes. Park et al. (1993) have presented the friction factor–Reynolds number relations for rectangular ducts and Capobianchi and Irvine (1992) for concentric annular ducts.

Extended Modified Power-Law Model Fluids

Solutions for the friction factor-modified Reynolds number product using the extended modified power-law models are generally functions of three parameters: the flow index, n, a shear rate parameter, β^*, and the ratio of the limiting Newtonian viscosities, R^*, defined by

$$\beta^* = \frac{1+\beta}{1+\beta_\infty}; \; R^* = \frac{\beta_\infty}{\beta} = \frac{\mu_\infty}{\mu_0}, \tag{2.9.33}$$

Here, β is defined by Equation 2.9.30 above, and β_∞ is defined similarly except with μ_0 replaced by μ_∞. For solutions that use the extended modified power-law equations, β^* serves the analogous role to that of β above. Namely, β^* determines the shear rate region where the system is operating. β^* may be shown to range from 1 to $1/R^*$ for pseudoplastic fluids, and from $1/R^*$ to 1 for dilatant fluids. At the left endpoint of these ranges, the system is operating in the low shear rate Newtonian region, whereas it is in the high shear rate Newtonian region at the right endpoint. Hence, solutions at the endpoints approach Newtonian values. At the midpoint of the $\log_{10}(\beta^*)$ range, the system may be shown to be operating in the power-law region. Values then approach power-law values, but only if, in addition, μ_∞ differs from μ_0 by approximately four orders of magnitude or more. Otherwise, even when operating in the power-law region, values for fluids with smaller differences in their limiting viscosities fall between the power-law and Newtonian values, approaching the latter as $R^* \to 1$. This behavior is a direct consequence of the effective n discussed above departing further from the physical value of n and approaching 1 as $\mu_\infty \to \mu_0$ (i.e., $R^* \to 1$). Finally, when β^* is to the left or right of the midpoint of the $\log_{10}(\beta^*)$ range (excluding the endpoints), the system is operating in the low or high shear rate transition region, respectively. Results are then again between the Newtonian and power-law asymptotes. This behavior may be clearly seen in the square duct solutions shown in Figure 2.9.12 from Capobianchi (2008).

Solutions for the Darcy friction factor-modified Reynolds number product for laminar, hydrodynamically fully developed flows within ducts using the extended modified power-law models have appeared in the literature. Capobianchi (2008) solved the rectangular channel problem, including the parallel-plate duct, and provided correlation equations for the results. Similarly, Brewster (2013) solved the circular tube problem and also provided correlation equations. That study used the nondimensionalization scheme described above but defined an additional parameter, a dimensionless

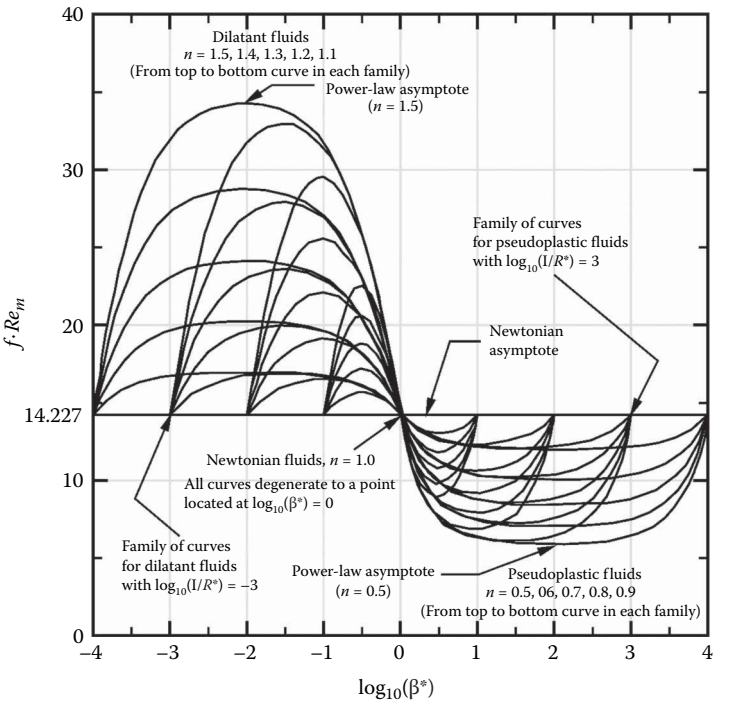

FIGURE 2.9.12 Fanning friction factor-modified Reynolds number product for laminar flow in the hydrodynamically fully developed region of a square duct with selected features indicated. (Modified from Capobianchi, M., *Int. J. Heat Mass Transfer*, 51, 1393–1401, 2008. With permission.)

reference viscosity, that is a function of only β^* and R^*, and whose range is 0–1. Results were displayed as a function of this parameter rather than β^* directly. Details may be found in the aforementioned references. Additional studies using the extended modified power-law models that include heat transfer and buoyancy-induced flows may be found in Section 3.2.4.

At this juncture, it is worthwhile to make two observations: the foregoing approaches are based on the choice of a specific viscosity model (power-law, or Bingham plastic, or Herschel–Bulkley, etc.). The material parameters appearing in these equations (n, K, τ_0, μ_0, μ_∞ or others) must be evaluated from the shear stress–shear rate data obtained using rheometers like a Couette cell, cone and plate, parallel plate or a capillary viscometer, for instance. The measurement of such data is detailed in several excellent books on rheometry (Whorlow, 1992; Macosko, 1994; Coussot, 2005). Bearing in mind that most non-Newtonian substances are characterized by the presence of transient structures (bubbles, droplets, flocs, micelles, aggregates and clusters of fine particles, entangled polymer molecules, for instance), such measurements are far from being straight forward. Some useful tips in this regard can be found in Coussot (2005) and Chhabra and Richardson (2008). Secondly, the preceding discussion necessitates *a priori* selection of a specific viscosity model. It is, however, possible to defer this choice to a later stage by developing a generalized approach for the laminar flow of time-independent fluids in a tube.

In the next section, we outline a generalized approach to estimate the pressure gradient in a pipe for the laminar flow of purely viscous fluids which will be subsequently extended to the case of noncircular ducts.

Generalized Approach for Laminar Flow of Purely Viscous Fluids

For the fully developed, steady and incompressible flow of a purely viscous fluid, the shear stress τ varies linearly with the radial position from being zero at the center of the pipe to its maximum value τ_w at the wall of the pipe. This combined with the general form of Equation 2.9.4 is possible to derive the following relationship (Chhabra and Richardson, 2008):

$$Q = \frac{\pi R^3}{\tau_w^3} \int_0^{\tau_w} \tau^2 g(\tau)\, d\tau. \tag{2.9.34}$$

Without assuming a specific form of the viscosity model, $g(\tau)$, one can deduce the following expression for the true shear rate at the tube wall:

$$\dot{\gamma}_w = \left(\frac{8V}{D}\right)\left(\frac{3n'+1}{4n'}\right), \tag{2.9.35}$$

where

$$n' = \frac{\log \tau_w}{\log\left(\dfrac{8V}{D}\right)}.$$

One can readily evaluate the value of n' by using the pressure gradient ($\tau_w = (D/4)(\Delta P / L)$)-volumetric flow rate ($8V / D$) information obtained using small diameter tubes. Naturally, $n' = 1$ denotes the case of Newtonian fluid behavior, $n' < 1$ corresponds to shear thinning, and finally, $n' > 1$ pertains to shear thickening or dilatant behavior. In the absence of end and slip effects, such a curve ($\log \tau_w$ vs. $\log 8V/D$) is unique irrespective of the pipe diameter as long as the laminar flow regime occurs. Over the range of shear rates over which n' is approximately constant, one can write a power-law type equation for this segment of the flow curve as

$$\tau_w = K' \left(\frac{8V}{D}\right)^{n'}. \tag{2.9.36}$$

Combining Equation 2.9.36 with the definition of the fanning friction factor, f, one obtains

$$f = \frac{16}{Re_{\text{gen}}}, \tag{2.9.37}$$

where the generalized Reynolds number, Re_{gen}, (also known as the Metzner–Reed Reynolds number) is defined as

$$Re_{\text{gen}} = \frac{\rho D^{n'} V^{2-n'}}{8^{n'-1} K'} = \frac{\rho VD}{\mu_{\text{eff}}}. \tag{2.9.38}$$

And, in turn, the effective viscosity, μ_{eff}, is given by

$$\mu_{\text{eff}} = K'\left(\frac{8V}{D}\right)^{n'-1}. \tag{2.9.39}$$

The similarity between Equations 2.9.39 and 2.9.7 is striking, except for the fact that n and K are true power-law constants whereas n' and K' appearing in Equation 2.9.36 are apparent constants because $\left(8V/D\right)$ is only the nominal (exact for Newtonian fluids) shear rate at the pipe wall. We conclude this section by noting the following relationships between n' and K' and the true rheological constants (Chhabra and Richardson, 2008).

For power-law model:

$$n = n';\ K' = K\left(\frac{3n+1}{4n}\right)^n. \tag{2.9.40}$$

For Bingham plastic model:

$$K' = \tau_w\left[\frac{K}{\tau_w\left(1-\frac{4}{3}\phi+\frac{\phi^4}{3}\right)}\right]^{n'}. \tag{2.9.41}$$

Similar correspondence can be established for any other viscosity model following the procedure outlined by Steffe (1996) and Chhabra and Richardson (2008).

Laminar Flow in Noncircular Ducts

Tubes of noncircular cross sections are finding increasing applications in the novel design of heat exchangers, heat sources and sinks used in electronic component cooling applications. Notwithstanding the significance of the detailed velocity profiles, it is readily conceded that the prediction of the pressure drop to sustain a given flow rate of a fluid with known rheology is the key parameter in such applications. While it is possible to solve the momentum equations to obtain the velocity profiles, secondary flows, etc., much effort has been expended in developing reliable schemes for the prediction of pressure drop in noncircular ducts. Perhaps the earliest attempt is that of Kozicki et al. (1967) who introduced two geometric parameters (a, b) characterizing the shape of the noncircular duct whose values can be evaluated using experimental throughput-pressure drop data or from analysis for a Newtonian fluid in the same duct. The values of a and b are assumed to be independent of the fluid rheology and extensive comparisons between the predictions and observations in wide-ranging shapes of duct (square, rectangular, triangular, elliptical, semicircular, for instance) indicate this to be a reasonable approximation, at least for purely viscous fluids (Chhabra

and Richardson, 2008). The values of a and b combined with the introduction of the familiar hydraulic diameter, D_h, allow the generalized Reynolds number for power-law fluids to be recast as

$$Re_g = \frac{\rho V^{2-n} D_h^n}{8^{n-1} K \left(b + \frac{a}{n} \right)^n}, \tag{2.9.42}$$

and in the laminar flow region, the Fanning friction factor, $f = 16/Re_{gen}$ applies. The values of the geometric parameters (a, b) for a range of shapes are listed in Table 2.9.2. The validity of this approach has been demonstrated extensively, for example, see Chhabra and Richardson (2008). Some further attempts have been made to improve upon the initial proposition of Kozicki et al. (1967). For instance, Delplace and Leuliet (1995) demonstrated that the two parameters a and b can be effectively reduced to one parameter, β_0, defined as follows:

$$\beta_0 = \frac{48}{f \cdot Re}, \tag{2.9.43}$$

$$a = \frac{1}{1+\beta_0}; \; b = \frac{\beta_0}{1+\beta_0}. \tag{2.9.44}$$

The value of β_0 can be estimated simply from the knowledge of the so-called Poiseuille number, that is, $f \cdot Re$ for Newtonian fluids. However, this approach presumes that the values of a and b always add up to 1 which results in some loss of accuracy. It is also worthwhile to add here that some researchers (Muzychka and Edge, 2008) have argued that the use of $\sqrt{A}$, where A is the flow area, as the characteristic linear dimension together with an aspect ratio as opposed to the use of the hydraulic diameter in conjunction with geometric parameters (a, b) leads to equally good predictions of the friction factor for power-law fluids in noncircular ducts.

Turbulent Flow in Circular and Noncircular Ducts

The prediction of pressure gradient in the turbulent flow of even purely viscous fluids is far more difficult than that for Newtonian fluids. The main difficulty stems from the fact that while $\tau_w = (D/4)(\Delta p / L)$ still gives the true value of the wall shear stress, the corresponding shear rate cannot be evaluated. In a pioneering study, Dodge and Metzner (1959) combined dimensional considerations with experimental data for a series of non-Newtonian fluids (purely viscous) to put forward the following correlation for friction factor for smooth circular pipes:

$$\frac{1}{\sqrt{f}} = \frac{4}{(n')^{3/4}} \log \left[Re_{gen} f^{(2-n')/2} \right] - \frac{0.4}{(n')^{1.2}}. \tag{2.9.45}$$

Equation 2.9.45 is plotted in Figure 2.9.13. Three observations about Equation 2.9.45 are in order at this juncture. First, Equation 2.9.45 reduces to the familiar Nikuradse equation for Newtonian fluids, that is, $n' = 1$. Second, the limited numerical results on the turbulent flow of power-law fluids in circular tubes are in line with these predictions thereby lending support to the validity of Equation 2.9.42 (Rudman et al., 2004; Gnambode et al., 2015). Finally, attention is drawn to the fact that the values of n' and K' appearing in the definition of the Re_{gen} and in Equation 2.9.45 need to be evaluated from the laminar $\tau_w - (8V/D)$ data spanning up to the expected range of τ_w value in the turbulent flow conditions. This constrains the applicability of this method rather severely. Irvine (1988), on the other hand, put forward the following explicit expression for friction factor:

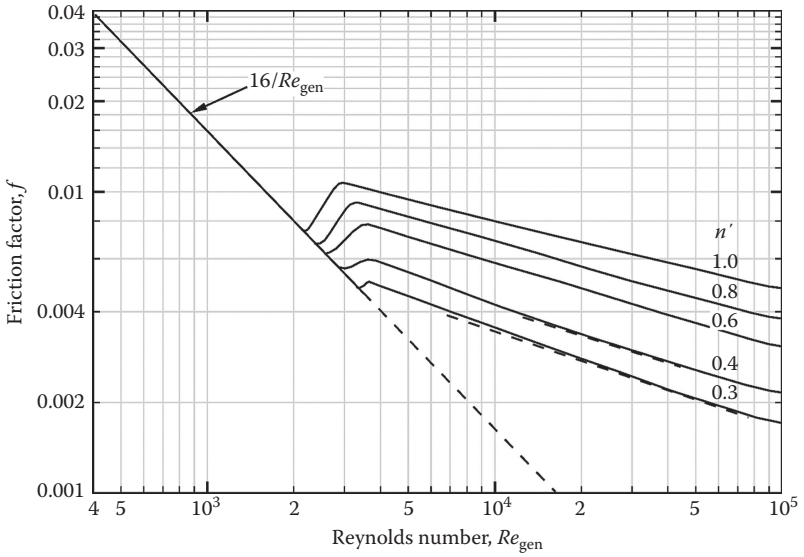

FIGURE 2.9.13 Friction factor–Reynolds number behavior for time-independent fluids as predicted by Equation 2.9.45.

$$f = \mathrm{F}(n) Re_{\mathrm{gen}}^{-\frac{1}{3n+1}}, \tag{2.9.46}$$

where $$\mathrm{F}(n) = \frac{2^{n+4}}{7^{7n}} \left(\frac{4n}{3n+1} \right)^{3n^2}$$

Both Equations 2.9.45 and 2.9.46 predict the value of friction factor with an accuracy of ~8–10% over the range of conditions as $\sim 0.35 \le n' \le 1$ and $Re_{\mathrm{gen}} \le 5 \times 10^4$. Further detailed discussion of the comparative performance of these as well as the numerous other friction factor correlations are available in the literature (Heywood and Cheng, 1984; Chhabra and Richardson, 2008; van den Heever et al., 2014).

For the case of Bingham plastic fluids in circular tubes, the following method due to Darby et al. (1992) has been shown to be reliable. In this approach, a weighted average friction factor is used as

$$f = \left(f_{\mathrm{L}}^{e} + f_{\mathrm{T}}^{e} \right)^{1/e}, \tag{2.9.47}$$

where f_{L} is given by the solution of the laminar expression, Equation 2.9.20 or 2.9.22, and the value of f_{T} is obtained from the following equation:

$$f_T = 10^{a_0} Re_{\mathrm{B}}^{-0.193}, \tag{2.9.48}$$

where

$$a_0 = -1.47 \left[1 + 0.146 \exp\left(-2.9 \times 10^{-5} He \right) \right], \tag{2.9.49}$$

and

$$e = 1.7 + \frac{4 \times 10^4}{Re_{\mathrm{B}}}. \tag{2.9.50}$$

This empirical formulation has been tested over wide range of conditions as $D \leq 335\,\text{mm}$, $10^3 \leq He \leq 6.6 \times 10^7$, and $Re_B \leq 3.4 \leq 10^5$.

Using the geometric parameters a and b, Equation 2.9.45 has also been extended to the turbulent flow of viscous fluids in noncircular ducts as

$$\frac{1}{\sqrt{f}} = \frac{4}{(n')^{3/4}} \log\left(Re_{gen} f^{(2-n')/2} \right) - \frac{0.4}{(n')^{1.2}} + 4(n')^{1/4} \log\left\{ \frac{4(a+bn')}{3n'+1} \right\}. \tag{2.9.51}$$

The limited experimental data available for flow in triangular, rectangular, and square ducts are in agreement with Equation 2.9.51 (Chhabra and Richardson, 2008). This section is concluded by noting that the value of $Re_{gen} <\sim 2100$ does seem to provide a conservative estimate of the cessation of the laminar flow regime both in circular and noncircular ducts for purely viscous fluids.

Effect of Viscoelasticity

In spite of the fact that much confusion exists in the literature concerning the role of fluid elasticity on pipe flow characteristics, some general inferences can, however, be drawn. In the laminar flow regime, the friction factor–Reynolds number relationships discussed in the preceding section are not influenced by the elasticity. However, for noncircular ducts, viscoelastic effects manifest itself in the form of recirculating regions (vortex formation) for certain shapes, though this does not appear to influence significantly the value of pressure gradient. In contrast, fluid elasticity gives rise to the well-known drag reduction effect under turbulent flow conditions in circular pipes. Indeed, it is possible to lower the pumping power requirements by up to 85% by simply adding trace amounts (parts per million) of high molecular weight polymers to a solvent (mostly water) under appropriate conditions in terms of the Reynolds number. Numerous hypotheses have been put forward to explain this phenomena (also known as the Toms effect), but none has proved to be completely satisfactory (Sellin et al., 1982; Gyr and Bewersdorff, 1995). Dosages of polymers (like polyethylene oxide, polyacrylamide, etc.) as small as 5 ppm can yield significant drag reduction, as shown in Figure 2.9.14 for polyethylene oxide polymer. Though initially the degree of drag reduction increases with

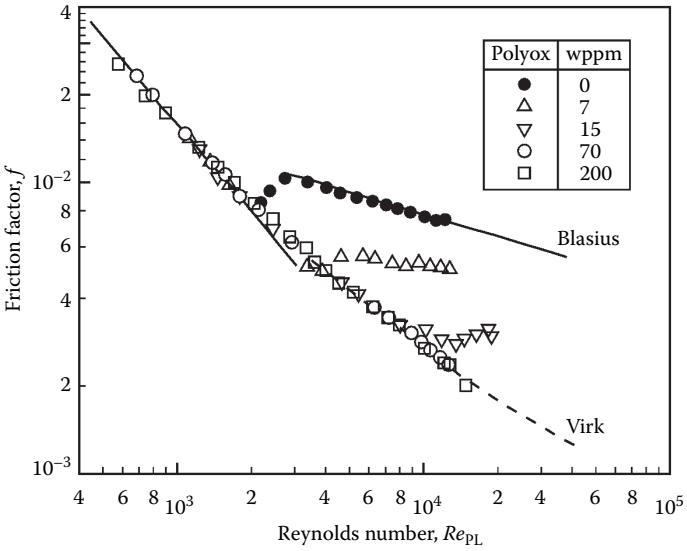

FIGURE 2.9.14 Drag reduction in friction factors for polyethylene oxide (Polyox) solutions in a small-diameter capillary tube. (From Cho, Y.I., Harnett, J.P., *Adv. Heat Transfer*, 15, 59–141, 1982. With permission.)

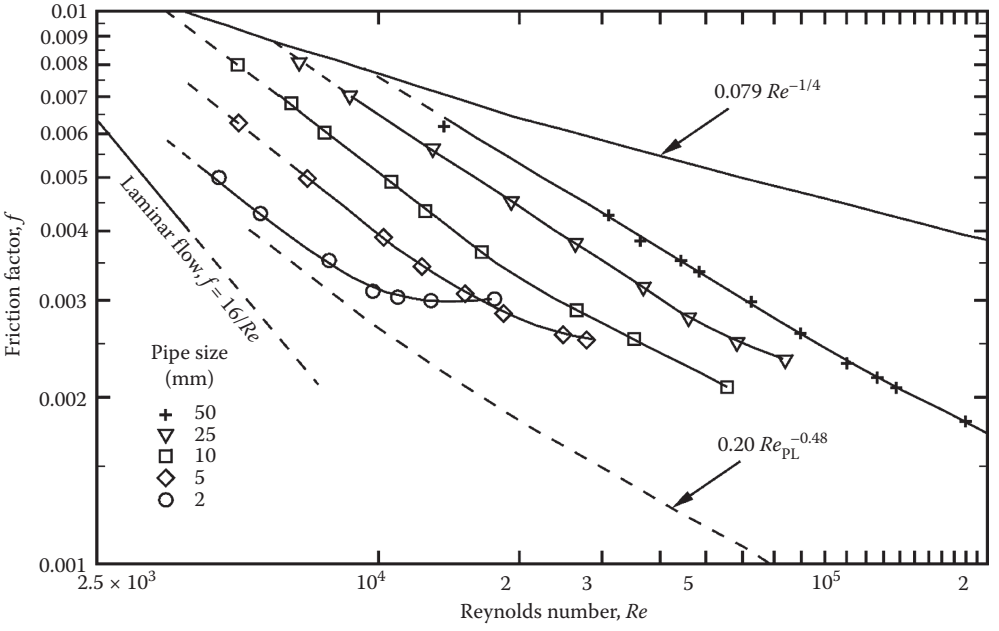

FIGURE 2.9.15 Effect of pipe diameter on friction factor (drag reduction) –10 wppm solutions of Alcomer 110L in water in pipes of various diameters. (From Hayes, J.W., Hutton, J.F., *Prog. Heat Mass Transfer*, 5, 195–209, 1972. With permission.)

polymer concentration (which varies from one polymer to another depending upon its molecular weight and architecture, and in some cases even with the pipe diameter, for instance), it reaches the so-called Virk's maximum drag reduction limit as seen in Figure 2.9.14. On the other hand, the effect of pipe diameter on drag reduction is depicted in Figure 2.9.15.

As of now, no reliable mechanism and/or predictive expression is available for predicting drag reduction quantitatively. Suffice it to add here, however, that the value of friction factor has an upper bound given by Blasius equation (pure water) $f = 0.079Re^{-1/4}$ and the lower bound is given by the Virk's maximum drag reduction asymptote approximated as $f = 0.20\,Re_{PL}^{-0.48}$.

However, no satisfactory information is currently available either to predict the onset or the extent of drag reduction in general (Gyr and Bewersdorff, 1995). In summary, our current understanding of the effect of viscoelasticity in turbulent flow regime in circular pipes is nowhere near as extensive or coherent as that for Newtonian fluids.

Nomenclature

A	Flow area, m^2
a, b	Geometric parameters, Equation 2.9.44, dimensionless
a_0	Constant, Equation 2.9.49, dimensionless
Bi	Bingham number (= $\tau_0 D / KV$), dimensionless
c	Duct width in Kozicki et al. (1967) approximation, Table 2.9.2, m
d_i	Concentric duct inner diameter in Kozicki et al. (1967) approximation, Table 2.9.2, m
d_0	Concentric duct outer diameter in Kozicki et al. (1967) approximation, Table 2.9.2, m
D	Pipe diameter, m

D_h	Hydraulic diameter (= 4 × A / wetted perimeter), m
e	Constant, Equation 2.9.47, dimensionless
f	Fanning friction factor, Equation 2.9.16, dimensionless
f_L	Fanning friction factor in laminar regime, dimensionless
f_T	Fanning friction factor in turbulent regime, dimensionless
$F(n)$	Function of n in Equation 2.9.46, dimensionless
$g(\tau)$	Shear rate function, s^{-1}
h	Duct height in Kozicki et al. (1967) approximation, Table 2.9.2, m
He	Hedstrom number, Equation 2.9.21, dimensionless
i	Index in Equation 2.9.25, dimensionless
K	Viscosity model parameter, Equation 2.9.6 and Equation 2.9.12a, Pa·s^n
K'	Apparent consistency coefficient, Equation 2.9.36, Pa·s^n
L	Pipe length, m
N	Number of sides in polygon duct in Kozicki et al. (1967) approximation, Table 2.9.2, dimensionless
N_1	First normal stress difference, Equation 2.9.3, Pa
N_2	Second normal stress difference, Equation 2.9.3, Pa
n	Viscosity model parameter, Equations 2.9.6 and 2.9.12a, dimensionless
n'	Apparent power-law index, Equation 2.9.36, dimensionless
p	Pressure, Pa
$\Delta p / L$	Pressure gradient, Pa/m
Q	Volumetric flow rate, m^3/s
R	Pipe radius, m
R*	Limiting viscosity ratio, μ_∞/μ_0, dimensionless
Re	Newtonian Reynolds number, dimensionless
Re_B	Bingham Reynolds number, Equation 2.9.21, dimensionless
Re_g	Power-law Reynolds number, Equation 2.9.31, dimensionless
Re_{gen}	Generalized Reynolds number, Equation 2.9.38, dimensionless
Re_m	Modified Reynolds number, Equation 2.9.28, dimensionless
Re_{PL}	Power-law Reynolds number, Equation 2.9.18, dimensionless
$\underline{\underline{S}}$	Stress tensor, Pa
t	Time, s
T	Temperature, K
V	Average velocity, m/s
V_x	x-Component of velocity, m/s
x, y, z	Cartesian coordinates

Greek Letters

α_1, α_2, α_3	Parameters, Equation 2.9.23, dimensionless
α^*	Geometric parameter in Kozicki et al. (1967) approximation, Table 2.9.2, dimensionless
β	Shear rate parameter based on μ_0, Equation 2.9.30, dimensionless
β_0	Constant, Equation 2.9.43, dimensionless
β_∞	Shear rate parameter, same as Equation 2.9.30 except based on μ_∞, dimensionless
β^*	Shear rate parameter, dimensionless
$\dot{\gamma}$	Rate of shear, s^{-1}
$\dot{\gamma}_{ij}$	Component of rate-of-strain tensor, s^{-1}

$\dot{\gamma}_w$	Rate of shear at the duct wall, s^{-1}
ε_i	Constants, Equation 2.9.25, dimensionless
θ	Vertex angle in isosceles duct in Kozicki et al. (1967) approximation, Table 2.9.2, degrees
μ	Viscosity, Pa·s
μ_{eff}	Effective viscosity, Pa·s
μ_0	Zero shear rate viscosity, Pa·s
μ_∞	Infinite shear rate viscosity, Pa·s
μ^*	Reference viscosity, Equation 2.9.29, Pa·s
ρ	Density, kg/m^3
τ	Extra stress tensor, Pa
τ_{ii}	Normal component of extra stress tensor, Pa
τ_{ij}	Shearing component of extra stress tensor, Pa
τ_0	Yield stress, Pa
τ_w	Wall shear stress, Pa
ϕ	Ratio $\left(= \tau_0 / \tau_w\right)$, dimensionless

Further Information

While it is not possible to include all of the interesting topics relating to non-Newtonian fluids in a Handbook like this one, some relevant references are indicated here. Cho and Hartnett (1982), Irvine and Karni (1987), and Lawal and Mujumdar (1989) have provided overviews of duct flows with and without heat transfer. External boundary layer type flows have been treated by Chhabra (2006, 2011) and by Ghosh et al. (1994). Momentum and heat-transfer characteristics in mechanically agitated vessels has been dealt with by Chhabra (2003). Non-Newtonian effects in porous media and particulate flows are reviewed by Chhabra (2006).

3.1 CONDUCTION HEAT TRANSFER

Robert F. Boehm

Introduction

Conduction heat-transfer phenomena are found virtually throughout the physical world and the industrial domain. The analytical description of this heat-transfer mode is one of the best understood processes. Some of the bases of the understanding of conduction date back to early history. It was recognized that by invoking certain relatively minor simplifications, mathematical solutions resulted directly. Some of these were easily formulated. What transpired over the years was a vigorous development of applications to a broad range of processes. Perhaps no single work better summarizes the wealth of these studies than does the book by Carslaw and Jaeger (1959). It provides solutions to a broad range of problems, ranging from topics related to the cooling of the earth to the current-carrying capacities of wires. The general analyses given there have been applied to a range of modern-day problems from laser heating to temperature control systems.

Today, conduction heat transfer is still an active area of research and application. A great deal of interest has been shown in recent years in topics like contact resistance—where a temperature difference develops between two solids that do not have perfect contact with each other. Additional issues of current interest include non-Fourier conduction, where the processes occur so fast that the equations described later do not apply. Also, the problems related to transport in miniaturized

systems are garnering a great deal of interest. Increased interest has also been focused on ways of handling composite materials, where the ability to conduct heat is very directional.

Much of the work in conduction analysis is now accomplished by the use of sophisticated computer codes. These tools have given the heat-transfer analyst the capability to solve problems in inhomogeneous media with very complicated geometries and with very involved boundary conditions. It is still important to understand analytical methods for determining the performance of conducting systems. At the minimum, these can be used as calibrations for numerical codes.

Fourier's Law

The basis of conduction heat transfer is *Fourier's law.* This law involves the idea that the heat flux is proportional to the temperature gradient in any direction *n*. *Thermal conductivity*, *k*, a property of materials that is temperature dependent, is the constant of proportionality:

$$q_k = -kA\frac{\partial T}{\partial n} \tag{3.1.1}$$

In many systems, the area A is a function of the distance in the direction n. One important extension is that this can be combined with the first law of thermodynamics to yield the *heat conduction equation*. For constant thermal conductivity, this is given as follows:

$$\nabla^2 T + \frac{\dot{q}_G}{k} = \frac{1}{\alpha}\ \frac{\partial T}{\partial t} \tag{3.1.2}$$

where α is the thermal diffusivity and $\dot{q}_G$ is the internal heat generation per unit volume. Some problems, typically steady-state, one-dimensional formulations where only the heat flux is desired, can be easily solved using Equation 3.1.1. Most conduction analyses are performed with Equation 3.1.2. In the latter—a more general approach—the temperature distribution is found from this equation and the appropriate boundary conditions. Then the heat flux, if desired, is found at any location using Equation 3.1.1. Normally, it is the temperature distribution that is of most importance. For example, it may be desirable to determine through analysis if a material will reach some critical temperature, like its melting point. Less frequently, the heat flux is the desired objective.

While there are times when one needs only to understand the temperature response of a structure, often the engineer is faced with a need to increase or decrease heat transfer to some specific level. Examination of the thermal conductivity of materials gives some insight to the range of possibilities that exist through simple conduction.

Of the more common engineering materials, pure copper exhibits one of the highest abilities to conduct heat, with a thermal conductivity approaching 400 W/m^2 K. Aluminum, also considered to be a good conductor, has a thermal conductivity a little over half that of copper. In order to increase the heat transfer above the values possible through simple conduction, more sophisticated designs are necessary that incorporate a variety of other heat-transfer modes like convection and phase change.

Decreasing the rate of heat transfer is accomplished with the use of insulation. A discussion of this follows.

Insulations

Insulating materials are used to decrease heat flow and thus decrease surface temperatures. These materials are found in a variety of forms, typically *loose fill, batt*, and *rigid*. Even a gas, like air, can be a good insulator if it can be kept from moving when it is heated or cooled. A vacuum is an excellent insulator. Usually, though, the engineering approach to insulation is the addition of a

low-conducting material to the surface. While there are many chemical forms, costs, and maximum operating temperatures of common types of insulators, it seems that when higher operating temperatures are required, the thermal conductivity and cost of the insulation will often also be higher.

Loose-fill insulation includes such materials as milled alumina-silica (maximum operating temperature of 1260°C and thermal conductivities in the range of 0.1–0.2 W/m^2 K) and perlite (maximum operating temperature of 980°C and thermal conductivities in the range of 0.05–1.5 $W/m^2 \cdot K$). Batt-type insulation includes one of the more common types—glass fiber. This type of insulation comes in a variety of densities which, in turn, have a profound effect on the thermal conductivity. Thermal conductivities for glass fiber insulation can range from about 0.03 to 0.06 W/m^2 K. Rigid insulations show a very wide range of types and performance characteristics. For example, a rigid insulation in foam form, polyurethane, is light in weight, shows a very low thermal conductivity (about 0.02 W/m^2 K), but has a maximum operating temperature only up to about 120°C. Rigid insulations in refractory form show quite different characteristics. For example, alumina brick is quite dense, has a thermal conductivity of about 2 $W/m^2 \cdot K$, but can remain operational to temperatures around 1760°C. Many insulations are characterized in the book edited by Guyer (1989).

Often, commercial insulation systems designed for high-temperature operation use a layered approach. Temperature tolerance may be critical. Perhaps a refractory material is applied in the highest temperature region, an intermediate-temperature foam insulation is used in the middle section, and a high-performance, lower operating-temperature insulation is used on the outer side near ambient conditions.

Analyses can be performed showing the effects of temperature variations of thermal conductivity. However, the most frequent approach is to assume that the thermal conductivity is constant at some temperature between the two extremes experienced by the insulation.

Plane Wall at Steady State

Consider steady-state heat transfer in a plane wall of thickness L, but of very large extent in both other directions. The wall has temperature T_1 on one side and T_2 on the other. If the thermal conductivity is considered to be constant, then Equation 3.1.1 can be integrated directly to give the following result:

$$q_k = \frac{kA}{L}\left(T_1 - T_2\right) \tag{3.1.3}$$

This can be used to determine the steady-state heat transfer through slabs.

An electrical circuit analog is widely used in one dimensional conduction analyses. This is accomplished by considering the temperature difference to be analogous to a voltage difference, the heat flux to be like current flow, and the remainder of Equation 3.1.3 to be like a thermal resistance. The latter is seen to be

$$R_k = \frac{L}{kA} \tag{3.1.4}$$

Heat transfer through walls made of layers of different types of materials can be easily found by summing the resistances in series or parallel form, as appropriate.

In the design of systems, seldom is a surface temperature specified or known. More often, the surface is in contact with a bulk fluid, whose temperature is known at some distance from the surface. Convection from the surface is then represented by Newton's law of cooling:

$$q = \overline{h}_c A\left(T_s - T_\infty\right) \tag{3.1.5}$$

This equation can also be represented as a temperature difference divided by a thermal resistance, which is $1/\bar{h}_c A$. It can be shown that a very low surface resistance, as might be represented by phase-change phenomena, effectively imposes the fluid temperature directly on the surface. Hence, usually a *known* surface temperature results from a fluid temperature being imposed directly on the surface through a very high heat-transfer coefficient. For this reason, in the later results given here, particularly those for transient systems, a convective boundary will be assumed. For steady-state results, this is less important because of the ability to add resistances via the circuit analogy.

Long, Cylindrical Systems at Steady State

For long (L), annular systems at steady-state conditions with constant thermal conductivities, the following two equations are the appropriate counterparts to Equations 3.1.3 and 3.1.4. The heat transfer can be expressed as follows:

$$q_k = \frac{2\pi Lk}{\ln\left[r_2/r_1\right]}(T_1 - T_2) \tag{3.1.6}$$

Here, r_1 and r_2 represent the radii of the annular sections. A thermal resistance for this case is as shown:

$$R_k = \frac{\ln[r_2 / r_1]}{2\pi Lk} \tag{3.1.7}$$

Overall Heat Transfer Coefficient

The *overall heat-transfer coefficient* concept is valuable in several aspects of heat transfer. It involves a modified form of Newton's law of cooling, as noted earlier, and it is written as follows:

$$Q = \bar{U}A\Delta T \tag{3.1.8}$$

In this formulation, $\bar{U}$ is the overall heat-transfer coefficient based upon the area A. Because the area for heat transfer in a problem can vary (as with a cylindrical geometry), it is important to note that the $\bar{U}$ is dependent upon which area is selected. The overall heat-transfer coefficient is usually found from a combination of thermal resistances. Hence, for a common-series combination-circuit analog, the $\bar{U}A$ product is taken as the sum of the resistances:

$$\bar{U}A = \frac{1}{\sum_{i=1}^{n} R_i} = \frac{1}{R_{\text{total}}} \tag{3.1.9}$$

For an example of the use of this concept, see Figure 3.1.1.

For steady-state conditions, the product $\bar{U}A$ remains constant for a given heat transfer and overall temperature difference. This can be written as follows:

$$\bar{U}_1 A_1 = \bar{U}_2 A_2 = \bar{U}_3 A_3 = \bar{U}A \tag{3.1.10}$$

If the inside area, A_1, is chosen as the basis, the overall heat-transfer coefficient can then be expressed as follows:

$$\bar{U}_1 = \frac{1}{\frac{1}{\bar{h}_{c,i}} + \frac{r_1 \ln\left(r_2/r_1\right)}{k_{\text{pipe}}} + \frac{r_1 \ln\left(r_3/r_2\right)}{k_{\text{ins}}} + \frac{r_1}{r_3 \bar{h}_{c,o}}} \tag{3.1.11}$$

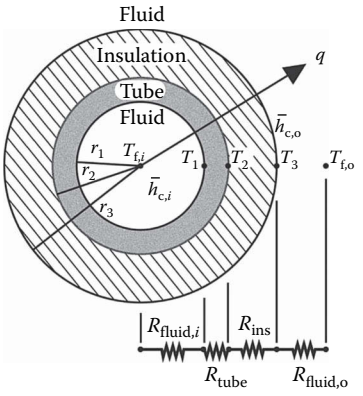

FIGURE 3.1.1 An insulated tube with convective environments on both sides shown with a resistance analog representation.

Critical Thickness of Insulation

Sometimes, adding insulation can cause an increase in heat transfer. This circumstance should be noted so that one can apply it when desired and design around it when an insulating effect is needed. Consider the circumstance shown in Figure 3.1.1. Assume that the temperature on the outside of the tube (inside of the insulation) is known. This could be determined if the inner heat-transfer coefficient is very large and the thermal conductivity of the tube is large. In this case, the inner fluid temperature will be almost the same temperature as the inner surface of the insulation. Alternatively, this could be applied to a coating (say an electrical insulation) on the outside of a wire. By forming the expression for the heat transfer in terms of the variables shown in Equation 3.1.11, and examining the change of heat transfer with variations in r_3 (i.e., the thickness of the insulation); the critical thickness of insulation can be found. While simple results are given in many texts (showing the critical radius as the ratio of the insulation thermal conductivity to the heat-transfer coefficient on the outside), Sparrow (1970) considered a heat-transfer coefficient that varies as follows:

$$\bar{h}_{c,o} \sim r_3^{-m} \left| T_3 - T_{f,o} \right|^n$$

For this case, it is found that the heat transfer is maximized at

$$r_3 = r_{crit} = \left[(1-m)/(1+n) \right] \frac{k_{ins}}{\bar{h}_{c,o}} \tag{3.1.12}$$

By examining the orders of magnitude of m, n, k_{ins}, and $\bar{h}_{c,o}$, the critical radius is often found to be on the order of a *few millimeters*. Hence, additional insulation on small-diameter cylinders such as narrow-gauge electrical wires could actually increase the heat dissipation. On the other hand, the addition of insulation to large-diameter pipes and ducts will almost always decrease the heat-transfer rate.

Internal Heat Generation

The analysis of temperature distributions and the resulting heat transfer in the presence of volume heat sources is required in some circumstances. These include phenomena such as nuclear fission processes, Joule heating, and microwave energy deposition. Consider first a slab of material $2L$ thick but otherwise very large, with internal generation. The outside of the slab is kept at temperature T_1.

To find the temperature distribution within the slab, the thermal conductivity is assumed to be constant. Equation 3.1.2 reduces to the following:

$$\frac{\mathrm{d}^2T}{\mathrm{d}x^2}+\frac{\dot{q}_\mathrm{G}}{k}=0 \tag{3.1.13}$$

Solving this equation by separating the variables, integrating twice, and applying boundary conditions gives

$$T(x)-T_1=\frac{\dot{q}_\mathrm{G}L^2}{2k}\left[1-\left(\frac{x}{L}\right)^2\right] \tag{3.1.14}$$

A similar type of analysis for a long cylindrical element of radius r_1 gives

$$T(r)-T_1=\frac{\dot{q}_\mathrm{G}r_1^2}{4k} \tag{3.1.15}$$

Two additional cases will be given. Both involve the situation when the rate of heat generation is dependent upon the local temperature, according to the following relationship:

$$\dot{q}_\mathrm{G}=\dot{q}_{\mathrm{G,o}}\left[1+\beta\left(T-T_0\right)\right] \tag{3.1.16}$$

For a plane wall of $2L$ thickness and a temperature of T_1 specified on each surface

$$\frac{T(x)-T_\mathrm{o}+1/\beta}{T_1-T_\mathrm{o}+1/\beta}=\frac{\cos\mu x}{\cos\mu L} \tag{3.1.17}$$

For a similar situation in a long cylinder with a temperature of T_1 specified on the outside radius r_1

$$\frac{T(r)-T_\mathrm{o}+1/\beta}{T_1-T_\mathrm{o}+1/\beta}=\frac{J_\mathrm{o}(\mu r)}{J_\mathrm{o}(\mu r_1)} \tag{3.1.18}$$

In Equation 3.1.18, J_o is the typical notation for the Bessel function. Variations of this function are tabulated in Abramowitz and Stegun (1964) or are available on many computer systems. In both of the cases shown here, the following holds:

$$\mu\equiv\sqrt{\frac{\beta\,\dot{q}_{\mathrm{G,o}}}{k}}$$

Fins

Fins are widely used to enhance the heat transfer (usually convective, but also radiative) from a surface. This is particularly true when the surface is in contact with a gas. Fins are used on air-cooled engines, electronic cooling forms, as well as in a number of other applications. Since the heat-transfer coefficient tends to be low in gas convection, area is added to the surface in the form of fins to decrease the convective thermal resistance.

The simplest fins to analyze are those usually found in practice—one-dimensional and constant in cross section. In simple terms, to be one-dimensional, the fins have to be long compared to a transverse dimension. Three cases are normally considered for analysis, and these are shown in Figure 3.1.2. They are the insulated-tip fin, the very long fin, and the convecting-tip fin.

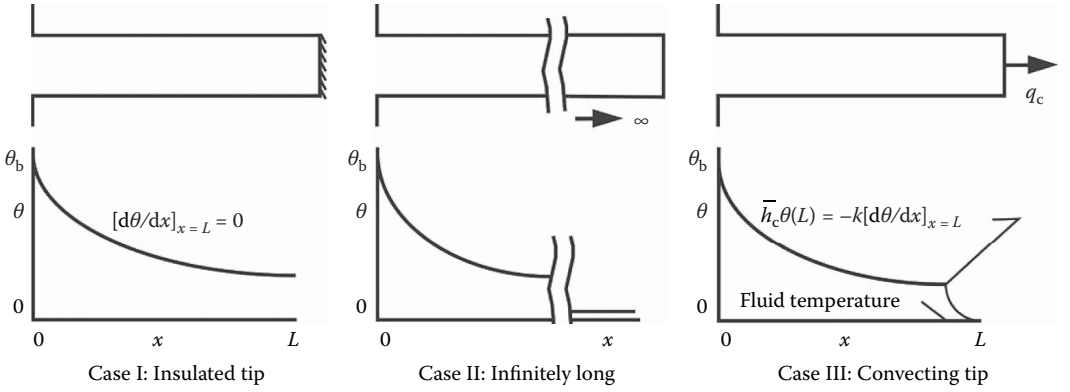

FIGURE 3.1.2 Three typical cases for one-dimensional, constant cross-section fins are shown.

For Case I, the solution to the governing equation and the application of the boundary conditions of the known temperatures at the base and the insulated tip yields

$$\text{Case I:} \qquad \theta = \theta_b = \frac{\cosh m(L-x)}{\cosh mL} \tag{3.1.19}$$

For the infinitely long case, the following simple form results:

$$\text{Case II:} \qquad \theta(x) = \theta_b e^{-mx} \tag{3.1.20}$$

The final case yields the following result:

$$\text{Case III:} \qquad \theta(x) = \theta_b \quad \frac{mL\cosh m(L-x) + \text{Bi}\sinh m(L-x)}{mL\cosh mL + \text{Bi}\sinh mL} \tag{3.1.21}$$

where $\text{Bi} \equiv \bar{h}_c\, L/k$.

In all three of the cases given, the following definitions apply:

$$\theta \equiv T(x) - T_\infty, \theta_b \equiv T(x=0) - T_\infty, \text{and } m^2 \equiv \frac{\bar{h}_c P}{kA}$$

Here, A is the cross section of the fin parallel to the wall. P is the perimeter around that area.

To find the amount of heat removed in any of these cases, the temperature distribution is used in Fourier's law, Equation 3.1.1. For most fins that truly fit the one-dimensional assumption (i.e., long compared to their transverse dimensions), all three equations will yield results that don't differ significantly.

Two performance indicators are found in the fin literature. The *fin efficiency* is defined as the ratio of the actual heat-transfer rate from a fin to the heat-transfer rate from an ideal fin:

$$\eta \equiv \frac{q_{\text{actual}}}{q_{\text{ideal}}} \tag{3.1.22}$$

The ideal heat transfer is found from convective gain or loss from an area the same size as the fin surface area, all at a temperature T_b. Fin efficiency is normally used to tabulate heat-transfer results for various types of fins, including those with nonconstant area or not meeting the one-dimensional

assumption. An example of the former can be developed from a result given by Arpaci (1966). Consider a straight fin of triangular profile, as shown in Figure 3.1.3. The solution is found in terms of modified Bessel functions of the first kind. Tabulations are given in Abramowitz and Stegun (1964):

$$\eta = \frac{I_1\left(2mL^{1/2}\right)}{mL^{1/2} I_o\left(2mL^{1/2}\right)} \tag{3.1.23}$$

Here, $m \equiv \sqrt{2\bar{h}_c L / kb}$.

The *fin effectiveness*, ε, is defined as the heat transfer from the fin compared to the bare-surface transfer through the same base area:

$$\varepsilon = \frac{q_{\text{actual}}}{q_{\text{bare base}}} = \frac{q_f}{\bar{h}_c A\left(T_b - T_\infty\right)} \tag{3.1.24}$$

Carslaw and Jaeger (1959) give an expression for the effectiveness of a fin of constant thickness around a tube (see Figure 3.1.3b). This is given as $\mu \equiv \sqrt{2\bar{h}_c / kb}$

$$\varepsilon = \frac{2}{\mu b} \frac{I_1(\mu r_2) K_1(\mu r_1) - K_1(\mu r_2) I_1(\mu r_1)}{I_o(\mu r_1) K_1(\mu r_2) + K_o(\mu r_1) I_1(\mu r_2)} \tag{3.1.25}$$

Here, the notations *I* and *K* denote Bessel functions that are given in Abramowitz and Stegun (1964).

Fin effectiveness can be used as one indication whether or not fins should be added. A rule of thumb indicates that if the effectiveness is less than about three, fins should not be added to the surface.

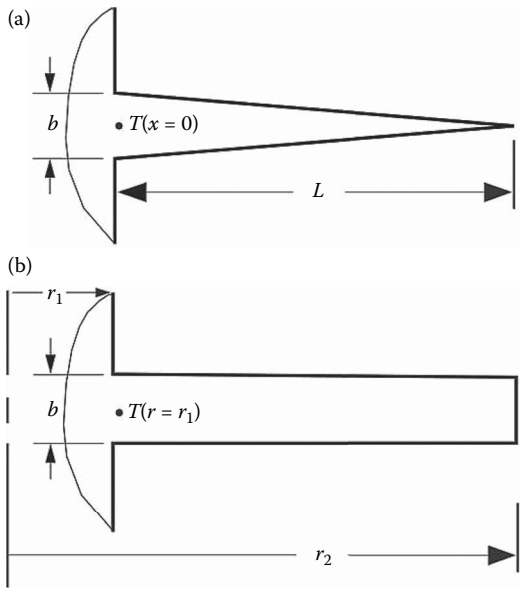

FIGURE 3.1.3 Two fin examples with a cross-sectional area that varies with distance from the base. (a) Straight triangular fin. (b) Annular fin of constant thickness.

Transient Systems with Negligible Internal Resistance

Consider the transient cooling or heating of a body with surface area A and volume V. This is taking place by convection through a heat-transfer coefficient $\bar{h}_c$ to an ambient temperature of T_∞. Assume the thermal resistance to conduction inside the body is significantly less than the thermal resistance to external convection (as represented by Newton's law of cooling) on the surface of the body. This ratio is denoted by the *Biot number*, Bi:

$$\mathrm{Bi} = \frac{R_k}{R_c} = \frac{\bar{h}_c (V/A)}{k} \tag{3.1.26}$$

The temperature (which will be uniform throughout the body at any time for this situation) response with time for this system is given by the following relationship. Note that the shape of the body is not important—only the ratio of its volume to its area matters:

$$\frac{T(t) - T_\infty}{T_o - T_\infty} = \mathrm{e}^{-\frac{\bar{h}_c A t}{\rho V c}} \tag{3.1.27}$$

Typically, this will hold for the Biot number being less than (about) 0.1.

Bodies with Significant Internal Resistance

When a body is being heated or cooled transiently in a convective environment, but the internal thermal resistance of the body cannot be neglected, the analysis becomes more complicated. Only simple geometries (a symmetrical plane wall, a long cylinder, a composite of geometrical intersections of these geometries, or a sphere) with an imposed step change in ambient temperature are addressed here.

The first geometry considered is a large slab of minor dimension $2L$. If the temperature is initially uniform at T_o, and at time 0+, it begins convecting through a heat-transfer coefficient to a fluid at T_∞, the temperature response is given by

$$\theta = 2\sum_{n=1}^{\infty}\left(\frac{\sin\lambda_n L}{\lambda_n L + \sin\lambda_n L\cos\lambda_n L}\right)\exp\left(-\lambda_n^2 L^2 \mathrm{Fo}\right)\cos(\lambda_n x) \tag{3.1.28}$$

and λ_n are the roots of the transcendental equation: $\lambda_n L \tan \lambda_n L = \mathrm{Bi}$. The following definitions hold:

$$\mathrm{Bi} \equiv \frac{\bar{h}_c L}{k} \qquad \mathrm{Fo} \equiv \frac{\alpha t}{L^2} \qquad \theta \equiv \frac{T - T_\infty}{T_o - T_\infty}$$

The second geometry considered is a very long cylinder of diameter $2R$. The temperature response for this situation is

$$\theta = 2\mathrm{Bi}\sum_{n=1}^{\infty}\frac{\exp\left(-\lambda_n^2 R^2 \mathrm{Fo}\right) J_o\left(\lambda_n r\right)}{\left(\lambda_n^2 R^2 + \mathrm{Bi}^2\right) J_o\left(\lambda_n R\right)} \tag{3.1.29}$$

Now, λ_n are the roots of $\lambda_n R\, J_1(\lambda_n R) - \mathrm{Bi}\, J_o(\lambda_n R) = 0$, and

$$\mathrm{Bi} = \frac{\bar{h}_c R}{k} \qquad \mathrm{Fo} = \frac{\alpha t}{R^2} \qquad \theta = \frac{T - T_\infty}{T_o - T_\infty}$$

The common definition of Bessel's functions applies here.

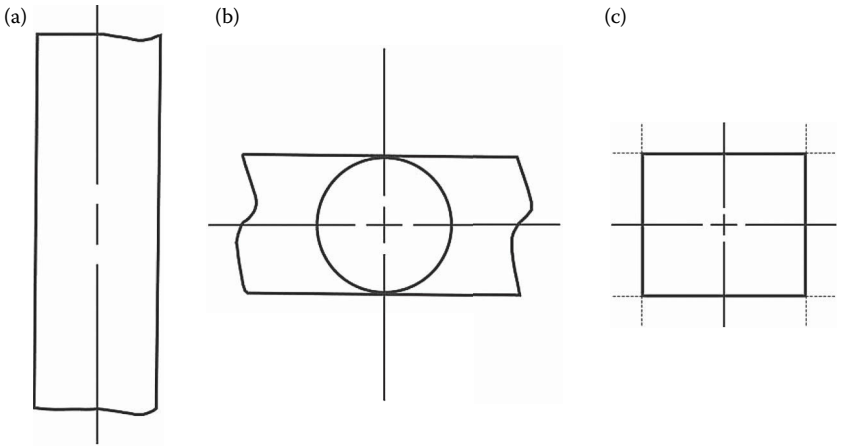

FIGURE 3.1.4 Three types of bodies that can be analyzed with methods given in this section. (a) Large plane wall of $2L$ thickness. (b) Long cylinder with $2R$ diameter. (c) Composite intersection.

For the similar situation involving a solid sphere, the following holds:

$$\theta = 2\sum_{n=1}^{\infty} \frac{\sin(\lambda_n R) - \lambda_n R\cos(\lambda_n R)}{\lambda_n R - \sin(\lambda_n R)\cos(\lambda_n R)} \exp\left(-\lambda_n^2 R^2 \mathrm{Fo}\right) \frac{\sin(\lambda_n r)}{\lambda_n r} \tag{3.1.30}$$

and λ_n are found as the roots of $\lambda_n R\cos\lambda_n R = (1 - \mathrm{Bi})\sin\lambda_n R$. Otherwise, the same definitions hold as were given for the cylinder.

Solids that can be envisioned as the geometrical intersection of the simple shapes described earlier can be analyzed with a simple product of the individual shape solutions. For these cases, the solution is found as the product of the dimensionless temperature functions for each of the simple shapes, with appropriate distance variables taken in each solution. This is illustrated in the right-hand diagram in Figure 3.1.4. For example, a very long rod of rectangular cross section can be seen as the intersection of two large plates. A short cylinder represents the intersection of an infinitely long cylinder and a plate. The temperature at any location within the short cylinder is

$$\theta_{2R,2L\ \mathrm{Rod}} = \theta_{\mathrm{Infinite}\ 2R\ \mathrm{Rod}}\theta_{2L\ \mathrm{Plate}} \tag{3.1.31}$$

Details of the formulation and solution of the partial differential equations in heat conduction are found in the text by Arpaci (1966).

Finite Difference Analysis of Conduction

Today, numerical solution of conduction problems is the most used analysis approach. Two general techniques are applied for this: those based upon finite-difference ideas and those based upon finite-element concepts. General numerical formulations are introduced in Chapter 5 of this text. Here, we briefly introduce some finite-difference concepts as they might be applied in heat conduction analysis.

First, consider formulation ideas. Consider the two-dimensional form of Equation 3.1.2, neglecting heat generation. This is given by

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} = \frac{1}{\alpha}\frac{\partial T}{\partial t} \tag{3.1.32}$$

By using finite-difference approximations to the first and second derivatives, the following results:

$$\frac{T_{i+1,j} - 2T_{i,j} - T_{i-1,j}}{\Delta x^2} + \frac{T_{i,j+1} - 2T_{i,j} - T_{i,j-1}}{\Delta y^2} = \frac{T'_{i,j} - T_{i,j}}{\alpha \Delta t} \tag{3.1.33}$$

In this notation, i denotes node center locations in the x-direction, j indicates node center locations in the y-direction, and $T_{i,j} = T(i, j, t)$, and $T'_{i,j} = T(i, j, t+\Delta t)$. As written, the form is denoted as the *explicit* formulation because the forward difference is used for the time derivative (a new time-step temperature is found in terms of all of the old time-step temperatures). If the time derivative is taken as the backward difference, then the new (and, hence, unknown) temperatures at all surrounding nodes are used with the known (old) temperature at each node to find the temperatures at the new time. Because each equation contains a number of unknowns that must be found simultaneously, the result is termed the *implicit* formulation. This is shown below for a general interior node:

$$\frac{T'_{i+1,j} - 2T'_{i,j} - T'_{i-1,j}}{\Delta x^2} + \frac{T'_{i,j+1} - 2T'_{i,j} - T'_{i,j-1}}{\Delta y^2} = \frac{T'_{i,j} - T_{i,j}}{\alpha \Delta t} \tag{3.1.34}$$

A formal differencing approach, where finite differences are generated directly from partial derivatives, can be carried out for each application. However, the possibility of unusual geometries and mixing of boundary conditions often results in situations that are not easily differenced. For this reason, an energy balance method often yields an approach that can be more easily applied physically.

Attention is drawn to a one-dimensional slab (very large in two directions compared to the thickness). The slab is divided across the thickness into smaller subslabs (denoted as nodes in what follows), and this is shown in Figure 3.1.5. All nodes are of thickness Δx except for the two boundaries where the thickness is $\Delta x/2$. A characteristic temperature for each node is assumed to be represented by the temperature at the node center. Of course this assumption becomes more accurate as the size of the node becomes smaller. On the periphery of the object being analyzed, the location representing the temperature of the node is located on the boundary of the object, and this results in fractionally sized nodes at these positions. Hence, with the two boundary node centers located exactly on the boundary, a total of n nodes are used ($n-2$ full, interior nodes and half-nodes on each of the two boundaries).

In the analysis, a general interior node i (this applies to all nodes 2 through $n-1$) is considered for an overall energy balance. Conduction in from node $i-1$ and from node $i+1$, as well as any heat generation present, is assumed to be energy per unit time flowing into the node. This is then equated

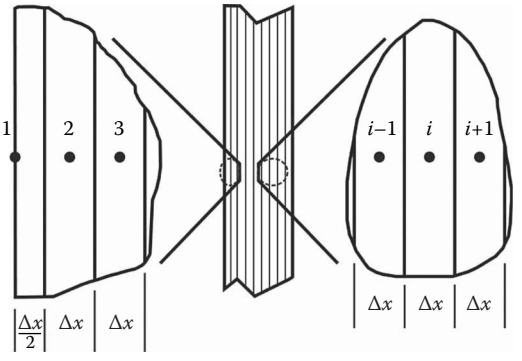

FIGURE 3.1.5 Shown are details of the one-dimensional finite differencing of a slab for a general interior node as well as one surface node.

to the time rate of change of energy within the node. A backward difference on the time derivative is applied here, and the notation $T_i' \equiv T_i(t+\Delta t)$ is used. The balance gives the following on a per unit area basis:

$$\frac{T'_{i-1}-T'_i}{\Delta x/k_-}+\frac{T'_{i+1}-T'_i}{\Delta x/k_+}+\dot{q}_{\mathrm{G},i}\Delta x=\rho\ \Delta x\ c_\mathrm{p}\frac{T'-T'_i}{\Delta t} \tag{3.1.35}$$

In this equation, different thermal conductivities have been used to allow for possible variations in properties throughout the solid.

The analysis of the boundary nodes will depend upon the nature of the conditions there. For the purposes of illustration, convection will be assumed to be occurring off of the boundary at node 1. A balance similar to Equation 3.1.35, but now for node 1, gives the following:

$$\frac{T'_\infty-T'_1}{1/h_\mathrm{c}}+\frac{T'_2-T'_1}{\Delta x/k_+}+\dot{q}_{\mathrm{G},1}\frac{\Delta x}{2}=\rho\ \frac{\Delta x}{2}\ c_\mathrm{p}\frac{T'_1-T_1}{\Delta t} \tag{3.1.36}$$

If the heat-transfer situation in the slab is symmetrical about the slab center line, consideration of this aspect allows only half of the slab to be analyzed. Consideration of the half-node located on the left-hand side of the centerline yields

$$\frac{T'_{n-1}-T'_n}{\Delta x/k_+}+0+\dot{q}_{\mathrm{G},n}\frac{\Delta x}{2}=\rho\ \frac{\Delta x}{2}\ c_\mathrm{p}\frac{T'_n-T_n}{\Delta t} \tag{3.1.37}$$

Here, the zero shown as the second term denotes the fact that no energy flows across the centerline.

After all n equations are written, it can be seen that there are n unknowns represented in these equations: the temperature at all nodes. If one or both of the boundary conditions is known in terms of specified temperatures, this will decrease the number of equations and unknowns by one or two, respectively. To determine the temperature as a function of time, the time step is arbitrarily set, and all the temperatures are found by simultaneous solution at $t=0+\Delta t$. This is denoted by the matrix system shown below. For the situation shown here, the thermal conductivity is taken to be constant throughout the slab, and no internal heat generation is considered. With these simplifications, the system of equations to be solved (using Equations 3.1.35 through 3.1.37) is

$$\begin{bmatrix}
(1+2\mathrm{Fo}+2\mathrm{Fo}Bi) & -\mathrm{Fo} & 0 & 0 & \cdots & 0 \\
-\mathrm{Fo} & (1+2\mathrm{Fo}) & -\mathrm{Fo} & 0 & \cdots & 0 \\
\cdots & -\mathrm{Fo} & (1+2\mathrm{Fo}) & -\mathrm{Fo} & \cdots & 0 \\
\cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\
\cdots & \cdots & \cdots & -\mathrm{Fo} & (1+2\mathrm{Fo}) & -\mathrm{Fo} \\
\cdots & \cdots & \cdots & \cdots & -2\mathrm{Fo} & (1+2\mathrm{Fo})
\end{bmatrix}
\begin{bmatrix} T'_1 \\ T'_2 \\ T'_3 \\ \cdots \\ T'_{n-1} \\ T'_n \end{bmatrix}
=
\begin{bmatrix} 2\mathrm{Fo}BiT'_\infty+T_1 \\ T_2 \\ T_3 \\ \cdots \\ T_{n-1} \\ T_n \end{bmatrix} \tag{3.1.38}$$

The time is then advanced by Δt and the temperatures are again found by simultaneous solution.

The finite-difference approach just outlined using the backward difference for the time derivative is termed the *implicit* technique, and it results in an $n \times n$ system of linear simultaneous equations. If the forward difference is used for the time derivative, then only one unknown will exist in each equation. This gives rise to what is called an *explicit* or "marching" solution. While this type of system is more straightforward to solve because it deals with only one equation at a time with one unknown, a *stability criterion* must be considered which limits the time step relative to the distance step.

Two- and three-dimensional problems are handled in conceptually the same manner. One-dimensional heat fluxes between adjoining nodes are again considered. Now there are contributions from each of the dimensions represented. Details are outlined in the book by Jaluria and Torrance (2003).

Defining Terms

Biot number: Ratio of the internal (conductive) resistance to the external (convective) resistance from a solid exchanging heat with a fluid.

Explicit formulation: All temperatures in the differenced form of the transient heat conduction equation are at the current time step except for in the time derivative, where the future time value is given.

Fin: Additions of material to a surface to increase area and thus decrease the external thermal resistance from convecting and/or radiating solids.

Fin effectiveness: Ratio of the actual heat transfer from a fin to the heat transfer from the same cross-sectional area of the wall without the fin.

Fin efficiency: Ratio of the actual heat transfer from a fin to the heat transfer from a fin with the same geometry but completely at the base temperature.

Fourier's law: The fundamental law of heat conduction. Relates the local temperature gradient to the local heat flux, both in the same direction.

Heat conduction equation: A partial differential equation in temperature, spatial variables, time, and properties that, when solved with appropriate boundary and initial conditions, describes the variation of temperature in a conducting medium.

Implicit formulation: All temperatures in the differenced form of the transient heat conduction equation are at the new time step except for in the time derivative, where the current time value is given.

Overall heat-transfer coefficient: The analogous quantity to the heat transfer coefficient found in convection (Newton's law of cooling) that represents the overall combination of several thermal resistances, both conductive and convective.

Thermal conductivity: The temperature dependent property of a material that relates a temperature gradient to a heat flux.

3.2 CONVECTION HEAT TRANSFER

3.2.1 Natural Convection

Swati A. Patel, Raj P. Chhabra, George D. Raithby, and K.G. Terry Hollands

The presence of temperature gradient in a fluid coupled with the fluid motion results in heat transfer from the region of high temperature to that of lower temperature principally by convection. It is customary to classify the mode of heat transfer as free or natural convection when the fluid motion is solely due to the density difference which itself stems from the temperature variation in the fluid. On the other hand, when the fluid motion is induced by a mechanical device (pump, fan, blower, mechanical stirrer, rotation, etc.), heat transfer occurs in the forced convection regime. In practice, both these modes contribute in varying proportions to the overall heat transfer depending upon the strength of the buoyancy-induced flow vis-à-vis that of the externally imposed flow. The relative importance of the two modes is ascertained via the use of the familiar Richardson number, $\mathrm{Ri}=\mathrm{Gr}/\mathrm{Re}^2$, which is really a measure of the ratio of the buoyancy to inertial forces. Naturally, vanishingly small values of the Richardson number ($\mathrm{Ri} \to 0$) correspond to the forced convection regime, whereas large values of the Richardson number ($\mathrm{Ri} \to \infty$) denote the other limit of the pure natural convection. Indeed, the values of the Richardson number on the order of unity, $\mathrm{Ri} \sim \mathrm{O}(1)$, denote the case when the two flow velocities are of comparable magnitude. Thus, heat transfer occurs in the mixed convection regime for the intermediate values of the Richardson number. Depending upon the orientations of these two velocities, it is customary to further classify the mixed-convection regime into three types, namely aiding-buoyancy, opposing-buoyancy, and cross-buoyancy, as shown schematically in Figure 3.2.1 for the case of a heated horizontal cylinder. The limiting case of the natural convection is dealt with in this section, whereas that of the forced and mixed convection is treated in Section 3.2.2, and the analogous information for non-Newtonian fluids is presented in Section 3.2.4.

As noted earlier, natural convection heat transfer occurs when the fluid motion is induced solely by density differences that are themselves caused by heating or by the concentration gradient of a solute. The schematics of the free convection is shown in Figure 3.2.2 along with the nomenclature used in this section, where a body at surface temperature T_s is immersed in a quiescent fluid at temperature $T_\infty < T_s$, thereby resulting in heat transfer at the rate of q from the heated object to the ambient fluid.

Notwithstanding the fundamental significance of the temperature and velocity profiles especially in the processing of temperature-sensitive materials (such as that encountered in food-, pharma- and personal care product sectors), it is readily conceded that the need to estimate the overall heat-transfer coefficient to size the process equipment and/or to modulate the rate of heating or cooling in a given application frequently arises in process engineering calculations. This information is conveniently expressed in terms of the dimensionless correlations for Nusselt number. Over the years, based on a combination of the boundary layer approximations, numerical solutions of the coupled momentum and energy equations, and experimental results aided by dimensional considerations, reliable correlations have been developed which span wide ranges of conditions, in terms of the range of Grashof number and Prandtl number or Rayleigh numbers for scores of body shapes and type of boundary conditions (constant temperature or constant heat flux or mixed), etc. An excellent review of the pertinent literature in this field is available (Martynenko and Khramtsov, 2005).

In this section, some of the widely used correlations for the average Nusselt number are provided from which the heat-transfer rate q from surface area A_s can be estimated for a range of shapes for which reliable results have accrued in the literature. The Nusselt number is defined as

$$\mathrm{Nu} = \frac{\bar{h}_c L_c}{k} = \frac{q L_c}{A_s \Delta T k}, \tag{3.2.1}$$

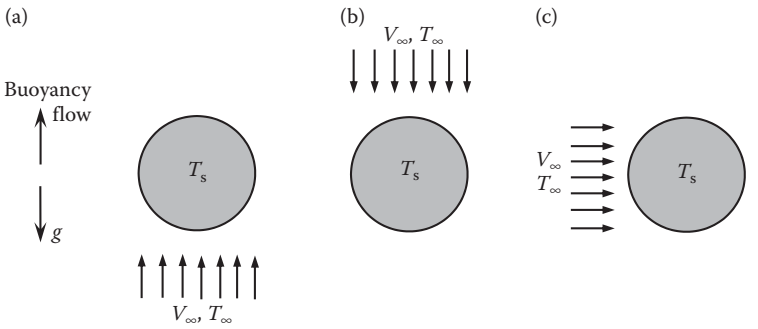

FIGURE 3.2.1 Schematics of mixed-convection regimes (a) aiding-buoyancy, (b) opposing-buoyancy, and (c) cross-buoyancy.

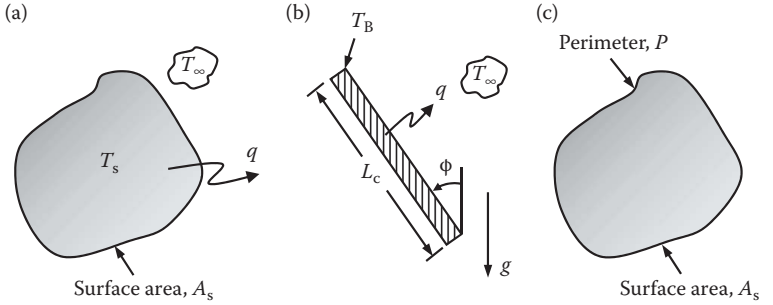

FIGURE 3.2.2 Nomenclature for external heat transfer (a) general sketch, (b) for a tilted flat plate, and (c) defines the length scale for horizontal surfaces.

where $\Delta T = T_s - T_\infty$ is the temperature difference driving the heat transfer. For the simplest case of the constant thermophysical properties (except density), infinite extent of fluid and negligible viscous dissipation, a dimensional analysis of such problems leads to the following general functional relationship:

$$\text{Nu} = f(\text{Ra or Gr, Pr, geometric shape, boundary conditions}) \tag{3.2.2}$$

For given thermal boundary conditions (e.g., isothermal wall and uniform T_∞), and for a given geometry (e.g., a cube or a sphere or a cylinder), Equation 3.2.2 states that the value of the average Nusselt number, Nu, depends only on the Rayleigh number, Ra, and Prandtl number, Pr, or combinations thereof. The length scales that appear in the definitions of the Nusselt number, Nu, and Rayleigh number, Ra, are defined, for each geometry considered, in a separate figure. For small values of ΔT, i.e., $(T_s - T_\infty)$, the fluid properties are generally evaluated at the mean film temperature, i.e., $T_f = (T_s + T_\infty)/2$. The exception is that β, the temperature coefficient of volume expansion, is evaluated at T_∞ for external natural convection (Figures 3.2.2 through 3.2.4) in a gaseous medium. Additional correction is needed when the temperature dependence of the density cannot be well approximated by the familiar Boussinesq relation (Kays et al., 2004).

The functional dependence of the average Nusselt number on the Prandtl number, Pr, is approximately independent of the geometry, and the following Pr-dependent function has been found to be useful for consolidating results for a range of shapes, at least in the laminar heat-transfer regime (Churchill and Usagi, 1972):

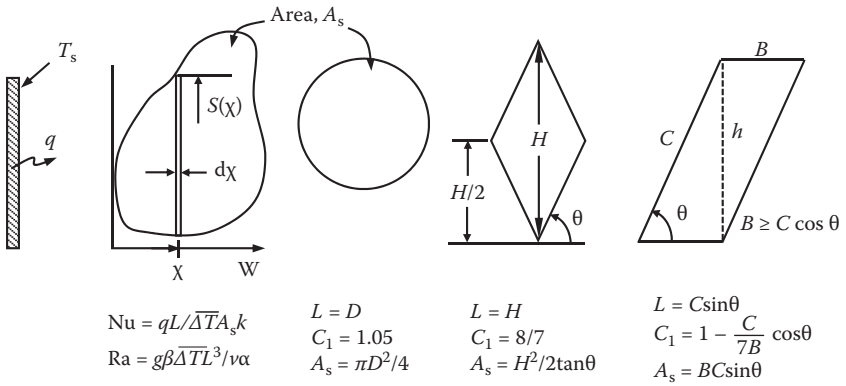

FIGURE 3.2.3 Nomenclature for heat transfer from planar surfaces of different shapes.

$$\bar{C}_\ell = \frac{0.671}{\left(1+\left(\frac{0.492}{\mathrm{Pr}}\right)^{9/16}\right)^{4/9}} \tag{3.2.3}$$

C_t^V and C_t^H functions, defined in Equations 3.2.4 and 3.2.5, will be useful for turbulent heat transfer:

$$C_t^V = \frac{0.13\mathrm{Pr}^{0.22}}{\left(1+0.61\mathrm{Pr}^{0.81}\right)^{0.42}} \tag{3.2.4}$$

$$C_t^H = 0.14\left(\frac{1+0.0107\mathrm{Pr}}{1+0.01\mathrm{Pr}}\right). \tag{3.2.5}$$

The superscripts V and H refer to the vertical and horizontal surface orientation.

The Nusselt numbers for fully laminar and fully turbulent heat-transfer regimes are denoted by Nu_ℓ and Nu_t, respectively. Once known, these two extreme values are blended (Churchill and Usagi, 1972) as follows to obtain the equation for the Nusselt number, Nu spanning the full range of laminar and turbulent flow regimes as

$$\mathrm{Nu} = \left(\left(\mathrm{Nu}_\ell\right)^m + \left(\mathrm{Nu}_t\right)^m\right)^{1/m}. \tag{3.2.6}$$

The value of the blending parameter m in Equation 3.2.6 depends on the body shape and orientation.

The equation for Nu_ℓ in this section is usually expressed in terms of Nu^T, the Nusselt number that would be valid if the thermal boundary layer were thin ($\mathrm{Pr} \to \infty$ or $\mathrm{Gr} \to \infty$). The difference between Nu_ℓ and Nu^T accounts for the effect of the large boundary layer thicknesses encountered in natural convection.

It is assumed that the wall temperature of a body exceeds the ambient fluid temperature ($T_s > T_\infty$). For $T_s < T_\infty$, the same correlations apply with $(T_\infty - T_s)$ replacing $(T_s - T_\infty)$ for a geometry that is rotated 180° relative to the gravitational vector; for example, the correlations for a horizontal heated upward-facing flat plate apply to a cooled downward-facing flat plate of the same planform.

Correlations for External Natural Convection

This section deals with problems where the body shapes shown in Figures 3.2.2 through 3.2.4 are heated while immersed in a quiescent cold fluid. Different cases are detailed as follows:

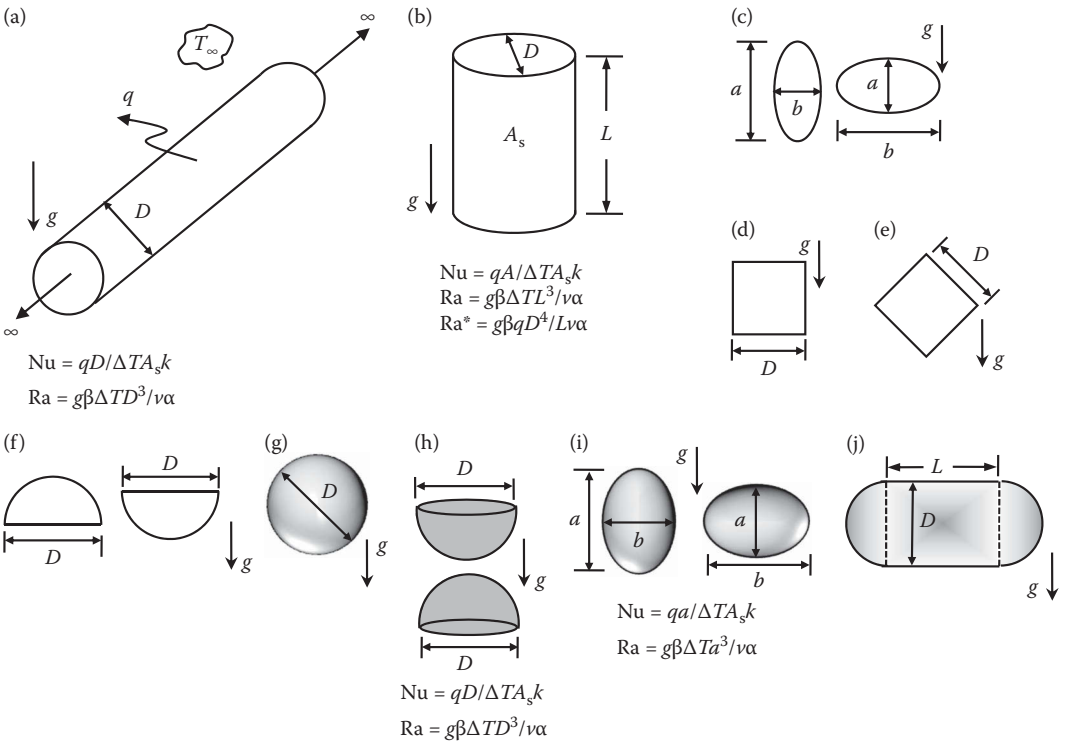

FIGURE 3.2.4 Definitions for computing heat transfer from a long circular cylinder (a), from the lateral surface of a vertical circular cylinder (b), from a long elliptical cylinder (c), square cylinder (d), inclined square cylinder (e), semicircular cylinder (f), from a sphere (g), from a hemisphere (h), spheroid (i), and from a compound body (j).

1. *Isothermal vertical (ϕ=0) flat plate, Figure 3.2.2b.* For heat transfer from a vertical plate (Figure 3.2.2b), for $1 < \mathrm{Ra} < 10^{12}$, the relevant expressions for the Nusselt number are written as

$$\mathrm{Nu}^{\mathrm{T}} = \bar{C}_\ell \mathrm{Ra}^{1/4}$$

$$\mathrm{Nu}_\ell = \frac{2.0}{\ln\left(1 + \dfrac{2.0}{\mathrm{Nu}^{\mathrm{T}}}\right)} \tag{3.2.7}$$

$$\mathrm{Nu}_{\mathrm{t}} = \frac{C_{\mathrm{t}}^{\mathrm{V}} \mathrm{Ra}^{1/3}}{\left(1 + 1.4 \times 10^9 \dfrac{\mathrm{Pr}}{\mathrm{Ra}}\right)}$$

$\bar{C}_\ell$ and $C_{\mathrm{t}}^{\mathrm{V}}$ are given by Equations 3.2.3 and 3.2.4. In a given situation, the value of the Nusselt number, Nu, is obtained by substituting the expressions of the Nu_ℓ and Nu_{t} from Equation 3.2.7 into Equation 3.2.6 with m=6.

2. *Vertical flat plate with uniform heat flux, Figure 3.2.2b.* If the plate surface has a constant (known) heat flux (q) prescribed on its surface, rather than being isothermal, the objective is to calculate the average temperature difference, $\overline{\Delta T}$, between the plate and the fluid. For this situation, and for $15 < \mathrm{Ra}^* < 10^5$,

$$\mathrm{Nu}^{\mathrm{T}} = \bar{G}_{\mathrm{l}}(\mathrm{Ra}^{*})^{1/5}$$

$$\mathrm{Nu}_{\ell} = \frac{1.83}{\ln\left(1+\dfrac{1.83}{\mathrm{Nu}^{\mathrm{T}}}\right)} \tag{3.2.8a}$$

$$\mathrm{Nu}_{\mathrm{t}} = (C_{\mathrm{t}}^{\mathrm{V}})^{3/4}(\mathrm{Ra}^{*})^{1/4}$$

$$\bar{G}_{\ell} = \frac{6}{5}\left(\frac{\mathrm{Pr}}{4+9\sqrt{\mathrm{Pr}}+10\mathrm{Pr}}\right)^{1/5}. \tag{3.2.8b}$$

The modified Rayleigh number, Ra*, is defined as $\mathrm{Ra}^{*} = \mathrm{Nu}\times\mathrm{Ra} = g\beta q L^{4}/\left(A_{\mathrm{s}}\nu\alpha k\right)$, and $C_{\mathrm{t}}^{\mathrm{V}}$ is given by Equation 3.2.4. Find Nu by inserting these expressions for Nu_{ℓ} and Nu_{t} into Equation 3.2.6 with $m=6$. The $\bar{G}_{\ell}$ expression given by Equation 3.2.8a is due to Fujii and Fujii (1976).

3. *Horizontal upward-facing ($\phi=90°$) plates, Figure 3.2.2b.* For horizontal isothermal surfaces of various planforms, correlations are given in terms of a length scale L^{*} (Goldstein et al., 1973), defined in Figure 3.2.2c. For $\mathrm{Ra}\geq 1$,

$$\mathrm{Nu}^{\mathrm{T}} = 0.835\bar{C}_{\ell}\mathrm{Ra}^{1/4}$$

$$\mathrm{Nu} = \frac{1.4}{\ln\left(1+\dfrac{1.4}{\mathrm{Nu}^{\mathrm{T}}}\right)} \tag{3.2.9}$$

$$\mathrm{Nu}_{\mathrm{t}} = C_{\mathrm{t}}^{\mathrm{H}}\mathrm{Ra}^{1/3}.$$

The value of the average Nusselt number, Nu, is obtained by substituting Nu_{ℓ} and Nu_{t} from Equation 3.2.9 into Equation 3.2.6 with $m=10$. For nonisothermal surfaces, replace ΔT by $\overline{\Delta T}$.

4. *Horizontal downward-facing ($\phi=-90°$) plates, Figure 3.2.2c.* For horizontal downward-facing plates of various planforms, the main buoyancy force is into the plate so that only a very weak force drives the fluid along the plate; for this reason, only laminar flows have been investigated. For this case, the following equation applies for $\mathrm{Ra} < 10^{10}$, $\mathrm{Pr}\geq 0.7$:

$$\mathrm{Nu}^{\mathrm{T}} = H_{\ell}\mathrm{Ra}^{1/5}$$

$$H_{\ell} = \frac{0.527}{\left[1+\left(\dfrac{1.9}{\mathrm{Pr}}\right)^{9/10}\right]^{2/9}} \tag{3.2.10}$$

$$\mathrm{Nu}_{\ell} = \frac{2.45}{\ln\left(1+\dfrac{2.45}{\mathrm{Nu}^{\mathrm{T}}}\right)}.$$

The expression for H_{ℓ} is based on the results of Fujii et al. (1973).

5. *Inclined plates, downward facing ($-90°\leq\phi\leq 0$), Figure 3.2.2b.* First calculate q from *Case 1* with g replaced by $g\cos\phi$; then calculate q from *Case 4* (horizontal plate) with g replaced by $g\sin(-\phi)$, and use the maximum of these two values of q for further calculations.
6. *Inclined plates, upward facing ($0\leq\phi\leq 90$), Figure 3.2.2b.* First calculate q from *Case 1* with g replaced by $g\cos\phi$; then calculate q from *Case 3* with g replaced by $g\sin\phi$, and use the maximum of these two values of q for further calculations.

7. *Vertical and tilted isothermal plates of various planforms, Figure 3.2.3.* The line of constant χ in Figure 3.2.3 is the line of steepest ascent on the plate. Provided all such lines intersect the plate edges just twice, as shown in the figure, the thin-layer (Nu^T) heat transfer can be found by subdividing the body into strips of width $\Delta\chi$, calculating the heat transfer from each strip, and adding them up to obtain the overall heat transfer. For laminar flow from an isothermal vertical plate, this results in the following expression:

$$Nu^T = C_1 \bar{C}_\ell Ra^{1/4}, \tag{3.2.11}$$

where

$$C_1 \equiv \frac{L^{1/4}}{A} \int_0^W S^{3/4}\, d\chi.$$

Symbols are defined in Figure 3.2.3, along with L and calculated C_1 values for some plate shapes. If the plate is vertical, follow the procedure in *Case 1* earlier (isothermal vertical flat plate) except replacing the expression for Nu^T in Equation 3.2.7 by Equation 3.2.11. If the plate is tilted, follow the procedure described in *Case 5* or *6* (as appropriate) but again use Equation 3.2.11 for Nu^T in Equation 3.2.7.

8. *Horizontal cylinders, Figure 3.2.4a.* For a long, horizontal circular cylinder, one can use the following expressions for Nu_ℓ and Nu_t:

$$\begin{aligned} Nu^T &= 0.772 \bar{C}_\ell Ra^{1/4} \\ Nu_\ell &= \frac{2f}{\left(1 + \dfrac{2f}{Nu^T}\right)} \\ Nu_t &= \bar{C}_t Ra^{1/3}. \end{aligned} \tag{3.2.12}$$

$\bar{C}_t$ is given in Table 3.2.1. For $Ra > 10^{-2}$, $f = 0.8$ can be used, but for the range $10^{-10} < Ra < 10^{-2}$, use $f = 1 - 0.13/(Nu^T)^{0.16}$. To find Nu, the values of Nu_ℓ and Nu_t from Equation 3.2.12 are substituted into Equation 3.2.6 with $m = 15$ (Clemes et al., 1994).

The following correlation due to Churchill and Chu (1975) is convenient and fairly reliable ($Ra > 10^{-6}$) over the laminar and turbulent flow regimes for an isothermal horizontal cylinder:

$$Nu = 0.60 + \frac{0.387\, Ra^{1/6}}{\left\{\left[1 + \left(\dfrac{0.559}{Pr}\right)^{9/16}\right]^{16/9}\right\}^{1/6}}. \tag{3.2.13}$$

TABLE 3.2.1
Values of $\bar{C}_t$ for Various Shapes and Prandtl Numbers

Pr→	0.01	0.022	0.10	0.71	2.0	6.0	50	100	2000
Horizontal cylinder	0.077	0.81	0.90	0.103	0.108	0.109	0.100	0.097	0.088
Sphere	0.074	0.078	0.088	0.104	0.110	0.111	0.101	0.97	0.086

The corresponding expression for the constant heat flux condition spanning laminar and turbulent flow regimes and $0.022 \le \mathrm{Pr} \le 7640$, $\mathrm{Ra} > 1$ is given as (Churchill and Thelen, 1975)

$$\sqrt{\mathrm{Nu}} = 0.60 + \frac{\left(0.0033\mathrm{Ra}\right)^{1/6}}{\left\{\left[1+\left(\frac{0.44}{\mathrm{Pr}}\right)^{9/16}\right]^{16/9}\right\}^{1/6}}. \tag{3.2.14}$$

The physical properties are evaluated at the mean film temperature.

9. *Vertical cylinders (*$\phi = 90°$*), Figure 3.2.4b.* For high values of the Rayleigh number and cylinders of large diameter, the heat transfer from a vertical cylinder approaches that for a vertical flat plate. This is so due to the fact that the boundary layer thickness is much smaller than the diameter of the cylinder and one can thus neglect the curvature effects. Let the Nu^{T} and Nu_{ℓ} equations for a vertical flat plate of height L, Equation 3.2.7, be rewritten here as $\mathrm{Nu}_{\mathrm{p}}^{\mathrm{T}}$ and Nu_{p}, respectively. At smaller Ra and diameter, transverse curvature plays a role, which is accounted for in the following equations:

$$\mathrm{Nu}_{\ell} = \frac{0.9\xi\mathrm{Nu}_{\mathrm{p}}}{\ln\left(1+0.9\xi\right)}, \tag{3.2.15}$$

where

$$\xi = \frac{2L/D}{\mathrm{Nu}_{\mathrm{p}}^{\mathrm{T}}}.$$

These equations are valid for purely laminar flow. To obtain Nu, blend Equation 3.2.15 for Nu_{ℓ} with Equation 3.2.7 for Nu_{t} using Equation 3.2.6 with $m = 10$.

10. *Horizontal elliptical cylinder*, *Figure 3.2.4c*. For a long isothermal elliptical cylinder with an aspect ratio E (=a/b) (axis along the flow to the axis normal to the flow), the following expression based on $L_{\mathrm{c}} = 2b$ (characteristic linear scale) can be used to evaluate the average heat-transfer coefficient in the fully laminar flow regime (Sasmal and Chhabra, 2012a):

$$\mathrm{Nu} = 0.833(\mathrm{Ra}^{1/4})^{0.89} E^{a_0}. \tag{3.2.16}$$

The values of coefficient, $a_0 = -0.116$ $(0.2 \le E < 1)$ and $a_0 = -0.321$ $(1 < E \le 5)$ in this expression fit the numerical data in the range of Rayleigh number, $7.2 \le \mathrm{Ra} \le 10^7$ and Prandtl number, $0.72 \le \mathrm{Pr} \le 100$.

11. *Horizontal square cylinder*, *Figure 3.2.4d*. For a long isothermal square cylinder of side D, one can use the following expression for Nu (Sasmal and Chhabra, 2011):

$$\mathrm{Nu} = 0.605(\mathrm{Ra}^{1/4})^{0.924}. \tag{3.2.17}$$

Equation 3.2.17 approximates the numerical results for the average heat-transfer coefficient in the range, $7.2 \le \mathrm{Ra} \le 10^7$ and Prandtl number, $0.72 \le \mathrm{Pr} \le 100$ with an error of 11%.

12. *Horizontal inclined square cylinder*, *Figure 3.2.4e*. For a long tilted isothermal square cylinder of side length D, the heat-transfer coefficient in the laminar regime is given by the following expression (based on the characteristic linear scale, $L_{\mathrm{c}} = D$) over the range of Rayleigh number, $7.2 \le \mathrm{Ra} \le 10^7$ and Prandtl number, $0.72 \le \mathrm{Pr} \le 100$ (Sasmal and Chhabra, 2012b):

$$\mathrm{Nu} = 0.761(\mathrm{Ra}^{1/4})^{0.924}. \tag{3.2.18}$$

13. *Horizontal semicircular cylinder, Figure 3.2.4f.* For a long isothermal semicircular cylinder with its flat surface oriented in the upward direction, one can use the following expression for Nu (Chandra and Chhabra, 2012):

$$\mathrm{Nu} = 0.93(\mathrm{Ra}^{1/4})^{0.79}. \tag{3.2.19}$$

In the case of the opposite configuration of the flat surface oriented downward, the average heat-transfer coefficient can be calculated from the following expression (Tiwari and Chhabra, 2013):

$$\mathrm{Nu} = 0.72(\mathrm{Ra}^{1/4})^{0.90}. \tag{3.2.20}$$

Equations 3.2.19 and 3.2.20 are based on the numerical results over the range of Rayleigh number as $7.2 \le \mathrm{Ra} \le 10^7$ and Prandtl number as $0.72 \le \mathrm{Pr} \le 100$ and use the diameter as the characteristic linear scale in the definitions of the Nu and Ra.

14. *Spheres, Figure 3.2.4g.* For spheres use Equation 3.2.6, with $m=6$, and with

$$\mathrm{Nu}_\ell = 2 + 0.878\bar{C}_\ell \mathrm{Ra}^{1/4} \qquad \text{and} \qquad \mathrm{Nu}_\mathrm{t} = \bar{C}_\mathrm{t}\mathrm{Ra}^{1/3}. \tag{3.2.21}$$

The values of $\bar{C}_\mathrm{t}$ are presented in Table 3.2.1.
An alternative correlation of the average Nusselt number for an isothermal sphere (Jafarpur and Yovanovich, 1992) is given as

$$\mathrm{Nu} = \frac{0.589\mathrm{Ra}^{1/4}}{\left[1+\left(\dfrac{0.5}{\mathrm{Pr}}\right)^{9/16}\right]^{4/9}}, \tag{3.2.22}$$

which asymptotically reduces to the following limiting results:

$$\mathrm{Pr} \to 0 : \mathrm{Nu} = 0.714\mathrm{Ra}^{1/4}\mathrm{Pr}^{1/4}. \tag{3.2.23}$$

$$\mathrm{Pr} \to \infty : \mathrm{Nu} = 0.6\mathrm{Ra}^{1/4}. \tag{3.2.24}$$

15. *Hemisphere, Figure 3.2.4h.* The heat-transfer coefficient for an inverted or upright hemisphere can be evaluated from the following expressions (Sasmal and Chhabra, 2014):

$$\text{for } \mathrm{Ra} < 10^4, \mathrm{Nu} = 2.255 + a_1(\mathrm{Ra}^{1/4})^{b_1}. \tag{3.2.25a}$$

$$\text{for } 10^4 < \mathrm{Ra} \le 10^7, \mathrm{Nu} = a_2(\mathrm{Ra}^{1/4})^{b_2}. \tag{3.2.25b}$$

The values of the fitting coefficients a_1, b_1, a_2, and b_2 for the inverted configuration, respectively, are 0.332, 1.2, 1.102, and 0.815 and for an upright hemisphere, the corresponding values are 0.343, 1.18, 1.14, and 0.8, respectively.

16. *Spheroids, Figure 3.2.4i.* For spheroids of aspect ratio, $E=a/b$ (ratio of the axis along the direction of the gravity to the axis transverse to the direction of the gravity), one can use the following expressions for Nu (Gupta et al., 2014):

$$\text{for } \mathrm{Ra} < 10^4, \mathrm{Nu} = \mathrm{Nu}_\infty + 0.706(\mathrm{Ra}^{1/4})^{1.109}E^{-0.166}. \tag{3.2.26a}$$

$$\text{for } 10^4 < \mathrm{Ra} \le 10^7, \mathrm{Nu} = 1.32(\mathrm{Ra}^{1/4})^{0.813}(2.34 - E^{0.368}). \tag{3.2.26b}$$

TABLE 3.2.2
Values of Nusselt Number in the Conduction Limit (Nu_∞)

E	0.2	0.5	1	2	5
Nu_∞	5.37	3.08	2	1.2	0.52

The values of Nu_∞ (conduction limit) are tabulated in Table 3.2.2. Equations 3.2.26a and 3.2.26b fit the numerical results with average errors of ~6% and ~11%, respectively. The characteristic linear dimension in this case is 2*b*.

17. *Combined shapes, Figure 3.2.4j.* For combined shapes, such as the cylinder in Figure 3.2.4j with spherical end caps, calculate the heat transfer from the cylinder of length L (*Case 8*), the heat transfer from a sphere of diameter D (*Case 14*) and add to obtain the total transfer. Other shapes can be treated in a similar manner.

    The effect of viscous dissipation on heat transfer from a horizontal cylinder has been studied by Fand et al. (1977), whereas the influence of very small Grashof numbers (microgravity situations) has been studied by Mograbi et al. (2002). In view of the fact that it is unlikely that the numerical and/or experimental studies will ever span all possible body shapes of interest, some attempts have also been made to introduce shape factors, characteristic linear dimension (like $\sqrt{A_s}$) combined with the consideration of the orientation to develop an approach with universal appeal. This body of literature has been reviewed by Lee et al. (1991) and Eslami and Jafarpur (2012).

Correlations for Open Cavities

There are situations where the fluid motion is constrained by the presence of solid boundaries, which themselves may be at different temperatures both of which, in turn, may deviate from the ambient temperature. A representative selection of examples of this class of problems is shown in Figure 3.2.5. The solid walls partially enclose a fluid region (cavity), where boundary openings permit the fluid to enter and leave the system. Faraway upstream from its point of entry, the fluid is at the ambient temperature, T_∞. Since access of the ambient fluid to the heated surfaces is restricted, some of the heated surface is not in contact with the cool ambient to which heat can be transferred. Therefore, this part of the surface does not contribute directly to the overall heat transfer. As the sizes of the boundary openings are increased, these situations approach the problems described in Figure 3.2.4 (e.g., value of L in Figure 3.2.5a or the value of b in Figures 3.2.5c and 3.2.5d, etc.), the previous class of problems is approached; for example, when the plate spacing in Figure 3.2.5a (Case 18) becomes very large, the heat transfer from each vertical surface is given by *Case 1*.

18. *Isothermal vertical channels, Figures 3.2.5a and b.* Figure 3.2.5a shows an open cavity bounded by two vertical walls and open at the top and bottom. The large opposing plates are isothermal, maintained at temperatures T_1 and T_2, respectively, and the spacing between these plates is small. $\overline{\Delta T}$ is the average temperature difference between the plates and the fluid temperature T_∞ as shown in Figure 3.2.4a, but T_1 and T_2 must not straddle T_∞. For this case,

$$\mathrm{Nu} = \left(\left(\frac{\mathrm{Ra}}{f\,\mathrm{Re}} \right)^m + \left(C_1 \bar{C}_\ell \mathrm{Ra}^{1/4} \right)^m \right)^{1/m} \qquad \mathrm{Ra} \le 10^5, \tag{3.2.27}$$

where f Re is the product of friction factor and Reynolds number for fully developed flow through the gap between the two plates, and C_1 is a constant that accounts for the

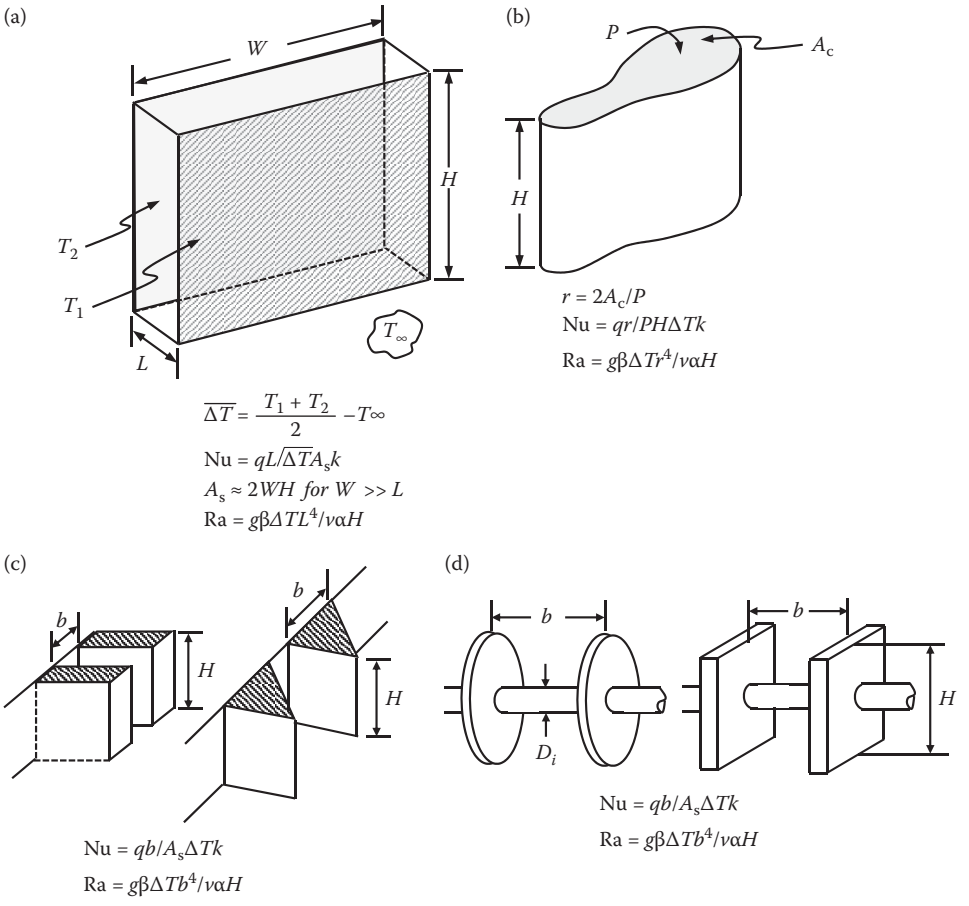

FIGURE 3.2.5 Nomenclature for various open-cavity problems.

augmentation of heat transfer, relative to a vertical flat plate (*Case 1*), due to the chimney effect. The f Re factor accounts for the cross-sectional shape (Elenbaas, 1942a). Symbols are defined in Figure 3.2.5a and b; in the Nu equation, q is the total heat transferred to the ambient fluid from all heated surfaces.

For the parallel plate channel shown in Figure 3.2.5a, use f Re = 24, $m = -1.9$, and for gases $C_1 \approx 1.2$. It should be noted, however, that C_1 must approach 1.0 as Pr increases or as the plate spacing increases. For channels of circular cross section (Figure 3.2.5b), f Re = 16, $m = -1.03$, and for gases $C_1 \approx 1.17$. For other cross-sectional shapes like the square (f Re = 14.23), hexagonal (f Re = 15.05), or equilateral triangle (f Re = 13.3), use Equation 3.2.27 with the appropriate f Re, and with $m = -1.5$, and $C_1 \approx 1.2$ for gases.

The heat-transfer per unit cross-sectional area, q/A_c, for a given channel length H and temperature difference, passes through a maximum at approximately Ra_{max}, where

$$\mathrm{Ra}_{max} = \left(\frac{f\,\mathrm{Re} C_1 \bar{C}_\ell}{2^{1/m}} \right)^{4/3}. \tag{3.2.28}$$

The limiting values of Ra_{max} provide the value of hydraulic radius $r = 2A_c/P$ at this maximum.

19. *Isothermal triangular fins, Figure 3.2.5c*. For a large array of triangular fins (Karagiozis et al., 1994) in air, for $0.4 < \mathrm{Ra} < 5 \times 10^5$:

$$\mathrm{Nu} = \bar{C}_\ell \mathrm{Ra}^{1/4}\left[1+\left(\frac{3.26}{\mathrm{Ra}^{0.21}}\right)^3\right]^{-1/3}. \tag{3.2.29}$$

In this equation, b is the average fin spacing (Figure 3.2.5c), defined such that bL is the cross-sectional flow area between two adjacent fin surfaces up to the plane of the fin tips. For Ra < 0.4, Equation 3.2.29 underestimates the convective heat transfer. When such fins are mounted horizontally (vertical baseplate, but the fin tips are horizontal), there is a substantial reduction in the convective heat transfer (Karagiozis et al., 1994).

20. *U-channel fins, Figure 3.2.5c*. For the fins most often used as heat sinks, there is some uncertainty about the heat transfer at low Rayleigh numbers. By using a conservative approximation applying for Ra < 100 (that underestimates the real heat transfer), the following equation can be used:

$$\mathrm{Nu} = \left[\left(\frac{\mathrm{Ra}}{24}\right)^{-2} + \left(C_1 \bar{C}_\ell \mathrm{Ra}\right)^{-2}\right]^{-0.5}. \tag{3.2.30}$$

For air, the value of C_1 depends on the aspect ratio of the fin as follows (Karagiozis, 1991):

$$C_1 = \left[1+\left(\frac{H}{b}\right), 1.16\right]_{\min}. \tag{3.2.31}$$

Equation 3.2.30 agrees well with measurements for Ra > 200, but for smaller Ra it severely underpredicts the value of the Nusselt number well below data because the leading term does not account for heat transfer from the fin edges and for three-dimensional conduction from the entire array.

21. *Circular fins on a horizontal tube, Figure 3.2.5d*. For heat transfer from an array of circular fins (Edwards and Chaddock, 1963), for $H/D_i = 1.94$, $5 < \mathrm{Ra} < 10^4$, and for air,

$$\mathrm{Nu} = 0.125\mathrm{Ra}^{0.55}\left[1-\exp\left(-\frac{137}{\mathrm{Ra}}\right)\right]^{0.294}. \tag{3.2.32}$$

A more general, but also more complex, relation for this case is reported by Raithby and Hollands (1985).

22. *Square fins on a horizontal tube, Figure 3.2.5d*. Heat transfer (Elenbaas, 1942b) from square fins (excluding the cylinder that connects them) is correlated for gases by

$$\mathrm{Nu} = \left[\left(\frac{\mathrm{Ra}^{0.89}}{18}\right)^m + \left(0.62\mathrm{Ra}^{1/4}\right)^m\right]^{1/m} \quad \text{where} \quad m = -2.7. \tag{3.2.33}$$

Heat Transfer in Enclosures

This section deals with cavities where the bounding walls are entirely closed, so that no mass can enter or leave the cavity. The fluid motion inside the cavity is driven by natural convection, which enhances the heat transfer among the interior surfaces that bound the cavity and the resulting value of the Nusselt number is in excess of its conduction limit.

23. *Extensive horizontal layers, Figure 3.2.6a*. If the heated plate, in a horizontal parallel plate cavity, is on the top ($\theta = 180°$), heat transfer occurs by conduction alone, so that Nu = 1. For heat transfer from below ($\theta = 0°$) (Hollands, 1984):

$$\mathrm{Nu} = 1 + \left[1 - \frac{1708}{\mathrm{Ra}}\right]^{\bullet}\left[k_1 + 2\left(\frac{\mathrm{Ra}^{1/3}}{k_2}\right)^{1-\ln\left(\mathrm{Ra}^{1/3}/k_2\right)}\right] + \left[\left(\frac{\mathrm{Ra}}{5830}\right)^{1/3} - 1\right]^{\bullet}, \qquad (3.2.34)$$

where

$$[x]^{\bullet} = (x,0)_{\max}; \qquad k_1 = \frac{1.44}{1 + \left(\frac{0.018}{\mathrm{Pr}}\right) + \left(\frac{0.00136}{\mathrm{Pr}^2}\right)}; \qquad k_2 = 75\exp(1.5\mathrm{Pr}^{-1/2}). \quad (3.2.35)$$

The equation has been validated for $\mathrm{Ra} < 10^{11}$ for water, up to $\mathrm{Ra} < 10^{8}$ for air, and over a smaller Ra range for other fluids. Equation 3.2.34 applies to extensive layers: $W/L \geq 5$. Correlations for nonextensive layers are provided by Raithby and Hollands (1985).

24. *Vertical layers, Figure 3.2.6a, with* $\theta = 90°$. $W/L > 5$. For a vertical, gas-filled ($\mathrm{Pr} \approx 0.7$) cavity with $H/L \geq 5$, the following equation closely fits the data, for example, that of Shewen et al. (1996) for Ra $(H/L)^3 \leq 5 \times 10^{10}$ and $H/L \geq 40$:

$$\mathrm{Nu}_1 = \left[1 + \left(\frac{0.0665\mathrm{Ra}^{1/3}}{1 + \left(\frac{9000}{\mathrm{Ra}}\right)^{1.4}}\right)^2\right]^{1/2}$$

$$\mathrm{Nu}_2 = 0.242\left(\mathrm{Ra}\frac{L}{H}\right)^{0.273} \qquad (3.2.36)$$

$$\mathrm{Nu} = [\mathrm{Nu}_1, \mathrm{Nu}_2]_{\max}.$$

For $\mathrm{Pr} \geq 4$, the following equation is recommended (Seki et al., 1978) for Ra $(H/L)^3 < 4 \times 10^{12}$:

$$\mathrm{Nu} = \left[1, 0.36\mathrm{Pr}^{0.051}\left(\frac{L}{H}\right)^{0.36}\mathrm{Ra}^{0.25}, 0.084\mathrm{Pr}^{0.051}\left(\frac{L}{H}\right)^{0.1}\mathrm{Ra}^{0.3}\right]_{\max} \qquad (3.2.37a)$$

And for Ra $(H/L)^3 > 4 \times 10^{12}$

$$\mathrm{Nu} = 0.039\mathrm{Ra}^{1/3}. \qquad (3.2.37b)$$

25. *Tilted layers, Figure 3.2.6a, with* $0 \leq \theta \leq 90°$, $W/L > 8$. For gases ($\mathrm{Pr} \approx 0.7$), $0 \leq \theta \leq 60°$, and $\mathrm{Ra} \leq 10^5$ (Hollands et al., 1976), one can use

$$\mathrm{Nu} = 1 + 1.44\left[1 - \frac{1708}{\mathrm{Ra}\cos\theta}\right]^{\bullet}\left[1 - \frac{1708(\sin 1.8\theta)^{1.6}}{\mathrm{Ra}\cos\theta}\right] + \left[\left(\frac{\mathrm{Ra}\cos\theta}{5830}\right)^{1/3} - 1\right]^{\bullet}. \quad (3.2.38)$$

See Equation 3.2.35 for definition of [x]. For $60° \leq \theta \leq 90°$, linear interpolation is recommended using Equations 3.2.36 for $\theta = 90°$ and 3.2.38 for $\theta = 60°$.

26. *Concentric cylinders, Figure 3.2.6b.* For heat transfer across the gap between horizontal concentric cylinders, the Nusselt number is defined as $\mathrm{Nu} = q' \ln(D_o/D_i)/(2\pi k \Delta T)$ where q' is the heat-transfer per unit length of cylinder. For $\mathrm{Ra} \leq 8 \times 10^7$, $0.7 \leq \mathrm{Pr} \leq 6000$, $1.15 \leq D_o/D_i \leq 8$ (Raithby and Hollands, 1975),

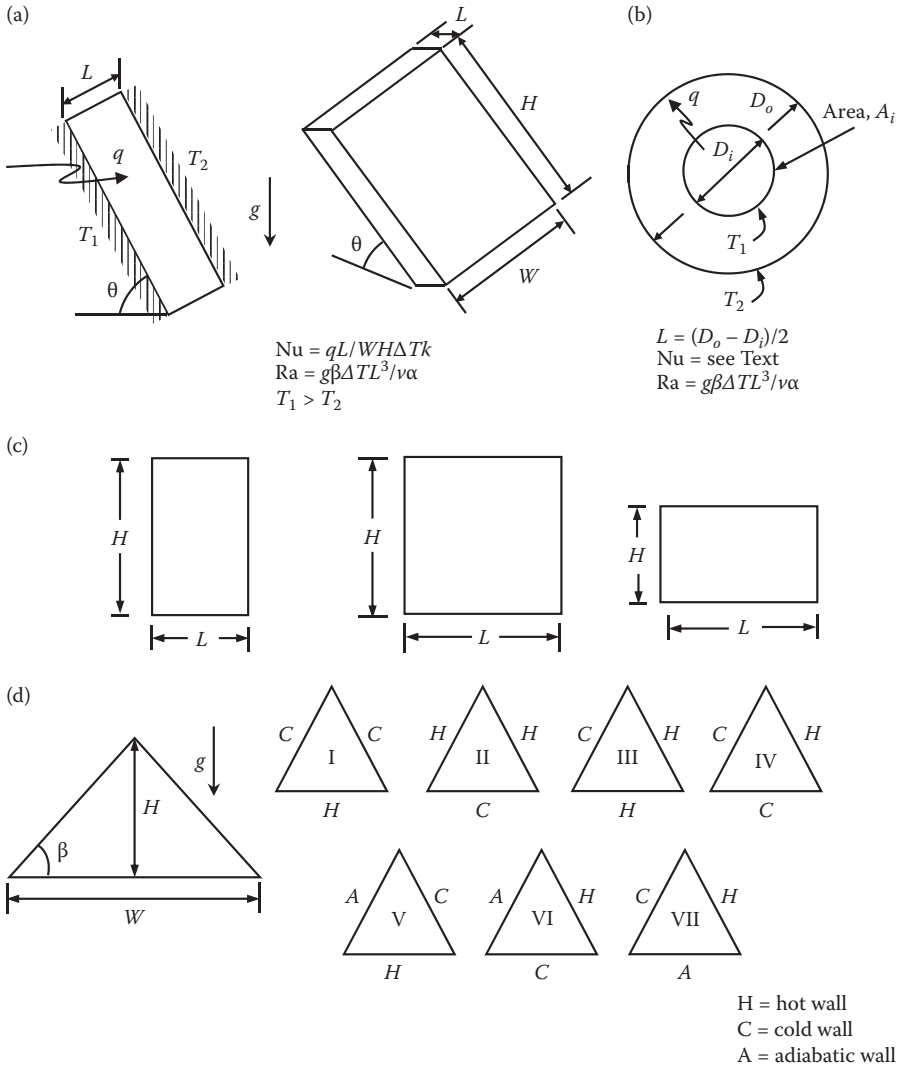

FIGURE 3.2.6 Nomenclature for enclosure problems.

$$\mathrm{Nu} = \left[0.603\bar{C}_\ell \frac{\ln\left(D_o/D_i\right)\mathrm{Ra}^{1/4}}{\left[\left(L/D_i\right)^{3/5} + \left(L/D_o\right)^{3/5}\right]^{5/4}}, 1 \right]_{\max} . \tag{3.2.39}$$

For eccentric cylinders, see Raithby and Hollands (1985).

27. *Concentric spheres, Figure 3.2.6b.* The heat transfer between concentric spheres is given by the following equation (Raithby and Hollands, 1975) for $\mathrm{Ra} \le 6 \times 10^8$, $5 \le \mathrm{Pr} \le 4000$, $1.25 < D_o/D_i \le 2.5$:

$$\mathrm{Nu} = \frac{qL}{D_i D_o k \Delta T} = \left[1.16\bar{C}_\ell \left(\frac{L}{D_i} \right)^{1/4} \frac{\mathrm{Ra}^{1/4}}{\left[\left(D_i/D_o\right)^{3/5} + \left(D_i/D_o\right)^{5/4}\right]}, 1 \right]_{\max} . \tag{3.2.40}$$

For eccentric spheres, see Raithby and Hollands (1985).

28. *Rectangular enclosures*, *Figure 3.2.6c*. A comprehensive review of the buoyancy-driven flow in a rectangular cavity is presented in Bejan (2013) and Martynenko and Khramtsov (2005) spanning laminar and turbulent regimes. From various different configurations of the buoyancy-driven flow in an enclosure of height H and horizontal length L, one of the most studied cases involves a two-dimensional rectangular cavity with differentially heated vertical side walls while the other two walls are adiabatic. Other configurations found in the literature consist of differentially heated horizontal surfaces with insulated vertical walls, sidewalls with uniform heat flux, a heat flux given on the one vertical surface and the temperature on the other, partially divided enclosures, etc. One must resort to the original publications for these cases.
29. *Triangular enclosures*, *Figure 3.2.6d*. The heat-transfer coefficient for isosceles triangular enclosures (aspect ratio, $AR=H/W$) with possible nontrivial combinations of isothermal and adiabatic side walls and bottom can be evaluated by the following equations in laminar regime.

    Configuration VII: For $4.1 \times 10^6 \le \mathrm{Ra}_H \le 12.7 \times 10^6$, Pr=0.71 (Flack and Witt, 1979a, b; Flack et al., 1979)

$$0.29 \le AR \le 0.87, \mathrm{Nu} = 0.269\mathrm{Ra}_{\mathrm{H}}^{0.34} \tag{3.2.41}$$

    Configuration I: For $11.26 \times 10^2 \le \mathrm{Ra}_H \le 9 \times 10^4$, Pr=0.71 (Akinsete and Coleman, 1979a, b, 1982; Coleman, 1980)

$$0.0625 \le AR \le 1, \mathrm{Nu} = 1.122\mathrm{Ra}_{\mathrm{w}}^{0.0535} AR^{-1.19} \tag{3.2.42}$$

    Configuration I, II: For $7.5 \times 10^4 \le \mathrm{Ra}_{\mathrm{H}} \le 2 \times 10^5$, Pr=0.71 (Flack, 1980)

$$AR = 1, \mathrm{Nu} = 0.21\mathrm{Ra}_{\mathrm{H}}^{0.30} \tag{3.2.43}$$

    Configuration I: For $7.5 \times 10^4 \le \mathrm{Gr}_H \le 2 \times 10^5$, Pr=0.72, 6 (Poulikakos and Bejan, 1983)

$$0.2 \le AR \le 1, \mathrm{Nu} = AR^{0.5}\mathrm{Ra}_{\mathrm{H}}^{0.25} \tag{3.2.44}$$

    Configuration I: For $7.1 \times 10^2 \le \mathrm{Ra}_{\mathrm{H}} \le 7.1 \times 10^5$, Pr=0.71 (Hasani and Chung, 1997)

$$0.2 \le AR \le 1, \mathrm{Nu} = 3.778 + 0.332\mathrm{Ra}_{\mathrm{H}}^{0.124} AR^{1.375} \tag{3.2.45}$$

    Configuration II: For $7.1 \times 10^2 \le \mathrm{Ra}_{\mathrm{H}} \le 7.1 \times 10^5$, Pr=0.71 (Hasani and Chung, 1997)

$$0.2 \le AR \le 0.6, \mathrm{Nu} = 3.855 + 0.0043\mathrm{Ra}_{\mathrm{H}}^{0.588} AR^{0.323} \tag{3.2.46a}$$

$$0.6 \le AR \le 1.0, \mathrm{Nu} = 4.342 + 0.0033\mathrm{Ra}_{\mathrm{H}}^{0.6004} AR^{0.699}. \tag{3.2.46b}$$

30. *Array of circular cylinders* (*vertical and horizontal*). For calculating the heat-transfer coefficient for a cylinder array arranged in a vertical line, one can use the following expression (Tokura et al., 1983):

$$\mathrm{Nu}_N = 0.410\mathrm{Ra}^{1/4} \ln\left[\left\{\left(b/d\right)/1.3\right\}^{0.055N}\right] + 0.434. \tag{3.2.47}$$

TABLE 3.2.3
Values of a_3 and b_3 in Equation 3.2.48

s/D→	0.7	0.8333	1.0
a_3	0.5972	0.6186	0.5735
b_3	0.0713	0.0488	0.0301

Equation 3.2.47 fits the experimental data within ±10% in the range of $[(b/d)/1.3]^{0.055N} = 0.7$ to 1.2, $1 < S/d < 40$, $\mathrm{Gr} = 4 \times 10^4$ to 4×10^5 and $\mathrm{Pr} = 0.71$, where *S/D* is the distance between parallel plates and *b/D* is the spacing ratio defined as diameter-to-diameter distance.

For two differentially heated vertically aligned cylinders in an adiabatic circular enclosure with spacing *s/D*, center-to-center distance, the following expression for the average Nusselt number can be used (Ho et al.,1993):

$$\mathrm{Nu} = a_3 \mathrm{Ra}^{b_3}, \tag{3.2.48}$$

where the values of fitted parameters a_3 and b_3 for $10^4 \le \mathrm{Ra} \le 10^7$ and $\mathrm{Pr} = 0.71$ are given in Table 3.2.3.

Example Calculations

Problem 3.2.1: Heat transfer from a vertical plate, Figure 3.2.7a. For the vertical isothermal surface in Figure 3.2.7a with $T_s = 40°\mathrm{C}$, $H_1 = H_2 = W_1 = W_2 = 1$ m and for an ambient air temperature of $T_\infty = 20°\mathrm{C}$ (at 1 atm), find the rate of heat transfer from one side of the plate.

Properties: At $T_f = (T_w + T_\infty)/2 = 30°\mathrm{C}$ and atmospheric pressure for air: $\nu = 1.59 \times 10^{-5}$ m²/s, $\alpha = 2.25 \times 10^{-5}$ m²/s, $\mathrm{Pr} = 0.71$, $k = 0.0263$ W/mK. At T_∞, $\beta \approx 1/T_\infty = 1(273+20) = 0.00341$ K⁻¹.

Solution: For the geometry shown in Figure 3.2.7a

$$A_s = (H_1 + H_2)W_1 + \left(H_1 + \frac{H_2}{2}\right)W_2 = 3.5 \text{ m}^2 \quad \text{(plate surface area)}$$

$$\int_0^{W_1+W_2} S^{3/4}\, d\chi = (H_1+H_2)^{3/4} W_1 + \frac{4}{7}\frac{W_2}{H_2}\left[(H_1+H_2)^{7/4} - H_1^{7/4}\right] = 3.03 \text{ m}^{7/4}$$

$$L^{1/4} = (H_1 + H_2)^{1/4} = 1.19 \text{ m}^{1/4}.$$

Using Equation 3.2.11,

$$C_1 = \frac{L^{1/4} \int_0^{W_1+W_2} S^{3/4}\, d\chi}{A_s} = \frac{1.19 \times 3.03}{3.5} = 1.03$$

$$\mathrm{Ra} = \frac{g\beta_\infty L^3 (T_w - T_\infty)}{\upsilon\alpha} = \frac{9.81 \times 0.00341 \times 2^3 \times (40-20)}{1.59 \times 10^{-5} \times 2.25 \times 10^{-5}} = 1.50 \times 10^{10}$$

$\bar{C}_\ell = 0.514$ from Equation 3.2.3; $C_t = C_t^V = 0.103$ from Equation 3.2.4. $\mathrm{Nu}^T = C_1 \bar{C}_\ell \mathrm{Ra}^{1/4} = 185$ from Equation 3.2.11.

$$\left.\begin{aligned} \mathrm{Nu_t} &= \frac{2.0}{\ln\left(1+2.0/\mathrm{Nu^T}\right)} = 186 \\ \mathrm{Nu_t} &= C_t^{V}\mathrm{Ra}^{1/3}\Big/\left(1+1.4\times10^{9}\,\mathrm{Pr}/\mathrm{Ra}\right) = 238 \end{aligned}\right\} \text{(from Equation (3.2.7))}$$

$$Nu = \frac{qL}{A\Delta Tk} = \left(Nu_\ell^6 + Nu_t^6\right)^{1/6} = 246$$

from Equation 3.2.6 with $m=6$.

$$q = \frac{A_s\Delta Tk\mathrm{Nu}}{L} = \frac{3.5\times20\times0.0263\times246}{2} = 226W.$$

Comments: Since $\mathrm{Nu}_\ell < \mathrm{Nu_t}$, the heat transfer is primarily in the turbulent regime. One must ascertain if it is justified to neglect radiation in this case. Had the surface been specified to be at constant heat flux, rather than isothermal, the equations in this section can be used to find the approximate average temperature difference between the plate and fluid.

Problem 3.2.2: Heat transfer from horizontal strip, Figure 3.2.7b. Find the rate of heat loss per unit length from a very long strip of width $W=0.1$ m with a surface temperature of $T_s=70°C$ in water at $T_\infty=30°C$.

Properties: At $T_f=(T_s+T_\infty)/2=50°C$

$$\nu = 5.35\times10^{-7}\mathrm{m^2/s} \quad \alpha = 1.56\times10^{-7}\mathrm{m^2/s} \quad \mathrm{Pr} = 3.42$$

$$k = 0.645\ \mathrm{W/mK} \quad \beta = 2.76\times10^{-4}K^{-1}$$

Solution: This problem corresponds to *Case 3* and Figure 3.2.2c.

$$C_t^{H} = 0.14.$$

From Equation 3.2.5 and $\bar{C}_l = 0.563$ from Equation 3.2.3,

$$L^* = \lim_{H\to\infty}\left(\frac{WH}{2W+2H}\right) = \frac{W}{2} = 0.05\ \mathrm{m}.$$

From Figure 3.2.2c and Equation 3.2.9,

$$\mathrm{Ra} = \frac{g\beta\Delta TL^{*3}}{\upsilon\alpha} = 1.62\times10^{8} \qquad \mathrm{Nu^T} = 0.835\bar{C}_l\mathrm{Ra}^{1/4} = 55.6$$

$$\mathrm{Nu}_\ell = \frac{1.4}{\ln\left(1+1.4/\mathrm{Nu^T}\right)} = 56.3 \qquad \mathrm{Nu_t} = C_t^{H}\mathrm{Ra}^{1/3} = 76.3$$

$$\mathrm{Nu} = \frac{q}{WH\Delta T}\frac{L^*}{k} = \left(\mathrm{Nu}_l^{10} + \mathrm{Nu}_t^{10}\right)^{0.1} = 76.7$$

$$q/H = \frac{W\Delta Tk\mathrm{Nu}}{L^*} = 3960\ \mathrm{W/m}.$$

Comments: Turbulent heat transfer is dominant. Radiation can be ignored (since it lies in the far infrared region where it is not transmitted by the water).

Problem 3.2.3: Heat loss across a window cavity, Figure 3.2.7c. The interior glazing is at temperature $T_1=10°C$, the exterior glazing at $T_2=-10°C$, the window dimensions are $W=1$ m, $H=1.7$ m,

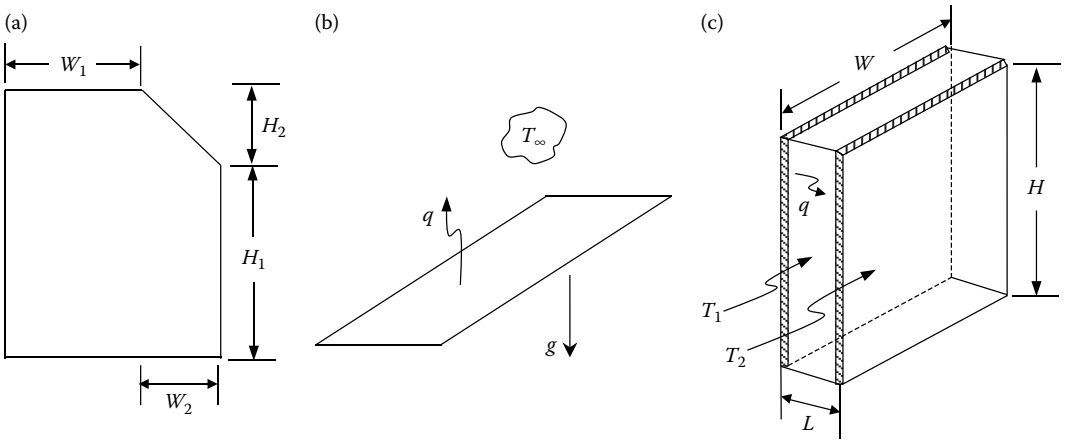

FIGURE 3.2.7 Sketches for example problems.

and the air gap between the glazings is $L = 10$ mm and is at atmospheric pressure. Find the heat loss across the window.

Properties: At $\overline{T} = (T_1 + T_2)/2 = 0^\circ\text{C} = 273\ \text{K}$

$$\nu = 1.35 \times 10^{-5}\ \text{m}^2/\text{s} \quad \alpha = 1.89 \times 10^{-5}\ \text{m}^2/\text{s} \quad \text{Pr} = 0.71$$

$$k = 0.024\ \text{W/mK} \quad \beta = 1/273 = 3.66 \times 10^{-3} \cdot K^{-1}$$

Solution: The appropriate correlations are given in *Case 24* and by Equation 3.2.36:

$$\text{Ra} = \frac{g\beta(T_1 - T_2)L^3}{\upsilon\alpha} = \frac{9.81 \times 3.66 \times 10^{-3} \times 20 \times (0.01)^3}{1.35 \times 10^{-5} \times 1.89 \times 10^{-5}} = 2.81 \times 10^3$$

$$\text{Nu}_1 = \left[1 + \left\{ \frac{0.0665\text{Ra}^{1/3}}{1 + \left(\frac{9000}{\text{Ra}} \right)^{1.4}} \right\}^2 \right]^{1/2} = 1.01$$

$$\text{Nu}_2 = 0.242\left(\text{Ra}\frac{L}{H} \right)^{0.273} = 0.242\left(2.81 \times 10^3 \times \frac{0.01}{1.7} \right)^{0.273} = 0.520$$

$$\text{Nu} = \frac{qL}{WH(T_1 - T_2)k} = (\text{Nu}_1, \text{Nu}_2)_{\max} = 1.01$$

$$q/WH = \frac{\text{Nu}(T_1 - T_2)k}{L} = \frac{1.01 \times 20 \times 0.024}{0.01} = 48.5\ \text{W/m}^2.$$

Comments: For pure conduction across the air layer, Nu = 1.0. For the calculated value of Nu = 1.01, convection must play little role. For standard glass, the heat loss by radiation would be roughly double the natural convection value just calculated.

In this section, the results only for a range of representative configurations have been included and a more exhaustive coverage can be found in the book of Martynenko and Khramtsov (2005).

Special Nomenclature

Note that nomenclature for each geometry considered is provided in the figures that are referred to in the text.

$\overline{C}_{\ell}$ = function of Prandtl number, Equation 3.2.3
C_t^V = function of Prandtl number, Equation 3.2.4
C_t^H = function of Prandtl number, Equation 3.2.5
$\overline{C}_t$ = surface averaged value of C_t, Equation 3.2.12

Further Information

There are several excellent heat-transfer textbooks that provide fundamental information and correlations for natural convection heat transfer (e.g., Kreith et al., 2011; Bergman et al., 2011). The correlations in this section closely follow the recommendations of Raithby and Hollands (1985), but that reference considers many more problems. Alternative equations are provided by Churchill and coworkers (1972, 1975) and by Martynenko and Khramtsov (2005). Good reviews of free convection in enclosures are available (Khalifa, 2001a, b; Bairi et al., 2014; Kamiya et al., 2010), which should be consulted for further details.

3.2.2 Forced Convection: External Flows

Anoop K. Gupta, Raj P. Chhabra, and N.V. Suryanarayana

Introduction

In this section, we consider forced convection heat transfer between a solid surface and an adjacent fluid, which is in motion relative to the solid surface. If the surface temperature is different from that of the fluid, heat is transferred by forced convection. The velocity and temperature of the fluid far away from the solid surface are at the free-stream velocity (U_∞) and temperature (T_∞) conditions, respectively. Both are usually known or specified in a given situation. We are then required to find the heat flux from or to the surface with specified surface temperature or the surface temperature if the heat flux is specified. The specified temperature or heat flux either may be uniform or may vary along the surface. The convective heat-transfer coefficient h is defined by the equation

$$q'' = h(T_s - T_\infty). \tag{3.2.49}$$

In Equation 3.2.49 with the local heat flux, we obtain the local heat-transfer coefficient, and with the average heat flux with a uniform surface temperature, we get the average heat-transfer coefficient. For a specified heat flux, the local surface temperature is obtained by employing the local convective heat-transfer coefficient in Equation 3.2.49.

Many correlations for estimating the convective heat-transfer coefficient are available, which endeavor to combine the approximate analytical, numerical, and experimental data. Depending upon the idealizations inherent in the analytical and experimental results vis-à-vis the conditions encountered in an application, one should not expect the actual value of the heat-transfer coefficient to be known very precisely, and uncertainties of the order of ±20% or even more are not uncommon.

Many different correlations to determine the convective heat-transfer coefficient have been developed for a range of geometries. In this section, only a selection of widely used correlations for common shapes is given. For other correlations and more details, refer to the books given in the bibliography at the end of this section.

Flat Plate

With a fluid flowing parallel to a flat plate (Figure 3.2.8), changes in velocity and temperature of the fluid are confined to a thin region adjacent to the solid boundary—the boundary layers of thicknesses δ and δ_T, both of which increase with x. Depending upon the conditions, several possibilities exist:

1. Flows without or with pressure gradient
2. Laminar or turbulent boundary layer
3. Negligible or significant viscous dissipation (effect of frictional heating)
4. $Pr \geq 0.7$ (gases and most liquids) or $Pr \ll 1$ (liquid metals)

Each of these is given consideration in the following sections.

Flows with Zero Pressure Gradient and Negligible Viscous Dissipation

When the free-stream pressure is uniform, the free-stream velocity is also uniform. Whether the boundary layer is laminar or turbulent is determined by the value of the local Reynolds number Re_x ($\rho U_\infty x/\mu$) and the shape of the solid surface at the entrance of the flow. With a sharp edge at the leading edge (Figure 3.2.8), the boundary layer is initially laminar, but at some distance downstream there is a transition region where the boundary layer is neither fully laminar nor fully turbulent. Farther downstream of the transition region, the boundary layer becomes fully turbulent. For engineering applications, the existence of the transition region is usually neglected and it is assumed

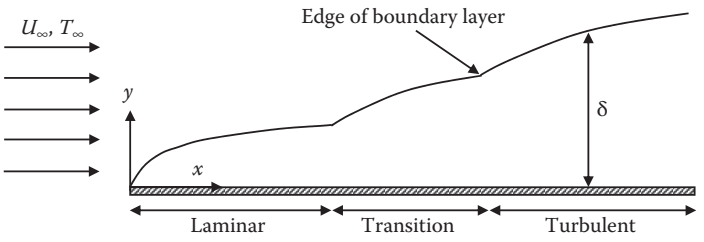

FIGURE 3.2.8 Flow of a fluid over a flat plate with laminar, transition, and turbulent boundary layers.

that the boundary layer becomes turbulent if the Reynolds number, Re_x, is greater than the critical Reynolds number, Re_{cr}. A typical value of 5×10^5 for the critical Reynolds number is generally accepted for a flat plate, but it can be greater if the free-stream turbulence is low and lower if the free-stream turbulence is high, the surface is rough, or the surface does not have a sharp edge at entrance. If the entrance is blunt, the boundary layer may be turbulent from the leading edge itself, albeit a very thin laminar sublayer exists very close to the surface of the plate even under these conditions. The momentum transfer in the y-direction occurs solely by diffusion within the boundary layer. The velocity gradient dU_x/dy gradually decreases with increasing y from its maximum value at $y=0$ to zero at $y=\delta$.

Temperature Boundary Layer

Analogous to the velocity boundary layer, there exists a temperature boundary layer adjacent to a heated (or cooled) plate. The temperature of the fluid changes from the surface temperature (T_s) to the free-stream temperature (T_∞) at the edge of the thermal boundary layer (Figure 3.2.9). By analogy with momentum transfer, heat transfer inside the thermal boundary layer occurs by conduction in the y-direction.

The velocity boundary layer thickness δ depends on the Reynolds number Re_x. The thermal boundary layer thickness δ_T depends both on the Reynolds number (Re_x) and Prandtl number (Pr) as well as on the type of thermal boundary condition prescribed on the surface of the plate as follows:

In the laminar regime, $Re_x < Re_{cr}$:

$$\frac{\delta}{x} = \frac{5}{\sqrt{Re_x}}. \tag{3.2.50a}$$

$$\text{For } Pr > 0.7: \frac{\delta}{\delta_T} = Pr^{1/3}: \tag{3.2.50b}$$

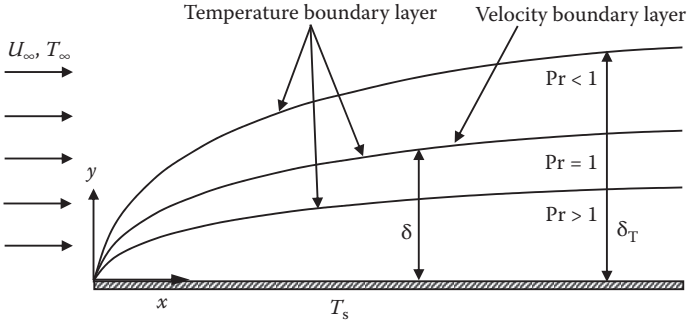

FIGURE 3.2.9 Temperature boundary layer thickness relative to velocity boundary layer thickness.

$$\text{For Pr} << 1 : \frac{\delta}{\delta_T} = \text{Pr}^{1/2} : \tag{3.2.50c}$$

In the turbulent regime, $\text{Re}_{cr} < \text{Re}_x$:

$$\frac{\delta}{x} = \frac{0.37}{\text{Re}_x^{0.2}} \text{ and } \delta \approx \delta_T. \tag{3.2.51}$$

Both these results are based on the assumptions of incompressible flow and constant values of the thermophysical properties of the fluid and negligible viscous dissipation effects. The viscous dissipation and high-speed effects can be neglected if $\text{Pr}^{1/2}\text{Ec}/2 << 1$. These effects are considered in later sections. The Eckert number, Ec, is defined as $\text{Ec} = U_\infty^2 / C_p(T_s - T_\infty)$.

With a rectangular thin plate of length L in the direction of the flow and infinitely wide in the lateral direction, the average heat-transfer coefficient h_L for the case of isothermal surface is given by

$$h_L = \frac{1}{L}\int_0^L h_x \mathrm{d}x. \tag{3.2.52}$$

Laminar Boundary Layer (Figure 3.2.10) ($\text{Re}_x < \text{Re}_{cr}$, $\text{Re}_L < \text{Re}_{cr}$): With heating or cooling starting from the leading edge (at $x=0$), the following correlations are recommended for estimating the value of the Nusselt number. In all equations presented herein, the fluid properties are evaluated at the film temperature defined as the arithmetic mean of the surface and free-stream temperatures, that is, $(T_s + T_\infty)/2$ unless otherwise stated.

Local Heat Transfer Coefficient (Uniform Surface Temperature)

The Nusselt number based on the local convective heat-transfer coefficient is expressed as

$$\text{Nu}_x = f_{\text{Pr}}\text{Re}_x^{1/2} \tag{3.2.53}$$

The classical expression for f_{Pr} is $0.564\text{Pr}^{1/2}$ for liquid metals with very low Prandtl numbers, $0.332\text{Pr}^{1/3}$ for $0.7 < \text{Pr} < 50$ and $0.339\text{Pr}^{1/3}$ for very large values of the Prandtl number. The two widely used correlations (valid for all Prandtl numbers) are due to Churchill (1976), Equation 3.2.54, and Rose (1979), Equation 3.2.55, as follows:

$$\text{Nu}_x = \frac{0.3387\text{Re}_x^{1/2}\text{Pr}^{1/3}}{\left[1+\left(\frac{0.0468}{\text{Pr}}\right)^{2/3}\right]^{1/4}}, \tag{3.2.54}$$

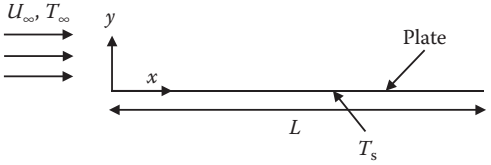

FIGURE 3.2.10 Heated flat plate with heating from the leading edge.

$$\mathrm{Nu}_x = \frac{\mathrm{Re}_x^{1/2}\mathrm{Pr}^{1/2}}{\left[27.8 + 75.9\mathrm{Pr}^{0.306} + 657\mathrm{Pr}\right]^{1/6}}. \tag{3.2.55}$$

In the wide range of Prandtl number as $0.001 < \mathrm{Pr} < 2000$, Equations 3.2.54 and 3.2.55 yield values of the local Nusselt number, which are within ~1.5% and ~0.5% of the exact numerical results based on the solution of the boundary layer energy equations.

Average Heat-Transfer Coefficient

The average heat-transfer coefficient is given by

$$\mathrm{Nu}_L = 2\mathrm{Nu}_{x=L}. \tag{3.2.56}$$

From Equation 3.2.56, it is clear that the average heat-transfer coefficient over a length L is twice the local heat-transfer coefficient at $x=L$.

Uniform Heat Flux

Local Heat Transfer Coefficient

In this case, the need to estimate the unknown temperature frequently arises via the application of Equation 3.2.49. A good summary of the available results is given in Schlichting and Gersten (2011). From an engineering application standpoint, one of the widely used predictive correlation spanning the complete range of Prandtl numbers is that of Churchill and Ozoe (1973), which is written as follows:

$$\mathrm{Nu}_x = \frac{0.886\mathrm{Re}_x^{1/2}\mathrm{Pr}^{1/2}}{\left[1 + \left(\frac{\mathrm{Pr}}{0.0207}\right)^{2/3}\right]^{1/4}}. \tag{3.2.57}$$

Note that for surfaces with uniform heat flux, the local convective heat-transfer coefficient is used to determine the local surface temperature. The total heat-transfer rate being known, an average heat-transfer coefficient is generally not needed and not defined.

Turbulent Boundary Layer ($\mathrm{Re}_x > \mathrm{Re}_{cr}$, $\mathrm{Re}_L > \mathrm{Re}_{cr}$): For turbulent boundary layers with heating or cooling starting from the leading edge, one can use the following correlations:

Local Heat Transfer Coefficient

$$\mathrm{Re}_{cr} < \mathrm{Re}_x < 10^7:$$

$$\mathrm{Nu}_x = 0.0296\mathrm{Re}_x^{4/5}\mathrm{Pr}^{1/3}. \tag{3.2.58}$$

$$10^7 < \mathrm{Re}_x:$$

$$\mathrm{Nu}_x = 1.596\mathrm{Re}_x(\ln \mathrm{Re}_x)^{-2.584}\mathrm{Pr}^{1/3}. \tag{3.2.59}$$

Equation 3.2.59 is obtained by applying Colburn's j-factor in conjunction with the friction factor suggested by Schlichting and Gersten (2011).

In laminar boundary layers, the convective heat-transfer coefficient with uniform heat flux is approximately 36% higher than that for uniform surface temperature conditions. With turbulent boundary layers, the difference is very small and *the correlations for the local convective heat-transfer coefficient can be used for both uniform surface temperature and uniform heat flux with approximately the same level of confidence.*

Average Heat Transfer Coefficient

If the boundary layer is initially laminar over the initial part of the plate followed by the establishment of a turbulent boundary layer at $\mathrm{Re}_x = \mathrm{Re}_{cr}$, the following correlations for $0.7 < \mathrm{Pr} < 60$ are suggested:

$$\mathrm{Re}_{cr} < \mathrm{Re}_L < 10^7:$$

$$\mathrm{Nu}_L = \left[0.664\mathrm{Re}_L^{1/2} + 0.037\left(\mathrm{Re}_L^{4/5} - \mathrm{Re}_{cr}^{4/5}\right)\right]\mathrm{Pr}^{1/3}. \tag{3.2.60}$$

If $\mathrm{Re}_{cr} < \mathrm{Re}_L < 10^7$ and $\mathrm{Re}_{cr} = 10^5$, Equation 3.2.60 simplifies to

$$\mathrm{Nu}_L = \left(0.037\mathrm{Re}_L^{4/5} - 871\right)\mathrm{Pr}^{1/3}, \tag{3.2.61}$$

$10^7 < \mathrm{Re}_L$ and $\mathrm{Re}_{cr} = 5 \times 10^5$, the corresponding result is given as follows:

$$\mathrm{Nu}_L = \left[1.963\mathrm{Re}_L\left(\ln \mathrm{Re}_L\right)^{-2.584} - 871\right]\mathrm{Pr}^{1/3}. \tag{3.2.62}$$

Uniform Surface Temperature—Pr > 0.7: Unheated Starting Length

If heating starts from the leading edge at a distance ($x = x_0$), as shown in Figure 3.2.11, the correlations have to be modified. Correlation for the local convective heat-transfer coefficient for laminar and turbulent boundary layers are given by Equations 3.2.63 and 3.2.64 (Kays et al., 2004)—the constants in Equations 3.2.63 and 3.2.64 have been modified to be consistent with the friction factors. These correlations are also useful as building blocks for finding the heat-transfer rates when the surface temperature varies in a predefined manner. Equations 3.2.65 and 3.2.66, developed by Thomas (1977), provide the average heat-transfer coefficients based on Equations 3.2.63 and 3.2.64.

Local Convective Heat Transfer Coefficient

$$\mathrm{Re}_x < \mathrm{Re}_{cr}:$$

$$\mathrm{Nu}_x = \frac{0.332\mathrm{Re}_x^{1/2}\mathrm{Pr}^{1/3}}{\left[1 - \left(\frac{x_0}{x}\right)^{3/4}\right]^{1/3}} \tag{3.2.63}$$

$$\mathrm{Re}_x > \mathrm{Re}_{cr}:$$

$$\mathrm{Nu}_x = \frac{0.0296\mathrm{Re}_x^{4/5}\mathrm{Pr}^{3/5}}{\left[1 - \left(\frac{x_0}{x}\right)^{9/10}\right]^{1/9}} \tag{3.2.64}$$

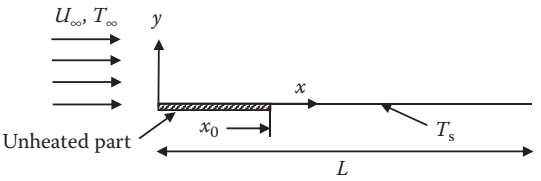

FIGURE 3.2.11 Heated flat plate with unheated starting length ($x \le x_0$).

Average Heat Transfer Coefficient over the Length ($L-x_0$)

$$\mathrm{Re}_L < \mathrm{Re}_{\mathrm{cr}}:$$

$$h_{L-x_0} = \frac{0.664\mathrm{Re}_L^{1/2}\mathrm{Pr}^{1/3}\left[1-\left(\frac{x_0}{L}\right)^{3/4}\right]^{2/3}k}{L-x_0} = 2\frac{1-(x_0/L)^{3/4}}{1-(x_0/L)}h_{x=L}. \tag{3.2.65}$$

In Equation 3.2.65, evaluate $h_{x=L}$ from Equation 3.2.63.

$$\mathrm{Re}_{\mathrm{cr}} = 0:$$

$$h_{L-x_0} = \frac{0.037\mathrm{Re}_L^{4/5}\mathrm{Pr}^{3/5}\left[1-\left(\frac{x_0}{L}\right)^{9/10}\right]^{8/9}k}{L-x_0} = 1.25\frac{1-(x_0/L)^{9/10}}{1-(x_0/L)}h_{x=L}. \tag{3.2.66}$$

In Equation 3.2.66, evaluate $h_{x=L}$ from Equation 3.2.64.

Flat Plate with Prescribed Nonuniform Surface Temperature

In practice, one can encounter the situation where the surface temperature varies in a prescribed manner. In this case, one can apply Equations 3.2.63 through 3.2.66 locally by dividing the total temperature difference into smaller steps. Figure 3.2.12 shows the arbitrarily prescribed surface temperature with a uniform free-stream temperature of the fluid. If the surface temperature is a differentiable function of the coordinate x, the local heat flux can be determined by an expression that involves integration (Kays et al., 2004). If the surface temperature can be approximated as a series of step changes in the surface temperature, the resulting expression for the local heat flux and the total heat-transfer rate is the summation of the individual simple algebraic expressions. Here the method using such an algebraic simplification is presented.

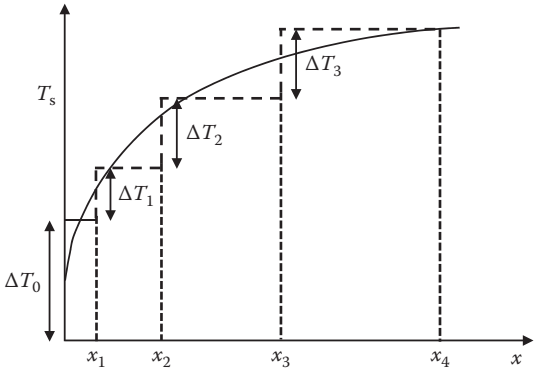

FIGURE 3.2.12 Arbitrary surface temperature approximated as a finite number of step changes.

The local heat flux at a distance x from the leading edge is given by

$$q''_x = \sum_1^n h_{xi} \Delta T_{si}, \tag{3.2.67}$$

where h_{xi} denotes the local heat-transfer coefficient at the position x due to a single step change in the surface temperature ΔT_{si} at location x_i ($x_i < x$). Referring to Figure 3.2.12, the local heat flux at x ($x_3 < x < x_4$) is given by

$$q''_x = h_x(x,0)\Delta T_0 + h_x(x,x_1)\Delta T_1 + h_x(x,x_2)\Delta T_2 + h_x(x,x_3)\Delta T_3, \tag{3.2.68}$$

where $h_x(x, x_1)$ is the local heat-transfer coefficient at x with heating starting from x_1; the local heat transfer is determined from Equation 3.2.63 if the boundary layer is laminar and Equation 3.2.64 if the boundary layer is turbulent from the leading edge. For example, $h_x(x, x_2)$ in the third term is given by

$\mathrm{Re}_x < \mathrm{Re}_{cr}$:

$$h_x(x,x_2) = \frac{0.332\left(\dfrac{\rho U_\infty x}{\mu}\right)^{1/2} \mathrm{Pr}^{1/3}}{\left[1-\left(\dfrac{x_2}{x}\right)^{3/4}\right]^{1/3}} \frac{k}{x}, \tag{3.2.69a}$$

$\mathrm{Re}_x > \mathrm{Re}_{cr}$:

$$h_x(x,x_2) = \frac{0.0296\left(\dfrac{\rho U_\infty x}{\mu}\right)^{4/5} \mathrm{Pr}^{3/5}}{\left[1-\left(\dfrac{x_2}{x}\right)^{9/10}\right]^{1/9}} \frac{k}{x}. \tag{3.2.69b}$$

The procedure for finding the total heat-transfer rate from $x=0$ to $x=L$ is somewhat similar. Denoting the width of the plate by W,

$$\frac{q}{W} = \sum h_{L-x_i} \Delta T_i \left(L - x_i\right), \tag{3.2.70}$$

where h_{L-x_i} is the average heat-transfer coefficient over the length $(L-x_i)$ due to a step change ΔT_i in the surface temperature at x_i. For example, the heat-transfer coefficient in the third term in Equation 3.2.70 is obtained by replacing x_0 by x_2 in Equations 3.2.65 or 3.2.66 depending on whether $\mathrm{Re}_L < \mathrm{Re}_{cr}$ or $\mathrm{Re}_{cr}=0$.

Flows with Pressure Gradient and Negligible Viscous Dissipation

Although most of the correlations available in the literature for flat plates are for a semi-infinite fluid medium adjacent to the plate, most applications of practical interest deal with fluid flowing between two plates. If the spacing between the plates is significantly greater than the maximum boundary layer thickness, the medium can be assumed to approach a semi-infinite medium because the boundary layers along the two plates develop independent of each other. In such a case, if the plates are parallel to each other and if the pressure drop is negligible compared with the absolute pressure of the system, the pressure gradient can be assumed to be negligible. If the plates are nonparallel and if the boundary layer thickness is very much smaller than the spacing between the plates at that

location, the medium can still be considered as approaching a semi-infinite medium with a nonnegligible pressure gradient. In such flows, the free-stream velocity (core velocity outside the boundary layer) is related to the pressure variation by the Bernoulli equation:

$$\frac{p}{\rho}+\frac{U_\infty^2}{2}+zg=\text{constant}. \tag{3.2.71}$$

Another situation where the free-stream velocity varies in the direction of flow giving rise to a pressure gradient is the flow over a wedge. For the family of flows for which the solutions are applicable, the free-stream velocity at the edge of the boundary layer is related to the x-coordinate by a power law, $U_\infty = cx^m$. Flows over semi-infinite wedges (Figure 3.2.13) satisfy that condition. The exponent m is related to the wedge angle $\beta\pi$ as

$$\beta=\frac{2m}{1+m} \quad \text{or} \quad m=\frac{\beta}{2-\beta}. \tag{3.2.72}$$

With laminar boundary layers, the boundary layer thickness, friction factor, and Nusselt numbers are defined by

$$\frac{\delta}{x}=\frac{c_1}{\sqrt{\text{Re}_x}};\ \frac{C_{fx}}{2}=\frac{\tau_w}{\rho U_\infty^2}=\frac{c_2}{\sqrt{\text{Re}_x}};\ \text{Nu}_x=c_3\text{Re}_x^{1/2}. \tag{3.2.73}$$

The values of c_1, c_2, and c_3 are available in Burmeister (1993). For example, for $\beta=0.5$ (wedge angle$=90°$), $m=1/3$, $c_1=3.4$, $c_2=0.7575$, and $c_3=0.384$ for Pr$=0.7$, and $c_3=0.792$ for Pr $= 5$. Re_x is based on $U_\infty=cx^m$; the free-stream velocity is not uniform.

Uniform Temperature: Flat Plate with Injection or Suction with External Flows of a Fluid Parallel to the Surface

Injection (Figure 3.2.14) or suction has engineering applications to control boundary layers and to regulate the rate of heating and cooling. When the free-stream temperature of the fluid is high, as in gas turbines, a cooling fluid is introduced into the mainstream to cool the surface. If the cooling fluid is introduced at discrete locations (either perpendicular to the surface or at an angle), it is known as film cooling. If a fluid is introduced or withdrawn through a porous medium, it is known as transpiration (Figure 3.2.14). An application of suction is to delay or prevent boundary layer separation thereby influencing the hydrodynamic forces.

Analytical solutions for a laminar boundary layer with transpiration suction or blowing are available if the velocity perpendicular to the surface varies in the following manner:

$$v_0=\text{constant}\ x^{(m-1)/2} \tag{3.2.74}$$

Solutions are limited to the cases of the injected fluid being at the same temperature as the surface and the injected fluid being the same as the free-stream fluid. Positive values of v_0 indicate blowing,

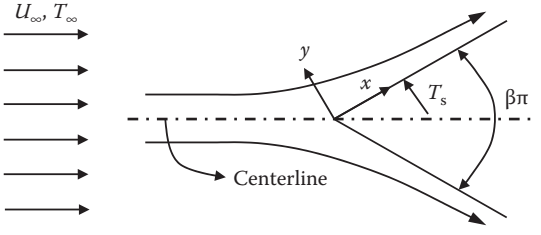

FIGURE 3.2.13 Flow over a wedge. ($\beta\pi$ is the wedge angle.)

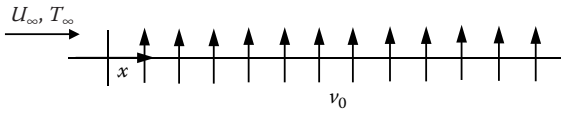

FIGURE 3.2.14 Flat plate with transpiration injection.

and negative values indicate suction. Values of $\mathrm{Nu}_x / \mathrm{Re}_x^{1/2}$ for different values of Pr and for different values of blowing or suction parameter are given in Kays et al. (2004).

For example, for a laminar boundary layer over a flat plate for air (Pr = 0.7), the value of $\mathrm{Nu}_x / \mathrm{Re}_x^{1/2}$ is 0.722 for $(v_0 / U_\infty)\sqrt{\rho U_\infty x / \mu} = -0.75$ (suction), and the corresponding value is 0.166 for $(v_0 / U_\infty)\sqrt{\rho U_\infty x / \mu} = 0.25$ (blowing). Heat transfer coefficient increases with suction which leads to a thinning of the boundary layer. Blowing increases the boundary layer thickness and decreases the heat-transfer coefficient.

For *turbulent boundary layers*, Kays et al. (2004) suggest the following procedure for finding the friction factor and convective heat-transfer coefficient in terms of a blowing parameter for momentum (B_f) and heat transfer (B_h) which are defined as follows:

$$B_\mathrm{f} = \frac{v_0 / U_\infty}{C_\mathrm{f} / 2}, \tag{3.2.75}$$

$$B_\mathrm{h} = \frac{v_0 / U_\infty}{\mathrm{St}} = \frac{\dot{m}'' / G_\infty}{\mathrm{St}}, \tag{3.2.76}$$

where

v_0 = velocity normal to the plate
U_∞ = free-stream velocity
$\dot{m}''$ = mass flux of the injected fluid at the surface (ρv_0)
G_∞ = mass flux in the free stream (ρU_∞)
St = Stanton number = $\mathrm{Nu}_x / \mathrm{Re}_x \mathrm{Pr} = h / \rho U_\infty c_p$

The friction factors, C_f and C_{f_0}, and Stanton numbers, St and St_0, with and without blowing or suction are related by the relations:

$$\frac{C_\mathrm{f}}{C_{\mathrm{f}_0}} = \frac{\ln(1 + B_\mathrm{f})}{B_\mathrm{f}}, \tag{3.2.77}$$

$$\frac{\mathrm{St}}{\mathrm{St}_0} = \frac{\ln(1 + B_\mathrm{h})}{B_\mathrm{h}}. \tag{3.2.78}$$

In Equations 3.2.77 and 3.2.78, C_{f_0} and St_0 are the values of the friction factor and Stanton number with $v_0 = 0$ (no blowing or suction), and C_f and St are the corresponding quantities with blowing or suction at the same values of Re_x ($= \rho U_\infty x / \mu$).

For the more general case of variable free-stream velocity, temperature difference, and transpiration rate, refer to Kays et al. (2004).

Flow over Flat Plate with Zero Pressure Gradient: Effect of High-Speed and Viscous Dissipation

In the boundary layer, the velocity of the fluid is reduced from U_∞ at the edge of the boundary layer to zero at the plate leading to a reduction in the kinetic energy of the fluid. Inside the boundary layer, there is also the work done by viscous forces due to shearing in the fluid; the magnitude of such viscous work is related to the velocity of the fluid, the velocity gradient, and the viscosity of the fluid. The net effect of such a reduction in the kinetic energy and the required viscous work is to increase

the internal energy of the fluid in the boundary layer. The increase in the internal energy may be expected to lead to an increase in the temperature; but because of the heat transfer to the adjacent fluid, the actual increase in the internal energy (and the temperature) will be less than the sum of the decrease in the kinetic energy and viscous work transfer. The actual temperature increase of the fluid depends on the decrease in the kinetic energy, the viscous work transfer, and the heat transfer from the fluid. The maximum temperature in the fluid with an adiabatic plate is known as the adiabatic wall temperature (which occurs at the wall) and is given by

$$T_{aw} = T_\infty + r\frac{U_\infty^2}{2C_p}. \tag{3.2.79}$$

In Equation 3.2.79, r is the (dimensionless) recovery factor and is really ratio of the internal energy to the kinetic energy of the fluid per unit mass. The value of r solely depends on the Prandtl number as follows (Eckert and Drake, 1972):

Laminar boundary layer: $0.6 < \mathrm{Pr} < 15$: $r = \mathrm{Pr}^{1/2}$
Turbulent boundary layer: $r = \mathrm{Pr}^{1/3}$
Equation 3.2.79 can now be recast as

$$\frac{T_{aw} - T_\infty}{T_s - T_\infty} = \frac{r}{2}\frac{U_\infty^2}{C_p(T_s - T_\infty)}. \tag{3.2.80}$$

From Equation 3.2.80, the maximum increase in the fluid temperature as a fraction of the difference between the plate and free-stream temperatures is given by r Ec/2. For instance, with air flowing over a plate at 500 m/s, the increase in the temperature of the air can be as high as 105°C. With T_s=40°C and T_∞=20°C, the temperature of the air close to the plate can be higher than the plate temperature. It is thus possible that although the plate temperature is higher than the free-stream temperature, the heat transfer is from the air to the plate. At a Mach number greater than 0.1 for gases, viscous dissipation becomes significant.

The temperature profiles for high-speed flows for different values of T_s are shown in Figure 3.2.15. In high-speed flows, as heat transfer can be from the fluid to the plate even if the plate temperature is greater than the fluid temperature, the definition of the convective heat-transfer coefficient given in Equation 3.2.49 is not adequate. On the other hand, as the heat transfer is always from the plate to the fluid if $T_s > T_{aw}$, the adiabatic wall temperature (akin to the adiabatic flame temperature in combustion applications) is more appropriate as the reference temperature for defining the heat-transfer coefficient. Thus, in high-speed flows, the definition of the convective heat-transfer coefficient is given by

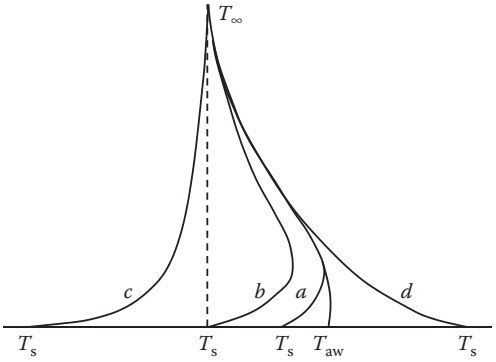

FIGURE 3.2.15 Temperature profiles for high-speed flows: (a) $T_\infty < T_s < T_{aw}$; (b) $T_s = T_\infty$; (c) $T_s << T_\infty$; (d) $T_s > T_{aw}$.

$$q'' = h(T_s - T_{aw}). \tag{3.2.81}$$

Equation 3.2.81 is consistent with Equation 3.2.49 as the adiabatic wall temperature equals the free-stream temperature if the effects of viscous dissipation and reduced kinetic energy in the boundary layer are neglected. With the adiabatic wall temperature as the fluid reference temperature for the definition of the convective heat-transfer coefficient, equations for low speeds can also be used for high-speed flows. Because of the greater variation in the fluid temperature in the boundary layer, the variation of the physical properties of the fluid due to temperature variation becomes important. It is found that the correlations are best approximated if the properties are evaluated at the reference temperature T^* defined by Eckert (1956):

$$T^* = 0.5(T_s + T_\infty) + 0.22(T_{aw} - T_\infty). \tag{3.2.82}$$

With the fluid properties evaluated at the reference temperature given by Equation 3.2.82, Equation 3.2.83 through 3.2.88 are applicable to high-speed flows with Prandtl numbers less than 15. It should be noted that the adiabatic wall temperatures in the laminar and turbulent regions are different affecting both the temperature at which the properties are evaluated and the temperature difference for determining the local heat flux. Therefore, when the boundary layer is partly laminar and partly turbulent, an average value of the heat-transfer coefficient cannot be defined as the adiabatic wall temperatures in the two regions are different. In such cases, the heat-transfer rate in each region is determined separately to find the total heat-transfer rate.

Laminar:

$$\mathrm{Re}_x < \mathrm{Re}_{cr}: \quad \mathrm{Nu}_x = 0.332\mathrm{Re}_x^{1/2}\mathrm{Pr}^{1/3} \tag{3.2.83}$$

$$\mathrm{Re}_L < \mathrm{Re}_{cr}: \quad \mathrm{Nu}_L = 0.664\mathrm{Re}_L^{1/2}\mathrm{Pr}^{1/3} \tag{3.2.84}$$

Turbulent:

$$10^7 > \mathrm{Re}_x > \mathrm{Re}_{cr}: \quad \mathrm{Nu}_x = 0.0296\mathrm{Re}_x^{4/5}\mathrm{Pr}^{1/3}, \tag{3.2.85}$$

$$10^7 < \mathrm{Re}_x < 10^9: \quad \mathrm{Nu}_x = 1.596\mathrm{Re}_x(\ln \mathrm{Re}_x)^{-2.584}\mathrm{Pr}^{1/3}, \tag{3.2.86}$$

$$\mathrm{Re}_{cr} = 0, \mathrm{Re}_L < 10^7: \quad \mathrm{Nu}_L = 0.037\mathrm{Re}_L^{4/5}\mathrm{Pr}^{1/3}, \tag{3.2.87}$$

$$\mathrm{Re}_{cr} = 0, 10^7 < \mathrm{Re}_L < 10^9: \quad \mathrm{Nu}_L = 1.967\mathrm{Re}_L(\ln \mathrm{Re}_L)^{-2.584}\mathrm{Pr}^{1/3}. \tag{3.2.88}$$

When the temperature variation in the boundary layer is large, such that the assumption of constant specific heat is not justified, Eckert (1956) suggests that the properties be evaluated at a reference temperature corresponding to the specific enthalpy of the fluid, i^* given by

$$i^* = 0.5(i_s + i_\infty) + 0.22(i_{aw} - i_\infty), \tag{3.2.89}$$

where i is the specific enthalpy of the fluid evaluated at the temperature corresponding to the subscript. Equation 3.2.89 gives the same values as Equation 3.2.82 if C_p is constant or varies linearly with temperature.

At very high speeds, the gas temperature may reach the values of temperatures that are sufficient to cause disassociation and chemical reactions; these and other effects need to be taken into account in such cases.

Flow over Cylinders, Spheres, and Other Geometries

Flows over a flat plate and wedges were classified as laminar or turbulent, depending on the Reynolds number, and numerous correlations for the local and average convective heat-transfer coefficients for a range of conditions have been developed over the years. But flows over cylinders (perpendicular to the axis) and spheres are more complex. In general, the flow over cylinders and spheres may have a laminar boundary layer followed by a turbulent boundary layer and a wake region depending on the Reynolds number with the diameter as the characteristic length (Figures 3.2.16 and 3.2.17). Because of the complexity of the flow patterns, only correlations for the average heat-transfer coefficients have been developed.

Cylinders: One can use the following correlation proposed by Churchill and Bernstein (1977): $\mathrm{Pe} > 0.2$. Evaluate properties at $(T_s + T_\infty)/2$:

$$\mathrm{Re}_d > 4\times10^5: \quad \mathrm{Nu}_d = 0.3 + \frac{0.62\mathrm{Re}_d^{1/2}\mathrm{Pr}^{1/3}}{\left[1+(0.4/\mathrm{Pr})^{2/3}\right]^{1/4}}\left[1+\left(\frac{\mathrm{Re}_d}{282{,}000}\right)^{5/8}\right]^{4/5}, \tag{3.2.90}$$

$$10^4 < \mathrm{Re}_d < 4\times10^5: \quad \mathrm{Nu}_d = 0.3 + \frac{0.62\mathrm{Re}_d^{1/2}\mathrm{Pr}^{1/3}}{\left[1+(0.4/\mathrm{Pr})^{2/3}\right]^{1/4}}\left[1+\left(\frac{\mathrm{Re}_d}{282{,}000}\right)^{1/2}\right], \tag{3.2.91}$$

$$\mathrm{Re}_d < 10^4: \quad \mathrm{Nu}_d = 0.3 + \frac{0.62\mathrm{Re}_d^{1/2}\mathrm{Pr}^{1/3}}{\left[1+(0.4/\mathrm{Pr})^{2/3}\right]^{1/4}}. \tag{3.2.92}$$

For the flow of liquid metals with very small values of the Prandtl number, one can use the following correlation suggested by Ishiguro et al. (1979):

$$1 < \mathrm{Pe} < 100: \mathrm{Nu}_d = 1.125\mathrm{Pe}^{0.413}. \tag{3.2.93}$$

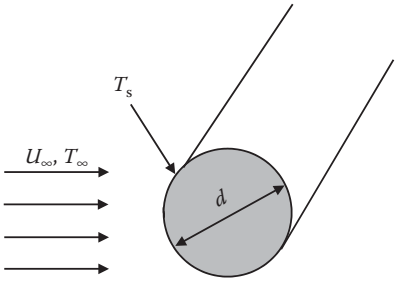

FIGURE 3.2.16 A fluid stream in cross flow over a cylinder.

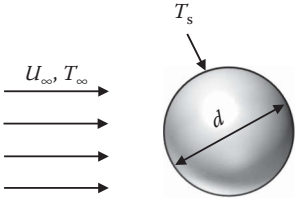

FIGURE 3.2.17 A fluid flowing over a sphere.

For more information on heat transfer with flow over cylinders, refer to Morgan (1975), Zukauskas (1987), Polyanin et al. (2002), Zdravkovich (1997, 2003) and Kakac et al. (2014).

Spheres: For flows over spheres (Figure 3.2.17), one can use any one of the following correlations:

1. Whitaker (1972): Evaluate properties at T_∞ except μ_s at T_s.

$$3.5 < \mathrm{Re}_d < 7.6\times10^4, \quad 0.71 < \mathrm{Pr} < 380, \quad 1 < \mu/\mu_s < 3.2$$

$$\mathrm{Nu}_d = 2.0 + \left(0.4\mathrm{Re}_d^{1/2} + 0.06\mathrm{Re}_d^{2/3}\right)\mathrm{Pr}^{2/5}\left(\frac{\mu}{\mu_s}\right)^{1/4}. \tag{3.2.94}$$

2. Achenbach (1978): For air ($\mathrm{Pr} = 0.71$) only. Evaluate properties at $(T_s + T_\infty)/2$:

$$100 < \mathrm{Re}_d < 2\times10^5$$

$$\mathrm{Nu}_d = 2.0 + \left(0.25\mathrm{Re}_d + 3\times10^{-4}\mathrm{Re}_d^{1.6}\right)^{1/2}, \tag{3.2.95}$$

$$4\times10^5 < \mathrm{Re}_d < 5\times10^6$$

$$\mathrm{Nu}_d = 430 + 5\times10^{-3}\mathrm{Re}_d + 2.5\times10^{-10}\mathrm{Re}_d^2 - 3.1\times10^{-17}\mathrm{Re}_d^3. \tag{3.2.96}$$

3. *Liquid Metals*: From experimental results with liquid sodium, Witte (1968) proposed

$$3.6\times10^4 < \mathrm{Re}_d < 1.5\times10^5: \quad \mathrm{Nu}_d = 2 + 0.386\mathrm{Pe}^{1/2}. \tag{3.2.97}$$

More information on the predictive correlations for spheres can be found in Clift et al. (1978) and Michaelides (2006).

Other Geometries: For geometries other than cylinders and spheres, use Equation 3.2.98 with the characteristic dimensions and values of the constants given in Table 3.2.4.

$$\mathrm{Nu}_D = c\mathrm{Re}_D^m. \tag{3.2.98}$$

Although Equation 3.2.98 is based on experimental data with gases, it can be extended to fluids with moderate Prandtl numbers by multiplying Equation 3.2.98 by the factor $(\mathrm{Pr}/0.7)^{1/3}$.

Heat Transfer across Tube Banks

When tube banks are used in heat exchangers, the flow over the tubes in the second and subsequent rows of tubes is different from the flow over a single tube. Even in the first row, the flow is modified by the presence of the neighboring tubes. The extent of modification depends on the spacing between the tubes and the Reynolds number of the flow. If the spacing is very much greater than the diameter of the tubes, correlations for single tubes can be used due to little or no hydrodynamic interaction between the cylinders. Correlations for flow over tube banks when the spacing between tubes in a row and a column is not much greater than the diameter of the tubes have been developed for use in heat-exchanger applications. Two arrangements of the tubes are considered—aligned and staggered as shown in Figure 3.2.18. The nomenclature used in this section is also shown in this figure.

For the average convective heat-transfer coefficient with tubes at uniform surface temperature, from experimental results, Zukauskas (1987) recommends correlations of the following form:

$$\mathrm{Nu}_d = c\left(\frac{a}{b}\right)^p \mathrm{Re}_d^m \mathrm{Pr}^n \left(\frac{\mathrm{Pr}}{\mathrm{Pr}_s}\right)^{0.25}. \tag{3.2.99}$$

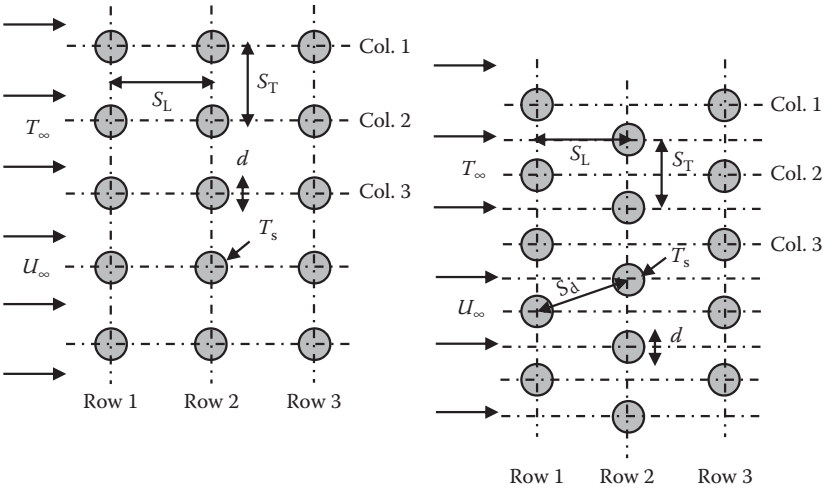

FIGURE 3.2.18 Schematics of in-line (or aligned arrangement) on the left and staggered arrangement on the right. ($a=S_T/d$; $b=S_L/d$.)

In Equation 3.2.99, all physical properties are evaluated at the arithmetic mean of the inlet and exit temperatures of the fluid, except Pr_s which is evaluated at the surface temperature, T_s, of the cylinders. The values of the constants c, p, m, and n are given in Tables 3.2.5 and 3.2.6 for in-line and staggered arrangements, respectively.

The maximum average velocity in between the tubes is used in the calculation of the Reynolds number, Re_d. The maximum velocities for the in-line and staggered arrangements are given by the following expressions:

$$\text{In-line}: U_{\max} = \frac{U_\infty S_T}{S_T - d}, \tag{3.2.100}$$

$$\text{Staggered}: S_d > \frac{S_T + d}{2}.U_{\max} = \frac{U_\infty S_T}{S_T - d}, \tag{3.2.101}$$

$$\text{Staggered}: S_d < \frac{S_T + d}{2}.U_{\max} = \frac{U_\infty S_T}{2(S_d - d)}, \tag{3.2.102}$$

$$S_d = \left[S_L^2 + \left(\frac{S_T}{2} \right)^2 \right]^{1/2}.$$

Equation 3.2.99 is prescribed for tube banks with 16 or more rows. When there are fewer than 16 rows, the heat transfer coefficient given by Equation 3.2.99 is multiplied by the correction factor c_1 defined by Equation 3.2.103 and given in Table 3.2.7.

$$h_N = c_1 h_{16}, \tag{3.2.103}$$

where

h_N=heat transfer coefficient with N rows (fewer than 16)

h_{16}=heat transfer coefficient for $N \geq 16$ (number of rows)

As expected, the correction factor c_1 approaches the value of unity as value of N approaches $N \to 16$.

TABLE 3.2.4
Values of *c* and *m* in Equation 3.2.98 (Jakob, 1949)

Geometry	Re_d	c	m
	$5000–10^5$	0.092	0.675
	2500–8000	0.160	0.699
	$5000–10^5$	0.222	0.588
	2500–7500	0.261	0.624
	$5000–1.95\times10^4$ $1.95\times10^4–10^5$	0.144 0.035	0.638 0.782
	$5000–10^5$	0.138	0.638
	$2500–1.5\times10^4$	0.224	0.612
	$3000–1.5\times10^4$	0.085	0.804
	$4000–1.5\times10^4$	0.205	0.731

Note: Characteristic dimension is the equivalent circular diameter = Perimeter/π. For example, for a square rod with each side a, $D = 4a/\pi$. Flow is from right to left.

	Number of Rows (N)							
Tube Arrangement	**1**	**2**	**3**	**4**	**5**	**7**	**10**	**13**
In-line	0.70	0.80	0.86	0.90	0.93	0.96	0.98	0.99
Staggered	0.64	0.76	0.84	0.89	0.93	0.96	0.98	0.99

Pressure Drop: With tube banks, pressure drop is a significant factor, as it determines the fan or pump power required to maintain the required fluid flow. Zukauskas (1987) recommends that the pressure drop be computed from the relation

$$\Delta p = p_i - p_e = N\chi \frac{\rho U_{max}^2}{2} f, \tag{3.2.104}$$

where p_i and p_e are the fluid pressures at the inlet and exit of the tube banks. The values of χ and f are presented in Figure 3.2.19a. In Figure 3.2.19a, the friction factor f for in-line arrangement is presented for different values of b (S_L/d) for $S_L=S_T$. For values of S_L/S_T other than 1, the correction factor χ is given in the inset for different values of $(a-1)/(b-1)$. Similarly, the friction factor for staggered arrangement (for equilateral triangle arrangement) and a correction factor for different values of a/b are also given in Figure 3.2.19b. The value of friction factor f is for one row of tubes; the total pressure drop is obtained by multiplying the pressure drop for one row by the number of rows N in the tube bank.

The temperature of the fluid varies in the direction of flow, and, therefore, the value of the convective heat transfer coefficient (which depends on the temperature-dependent properties of the fluid) also varies in the direction of flow. However, it is common practice to compute the total heat

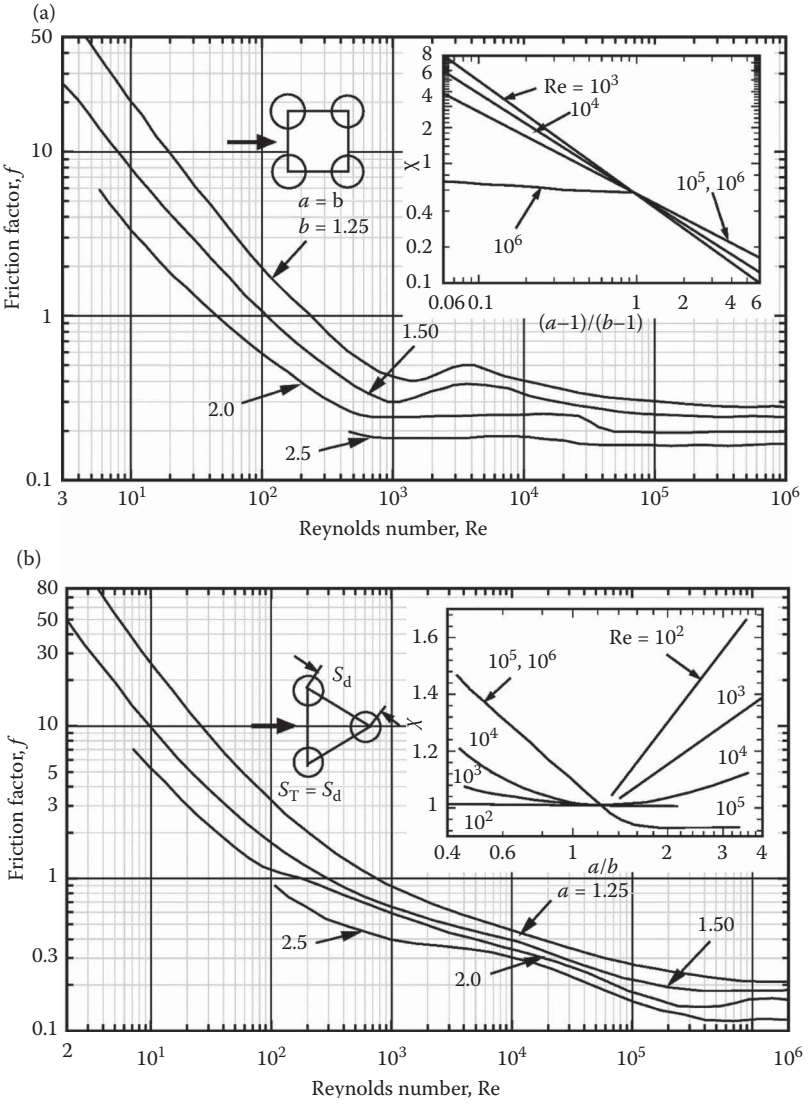

FIGURE 3.2.19 Friction factors for tube banks. (a) In-line arrangement; (b) staggered arrangement (Zukauskas, 1987).

transfer rate with the assumption of uniform convective heat transfer coefficient evaluated at the arithmetic mean of the inlet and exit temperatures of the fluid. With such an assumption of uniform convective heat transfer coefficient, uniform surface temperature and constant specific heat (evaluated at the mean fluid temperature), the inlet and exit fluid temperatures are related by

$$\ln\left(\frac{T_s - T_e}{T_s - T_i}\right) = -\frac{hA_s}{\dot{m}c_p}. \tag{3.2.105}$$

The heat transfer rate to the fluid is given by the equation

$$q = m \cdot c_p \left(T_e - T_i\right). \tag{3.2.106}$$

Example 3.2.4

A heat exchanger with aligned tubes is used to heat 40 kg/s of air from 10°C to 50°C with the tube surfaces maintained at 100°C. Details of the heat exchanger are as follows:

Diameter of tubes: 25 mm
Number of columns: 20
Length of each tube: 3 m
$S_L = S_T = 75$ mm
Determine the number of rows required for this application.

Solution: Average air temperature $= (T_i + T_e)/2 = (10+50)/2 = 30°C$. Properties of atmospheric air (from Suryanarayana, 1995):

$$\rho = 1.165 \text{ kg/m}^3;\ c_p = 1007 \text{ J/kg K}$$

$$\mu = 1.865 \times 10^{-5} \text{Pa} \cdot \text{s};\ k = 0.0264 \text{ W/mK}$$

$$\text{Pr} = 0.712;\ \text{Pr}_s \text{ (at 100°C)} = 0.705$$

To find U_{max}, we need the minimum area of cross section for fluid flow (Figure 3.2.20).
$H = 20 \times 0.075 = 1.5$ m
$A_{min} = 20(0.075 - 0.025) \times 3 = 3 \text{ m}^2$

$$U_{max} = \frac{\dot{m}}{\rho A_{min}} = \frac{40}{1.165 \times 3} = 11.44 \text{ m/s}$$

$$\text{Re}_d = \frac{\rho U_{max} d}{\mu} = \frac{1.165 \times 11.44 \times 0.025}{1.865 \times 10^{-5}} = 17{,}865$$

With values from Table 3.2.5, $c = 0.27$, $m = 0.63$, $n = 0.36$

$$\text{Nu}_d = 0.27 \times 17{,}865^{0.63} \times 0.712^{0.36} \left(\frac{0.712}{0.705}\right)^{0.25} = 114.3$$

$$h = \frac{114.3 \times 0.0264}{0.025} = 120.7 \text{ W/m}^2\text{K}$$

From Equation 3.2.105,

$$\ln\left(\frac{100-50}{100-10}\right) = -\frac{120.7 \times A_s}{40 \times 1007},$$

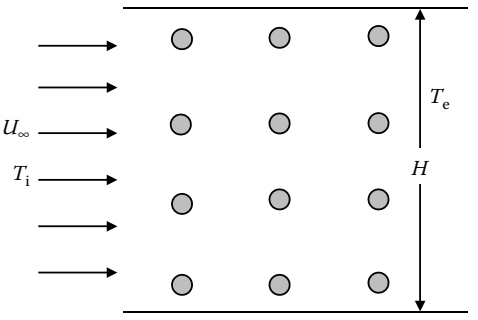

FIGURE 3.2.20 Aligned tube heat exchanger (only a few of the 20 columns and rows are shown).

where $A_s = \pi \times 0.025 \times 3 \times 20 \times N$
N = number of rows = 42
Fan Power: From the first law of thermodynamics (see Chapter 1), the fan power is

$$\dot{W}_F = \dot{m}\left(\frac{p_i}{\rho_i} - \frac{p_e}{\rho_e} + \frac{v_e^2}{2}\right).$$

p_i and p_e are the pressures at inlet and exit of the heat exchanger, and v_e is the fluid velocity at exit. Assuming constant density evaluated at $(T_i + T_e)/2$, the pressure drop is found from Figure 3.2.19a.

$$\mathrm{Re}_d = 17,865: \; a = b = 75/25 = 75/25 = 3.$$

In Figure 3.2.19a, although the friction factor is available for values of b up to 2.5, we will estimate the value of f for $b = 3$. From Figure 3.2.19a, $f \approx 0.11$. The correction factor $c = 1$.

$$p_i - p_e = N\chi \frac{\rho U_{max}^2}{2} f = 42 \times 1 \frac{1.165 \times 11.44^2}{2} \times 0.11 = 352.2 \text{ kPa},$$

$$v_e = \frac{11.44 \times 50}{75} = 7.63 \text{ m/s},$$

$$\dot{W}_F = 40\left(352.2 + \frac{7.63^2}{2}\right) = \underline{15,250 \text{ W}} \text{ or } \underline{15.25 \text{ kW}}.$$

Heat Transfer with Jet Impingement

Jet impingement (Figure 3.2.21) on a heated (or cooled) surface results in high heat transfer rates, and is used in annealing of metals, tempering of glass, cooling of electronic equipment, internal combustion engines, and in a wide variety of industries–textiles, paper, wood, and so on. Usually, the jets are circular, issuing from a round nozzle of diameter d, or rectangular, issuing from a slot of width w. They may be used singly or in an array. The jets may impinge normally to the heated surface or at an angle. If there is no parallel solid surface close to the heated surface, the jet is said to be free; in the presence of a parallel surface close to the heated surface, the jet is termed confined. In this section, only single, free jets (round or rectangular) impinging normally to the heated surface are considered.

Jets may be submerged within the fluid from the nozzle exiting into a body of a fluid (usually the same fluid), for example, air impinging on a surface surrounded by atmospheric air. In submerged jets, entrained fluid (the part of the surrounding fluid dragged by the jet) has a significant effect on the flow and heat-transfer characteristics of the jet, but the effect of gravity is usually negligible. In free-surface jets—a liquid jet in an atmosphere of air is a good approximation to a free-surface jet—the entrainment effect is usually negligible, but the effect of gravity may be significant.

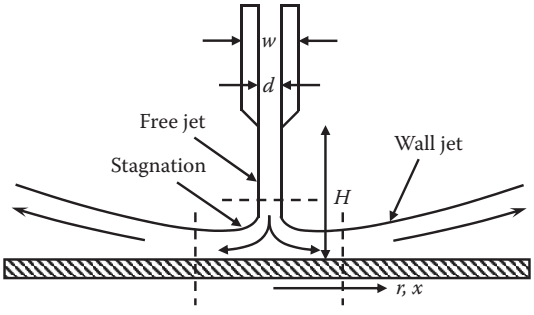

FIGURE 3.2.21 Circular jet of diameter d or a rectangular jet of width w.

A jet is usually divided into three regions: a free-jet region, a stagnation region, and a wall-jet region. In the free-jet region, the effect of the target surface on the flow is negligible. In the stagnation region, the target surface affects the flow field, and the velocity parallel to the surface increases while the velocity component normal to the surface decreases. At the beginning of the stagnation region, the axial velocity of the fluid is very much greater than the radial component (or the x-component) of the velocity. The stagnation region is followed by the wall-jet region where the radial component (or the x-component) of the velocity is much greater than the axial velocity.

The heat-transfer coefficient is a function of H/d (or H/w), Re_d ($\rho v_j d/\mu$) or ($\rho v_j 2w/\mu$), and Pr and depends on the region (stagnation or wall jet), whether it is submerged or non-submerged and whether the flow adjacent to the plate is laminar or turbulent. Some of the heat-transfer correlations suggested by different researchers are given below. All the correlations are for single jets.

Submerged Jets: Single Circular Jets

$$\mathrm{Re}_d = \frac{4\dot{m}}{\pi d\mu}; \quad \mathrm{Nu}_d = \frac{hd}{k},$$

where $\dot{m}$= mass rate of the fluid

Average heat-transfer coefficients up to radius r (Martin, 1990):

$$\mathrm{Nu}_d = 2\left(\frac{d}{r}\right)\frac{1-1.1(d/r)}{1+0.1\{(H/d)-6\}(d/r)}\left[\mathrm{Re}_d\left(1+\frac{\mathrm{Re}_d^{0.55}}{200}\right)\right]^{1/2}\mathrm{Pr}^{0.42}. \tag{3.2.107}$$

Range of validity:

$$2000 \le \mathrm{Re}_d \le 4 \times 10^5; 2.5 \le r/d < 7.5; 2 \le H/d \le 2.$$

Local convective heat-transfer coefficient at radius r (Webb and Ma, 1995):

$$\mathrm{Nu}_d = 1.29\mathrm{Re}_d^{1/2}\mathrm{Pr}^{0.4}\left\{\left[\frac{\tanh(0.88r/d)}{r/d}\right]^{-8.5} + \left[1.69\left(\frac{r}{d}\right)^{-1.07}\right]^{-17}\right\}^{-1/17}. \tag{3.2.108}$$

Submerged Jets: Single Rectangular Jet

$$\mathrm{Re}_w = \frac{\rho v_j(2w)}{\mu} = \frac{2\dot{m}}{\mu},$$

where $\dot{m}$ = mass rate of flow per unit length of jet

$$\mathrm{Nu}_w = \frac{h(2w)}{k}.$$

Average heat-transfer coefficient (Martin, 1990):

$$\mathrm{Nu}_w = \frac{1.53\mathrm{Pr}^{0.42}\mathrm{Re}_w^m}{\frac{x}{2w}+\frac{H}{2w}+1.39}, \tag{3.2.109}$$

where $m = 0.695 - \left[\frac{x}{2w}+\left(\frac{H}{2w}\right)^{1.33}+3.06\right]^{-1}$.

TABLE 3.2.8
Correlations for Free-Surface Jets $r_v/d = 0.1773\ Re_d^{1/3}$

Range of r	Range of Pr	Nu_d
$r/d < 0.787$	$0.15 \le Pr \le 3$	$0.715Re_d^{1/2}Pr^{0.4}$ (3.2.110)
	$Pr > 3$	$0.797Re_d^{1/2}Pr^{0.4}$ (3.2.111)
$0.787 < r/d < r_v/d$		$0.632Re_d^{1/2}Pr^{1/3}\left(\frac{d}{r}\right)^{1/2}$ (3.2.112)
$r_v/d < r/d < r_t/d$		$\frac{0.407Re_d^{1/3}Pr^{1/3}(d/r)^{2/3}}{\left[\frac{0.1713}{(r/d)^2}+\frac{5.147}{Re_d}\frac{r}{d}\right]^{2/3}\left[\frac{(r/d)^2}{2}+C\right]^{1/3}}$, (3.2.113)
		where
		$C = -5.051\times10^{-5}Re_d^{2/:}$
		$\frac{r_t}{d} = \left\{-\frac{s}{2}+\left[\left(\frac{s}{2}\right)^2+\left(\frac{p}{3}\right)^3\right]^{1/2}\right\}^{1/3} + \left\{-\frac{s}{2}+\left[\left(\frac{s}{2}\right)^2-\left(\frac{p}{3}\right)^3\right]^{1/2}\right\}^{1/3}$
		$p = \frac{-2C}{0.2058Pr-1}$ $s = \frac{0.00686Re_dPr}{0.2058Pr-1}$
$r > r_t$	$Pr < 3.9$	$\frac{0.25}{\frac{1}{Re_dPr}\left[1-\left(\frac{r_t}{r}\right)^2\right]\left(\frac{r}{d}\right)^2+0.13\frac{h}{d}+0.0371\frac{h_t}{d}}$, (3.2.114)
		where $h_t = h$ at r_t and $\frac{h}{d} = \frac{0.1713}{r/d}+\frac{5.147}{Re_d}\left(\frac{r}{d}\right)^2$

Free-Surface Jets: Single Circular Jet. Correlations are given in Table 3.2.8 (Liu et al., 1991; Webb and Ma, 1995).

3.2.3 Forced Convection: Internal Flows

Anoop K. Gupta, Raj P. Chhabra, and N.V. Suryanarayana

Introduction

Heat transfer to (or from) a fluid flowing inside a tube or duct is termed *internal forced convection*. The fluid flow may be laminar or turbulent depending upon the value of the duct Reynolds number. If the Reynolds number based on the average velocity of the fluid and diameter of the tube ($\rho v d/\mu$) is less than 2100 (Reynolds numbers in the range of 2000–2300 are cited in different sources), the flow is laminar. If the Reynolds number is >5000 or so, the flow is turbulent. The flow with a Reynolds number in the range 2100–5000 is considered to be in the transitional regime. With heating or cooling of the fluid, there may or may not be a change in the phase of the fluid. Here, only heat transfer to or from a single-phase fluid is considered, i.e., without boiling or condensation.

Fully Developed Velocity and Temperature Profiles

When a fluid enters a tube from a large reservoir, the velocity profile at the entrance is almost uniform as shown in Figure 3.2.22. The fluid in the immediate vicinity of the tube surface is decelerated in order to comply with the no-slip condition at the wall and the velocity increases from zero at the surface to u_c at a distance δ from the surface (i.e., inside the hydrodynamic boundary layer formed on the wall of the duct); in the region $r=0$ to $(R-\delta)$ the velocity is uniform. The value of δ increases in the direction of flow, and with constant fluid density, the value of the uniform velocity u_c increases. At some location downstream, δ reaches its maximum possible value, equal to the radius of the tube, and from that point onward the velocity profile does not change in the axial direction. This condition corresponds to the hydrodynamically developed flow.

The region where δ increases, i.e., where the velocity profile changes, is known as the entrance region or hydrodynamically developing region. The region downstream from the axial location where δ reaches its maximum value and the velocity profile does not change is the fully developed velocity profile or hydrodynamically fully developed region. Similarly, downstream of the location where heating or cooling of the fluid starts, the temperature profile changes in the direction of flow. But beyond a certain distance, the dimensionless temperature profile does not change in the direction of flow. The region where the dimensionless temperature profile changes is the thermally developing region or the thermal entrance region, and the region where the dimensionless temperature profile does not change is the thermally fully developed region. For simultaneously developing velocity and temperature profiles in laminar flows, the hydrodynamic and thermal entrance lengths for a circular pipe are given by

$$\frac{L_e}{d} = 0.0565\mathrm{Re}_d \tag{3.2.115}$$

$$\frac{L_{e,th}}{d} = 0.053\mathrm{Re}_d\mathrm{Pr} \quad \text{(Uniform heat flux)} \tag{3.2.116}$$

$$\frac{L_{e,th}}{d} = 0.037\mathrm{Re}_d\mathrm{Pr} \quad \text{(Uniform surface temperature)}. \tag{3.2.117}$$

In most engineering applications, with turbulent flows, correlations for fully developed conditions can be used after about 10–20 diameters down stream from where the heating starts. More details can be found in Kakac et al. (2014).

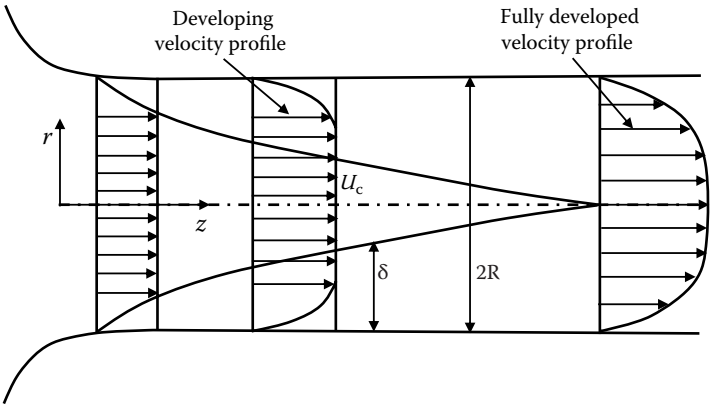

FIGURE 3.2.22 Developing and fully developed velocity profiles.

Convective Heat Transfer Coefficient and Bulk Temperature

The reference temperature for defining the convective heat-transfer coefficient is the bulk temperature T_b, and the convective heat flux is given by

$$q'' = h\left(T_s - T_b\right). \tag{3.2.118}$$

The bulk temperature T_b is determined from the relation

$$T_b = \frac{\int_{A_c} \rho v C_p T \, dA_c}{\int_{A_c} \rho v C_p \, dA_c}, \tag{3.2.119}$$

where A_c is the cross-sectional area perpendicular to the axis of the tube.

If the fluid is drained from the tube at a particular axial location and thoroughly mixed, the temperature of the mixed fluid is the bulk temperature. It is also known as the mixing cup temperature. With heating or cooling of the fluid, the bulk temperature varies in the direction of flow. In some cases, we use the term *mean fluid temperature*, T_m, to represent the arithmetic mean of the fluid bulk temperatures at inlet and exit of the tube.

Heat Transfer Correlations

Laminar Flows: Entrance Region

For laminar flows in a tube with uniform surface temperature, in the entrance region, the correlation of Sieder and Tate (1936) is

$$\overline{\mathrm{Nu}}_d = 1.86\left(\frac{\mathrm{Re}_d \mathrm{Pr}}{L/d}\right)^{1/3}\left(\frac{\mu}{\mu_s}\right)^{0.14} \tag{3.2.120}$$

valid for

$$\frac{L}{d} < \frac{\mathrm{Re}_d \mathrm{Pr}}{8}\left(\frac{\mu}{\mu_s}\right)^{0.42}; \; 0.48 < \mathrm{Pr} < 16{,}700; \; 0.0044 < \frac{\mu}{\mu_s} < 9.75.$$

The overbar in the Nusselt number indicates that it is formed with the average heat-transfer coefficient over the entire length of the tube. Properties of the fluid are evaluated at the arithmetic mean of the inlet and exit bulk temperatures. The (μ / μ_s) term accounts for the variation of the viscosity across the diameter of the tube. In Equation 3.2.120, the heat-transfer coefficient was determined from

$$q = \bar{h}\pi dL\left(T_s - \frac{T_{bi} + T_{be}}{2}\right). \tag{3.2.121}$$

Therefore, to find the total heat-transfer rate with $\bar{h}$ from Equation 3.2.120, one needs to employ Equation 3.2.121 to account for the axial variation in the available driving force for heat transfer.

Alternate empirical correlations have been proposed by Hausen (1943) for a range of conditions in the laminar entrance flow in a tube. For instance, for the case of the constant wall temperature and fully developed velocity profile, Hausen (1943) proposed

$$\mathrm{Nu_d} = 3.66 + \frac{0.0668(d/z)\mathrm{Pe}}{1 + 0.04[(d/z)\mathrm{Pe}]^{2/3}}. \tag{3.2.122}$$

Equation 3.2.122 gives the mean Nusselt number over the length z of the pipe (measured from the inlet). Naturally, for large values of $(z/d)(1/\mathrm{Pe})$, Equation 3.2.122 yields the expected limiting value of $\mathrm{Nu_d} = 3.66$.

On the other hand, when both the velocity and temperature fields are developing simultaneously, Hausen (1943) presented the following approximate expression for Nusselt number for the case of constant heat input and parabolic velocity profile:

$$\mathrm{Nu_d} = 4.36 + \frac{0.023(d/z)\mathrm{Pe}}{1 + 0.0012[(d/z)\mathrm{Pe}]^{0.8}}, \tag{3.2.123}$$

where

$$\mathrm{Pe} = \mathrm{Re}\cdot\mathrm{Pr} = \left(\rho v d C_p / k\right).$$

Laminar Flows: Fully Developed Velocity and Temperature Profiles

Evaluate properties at the bulk temperature.

$$\text{Uniform Surface Temperature}: \mathrm{Nu_d} = 3.66, \tag{3.2.124}$$

$$\text{Uniform Surface Heat Flux}: \ \mathrm{Nu_d} = 4.36. \tag{3.2.125}$$

Turbulent Flows

If the flow is turbulent, the difference between the correlations with uniform surface temperature and uniform surface heat flux is not significant and the correlations can be used for both cases. For turbulent flows, Gnielinski (1976, 1990) recommends the following:

Evaluate properties at the bulk temperature.

$$0.6 < \mathrm{Pr} < 2000; \quad 2300 < \mathrm{Re_d} < 10^6; \quad 0 < d/L < 1$$

$$\mathrm{Nu_d} = \frac{(f/2)\left(\mathrm{Re_d} - 1000\right)\mathrm{Pr}}{1 + 12.7\left(f/2\right)\left(\mathrm{Pr}^{2/3} - 1\right)}\left[1 + \left(\frac{d}{L}\right)^{2/3}\right], \tag{3.2.126}$$

where

$$f = \left[1.58 \ln(Re_d) - 3.28\right]^{-2}. \tag{3.2.127}$$

f = fanning friction factor = $2\tau_w/\rho v^2$.

To reflect the effect of variation of fluid properties with temperature, multiply the Nusselt numbers in Equation 3.2.126 by $(T_b/T_s)^{0.45}$ for gases and $(\mathrm{Pr}/\mathrm{Pr}_s)^{0.11}$ for liquids where the temperatures are absolute, and T and Pr with a subscript s are to be evaluated at the surface temperature. The equations can be used to evaluate the heat transfer coefficient in the developing profile region. To determine the heat-transfer coefficient in the fully developed region, set $d/L = 0$, i.e., $L \to \infty$. A simpler correlation (fully developed region) is the so-called Dittus–Boelter (1930) equation. Evaluate properties at T_b.

$$0.7 \le \mathrm{Pr} \le 160;\ \mathrm{Re}_d > 10{,}000;\ d/L > 10$$

$$\mathrm{Nu}_d = 0.023 \mathrm{Re}_d^{0.8} \mathrm{Pr}^n, \tag{3.2.128}$$

where $n = 0.4$ for heating ($T_s > T_b$) and $n = 0.3$ for cooling ($T_s < T_b$).

For liquid metals with Pr << 1, the following correlations due to Sleicher and Rouse (1975) are recommended:

Uniform surface temperature:

$$\mathrm{Nu}_{d,b} = 4.8 + 0.0156 \mathrm{Re}_{d,f}^{0.85} \mathrm{Pr}_s^{0.93}, \tag{3.2.129}$$

Uniform heat flux:

$$\mathrm{Nu}_{d,b} = 6.3 + 0.0167 \mathrm{Re}_{d,f}^{0.85} \mathrm{Pr}_s^{0.93}. \tag{3.2.130}$$

Subscripts b, f, and s indicate that the variables are to be evaluated at the bulk temperature, film temperature (arithmetic mean of the bulk and surface temperatures), and surface temperature, respectively.

In the computations of the Nusselt number, the thermophysical properties (evaluated at the bulk temperature) vary in the direction of flow and hence give different values of h at different locations. In many cases, a representative average value of the convective heat-transfer coefficient is needed. Such an average value can be obtained either by taking the arithmetic average of the convective heat-transfer coefficients evaluated at the inlet and exit bulk temperatures or the convective heat-transfer coefficient evaluated at the arithmetic mean of the inlet and exit bulk temperatures. If the variation of the convective heat-transfer coefficient is large, it may be appropriate to divide the tube into shorter lengths with smaller variation in the bulk temperatures and evaluating the average heat-transfer coefficient in each section and eventually adding up the individual rate of heat transfer to estimate the overall rate of heat transfer.

Uniform Surface Temperature: Relation between the Convective Heat Transfer Coefficient and the Total Heat Transfer Rate

With a uniform surface temperature, employing an average value of the convective heat-transfer coefficient, the local convective heat flux varies in the direction of flow. To relate the convective heat-transfer coefficient to the temperatures and the surface area, we have, for the elemental length Δz (Figure 3.2.23),

$$\dot{m} C_p \frac{dT_b}{dz} = h \frac{dA_s}{dz} \left(T_s - T_b\right). \tag{3.2.131}$$

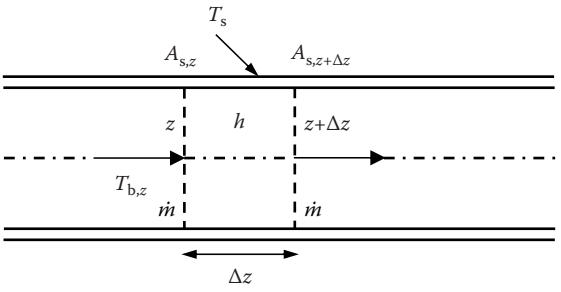

FIGURE 3.2.23 Elemental length of a tube for determining heat-transfer rate.

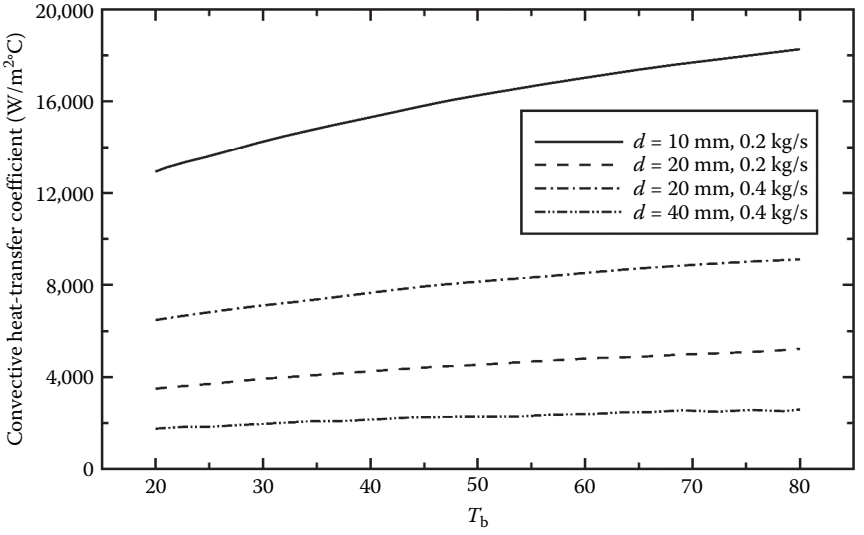

FIGURE 3.2.24 Variation of h with T_b in 1-, 2-, and 4-cm-diameter tubes with water flow rates of 0.2 kg/s and 0.4 kg/s with uniform surface temperature.

Assuming a suitable average convective heat-transfer coefficient over the entire length of the tube, separating the variables, and integrating the equation from $z=0$ to $z=L$, we obtain

$$\ln\frac{T_s - T_{be}}{T_s - T_{bi}} = -\frac{hA_s}{\dot{m}C_p}. \tag{3.2.132}$$

Equation 3.2.132 gives the exit temperature. For a constant-density fluid or an ideal gas, the heat-transfer rate is determined from

$$q = \dot{m}C_p\left(T_{be} - T_{bi}\right). \tag{3.2.133}$$

Equation 3.2.132 was derived on the basis of uniform convective heat-transfer coefficient. However, if the functional relationship between h and T_b is known, Equation 3.2.131 can be integrated by substituting the relationship. The convective heat-transfer coefficient variation with T_b for water in two tubes of different diameters for two different flow rates is shown in Figure 3.2.24. From the figure, it is clear that the heat-transfer coefficient, h, can be very well approximated as a linear function of T. By substituting such a linear function relationship into Equation 3.2.131, it can be shown that

$$\ln \frac{h_i}{h_e} \frac{T_s - T_{be}}{T_s - T_{bi}} = -\frac{h_s A_s}{\dot{m} C_p}, \tag{3.2.134}$$

where h_i, h_e, and h_s are the values of the convective heat-transfer coefficient evaluated at bulk temperatures of T_{bi}, T_{be}, and T_s, respectively. Although it has been demonstrated that h varies approximately linearly with the bulk temperature with water as the fluid, the variation of h with air or oil as the fluid is much smaller and is very well approximated by a linear relationship. For other fluids, it is suggested that the relationship be verified before employing Equation 3.2.134. (*Note:* It is tempting to determine the heat-transfer rate from the relation

$$q = hA_s \frac{\left(T_s - T_{be}\right) + \left(T_s - T_{bi}\right)}{2}. \tag{3.2.135}$$

Replacing q by Equation 3.2.133 and solving for T_{be} for defined values of the mass flow rate and tube surface area, the second law of thermodynamics will be violated if $hA_s/\dot{m}C_p > 2$. Use of Equation 3.2.132 or 3.2.134 ensures that no violation of the second law occurs however large A_s is.)

Uniform Surface Heat Flux

If the imposed heat flux is known, the total heat-transfer rate for a defined length of the tube is also known. From Equation 3.2.133, the exit temperature of the fluid is determined. The fluid temperature at any location in the pipe is known from the heat-transfer rate up to that location ($q = q''A_s$) and Equation 3.2.133. The convective heat-transfer coefficient is used to find the surface temperature of the tube.

Temperature Variation of the Fluid with Uniform Surface Temperature and Uniform Heat Flux

The fluid temperature variations in the two cases are different. With the assumption of uniform heat-transfer coefficient, with a uniform surface temperature the heat flux decreases in the direction of flow leading to a progressively decreasing rate of temperature change in the fluid with axial distance. With uniform heat flux, the surface and fluid temperatures vary linearly except in the entrance region where the higher heat-transfer coefficient leads to a smaller difference between the surface and fluid temperatures. The variation of the fluid temperature in the two cases is shown in Figure 3.2.25.

Convective Heat Transfer in Noncircular Tubes

Laminar flows: The Nusselt numbers for laminar flows have been analytically determined for different noncircular ducts. Some of them can be found in Shah and London (1978), Kakac et al. (1987, 2014), Kays et al. (2004), and Burmeister (1993). A few of the results are given later. The characteristic length for the definition of the Reynolds number and Nusselt number is the hydraulic mean diameter defined as

$$d_h = \frac{4 \times \text{cross-sectional area}}{\text{wetted perimeter}}. \tag{3.2.136}$$

Infinite parallel plates: a = spacing between plates, $d_h = 2a$
Both plates maintained at uniform and equal temperatures: Nu = 7.54
Both plates with imposed uniform and equal heat fluxes: Nu = 8.24
Rectangular ducts: a = longer side, b = shorter side, $d_h = 2ab/(a+b)$

b/a	1	0.7	0.5	0.25	0.125
Uniform surface temperature	2.98	3.08	3.39	4.44	5.6
Uniform heat flux[a]	3.61	3.73	4.12	5.33	6.49

[a] Uniform axial heat flux but circumferentially uniform surface temperature.

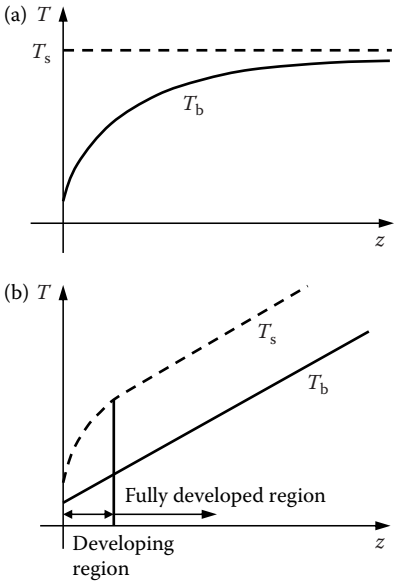

FIGURE 3.2.25 Variation of fluid temperature in a tube with (a) uniform surface temperature and (b) uniform heat flux.

Equilateral triangle: $d_h = a/3^{1/2}$, a = length of each side
Uniform surface temperature: Nu = 2.35
Uniform surface heat flux: *Nu = 3.0

Coaxial tubes: With coaxial tubes many different cases arise—each tube maintained at uniform but different temperatures, each tube subjected to uniform but different heat fluxes (an insulated surface is a special case of imposed heat flux being zero), or a combinations of uniform surface temperature of one tube and heat flux on the other. The manner in which the heat-transfer coefficient is determined for uniform but different heat fluxes on the two tubes is described below. Define:

$$d_h = 2(r_o - r_i); \qquad r^* = r_i/r_o\,,$$

$$q_i'' = h_i(T_i - T_b); \mathrm{Nu}_i = \frac{h_i d_h}{k}; q_o'' = h_o(T_o - T_b); \mathrm{Nu}_o = \frac{h_o d_h}{k},$$

$$q_o'' = 0; \quad \mathrm{Nu}_{ii} = \frac{h_i d_h}{k} \text{ and } q_i'' = 0; \quad \mathrm{Nu}_{oo} = \frac{h_o d_h}{k},$$

then

$$\mathrm{Nu}_i = \frac{\mathrm{Nu}_{ii}}{1 - \dfrac{q_o''}{q_i''}\theta_i^*} \text{ and } \mathrm{Nu}_o = \frac{\mathrm{Nu}_{oo}}{1 - \dfrac{q_i''}{q_o''}\theta_o^*}. \tag{3.2.137}$$

Some of the values needed for the computations of Nu_i and Nu_o (taken from Kays et al., 2004) are given in Table 3.2.9.

TABLE 3.2.9
Values for Use with Equation 3.2.137

r^*	Nu_{ii}	Nu_{oo}	θ_i^*	θ_o^*
0.05	17.81	4.792	2.18	0.0294
0.1	11.91	4.834	1.383	0.0562
0.2	8.499	4.883	0.905	0.1041
0.4	6.583	4.979	0.603	0.1823
0.6	5.912	5.099	0.473	0.2455
0.8	5.58	5.24	0.401	0.299
1.0	5.385	5.385	0.346	0.346

For a more detailed information on heat transfer and friction factors for laminar flows in noncircular tubes, refer to Shah and London (1978) and Kakac et al. (1987, 2014).

Turbulent flows: For noncircular tubes, estimates of the convective heat-transfer coefficient can be obtained by employing equations for circular tubes with d_h replacing d in the computations of the Reynolds and Nusselt numbers. To determine the heat-transfer coefficients in developing regions and for more accurate values with turbulent flows in noncircular tubes refer to Kakac et al. (1987, 2014) and the references in that book.

Mixed Convection

If the fluid velocity is low, the effect of natural convection becomes significant and the heat-transfer rate may be increased or decreased by natural convection. From a review of experimental results, Metais and Eckert (1964) developed maps to delineate the different regimes where one or the other mode is dominant and where both are significant. Figures 3.2.26 and 3.2.27 show the relative significance of natural and forced convection in vertical and horizontal tubes. The maps are applicable for $10^{-2} < \Pr(d/L) < 1$ where d and L are the diameter and the axial length of the tube. The maps show the limits of forced and natural convection regimes. The limits are delineated "in such a way that the actual heat flux under the combined influence of the forces does not deviate by more than 10% from the heat flux that would be caused by the external forces alone or by the body forces alone." The Grashof number is based on the diameter of the tube.

For flows in horizontal tubes, correlations were developed for the mixed convection regime in isothermal tubes by Depew and August (1971) and for uniform heat flux by Morcos and Bergles (1975).

Uniform Surface Temperature

Fully developed velocity profile, developing temperature profile:

$$L/d < 28.4;\ 25 < \mathrm{Gz} < 712;\ 0.7 \times 10^5 < \mathrm{Gr} < 9.9 \times 10^5$$

μ_s = dynamic viscosity, evaluated at the wall temperature

All other properties at the average bulk temperature of the fluid

$$\mathrm{Gz} = \frac{\dot{m}C_p}{kL} \quad \mathrm{Gr} = g\beta\Delta T d^3/\nu^2,$$

$$\mathrm{Nu}_d = 1.75\left[\mathrm{Gz} + 0.12\left(\mathrm{GzGr}^{1/3}\mathrm{Pr}^{0.36}\right)^{0.88}\right]^{1/3}(\mu_b/\mu_s)^{0.14}. \tag{3.2.138}$$

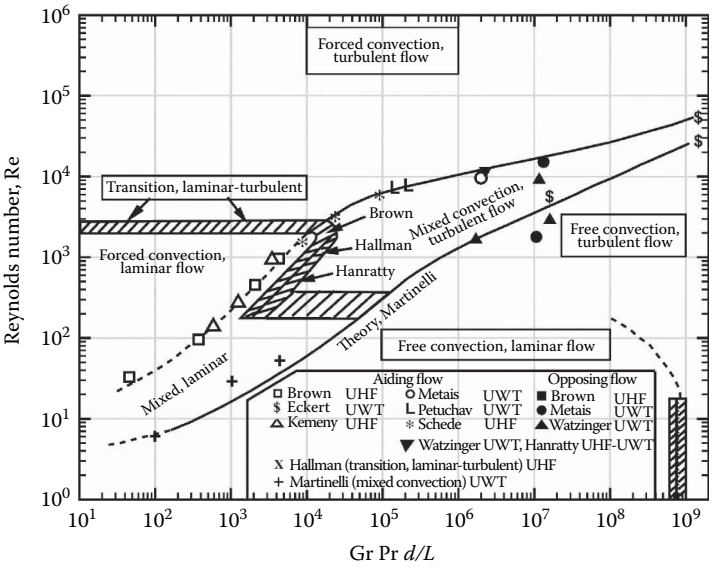

FIGURE 3.2.26 Map delineating forced, mixed, and natural convection—vertical tubes.

Uniform Heat Flux

Properties at $(T_s+T_b)/2$: $3\times10^4 < \mathrm{Ra} < 10^6$, $4 < \mathrm{Pr} < 175$, $2 < hd^2/(k_w t) < 66$, k_w=tube wall thermal conductivity, t=tube wall thickness.

$$\mathrm{Gr}_d^* = g\beta d^4 q_w''/(v^2 k); \qquad P_k = kd/(k_w t); \qquad \mathrm{Ra}_d = g\beta\Delta T d^3 \mathrm{Pr}/v^2,$$

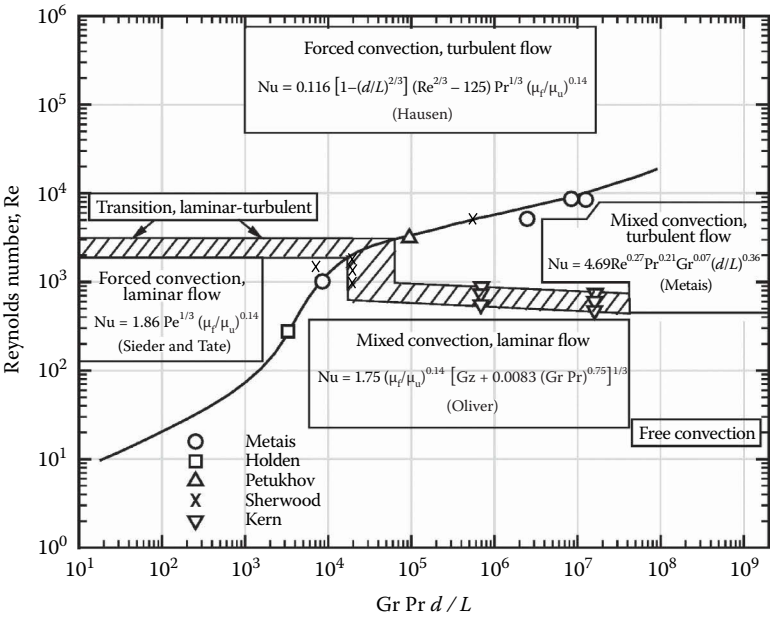

FIGURE 3.2.27 Map delineating forced, mixed, and natural convection—horizontal tubes.

$$\mathrm{Nu_d} = \left\{ 4.36^2 + \left[0.145 \left(\frac{\mathrm{Gr_d^* Pr}^{1.35}}{P_w^{0.25}} \right)^{0.265} \right]^2 \right\}^{0.5} . \tag{3.2.139}$$

In Equations 3.2.138 and 3.2.139, evaluate fluid properties at the arithmetic mean of the bulk and wall temperatures.

ACKNOWLEDGMENT

The preparation of this section was greatly facilitated by the award of the JC Bose Fellowship (Department of Science & Technology, Government of India, New Delhi) to R.P. Chhabra for the period 2015–2020. This support is gratefully acknowledged.

3.2.4 Convection Heat Transfer in Non-Newtonian Fluids

Swati A. Patel, Raj P. Chhabra, Thomas F. Irvine, Jr., and Massimo Capobianchi

Introduction

The general characteristics of non-Newtonian fluids are described in Section 2.9 and will not be repeated here. Topics to be included in this section are laminar and turbulent heat transfer in fully developed duct flows, and laminar convection heat transfer in vertical channels and in external boundary layer flows over plates and several other common geometries.

For non-Newtonian flows, except for certain classes of fluids which exhibit a slip phenomenon at solid boundaries, the boundary condition is taken as no-slip or zero (tangential) velocity at all solid surfaces. For heat-transfer analyses, however, the situation is more complicated because there are many different ways to heat a wall, which in turn affects the type of thermal boundary conditions prescribed on solid boundaries.

In general, the rate of heat transfer from a surface, or the temperature difference between the wall and the fluid, is calculated using the equation $q_c = h_c A_q \Delta T$. Since the heat-transfer coefficient can vary considerably for different thermal boundary conditions or due to temperature-dependent properties or due to significant viscous dissipation effects, it is important that the conditions and other restrictions be specified correctly. Although the number of thermal boundary conditions is, in principle, infinite, several classical types have been identified and are in common use. They are usually identified in terms of the Nusselt number, $\mathrm{Nu} = h_c L/k$, with a particular subscript. For example, for duct flow, the symbol Nu_T is used to specify the Nusselt number when the wall temperature is constant in both the flow and peripheral directions. Other thermal boundary conditions are described in Table 3.2.10 for duct heat transfer and will be used throughout this section.

It should be noted that because of the symmetry in circular and parallel plate ducts, Nu_{H1} and Nu_{H2} are identical and are referred to simply as Nu_H. Nu_{H4} with wall conduction is a more complicated problem where the energy equations must be solved simultaneously in both the wall and the fluid. Such problems are called conjugated. In the Nu_{H4} situation, the designer has the flexibility of affecting the heat transfer by varying either or both the characteristics of the duct wall or the convective fluid. In the heat-transfer relations to be considered later, care will be taken to identify the proper thermal boundary conditions using the nomenclature introduced in Table 3.2.10.

Laminar Duct Flow for Purely Viscous, Time-Independent, Non-Newtonian Fluids

Modified Power Law Fluids

As discussed in Section 2.9, a constitutive equation for pseudoplastic fluids (flow index, $n < 1$) is the modified power-law equation:

$$\mu_a = \frac{\mu_o}{1 + \dfrac{\mu_o}{K}\left(\dot{\gamma}\right)^{1-n}}. \tag{3.2.140}$$

Equation 3.2.140 describes the flow curve from the zero shear rate Newtonian region through the power-law region, including the low shear rate transition region. It thus has the characteristic that at low shear rates, the apparent viscosity approaches that of a Newtonian fluid while at large shear rates, it approaches that of a power-law fluid. It is therefore valid for fluids that exhibit no return to the Newtonian behavior at high shear rates. But as indicated in Section 2.9, it is also appropriate for fluids that transition back to Newtonian behavior at high shear rates, provided that the limiting Newtonian viscosities differ by approximately four orders of magnitude or more, and that all the shear rates in the flow field are within the zero shear rate Newtonian region through the power-law region. Solutions that use this constitutive equation entail a shear rate parameter, β, which describes

TABLE 3.2.10
Thermal Boundary Conditions for Duct Heat Transfer

1	Constant wall temperature in both the flow and circumferential direction	Nu_T
2	Constant heat flux in the flow direction and constant temperature in the circumferential direction	Nu_{H1}
3	Constant heat flux in the flow and circumferential directions	Nu_{H2}
4	Constant heat flux per unit volume in the wall with circumferential wall heat conduction	Nu_{H4}

whether any particular system is in the Newtonian, transitional, or power-law region. For duct flow, β is given by

$$\beta = \frac{\mu_o}{K}\left(\frac{\bar{u}}{D_H}\right)^{1-n}. \tag{3.2.141}$$

If $\log_{10}\beta > 2$: Power law region

If $\log_{10}\beta < -2$: Newtonian region

If $-2 < \log_{10}\beta \leq 2$: Transition region

For fully developed flow, the characteristic length is the hydraulic diameter, D_H, and the fluid temperature is the "bulk" temperature defined as

$$T_b = \frac{1}{A_c\bar{u}}\int_{A_c} uT\,dA_c. \tag{3.2.142}$$

Figure 3.2.28 illustrates the values of Nu_T vs. β for a circular duct with the flow index, n, as a parameter. It is seen here that the effect of β on Nu_T is only moderate, but for some applications, it may be important to know at what value of β the system is operating. The situation is similar for boundary condition Nu_H.

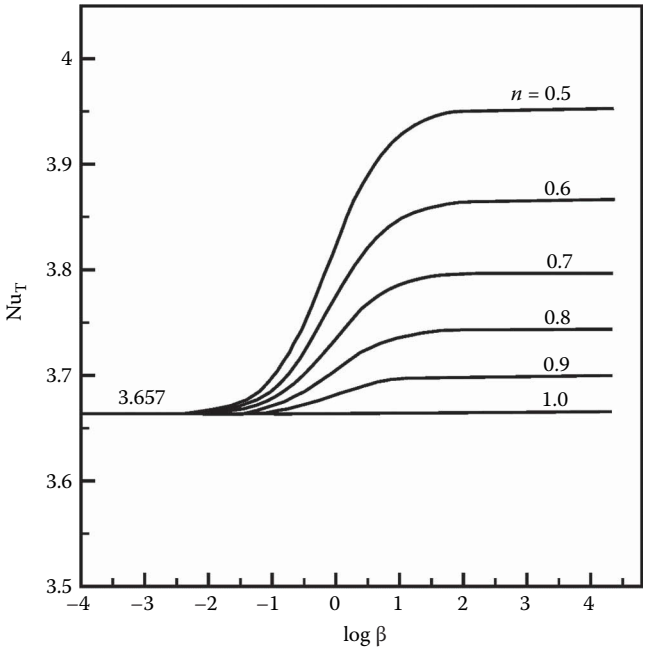

FIGURE 3.2.28 Variation of the fully developed circular duct Nusselt numbers, Nu_T, with the shear rate parameter β and n. (From Irvine, T.F. et al., Graetz problem solutions for a modified power-law fluid, *ASME Symposium on Fundamentals of Forced Convection Heat Transfer*, ASME publ. HTD 101, pp. 123–127, 1988.)

Although Figure 3.2.28 shows the Nusselt number relation graphically, it is convenient to have simple correlation equations to represent the solutions for both boundary conditions. For fully developed Nusselt numbers with values of $0.5 \le n \le 1.0$ and $10^{-4} \le \beta \le 10^4$, Irvine et al. (1988) presented the following equation that represents both solutions with a maximum difference of 1.5%:

$$\mathrm{Nu} = \frac{\mathrm{Nu_N}(1+\beta)}{1+\dfrac{\mathrm{Nu_N}\beta}{\mathrm{Nu_P}}}. \tag{3.2.143}$$

The Newtonian Nusselt numbers are $\mathrm{Nu_N}=3.6568$ for $\mathrm{Nu_T}$, and $\mathrm{Nu_N}=4.3638$ for $\mathrm{Nu_H}$. In addition, Table 3.2.11 lists the power-law Nusselt numbers, $\mathrm{Nu_{TP}}$ and $\mathrm{Nu_{HP}}$, for $\log_{10}\beta=4$, i.e., well into the power law region.

Graetz solutions for the thermal entrance lengths are also available. They assume that the velocity profile is fully developed at the duct entrance and present the duct lengths required for the Nusselt numbers to reach within 1% of the fully developed values. Figure 3.2.29 shows these thermal entrance lengths for $\mathrm{Nu_T}$ thermal boundary condition. The situation is similar for the other boundary condition $\mathrm{Nu_H}$.

A correlation equation for the thermal entrance lengths for both the $\mathrm{Nu_T}$ and $\mathrm{Nu_H}$ boundary conditions by Irvine et al. (1988) represents the numerical solutions within 0.5% for $0.5 \le n \le 1.0$ and $-4 \le \log_{10}\beta \le 4$. Table 3.2.12 lists the power-law thermal entrance lengths, which are needed to evaluate the following correlation equation:

$$x^+_{\mathrm{ent},\beta,n} = \frac{x^+_{\mathrm{ent,N}}(1+\beta)}{1+\dfrac{x^+_{\mathrm{ent,N}}(\beta)}{x^+_{\mathrm{ent,P}}}}, \tag{3.2.144}$$

where $x^+_{\mathrm{ent},\beta,n}$ is the modified power-law dimensionless entrance length defined as $x^+_{\mathrm{ent},\beta,n} = (x_{\mathrm{ent},\beta,n}/D_{\mathrm{H}})/\mathrm{Pe}$, and $x^+_{\mathrm{ent,N}}$ and $x^+_{\mathrm{ent,P}}$ are the corresponding Newtonian and power-law values, respectively. The Newtonian dimensionless entrance lengths are $x^+_{\mathrm{ent,N}} = 0.03347$ for $\mathrm{Nu_T}$ and $x^+_{\mathrm{ent,N}} = 0.04309$ for $\mathrm{Nu_H}$.

Only one noncircular geometry using the modified power-law equation has been studied in the archival literature for laminar fully developed heat transfer (Capobianchi and Irvine, 1992). A correlation equation ($n<1$) for $\mathrm{Nu_{H1}}$ for a concentric annuli with constant heat flux at the inner wall and the outer wall insulated is

$$\mathrm{Nu_{H1}} = \frac{1+\beta}{\dfrac{1}{\mathrm{Nu_{H1,N}}}+\dfrac{\beta}{\mathrm{Nu_{H1,P}}}}. \tag{3.2.145}$$

Extended Modified Power Law Fluids

The extended modified power-law constitutive equations discussed in Section 2.9 describe the flow curve for purely viscous, non-Newtonian fluids with no yield stress that revert back to Newtonian behavior at high shear rates. They span the entire shear rate regime, from zero to the high-shear-rate Newtonian regions, and are valid for any limiting viscosity ratio, $R* = \mu_\infty/\mu_0$. Analyses that use these equations generate a shear rate parameter, β*, whose function is analogous to the parameter β in modified power-law solutions. That is, the value of β* determines the shear rate regime where the system is operating. The definition of β*, its valid range, and the interpretation of its value relative to the shear rate regime is discussed in detail in Section 2.9 and thus no repetition is included here.

Capobianchi and Wagner (2010) obtained numerical solutions for the Nusselt number for fully developed, laminar flows of extended modified power-law fluids in rectangular ducts with n in the range of 0.50–1.50 in increments of 0.10, and $|\log_{10}(R*)| = 1$, 2, 3, and 4. Here, the length scale used in the Nusselt number definition is the hydraulic diameter. They solved both the T and H1 boundary conditions and presented their results graphically for duct aspect ratios, $\alpha*$, of 0.25 and 1.00 (square duct), and in terms of correlation equations with associated constants for $\alpha* = 0.25$, 0.50, 0.75, and 1.00. The latter may be found in Table 3.2.13 and generally overestimate the numerical data by no more than 0.25% for all values of $\alpha*$ when n is restricted to the range ($0.80 \le n \le 1.20$). Outside this range, they overestimate numerical data by more than 20% and are thus not recommended.

Graphical results for the T and H1 boundary conditions for a square duct (i.e., $\alpha* = 1.00$) are shown in Figures 3.2.30 and 3.2.31, respectively. Note that, as in the case of the friction factor—Reynolds number product, the behavior of the Nusselt number follows expected trends; it approaches the Newtonian values at the endpoints of each curve and power-law values at the midpoint of each curve (when plotted in logarithmic coordinates). But power-law values are approached only if, in addition, the limiting viscosities differ sufficiently, by approximately four orders of magnitude or more. Otherwise, the value at the midpoint of each curve is somewhere between the respective power law and Newtonian asymptotes, approaching the latter as $R* \to 1$. This is a result of the effective value of n being closer to 1 than its physical value as the limiting viscosities approach each other. The reader is referred to Section 2.9 for additional details. Finally, it may be noted that, for pseudoplastic fluids, Nusselt numbers are always higher than the Newtonian value and that, referring to Section 2.9, these are associated with pressure drops that are always smaller than Newtonian values. However, the friction factor—Reynolds number product generally departs from Newtonian values far more than the Nusselt number. In fact, the Newtonian Nusselt number was found to underestimate the actual Nusselt number by no more than 7.7% for pseudoplastic fluids, and to overestimate it by no more than 3.3% for dilatant fluids. Thus, in light of the typical uncertainties associated with heat-transfer computations, use of the Newtonian values for calculations involving pseudoplastic or dilatant fluids may be justified depending on the desired solution accuracy.

Power Law Fluids

The mean Nusselt numbers for square ducts and power-law fluids can be found in Chandrupatla and Sastri (1977) and, for isosceles triangular ducts, in Cheng (1984). Thermally developing and thermally developed laminar heat transfer in rectangular channels has been studied by Hartnett and Kostic (1989).

For other cross-sectional shapes, a power-law approximate correlation has been proposed by Cheng (1984):

$$\mathrm{Nu_P} = \mathrm{Nu_N}\left[\frac{(a+bn)}{(a+b)n}\right]^{1/3}, \tag{3.2.146}$$

where a and b are the Kozicki geometric constants listed in Table 2.9.2 in the section on non-Newtonian flows. Equation 3.2.146 applies to any thermal boundary condition. For circular ducts, Equation 3.2.146 predicts the correct solution for both $\mathrm{Nu_T}$ and $\mathrm{Nu_H}$ cases.

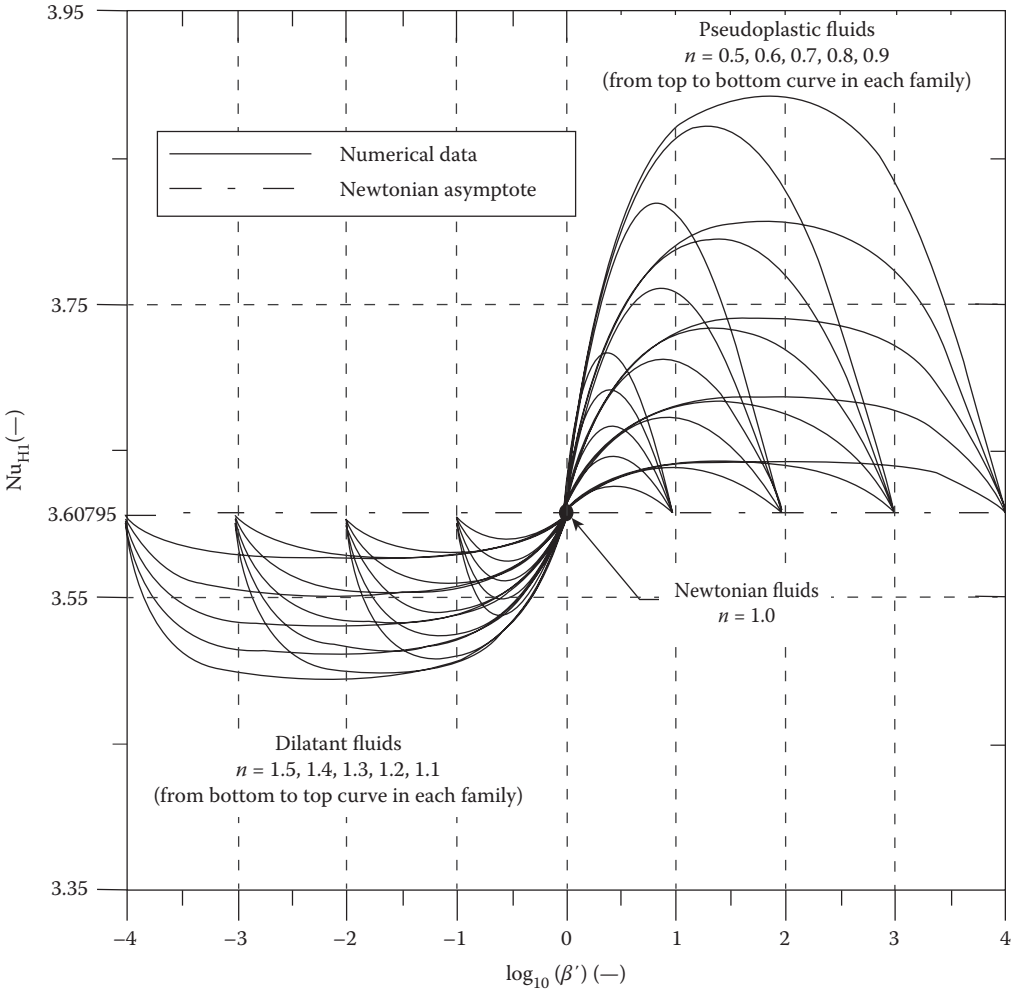

FIGURE 3.2.31 Nusselt number results for a square duct with the H1-boundary condition. (Modified from Capobianchi, M. and Wagner, D., *Int. J. Heat Mass Transfer*, 53, 558–563, 2010.)

Turbulent Duct Flow for Purely Viscous Non-Newtonian Fluids

It is known that in turbulent flow the type of thermal boundary condition has much less effect than that in laminar flow. Therefore, turbulent flow heat-transfer investigations are often reported without specifying the thermal boundary conditions. Yoo (1974) has presented an empirical correlation for turbulent heat transfer in circular ducts for purely viscous power-law fluids.

$$\mathrm{St}\mathrm{Pr}_a^{2/3} = 0.0152\mathrm{Re}_a^{-0.155}. \tag{3.2.147}$$

Equation 3.2.147 describes most of the experimental data available in the literature with a mean deviation of 2.3%. Equation 3.2.147 is recommended in order to predict the turbulent fully developed heat transfer in the ranges $0.2 \le n \le 0.9$ and $3000 \le \mathrm{Re}_a \le 90{,}000$. The Reynolds number and Prandtl numbers in Equation 3.2.147 are based on the apparent viscosity at the wall, μ_a, that is,

$$\mathrm{Re}_a = \frac{\rho \bar{u} D_\mathrm{H}}{\mu_a}, \tag{3.2.148}$$

$$\mathrm{Pr}_a = \frac{\mu_a c_p}{k}. \tag{3.2.149}$$

In order to evaluate Equations 3.2.148 and 3.2.149 in terms of the rheological properties and operating parameters, an expression must be obtained for μ_a in terms of these quantities. The value of μ_a is evaluated by considering that μ_a is determined from fully developed laminar circular tube power-law fluid flow for which it can be shown that (Irvine and Karni, 1987)

$$\mu_a = K\left(\frac{3n+1}{4n}\right)^{n-1}\left(\frac{8\bar{u}}{D_\mathrm{H}}\right)^{n-1}, \tag{3.2.150}$$

assuming that the quantities K, n, c_p, and k are constant. It is also of interest to note here that the Prandtl number is no longer a thermophysical property for power-law fluids but depends upon the average velocity, $\bar{u}$, and the hydraulic diameter, D_H.

Hartnett and Rao (1987) have investigated fully developed turbulent heat transfer for a rectangular duct with a 2:1 aspect ratio and proposed the following equation which generally agreed with their experimental data within ±20%:

$$\mathrm{Nu} = \left(0.0081 + 0.0149n\right)\mathrm{Re}_a^{0.8}\mathrm{Pr}_a^{0.4}. \tag{3.2.151}$$

Viscoelastic Fluids

An important characteristic of viscoelastic fluids is their large hydrodynamic and thermal entrance lengths. Cho and Hartnett (1982) have reported hydrodynamic entrance lengths of up to 100 diameters and thermal entrance lengths up to 200–800 diameters depending upon the Reynolds and Prandtl numbers and the level of fluid elasticity. These can be compared with Newtonian fluids entrance lengths which are of the order of 10–15 diameters. Therefore, care must be used in applying the fully developed relations to practical situations.

Cho et al. (1980) reported heat-transfer measurements in the thermal entrance region and recommend the following empirical equation for saturated aqueous polymer solutions for $6000 \le \mathrm{Re}_a$ and x/D_H values up to 450:

$$J_\mathrm{H} = 0.13\left(x/D_\mathrm{H}\right)^{-0.24}\mathrm{Re}_a^{-0.45}, \tag{3.2.152}$$

where

$$J_\mathrm{H} = \mathrm{St}\,\mathrm{Pr}_a^{2/3} \text{ and } \mathrm{St} = h_c/\rho c_p \bar{u}.$$

All of the reported fully developed turbulent flow heat-transfer measurements have been plagued by solute and solvent, thermal entrance, and degradation effects, and thus there is a considerable scatter in the results. Degradation effects can be reduced or eliminated by using large amounts of polymer (500–10,000 wppm) so that the solution becomes saturated. Cho and Hartnett (1982) attempted to eliminate these effects by using a thermal entrance length of 430 diameters and saturated polymer solutions which should yield maximum heat-transfer reductions. Their experimental results for fully developed heat transfer were correlated for a Reynolds number range $3500 \le \mathrm{Re}_a \le 40{,}000$ and concentration solutions of 500–5000 wppm of polyacrylamide and polyethylene oxide by

$$J_\mathrm{H} = 0.03\mathrm{Re}_a^{-0.45}. \tag{3.2.153}$$

For viscoelastic fluids in fully developed (hydrodynamically and thermally) *laminar flow in circular ducts*, there is no apparent viscoelastic effect. Thus, the heat-transfer relations are the same as

those for time-independent fluids such as power-law or modified power-law fluids. The same situation holds for thermal entrance region heat transfer (Graetz problem). Relations for the laminar Nusselt numbers in thermal entrance regions are presented by Cho and Hartnett (1982).

Free Convection Flows and Heat Transfer

Free convection information available in the heat-transfer literature is concentrated on heat transfer to power-law fluids for vertical plates, spheres and cylinders, and in parallel plate channels. For free convection flows, however, the velocities and thus the shear rates are low and care must be taken that the flow for a particular fluid is in the power-law shear rate region before using power-law solutions or correlations. Comprehensive review articles on free convection with non-Newtonian fluids in external flows have been presented by Shenoy and Mashelkar (1982), Irvine and Karni (1987) and Chhabra (2006).

Internal Flows

Vertical Parallel Plates

Irvine et al. (1982) provided a numerical solution for buoyancy-induced, laminar flows of power-law fluids in vertical, parallel plate channels. Their results are presented graphically in Figure 3.2.32. Of interest are the average Nusselt number $\overline{\mathrm{Nu}}_{\mathrm{T}b}$ and the dimensionless average flow velocity between the plates, U_{o}^{+}. These are shown on the left and right ordinates, respectively, in Figure 3.2.32. The characteristic dimension in the Nusselt and Grashof numbers is the plate spacing, b. The dimensionless quantities used in Figure 3.2.32 are defined as follows:

$$\overline{\mathrm{Nu}}_{\mathrm{T}b} = \frac{\overline{h}_{\mathrm{c}} b}{k} \qquad U_{\mathrm{o}}^{+} = \frac{b u_{\mathrm{o}}}{L u^{*}} \tag{3.2.154}$$

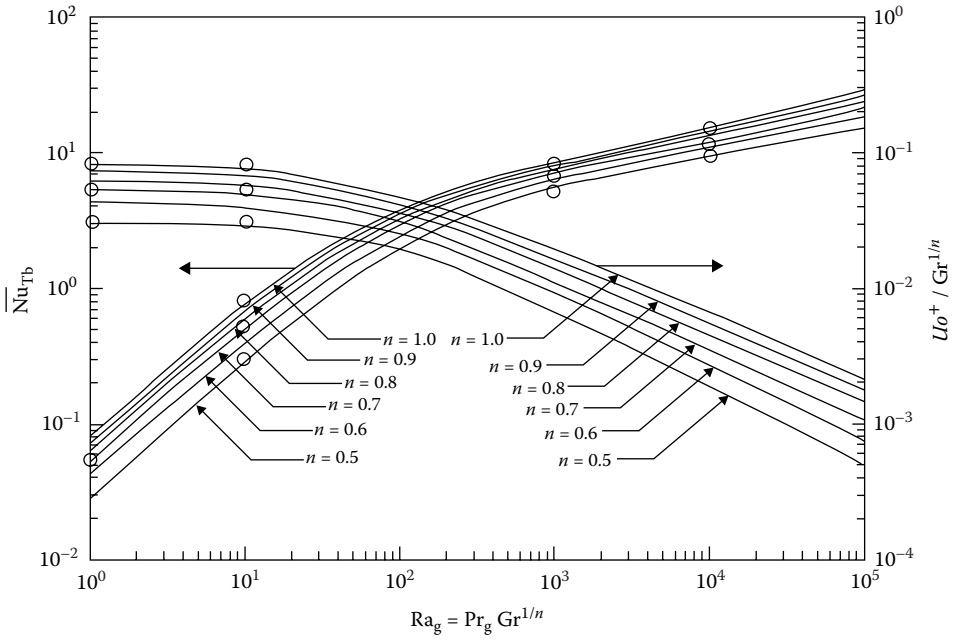

FIGURE 3.2.32 Free convection average Nusselt number, $\overline{\mathrm{Nu}}_{\mathrm{T}b}$, and dimensionless average velocity, U_{o}^{+}, between vertical plates for a power-law fluid vs. generalized Rayleigh number for the T boundary condition. (From Irvine, T.F. et al., Vertical channel free convection to a power-law fluid, ASME Paper 82-WA/HT-69, 1982.)

$$\mathrm{Pr_g} = \frac{\rho c_p}{k}\left[\frac{v_k^{1/(2-n)}}{\left(\frac{L}{b}\right)^{(l-n)/(2-n)} b^{(2n-2)/(2-n)}}\right];\ v_K = \frac{K}{\rho} \tag{3.2.155}$$

$$\mathrm{Gr_g} = \frac{g\alpha\left(T_s - T_\infty\right)b^{(n+2)/(2-n)}}{v_K^{2/(2-n)}\left(\frac{L}{b}\right)^{n/(2-n)}};\qquad u^* = \frac{v_K^{1/(2-n)} b^{(1-2n)/(2-n)}}{L^{(1-n)/(2-n)}} \tag{3.2.156}$$

For vertical parallel plates for the average Nusselt number, $\overline{\mathrm{Nu}}_{\mathrm{H}b}$ and the between plate average velocity, Schneider and Irvine (1984) have presented graphical results similar to Figure 3.2.32.

Lee et al. (1998) have presented a numerical solution for the laminar flow of a *modified power-law fluid* between vertical plates. They have also calculated thermal entrance regions and shown that if a parallel plate system is actually operating in the transition region and if the power-law solution is used, both the total heat transfer and the velocity between plates can differ by over an order of magnitude. It is important to consider the shear rate parameter in order to determine which free convection solution to use.

External Flows

Vertical Plates

For a vertical plate with a modified power-law fluid and a thermal boundary condition $\bar{N}u_{\mathrm{T}}$, in laminar flow, the following relation is recommended by Shenoy and Mashelkar (1982):

$$\bar{\mathrm{N}}\mathrm{u}_{TL} = T(n)\mathrm{Gr}_{TL}^{1/(2n+2)}\,\mathrm{Pr}_{TL}^{n/(3n+1)}, \tag{3.2.157}$$

where $\bar{\mathrm{N}}\mathrm{u}_{TL}$ is the average Nusselt number and

$$\mathrm{Gr}_{TL} = \frac{\rho^2 L^{n+2}}{K^2}\left[g\alpha\left(T_s - T_\infty\right)\right]^{2-n}, \tag{3.2.158}$$

$$\mathrm{Pr}_{TL} = \frac{\rho c_p}{k}\left(\frac{K}{\rho}\right)^{2/(n+1)} L^{(n-1)/(2n+2)}\left[g\alpha\left(T_s - T_\infty\right)\right]^{(3n-3)/(2n+2)}, \tag{3.2.159}$$

where α is the isobaric thermal expansion coefficient.

In the range $0.5 \le n \le 1$, $T(n)$ can be approximated by

$$T\left(n\right) = 0.1636n + \ 0.5139. \tag{3.2.160}$$

The characteristic dimension in the Nusselt and Grashof numbers is the plate height, L.

For thermal boundary conditions $\mathrm{Nu_H}$, the following relation is also recommended by Shenoy and Mashelkar (1982). Since the heat flux, q_w, is specified in this case, the local plate temperature at any x (measured from the bottom of the plate) can be obtained from the local Nusselt number $\mathrm{Nu}_{\mathrm{H}x}$. The heat-transfer coefficient is defined in terms of the difference between the wall and free-stream temperatures.

$$\mathrm{Nu}_{\mathrm{H}x} = 0.619\left[\mathrm{Gr}_{\mathrm{H}x}^{(3n+2)/(n+4)}\mathrm{Pr}_{\mathrm{H}x}^{n}\right]^{0.213}, \tag{3.2.161}$$

where

$$\mathrm{Gr}_{\mathrm{H}x} = \frac{\rho^2 x^4}{k^2}\left(\frac{g\alpha q_w}{k}\right)^{2-n} \tag{3.2.162}$$

$$\mathrm{Pr}_{\mathrm{H}x} = \frac{\rho c_p}{K}\left(\frac{K}{\rho}\right)^{5/(n+4)} x^{(2n-2)/(n+4)}\left(\frac{g\alpha q_w}{k}\right)^{(3n-3)/(n+4)} \tag{3.2.163}$$

Recently, Capobianchi and Aziz (2012, 2014) have solved numerically for the average Nusselt number problem for laminar, natural convection between a vertical surface and pseudoplastic and dilatant fluids for both the constant temperature ($\overline{\mathrm{Nu}}_{TL}$) and the constant heat flux ($\overline{\mathrm{Nu}}_{HL}$) boundary conditions. They used the extended modified power-law equation for the apparent viscosity in their formulation and provided solutions in both graphical and tabular form. Representative plots of the results are shown in Figures 3.2.33 through 3.2.36, and the tabular results are provided in Tables 3.2.14 through 3.2.17. For both boundary conditions, the Nusselt number may be seen to be a function of n, the Boussinesq number, Bo, and the Prandtl number, Pr*, defined as

$$\mathrm{Bo} = \frac{g\alpha L^3 \Delta T^*}{\alpha_{\mathrm{T}}^2} : \mathrm{Pr} = \frac{\mu^*/\rho}{\alpha_{\mathrm{T}}}. \tag{3.2.164}$$

Here, α_T is the thermal diffusivity and μ^* is the extended modified power-law reference viscosity. The definition of the temperature difference, ΔT^*, depends on the boundary condition and equals $(T_s - T_\infty)$ for the constant temperature boundary condition, and is given by qwL/k for the constant heat flux case. Furthermore, Pr^* may be expressed in terms of R^*, β^*, and the Prandtl number based on μ_0, Pr_0. For pseudoplastic and dilatant fluids, respectively, Pr^* becomes

$$Pr^* = \frac{Pr_0}{\beta}, \tag{3.2.165}$$

$$Pr^* = \beta^* R^* Pr_0. \tag{3.2.166}$$

It should be noted that the bulk velocity, V, in the definitions of β and β_∞ (i.e., within the definition of β^*, see Section 2.9) is replaced by a reference velocity, u^*, that depends on the boundary condition. For the constant temperature and constant heat flux boundary conditions, u^* is given, respectively, by

$$u^* = \frac{\alpha_T / L}{\left(\frac{1+Pr^*}{Bo}\right)^{1/2}}, \tag{3.2.167}$$

$$u^* = \frac{\alpha_T / L}{\left(\dfrac{1+\mathrm{Pr}^*}{\mathrm{Bo}}\right)^{2/5}}. \tag{3.2.168}$$

Consequently, since there is no imposed velocity in natural convection problems and, instead, a reference velocity is used that depends on both Pr* and Bo, a practical complication exists in evaluating β^* for a given situation. Namely, β^* is only known implicitly and must be evaluated iteratively. The reader is referred to Capobianchi and Aziz (2014) for a description of the recommended iterative technique.

Referring to Figures 3.2.33 through 3.2.36, the results may be seen to group as a function of Bo. The heavy lines in each group are the Newtonian values, the remaining curves being the non-Newtonian solutions. It may be noted that Nusselt numbers for pseudoplastic fluids always exceed their Newtonian counterparts, and that the opposite is true for dilatant fluids. As in the case of the other studies that use the extended modified power-law equations, the endpoints of each curve approach the Newtonian values, while the midpoint (when plotted in logarithmic coordinates) approach the power-law values. And as before, the latter is true only if, in addition, the limiting viscosities, μ_0 and μ_∞, differ by about four orders of magnitude or more. Thus, the behavior in all such studies is analogous.

Sphere and Horizontal Cylinder

For flow over a sphere, the correlation for power-law fluids by Amato and Tien (1976) is

$$\overline{Nu}_{Tr} = c_1 Z^{c_2}, \tag{3.2.169}$$

where

$$Z = Gr_{Tr}^{1/(2n+2)} Pr_{Tr}^{n/(3n+1)} \tag{3.2.170}$$

and

$$c_1 = 0.996 \pm 0.120, c_2 = 0.682 \quad \text{for } Z < 10$$

$$c_1 = 0.489 \pm 0.005, c_2 = 1.10 \qquad \text{for } 10 \le Z \le 40,$$

where the characteristic dimension in all dimensionless variables is the sphere radius, r, and Gr_{Tr} and Pr_{Tr} are defined in Equations 3.2.158 and 3.2.159, respectively.

For pseudoplastic fluids flowing over a cylinder, an experimental correlation proposed by Gentry and Wollersheim (1974) for the average Nusselt number, $\overline{Nu}_{TD}$, is

$$\overline{Nu}_{TD} = \frac{\overline{h}_c D}{k} = 1.19\left(Gr_{TD} Pr_{TD}\right)^{0.2}, \tag{3.2.171}$$

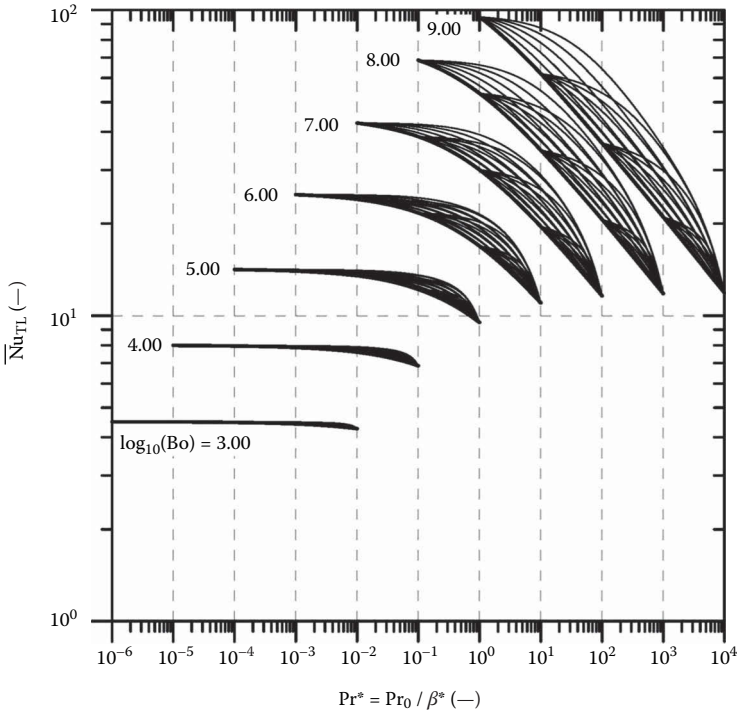

FIGURE 3.2.33 $\overline{\mathrm{Nu}}_{TL}$ for pseudoplastic fluids. The curves in heavy-weight lines are Newtonian fluid (n=1.00) solutions. Curves in normal-weight lines are pseudoplastic fluid solutions for n=0.50, 0.60, 0.70, 0.80, and 0.90, proceeding from the upper to the lower curve in each family. (Modified from Capobianchi, M. and Aziz, A., *ASME J. Heat Transfer*, 134(12), 122502, 2012.)

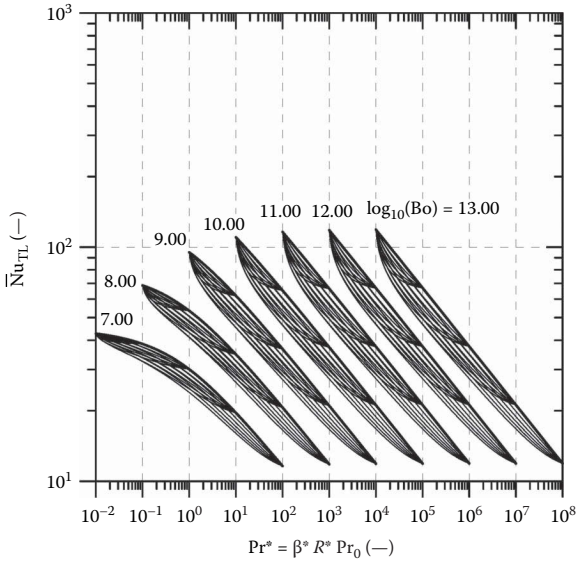

FIGURE 3.2.34 $\overline{\mathrm{Nu}}_{TL}$ for dilatant fluids. The curves in heavy-weight lines are Newtonian fluid (n=1.00) solutions. Curves in normal-weight lines are dilatant fluid solutions for n=1.50, 1.40, 1.30, 1.20, and 1.10, proceeding from the lower to the upper curve in each family. (Modified from Capobianchi, M. and Aziz, A., *ASME J. Heat Transfer*, 134(12), 122502, 2012.)

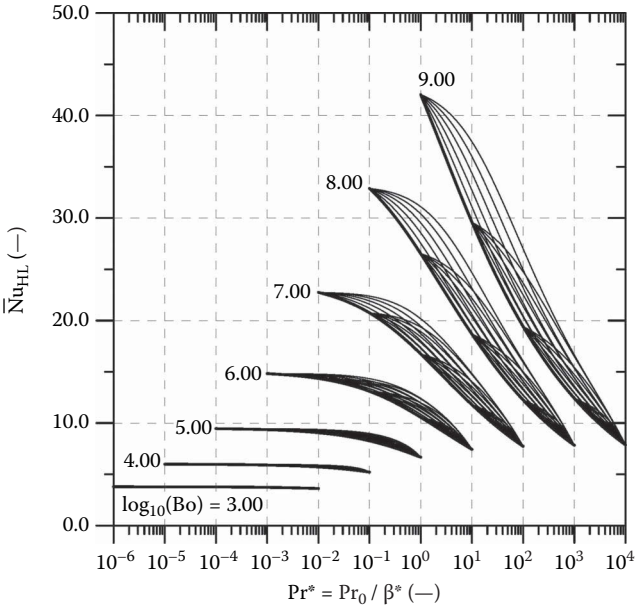

FIGURE 3.2.35 $\overline{Nu}_{HL}$ for pseudoplastic fluids. The curves in heavy-weight lines are Newtonian fluid (n=1.00) solutions. Curves in normal-weight lines are pseudoplastic fluid solutions for n=0.50, 0.60, 0.70, 0.80, and 0.90, proceeding from the upper to the lower curve in each family. (Modified from Capobianchi, M. and Aziz, A., *ASME J. Heat Transfer*, 136(9), 092501, 2014.)

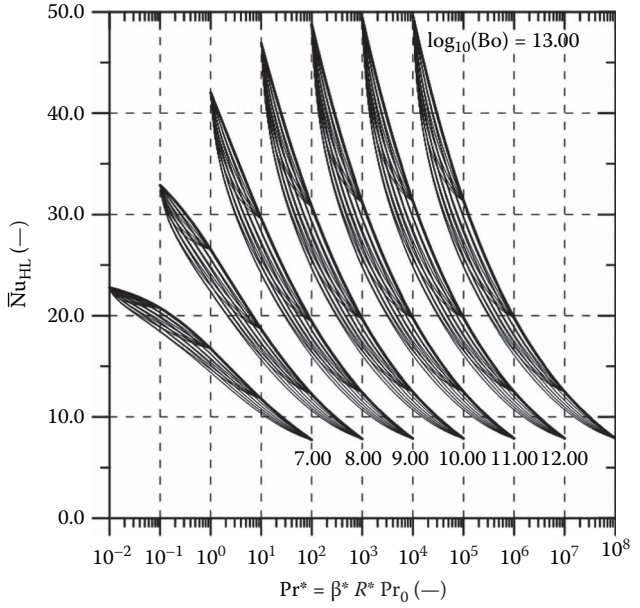

FIGURE 3.2.36 $\overline{Nu}_{HL}$ for dilatant fluids. The curves in heavy-weight lines are Newtonian fluid (n=1.00) solutions. Curves in normal-weight lines are dilatant fluid solutions for n=1.50, 1.40, 1.30, 1.20, and 1.10, proceeding from the lower to the upper curve in each family. (Modified from Capobianchi, M. and Aziz, A., *ASME J. Heat Transfer*, 136(9), 092501, 2014.)

where Gr_{TD} and Pr_{TD} are defined in Equations 3.2.158 and 3.2.159 with the cylinder diameter, D, being used instead of L.

Suffice it to add here that the recent numerical studies of Prhashanna and Chhabra (2010, 2011) for a sphere and cylinder (Table 3.2.18) lend further support to the reliability of Equations 3.2.169 and 3.2.171. The scant results for a range of other shapes including hemispheres, spheroids, and cylinders of various cross sections are also listed in Table 3.2.18 along with the applicable ranges of conditions. Broadly, all else being equal, shear-thinning fluid behavior ($n < 1$) promotes heat transfer over and above that seen in Newtonian fluids. Indeed, it is possible to realize up to 30%–40% augmentation in heat transfer under appropriate conditions. On the other hand, heat-transfer deteriorates in shear-thickening fluids ($n > 1$) by about 15%–20%.

Similarly, the corresponding studies on free convection in Bingham plastic fluids have also been reported for a sphere and a horizontal cylinder, elliptical and semicircular cylinder (Table 3.2.19). The Bingham plastic and other viscoplastic fluids differ from the power law and other generalized Newtonian fluids in a significant manner, which directly impinges on convective heat transport. In a given situation, a Bingham fluid may or may not yield depending upon the magnitude of the prevailing stress *vis-à-vis* the fluid yield stress. Consequently, the flow domain is spanned by the coexistence of solid-like (unyielded) and fluid-like (yielded) regions. Naturally, heat transfer occurs by conduction in solid-like regions and convection is limited only to the fluid-like regions. In steady-state situations, the overall rate of heat transfer is thus limited by conduction. Next, it stands to reason that for a given Bingham number (nondimensionalized yield stress), there exists a critical Rayleigh number denoting the onset of buoyancy-induced flow in these systems. Thus, for a given geometry and boundary conditions, the average Nusselt number decreases, with the increasing Bingham umber, from its maximum value (at $Bn = 0$, i.e., Newtonian fluid) to its minimum value (corresponding to conduction) at high Bingham numbers (Tables 3.2.20 and 3.2.21).

Forced Convection Heat Transfer

Early attempts in this field are based on the standard boundary layer analysis, which is generally valid in the limit of thin boundary layers wherein the curvature effects can also be neglected. This body of knowledge has been summarized by Chhabra (2006). However, over the past 15–20 years, the full momentum and energy equations have been solved, mainly for power law and Bingham plastic fluids, for an isothermal sphere, spheroid, and hemisphere as well as for two-dimensional cylinders of various cross sections. A summary of the predictive correlations based on the numerical results is presented in Table 3.2.22 for power law, values of constants used in Table 3.2.22 is described in Table 3.2.23, and in Table 3.2.24 for Bingham plastic fluids for a range of shapes. In overall terms, shear-thinning viscosity ($n < 1$) promotes heat transfer whereas shear-thickening fluid ($n > 1$) behavior impedes it with reference to that in Newtonian fluids otherwise under identical conditions. Similar enhancement is also possible in Bingham plastic fluids due to the sharpening of the temperature gradients in the thin fluid-like layer adjacent to the heated object (Tables 3.2.25 and 3.2.26).

From the foregoing discussion, it is abundantly clear that it is possible to modulate the rate of heat transfer by tuning the non-Newtonian characteristics (shear-thinning viscosity, yield stress) of the liquid medium via the use of suitable additives like clays, polymers, etc., in small doses. This approach is routinely used in food-, personal care-, and pharma-sectors to achieve improved functionality of a given product. Similarly, it is also possible to achieve some economy in energy consumption in chemical and allied processing industries on account of shear-thinning behavior.

Further Information

Other sources which may be consulted for more detailed information are Cho and Hartnett (1982), Shenoy and Mashelkar (1982), Irvine and Karni (1987), Hartnett and Kostic (1989), and Chhabra (2006, 2011).

3.3 RADIATIVE HEAT TRANSFER

Michael F. Modest

Nature of Thermal Radiation

All materials continuously emit and absorb radiative energy by lowering or raising their molecular energy levels. This thermal radiative energy may be viewed as consisting of electromagnetic waves or of massless energy parcels, called *photons*. Electromagnetic waves travel through any medium at the speed of light c, which is $c_0 = 2.998 \times 10^8$ m/s in vacuum and approximately the same in most gases such as air and combustion products. They are characterized by their wavelength λ (usually measured in $\mu m = 10^{-6}$ m) or frequency ν (usually measured in cycles/s = Hz), which are related by

$$\nu = \frac{c}{\lambda} \tag{3.3.1}$$

The strength and wavelengths of *emission* and *absorption* depend on the temperature and nature of the material.

The ability of photons to travel unimpeded through vacuum and gases makes thermal radiation the dominant mode of heat transfer in vacuum, low-pressure environments, and outer space applications (due to the near absence of conduction and convection). Its temperature dependence (as given by Equation 3.3.3), on the other hand, guarantees that radiative heat transfer is of utmost importance in high-temperature applications (including solar radiation: with the sun being a high-temperature heat source at an effective temperature of $T_{sun} = 5777\,\mathrm{K}$).

When an electromagnetic wave traveling through a gas (or vacuum) strikes the surface of a medium, the wave may be partly or totally reflected and any nonreflected part will penetrate into the medium. If a wave passes through a medium without any attenuation, the material is called *transparent*. A body with partial attenuation is known as *semitransparent*, and a body through which none of the incoming radiation penetrates is called *opaque*. Most gases are rather transparent to radiation (except for narrow spectral regions, called absorption bands), while most solids tend to be strong absorbers for most wavelengths, making them opaque over a distance of a few nanometers (electrical conductors, i.e., metals) to a few micrometers (ceramics and semiconductors), or more (dielectrics).

Blackbody Radiation

The total amount of radiative energy emitted from a surface into all directions above it is termed emissive power; we distinguish between spectral (at a given wavelength λ, per unit wavelength) and total (encompassing all wavelengths) emissive power. The magnitude of emissive power depends on wavelength λ, temperature T, and a surface property, called emittance ε, which relates the ability of a surface to emit radiative energy to that of an ideal surface, which emits the maximum possible energy (at a given wavelength and temperature). Such an ideal surface is known as a "blackbody" or "black surface," since it absorbs all incoming radiation; that is, it reflects no radiation and is, therefore, invisible ("black") to the human eye. The spectral distribution of the emissive power of a black surface (i.e., its dependence on the spectral variable, say λ) is given by Planck's law as

$$E_{b\lambda} = \frac{C_1}{\lambda^5 \left[e^{C_2/\lambda T} - 1 \right]}, \quad C_1 = 3.7419 \times 10^{-16}\,\mathrm{Wm}^2, \quad C_2 = 14{,}388\,\mu\mathrm{mK} \tag{3.3.2}$$

where C_1 and C_2 are sometimes called Planck function constants, or the first and second radiation constant, respectively. The total emissive power of a blackbody is given by

$$E_b = \int_0^\infty E_{b\lambda}\, d\lambda = \sigma T^4, \quad \sigma = 5.670 \times 10^{-8}\ \mathrm{W/m^2\,K^4} \tag{3.3.3}$$

with σ known as the Stefan–Boltzmann constant. Figure 3.3.1 shows the spectral solar irradiation that impinges on Earth, which closely resembles the spectrum of a blackbody at 5777 K. The general behavior of Planck's law is depicted in Figure 3.3.2, together with the fractional emissive power, $f(\lambda T)$, defined as

$$f(\lambda T) = \frac{1}{E_b}\int_0^\lambda E_{b\lambda}(\lambda, T)\ d\lambda \tag{3.3.4}$$

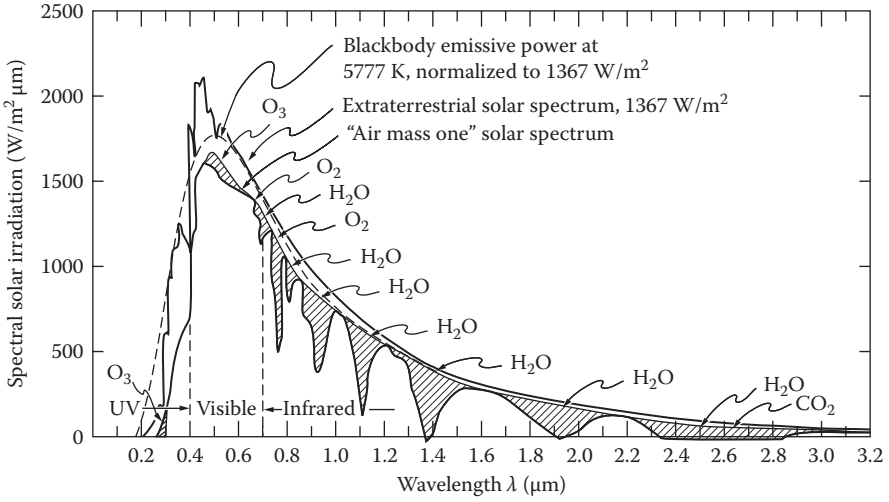

FIGURE 3.3.1 Solar irradiation onto Earth.

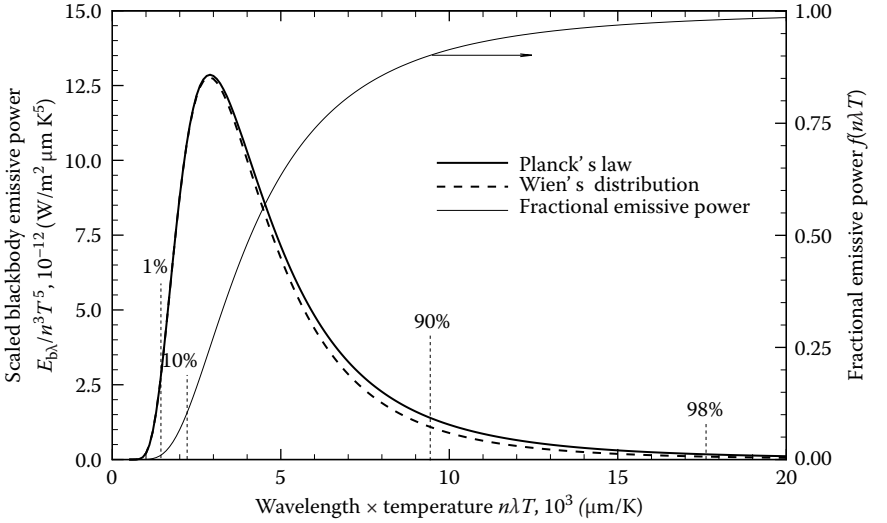

FIGURE 3.3.2 Normalized blackbody emissive power spectrum.

Note that 90% of all blackbody emission takes place between the wavelengths of $\lambda T > 2200\,\mu\text{m K}$ and $\lambda T < 9400\,\mu\text{m K}$. This implies that—for typical high-temperature heat-transfer applications in the range between 1000 and 2000 K—infrared wavelengths in the range $1\,\mu\text{m} < \lambda < 10\,\mu\text{m}$ govern the heat-transfer rates. For solar applications shorter wavelengths, down to $\lambda \cong 0.4\,\mu\text{m}$ are also important. Also shown in Figure 3.3.2 is Wien's law:

$$E_{b\lambda} = \frac{C_1}{\lambda^5} e^{-C_2/\lambda T} \tag{3.3.5}$$

which approximates Planck's law accurately over the part of the spectrum that is important to heat transfer, and that is easier to manipulate mathematically.

Example 3.3.1

What fraction of total solar emission falls into the visible spectrum (0.4 – 0.7 μm)?

Solution: With a solar temperature of 5777 K, it follows that for

$$\lambda_1 = 0.4\,\mu\text{m}, \quad \lambda_1 T_{\text{sun}} = 0.4 \times 5777 = 2311\ \mu\text{mK}$$

and for

$$\lambda_2 = 0.7\,\mu\text{m}, \quad \lambda_2 T_{\text{sun}} = 0.7 \times 5777 = 4044\ \mu\text{mK}$$

From Figure 3.3.2, we can estimate $f(\lambda_1 T_{\text{sun}}) \cong 12\%$ and $f(\lambda_2 T_{\text{sun}}) \cong 49\%$. Thus, the visible fraction of sunlight is $49 - 12 \cong 37\%$: With a bandwidth of only 0.3 μm, the human eye responds to approximately 37% of all emitted sunlight!

Radiative Exchange between Opaque Surfaces

Radiative Properties of Surfaces

Strictly speaking, the surface of an enclosure wall can only reflect radiative energy and allow a part of it to penetrate into the substrate. A surface cannot absorb or emit photons: Attenuation takes place inside the solid, as does emission of radiative energy (with some of the emitted energy escaping through the surface into the enclosure). In practical systems, the thickness of the surface layer over which absorption of *irradiation* from inside the enclosure occurs is very small compared with the overall dimension of an enclosure—usually a few nanometers for metals and a few micrometers for most nonmetals. The same may be said about emission from within the walls that escapes into the enclosure. Thus, in the case of opaque walls it is customary to speak of absorption by and emission from a "surface," although a thin surface layer is implied. Four fundamental radiative properties are defined:

$$\text{Reflectance}, \rho \equiv \frac{\text{Reflected part of incoming radiation}}{\text{Total incoming radiation}} \tag{3.3.6a}$$

$$\text{Absorptance}, \rho \equiv \frac{\text{Absorbed part of incoming radiation}}{\text{Total incoming radiation}} \tag{3.3.6b}$$

$$\text{Transmittance}, \tau \equiv \frac{\text{Transmitted part of incoming radiation}}{\text{Total incoming radiation}} \tag{3.3.6c}$$

$$\text{Emittance}, \varepsilon \equiv \frac{\text{Energy emitted from a surface}}{\text{Energy emitted by a black surface at same temperature}} \tag{3.3.6d}$$

Since all incoming radiation must be reflected, absorbed, or transmitted, it follows that

$$\rho + \alpha + \tau = 1 \tag{3.3.7}$$

In most practical applications, surface layers are thick enough to be opaque ($\tau = 0$)leading to $\rho + \alpha = 1$. All four properties may be functions of wavelength, temperature, incoming direction (except emittance), and outgoing direction (except absorptance).

Directional behavior. For heat-transfer applications, the dependence on incoming direction for absorptance (as well as ρ and τ) and outgoing direction for emittance is generally weak and is commonly neglected; that is, it is assumed that the surface absorbs and emits *diffusely.* Then, for an opaque surface, at any given wavelength

$$\varepsilon_\lambda = \alpha_\lambda = 1 - \rho_\lambda \tag{3.3.8}$$

Published values of emittance are generally either "normal emittance" (the directional value of ε_λ in the direction perpendicular to the surface) or "hemispherical emittance" (an average value over all outgoing directions). The difference between these two values is often smaller than experimental accuracy and/or repeatability.

Reflected energy (due to a single, distinct incoming direction) may leave the surface into a single direction ("specular" reflection, similar to reflection from a mirror for visible light), or the reflection may spread out over all possible outgoing directions. In the extreme case of equal amounts going into all directions, we talk about "diffuse" reflection. Smooth surfaces (as compared with the wavelength of radiation) tend to be specular reflectors, while rough surfaces tend to be more or less diffusely reflecting. Analysis is vastly simplified if diffuse reflections are assumed. Research has shown that—except for some extreme geometries and irradiation conditions susceptible to beam channeling (irradiated open cavities, channels with large aspect ratios)—radiative heat-transfer rates are only weakly affected by the directional distribution of reflections. Therefore, it is common practice to carry out radiative heat-transfer calculations assuming only diffuse reflections.

Spectral dependence. The emittance of a surface generally varies strongly and in complex ways with wavelength, depending on the material, surface layer composition, and surface structure (roughness). Therefore, unlike bulk material properties (such as thermal conductivity) the surface emittance may display significant differences between two ostensibly identical samples, and even for one and the same sample measured at different times (due to surface roughness and contamination). Despite these difficulties, surfaces may be loosely grouped into two categories—metals and nonconductors (dielectrics), and some generalizations can be made.

Polished metals. Smooth, purely metallic surfaces (i.e., without any nonmetallic surface contamination, such as metal oxides) tend to have very low emittances in the infrared. For many clean metals $\varepsilon_\lambda < 0.1$ for $\lambda > 2\,\mu\text{m}$, and spectral as well as temperature dependence are generally well approximated by the proportionality $\varepsilon_\lambda \propto \sqrt{T/\lambda}$ in the infrared. However, for shorter wavelengths ($\lambda < 1\,\mu\text{m}$), emittance values may become quite substantial, and temperature dependence is usually reversed (decreasing, rather than increasing, with temperature). Typical room temperature behavior of several metals is shown in Figure 3.3.3. Caution needs to be exercised when choosing an emittance value for a metal surface: Unless extraordinary care is taken to keep a polished metal clean (i.e., free from oxidation and/or surface contamination), its emittance may soon become several times the value of the original, polished specimen (e.g., consider the formation of aluminum oxide on top of aluminum, Figure 3.3.3).

Ceramics and refractories. Smooth ceramics tend to have fairly constant and intermediate emittance over the near-to mid-infrared, followed by a sharp increase somewhere between 4 and 10 μm. At short wavelengths, these materials display strong decreases in emittance, so that a number of them may appear white to the human eye even though they are fairly black in the infrared. The temperature dependence of the emittance of ceramics is rather weak; generally a slight increase with temperature is observed in the infrared. The spectral emittance of a few ceramics is also shown in Figure 3.3.3.

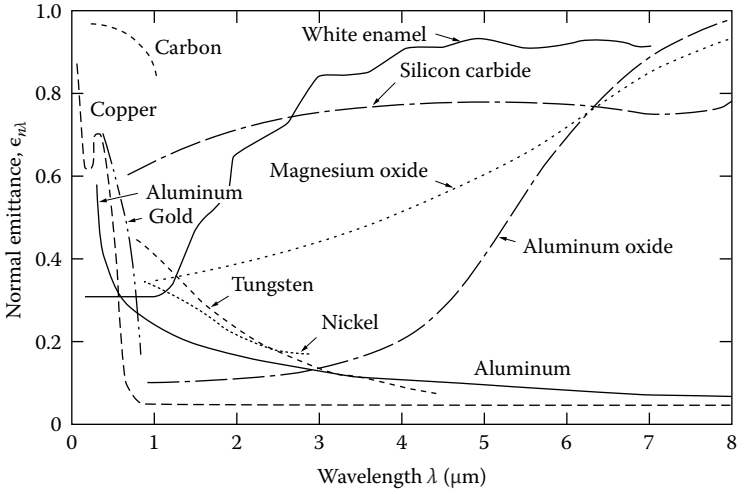

FIGURE 3.3.3 Normal, spectral emittances for selected materials.

Other nonconductors. The behavior of most electrically nonconducting materials is governed by surface structure, nonhomogeneity, dopants, porosity, flaws, surface films, etc. The emittance may vary irregularly across the spectrum because of various emission bands, influence of flaws, etc., making any generalization impossible. This irregularity may be exploited to obtain surfaces of desired spectral behavior, so-called selective surfaces. Some selective surfaces (as compared with a common steel) are depicted in Figure 3.3.4. For a solar collector, it is desirable to have a high spectral emittance for short wavelengths $\lambda < 2.5\mu m$ (strong absorption of solar irradiation), and a low value for $\lambda > 2.5\mu m$ (to minimize reemission from the collector). The opposite is true for a spacecraft radiator panel used to reject heat into space.

It is clear that (1) values of spectral surface emittance are subject to great uncertainty and (2) only a relatively small range of infrared wavelengths are of importance. Therefore, it is often assumed that the surfaces are "gray", that is, the emittance is constant across (the important fraction of) the

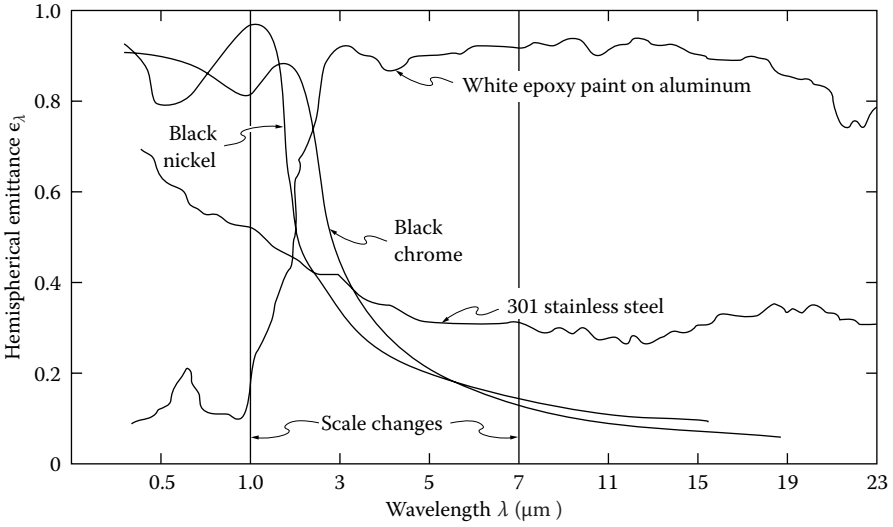

FIGURE 3.3.4 Spectral, hemispherical reflectance of several spectrally selective surfaces.

spectrum, $\varepsilon_\lambda \neq \varepsilon_\lambda(\lambda)$, since this assumption also vastly simplifies analysis. Table 3.3.1 gives a fairly detailed listing of total emittances of various materials, defined as

$$\varepsilon(T) = \frac{1}{E_b(T)} \int_0^\infty \varepsilon_\lambda(\lambda, T) E_{b\lambda}(T)\ d\lambda \tag{3.3.9}$$

which may be enlisted for a gray analysis.

View Factors

In many engineering applications, the exchange of radiative energy between surfaces is virtually unaffected by the medium that separates them. Such (radiatively) *nonparticipating media* include vacuum as well as monatomic and most diatomic gases (including air) at low to moderate temperature levels (i.e., before ionization and dissociation occurs). Examples include spacecraft heat rejection systems, solar collector systems, radiative space heaters, illumination problems, and so on. It is common practice to simplify the analysis by making the assumption of an *idealized enclosure* and/or of *ideal surface properties*. The greatest simplification arises if all surfaces are black: For such a situation no

reflected radiation needs to be accounted for, and all emitted radiation is diffuse (i.e., the radiative energy leaving a surface does not depend on direction). The next level of difficulty arises if surfaces are assumed to be gray, diffuse emitters (and, thus, absorbers) as well as gray, diffuse reflectors. The vast majority of engineering calculations are limited to such ideal surfaces, since, particularly, the effects of nondiffuse reflections are usually weak (see discussion in previous section).

Thermal radiation is generally a long-range phenomenon. This is always the case in the absence of a participating medium, since photons will travel unimpeded from surface to surface. Therefore, performing a thermal radiation analysis for one surface implies that all surfaces, no matter how far removed, that can exchange radiative energy with one another must be considered simultaneously. How much energy any two surfaces exchange depends in part on their size, separation, distance, and orientation, leading to geometric functions known as *view factors*, defined as

$$F_{i-j} = \frac{\text{Diffuse energy leaving } A_i \text{ directly toward and intercepted by } A_j}{\text{Total diffuse energy leaving } A_i} \tag{3.3.10}$$

In order to make a radiative energy balance, we always need to consider an entire *enclosure* rather than an infinitesimal control volume (as is normally done for other modes of heat transfer, i.e., conduction or convection). The enclosure must be closed so that irradiation from all possible directions can be accounted for, and the enclosure surfaces must be *opaque* so that all irradiation is accounted for, for each direction. In practice, an incomplete enclosure may be closed by introducing artificial surfaces. An enclosure may be idealized in two ways, as indicated in Figure 3.3.5: by replacing a complex geometric shape with a few simple surfaces, and by assuming surfaces to be isothermal with constant (i.e., average) heat flux values across them. Obviously, the idealized enclosure approaches the real enclosure for sufficiently small isothermal subsurfaces.

Mathematically, the view factor needs to be determined from a double surface integral, that is,

$$F_{i-j} = \frac{1}{A_i} \int_{A_i} \int_{A_j} \frac{\cos\theta_i \cos\theta_j}{\pi S_{ij}^2} \, dA_j \, dA_i \tag{3.3.11}$$

where θ_i and θ_j are the angles between the surface normals on A_i and A_j, respectively, and the line (of length S_{ij}) connecting two points on the two surfaces. Analytical solutions to Equation 3.3.11 may be found for relatively simple geometries. A few graphical results for important geometries are shown in Figures 3.3.6 through 3.3.8. More extensive tabulations as well as analytical expressions may be found in textbooks on the subject area (Modest, 2013; Howell et al., 2015) as well as view factor catalogs (Howell, 1982). For nontrivial geometries view factors must be calculated numerically, either (1) by numerical quadrature of the double surface integral in Equation 3.3.11, or (2) by converting Equation 3.3.11 into a double-line integral, followed by numerical quadrature, or (3) by a Monte Carlo method (statistical sampling and tracing of selected light rays).

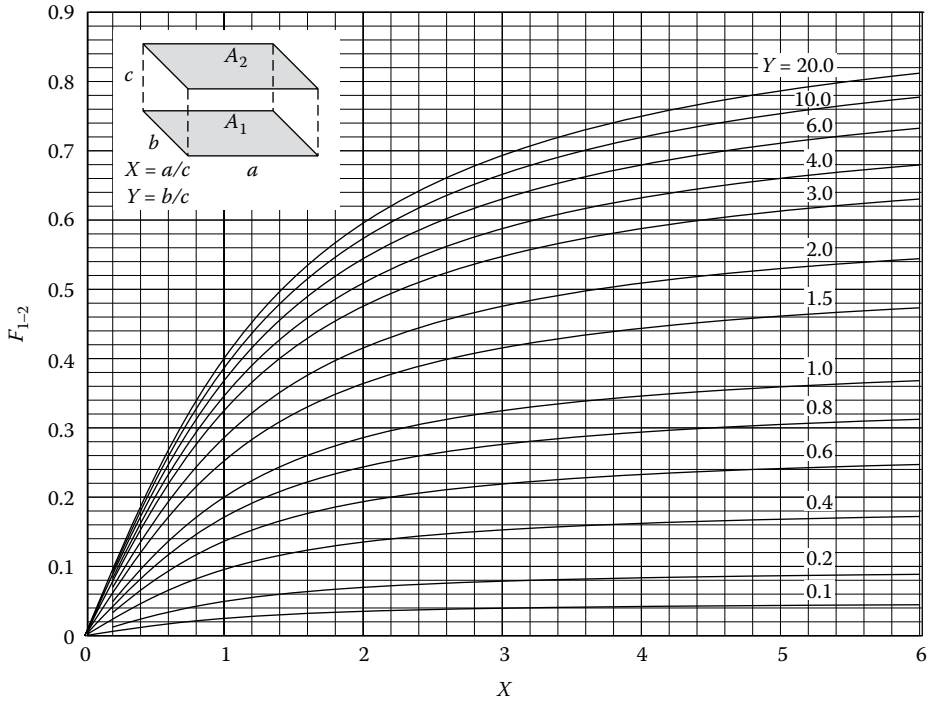

FIGURE 3.3.7 View factor between identical, parallel, directly opposed rectangles.

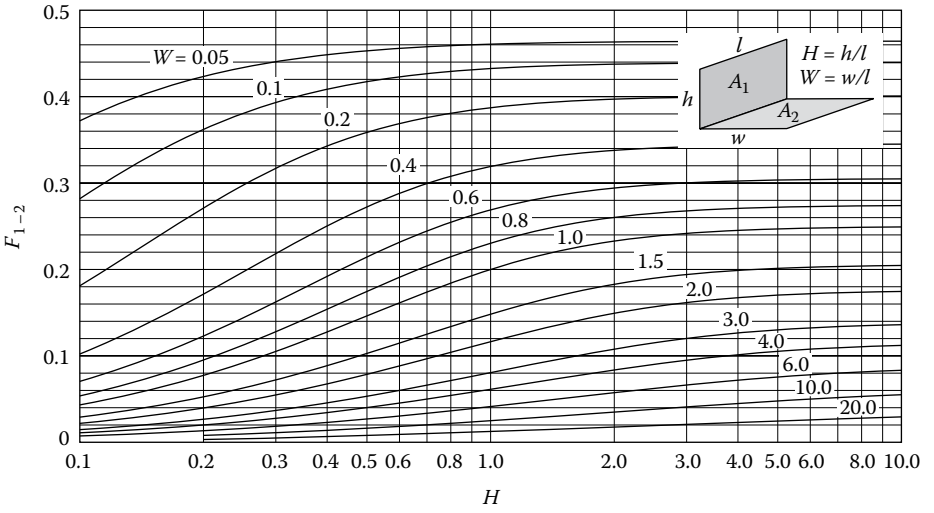

FIGURE 3.3.8 View factor between perpendicular rectangles with common edge.

View Factor Algebra

For simple geometries, analytical values can often be found by expressing the desired view factor in terms of other, known ones. This method is known as view factor algebra, by manipulating the two relations,

$$\text{Reciprocity rule}: A_i F_{i-j} = A_j F_{j-i} \tag{3.3.12}$$

$$\text{Summation rule}: \sum_{j=1}^{N} F_{i-j} = 1, \quad i = 1, N \tag{3.3.13}$$

assuming that the (closed) configuration consists of N surfaces. The reciprocity rule follows immediately from Equation 3.3.11, while the summation rule simply states that the fractional energies leaving surface A_i must add up to a whole.

Example 3.3.2

Assuming the view factor for a finite corner (as shown in Figure 3.3.8) is known, determine the view factor F_{3-4}, between the two perpendicular strips as shown in Figure 3.3.9.

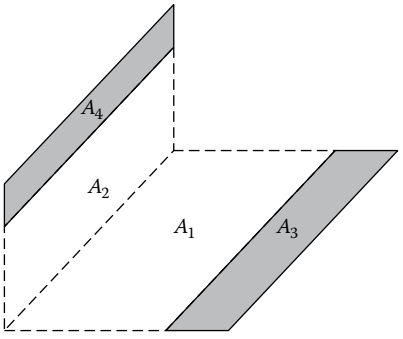

FIGURE 3.3.9 Configuration for Example 3.3.2 (strips on a corner piece).

Solution. From the definition of the view factor, and since the energy traveling to A_4 is the energy going to A_2 and A_4 minus the one going to A_2, it follows that

$$F_{3-4} = F_{3-(2+4)} - F_{3-2}$$

and, using reciprocity,

$$F_{3-4} = \frac{1}{A_3}\left[\left(A_2 + A_4\right)F_{(2+4)-3} - A_2F_{2-3}\right]$$

Similarly, we find

$$F_{3-4} = \frac{A_2 + A_4}{A_3}\left(F_{(2+4)-(1+3)} - F_{(2+4)-1}\right) - \frac{A_2}{A_3}\left(F_{2-(1+3)} - F_{2-1}\right)$$

All view factors on the right-hand side are corner pieces and, thus, are known from Figure 3.3.8.

Crossed-Strings Method: A special type of view factor algebra may be used to determine all the view factors in long enclosures with constant cross section. The method is called the crossed-strings method since the view factors can be determined experimentally with four pins, a roll of string, and a yardstick. Consider the configuration in Figure 3.3.10, which shows the cross section of an infinitely long enclosure, continuing into and out of the plane of the figure. Repeatedly applying reciprocity and summation rules allows the evaluation of F_{1-2} as

$$F_{1-2} = \frac{\left(A_{bc} + A_{ad}\right) - \left(A_{ac} + A_{bd}\right)}{2A_1} \tag{3.3.14}$$

where A_{ab} is the area (per unit depth) defined by the length of the string between points a and b, etc. This formula is easily memorized by looking at the configuration between any two surfaces as a generalized "rectangle," consisting of A_1, A_2, and the two sides A_{ac} and A_{bd}. Then

$$F_{1-2} = \frac{\text{diagonals} - \text{sides}}{2 \times \text{originating area}} \tag{3.3.15}$$

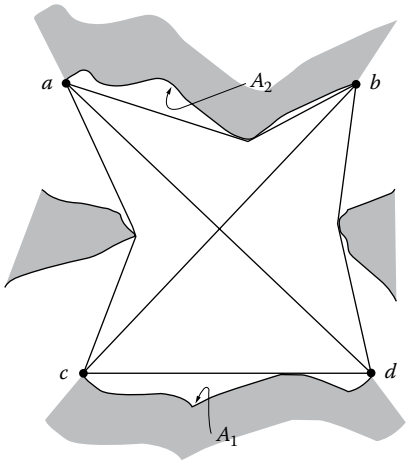

FIGURE 3.3.10 The crossed-strings method for arbitrary two-dimensional configurations.

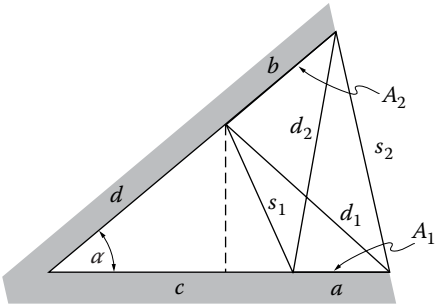

FIGURE 3.3.11 Infinitely long wedge-shaped groove for Example 3.3.3.

Example 3.3.3

Calculate F_{1-2} for the configuration shown in Figure 3.3.11.

Solution. From the figure, it is obvious that

$$s_1^2 = (c - d\cos\alpha)^2 + d^2\sin^2\alpha = c^2 + d^2 - 2cd\cos\alpha$$

Similarly, we have

$$s_2^2 = (a+c)^2 + (b+d)^2 - 2(a+c)(b+d)\cos\alpha$$

$$d_1^2 = (a+c)^2 + d^2 - 2(a+c)d\cos\alpha$$

and

$$d_2^2 = c^2 + (b+d)^2 - 2c(b+d)\cos\alpha$$

$$F_{1-2} = \frac{d_1 + d_2 - (s_1 + s_2)}{2a}$$

Radiative Exchange between Opaque Surfaces (Net Radiation Method)

Consider an enclosure consisting of N opaque surfaces. The enclosure is closed, or, if not, no surface external to the surface reflects or emits radiation into the enclosure (i.e., the open configuration may be artificially closed by replacing openings with cold, black surfaces); any external radiation entering the enclosure is dealt with individually for each surface [see Equation 3.3.17]. All surfaces are assumed to be gray, and emit and reflect diffusely. Traditionally, the *radiosity* J of the surfaces is determined, defined as the total diffuse radiative energy leaving a surface (by emission and reflection),

$$J_i = \varepsilon_i E_{bi} + \rho_i H_i, \quad i = 1, N \tag{3.3.16}$$

where H_i is the incoming radiative flux per unit area (irradiation) onto surface A_i. This leads to N simultaneous equations for the unknown radiosities, specifically,

$$J_i = \varepsilon_i E_{bi} + (1-\varepsilon_i)\left[\sum_{j=1}^{N} J_j F_{i-j} + H_{oi}\right] \tag{3.3.17a}$$

or

$$J_i = q_i + \sum_{j=1}^{N} J_j F_{i-j} + H_{oi} \tag{3.3.17b}$$

depending on whether surface temperature or surface flux are known on surface A_i. In Equation 3.3.17, H_{oi} is irradiation onto surface A_i from outside the enclosure, if any; H_{oi} is always zero for closed configurations, but is useful in the presence of external light sources (such as solar energy, lasers, etc.). The radiosity neither is a useful quantity to determine, nor is there a need to determine it. Eliminating the radiosities from Equations 3.3.17a and 3.3.17b leads to N simultaneous equations in temperature (E_{bi}) and heat flux (q_i):

$$\frac{q_i}{\varepsilon_i} - \sum_{j=1}^{N} \left(\frac{1}{\varepsilon_j} - 1 \right) F_{i-j} q_j + H_{oi} = E_{bi} - \sum_{j=1}^{N} F_{i-j} E_{bj} \tag{3.3.18}$$

Note that no artificial closing surfaces ($j > N$) appear in Equation 3.3.18, since for these surfaces $\varepsilon_j = 1$ and $E_{bj} = 0$. Thus, such closing surfaces may simply be ignored in the analysis.

Since Equation 3.3.18 is a set of N equations, this requires that N values of emissive power E_{bi} and/or flux q_i must be given as boundary conditions, in order to solve for the remaining N unknowns. For computer calculations, Equation 3.3.18 may be recast in matrix form

$$\mathbf{C} \cdot \mathbf{q} = \mathbf{A} \cdot \mathbf{e_b} - \mathbf{h_o} \tag{†(3.3.19a)}$$

where

$$C_{ij} = \frac{\delta_{ij}}{\varepsilon_j} - \left(\frac{1}{\varepsilon_j} - 1 \right) F_{i-j} \tag{3.3.19b}$$

$$A_{ij} = \delta_{ij} - F_{i-j} \tag{3.3.19c}$$

δ_{ij} is Kronecker's delta, that is,

$$\delta_{ij} = \begin{cases} 1 \text{ if } i = j \\ 0 \text{ if } i \neq j \end{cases} \tag{3.3.20}$$

and $\mathbf{q}$, $\mathbf{e_b}$, and $\mathbf{h_o}$ are vectors of the surface heat fluxes q_i, emissive powers E_{bi}, and external irradiations H_{oi} (if any). For example, if the temperatures are given for all the surfaces, and the heat fluxes are to be determined, Equation (3.3.19) is solved by matrix inversion, and

$$\mathbf{q} = \left(\mathbf{C^{-1}} \cdot \mathbf{A} \right) \cdot \mathbf{e_b} - \left(\mathbf{C^{-1}} \cdot \mathbf{h_o} \right) \tag{3.3.21}$$

Example 3.3.4

A right-angled groove, consisting of two long black surfaces of width a, is exposed to solar radiation q_{sol} (Figure 3.3.12). The entire groove surface is kept isothermal at temperature T. Determine the net radiative heat-transfer rate from the groove.

Solution. We may employ Equation 3.3.19. However, the enclosure is not closed, and we must close it artificially. We note that any radiation leaving the cavity will not come back (barring any reflection from other surfaces nearby). Thus, our artificial surface should be black. We also assume that, with the exception of the (parallel) solar irradiation, no external radiation enters the cavity.

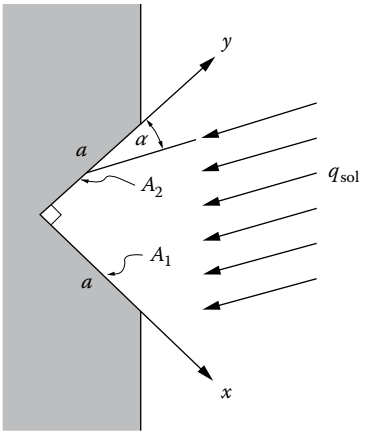

FIGURE 3.3.12 Right-angled groove exposed to solar irradiation, Example 3.3.4.

Since the solar irradiation is best treated separately through the external irradiation term H_o, our artificial surface is nonemitting. Both criteria are satisfied by covering the groove with a black surface at 0 K (A_3). Even though we now have three surfaces, the last one does not really appear in Equation 3.3.18 (since $E_{b3} = 0$ and $1/\varepsilon_3 - 1 = 0$):

$$q_1 = E_{b1} - F_{1-2}E_{b2} - H_{o1} = \sigma T^4(1 - F_{1-2}) - q_{sol}\cos\alpha$$

$$q_2 = E_{b2} - F_{2-1}E_{b1} - H_{o2} = \sigma T^4(1 - F_{2-1}) - q_{sol}\sin\alpha$$

From the crossed-strings method, Equation 3.3.15, we find

$$F_{1-2} = \frac{a + a - \left(\sqrt{2}a + 0\right)}{2a} = \frac{1}{2}\left(2 - \sqrt{2}\right) = 0.293 = F_{2-1}$$

and

$$Q' = a(q_1 + q_2) = a\left[\sqrt{2}\sigma T^4 - q_{sol}(\cos\alpha + \sin\alpha)\right]$$

Example 3.3.5

Consider a very long duct as shown in Figure 3.3.13. The duct is 30×40 cm in cross section, and all surfaces are covered with a gray, diffuse surface material. Top and bottom walls are at

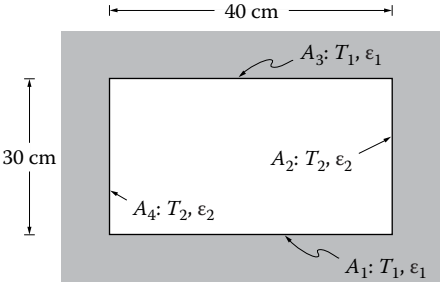

FIGURE 3.3.13 Two-dimensional gray, diffuse duct for Example 3.3.5.

$T_1 = T_3 = 1000$ K with $\varepsilon_1 = \varepsilon_3 = 0.3$, while the side walls are at $T_2 = T_4 = 600$ K with $\varepsilon_2 = \varepsilon_4 = 0.8$ as shown. Determine the net radiative heat-transfer rates for each surface.

Solution. Using Equation 3.3.18 for $i = 1$ and $i = 2$ and noting that $F_{1-2} = F_{1-4}$ and $F_{2-1} = F_{2-3}$, as well as $q_1 = q_3$ and $q_2 = q_4$,

$$i = 1: \quad \frac{q_1}{\varepsilon_1} - 2\left(\frac{1}{\varepsilon_2} - 1\right)F_{1-2}q_2 - \left(\frac{1}{\varepsilon_1} - 1\right)F_{1-3}q_1 = 2F_{1-2}(E_{b1} - E_{b2})$$

$$i = 2: \quad \frac{q_2}{\varepsilon_2} - 2\left(\frac{1}{\varepsilon_1} - 1\right)F_{2-1}q_1 - \left(\frac{1}{\varepsilon_2} - 1\right)F_{2-4}q_2 = 2F_{2-1}(E_{b2} - E_{b1})$$

The view factors are readily evaluated from the crossed-strings method as $F_{1-2} = \frac{1}{4}$, $F_{1-3} = 1 - 2F_{1-2} = \frac{1}{2}$, $F_{2-1} = \frac{4}{3}F_{1-2} = \frac{1}{3}$, and $F_{2-4} = 1 - 2F_{2-1} = \frac{1}{3}$. Substituting these, as well as emittance values, into the relations reduces them to the simpler form of

$$\left[\frac{1}{0.3} - \left(\frac{1}{0.3} - 1\right)\frac{1}{2}\right]q_1 - 2\left(\frac{1}{0.8} - 1\right)\frac{1}{4}q_2 = 2 \times \frac{1}{4}(E_{b1} - E_{b2})$$

$$-2\left(\frac{1}{0.3} - 1\right)\frac{1}{3}q_1 + \left[\frac{1}{0.8} - \left(\frac{1}{0.8} - 1\right)\frac{1}{3}\right]q_2 = 2 \times \frac{1}{3}(E_{b2} - E_{b1})$$

or

$$\frac{13}{6}q_1 - \frac{1}{8}q_2 = \frac{1}{2}(E_{b1} - E_{b2})$$

$$-\frac{14}{9}q_1 + \frac{7}{6}q_2 = -\frac{2}{3}(E_{b1} - E_{b2})$$

Thus,

$$\left(\frac{13}{6} \times \frac{7}{6} - \frac{14}{9} \times \frac{1}{8}\right)q_1 = \left(\frac{1}{2} \times \frac{7}{6} - \frac{2}{3} \times \frac{1}{8}\right)(E_{b1} - E_{b2})$$

$$q_1 = \frac{3}{7} \times \frac{1}{2}(E_{b1} - E_{b2}) = \frac{3}{14}\sigma(T_1^4 - T_2^4)$$

and

$$\left(-\frac{1}{8} \times \frac{14}{9} + \frac{7}{6} \times \frac{13}{6}\right)q_2 = \left(\frac{1}{2} \times \frac{14}{9} - \frac{2}{3} \times \frac{13}{6}\right)(E_{b1} - E_{b2})$$

$$q_2 = -\frac{3}{7} \times \frac{2}{3}(E_{b1} - E_{b2}) = -\frac{2}{7}\sigma(T_1^4 - T_2^4)$$

Finally, substituting values for temperatures,

$$Q_1' = 0.4\,\text{m} \times \frac{3}{14} \times 5.670 \times 10^{-8}\ \text{W/m}^2\text{K}^4(1000^4 - 600^4)\text{K}^4 = 4230\ \text{W/m}$$

$$Q_2' = -0.3\,\text{m} \times \frac{2}{7} \times 5.670 \times 10^{-8}\ \text{W / m}^2\text{K}^4(1000^4 - 600^4)\text{K}^4 = -4230\ \text{W/m}$$

Note that, for conservation of energy, both heat-transfer rates must add up to zero.

Small body inside isothermal enclosure. An especially simple—but important—case occurs if a small, convex body A_1 (i.e., a surface that cannot "see" itself, or $F_{1-1} = 0$) is totally enclosed by an isothermal enclosure A_2. Then, with $N = 2$ and $F_{1-2} = 1$, Equation 3.3.18 reduces to

$$q_1 = \frac{E_{b1} - E_{b2}}{\dfrac{1}{\varepsilon_1} + \dfrac{A_1}{A_2}\left(\dfrac{1}{\varepsilon_2} - 1\right)} = \frac{\sigma(T_1^4 - T_2^4)}{\dfrac{1}{\varepsilon_1} + \dfrac{A_1}{A_2}\left(\dfrac{1}{\varepsilon_2} - 1\right)} \tag{3.3.22}$$

If the enclosure is large, that is, $A_1 \ll A_2$, then Equation 3.3.22 simplifies further to

$$q_1 = \varepsilon_1 \sigma(T_1^4 - T_2^4) \tag{3.3.23}$$

Radiation shields. If it is desired to minimize radiative heat transfer between two surfaces, it is common practice to place one or more radiation shields between them (usually thin metallic sheets of low emittance). If two surfaces A_i and A_j are close together, so that $A_i \cong A_j$ and $F_{i-j} \cong 1$, then the radiative exchange between them is, from Equation 3.3.22,

$$q = \frac{E_{bi} - E_{bj}}{R_{ij}}, \quad R_{ij} = \frac{1}{\varepsilon_i} + \frac{1}{\varepsilon_j} - 1 \tag{3.3.24}$$

where R_{ij} is termed the *radiative resistance*. Equation 3.3.24 is seen to be analogous to an electrical circuit with "current" q and "voltage potential" $E_{bi} - E_{bj}$. Therefore, expressing radiative fluxes in terms of radiative resistances is commonly known as *network analogy*. The network analogy is a very powerful method of solving one-dimensional problems (i.e., whenever only two isothermal surfaces see each other, such as infinite parallel plates, or when one surface totally encloses another). Consider, for example, two large parallel plates, A_1 and A_N, separated by $N - 2$ radiation shields, as shown in Figure 3.3.14. Let each shield have an emittance ε_S on both sides. Then, by applying Equation 3.3.24 to any two consecutive surfaces and using the fact that q remains constant throughout the gap,

$$q = \frac{E_{b1} - E_{b2}}{R_{12}} = \cdots = \frac{E_{bk-1} - E_{bk}}{R_{k-1,k}} = \cdots = \frac{E_{bN-1} - E_{bN}}{R_{N-1,N}} = \frac{E_{b1} - E_{bN}}{\displaystyle\sum_{j-2}^{N} R_{j-1,j}} \tag{3.3.25}$$

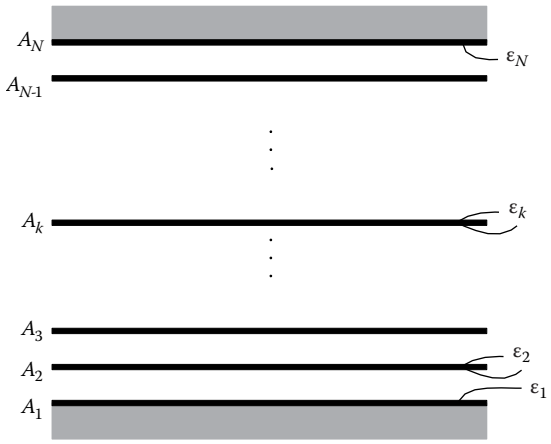

FIGURE 3.3.14 Placement of radiation shields between two large, parallel plates.

where

$$R_{j-1,j} = \frac{1}{\varepsilon_{j-1}} + \frac{1}{\varepsilon_j} - 1 \tag{3.3.26}$$

and, if $= \varepsilon_2 = \varepsilon_3 = \cdots = \varepsilon_{N-1} = \varepsilon_S$,

$$\sum_{j=2}^{N} R_{j-1,j} = \frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_N} - 1 + (N-2)\left(\frac{2}{\varepsilon_S} - 1\right) \tag{3.3.27}$$

Equations 3.3.24 through 3.3.27 are also valid for concentric cylinders, concentric spheres, and similar configurations, as long as $r_N - r_1 \ll r_1$. Also, the relations are readily extended to shields with nonidentical emittance.

While the network analogy can (and has been) applied to configurations with more than two surfaces seeing each other, this leads to very complicated circuits (since there is one resistance between any two surfaces). For such problems, the network analogy is not recommended, and the net radiation method, Equation 3.3.18, should be employed.

Radiative Exchange within Participating Media

In many high-temperature applications, when radiative heat transfer is important, the medium between surfaces is not transparent, but is "participating, " that is, it absorbs, emits, and (possibly) scatters radiation. In a typical combustion process this interaction results in (1) continuum radiation due to tiny, burning soot particles (of dimension $< 1\,\mu\text{m}$) and also due to larger suspended particles, such as coal particles, oil droplets, fly ash; (2) banded radiation in the infrared due to emission and absorption by molecular gaseous combustion products, mostly water vapor and carbon dioxide; and (3) chemiluminescence due to the combustion reaction itself. While chemiluminescence may normally be neglected, particulates as well as gas radiation generally must be accounted for.

Radiative Properties of Molecular Gases

When a photon (or an electromagnetic wave) interacts with a gas molecule, it may be absorbed, raising the energy level of the molecule. Conversely, a gas molecule may spontaneously lower its energy level by the emission of an appropriate photon. This leads to large numbers of narrow spectral lines, which partially overlap and together form so-called vibration–rotation bands. As such, gases tend to be transparent over most of the spectrum, but may be almost opaque over the spectral range of a band. The *absorption coefficient* κ_λ is defined as a measure of how strongly radiation is absorbed or emitted along a path of length, L, leading to the spectral absorptivity and emissivity for this path, or

$$\alpha_\lambda = \varepsilon_\lambda = 1 - e^{-\kappa_\lambda L} \tag{3.3.28}$$

This exponential decay of incident radiation is often called *Beer's law*. Although gases are distinctly nongray, for simple heat-transfer calculations it is often sufficient to determine the total emissivity for an isothermal path [compare Equation 3.3.9]

$$\varepsilon = \frac{1}{E_b} \int_0^\infty (1 - e^{-\kappa_\lambda L}) E_{b\lambda}(T_g)\, d\lambda \tag{3.3.29}$$

For a mixture of gases the total emissivity is a function of path length L, gas temperature T_g, partial pressure (s) of the absorbing gas(es) p_a, and total pressure p. For the—in combustion applications

most important—mixture of nitrogen with water vapor and/or carbon dioxide, the total emissivity may be calculated from Leckner (1972). First, the individual emissivities for water vapor and carbon dioxide, respectively, are calculated separately from

$$\varepsilon(p_a L, p, T_g) = \varepsilon_0(p_a L, T_g)\left(\frac{\varepsilon}{\varepsilon_0}\right)(p_a L, p, T_g) \tag{3.3.30a}$$

$$\left(\frac{\varepsilon}{\varepsilon_0}\right)(p_a L, p, T_g) = \left[1 - \frac{(a-1)(1-P_E)}{a+b-1+P_E}\exp\left(-c\left[\log_{10}\frac{(p_a L)_m}{p_a L}\right]^2\right)\right] \tag{3.3.30b}$$

$$\varepsilon_0(p_a L, T_g) = \exp\left[\sum_{i=0}^{N}\sum_{j=0}^{N} c_{ji}\left(\frac{T_g}{T_0}\right)^j\left(\log_{10}\frac{p_a L}{(p_a L)_0}\right)^i\right] \tag{3.3.30c}$$

Here ε_0 is the total emissivity of a reference state, that is, for the case of $p = 1$ bar and $p_a \to 0$ (but $p_a L > 0$), and the correlation constants a, b, c, c_{ji}, P_E, $(p_a L)_0$, $(p_a L)_m$, and $(p_a L)_m$ are given in Table 3.3.2 for water vapor and carbon dioxide. (For convenience, plots of ε_0 are given in Figures 3.3.15 for CO_2 and 3.3.16 for H_2O.) The total emissivity of a mixture of nitrogen with both water vapor and carbon dioxide is calculated from

$$\varepsilon_{CO_2+H_2O} = \varepsilon_{CO_2} + \varepsilon_{H_2O} - \Delta\varepsilon \tag{3.3.31}$$

$$\Delta\varepsilon = \left(\frac{\zeta}{10.7+101\zeta} - 0.0089\zeta^{10.4}\right)\left(\log_{10}\frac{(p_{H_2O}+p_{CO_2})L}{(p_a L)_0}\right)^{2.76} \tag{3.3.32a}$$

TABLE 3.3.2
Correlation Constants for the Determination of the Total Emissivity for Water Vapor and Carbon Dioxide

c	0.5			1.47			

Note: $T_0 = 1000\,\text{K}, p_0 = 1\,\text{bar}, t = T/T_0, (p_a L)_0 = 1\,\text{bar cm}.$

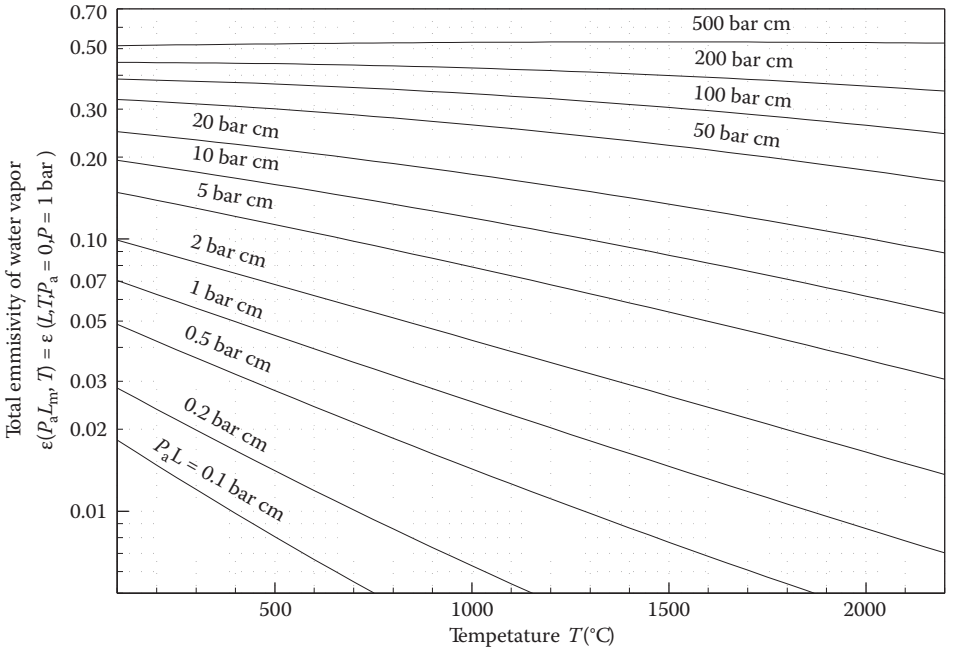

FIGURE 3.3.15 Total emissivity of water vapor at reference state (total gas pressure $p = 1$ bar, partial pressure of H_2O $p_a \to 0$).

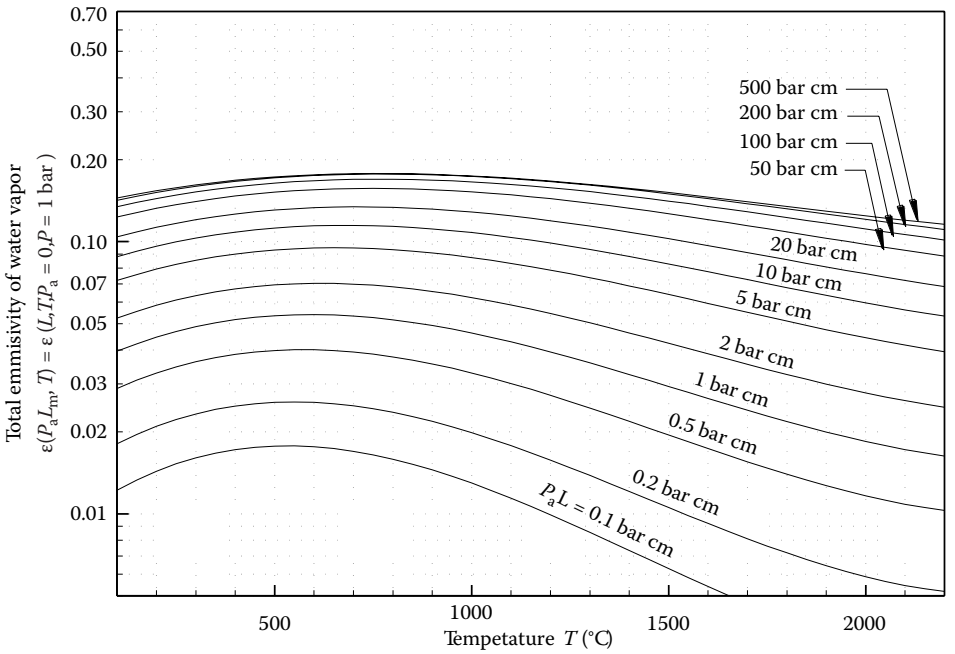

FIGURE 3.3.16 Total emissivity of carbon dioxide at reference state (total gas pressure $p = 1$ bar, partial pressure of CO_2 $p_a \to 0$).

$$\zeta = \frac{p_{H_2O}}{p_{H_2O} + p_{CO_2}} \tag{3.3.32b}$$

where the $\Delta\varepsilon$ compensates for overlap effects between H_2O and CO_2 bands, and the ε_{CO_2} and ε_{H_2O} are calculated from Equation 3.3.30.

If radiation emitted externally to the gas (e.g., by emission from an adjacent wall at temperature T_s) travels through the gas, the total amount absorbed by the gas is of interest. This leads to the absorptivity of a gas path at T_g with a source at T_s:

$$\alpha(p_a L, p, T_g, T_s) = \frac{1}{E_b(T_s)} \int_0^\infty \left(1 - e^{-\kappa_\lambda(T_g)L}\right) E_{b\lambda}(T_s)\, d\lambda \tag{3.3.33}$$

which for water vapor or carbon dioxide may be estimated from

$$\alpha(p_a L, p, T_g, T_s) = \left(\frac{T_g}{T_s}\right)^{1/2} \varepsilon\left(p_a L \frac{T_s}{T_g}, p, T_s\right) \tag{3.3.34}$$

where ε is the emissivity calculated from Equation 3.3.30 evaluated at the temperature of the surface T_s, and using an adjusted pressure path length, $p_a L T_s / T_g$. For mixtures of water vapor and carbon dioxide, band overlap is again accounted for by taking

$$\alpha_{CO_2+H_2O} = \alpha_{CO_2} + \alpha_{H_2O} - \Delta\varepsilon \tag{3.3.35}$$

with $\Delta\varepsilon$ evaluated for a pressure path length of $p_a L T_s / T_g$.

Example 3.3.6

Consider a layer of a gas mixture at 1000 K and 5 bar that consists of 10% carbon dioxide and 70% nitrogen. What is its emissivity for a path length of 1.76 m, and its absorptivity (for the same path) if the layer is irradiated by a source at 1500 K?

Solution. First, we calculate the total emissivity of the CO_2 at the reference state ($p = 1$ bar, $p_a \to 0$) for a length of 1.76 m from Equation 3.3.30c or Figure 3.3.15. With

$$T_g = 1000\,\text{K} = 727^\circ\text{C} \text{ and } p_a L = 0.1 \times 5\,\text{bar} \times 1.76\,\text{m} = 88\,\text{bar cm}$$

one gets, interpolating Figure 3.3.15, $\varepsilon_0 \cong 0.15$. The correction factor in Equation 3.3.30b is calculated from Table 3.3.2 with $P_E = 5 + 0.28 \times 0.5 = 5.14$, $a = 1.1$, $b = 0.23$, $c = 1.47$, and $(p_a L)_m = 0.225$ bar cm. Thus,

$$\frac{\varepsilon}{\varepsilon_0} = 1 - \frac{0.1 \times (-4.14)}{0.33 + 5.14} \exp\left(-1.47\left(\log_{10}\frac{0.225}{88}\right)^2\right) \cong 1$$

and

$$\varepsilon \cong 0.15$$

To calculate the absorptivity ε_0 must be found for a temperature of

$$T_s = 1500\,\text{K} = 1227^\circ\text{C} \text{ and } p_a L \frac{T_s}{T_g} = 88 \times 1500 / 1000 = 132\,\text{bar cm}$$

From Figure 3.3.15, it follows that $\varepsilon_0 \cong 0.15$ again and, with $\varepsilon / \varepsilon_0$ pretty much unchanged, from Equation 3.3.34,

$$\alpha \cong \left(\frac{1000}{1500}\right)^{1/2} \times 0.15 \times 1.00 = 0.122$$

Radiative Properties of Particle Clouds

Nearly all flames are visible to the human eye and are, therefore, called *luminous* (sending out light). Apparently, there is some radiative emission from within the flame at wavelengths where there are no vibration–rotation bands for any combustion gases. This luminous emission is known today to come from tiny char (almost pure carbon) particles, called soot, which are generated during the combustion process. The "dirtier" the flame is (i.e., the higher the soot content), the more luminous it is.

Radiative properties of soot. Soot particles are produced in fuel-rich flames, or fuel-rich parts of flames, as a result of incomplete combustion of hydrocarbon fuels. As shown by electron microscopy, soot particles are generally small and spherical, ranging in size between approximately 50 and 800 Å (0.005 – 0.08 μm), and up to about 3000 Å in extreme cases. While mostly spherical in shape, soot particles may also appear in agglomerated chunks and even as long agglomerated filaments. It has been determined experimentally in typical diffusion flames of hydrocarbon fuels that the volume percentage of soot generally lies in the range between $10^{-4}\%$ to $10^{-6}\%$

Since soot particles are very small, they are generally at the same temperature as the flame and strongly emit thermal radiation in a continuous spectrum over the infrared region. Experiments have shown that soot emission often is considerably stronger than the emission from the combustion gases.

For a simplified heat-transfer analysis, it is desirable to use suitably defined mean absorption coefficients and emissivities. If the soot volume fraction, f_v, is known as well as an appropriate spectral average of the complex index of refraction of the soot, $m = n - ik$, one may approximate the spectral absorption coefficient by (Felske and Tien, 1977) using

$$\kappa_\lambda = C_0 \frac{f_v}{\lambda} \quad C_0 = \frac{36\pi nk}{\left(n^2 - k^2 + 2\right)^2 + 4n^2k^2} = 6\pi E(m) \tag{3.3.36}$$

where the "refractive index function" $E(m)$ is commonly used in the soot literature. A total, or spectral average absorption coefficient may be taken as

$$\kappa_m = 3.72 f_v C_0 T / C_2 \tag{3.3.37}$$

where $C_2 = 1.4388$ mK is the second Planck function constant. Substituting Equation 3.3.37 into Equation 3.3.29 gives a total soot cloud emissivity of

$$\varepsilon(f_v TL) = 1 - e^{-\kappa_m L} = 1 - e^{-3.72 C_0 f_v TL / C_2} \tag{3.3.38}$$

Pulverized coal and fly ash dispersions. To calculate the radiative properties of arbitrary size distributions of coal and ash particles, one must have knowledge of their complex index of refraction as a function of wavelength and temperature. Data for carbon and different types of coal indicate that its real part, n, varies little over the infrared and is relatively insensitive to the type of coal (e.g., anthracite, lignite, bituminous), while the absorptive index, k, may vary strongly over the spectrum and from coal to coal. If the number and sizes of particles are known and if a suitable average value for the complex index of refraction can be found, then the spectral absorption coefficient of the

dispersion may be estimated by a correlation given by Buckius and Hwang (1980). Substitution into Equation 3.3.29 can then provide an estimate of the total emissivity. If both soot as well as larger particles are present in the dispersion, the absorption coefficients of all constituents must be added before applying Equation 3.3.29.

Mixtures of molecular gases and particulates. To determine the total emissivity of a mixture, it is generally necessary to find the spectral absorption coefficient κ_λ of the mixture (i.e., the sum of the absorption coefficient of all contributors), followed by numerical integration of Equation 3.3.29. However, since the molecular gases tend to absorb only over a small part of the spectrum, to some degree of accuracy

$$\varepsilon_{\text{mix}} \cong \varepsilon_{\text{gas}} + \varepsilon_{\text{particulates}} \tag{3.3.39}$$

Equation 3.3.39 gives an upper estimate since overlap effects result in lower emissivity [compare Equation 3.3.31 for gas mixtures].

Heat Exchange in the Presence of a Participating Medium

The calculation of radiative heat-transfer rates through an enclosure filled with a participating medium is a challenging task, to say the least. High-accuracy calculations are rare and a topic of ongoing research. There are, however, several simplistic models available that allow the estimation of radiative heat-transfer rates, and relatively accurate calculations for some simple cases.

Diffusion approximation. A medium through which a photon can only travel a short distance without being absorbed is known as *optically thick*. Mathematically, this implies that $\kappa_\lambda L \gg 1$ for a characteristic dimension L, across which the temperature does not vary substantially. For such an optically thick, nonscattering medium the spectral radiative flux may be calculated from

$$\mathbf{q} = -\frac{4}{3\kappa_\lambda} \nabla E_{\text{b}\lambda} \tag{3.3.40}$$

similar to Fourier's diffusion law for heat conduction. Note that a medium may be optically thick at some wavelengths, but thin ($\kappa_\lambda L \ll 1$) at others (e.g., molecular gases!). For a medium that is optically thick for all wavelengths, Equation 3.3.40 may be integrated over the spectrum, yielding the total radiative flux

$$\mathbf{q} = -\frac{4}{3\kappa_{\text{R}}} \nabla E_{\text{b}} = -\frac{4}{3\kappa_{\text{R}}} \nabla(\sigma T^4) = -\frac{16\sigma T^3}{3\kappa_{\text{R}}} \nabla T \tag{3.3.41}$$

where κ_{R} is the suitably averaged absorption coefficient, termed the *Rosseland-mean absorption coefficient*. For a cloud of soot particles, $\kappa_{\text{R}} \cong \kappa_m$ from Equation 3.3.37 is a reasonable approximation. Equation 3.3.41 may be rewritten by defining a "radiative conductivity" k_{R},

$$\mathbf{q} = -k_{\text{R}} \nabla T \qquad k_{\text{R}} = \frac{16\sigma T^3}{3\kappa_{\text{R}}} \tag{3.3.42}$$

This form shows that the diffusion approximation is mathematically equivalent to conductive heat transfer with a (strongly) temperature-dependent conductivity.

Note: More accurate calculations show that, in the absence of other modes of heat transfer (conduction, convection), there is generally a temperature discontinuity near the boundaries ($T_{\text{surface}} \neq T_{\text{adjacentmedium}}$), and, unless boundary conditions that allow such temperature discontinuities are chosen, the diffusion approximation will do very poorly in the vicinity of bounding surfaces.

Example 3.3.7

A soot cloud is contained between two walls at $T_1 = 1000$ K and $T_2 = 2000$ K, spaced 1 m apart. The effective absorption coefficient of the medium is $\kappa_R = 10\ \text{m}^{-1}$ and the effective thermal conductivity is $k_c = 0.1$W/mK. Estimate the total heat flux between the plates (ignoring convection effects).

Solution. For simplicity, we may want to assume a constant total conductivity $k = k_c + k_R$, leading to

$$q = -k\frac{\mathrm{d}T}{\mathrm{d}x} = k\frac{T_2 - T_1}{L}$$

where k_R must be evaluated at some effective temperature. Choosing, based on its temperature dependence,

$$k_R \cong \frac{8\sigma}{3\kappa_R}(T_1^3 + T_2^3) = \frac{8\times 5.670\times 10^{-8}\ \text{W/m}^2\text{K}^4}{3\times 10/\text{m}}(1000^3 + 2000^3)\text{K}^3 = 136\,\text{W/mK}$$

gives

$$q = (0.1 + 136)\frac{2000 - 1000}{1}\,\text{W/m}^2 = 136\,\text{kW/m}^2\text{K}$$

Note that (1) conduction is negligible in this example and (2) the surface emittances do not enter the diffusion approximation. While a more accurate answer can be obtained by taking the temperature dependence of k_R into account, the method itself should be understood as a relatively crude approximation.

Mean beam length method. Relatively accurate yet simple heat-transfer calculations can be carried out if an isothermal, absorbing–emitting, but not scattering medium is contained in an isothermal, black-walled enclosure. While these conditions are, of course, very restrictive, they are met to some degree by conditions inside furnaces. For such cases, the local heat flux on a point of the surface may be calculated from

$$q = \left[1 - \alpha(L_m)\right]E_{bw} - \varepsilon(L_m)E_{bg} \tag{3.3.43}$$

where E_{bw} and E_{bg} are blackbody emissive powers for the walls and medium (gas and/or particulates), respectively, and $\alpha(L_m)$ and $\varepsilon(L_m)$ are the total absorptivity and emissivity of the medium for a path length L_m through the medium. The length L_m, known as the average mean beam length, is a directional average of the thickness of the medium as seen from the point on the surface. On a spectral basis, Equation 3.3.43 is exact, provided the previous conditions are met and provided an accurate value of the (spectral) mean beam length is known. It has been shown that spectral dependence of the mean beam length is weak (generally less than ±5% from the mean). Consequently, total radiative heat flux at the surface may be calculated very accurately from Equation 3.3.43, provided the emissivity and absorptivity of the medium are also known accurately. The mean beam lengths for many important geometries have been calculated and are collected in Table 3.3.3. In this table, L_0 is known as the geometric mean beam length, which is the mean beam length for the optically thin limit ($\kappa_\lambda \to 0$), and L_m is a spectral average of the mean beam length. For geometries not listed in Table 3.3.3, the mean beam length may be estimated from

$$L_0 \cong 4\frac{V}{A} \quad L_m \cong 0.9L_0 \cong 3.6\frac{V}{A} \tag{3.3.44}$$

where V is the volume of the participating medium and A is its entire bounding surface area.

TABLE 3.3.3
Mean Beam Lengths for Radiation from a Gas Volume to a Surface on Its Boundary

Geometry of Gas Volume	Characterizing Dimension L	Geometric Mean Beam Length L_0/L	Average Mean Beam Length L_m/L	L_m/L_0
Sphere radiating to its surface	Diameter, $L=D$	0.67	0.65	0.97
Infinite circular cylinder to bounding surface	Diameter, $L=D$	1.00	0.94	0.94

To 1×4 face		0.90	0.82	0.91
To 1×1 face		0.86	0.71	0.83
To all faces		0.89	0.81	0.91

Example 3.3.8

An isothermal mixture of 10% CO_2 and 90% nitrogen at 1000 K and 5 bar is contained between two large, parallel, black plates, which are both isothermal at 1500 K. Estimate the net radiative heat loss from the surfaces.

Solution. The heat loss may be calculated from Equation 3.3.43, after determining the mean beam length, followed by evaluation of $\varepsilon(L_m)$ and $\alpha(L_m)$. From Table 3.3.3, it is clear that $L_m = 1.76 \times$ thickness of slab = 1.76 m. It turns out that the necessary $\varepsilon(L_m) = 0.15$ and $\alpha(L_m) = 0.122$ have already been calculated in Example 3.3.6. Thus, the heat flux is immediately calculated from Equation 3.3.43 as

$$q = (1-0.122)5.670\times10^{-8}\times1500^4 - 0.15\times5.670\times10^{-8}\times1000^4$$

$$= 2.44\times10^5\ \text{W/m}^2 = 244\ \text{kW/m}^2$$

Advanced Concepts

Radiative transfer in a participating medium is governed by the so-called radiative transfer equation (RTE), an energy balance for spectral radiative intensity I_λ traveling in a specific direction $\hat{s}$,

$$\frac{dI_\lambda}{ds} = \kappa_\lambda I_{b\lambda} - \beta_\lambda I_\lambda(\hat{s}) + \frac{\sigma_{s\lambda}}{4\pi}\int_{4\pi} I_\lambda(\hat{s})\Phi_\lambda(\hat{s},\hat{s}')\,d\Omega', \tag{3.3.45}$$

in which $I_{b\lambda} = E_{b\lambda}/\pi$ is the blackbody intensity, κ_λ is the *absorption coefficient* [the ability of a medium to absorb and emit radiation, as given in Equation 3.3.28], $\sigma_{s\lambda}$ is the *scattering coefficient* (the ability of a medium to scatter radiation), $\beta_\lambda = \kappa_\lambda + \sigma_{s\lambda}$ is called the *extinction coefficient*, and $\Phi_\lambda(\hat{s},\hat{s}')$ the scattering phase function (the probability that radiation traveling in the direction of $\hat{s}$ is scattered, i.e., redirected, into the direction of $\hat{s}'$). The RTE states that the strength of a light beam traveling along a path s is augmented by emission from the medium (first term on the RHS), is diminished by absorption and outscattering, that is, scattering *away* from $\hat{s}$ (second term), and increased by inscattering, that is, scattering from all other directions *into* direction $\hat{s}$ (last term). The RTE is a five-dimensional (three space coordinates, and two direction coordinates with local origins) integro-differential equation, which is extremely difficult to solve. The problem is compounded by the complicated spectral behavior usually exhibited by the medium's radiation properties (κ_λ, $\sigma_{s\lambda}$ and Φ_λ). Therefore, numerous approximate and/or numerical techniques have been developed to solve the RTE and to deal with the complicated spectral behavior.

RTE solution methods. All RTE solution methods attempt to either approximate the directional dependence of radiative intensity or express it numerically. The next level of sophistication beyond the diffusion and mean-beam-length approximations are the so-called flux methods. The two-flux model, assuming the intensity to have two constant but different values across two hemispheres of directions, has been successfully applied to one-dimensional problems (Modest, 2013); the six-flux method can be applied to more general geometries, but must be tailored toward each individual problem. The most popular numerical methods are the *spherical harmonics* and the *discrete ordinates* methods and, more recently, the statistical (photon) *Monte Carlo* method. In the first, the directional dependence of intensity is expanded into a series of spherical harmonics, truncated at the *N*th level and resulting in the so-called P-N methods. While higher-order P-N methods are difficult to implement, its lowest order, the *P*–1 approximation, is very popular because of its simplicity and surprising accuracy. Reducing the RTE into a single elliptical partial differential equation, it is easy to implement and has been incorporated into most modern commercial CFD codes. The *P*–1 approximation assumes a near-isotropic intensity distribution and is, therefore, accurate in emission-dominated applications (such as combustion of fuels and high-temperature combustion products) and optically thick systems (large κ_λ); the method fails for predicting heat exchange between hot and cold surfaces separated by an optically thin medium (small κ_λ). The *discrete ordinates* method (DOM) finite differences the directional dependence of intensity, requiring the simultaneous solution of many hyperbolic partial differential equations (Modest, 2013). Because it can be carried to arbitrary levels of accuracy (albeit at a steep computational price) it, and its modern finite-volume implementation (FVM) (Modest, 2013) are also incorporated into most CFD codes. In the photon Monte Carlo (PMC) method, statistically meaningful photon bundles are traced from their point of emission until they are absorbed or leave the computational domain (Modest, 2013). Unlike conventional RTE solvers, the PMC method is easily applied to problems of great complexity (in geometry and/or radiative properties), and is the only method that can produce "exact" results. Because of the independent sampling of photons, the method is also ideal for parallel computing. Their disadvantages are that Monte Carlo methods require the tracing of millions of photon bundles to obtain accurate results, that is, they require vast computer resources, and furthermore, like those from any statistical method, their results display statistical scatter, which can make it difficult to combine them with conventional flow solvers. Some commercial codes also offer the older *discrete transfer* method, which is today known to be less accurate and less efficient (Modest, 2013), and is, thus, not recommended.

Spectral Models. As indicated earlier, the spectral variations of radiation properties of gases and particles are extremely difficult to predict and to deal with. While particles tend to have a distribution of particle sizes and shapes, thus smoothing out spectral variations and allowing the assumption of gray

or near-gray behavior, this is almost never the case for molecular gases (but may result in errors of hundreds, and even thousands, of percent). This has prompted the development of a number of approximate models, which may be loosely grouped into four groups: (1) line-by-line calculations, (2) narrow band models, (3) wide band models, and (4) global models. In line-by-line calculations (LBL), the spectral variation of the gas absorption coefficient is followed in small steps across the entire spectrum, requiring 1,000,000 RTE evaluations or more, making this method suitable only for bench marking. Narrow band models take advantage of the fact that the gas absorption coefficient varies much more rapidly across the spectrum than other quantities, such as emissive power or surface emittance. The models predict gas transmissivities averaged across small spectral ranges, the most successful ones being the so-called statistical narrow band models (SNB), in particular the Malkmus model (Modest, 2013). Wide band models (WBM) are similar to narrow band models, but average over an entire vibration–rotation band and usually employ correlations of somewhat dated experimental data. Finally, global models look at the entire spectrum, the most successful one being the *weighted sum of gray gases* (WSGG) first introduced by Hottel and Sarofim (1967). The most modern, accurate and efficient approach is the method of *full-spectrum correlated k-distributions* (FSCK), in which the absorption coefficient is reordered across the spectrum into a monotonically increasing function. This method also exists in narrow band and wide band forms, and can result in (near-) exact answers at a tiny fraction of the costs for LBL calculations. If the statistical photon Monte Carlo method is employed, spectral variations of radiative properties are readily incorporated into the sampling and LBL-accurate PMC solutions can be obtained. While for conventional RTE solvers LBL accuracy increases computational effort by 6 orders of magnitude over gray media, for PMC calculations the increase in effort is only a few tens of percent. Therefore, if accurate spectral modeling is required, LBL PMC solvers are computationally competitive with the more traditional *P-N* and DOM methods. For more detailed information on spectral modeling, the reader is referred to Modest (2013). Apparently, as of 2015 none of the better known CFD packages includes a credible nongray spectral model.

Defining Terms

Absorptance: The ability of a solid material to absorb (i.e., trap and convert to other forms of energy) incoming radiation; gives the fraction of incoming radiation that is absorbed by the medium.

Absorptivity: The fraction of incoming radiation that is absorbed by a column of a radiatively participating medium (e.g., a gas or a particle cloud).

Absorption coefficient: The ability of a medium to absorb (i.e., trap and convert to other forms of energy) radiative energy over a unit path length; the reciprocal of the mean distance a photon travels before being absorbed.

Blackbody: Any material or configuration that absorbs all incoming radiation completely. A blackbody also emits the maximum possible amount of radiation as described by Planck's law.

Diffuse surface: A surface that emits and/or reflects equal amounts of radiative energy (photons) into all directions. Or a surface that absorbs and/or reflects equal amounts of radiation independent of incoming direction.

Emissive power: The rate of radiative energy leaving a surface through emission. The maximum amount of emissive power is emitted by a blackbody with a spectral strength described by Planck's law.

Emittance: The ability of a solid material to emit (i.e., convert internal energy into electromagnetic waves or photons) thermal radiation; gives the fraction of emission as compared with a blackbody.

Emissivity: The ability of a column of a radiatively participating medium (e.g., a gas or a particle cloud) to emit thermal radiation; gives the fraction of emission as compared with an opaque (i.e., infinitely long) column.

Gray: A medium whose radiative properties (such as absorptance, emittance, reflectance, absorption coefficient) do not vary with wavelength.

Irradiation: Incoming radiative flux onto a surface from outside it.

Network analogy: Expressing radiative heat exchange between surfaces in terms of an electrical network, with heat flux as "current," differences in emissive power as "potentials," and defining radiative resistances.

Opaque medium: A medium of sufficient thickness that absorbs all nonreflected irradiation; no radiation is transmitted through the medium.

Photon: A massless particle carrying energy in the amount of $h\nu$; the quantum mechanical alternative view of an electromagnetic wave carrying radiative energy.

Planck's law: The law describing the spectral distribution of the radiative energy emitted (emissive power) of a blackbody.

Radiosity: Total radiative flux leaving a surface (diffusely), consisting of emitted as well as reflected radiation.

Reflectance: The ability of an interface, or of a medium or of a composite with a number of interfaces, to reflect incoming radiation back into the irradiating medium.

Semitransparent: See transparent.

Spectral value: The value of a quantity that varies with wavelength at a given wavelength; for dimensional quantities the amount per unit wavelength.

Transmittance: The fraction of incoming radiation that is transmitted through a layer of a solid material.

Transmissivity: The fraction of incoming radiation that is transmitted by a column of a radiatively participating medium (e.g., a gas or a particle cloud).

Transparent: The ability of a medium to let incoming radiation pass through it. A medium that lets all radiation pass through it is called transparent, a medium that only allows a part to pass through it is called semitransparent.

View factor: The fraction of diffuse radiant energy leaving one surface that is intercepted by another surface.

3.4 PHASE-CHANGE

3.4.1 Boiling and Condensation

Van P. Carey

Introduction

Liquid–vapor phase-change processes play an important role in many technological applications. The virtually isothermal heat transfer associated with boiling and condensation processes makes their inclusion in power and refrigeration processes highly advantageous from a thermodynamic efficiency standpoint. In addition, the high heat-transfer coefficients associated with boiling and condensation have made the use of these processes increasingly attractive in the thermal control of compact devices that have high heat dissipation rates. Applications of this type include the use of boiling heat transfer to cool electronic components in computers and the use of compact evaporators and condensers for thermal control of aircraft avionics and spacecraft environments. Liquid–vapor phase-change processes are also of critical importance to nuclear power plant design, both because they are important in normal operating circumstances, and because they dominate many of the accident scenarios that are studied as part of design evaluation.

The heat transfer and fluid flow associated with liquid–vapor phase-change processes are typically among the more complex transport circumstances encountered in engineering applications. These processes have all the complexity of single-phase convective transport, plus additional elements resulting from motion of the interface, nonequilibrium effects, and dynamic interactions between the phases. Due to the highly complex nature of these processes, development of methods to accurately predict the associated heat and mass transfer is often a formidable task.

In this section, commonly used variables not defined in the nomenclature are as follows: q'' = surface heat flux, μ_l = liquid viscosity, μ_v = vapor viscosity, Pr_l = liquid Prandtl number, T_w = wall surface temperature, T_{sat} = saturation temperature, c_{pl} = liquid specific heat, k_v = vapor thermal conductivity, g = gravitational acceleration, G = mass flow per unit of cross-sectional area, h_{lv} = latent heat of vaporization, and x = mass quality.

Thermophysics of Boiling Processes

Four thermophysical mechanisms that play important roles in boiling processes are (1) surface tension effects, (2) surface wetting characteristics of the liquid, (3) metastable phase stability, and (4) surface morphology effects.

Anyone who has watched small bubbles rise in a carbonated beverage or a pot of boiling water has undoubtedly noticed that the bubbles are almost perfectly spherical, as if an elastic membrane were present at the interface to pull the vapor into a spherical shape. This apparent interfacial tension or *surface tension* σ is equivalent to an energy stored in the interface region per unit area. The excess energy in this region is due to the slightly larger separation of the liquid phase molecules adjacent to the gas phase.

The magnitude of the surface tension for a substance is directly linked to the strength of intermolecular forces in the material. Nonpolar liquids typically have the lowest surface tension. Water and other *polar molecules* have somewhat higher surface tension, and liquid metals, which exhibit metallic bond attraction, have very high surface tension. The surface tension of water at 20°C is 0.0728 N/m, whereas liquid mercury has a surface tension of 0.484 N/m at the same temperature. The surface tension for any pure liquid varies with temperature. It decreases almost linearly with increasing temperature, vanishing altogether at the critical point where the distinction between the phases disappears.

As a result of the surface tension at the interface, the pressure inside a spherical bubble of radius r must exceed that in the surrounding liquid by $2\sigma/r$:

$$P_v = P_l + \frac{2\sigma}{r}. \tag{3.4.1}$$

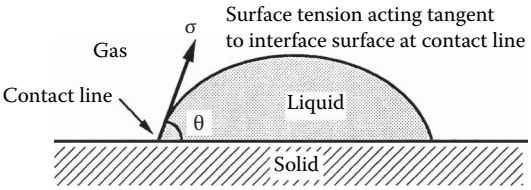

FIGURE 3.4.1 Definition of the contact angle θ.

By using the relation 3.4.1 between the pressures in the two phases, it can be shown that for the bubble to be in equilibrium with the surrounding liquid, the liquid must actually be superheated above the saturation temperature for the ambient liquid pressure. The amount of required superheating increases as the radius of curvature of the bubble interface decreases.

The wetting characteristics of the liquid are generally quantified in terms of a *contact angle* between the solid surface and the tangent to the interface at the point where it contacts the solid. This angle is measured through the liquid phase, as shown in Figure 3.4.1. In some systems, the wetting angle established at equilibrium may depend on the fluid motion history. For some systems, the contact angle established by liquid advancing over a solid surface is larger than that established when a liquid front recedes over the surface. This behavior is referred to as *contact angle hysteresis*. Contact angle hysteresis can have an important effect on boiling and condensation processes, particularly those involving water.

For a bubble with a specified vapor volume, the contact angle will dictate the radius of curvature of the bubble interface. The wetting behavior in combination with the surface tension effect thus determines the level of superheat required for the bubble to be in equilibrium with the surrounding liquid. The liquid must be heated above this superheat level for the bubble to grow. A steady boiling process can be sustained only if the liquid is heated above this threshold superheat level.

It can be shown from basic thermodynamic analysis that a necessary and sufficient condition for phase stability is that

$$\left(\frac{\partial P}{\partial v}\right)_T < 0, \tag{3.4.2}$$

where v is the specific volume. Below the critical temperature, extrapolation of the isotherms for the liquid and vapor phases consistent with an equation of state like the van der Waals equation results in an isotherm shape similar to that shown in Figure 3.4.2.

The locus of points where $(\partial P/\partial v)_T = 0$ are termed *spinodal curves*. Regions of metastable vapor and liquid exist between the saturation curve and the spinodal curves. The effects of surface tension discussed earlier require that fluid surrounding a vapor bubble be in the metastable superheated liquid region. Predictions of statistical thermodynamics imply that as $(\partial P/\partial v)_T$ approaches zero, the level of fluctuations in a fluid system increases. This, in turn, increases the probability that an embryonic new phase will form as a result of density fluctuations. Initiation of a phase change in this manner is termed *homogeneous nucleation*. Generally, a pure liquid must be heated to nearly 90% of its absolute critical temperature before homogeneous nucleation of vapor bubbles occurs.

In most physical systems of engineering interest, the bulk phase is in contact with solid walls of the containing structures or solid particulate contaminants. These solid phases may provide nucleation sites where phase change may occur if the system state is driven into the metastable range. Nucleation of vapor bubbles may preferentially occur at low-liquid superheat levels in crevices in the solid surface where gas is trapped. This type of nucleation at the solid surface of a containment wall is categorized as *heterogeneous nucleation*. Because solid containment walls usually contain microscopic crevice-type imperfections, heterogeneous nucleation is more common than homogeneous nucleation in systems where boiling occurs.

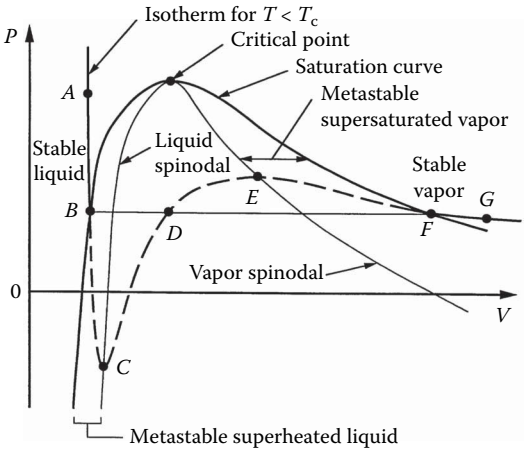

FIGURE 3.4.2 Spinodal lines and metastable regions on a *P–v* diagram.

Surface morphology affects boiling processes by facilitating entrapment in crevices of the heated walls of evaporator heat exchangers, which usually makes it easier to initiate the vaporization process. Vapor bubbles grow from these crevices until buoyancy or drag on the bubbles exceeds the surface tension force holding the bubble to the solid surface. The bubble then releases into the bulk liquid. A small remnant of vapor remains in the crevice after a bubble releases, and this remnant grows in size as further vaporization occurs until the bubble grows out of the crevice again. The result is a cyclic process of bubble growth and release known as the *ebullition cycle*. Crevices at which the ebullition cycle is sustained are said to be active nucleation sites. When the ebullition process occurs at many sites over a heated surface, the overall process is referred to as *nucleate boiling*, which is one possible mode of *pool boiling*. Note that contact angle requirements together with the surface morphology are primary factors that affect the shapes of the liquid–vapor interface and liquid regions in contact with the heated surface, which, in turn, strongly affect the heat transfer processes at the heated surface that are associated with the vaporization process.

Pool Boiling

Vaporization of liquid at the surface of a body immersed in an extensive pool of motionless liquid is generally referred to as pool boiling. The nature of the pool boiling process varies considerably depending on the conditions at which boiling occurs. The level of heat flux, the thermophysical properties of the liquid and vapor, the surface material and finish, and the physical size of the heated surface all may have an effect on the boiling process.

The regimes of pool boiling are most easily understood in terms of the so-called boiling curve: a plot of heat flux q'' vs. wall superheat $T_w - T_{sat}$ for the circumstances of interest. Many of the features of the classic pool boiling curve were determined in the early investigations of pool boiling conducted by Nukiyama (1934). Strictly speaking, the classic pool boiling curve defined by the work of this investigator and others applies to well-wetted surfaces for which the characteristic physical dimension L is large compared to the bubble or capillary length scale L_b defined as

$$L_b = \sqrt{\frac{\sigma}{g(\rho_l - \rho_v)}}. \tag{3.4.3}$$

The discussion in this section is limited to pool boiling of wetting liquids on surfaces with dimensions large compared with L_b. Additional information on features of the boiling curve when the liquid poorly wets the surface or when L/L_b is small can be found in Carey (2008). To make this

discussion concrete, we will assume that the ambient liquid surrounding the immersed body is at the saturation temperature for the ambient pressure. If the surface temperature of the immersed body is controlled and slowly increased, the boiling curve will look similar to that shown in Figure 3.4.3. The axes in this plot are logarithmic scales. The regimes of pool boiling encountered for an upward-facing horizontal flat surface as its temperature is increased are also indicated in Figure 3.4.3. The lateral extent of the surface is presumed to be much larger than L_b. At very low wall superheat levels, no nucleation sites may be active and heat may be transferred from the surface to the ambient liquid by natural convection alone and q'' increases slowly with $T_w - T_{sat}$.

Eventually, the superheat becomes large enough to initiate nucleation at some of the cavities on the surface. This *onset of nucleate boiling* (ONB) condition occurs at point *c* in Figure 3.4.3. Once nucleate boiling is initiated, any further increase in wall temperature causes the system operating point to move upward along section *d–f* of the curve in Figure 3.4.3. This portion of the curve corresponds to the nucleate boiling regime. The active sites are few and widely separated at low wall superheat levels. This range of conditions, corresponding to segment *d–e* of the curve, is sometimes referred to as the *isolated bubble regime*.

With increasing surface superheat, more sites become active, and the bubble frequency at each site generally increases. Eventually, the active sites are spaced so closely that bubbles from adjacent sites merge together during the final stages of growth and release. Vapor is being produced so rapidly that bubbles merging together form columns of vapor slugs that rise upward in the liquid pool toward its free surface. This higher range of wall superheat, corresponding to segment *e–f* of the boiling curve in Figure 3.4.3, is referred to as the *regime of slugs and columns*.

Increasing the wall superheat and heat flux within the regime of slugs and columns produces an increase in the flow rate of vapor away from the surface. Eventually, the volume fraction of vapor becomes so large, and the resulting vapor drag on the liquid moving toward the surface becomes so severe that liquid is unable to reach the surface fast enough to keep the surface completely wetted with liquid. Vapor patches accumulate at some locations, and evaporation of the liquid between the surface and some of these patches dries out portions of the surface.

If the surface temperature is held constant and uniform, dry portions of the surface covered with a vapor film will locally transfer a much lower heat flux than wetted portions of the surface

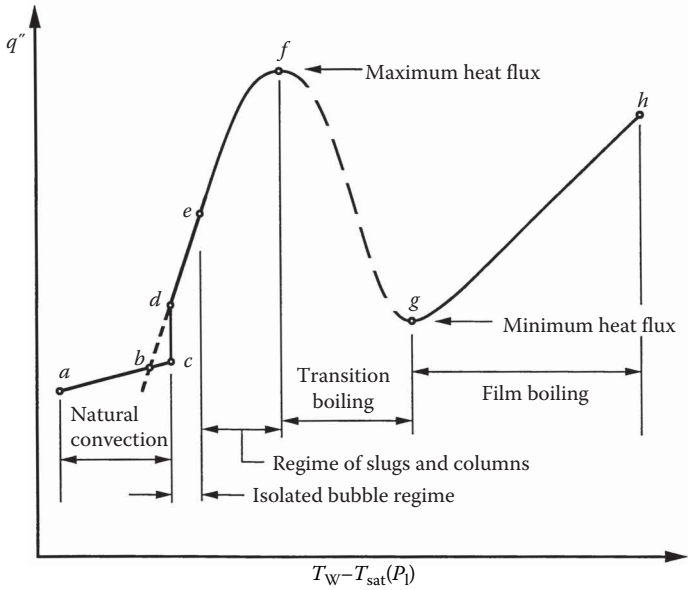

FIGURE 3.4.3 Pool boiling regimes for an independently controlled surface temperature.

where nucleate boiling is occurring. Because of the reduction in heat flux from intermittently dry portions of the surface, the mean overall heat flux from the surface is reduced. Thus, increasing the wall temperature within the slugs and columns region ultimately results in a peaking and rollover of the heat flux. The peak value of heat flux is called the *critical heat flux* (CHF), designated as point *f* in Figure 3.4.3

If the wall temperature is increased beyond the critical heat flux condition, a regime is encountered in which the mean overall heat flux decreases as the wall superheat increases. This regime, which is usually referred to as the *transition boiling* regime, corresponds to segment *f–g* on the boiling curve shown in Figure 3.4.3. The transition boiling regime is typically characterized by rapid and severe fluctuations in the local surface heat flux and/or temperature values (depending on the imposed boundary condition). These fluctuations occur because the dry regions are generally unstable, existing momentarily at a given location before collapsing and allowing the surface to be rewetted.

The vapor film generated during transition boiling can be sustained for longer intervals at higher wall temperatures. Because the intermittent insulating effect of the vapor blanketing is maintained longer, the time-averaged contributions of the blanketed locations to the overall mean heat flux are reduced. The mean heat flux from the surface thus decreases as the wall superheat is increased in the transition regime. As this trend continues, eventually a point is reached at which the surface is hot enough to sustain a stable vapor film on the surface for an indefinite period of time. The entire surface then becomes blanketed with a vapor film, thus making the transition to the *film boiling* regime. This transition occurs at point *g* in Figure 3.4.3.

Within the film boiling regime, the heat flux monotonically increases as the superheat increases. This trend is a consequence of the increased conduction and/or convection transport due to the increased driving temperature difference across the vapor film. Radiative transport across the vapor layer may also become important at higher wall temperatures.

Once a surface is heated to a superheat level in the film boiling regime, if the surface temperature is slowly decreased, in general the system will progress through each of the regimes described earlier in reverse order. However, the path of the boiling curve may differ significantly from that observed for increasing wall superheat, depending on whether the surface heat flux or temperature is controlled.

Experimental evidence summarized by Witte and Lienhard (1982) implies that the path of the transition boiling curve is determined, to a large degree, by the wetting characteristics of the liquid on the solid surface. For a given wall superheat level in the transition boiling regime, a higher heat flux is generally obtained if the liquid wets the surface than if it poorly wets the surface. For systems that exhibit contact angle hysteresis, the transition boiling curves obtained for decreasing and increasing wall superheat may therefore be somewhat different. The transition boiling curve for decreasing wall superheat may be significantly below that for increasing superheat for such circumstances, as indicated in Figure 3.4.4.

For an electrically heated surface, the rise in temperature associated with the jump from nucleate to film boiling at the critical heat flux is very often large enough to melt component materials and burn out the component. As a result, the critical heat flux is often referred to as the *burnout heat flux* to acknowledge the potentially damaging effects of applying this heat flux level to components cooled by nucleate boiling. Once the jump to film boiling has been made, any further increase in applied heat flux increases the wall superheat, and the system follows basically the same film boiling curve as in the temperature-controlled case.

Correlations of nucleate pool boiling heat-transfer data have typically been used as tools to predict nucleate boiling heat transfer in engineering systems and heat exchangers. Many investigators have proposed methods of correlating data of this type; so many, in fact, that a complete discussion of them all could easily fill a major portion of this section. In this section, three of the more commonly used correlation methods will be mentioned. However, before proceeding, two aspects of the interpretation of such correlations are worth noting. First, experimental data indicate that

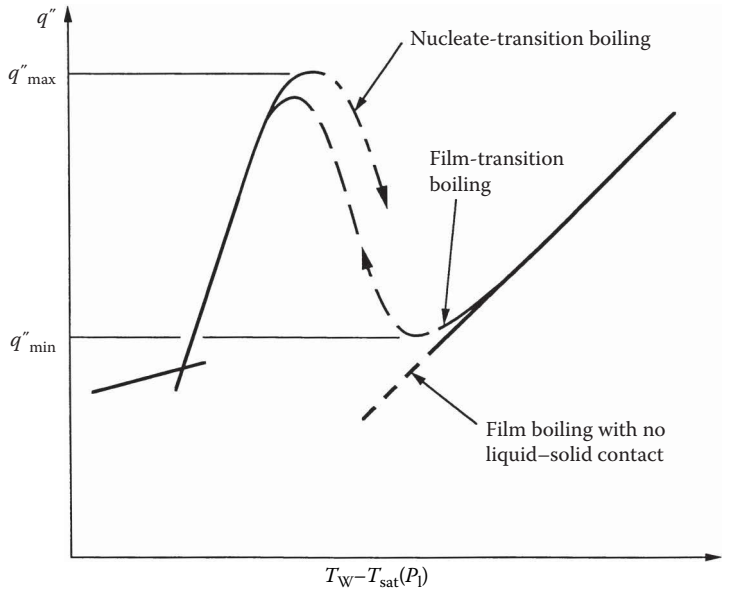

FIGURE 3.4.4 Relative locations of the nucleate transition and film transition portions of the pool boiling curve.

the subcooling of the liquid pool has a negligible effect on the nucleate boiling heat-transfer rate. Consequently, the pool boiling correlations are generally regarded as being valid for both subcooled and saturated nucleate boiling. Second, it has also been observed that at moderate to high heat flux levels, a pool boiling heat-transfer correlation developed for one heated surface geometry in one specific orientation often works reasonably well for other geometries and/or other orientations. Hence, although a correlation was developed for a specific geometry and orientation, it may often be used for other geometries, at least at moderate to high heat flux levels.

Having taken note of the earlier points, a commonly used correlation for nucleate boiling heat transfer developed by Rohsenow (1962) is

$$\frac{q''}{\mu_l h_{fg}}\left[\frac{\sigma}{g(\rho_l-\rho_v)}\right]^{1/2}=\left(\frac{1}{C_{sf}}\right)^{1/r}\mathrm{Pr}_l^{-s/r}\left[\frac{c_{pl}\left[T_w-T_{sat}(P_l)\right]}{h_{fg}}\right]^{1/r}. \tag{3.4.4}$$

Values of $r=0.33$ and $s=1.7$ are recommended for this correlation, but for water s should be changed to 1.0. The values of C_{sf} in this correlation vary with the type of solid surface and the type of fluid in the system. This empirically accounts for material property and/or wetting angle effects. Recommended values of C_{sf} for specific liquid–solid combinations are given by Rohsenow (1962), but whenever possible, an experiment should be conducted to determine the appropriate value of C_{sf} for the particular solid–liquid combination of interest. If this is not possible, a value of $C_{sf}=0.013$ is recommended as a first approximation.

In a more recent study, Stephan and Abdelsalam (1980) proposed the following correlations based on dimensional analysis and an optimal fit to experimental data for water:

$$q''=\{C_1[T_w-T_{sat}(P_l)]\}^{1/0.327}. \tag{3.4.5}$$

In this correlation, C_1 is a constant that varies with pressure, and these investigators provided a plot of C_1 versus pressure that can be used to obtain the value of C_1 for a pressure of interest. The value for boiling of water at atmospheric pressure is $C_1=3.75$. These investigators proposed similar

dimensional correlations for nucleate boiling of hydrocarbons, cryogenic fluids, and refrigerants, and they developed specific dimensionless correlations for nucleate boiling in each of these categories, in addition to the one above for water. Stephan and Abdelsalam (1980) also developed the following correlation that can be applied, with more limited accuracy, to any liquid:

$$\frac{q''D_b}{k_l(T_w - T_{sat})} = 0.23\left(\frac{q''D_b}{k_l T_{sat}}\right)^{0.674}\left(\frac{\rho_v}{\rho_l}\right)^{0.297}\left(\frac{h_{lv}D_b^2}{\alpha_l^2}\right)^{0.371}\left(\frac{\rho_l - \rho_v}{\rho_l}\right)^{-1.73}\left(\frac{\alpha_l^2\rho_l}{\sigma D_b}\right)^{0.35} \quad (3.4.6)$$

In this equation, D_b is the bubble diameter predicted by the bubble departure diameter correlation (6.98) developed by Fritz (1935): $D_d = 0.0208\theta\sqrt{\sigma/[g(\rho_l - \rho_v)]}$, where θ is the contact angle in degrees. Further information on these correlations for specific fluid categories can be obtained in the references by Stephan and Abdelsalam (1980) and Carey (2008).

As noted previously, the pool boiling curve generally exhibits a maximum heat flux or CHF at the transition between nucleate and transition boiling. This peak value is the maximum level of heat flux from the surface, which the system can provide in a nonfilm-boiling mode at a given pressure. The mechanism responsible for the CHF has been the subject of considerable investigation and debate over the past seven decades. As the heat flux increases, bubbles generated at the surface coalesce to form vapor columns or jets. Perhaps the most widely cited CHF model postulates that the CHF condition occurs when Helmholtz instability of the large vapor jets leaving the surface distorts the jets, blocking liquid flow to portions of the heated surface. Continued vaporization of liquid at locations on the surface that are starved of replacement liquid then leads to formation of a vapor blanket over part or all of the surface. According to Zuber (1959), for a flat horizontal surface, the predicted maximum heat flux q''_{max} is

$$q''_{max} = 0.131\rho_v h_{fg}\left[\frac{\sigma_g(\rho_l - \rho_v)}{\rho_v^2}\right]^{1/4}, \quad (3.4.7)$$

but Lienhard and Dhir (1973a) recommend that the constant 0.131 in this relation be replaced with 0.141. Other geometries are treated by Lienhard et al. (1973) and Lienhard and Dhir (1973b). An alternative model has been proposed by Haramura and Katto (1983). Lienhard and Witte (1985) discuss the development and limitations of hydrodynamic CHF theories.

In a more recent study, Kandlikar (2001) developed a model of the critical heat flux mechanism that is not based on hydrodynamic wave instability and includes the effects of contact angle and surface inclination. The model postulates that the critical heat flux condition is attained when the forces acting at the contact line of a bubble on the surface become unbalanced in a way that causes the bubble to spread laterally and blanket the surface.

Kandlikar (2001) argued that components of the surface tension, hydrostatic pressure forces, and evaporation change of momentum forces act parallel to the surface of the heater. Liquid moves toward the interface to replace mass lost by vaporization. The vapor that emerges from the interface on the inside of the bubble near the contact line leaves with a much higher velocity because the high density liquid must accelerate to sustain the same mass flux as low density vapor. The thrust from this accelerating flow acts to push the contact line and sidewall of the bubble laterally outward. The surface tension and hydrostatic pressure force components parallel to the surface act to resist any outward motion of the bubble sidewall and contact line. Kandlikar (2001) developed model relations for the forces on the side of the bubble parallel to the surface and interpreted the point at which they just balance as the incipient CHF condition. Solving for the heat flux at the force balance condition led to the following relation for the critical heat flux

$$q''_{max} = \rho_v h_{lv}\frac{1+\cos\theta}{16}\left[\frac{2}{\pi} + \frac{\pi}{4}(1+\cos\theta)\cos\Omega\right]^{1/2}\left[\frac{\sigma(\rho_l - \rho_v)g}{\rho_v^2}\right]^{1/4}. \quad (3.4.8)$$

The angle of the surface relative to the horizontal Ω was taken into account when constructing the force balance, making this relation applicable to horizontal or inclined surfaces. If both sides of Equation 3.4.8 are divided by the Zuber critical heat flux prediction, and Equation 3.4.7 is used to simplify the result, the following relation is obtained:

$$\frac{q''_{\max}}{q''_{\max,Z}} = \frac{1+\cos\theta}{2.096}\left[\frac{2}{\pi}+\frac{\pi}{4}(1+\cos\theta)\cos\Omega\right]^{1/2}. \tag{3.4.9}$$

Kandlikar (2001) concluded that the dynamic receding contact angle is the appropriate contact to use in this relation. This correlation indicates decreasing critical heat flux as the contact angle increases, which is consistent with the trend in available data. While there are aspects of contact angle effects that warrant further exploration, the modeling used in Kandlikar's (2001) analysis appears to be a promising approach that may lead to better understanding of the effects of contact angle on pool boiling critical heat flux.

As shown in Figure 3.4.3, the boundary between the transition boiling regime and the film boiling regime corresponds to a minimum in the heat flux vs. superheat curve. This condition is referred to as the *minimum heat flux* condition, referred to as the *Leidenfront point*. The minimum heat flux corresponds approximately to the lowest heat flux that will sustain stable film boiling.

For an infinite flat (upward-facing) heated surface, vapor generated at the interface during stable film boiling is released as bubbles at the nodes of a standing two-dimensional Taylor wave pattern. The following relation for the minimum heat flux $q''_{\min}$ was derived by Zuber (1959) and Berenson (1961):

$$q''_{\min} = 0.09\rho_v h_{fg}\left[\frac{\sigma_g(\rho_l-\rho_v)}{(\rho_l+\rho_v)^2}\right]^{1/4}. \tag{3.4.10}$$

$q''_{\min}$ correlations have been developed by Lienhard and Wong (1964) for horizontal cylinders and Gunnerson and Cronenberg (1980) for spheres.

In film boiling, transport of heat across the vapor film from the wall to the interface may occur by convection, conduction, and radiation. The radiation contribution depends on the nature of the solid surface, but when the radiation effect is small, the heat transfer for film boiling is independent of the material properties and finish of the surface. For buoyancy-driven laminar film boiling over a vertical flat isothermal surface in a pool of saturated liquid, the local heat-transfer coefficient from the surface can be obtained from the following relation:

$$h = \left[\frac{k_v^3 g\rho_v(\rho_l-\rho_v)h_{fg}}{4\mu_v(T_w-T_{sat})x}\right]^{1/4}. \tag{3.4.11}$$

At low surface temperatures, radiation effects are negligible and consideration of convective transport alone is sufficient to predict the heat transfer. At higher temperatures, radiation effects must also be included. If the vapor in the film absorbs and emits radiation at infrared wavelengths, a detailed treatment of the radiation interaction with the vapor may be necessary to accurately predict the film boiling heat transfer. Additional information on mechanisms such as interfacial waves, turbulence, and variable properties is summarized in Carey (2008).

Transition pool boiling has traditionally been interpreted as a combination of nucleate and film boiling alternately occurring over the heated surface, and a model of transition boiling that accounts for contact angle effects has been proposed by Ramilison and Lienhard (1987).

Internal Convective Boiling

Flow boiling in tubes is perhaps the most complex convective process encountered in applications. In most evaporator and boiler applications, the flow is either horizontal or vertically upward. Figure 3.4.5 schematically depicts a typical low-flux vaporization process in a horizontal round tube. In this example, liquid enters as subcooled liquid and leaves as superheated vapor. As indicated in Figure 3.4.5, the flow undergoes transitions in the boiling regime and the two-phase flow regime as it proceeds down the tubes. The regimes encountered depend on the entrance conditions and the thermal boundary conditions at the tube wall. At low quality, the vaporization process is dominated by nucleate boiling, with convective effects being relatively weak. As the quality increases, the flow quickly enters the annular film flow regime in which convective evaporation of the annular liquid film is the dominant heat-transfer mechanism. Often the conditions are such that liquid droplets are often entrained in the core vapor flow during annular flow evaporation. Eventually, the annular film evaporates away, leaving the wall dry. Mist-flow evaporation of entrained liquid droplets continues in the post-dryout regime until only vapor remains. Similar, sequences of flow and boiling regimes occurring in vertical upward flow, as indicated in Figure 3.4.6.

The boiling regime trends shown in Figures 3.4.5 and 3.4.6 are typical for low heat flux vaporization processes. At high wall superheat levels, transition boiling or film boiling can also occur. The transition from nucleate boiling to one of these regimes is termed a *departure from nucleate boiling* (DNB) or the CHF condition. However, the heat-transfer performance of an evaporator under transition or film boiling conditions is so poor that equipment is not usually designed to operate under such conditions.

Because low-quality or subcooled flow boiling are nucleate boiling dominated, the heat-transfer coefficient in these regimes is often predicted using a nucleate boiling correlation developed as a fit to pool boiling data. The usefulness of such an approach is a consequence of the fact that for most conditions of practical interest, nucleate boiling heat transfer is only weakly affected by liquid subcooling or liquid bulk convection.

For saturated convective boiling prior to dryout, relations to predict the heat-transfer coefficient have typically been formulated to impose a gradual suppression of nucleate boiling and gradual

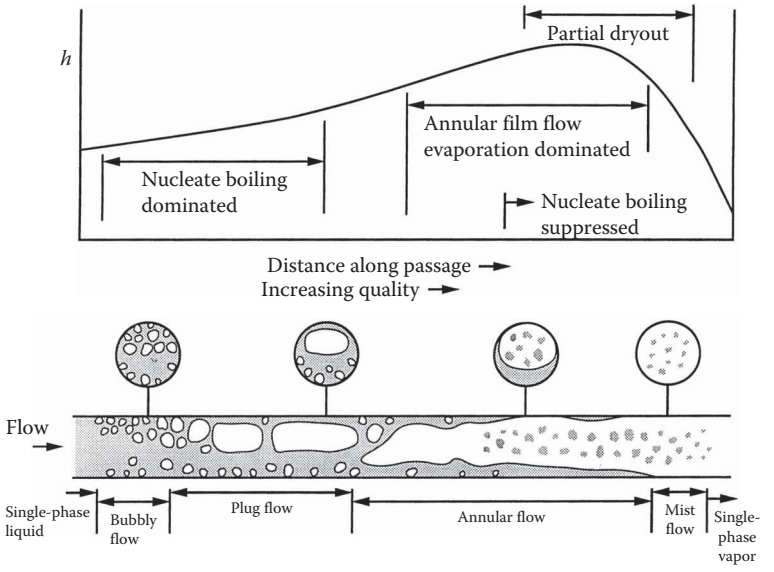

FIGURE 3.4.5 Qualitative variation of the heat-transfer coefficient h and flow regime with quality for internal convective boiling in a horizontal tube at moderate wall superheat.

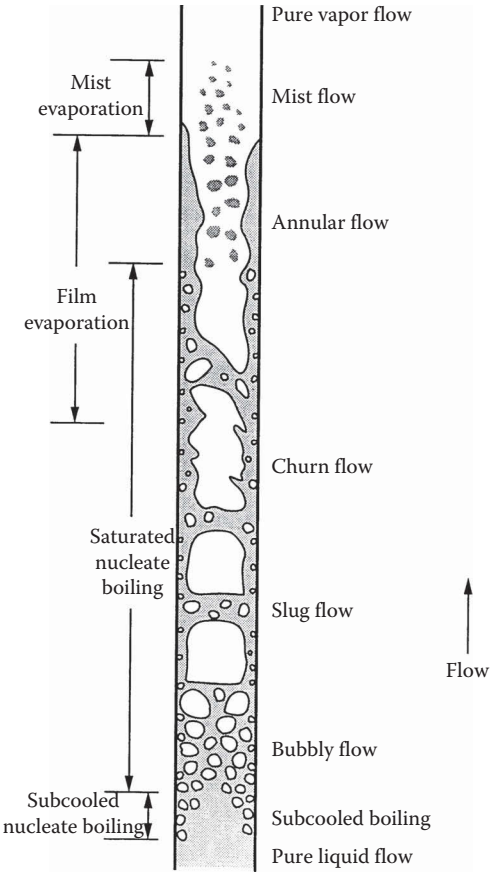

FIGURE 3.4.6 Flow regimes and boiling mechanisms for upflow convective boiling in a vertical tube at moderate wall superheat.

increase in liquid film evaporation heat transfer as the quality increases. A number of correlations based on such an approach have been developed. An early correlation of this type developed by Chen (1966) has been widely used. One of the better tools of this type for predicting the heat-transfer coefficient h is the correlation method proposed by Kandlikar (1991), which was developed to fit a very broad spectrum of heat-transfer data for flow boiling in vertical and horizontal tubes. For this method, the heat-transfer coefficient is computed as follows:

$$h = \text{the maximum of} \begin{Bmatrix} h_{\text{NBD}} \\ h_{\text{CBD}} \end{Bmatrix}, \tag{3.4.12}$$

where for the nucleate boiling dominant regime

$$h_{\text{NBD}} = 0.6683 \left(\frac{\rho_l}{\rho_v} \right)^{0.1} x^{0.16} (1-x)^{0.64} f_2 (\text{Fr}_{\text{le}}) h_{\text{le}} + 1058.0\ \text{Bo}^{0.7} F_{\text{K}} (1-x)^{0.8} h_{\text{le}} \tag{3.4.13}$$

and for the convective boiling dominant regime

$$h_{\mathrm{CBD}} = 1.1360\left(\frac{\rho_{\mathrm{l}}}{\rho_{\mathrm{v}}}\right)^{0.45} x^{0.72}\left(1-x\right)^{0.08} f_2\left(\mathrm{Fr}_{\mathrm{le}}\right) h_{\mathrm{le}} + 667.2\ \mathrm{Bo}^{0.7} F_{\mathrm{K}}\left(1-x\right)^{0.8} h_{\mathrm{le}}. \tag{3.4.14}$$

In this correlation, h_{le} is the single-phase heat-transfer coefficient for the liquid phase flowing alone, and Bo is the boiling number defined as:

$$\mathrm{Bo} = \frac{q''}{G h_{\mathrm{lv}}}. \tag{3.4.15}$$

Kandlikar (1991) later proposed use of the Petukhov–Popov (1963) and Gnielinski (1976) correlations to predict h_{le} because these appeared to better account for the Prandtl number effect for different fluids. For $0.5 \le \mathrm{Pr_l} \le 2000$ and $2300 \le \mathrm{Re_{le}} < 10^4$, h_{le} is therefore computed using the correlation of Gnielinski (1976)

$$h_{\mathrm{le}} = \left(\frac{k_{\mathrm{l}}}{D}\right)\frac{\left(\mathrm{Re_{le}} - 1000\right)\mathrm{Pr_l}\left(f/2\right)}{1 + 12.7\left(\mathrm{Pr_l}^{2/3} - 1\right)\left(f/2\right)^{0.5}}, \tag{3.4.16}$$

and for $0.5 \le \mathrm{Pr_l} \le 2000$ and $10^4 \le \mathrm{Re_{le}} \le 5 \times 10^6$, h_{le} is computed using the correlation of Petukhov and Popov (1963)

$$h_{\mathrm{le}} = \left(\frac{k_{\mathrm{l}}}{D}\right)\frac{\mathrm{Re_{le}}\mathrm{Pr_l}\left(f/2\right)}{1.07 + 12.7\left(\mathrm{Pr_l}^{2/3} - 1\right)\left(f/2\right)^{0.5}}. \tag{3.4.17}$$

In the aforementioned relations for h_{le}, f is the friction factor computed as

$$f = \left[1.58\ \ln\left(\mathrm{Re_{le}}\right) - 3.28\right]^{-2}. \tag{3.4.18}$$

$$\mathrm{Re_{le}} = \frac{GD}{\mu_{\mathrm{l}}}, \tag{3.4.19}$$

and the function $f_2(\mathrm{Fr_{le}})$ is defined as

$$f_2\left(\mathrm{Fr_{le}}\right) = \begin{cases} \left(25\mathrm{Fr_{le}}\right)^{0.3} & \text{for } \mathrm{Fr_{le}} < 0.04 \text{ for horizontal tubes} \\ 1 & \text{for } \mathrm{Fr_{le}} > 0.04 \text{ for horizontal tubes and for vertical tubes.} \end{cases} \tag{3.4.20}$$

Note that on the right side of Equations 3.4.13 and 3.4.14, the first term accounts for the convective effect, and the second term accounts for the nucleate boiling effect. The factor F_{K} is a fluid-dependent parameter, values of which are listed for various fluids in Table 3.4.1.

Methods for predicting the conditions at which dryout or a DNB transition occurs have typically been empirical in nature. Based on fits to extensive data, Levitan and Lantsman (1975) recommended the following relations for the DNB heat flux and the quality at which dryout occurs during flow boiling of water in a tube with an 8 mm diameter.

$$q''_{\mathrm{crit}} = \left[10.3 - 7.8\left(\frac{P}{98}\right) + 1.6\left(\frac{P}{98}\right)^2\right]\left(\frac{G}{1000}\right)^{1.2\left\{\left[0.25(P-98)/98\right]-x\right\}} e^{-1.5x}, \tag{3.4.21}$$

TABLE 3.4.1
Fluid Constant Values for the Kandlikar (1991) Correlation

Fluid	F_K
Water	1.00
R-11	1.30
R-12	1.50
R-13B1	1.31
R-22	2.20
R-113	1.30
R-114	1.24
R-134a	1.63
R-152a	1.10
Nitrogen	4.70
Neon	3.50

$$x_{\text{crit}} = \left[0.39 + 1.57\left(\frac{P}{98}\right) - 2.04\left(\frac{P}{98}\right)^2 + 0.68\left(\frac{P}{98}\right)^3\right]\left(\frac{G}{1000}\right)^{-0.5}. \tag{3.4.22}$$

In these relations, q''_{crit} is in MW/m^2, P is the pressure in bar, and G is in kg/m^2·s. To obtain values of q''_{crit} and x_{crit} for diameters other than 8 mm, Levitan and Lantsman (1975) recommended that the 8 mm values from these relations be corrected as follows:

$$q''_{\text{crit}} = \left(q''_{\text{crit}}\right)_{8\,\text{mm}}\left(\frac{8}{D}\right)^{1/2}, \tag{3.4.23}$$

$$x_{\text{crit}} = \left(x_{\text{crit}}\right)_{8\,\text{mm}}\left(\frac{8}{D}\right)^{0.15}, \tag{3.4.24}$$

where D is the diameter in millimeters. A good generalized empirical correlation for predicting dryout or CHF conditions in vertical uniformly heated tubes is that recently proposed by Katto and Ohno (1984).

In many cases, post-dryout mist flow evaporation is driven primarily by convective transport from the tube wall to the gas and then to the entrained droplets. In some circumstances, impingement of droplets onto the heat surface and radiation interactions may also be important. In cases where convection is dominant, predictions of the heat-transfer coefficient have been developed by modifying a single-phase correlation for the entire flow as vapor with a correction factor, which accounts for the presence of the entrained droplets. Often this correction factor has been presumed to be a function of property ratios. An example of such an approach is the correlation of Dougall and Rohsenow (1963) for which the heat-transfer coefficient h is given by

$$\frac{hD}{k_v} = 0.023\left[\left(\frac{GD}{\mu_v}\right)\left(x + \frac{\rho_v}{\rho_l}(1-x)\right)\right]^{0.8} \text{Pr}_{v,\text{sat}}^{0.4}. \tag{3.4.25}$$

For further information on mechanisms of convective boiling, see the texts of Collier and Thome (2002), Stephan (1992), and Carey (2008).

Thermophysics of Condensation Processes

As in the case of boiling, surface tension effects, surface wetting characteristics, metastable phase stability, and surface morphology also can play important roles in condensation processes. As a result of interfacial tension, the pressure inside a spherical liquid droplet of radius r must exceed that in the surrounding liquid by $2\sigma/r$, so that the liquid and surrounding vapor pressures at equilibrium are related as

$$P_l = P_v + \frac{2\sigma}{r} \tag{3.4.26}$$

A consequence of this and basic thermodynamics is that at equilibrium the surrounding vapor must actually be slightly supersaturated. The amount of supersaturation required at equilibrium increases as the radius of curvature of the bubble interface decreases.

For a liquid droplet on a solid surface with a specified volume, the wetting contact angle dictates the radius of curvature of the droplet interface. Because of the linkage between the interface curvature and the required equilibrium supersaturation, the wetting behavior thus determines the level above which the vapor supersaturation must be raised for the droplet to grow. Steady condensation on the droplet interface can be sustained only if the vapor is driven beyond this supersaturation level by cooling or pressurization. For such conditions, the vapor is in the metastable supersaturated range indicated in Figure 3.4.2.

Condensation on external surfaces of a body immersed in a gas phase generally falls into one or two categories: *dropwise condensation* or *film condensation*. In dropwise condensation, the liquid-phase condensate collects as individual droplets, which grow in size with time on the cold surface. This mode of condensation is most likely when the liquid poorly wets the solid surface. When the condensation rate is high or the liquid readily wets the surface, a film of liquid condensate covers the solid surface, and the process is referred to as film condensation.

Dropwise Condensation

Dropwise condensation may occur on a solid surface cooled below the saturation temperature of a surrounding vapor when the surface is poorly wetted except at locations where well-wetted contaminant nuclei exist. The poorly wetted surface condition can result from contamination or coating of the surface with a substance, which is poorly wetted by the liquid phase of the surrounding vapor. In practice, this can be achieved for steam condensation by (1) injecting a nonwetting chemical into the vapor, which subsequently deposits on the surface, (2) introducing a substance such as a fatty (i.e., oleic) acid or wax onto the solid surface, or (3) by permanently coating the surface with a low-surface-energy polymer or a noble metal. The effects of the first two methods are generally temporary, since the resulting surface films eventually are dissolved or eroded away. More recently, researchers have been exploring ways to microstructure or nanostructure the surface to promote dropwise condensation and enhance heat transfer. Examples of this type of research are described in publications by Ma et al. (2000), Varanasi et al. (2009), Dietz et al. (2010), and Lee et al. (2013).

During dropwise condensation, the condensate is usually observed to appear in the form of droplets, which grow on the surface and coalesce with adjacent droplets. When droplets become large enough, they are generally removed from the surface by the action of gravity or drag forces resulting from the motion of the surrounding gas. As the drops roll or fall from the surface, they merge with droplets in their path, effectively sweeping the surface clean of droplets. Droplets then begin to grow anew on the freshly exposed solid surface. This sweeping and renewal of the droplet growth process is responsible for the high heat transfer coefficients associated with dropwise condensation. Theoretical aspects of dropwise condensation are described in publications by Tanaka (1975, 1979), Wu et al. (2001), Vemuri and Kim (2006), and Lee et al. (2013). A discussion of correlations for the heat transfer coefficient associated with dropwise condensation is provided in the review article by Merte (1973) and the more recent work by Bonner (2013).

External Film Condensation

If the liquid phase fully wets a cold surface in contact with a vapor near saturation conditions, the conversion of vapor to liquid will take the form of film condensation. As the name implies, the condensation takes place at the interface of a liquid film covering the solid surface. Because the latent heat of vaporization must be removed at the interface to sustain the process, the rate of condensation is directly linked to the rate at which heat is transported across the liquid film from the interface to the surface.

The classic integral analysis of Nusselt (1916) for laminar falling-film condensation on a vertical surface considers the physical circumstances shown in Figure 3.4.7. The surface exposed to a motionless ambient of saturated vapor is taken to be isothermal with a temperature below the saturation temperature. Note that although a vertical surface is considered here, the analysis is identical for an inclined surface, except that the gravitational acceleration g is replaced by g sin Ω, with Ω being the angle between the surface and the horizontal. Because the liquid film flows down the surface because of gravity, this situation is sometimes referred to as *falling-film condensation*.

In its simplest form, the classic Nusselt analysis incorporates the following idealizations: (1) laminar flow, (2) constant properties, (3) that subcooling of liquid is negligible in the energy balance, (4) that inertia effects are negligible in the momentum balance, (5) that the vapor is stationary and exerts no drag, (6) that the liquid–vapor interface is smooth, and (7) that heat transfer across film is only by conduction (convection is neglected). With these idealizations, the following relation for the local heat transfer coefficient h can be obtained

$$\frac{hz}{k_l} = \left[\frac{\rho_l (\rho_l - \rho_v) g h_{fg} z^3}{4 k_l \mu_l (T_{sat} - T_w)} \right]^{1/4} . \tag{3.4.27}$$

Modified versions of this analysis have been subsequently developed that relax many of these assumptions. Laminar film condensation on a vertical surface can also be analyzed with a full boundary layer formulation. An example of this type of approach is the analysis presented by Sparrow and Gregg (1959).

The analyses described earlier do not include two physical mechanisms that can significantly affect the transport: (1) the effects of waves on the liquid–vapor interface and (2) interfacial vapor shear drag on the interface. The effects of interfacial shear have been studied analytically by numerous investigators. The effects of surface waves on laminar film condensation are more difficult to incorporate into theoretical analyses. In general, interfacial waves are expected to

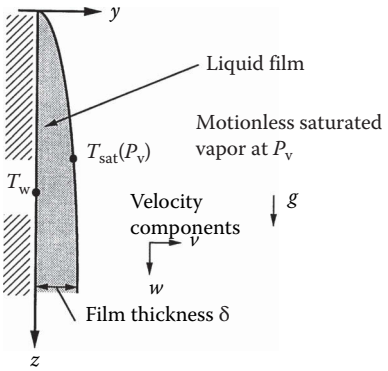

FIGURE 3.4.7 System model for the Nusselt analysis of falling-film condensation.

enhance convective heat transport in the film since it intermittently thins the film, increases the interfacial area, and induces mixing. Because of these effects, laminar film condensation heat transfer data are often significantly higher than the values predicted by simple boundary layer models.

As for any boundary layer flow, when the film Reynolds number becomes large enough, it is expected that a transition to turbulent flow will occur. Eddy diffusivity models of the resulting turbulent transport have been developed by Seban (1954), Dukler (1960), and others. This methodology was later extended to evaporation of a falling liquid film (see, e.g., Mills and Chung, 1973).

Subsequent studies (see, e.g., Mills and Chung, 1973) have suggested that the presence of the interface tends to damp larger turbulent eddies near the interface in the liquid film. This implies that a viscous sublayer exists at the interface as well as at the wall. Recent efforts to model turbulent falling-film evaporation and condensation processes have therefore included a variation of the eddy viscosity in which it goes to zero at both the wall and the interface. The analysis tools and correlations described earlier work reasonably well for values of liquid Prandtl number above 1. However, deviation of the predictions using these methods from heat transfer data for liquid metals can be quite significant.

Because of its importance to the design of tube-and-shell condensers, condensation on the outside of horizontal tubes has been the subject of numerous studies. The length of the tube perimeter over which the condensate flows is usually small for commonly used tubes. Consequently, the film Reynolds number is usually low and the flow in the liquid film is laminar.

With slight modification, the Nusselt (1916) analysis of laminar falling-film condensation over a flat plate can be adapted to film condensation on an isothermal horizontal cylinder. Doing so yields the following relation for the mean heat transfer coefficient:

$$\frac{\bar{h}D}{k_l} = 0.728\left[\frac{(\rho_l - \rho_v)gh_{fg}D^3\,\mathrm{Pr}_l}{\rho_l \nu_l^2 c_{pl}(T_{sat} - T_w)}\right]^{1/4}. \tag{3.4.28}$$

Selin (1961) found that better agreement with film condensation data for horizontal tubes was obtained by replacing the constant factor in Equation 3.4.28 by 0.61. Correlations similar to this single-tube relation have also been developed for the average condensation heat transfer coefficient for banks of round tubes.

Analytical treatment of laminar film condensation on a sphere is virtually the same as that for a horizontal cylinder. The only differences result from the angular variation of the body perimeter for a spherical geometry. A general analytical prediction of the local heat transfer coefficient for laminar film condensation on arbitrary axisymmetric bodies has been developed by Dhir and Lienhard (1971).

Condensation in the Presence of a Noncondensable Gas

In nature and in a number of technological applications, condensation of one component vapor in a mixture may occur in the presence of other noncondensable components. The most common example is the condensation of water vapor in the air on a cold solid surface. If the component gases are considered to be a mixture of independent substances, condensation of one component vapor will occur if the temperature of the surface is below the saturation temperature of the pure vapor at its partial pressure in the mixture. This temperature threshold is referred to as the *dew point* of the mixture.

Because only the vapor is condensed, the concentration of the noncondensable gas at the interface is higher than its value in the far ambient. This, in turn, decreases the partial pressure of the vapor at the interface below its ambient value. The corresponding saturation temperature at the interface is therefore lower than the bulk temperature. The resulting depression of the

interface temperature generally reduces the condensation heat transfer rate below that, which would result for pure vapor alone under the same conditions. Space limitations here preclude a detailed discussion of the effects of noncondensable gases. The interested reader may find more extensive discussions of this topic in the references by Collier and Thome (2002) and Carey (2008).

Internal Convective Condensation

In most power and refrigeration systems, the flow in the condenser is either horizontal or vertically downward. Figure 3.4.8 schematically depicts a typical condensation process in a horizontal round tube. Superheated vapor enters the tube and at the exit end the liquid is subcooled. At a point some distance downstream of the entrance, vapor begins to condense on the walls of the tube. The location at which this occurs is at or slightly before the bulk flow reaches the equilibrium saturation condition. In most condensers, the liquid readily wets the interior of the tube and at high vapor volume fractions the liquid forms a thin liquid film on the interior wall of the tube.

The vapor velocity is generally high at the inlet end of the condenser tube, and the liquid film is driven along the tube by strong vapor shear on the film. At low vapor flow rates, some stratification may occur and the film may be thicker on the bottom of the horizontal tube. At high vapor flow rates, turbulent stresses acting on the liquid may tend to keep the thickness of the liquid film nominally uniform over the perimeter of the tube.

In most condenser applications, shear-dominated annular flow persists to very low qualities and the overwhelming majority of the heat transfer occurs in this regime. The very last stage of the condensation process, corresponding to qualities less than a few percent, may occur in slug, plug, or bubbly two-phase flow. Generally, these regimes represent such a small portion of the overall heat transfer in the condenser that some inaccuracy in estimating the heat transfer coefficient for them is tolerated. As a first estimate, the heat transfer coefficient may be predicted using a correlation for pure single-phase liquid flow in the tube at the same total flow rate, or a correlation for annular flow condensation may simply be extrapolated to zero quality.

Because most of the heat duty occurs in the annular flow regime, accurate prediction of the overall heat transfer performance of the condenser requires a predictive methodology that accurately treats the transport in this regime. For this reason, the form of most correlation methods for predicting local convective condensation heat transfer coefficients is optimized to match data in the annular flow regime. One example of such a correlation is the following relation for the local heat transfer coefficient for annular flow condensation proposed by Traviss et al. (1973):

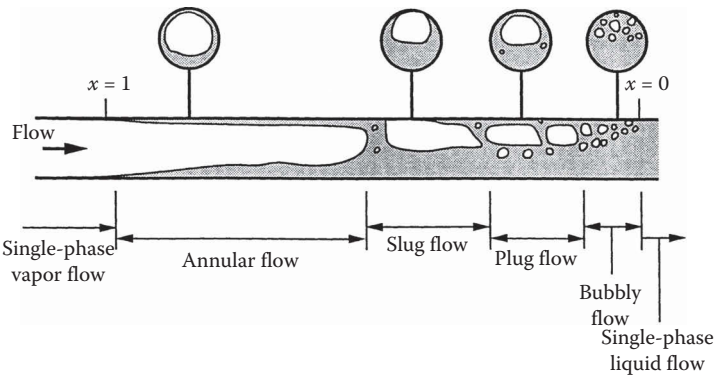

FIGURE 3.4.8 Flow regimes during horizontal cocurrent flow with condensation.

$$\frac{hD}{k_l} = \frac{0.15 \mathrm{Pr}_l \mathrm{Re}_l^{0.9}}{F_T} \left[\frac{1}{X_{tt}} + \frac{2.85}{X_{tt}^{0.476}} \right], \tag{3.4.29}$$

where

$$\mathrm{Re}_l = \frac{G(1-x)D}{\mu_l}, \quad X_{tt} = \left(\frac{1-x}{x} \right)^{0.9} \left(\frac{\rho_v}{\rho_l} \right)^{0.5} \left(\frac{\mu_l}{\mu_v} \right)^{0.1}, \tag{3.4.30}$$

and F_T is given by

$$\begin{aligned} F_T &= 5\mathrm{Pr}_l + 5\ln\{1 + 5\mathrm{Pr}_l\} + 2.5\ln\{0.0031\mathrm{Re}_l^{0.812}\} && \text{for} \quad \mathrm{Re}_l > 1125 \\ &= 5\mathrm{Pr}_l + 5\ln\{1 + \mathrm{Pr}_l(0.096\mathrm{Re}_l^{0.585} - 1)\} && \text{for} \quad 50 < \mathrm{Re}_l < 1125 \\ &= 0.707\mathrm{Pr}_l\mathrm{Re}_l^{0.5} && \text{for} \quad \mathrm{Re}_l < 50 \end{aligned} \tag{3.4.31}$$

Carey (2008) has shown that the generic form of this correlation can be derived from a theoretical model of annular flow condensation in a round tube. Several correlations of this general type have been developed as fits to experimental data; see Carey (2008) for a summary.

Correlation methods of this form have also been proposed for microchannels and channels of noncircular cross section. Wang and Rose (2005) noted that the data from several experimental investigations (see, e.g., Garimella, 2003) indicate that annular flow spans an increasing portion of the condensation process as the hydraulic diameter of the passage decreases. As a consequence, annular flow has been a main focus of efforts to empirically and theoretically predict convective condensation heat transfer in microchannels, and correlations of the form described earlier may be expected to work well for this type of passage. For annular flow condensation in rectangular microchannels, Wang et al. (2002) found that the following predictive correlation provided a best fit to 700 annular flow data for convective condensation heat transfer:

$$\frac{hD_h}{k_l} = 0.027\mathrm{Pr}_l\mathrm{Re}_l^{0.6792} x^{0.2208} \left(\frac{1.376 + 8X_{tt}^{1.655}}{X_{tt}^2} \right)^{0.5}. \tag{3.4.32}$$

In this equation, D_h is the hydraulic diameter of the rectangular microchannel, and the Reynolds number $\mathrm{Re}_l = G(1-x)D_h/\mu_l$ for the liquid flowing alone is based on D_h. At specified local conditions, this empirical correlation generally predicts a local heat transfer coefficient value that is lower than that predicted by the large round tube correlations discussed earlier. As noted by Wang et al. (2002), this suggests that the annular film in a small rectangular tube has a different configuration than that in round tubes for the same conditions.

A correlation methodology that can be used to predict internal convective condensation heat transfer for slug, plug, or wavy stratified flow has also been proposed by Rossen and Meyers (1965).

The predictions of the correlations discussed in this section may vary significantly for a given set of conditions. When possible, a correlation should be selected, which has been tested against data for conditions close to those for the application of interest. To predict the overall heat transfer performance of a condenser, methods to predict the local heat transfer coefficient must be combined with a scheme to numerically integrate finite-difference forms of the energy, mass, and momentum balances in the tube. For further information on such schemes, see the references by Collier and Thome (2002) and Carey (2008) (Figure 3.4.9).

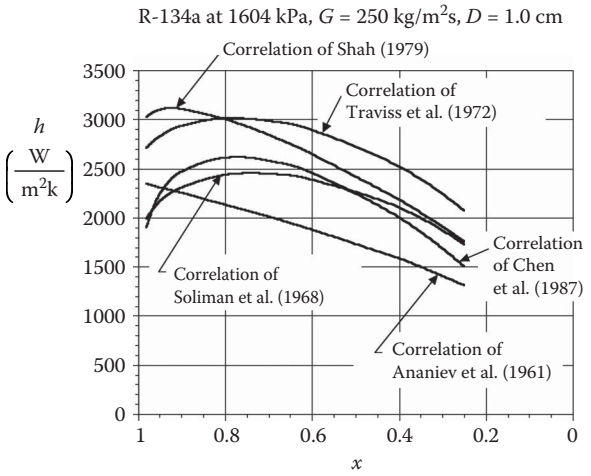

FIGURE 3.4.9 Comparison of the variation of h with x predicted by four correlation methods for internal convective condensation. References cited in this figure are listed in Chapter 11 of Carey (2008).

Defining Terms

Critical heat flux (CHF)	A maximum heat flux condition that characterizes the transition between nucleate boiling and transition boiling or film boiling.
Dropwise condensation	Condensation of vapor into liquid in discrete droplets, usually attained when a cold surface is poorly wetted by the liquid phase.
Film boiling	Generation of vapor at the interface of a vapor film entirely covers the hot surface.
Film condensation	Condensation of vapor onto the interface of a liquid film that completely covers a cold surface.
Minimum heat flux	A minimum heat flux condition on the classic boiling curve that characterizes the transition between film boiling and transition boiling. Also, sometimes referred to as the Leidenfrost point, it is a lower bound for heat flux values at which stable film boiling may occur.
Nucleate boiling	Generation of vapor at a hot surface by formation of bubbles at discrete nucleation sites with full liquid wetting of the surface.
Polar molecules	Molecules that have a permanent electric dipole moment. Examples include water and ammonia.
Pool boiling	Generation of vapor at the surface of a hot body immersed in an extensive liquid pool.
Transition boiling	Generation of vapor at a hot surface with intermittent or partial liquid wetting of the surface.

Further Information

The texts *Heat Transfer in Condensation and Boiling* by K. Stephan (Springer-Verlag, New York, 1992) and *Liquid–Vapor Phase Change Phenomena* by V.P. Carey (Taylor and Francis, Washington, DC, 2008 provide an introduction to the physics of boiling and condensation processes. The text by J.G. Collier and J.R. Thome, *Convective Boiling and Condensation* (3rd ed., McGraw-Hill, New York, 2002), summarizes more-advanced elements of convective boiling and condensation processes. The *ASHRAE Handbook of Fundamentals* (American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Atlanta, GA, 2013) provides some information on boiling and condensation heat transfer and is a good source of thermophysical property data needed to analyze boiling and condensation processes.

3.4.2 Particle Gas Convection

John C. Chen

Introduction

Heat transfer in two-phase systems involving gas and solid particles is encountered in several types of operations important in chemical, power, and environmental technologies. Chief among these are gas fluidized beds which are widely used to achieve either physical processing or chemical reactions that require interfacial contact between gas and solid particles. Currently, fluidized beds operate in either the *bubbling regime* or the *fast-circulating regime*. In the first case, particles are retained in the fluidized bed while the gas passes upward past the particles, partially as rising bubbles. In the second case, gas velocities exceed terminal velocity for the individual particles and the two phases flow through the fluidized bed in cocurrent upward flow. For those applications which require thermal control, convective heat transfer between the fluidized medium and heat transfer surfaces (either immersed tubes or the vessel walls) is an essential element of the process design.

Bubbling Fluidized Beds

Bubbling fluidization occurs when the superficial gas velocity exceeds a critical value wherein the gravitational body force on the solid particles is balanced by the shear force between particles and flowing gas. The superficial gas velocity at this condition, commonly called the minimum fluidization velocity (U_{mf}), marks the boundary between gas flow through packed beds and gas flow in fluidized beds. Wen and Yu (1966) derived the following general equation to estimate U_{mf} for spherical particles:

$$\mathrm{Re}_{mf} = \left[(33.7)^2 + 0.0408\,\mathrm{Ar} \right]^{1/2} - 33.7 \tag{3.4.33}$$

where

$$\mathrm{Re}_{mf} = \text{particle Reynolds number at } U_{mf} = \frac{U_{mf} d_p \rho_g}{\mu_g}$$

$$\mathrm{Ar} = \text{Archimedes number} = \frac{d_p^3 \rho_g (\rho_s - \rho_g) g}{\mu_g^2}$$

Increasing gas velocity beyond minimum fluidization causes the excess gas to collect into discrete bubbles that grow and rise through the fluidized matrix of solid particles. In this bubbling fluidization regime, the total pressure drop over the height of the fluidized bed, H, is equal to the hydrostatic pressure of the solid mass,

$$\Delta P = g \rho_s (1 - \varepsilon) H \tag{3.4.34}$$

where ε = volume fraction of gas (void fraction).

Tubes carrying cooling or heating fluids are often immersed in bubbling fluidized beds to extract or add thermal energy. The effective heat transfer coefficient at the surface of such tubes has been the objective of numerous experimental and analytical investigations. Data for the circumferentially averaged heat transfer coefficient for horizontal tubes are shown in Figure 3.4.10 for various types of solid particles. Characteristics representative of such systems are

- The heat transfer coefficient increases sharply as the gas velocity exceeds minimum fluidization velocity.
- After the initial increase, the heat transfer coefficient remains fairly constant over a significant range of the gas velocity beyond minimum fluidization velocity.

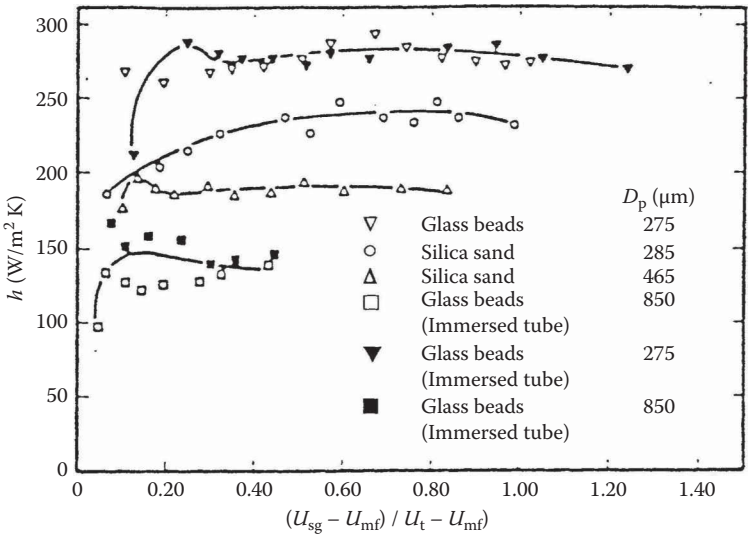

FIGURE 3.4.10 Average heat transfer coefficients for horizontal tubes immersed in bubbling fluidized beds. (From Biyikli, K. et al., *AIChE J.*, 29(5), 712–716, 1983. With permission.)

- The absolute magnitude of the heat transfer coefficient is severalfold greater than single-phase gas convection at the same superficial velocity.
- The heat transfer coefficient increases as particle size decreases.

Kunii and Levenspiel (1991) have shown that increasing gas pressure and density significantly increases the magnitude of the heat transfer coefficient as well as promoting the occurrence of minimum fluidization at a lower value of superficial gas velocity. The effect of bundle spacing is insignificant at 1-atm pressure but becomes increasingly more important as gas pressure and density increase. The data of Jacob and Osberg (1957) indicate that the convective heat transfer coefficient in fluidized beds increases with increasing thermal conductivity of the gas phase, for any given particle size.

Several different types of correlations have been suggested for predicting convective heat transfer coefficients at submerged surfaces in bubbling fluidized beds. The first type attributes the enhancement of heat transfer to the scouring action of solid particles on the gas boundary layer, thus decreasing the effective film thickness. These models generally correlate a heat transfer Nusselt number in terms of the fluid Prandtl number and a modified Reynolds number with either the particle diameter or the tube diameter as the characteristic length scale. Examples are

Leva's correlation for vertical surfaces and larger particles (Leva and Grummer, 1952);

$$\mathrm{Nu}_{\mathrm{dp}} = \frac{h_c d_p}{k_g} = 0.525\left(\mathrm{Re}_p\right)^{0.75} \tag{3.4.35}$$

where

$$\mathrm{Re}_p = \frac{d_p \rho_g U}{\mu_g}$$

Vreedenberg's (1958) correlation for horizontal tubes refers to the particle of diameter D_t.

$$\mathrm{Nu}_{\mathrm{Dt}} = \frac{h_c D_t}{k_g} = 420\left(\frac{\rho_s}{\rho_g}\mathrm{Re}_t\right)^{0.3}\left(\frac{\mu_g^2}{g\rho_s^2 d_p^3}\right)^{0.3}\left(\mathrm{Pr}_g\right)^{0.3} \tag{3.4.36}$$

for

$$\left(\frac{\rho_s}{\rho_g}\mathrm{Re}_t\right) > 2250$$

where

$$\mathrm{Re}_t = \frac{D_t \rho_g U}{\mu_g}$$

Molerus and Scheinzer (1989) developed an alternative type of correlation based on the supposition that the heat transfer is dominated by gas convection through the matrix of particles in the vicinity of the heat transfer surface. Their correlation takes the form:

$$\mathrm{Nu} = \frac{h_c d_p}{k_g} = 0.0247(\mathrm{Ar})^{0.4304}(\mathrm{Pr})^{0.33} \tag{3.4.37}$$

Figure 3.4.11 shows comparison of this model with experimental data obtained at three different pressures. The solid curve represents the relationship for fixed beds, while the dashed lines represent the behavior for fluidized beds (i.e., Equation 3.4.37) upon exceeding minimum fluidization.

A third type of model considers the heat transfer surface to be contacted alternately by gas bubbles and packets of packed particles, leading to a surface renewal process for heat transfer. Mickley and Fairbanks (1955) provided the first analysis of this renewal mechanism. Ozkaynak and Chen (1980) showed that if experimentally measured values of the packet contact time and residence times are used in the packet model analysis, excellent agreement is obtained.

Fast-Circulating Fluidized Beds

Fast fluidization occurs when the superficial gas velocity exceeds the terminal velocity of the solid particles, causing the particles to be suspended in cocurrent upward flow with the gas. This upward flow

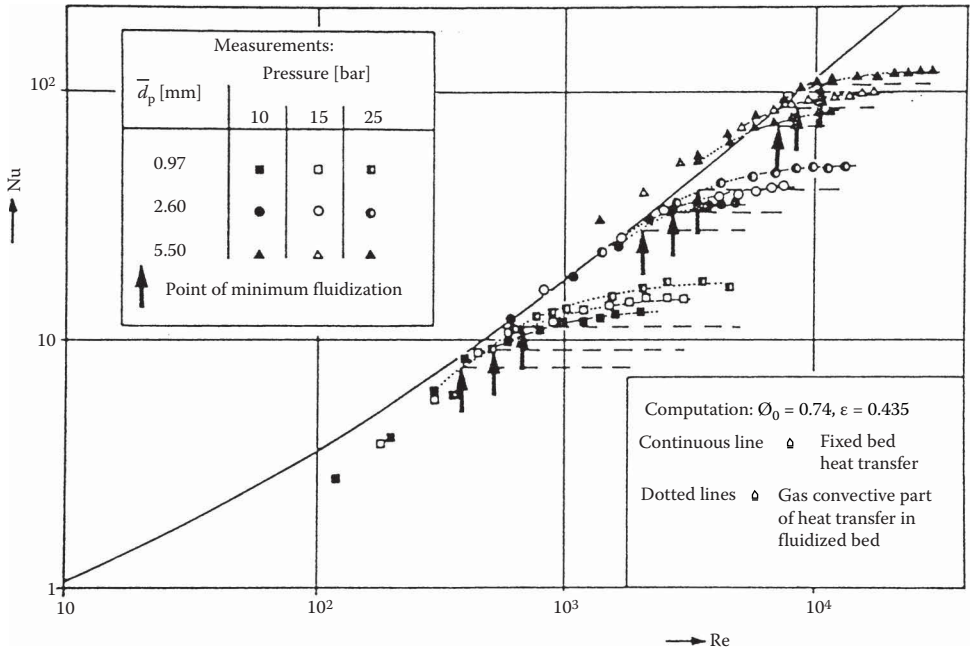

FIGURE 3.4.11 Correlation of Molerus and Scheinzer compared with experimental data (1989).

occurs in "rise reactors" wherein desired physical or chemical reactions occur. In most applications, the two-phase flow exits the top of the riser into a cyclone where the gas phase is separated and exhausted while the solid particles are captured and returned for reinjection at the bottom of the riser. The volumetric concentration of solid particles in these fast fluidized beds (FFBs) tend to be fairly dilute, often with average concentrations of less than 2%. Heat exchange with the particle/gas suspension is usually accomplished through the vertical wall surfaces or through vertical tubes immersed in the duct.

The heat transfer coefficient at vertical surfaces FFBs has been found to increase with increasing solid concentration, aside from other second-order parametric effects. Figure 3.4.12 shows heat transfer coefficients experimentally measured by Dou et al. (1994) for an FFB operating with sand particles of 124 μm mean diameter. Figure 3.4.12b shows that the heat transfer coefficient increased with solid mass flux, for a constant superficial gas velocity. Figure 3.4.12a shows that the heat transfer coefficient decreased parametrically with superficial gas velocity for a constant solid mass flux. Both figures indicate that heat transfer coefficients decrease with increasing elevation in the riser duct. These three parametric trends are all consistent with the hypothesis that heat transfer in FFBs increases with increasing concentration of the solid phase.

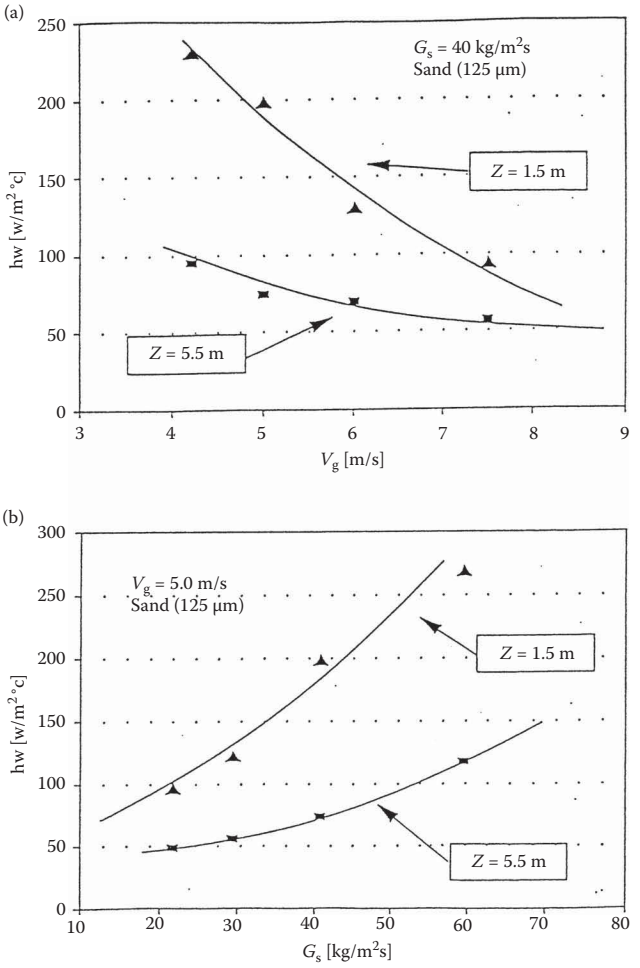

FIGURE 3.4.12 Heat transfer coefficients in fast fluidized beds; V_g is superficial gas velocity, G_s is mass flux of particles, and Z is elevation in FFB. (From Dou, S. et al., 1992. *Fluidization VII,* Engineering Foundation, 793–802. With permission.)

It is generally accepted that the effective heat transfer coefficient for surfaces in FFBs have contributions for gas-phase convection, particle-induced convection, and radiation:

$$h = h_g + h_p + h_r \tag{3.4.38}$$

In contrast to the situation in dense-bubbling fluidized beds, the relatively dilute concentration of solid particles in FFBs often results in significant contributions from all three heat transfer mechanisms. The radiation coefficient can be obtained by a gray body model suggested by Grace (1985). The contribution of the gas phase convection (h_g) is commonly estimated based on correlations for gas flow alone at the same superficial gas velocity. Although the presence of particles may alter the turbulence characteristic of this gas flow, any errors caused by this procedure are usually small since h_g is generally smaller than the particle-phase convective coefficient h_p.

For most FFBs, the particle convective contribution to heat transfer is most important and the prediction of h_p is the major concern in thermal design. Unfortunately, mechanistically based models are still lacking and most design methods rely on empirical correlations which often combine the contributions of gas and particle phases into a single convective heat transfer coefficient (h_c). One such correlation proposed by Wen and Miller (1961) is

$$\mathrm{Nu}_{dp} = \frac{h_c d_p}{k_g} = \left(\frac{C_{pp}}{C_{pg}}\right)\left(\frac{\rho_{susp}}{\rho_p}\right)^{0.3}\left(\frac{V_t}{g d_p}\right)^{0.21} \mathrm{Pr}_g \tag{3.4.39}$$

where V_t=terminal velocity of particle.

Other correlations have been proposed by Fraley (1983) and Martin (1984). These correlations are useful as a starting point but have not yet been verified over wide parametric ranges. Large deviations can occur when compared with measurements obtained outside of the experimental parametric ranges.

3.4.3 Melting and Freezing

Vasilios Alexiades and Jan Kośny

Introduction

Phase-change processes and latent heat storage play an important role in many aspects of our lives, including materials manufacturing (casting of metals and plastics, crystal growth), food preservation (freezing and thawing, freeze dehydration), medical technologies (cryosurgery, cryopreservation of tissues), transportation (aircraft icing), powerline and pipeline icing, and energy conservation (latent heat storage), among many others.

Melting and freezing are among the most familiar processes in everyday life. Melting occurs when a solid is heated above its melting point T_m and changes phase from solid to liquid. At T_m, the solid and liquid phases coexist in thermodynamic equilibrium. The melting point of a pure substance depends on pressure; its value is usually specified at standard (atmospheric) pressure. Conversely, lowering the temperature of a liquid below T_m normally results in formation of a solid—the process is called freezing, solidification, or crystallization.

The primary quantities involved in describing melting/freezing are: thermal energy (enthalpy), which consists of sensible heat and latent heat, along with temperature, composition, and pressure in some cases.

In a solid, atoms are held together by strong intermolecular forces, and vibrate about stable positions. Atoms in a liquid have higher (thermal) energy, are only loosely bound, and vibrate much more. It takes a certain amount of energy, L Joules per gram, to break the bonds of a solid and render it a liquid. This energy L is called *latent heat* of melting.

Physically, a change of phase occurs due to loss of thermodynamic stability in favor of another, more favorable, phase. Below T_m, the solid configuration has lower free energy, so it is more stable. At T_m, solid and liquid have the same free energy, but their enthalpies differ by L. Above T_m, liquid has lower free energy, so it is favored thermodynamically and thus, a solid melts by absorbing the latent heat. The most prominent feature is the absorption or release of latent heat. The region where this occurs is the *interface*, where the phases coexist and across which the enthalpy jumps by L. Its thickness may be a few Angstroms or several centimeters, and its structure may be very complex, depending on several factors (composition, rate of cooling, temperature gradients, surface tension, supercooling, etc.).

Mathematically, problems involving unknown interfaces are called moving boundary problems (often called free boundary problems when time-independent). The location of the interface, being unknown, renders such problems de facto *nonlinear*, the major source of difficulty in treating them.

The latent heat concept was introduced by Joseph Black (1728–1799) who found it experimentally in 1758–1762. Lame-Clapeyron in 1831 incorporated latent heat into heat conduction, and in the early 1860s, Franz Neumann (1798–1895) found the similarity solution that bears his name ("The Stefan Problem" section). Jozef Stefan (1835–1893) clearly formulated the Stefan problem in 1889 while studying freezing of soil (discussed later in "The Stefan Problem" section).

The melting point T_m and the latent heat L are found experimentally, usually with differential scanning calorimetry (DSC). Pure crystalline solids melt at a well-determined temperature T_m, whereas amorphous solids and mixtures or alloys typically melt over a range of temperatures.

Solidification and Supercooling

Freezing, or solidification, the reverse of melting, is a phase transition process in which a liquid turns into a solid when its temperature is lowered below its freezing point. Ideally, the freezing point and heat of fusion of a melt would be the same as the melting point and latent heat of melting of the material. However, creating a stable crystalline structure is much harder than taking one apart,

so the phenomenon of *supercooling* often arises (sometimes also referred to as "undercooling"), whereas superheating is very rare.

At the *microscopic level*, crystallization proceeds by nucleation and subsequent crystal growth. Thus, the first step in the process of crystallization is *nucleation*, in which molecules start to form nano-sized clusters, arranging themselves in the lattice pattern that defines the crystal structure of the material being solidified. There is an energy barrier for (homogeneous) nucleation: if a nucleus is too small, the amount of energy bound in its volume may not be sufficient to create its surface. Thus, the liquid may supercool significantly below T_m without crystalizing. However, this is a thermodynamically *metastable* state; small perturbations will induce rapid nucleation. The presence of seed crystals or foreign particles, even dust, provides sites for (heterogeneous) nucleation, reducing the degree of supercooling. Following nucleation, growth of stable nuclei is governed by free energy minimization considerations, involving competition between volume and surface terms and other effects (surface tension, curvature, capillarity, Marangoni effects, etc.). The structure of the interface may be planar, columnar, dendritic, or amorphous, and difficult to model. The study of microstructural evolution and morphological instabilities is a large and still active field of research in materials science, as they impact the strength of the resulting solid and several of its properties (Kim, 1978; Zaeema and Mesarovicb, 2011; Colin, 2014). In the following sections, we concentrate on *macroscopic aspects* and do not discuss microstructural/morphological aspects any further.

Figure 3.4.13 depicts DSC measured data for *n*-octadecane paraffin. A small hysteresis between melting and freezing curves can be seen, the melting point is 27°C and the freezing point 26°C. Measuring the melting point T_m is more reliable and reproducible, whereas the freezing point is not considered to be a characteristic property of the material.

There are several inorganic substances (hydrated salts), called congruents, which melt and solidify cleanly, with the liquid and solid phases having the same chemical composition. In semi-congruent substances, a salt hydrate and an aqueous solution are formed during the fusion process. This reaction needs to be overturned before freezing to avoid volume reduction of the active phase changing material, which compromises the overall system thermal performance. Usually, semi-congruent melting substances can be modified with additives to render them congruent. Some combinations of an anhydrous salt and an aqueous solution can become incongruent during melting. Unless such material is modified, the anhydrous salt will settle down due to gravity, resulting in a gradual loss in heat storage performance. The most suitable methods of preventing this process are either through thickening the salt solution or through gelling. Thickening means addition of a material to the salt hydrate that increases the viscosity and hereby holds the salt hydrate together (Farid et al., 2004; Mehling and Cabeza, 2008). Gelling means adding a cross-linked material (e.g., polymer) to the salt

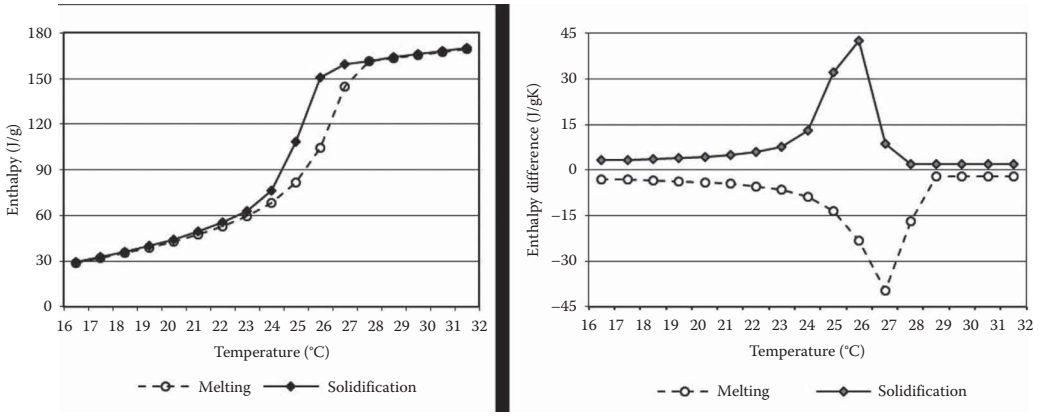

FIGURE 3.4.13 Differential scanning calorimeter (DSC) data for *n*-octadecane. Left: enthalpy vs. temperature. Right: enthalpy difference curves for melting and freezing.

to create a three-dimensional network that holds the salt hydrate together; hence, when anhydrous salt crystals are formed, phase separation does not occur.

Phase Diagrams

The thermodynamic state of a material is determined by its temperature *T*, pressure *P*, and composition *C*. Equality of temperatures ensures thermal equilibrium, equality of pressures ensures mechanical equilibrium, and equality of chemical potentials ensures chemical equilibrium. Phases are regions in (*T*, *P*, *C*)-space, where the material is thermodynamically stable. Phase transitions occur along boundaries between different phases. They are represented commonly by two-dimensional (2D) phase diagrams that are projections on the (*T, P*)-plane, or (*C, T*)-plane, and so on.

Figure 3.4.14 depicts a phase diagram that summarizes the effect of temperature and pressure on a pure substance in a closed container. The melting point of a substance depends on pressure and is usually specified at standard pressure. The phase diagram shown in the figure is divided into three main areas, which represent the solid, liquid, and gaseous states of the substance. The point *B*, called the triple point, represents the only combination of temperature and pressure at which a pure substance can exist simultaneously as a solid, a liquid, and a gas phase. The line between points *B* and *D*, representing solid–liquid equilibria, has, for most materials, a small positive slope. This is because melting points of most solids do not depend very much on changes in pressure. However, for water, the slope of this line is slightly negative because water can melt at temperatures near its freezing point when subjected to increased pressure. The line connecting points *A* and *B* represents solid–gas equilibria. At these temperatures and pressures, the rate at which the solid sublimes to form a gas is equal to the rate at which the gas turns into a solid. Similarly, the solid line between points *B* and *C* shows for gases and liquids the temperature dependence of the vapor pressure. Besides, in the top right corner of the figure, above the critical point, the supercritical fluid (SCF) area is shown. The critical point *C* represents the end point of a phase equilibrium curve. At the critical point, phase boundaries disappear. SCF is a phase at a temperature and pressure above the critical point, where distinct liquid and gas phases do not exist. This is because there is no surface tension in an SCF, as there is no liquid–gas phase boundary. That is why SCF can easily effuse through solids like a gas, and dissolve materials like a liquid.

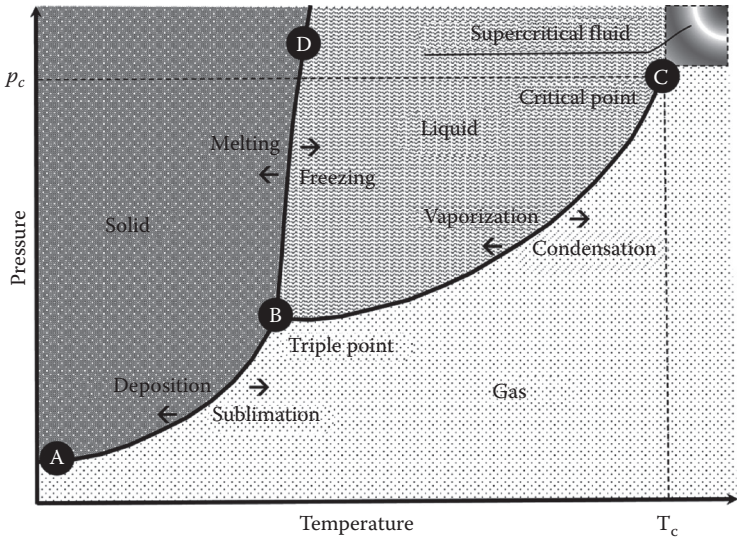

FIGURE 3.4.14 Schematic phase diagram showing the phases of a pure substance as a function of temperature and pressure.

In the general case of a multicomponent, multiphase system, the number of variables, f=degrees of freedom, needed to specify the thermodynamic state is given by the *Gibbs phase rule:* $f=2+N_{components}-N_{phases}$, (Lupis, 1983). Thus, for a pure material, $N_{components}=1$, in the liquid or solid phase: $f=2+1-1=2$, namely T and P are needed to specify the thermodynamic state, whereas along a phase coexistence curve: $f=2+1-2=1$, only one, either T or P suffices. On the other hand, for a binary system $N_{components}=2$ in the liquid or solid phase: $f=2+2-1=3$, namely T, P, C are needed, whereas in the mushy region of the phase diagram $N_{phases}=2, f=2$.

For multicomponent materials (alloys, blends, mixtures), the C–T phase diagram (at a fixed pressure) can be very complex, and the effect of composition is much more dramatic than that of pressure.

The simplest phase diagram for a binary alloy arises when the two components A and B are soluble in all proportions in each other, as is the case for the Si–Ge alloy shown in Figure 3.4.15.

The lens-shaped region between the solidus and the liquidus curves is a mushy region, containing states (C, T) that are mixtures of solid and liquid of different compositions coexisting at equilibrium. This miscibility gap arises from equality of chemical potentials of coexisting phases for each component, as required for a thermodynamic equilibrium (Lupis, 1983).

When cooling down a liquid at some composition C_o (% fraction of component B), solidification begins at $T_o=T^{liquidus}(C_o)$. But at that temperature, liquid of composition C_o is at equilibrium with solid at composition $C^{solidus}(T_o)$, which is what will precipitate out of solution at first. This enriches B in liquid and creates segregation of components, which will set up mass diffusion in the liquid; concurrently the released latent heat must be transferred away before the temperature can be reduced further. It is a coupled conduction–diffusion process. The solid forming will be progressively richer in B, of compositions determined by the lever rule. The mean composition remains at C_o, and the mushy material is *constitutionally supercooled*. This will continue till the temperature decreases down to $T^{solidus}(C_o)$. Thus, solidification occurs over the extended temperature range from $T^{liquidus}(C_o)$ down to $T^{solidus}(C_o)$. A more detailed discussion can be found in (Alexiades and Solomon, 1993, §2.5).

Other Effects

Many different physical phenomena *may* influence a melting process, and especially a freezing process, that can greatly complicate the situation. They include the following:

- Heat and mass transfer by conduction/convection/radiation,
- Possible gravitational, chemical, elastic, electromagnetic effects,

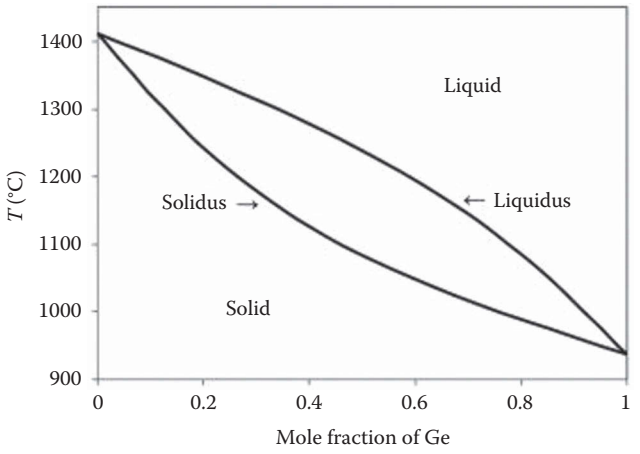

FIGURE 3.4.15 Phase diagram of a Si–Ge binary alloy.

- Variation of thermophysical properties,
- Variation of phase-change temperature,
- Density changes,
- Latent heat evolution over a range of temperatures (rather than at a single T_m),
- Nucleation difficulties, supercooling,
- Surface tension/capillarity/Marangoni, curvature effects.

This is a daunting list. The last two operate at microscopic scales and pertain only to the microstructure during solidification. The rest operate at macroscopic scales for any phase-change process. It is always necessary to make reasonable simplifying assumptions and focus only on essentials relevant to a specific investigation. It is better to start with basic ingredients and progressively incorporate more effects, if deemed necessary.

The core ingredients which give rise to the Stefan problem (discussed in the next section) and which are widely applicable in many situations are the following:

- Heat transfer by conduction only,
- Pure material,
- Constant thermophysical properties in each phase,
- Phase-change temperature is fixed at some known T_m,
- Density is constant and the same in both phases (else there will be movement, and hence convection, bringing in the Navier–Stokes equations!),
- Latent heat is released or absorbed at T_m,
- Microscopic aspects are ignorable.

With this in mind, in the next section, we will discuss the formulation and (exact) solution of the one-dimensional Stefan problem, which in fact serves as prototype of all phase-change problems. In "Analytical Approximations" section, some analytical approximations (quasi-stationary) and melt-time estimates are presented. Finally, in "Numerical Approaches" section, numerical methods are discussed, concentrating on the enthalpy formulation, its discretization, and algorithm.

The Stefan Problem

The prototype of all phase-change problems is the so-called *Stefan problem*, named after Jozef Stefan (1835–1893), even though it had been studied by Lame-Clapeyron in 1831, and an explicit solution had been found by Franz Neumann (1798–1895) in the 1860s.

The Stefan problem is a mathematical model for melting a solid, or freezing a liquid by heat conduction, assuming that the phases are separated by a (locally planar) *moving* front, whose position at time t, denoted by $x=X(t)$, is to be found along with the temperature field $T(x, t)$. The phase-change front (interface) is assumed to be sharp, a surface of zero thickness, along which the temperature is the melting temperature T_m and where the latent heat is absorbed or released.

As mentioned at the end of "The Enthalpy Method" section, the major physical simplifying assumptions are: pure material, constant density (and same in both phases), changing phase at a known T_m, with sharp interface.

Analytical solutions for phase-change processes in pure substances are discussed in Evans (1951), Carslaw and Jaeger (1959), Rubinstein (1971), Crank (1984), Hill (1987), Alexiades and Solomon (1993), among others. Today, the solution of the Stefan problem is widely considered as one of the most used analytical solutions for one-dimensional solid–liquid phase transition.

One-Phase Stefan Problem

The simplest possible phase-change problem involves melting of a phase-change material (PCM) that is initially *solid at its melting temperature* T_m, by imposing a temperature $T_L > T_m$ on its surface, in one space dimension (a rod or a slab, insulated laterally).

Physical Problem: Slab at T_m Melting from the Left

Consider a slab $0 \le x \le \ell$ of phase-change material whose melting temperature is T_m and latent heat of melting L. Initially, the PCM is *solid at temperature* T_m. Melting is induced by imposing a temperature $T_L > T_m$ at the left face $x=0$ (while keeping the right face $x=\ell$ at T_m).

A melt front $x=X(t)$ appears at $x=0$, which advances into the solid while the liquid is getting hotter. At any $t > 0$, the region $0 \le x \le X(t)$ is liquid at temperature $T(x, t)$; the rest remains solid at $T=T_m$. We assume constant thermophysical properties: density ρ, latent heat L, specific heat c_L, and thermal conductivity k_L (hence constant thermal diffusivity $\alpha_L = k_L/\rho c_L$).

The mathematical problem modeling this process is the following.

One-Phase Stefan Problem (for a Slab Initially at T_m Melting from the Left)

Find the interface location $X(t)$, $t > 0$, and the temperature $T(x, t)$, $0 \le x \le X(t) t > 0$, such that:

$$T_t = \alpha_L T_{xx} \quad \text{for } 0 < x < X(t),\ t > 0 \quad \text{(in liquid)} \tag{3.4.40}$$

$$T(X(t),t) = T_m,\ t > 0, \quad \text{(interface temperature } = T_m) \tag{3.4.41}$$

$$\rho L X'(t) = -k_L T_x(X(t),t) t > 0, \quad \text{(Stefan condition)} \tag{3.4.42}$$

$$X(0) = 0 \quad \text{(initially all solid)} \tag{3.4.43}$$

$$T(0,t) = T_L > T_m, \quad t > 0 \quad \text{(imposed temperature } = T_L) \tag{3.4.44}$$

Subscripts "t" and "x" denote partial derivative with respect to t and x, and $X'(t) = \mathrm{d}X/\mathrm{d}t$ in Equation 3.4.42 is the speed of the interface. The *Stefan condition* (Equation 3.4.42), expressing conservation of energy *across* the interface, is the additional condition needed to find the additional unknown $X(t)$. It says that the latent heat absorbed at the front equals the jump of heat flux $[[q]]_S^L \equiv q_L - q_S = -k_L T_x - 0$ across the front (here heat flux in solid $q_S = 0$ since $T \equiv T_m$); see Equation 3.4.51 discussed later.

Note that since the solid remains at T_m, the back face $x=\ell$ plays no role here, so the slab may be considered as extending to infinity. The problem admits a (similarity) solution, known as the *Neumann solution*, provided all parameters and data are constants (Alexiades and Solomon, 1993, p. 35). It is expressed in terms of a single parameter λ, which is the root of Equation 3.4.47.

Interface location:

$$X(t) = 2\lambda\sqrt{\alpha_L t}, \quad t > 0 \tag{3.4.45}$$

Temperature in liquid region $0 < x < X(t)$, $t > 0$:

$$T(x,t) = T_L - (T_L - T_m)\frac{\operatorname{erf}\left(\dfrac{x}{2\sqrt{\alpha_L t}}\right)}{\operatorname{erf}(\lambda)}. \tag{3.4.46}$$

The parameter λ is the unique solution to the transcendental equation

$$\lambda e^{\lambda^2} \operatorname{erf}(\lambda) = \frac{\mathrm{St}_L}{\sqrt{\pi}}, \text{ where } \mathrm{St}_L = \frac{c_L(T_L - T_m)}{L} = \text{Stefan number}, \tag{3.4.47}$$

with erf() as the error function.

For each $\mathrm{St}_L > 0$, the transcendental equation (Equation 3.4.47) has unique solution $\lambda > 0$, which depends only on the (dimensionless) parameter St_L. It can be computed easily by any root finder, for example, bisection or the Newton–Raphson rule.

The *Stefan number* St is the ratio of *sensible heat* $c\Delta T$ to *latent heat* L, and it completely characterizes the one-phase Stefan problem (as can be seen by its undimensionalization, (Alexiades and Solomon, 1993, p. 37). Small St signifies that latent heat dominates, whereas large St indicates that sensible heat dominates. Water and certain waxes have high latent heat, while metals have low latent heat. In particular, water has very high $L=333.4$ J/g, so it is an excellent heat storage material. For example, in the melting of ice at $T_\mathrm{m}=0°\mathrm{C}$ by holding it at body temperature $T_L=37°\mathrm{C}$, we have $\mathrm{St}_L=0.46$ (for water, $c_L=4.2$ J/g K). Similarly, in freezing food from $T_\mathrm{m}=0$ to $T_S=-20°\mathrm{C}$, $c_S\approx 2$ J/g K and so $\mathrm{St}_S=c_S(T_\mathrm{m}-T_S)/L=0.12$.

The Neumann solution (Equations 3.4.45 through 3.4.47) is in fact the *unique* solution of the one-phase Stefan problem. It shows that the front location is proportional to the square root of time, so it starts with infinite speed at $t=0$ (to accommodate the initial discontinuity at $x=0$). Solving Equation 3.4.45 for t gives the time for the melt front to reach a specific location $x=x_\mathrm{o}$: $t_\mathrm{melt}(x_\mathrm{o}) = x_\mathrm{o}^2 / (4\lambda^2\alpha_L)$.

For small $S_L\approx 0$, the root λ is also small and to first order $\lambda \approx \sqrt{(\mathrm{St}_L / 2)}$. This provides a good starting value for the Newton–Raphson iteration. Moreover, the ratio of erf()s in Equation 3.4.46 is $\approx x/X(t)$, so the Neumann temperature becomes $T(x,\, t)\approx T_L-(T_L-T_\mathrm{m})x/X(t)$. Thus, at each time t, the temperature is a line joining the point $(x=0,\, T=T_L)$ with $(x=X(t),\, T=T_\mathrm{m})$.

The analogous *freezing* problem and its solution can be obtained by simply replacing the subscript "L" by "S" and the latent heat L by $-L$. In this case, the imposed temperature will be $T_S < T_\mathrm{m}$ and the Stefan number for the solid will be $\mathrm{St}_S=(T_\mathrm{m}-T_S)/L$.

Two-Phase Stefan Problem

A more realistic case is the melting of a solid initially colder than T_m. In such a situation, there will be heat transfer in both phases.

Physical Problem: Slab Melting from the Left

Consider a slab $0\le x\le \ell$ of phase-change material whose melting temperature is T_m and latent heat of melting is L. Initially, the material is solid at some temperature $T_S < T_\mathrm{m}$. Melting is induced by imposing an elevated temperature $T_L > T_\mathrm{m}$ at the left face ($x=0$), while keeping the right face ($x=\ell$) insulated. We assume constant thermophysical properties: density ρ, latent heat L, specific heats c_L, c_S, thermal conductivities k_L, k_S (hence, constant thermal diffusivities $\alpha_L=k_L/\rho c_L$ and $\alpha_S=k_S/\rho c_S$, and a sharp interface $x=X(t)$.

At each time t, liquid occupies $[0,\, X(t))$ and solid $(X(t),\, \ell]$, separated by the melt front $x=X(t)$. Conservation of (thermal) energy *in each phase* is expressed by the heat conduction equation for temperature $T(x,\, t)$; the Stefan condition expresses conservation of energy *across* the interface. The mathematical problem modeling this process is the following.

Two-Phase Stefan Problem (for a Slab Melting from the Left)

Find the temperature $T(x,\, t)$, $0\le x\le \ell$, $t > 0$, and interface location $X(t)$, $t > 0$, such that:

$$T_t = \alpha_L T_{xx} \quad \text{for } 0 < x < X(t), t > 0 \quad \text{(in liquid)} \tag{3.4.48}$$

$$T_t = \alpha_S T_{xx} \quad \text{for } X(t) < x < \ell, t > 0 \quad \text{(in solid)} \tag{3.4.49}$$

$$T(X(t),t) = T_\mathrm{m}, \quad t > 0, \quad \text{(interface temperature} = T_\mathrm{m}) \tag{3.4.50}$$

$$\rho L X'(t) = -k_L T_x(X(t),t) + k_S T_x(X(t),t), \quad t > 0, \quad \text{(Stefan condition)} \tag{3.4.51}$$

$$X(0) = 0 \quad \text{(initially all solid)} \tag{3.4.52}$$

$$T(x,0) = T_S < T_\text{m}, \quad 0 \le x \le \ell \quad \text{(initial temperature } = T_S\text{)} \tag{3.4.53}$$

$$T(0,t) = T_L > T_\text{m}, \quad t > 0 \quad \text{(imposed temperature} = T_L\text{)} \tag{3.4.54}$$

$$-k_S T_x(\ell,t) = 0, \quad t > 0 \quad \text{(insulated boundary)} \tag{3.4.55}$$

This problem (Equations 3.4.48 through 3.4.56) does *not* admit an exact analytical solution. However, considering it on the semi-infinite slab [0, ∞) (with the boundary condition (Equation 3.4.55) replaced by $\lim_{x\to\infty} T(x, t) = T_S$), the problem *does* admit a (similarity) solution, provided all parameters and data are constants (Alexiades and Solomon, 1993, p. 47).

Neumann Solution of the Two-Phase Stefan Problem
Interface location:

$$X(t) = 2\lambda\sqrt{\alpha_L t}, \quad t > 0 \tag{3.4.56}$$

Temperature in liquid region $0 < x < X(t)$, $t > 0$:

$$T(x,t) = T_L - (T_L - T_\text{m})\frac{\text{erf}\left(\dfrac{x}{2\sqrt{\alpha_L t}}\right)}{\text{erf}(\lambda)}, \tag{3.4.57}$$

Temperature in solid region $x > X(t)$, $t > 0$:

$$T(x,t) = T_S + (T_\text{m} - T_S)\frac{\text{erf}\left(\dfrac{x}{2\sqrt{\alpha_S t}}\right)}{\text{erfc}\left(\lambda\sqrt{\alpha_L / \alpha_S}\right)}. \tag{3.4.58}$$

The parameter λ is the solution to the transcendental equation

$$\frac{\text{St}_L}{\exp(\lambda^2)\text{erf}(\lambda)} - \frac{\text{St}_S}{\nu\exp(\nu^2\lambda^2)\text{erfc}(\nu\lambda)} = \lambda\sqrt{\pi}, \tag{3.4.59}$$

where

$$\text{St}_L = \frac{c_L(T_L - T_\text{m})}{L}, \quad \text{St}_S = \frac{c_S(T_\text{m} - T_S)}{L}, \quad \nu = \sqrt{\frac{\alpha_L}{\alpha_S}}, \tag{3.4.60}$$

and erfc() = 1 − erf(), the complimentary error function.

Note that the value of λ depends only on the two *Stefan numbers* St_L, St_S, and the diffusivity ratio ν. The (dimensionless) transcendental equation (Equation 3.4.59) has exactly one root λ for each $\text{St}_L > 0$, $\text{St}_S \ge 0$, $\nu > 0$ (Alexiades and Solomon, 1993, p. 48)), which can easily be found using a root finder.

Small $\text{St}_L \approx 0$ implies small λ, and then to first-order Equation 3.4.59, it is approximately $\text{St}_L / (2\lambda^2) - \text{St}_S / (\nu\lambda\sqrt{\pi}) = 1$, whence

$$\lambda \approx \frac{1}{2}\left[-\frac{\text{St}_S}{\nu\sqrt{\pi}} + \sqrt{2\text{St}_L + \left(\frac{\text{St}_S}{\nu\sqrt{\pi}}\right)^2}\right] \quad \text{for } \text{St}_L \approx 0. \tag{3.4.61}$$

If, in addition, $St_S \gg St_L \approx 0$, Equation 3.4.61 simplifies to $\lambda \approx (\nu\sqrt{\pi}/2)(St_L / St_S)$.

Setting $T_S = T_m$, whence $St_S = 0$, the 2-phase Neumann solution reduces to the one-phase solution.

The analogous *freezing* problem and its solution is obtained by simply exchanging the subscripts "*L*" and "S" and replacing the latent heat *L* by –*L*.

Analytical Approximations

Exact explicit solutions, presented in "The Stefan Problem" section, provide complete information on how parameters influence the solution and what one is to expect, but exists only for the simplest Stefan problems, only in semi-infinite problems, and only for parameters constant in each phase. Moreover, very few explicit solutions are known in cylindrical or spherical geometries, and none for finite domains and higher dimensions. Thus, for more realistic problems, one must seek approximate solutions, of which there are two classes: *analytical approximations*, discussed in this section, and *numerical approximations*, discussed in the next section.

The four main types of analytical approximations for phase-change problems in use are the *quasi-stationary approximation*, the *Megerlin method*, the *heat balance integral*, and the broad class of *perturbation expansions*. The last one is a general classical methodology of applied mathematics that seeks solutions in the form of a series expansion in some small parameter entering the problem.

The applicability of the other methods relies on being able to simplify the problem to a form that fits the method, which then can generate solvable problems. The resulting solution may turn out to be quite accurate, at least for standard, simple processes. However, there is no way of checking the validity of physical simplifications made, and there are no a priori error estimates for the mathematical approximations. The validity of an analytical approximation may be judged only by comparing it with some other independently validated method and only for a class of very similar problems. Thus, at best, they can provide only qualitative "order of magnitude" information rather than quantitative results, and they are limited to only one-phase problems in one dimension. Nevertheless, when they work, they are very useful for rough sizing estimates of melt depth, melt time, heat flux, etc.

It should be noted that nowadays, in view of the versatility and relative ease of applying direct computational methods, only simple, easy to apply and easy to evaluate analytical solutions are really useful. But in fact, being analytic expressions, they can reveal qualitative behavior, e.g., dependence on parameters, in ways that numerical calculations cannot.

A word of warning on terminology: sometimes in the literature, analytical approximations are advertised as "exact solutions" because an approximate problem is solved "exactly."

We will present only the basics of the quasi-stationary approximation and some useful melt time estimates. The interested reader can refer to (Ozisik, 1993; Alexiades and Solomon, 1993, ch. 3) for more details and other methods.

The quasi-stationary (or quasi-static) approximation is the simplest of the analytical approximation, well suited for "back of the envelope" sizing estimates. It can be applied only to one-phase Stefan problems, but at any of the standard boundary conditions at $x = 0$.

The approximation is based on the physical assumption that *the sensible heat in the process is negligible compared to the latent heat*. This amounts to assuming a small Stefan number: $St \approx 0$

The quasi-stationary approximation consists of replacing the heat equation by the steady-state equation $T_{xx} = 0$, while the front still varies in time. Thus, $T(x, t)$ is linear in x and the temperature profile at any time can be found using the boundary conditions. Then the front location is found from the Stefan condition. We present the approximations for the standard boundary conditions here.

Quasi-Stationary Approximation for Imposed Temperature

The quasi-stationary approximation of the one-phase Stefan problem with imposed temperature at $x = 0$, which may be varying in time: $T(0, t) = T_L(t)$, is the following (Alexiades and Solomon, 1993, p. 128):

$$X^{\mathrm{qs}}(t)=\left(2\frac{k_L}{\rho L}\int_0^t [T_L(s)-T_{\mathrm{m}}]\,\mathrm{d}s\right)^{1/2},\quad t\ge 0, \tag{3.4.62}$$

$$T^{\mathrm{qs}}(x,t)=T_L(t)-[T_L(t)-T_{\mathrm{m}}]\frac{x}{X^{\mathrm{qs}}(t)},\quad 0\le x\le X^{\mathrm{qs}}(t), t\ge 0. \tag{3.4.63}$$

When $T_L(t)\equiv T_L$=constant, this simplifies to

$$X^{\mathrm{qs}}(t)=2\sqrt{\mathrm{St}_L/2}\sqrt{\alpha_L t},\quad t\ge 0, \tag{3.4.64}$$

$$T^{\mathrm{qs}}(x,t)=T_L(t)-[T_L(t)-T_{\mathrm{m}}]\frac{\dfrac{x}{2\sqrt{\alpha_L t}}}{\dfrac{}{2\sqrt{\mathrm{St}_L/2}}},\quad 0\le x\le X^{\mathrm{qs}}(t), t\ge 0, \tag{3.4.65}$$

which is in fact the Neumann solution for the case $\mathrm{St}_L\approx 0$. It follows that the quasi-stationary front $X^{\mathrm{qs}}(t)$ *overestimates* the actual front $X(t)$ and also $T^{\mathrm{qs}}(x, t) > T(x, t)$.

Quasi-Stationary Approximation for Imposed Flux

For imposed flux boundary conditions at $x=0$, namely, $-k_L\,\partial T/\partial x(0,t)=q_L(t)>0$, for a given $q_L(t)$, there is no explicit solution available, even for constant q_L. The quasi-stationary solution is easily found to be (Alexiades and Solomon, 1993, pp. 134–136)

$$X^{\mathrm{qs}}(t)=\frac{1}{\rho L}\int_0^t q_L(s)\mathrm{d}s,\quad t\ge 0 \tag{3.4.66}$$

$$T^{\mathrm{qs}}(x,t)=T_{\mathrm{m}}+\frac{q_L(t)}{k_L}\left[X^{\mathrm{qs}}(t)-x\right],\quad 0\le x\le X^{\mathrm{qs}}(t),\quad t\ge 0 \tag{3.4.67}$$

Example: *Constant flux* $q_L(t)\equiv q_L$. For constant imposed flux, the quasi-stationary temperature is linear in both x and t, the face temperature $T^{\mathrm{qs}}(0, t)$ grows linearly in time, and the melt time of a location x is $t^{\mathrm{qs}}_{\mathrm{melt}}(x)=\rho L\,x/q_L$.

Example: *Sinusoidal flux* $q_L(t)=q_{\max}\sin\left(\pi t/2t_{\mathrm{o}}\right)$. The solution is easily found, and one can check that after a full cycle $2t_{\mathrm{o}}$,

$$X^{\mathrm{qs}}(2t_{\mathrm{o}})=\frac{4t_{\mathrm{o}}q_{\max}}{\rho L\pi},\quad T^{\mathrm{qs}}(x,2t_{\mathrm{o}})=T_{\mathrm{m}}\ \text{(but liquid)}. \tag{3.4.68}$$

Quasi-Stationary Approximation for Convective Boundary Condition

The boundary condition for convective heating at $x=0$ by an ambient temperature $T_L(t) > T_{\mathrm{m}}$, with heat transfer coefficient h, is

$$-k_L\frac{\partial T}{\partial x}(0,t)=h[T_L(t)-T(0,t)],\quad t>0. \tag{3.4.69}$$

The quasi-stationary solution of the Stefan problem turns out to be (Alexiades and Solomon, 1993, pp. 137–139)

$$X^{\mathrm{qs}}(t)=\frac{-k_L}{h}+\left(\frac{k_L^2}{h^2}+2\frac{k_L}{\rho L}\int_0^t [T_L(s)-T_{\mathrm{m}}]\,\mathrm{d}s\right)^{1/2},\quad t\ge 0 \tag{3.4.70}$$

$$T^{\mathrm{qs}}(x,t) = T_{\mathrm{m}} + [T_L(t) - T_{\mathrm{m}}]\frac{h[X^{\mathrm{qs}}(t) - x]}{hX^{\mathrm{qs}}(t) + k_L}, \quad 0 \le x \le X^{\mathrm{qs}}(t), \quad t \ge 0 \tag{3.4.71}$$

and the temperature and flux at the face $x=0$ are

$$T^{\mathrm{qs}}_{\mathrm{face}}(t) = \frac{T_{\mathrm{m}} + \dfrac{hX^{\mathrm{qs}}(t)}{k_L}T_L(t)}{1 + \dfrac{hX^{\mathrm{qs}}(t)}{k_L}}, \quad t \ge 0, \tag{3.4.72}$$

$$q^{\mathrm{qs}}_{\mathrm{face}}(t) = \frac{k_L}{X^{\mathrm{qs}}(t)}[T^{\mathrm{qs}}_{\mathrm{face}}(t) - T_{\mathrm{m}}], \quad t \ge 0. \tag{3.4.73}$$

Solutions for axially or radially symmetric processes has been found by Alexiades and Solomon (1993, pp. 144–152).

Melt Time for a Simple PCM Body with Imposed Temperature

Consider a PCM initially solid at T_{m}, being melted due to a high temperature $T_L > T_{\mathrm{m}}$ imposed on its boundary. Assume that the melting process can be described in terms of a single *effective length* r, $0 \le r \le \ell$. If A is the surface area across which heat is transferred into the PCM and V its volume, define the *shape factor* ω by

$$1 + \omega = \ell\, A / V\,. \tag{3.4.74}$$

Then, $\omega=0$ for a PCM slab or rod of length ℓ insulated at one end, $\omega=1$ for a PCM cylinder of radius ℓ heated radially, and $\omega=2$ for a PCM sphere of radius ℓ. Note that $0 \le \omega \le 2$ always.

The one-phase (inward) melting process, for any $0 \le \omega \le 2$, may be formulated as follows:

$$\frac{\partial T}{\partial t} = \frac{\alpha_L}{r^{\omega}}\frac{\partial}{\partial r}\left(r^{\omega}\frac{\partial T}{\partial r}\right), \quad R(t) \le r \le \ell, \quad t > 0, \tag{3.4.75}$$

$$T(R(t),t) = T_{\mathrm{m}}, \quad \rho L = -k_L(R(t),t), \quad t > 0 \tag{3.4.76}$$

$$R(0) = \ell, \quad T(\ell,t) = T_L, \quad t > 0. \tag{3.4.77}$$

The PCM melts completely when the melt front $R(t)$ reaches $r=0$. Letting

$$\Delta T_L = T_L - T_{\mathrm{m}} \quad \text{and} \quad \mathrm{St}_L = c_L\,\Delta T_L / L, \tag{3.4.78}$$

the melt time of the PCM may be approximated by Alexiades and Solomon (1993, p. 169)

$$t_{\mathrm{melt}} \approx \frac{\ell^2}{2\alpha_L(1+\omega)\mathrm{St}_L}\left[1 + \left(025 + 017\omega^{0.7}\right)\mathrm{St}_L\right], \text{ valid for } 0 \le \mathrm{St}_L \le 4, \tag{3.4.79}$$

and the *average* heat flux at $r=\ell$ during the entire melting process by

$$\overline{q} \approx \frac{-2k_L\Delta T_L}{\ell}\left[1 + (0121 + 0.0424\,\omega)\mathrm{St}_L^{07645-02022\,\omega}\right]. \tag{3.4.80}$$

The *freezing time* of the analogous process is obtained by replacing the subscript L by S and the latent heat L by $-L$.

Note that these expressions, easily computable on a calculator or a spreadsheet, allow one to estimate correlations among parameters. Also note that the melt depth can be found by solving Equation 3.4.79 for ℓ.

Melt Time for a Simple PCM Body with Convective Boundary Conditions

For convective heating with heat transfer coefficient h and ambient temperature T_L, the boundary condition in Equation 3.4.77 reads as

$$-k_L \frac{\partial T}{\partial x} = h[T_L - T(\ell,t)], \quad t > 0, \tag{3.4.81}$$

and the melt time estimate (Equation 3.4.79) becomes

$$t_{\text{melt}} \approx \frac{\ell^2}{2\alpha_L(1+\omega)\text{St}_L}\left[1 + \frac{2}{\text{Bi}} + \left(025 + 017\,\omega^{0.7}\right)\text{St}_L\right], \tag{3.4.82}$$

valid for $0 \le \text{St}_L \le 4$, $\text{Bi} \ge 0.1$, where $\text{Bi} = h\ell/k_L$ is the Biot number of the process.

A very useful aspect of these melt time estimates is that we can explore the influence of parameters, especially of the shape and size of the PCM, by varying ω and ℓ.

Numerical Approaches

The literature on numerical methods for phase-change problems is huge. Currently, a Google search produces 864,000 results!

Phase-change processes are quite complex due to the presence of a moving boundary or region, in which heat and mass balance conditions have to be met—this renders the problem non-linear, and, in addition, the simulated material often has different thermophysical characteristics in different phases (Lamberg et al., 2004).

Numerical methods for addressing phase transition problems have been reviewed in many publications, including: Basu and Date (1988), Idelsohn et al. (1994), Hu and Argyropoulos (1996), Voller et al. (2006), Dutil et al. (2011), AL-Saadi and Zhai (2013). The earliest computational techniques for solving phase transition problems are an enthalpy-type method (Dusinberre, 1945) and a heat source method (Eyres et al., 1946).

Presently used direct numerical simulations methods of phase transition processes can be classified into two categories. The first category, often referred to as *front tracking or multi-domain methods*, uses independent conservation equations in each phase region and couples them with appropriate interface conditions at the (isothermal) moving front. The second category, known as *front capturing or fixed-domain methods*, uses a single region (continuum) formulation in which the interface does not appear explicitly, but can be "captured" from the solution. Over the years, various hybrid methods have also been developed that attempt to combine aspects of both categories in order to take advantage of the best features of each methodology.

Front Tracking Methods

Front tracking methods, also called interface tracing, apply to problems that (are assumed to) have a sharp interface whose precise location is considered crucial and should be tracked. This situation arises in pure materials without internal heating (classical Stefan problems), and in (microscopic) studies of morphological instabilities, among others.

Front tracking techniques follow the dynamic evolution of a moving interface across which physical variables are discontinuous. Usually they employ finite difference or finite-volume discretization of the heat equation; the numerically defined interface is propagated by a set of topologically connected marker points so as to satisfy an explicitly imposed interface (Stefan) condition. However, it is difficult to handle topological changes such as merging fronts or appearing and disappearing phases.

Various types of tracking methods have been developed over the years, such as the following:

a. Fixed grid (Lazaridis, 1969; Rao and Sastri, 1984);
b. Variable time step (Douglas and Gallie, 1955);

c. Variable space grid (Murray and Landis, 1959);
d. Front-fixing by coordinate transformations (Crank and Gupta, 1975; Hsiao, 1985);
e. Boundary integral formulations (Chuang and Szekely, 1972; ONeill, 1983);
f. Lagrangian-type adaptive meshes (Bonnerot and Janet, 1977; Lynch, 1982; Albert and ONeill, 1986; Zabaras and Ruan, 1990);
g. Front tracking for shocks and flames (Glimm et al., 1998)
h. Shyy's ELAFINT (Eulerian–Lagrangian algorithm for interface tracking (Shyy et al., 1996).

It should be noted that front tracking faces several limitations that complicate the solution procedure and restrict its applicability. These include the following: (a) The very formulation of the problem *assumes a priori* that there is a sharp front to be tracked, which may or may not be the case physically. (b) When the interface forms a singularity or changes its topology, tracking becomes difficult to continue beyond the singularity time. (c) It is computationally demanding and limited to modest deformation, especially when interface motion also includes expansion and contraction. The effort for significant topological changes in Lagrangian schemes seems to have reached its limit. To overcome such limitations, alternative methods arose from front capturing techniques, including *immersed boundary* (Uverdi and Tryggvason, 1992), and *level-set-type methods*, discussed in the next section.

Front Capturing Methods

In contrast to front tracking, front capturing methods solve the conservation law(s) over the entire region (posed in a weak sense mathematically), irrespective of phase, and the interface does not appear explicitly in the formulation. Its location can be "captured" from the solution in various ways. Field variables and parameters may change discontinuously between phases, and interfaces may be either sharp or entire (mushy) regions. In this approach, general hydrodynamics (Navier–Stokes + energy balance equations) can be solved on a *fixed Eulerian grid* rather efficiently by treating both phases as a single fluid.

Front capturing numerical approaches fall into two main classes:

1. *Volume of fluid (VoF)-type methods*, primarily the *enthalpy method* (presented in detail in "The Enthalpy Method" section). They arose from, and are very similar to, shock capturing schemes in computational fluid dynamics. The interface does not appear explicitly in the formulation, so no particular structure is assumed about it a priori. It may be a sharp front or a mushy region of any extent. The volume fraction of liquid (or solid), found from conservation laws and appropriate equations of state, is used as a phase indicator to capture the location and extent of phases at each time step. The formulations are general and applicable to complex multiphysics problems, such as multiphase flows, bubble flows, etc.
2. *Level set and phase field methods* (Sethian, 1999; Osher and Fedkiw, 2003). They are concerned with precise evolution and structure of interfaces, so they are appropriate in microscopic settings when the evolution of the front needs to be followed. They can handle topological changes easily on fixed Eulerian grids. The interface is represented as the (zero) level set of a smooth auxiliary function $\phi(x, t)$, so it is possible to compute the normal direction: $\vec{n} = \nabla\phi / |\nabla\phi|$, normal velocity: $\vec{v} = d\vec{x}/dt \cdot \vec{n}$, and mean curvature $\kappa = \nabla \cdot \vec{n}$ from ϕ. Thus, surface tension and curvature effects can be represented in detail.

The phase field and level set methods differ primarily in the interpretation and determination of the phase function ϕ.

In the *level set method*, ϕ is usually taken as distance from the front and it is updated from a kinematic advection equation (but then needs to be re-initialized, which is costly).

In the *phase field approach*, which arose from material science (Cahn–Hilliard equations) considerations, the function ϕ is an order parameter, normalized to be $=\pm 1$ in the bulk phases away from the front. The front is "diffuse": $-1 < \phi < 1$, and its width is controlled by a parameter in the model. The phase field ϕ can be chosen in various ways, usually as a solution of a Cahn–Hilliard-type equation, namely, an Euler–Lagrange equation for the extrema of a (configurational) free energy $J(\phi)$ containing surface and volume terms, and into which various desirable physical effects can be incorporated. Many variants and improvements exist to overcome various issues. Notable are "sharp interface" versions, where ϕ is chosen, e.g., as a hyperbolic tangent of the normal vector $\vec{n}$ (Sun and Beckermann, 2007). For a review, see Qin and Bhadeshia (2010). A comparison of some moving grid, level set, and phase field methods for the Stefan problem has been reported by Javierre et al. (2006).

The Enthalpy Method

The so-called *enthalpy* method is the simplest and most physical, versatile, adaptable, and robust numerical method available for phase-change problems in one, two, or three space dimensions (Alexiades and Solomon, 1993, Chap. 4). It is the basis on which most front capturing and many front tracking schemes are based. It is similar to the VoF and shock capturing schemes in computational fluid dynamics. It is based directly on the energy conservation law

$$\frac{\partial E}{\partial t} + \nabla \cdot Q = S\,, \tag{3.4.83}$$

with $E = \rho e$ the thermal energy (enthalpy per unit volume), Q the (heat) flux, and S any internal (volumetric) energy source or sink. For heat conduction, Q is given by Fourier's law

$$Q = -k\,\nabla T\,, \tag{3.4.84}$$

with T the temperature and k the thermal conductivity, which may be different in different phases and may also depend on T. The enthalpy formulation is based on two important facts:

- The Stefan condition is a "natural" interface condition: it is automatically satisfied by a (weak) solution of the energy conservation law (Equation 3.4.83) along any surface (or region) across which E experiences a jump.
- The recognition that temperature is a poor descriptor of phase, it only captures *sensible heat* but not latent heat, and it stays at T_m during absorption or release of latent heat. The natural and best descriptor is (thermal) energy itself.

By solving the partial differential equation (Equation 3.4.83) *throughout the region* (irrespective of phase), the energy is updated; we then need to find the phase and the temperature T, using the appropriate *equation of state* (EoS) relating energy and temperature. The location of the (moving) phase-change front does *not* appear explicitly in the formulation; it is found (captured) from the solution as the region where the energy jumps by an amount equal to the latent heat. It may be a sharp surface or a region; no a priori assumption about its structure is made. This is the major advantage of the enthalpy formulation over front tracking methods.

The difference between heat transfer without and with phase change is that in the latter case, the energy jumps by L (= latent heat) at T_m, whereas it is continuous in the former case. In heat conduction, the EoS is $de/dT = c_p =$ specific heat, or per unit volume $dE/dT = C_p := \rho c_p$, i.e., $E(T) =$ integral of the volumetric heat capacity $C_p(T)$. But during a change of phase, the latent heat is evolved at $T = T_m$ and the energy jumps by ρL at T_m. The EoS now is (referring to the energy of the *solid* at T_m):

$$E(T)=\begin{cases}\displaystyle\int_{T_{\mathrm{m}}}^{T} C_p^S(\tau)\,\mathrm{d}\tau \approx C_p^S[T-T_{\mathrm{m}}], & T<T_{\mathrm{m}} \quad \text{(solid)},\\ [0,\rho L], & T=T_{\mathrm{m}} \quad \text{(interface)},\\ \rho L+\displaystyle\int_{T_{\mathrm{m}}}^{T} C_p^L(\tau)\,\mathrm{d}\tau \approx \rho L + C_p^L[T-T_{\mathrm{m}}], & T>T_{\mathrm{m}} \quad \text{(liquid)}.\end{cases} \tag{3.4.85}$$

In the region where $0\le E\le \rho L$, the phases coexist; it is where the latent energy is absorbed or released. This is the "interface," which is not necessarily a sharp surface; it may be a region, often called the *mushy region*.

Note that since C_p^S and C_p^L are strictly positive, $E(T)$ depends monotonically on T, so it is invertible, i.e., it can be solved for T in terms of E.

The *liquid fraction* $\lambda=0$ in solid, $\lambda=E/\rho L$ in mushy, $\lambda=1$ in liquid is often used as a convenient phase indicator. Thus, we have the following characterizations of phases:

$$\begin{array}{lcccccl}\text{Solid} & \Leftrightarrow & E<0 & \Leftrightarrow & \lambda=0 & \Leftrightarrow & T<T_{\mathrm{m}},\\ \text{Mushy} & \Leftrightarrow & 0\le E\le \rho L & \Leftrightarrow & \lambda=E/\rho L & \Leftrightarrow & T=T_{\mathrm{m}},\\ \text{Liquid} & \Leftrightarrow & \rho L<E & \Leftrightarrow & \lambda=1 & \Leftrightarrow & T>T_{\mathrm{m}}.\end{array} \tag{3.4.86}$$

Once E is updated from the energy equation, the phase can be found from Equation 3.4.86, and then T can be found from Equation 3.4.85.

Remark 1: The case of *non-isothermal* phase change occurring over an extended temperature range $[T^{\text{solidus}}, T^{\text{liquidus}}]$ may be accommodated by replacing $T=T_{\mathrm{m}}$ in Equation 3.4.86 by $T^{\text{solidus}}\le T\le T^{\text{liquidus}}$.

In fact, instead of the simple EoS (Equation 3.4.85), more general equations of state may be used, see Alexiades and Autrique (2010).

Remark 2: We emphasize again that the front is *not* being tracked; it does not even appear explicitly in the formulation. It can be *captured* from the solution as the region where $0\le E\le \rho L$, see Equation 3.4.108.

Remark 3: The meaning of Equation 3.4.83, when E and Q are discontinuous, needs to be clarified. In fact, it must be interpreted in a *weak* sense mathematically, see Alexiades and Solomon (1993, Chap. 4).

Enthalpy Scheme

The energy conservation law (Equation 3.4.83) is valid in any number of (space) dimensions, for any appropriate constitutive law for flux Q, interpreted in a weak sense mathematically. It may be discretized by finite differences or finite volumes or finite elements. The finite-volume discretization is the most physical and easiest to implement computationally, so we present in the following an algorithm for the *finite-volume enthalpy scheme*, for a typical heat transfer problem, in one space dimension for simplicity. It can be extended to two or three dimensions easily.

To be specific, consider heat transfer in a slab occupying the region $\Omega=[a, b]$, initially at temperature $T=T_{\text{init}}(x)$, with convective heating at the left wall $x=a$, with heat transfer coefficient h and ambient $T_{\text{amb}}(t)\ge T_{\mathrm{m}}$, while keeping the back end $x=b$ insulated. If $T_{\text{init}}(x)\le T_{\mathrm{m}}$ and $T_{\text{amb}}(t)\ge T_{\mathrm{m}}$, then this would be a two-phase Stefan problem, more general than in "Two-Phase Stefan Problem" section. The material parameters involved are: $\rho=$const., c_p^L, c_p^S, k_L, k_S, h (which may depend on T), along with T_{m} and L.

The enthalpy formulation of this problem is as follows:

$$\text{Energy conservation } E_t + Q_x = 0, \quad a < x < b, 0 < t \le t_{\text{end}}, \tag{3.4.87}$$

$$\text{Constitutive law: } Q = -kT_x, \tag{3.4.88}$$

$$\text{Equation of state (3.4.85)}$$

$$\text{Initial condition: } T(x,0) = T_{\text{init}}(x), \quad a \le x \le b, \tag{3.4.89}$$

$$\text{Boundary conditions: } Q(a,t) = h[T_{\text{amb}}(t) - T(a,t)], Q(b,t) = 0, \quad t > 0, \tag{3.4.90}$$

for the given $T_{\text{init}}(x)$ and $T_{\text{amb}}(t)$. The only difference with plain heat conduction is the jump of energy in the EoS (Equation 3.4.85), which encodes the latent heat effect.

Space mesh: Choose an integer M and partition the interval $\Omega=[a, b]$ into M control volumes $V_i=[x_{i-1/2}, x_{i+1/2}]$, $i=1, 2, \ldots, M$, of width $\Delta x_i=x_{i+1/2}-x_{i-1/2}$. Place a node point x_i in V_i, and define the array of nodes $x_0=a, x_1, x_2, \ldots, x_M, x_{M+1}=b$. For a *uniform mesh*, $\Delta x=(b-a)/M$, and the nodes array is: $x_0=a, x_1=\Delta x/2, x_i=x_1+(i-1)\Delta x$ for $i=2, \ldots, M, x_{M+1}=b$. Note that x_0 and x_{M+1} are the boundaries, included into the mesh array for convenience.

Time steps: Choose time steps $\Delta t_n > 0$, small enough for accuracy and stability (see later text), and define the discrete times $t_0=0$, $t_{n+1}=t_n+\Delta t_n$, $n=0, 1,\ldots$. If $\Delta t_n=\Delta t$ for all n, then $t_n=n\Delta t$, and the number of time steps to get to the desired time t_{end} will be $N=t_{\text{end}}/\Delta t$.

Finite volume discretization of Equation 3.4.87: Integrating Equation 3.4.87 over the ith control volume $V_i=[x_{i-1/2}, x_{i+1/2}]$, $i=1, \ldots, M$ and over the time interval $[t_n, t_n+\Delta t_n]$ gives

$$\int_{t_n}^{t_{n+1}} \frac{\partial}{\partial t}\left(\int_{x_{i-1/2}}^{x_{i+1/2}} E(x,t)\,\mathrm{d}x\right)\mathrm{d}t + \int_{t_n}^{t_{n+1}}\int_{x_{i-1/2}}^{x_{i+1/2}} \frac{\partial}{\partial x} Q(x,t)\,\mathrm{d}x\,\mathrm{d}t = 0, \tag{3.4.91}$$

and carrying out integration of the derivatives leads to

$$\int_{x_{i-1/2}}^{x_{i+1/2}} E(x,t)\,\mathrm{d}x\Big|_{t_n}^{t_{n+1}} + \int_{t_n}^{t_{n+1}} [Q(x_{i+1/2},t) - Q(x_{i-1/2},t)]\,\mathrm{d}t = 0, \tag{3.4.92}$$

which expresses *exact discrete conservation*. Now define the discrete mean energy and mean flux as

$$E_i^n = \frac{1}{\Delta x}\int_{x_{i-1/2}}^{x_{i+1/2}} E(x,t_n)\,\mathrm{d}x = \text{ mean value of } E \text{ over } V_i \text{ at } t_n, i = 1,\ldots,M, \tag{3.4.93}$$

$$Q_{i-1/2}^{n+\theta} = \frac{1}{\Delta t}\int_{t_n}^{t_{n+1}} Q(x_{i-1/2},t)\,\mathrm{d}t = \text{ mean flux during } [t_n, t_{n+1}] \text{ through face at } x_{i-1/2}, i = 1,\ldots,M+1, \tag{3.4.94}$$

with *implicitness parameter* $0 \le \theta \le 1$. The superscript $^{n+\theta}$ denotes a time between t_n and t_{n+1} at which the mean value of flux is attained. With this notation, Equation 3.4.92 takes the form

$$E_i^{n+1} = E_i^n + \frac{\Delta t_n}{\Delta x}\left[Q_{i-1/2}^{n+\theta} - Q_{i+1/2}^{n+\theta}\right], \quad i = 1,\ldots,M, n = 0,1,\ldots \tag{3.4.95}$$

Note that no approximations have been made so far; this is still the *exact discrete conservation* of energy. It will update E_i to new time t_{n+1} once we specify how to compute the discrete fluxes. Also note that the updating scheme involves only the fluxes across the left and right faces of each control volume.

The first approximation comes from choosing a mean time for flux. For any $0 \le \theta \le 1$, we interpret the *mean time* $t_{n+\theta}$ as $t_{n+\theta} = (1-\theta)t_n + \theta\, t_{n+1}$, and assume that $Q^{n+\theta}_{i-1/2}$ is a convex combination of old $Q^{n}_{i-1/2}$ and new $Q^{n+1}_{i-1/2}$ values:

$$Q^{n+\theta}_{i-1/2} = (1-\theta)\, Q^{n}_{i-1/2} + \theta\, Q^{n+1}_{i-1/2}. \tag{3.4.96}$$

The standard choices for θ are 0, 1/2, 1:

- $\theta = 0$: Then the scheme is *explicit* (forward Euler time discretization). The right-hand side of Equation 3.4.95 is known at t_n, so the update requires only evaluation. However, the time step needs to be restricted to satisfy the Courant–Friedrichs–Lewy (CFL) stability condition, see Equations 3.4.102 and 3.4.103.
- $\theta = 1/2$: *Crank–Nicolson* scheme. It is implicit, so a system of equations needs to be solved at each time step. It is unconditionally stable, but not positivity-preserving unless Δt is restricted, see Equation 3.4.101.
- $\theta = 1$: *Backward Euler* scheme. It is implicit, so a system of equations needs to be solved at each time step. It is unconditionally stable, and positivity-preserving, so the time step needs to be restricted *only* for accuracy.

Discretization of Equation 3.4.88: The second approximation comes from discretization of flux, which involves the gradient of temperature. Let T_i denote the mean temperature of control volume V_i, $i = 1, \ldots, M$, and T_0, T_{M+1} the temperatures at the end points, consistently with our mesh. However, in order to approximate the gradient, the mean temperature T_i needs to be assigned to a specific location, which we take to be the node x_i of V_i. Then the natural discretization of Fourier's law (Equation 3.4.88) for heat flux across face $x_{i-1/2}$, i.e., from x_{i-1} to x_i, is

$$Q_{i-1/2} = -k_{i-1/2}\, \frac{T_i - T_{i-1}}{x_i - x_{i-1}}, \quad i = 1, \ldots, M+1, \tag{3.4.97}$$

but we need to clarify the value of $k_{i-1/2}$. It represents an "effective" conductivity for heat transfer from node x_{i-1} to node x_i. But this involves two, possibly different, conductivities k_{i-1} and k_i. Instead, let us view Fourier's law in terms of *resistivity* $= R = \Delta x/k$ (which is additive), see Alexiades and Solomon (1993, p. 188), so we define

$$\text{Resistivity of the path } [x_{i-1}, x_i] : R_{i-1/2} = \frac{x_{i-1/2} - x_{i-1}}{k_{i-1}} + \frac{x_i - x_{i-1/2}}{k_i}, \tag{3.4.98}$$

and write Equation 3.4.97 as

$$Q_{i-1/2} = -\frac{T_i - T_{i-1}}{R_{i-1/2}}. \tag{3.4.99}$$

Apart from boundary conditions, which are discussed later, Equation 3.4.99 constitute a discretization for heat transfer (in one-dimensional), with or without phase change. Phase change enters via the EoS (Equation 3.4.85), in which case, the nodal conductivities entering Equation 3.4.98 can be taken to be

$$\frac{1}{k_i} = \frac{\lambda_i}{k_L} + \frac{1-\lambda_i}{k_S}, \tag{3.4.100}$$

with λ_i the liquid fraction of node $i = 1, \ldots, M$. For other options, see Alexiades and Solomon (1993, p. 215).

Remark 4: Note that Equation 3.4.97 is a centered finite-difference approximation of the derivative, hence, it is second order, provided the face $x_{i-1/2}$ is chosen half-way between the nodes x_{i-1} and x_i, as is the case for a uniform mesh. Then the explicit and the fully implicit schemes are of second order in space and first order in time, whereas the Crank–Nicolson scheme is second order in both space and time.

Remark 5: It is possible to substitute E_i and fluxes in terms of temperature into Equation 3.4.95 to obtain schemes for directly updating the temperature with latent heat as a source term, (Shyy et al., 1996). We do not recommend such formulations, see Remark 6.

The *positive coefficient rule* is a simple and effective way to guarantee (strong) stability: when T_i^{n+1} is written as a linear combination of its neighbors T_{i-1}^n, T_i^n, T_{i+1}^n, all coefficients should be positive, (Patankar, 1980). This yields a restriction on the time step and ensures that the scheme will be *positivity-preserving* (non-negative values at t_n implies non-negative values at t_{n+1}), and thus free of unphysical oscillations. Positivity-preserving is stronger than and implies numerical stability. Applying the rule to the θ scheme (Equations 3.4.95, 3.4.96, 3.4.99, 3.4.98), in the general case of non-uniform mesh and possibly variable properties (temperature-dependent and/or phase-dependent), it yields the

$$\text{Strong CFL condition}: \mu \le \frac{1}{2(1-\theta)}, \text{ with } \mu = \frac{\Delta t_n}{\rho\, c_{pi}\, \Delta x_i}\, \frac{1}{R_{i\pm 1/2}}. \tag{3.4.101}$$

This shows that only the fully implicit scheme ($\theta = 1$) is truly unconditionally stable and positivity-preserving. All others need a restriction on the time step to preserve positivity. Even though implicit schemes ($0 < \theta < 1$) are stable in the von Neumann sense (errors remain bounded), they can produce unphysical oscillations for large time steps. The Crank–Nicolson scheme ($\theta = 1/2$) needs $\mu \le 1$, and the explicit scheme ($\theta = 0$) needs $\mu \le 1/2$.

The *explicit scheme* ($\theta = 0$) is, by far, the simplest and easiest to implement, as it does not involve any system solving. Moreover, it is also far easier to parallelize for concurrent computation on multi-processors, via domain decomposition using the Message Passing Interface (MPI) library, for demanding problems. The only price to be paid for this simplicity and convenience is that the time step Δt must be restricted to satisfy the CFL condition (Equation 3.4.101), which amounts to

$$\Delta t_n \le \frac{\rho\, c_{pi}\, \Delta x_i}{\dfrac{1}{R_{i-1/2}} + \dfrac{1}{R_{i+1/2}}}, \text{ or simply } \Delta t_n \le \frac{\Delta x_{\min}^2}{2\,\alpha_{\max}}, \tag{3.4.102}$$

with $\Delta x_{\min} = \min \Delta x_i$ and $\alpha_{\max} = \max \alpha_i$. For uniform mesh and constant thermophysical properties, it simplifies to the standard

$$\text{CFL condition}: \Delta t \le \frac{\Delta x^2}{2\,\alpha}, \text{ with } \alpha = \frac{k}{\rho c_p}. \tag{3.4.103}$$

Discretization of Boundary Conditions

The standard types of boundary conditions are Dirichlet, Neumann, and convective (robin) type. We discuss each type at $x = a$ for illustration.

1. Imposed temperature (Dirichlet) boundary condition: $T(a, t) = T_a(t) = \text{given}$. Here the boundary temperature $T_0^n = T_a(t_n)$ is specified, so by Equation 3.4.99, the boundary flux at $x = a$ is:

$$Q_{1/2}^n = -\frac{T_1^n - T_0^n}{R_{1/2}}, \text{with } R_{1/2} = \frac{x_1 - x_0}{k_1}. \tag{3.4.104}$$

Note that for a uniform mesh, $x_1 - x_0 = \Delta x/2$.

2. Imposed flux (Neumann) boundary condition: $Q(a, t) = q_a(t) = \text{given}$.

Here the boundary flux $Q_{1/2}^n = q_a(t_n)$ is specified, which is all the scheme needs to proceed. However, the boundary temperature will change and needs to be found. Solving Equation 3.4.104 for T_0, gives

$$T_0^n = T_1^n + R_{1/2}\, Q_{1/2}^n . \tag{3.4.105}$$

This involves the nodal value T_1, which will be updated from Equation 3.4.95.

A very important particular case is that of an *insulated boundary*: $q_a(t)=0$, so then $T_0^n = T_1^n$.

3. Convective boundary condition: $Q(a, t)=h[T_{\text{amb}}(t)-T(a, t)]$,

with $T_{\text{amb}}(t)$, a given ambient temperature. Here neither T nor Q is specified at the boundary, only a relation between them (Newton's law of cooling). Its discretization is $Q_{1/2}^n = h[T_{\text{amb}}(t_n)-T_0^n]$, or, using Equation 3.4.103, $-\dfrac{T_1^n - T_0^n}{R_{1/2}} = h[T_{\text{amb}}(t_n)-T_0^n]$. Solving for T_0^n gives

$$T_0^n = \frac{T_1^n + h\, R_{1/2}\, T_{\text{amb}}^n}{1 + h\, R_{1/2}} . \tag{3.4.106}$$

Substituting this into the expression for $Q_{1/2}^n$ yields

$$Q_{1/2}^n = -\frac{T_1^n - T_{\text{amb}}^n}{R_{1/2} + 1/h} . \tag{3.4.107}$$

Observe that $h \to \infty$ amounts to the imposed temperature case (Equation 3.4.104), as it should.

Algorithm for the Explicit Finite Volume Scheme

We present the complete finite-volume enthalpy algorithm for the melting problem mentioned at the beginning of "Enthalpy Scheme" section. For simplicity, we assume constant c_S, c_S, k_S, k_L, and uniform mesh.

- Read in data: M, a, b, t_{end}
- Set $\Delta x=(b-a)/M$, the time step Δt from Equation 3.4.103, and $N_{\text{steps}}=t_{\text{end}}/\Delta t$.
- Declare arrays $x(0{:}M+1)$, $T(0{:}M+1)$, $E(1{:}M)$, $\lambda(1{:}M)$, $R(1{:}M+1)$, $Q(1{:}M+1)$. Note that there is no reason to index time into the arrays.
- Set initial values: $T_i=T_{\text{init}}(x_i)$, $E_i=E(T_i)$ from Equation 3.4.85, and λ_i from Equation 3.4.86, $i=1{:}M$.
- Time stepping: for $n=1, \ldots, N_{\text{steps}}$, do:
  1. Set the boundary fluxes $Q_{1/2}$, Q_{M+1} from Equations 3.4.104–3.4.107, and internal fluxes from Equation 3.4.99, $i=2, \ldots, M$.
  2. Update energies E_i from Equation 3.4.95 to new time t_{n+1}.
  3. Update λ_i from Equation 3.4.86, and $R_{i-1/2}$ from Equations 3.4.98 and 3.4.100 to time t_{n+1}.
  4. Update T_i from Equation 3.4.85 and the boundary temperatures from Equations 3.4.106 and 3.4.105 to time t_{n+1}.

Now all quantities have been updated to new time and can go to 1 for the next time step.

For a pure material melting at T_{m}, the algorithm will generate only one mushy control volume, say volume $i=m$ at time t_n, and then the front location at that time can be computed for plotting by

$$X^n = x_{m-1/2} + \lambda_m\, \Delta x_m . \tag{3.4.108}$$

Remark 6: The latent heat effect is only felt in mushy nodes so each control volume should become mushy before changing phase. The aforementioned algorithm is robust in this respect, so skipping the transition indicates a bug or too large a time step. Some other implementations or algorithms may miss this, so one must be careful. Especially prone are schemes that directly update temperature either implicitly using too large a time step, or they account for the latent heat via a source term.

Remark 7: The algorithm generalizes to two or three dimensions easily. We only need to define fluxes in the other directions; the energy PDE will contain an additional pair of fluxes for each additional dimension. For example, in a two-dimensional Cartesian mesh of $M_x \times M_y$ nodes, there are two flux arrays: $Qx_{i-1/2,j}$ for $i=1{:}M_x+1$, $j=1{:}M_y$ and $Qy_{i,\,j-1/2}$ for $i=1{:}M_x$, $j=1{:}M_y+1$; the energy update (Equation 3.4.95) becomes:

$$E_{i,j}^{n+1} = E_i^n + \frac{\Delta t_n}{\Delta x \Delta y}\left[Q_{i-1/2,\,j}^n - Q_{i+1/2,\,j}^n + Q_{i,\,j-1/2}^n - Q_{i,\,j+1/2}^n\right], \quad i=1:M_x,\, j=1:M_y. \tag{3.4.109}$$

Heat Capacity Method

The heat capacity method is a fixed-domain, no front tracking, temperature-based method that incorporates the latent heat into the heat capacity $c_p(T)$. Temperature is updated directly by the heat equation. It assumes non-isothermal phase change over some interval $[T_m - \Delta T,\ T_m + \Delta T]$, within which thermal properties are taken to be convex combinations of solid and liquid properties, interpolated by the liquid fraction λ. There are two main approaches: (i) apparent heat capacity and (ii) effective heat capacity.

1. *Apparent heat capacity method* was introduced by Hashemi and Sliepcevich (1967) and has been developed by Idelsohn et al. (1994), Hu and Argyropoulos (1996), and Voller (1997). This method is relatively popular today because it updates temperature directly from the heat equation, and can use experimental results to formulate an empirical expression for heat capacity. Dynamic measurements can be performed for pure and homogenous materials, utilizing differential scanning calorimetry (DSC) with a step testing method, (Castellon et al., 2008; Gŭnther et al., 2009). For example, Fang and Medina (2009) used DSC to develop a mathematical formula for heat capacity of paraffinic products. In cases of non-uniform materials and composite blends, T-history method, (Zhang et al., 1999), or dynamic heat flow meter apparatus measurements need to be applied, (Kosny et al., 2009a, b; Shukla et al., 2013). Apparent heat capacity can also be estimated using numerical methods (Lemmon, 1981; Voller, 1997).
2. *Effective heat capacity method* became known thanks to the publications of Heim and Clark (2004), Minkowycz et al. (2006), Muhieddine et al. (2009), and Poirier (1988). Since the relationship between heat capacity and temperature is highly non-linear, an explicit scheme is often used. This may cause some inaccuracies in situations of sharp heat capacity changes with respect to temperature (Sadasivam et al., 2011). For single-component cases with well-defined melting point T_m, the temperature range $2\Delta T$ should be as small as possible.

Hybrid Methods

There are a large number of modified methods using components from one or both methods described previously. In the following, we mention a couple of such methods.

Quasi-enthalpy method: Pham (1985, 2006) introduced a hybrid scheme that consists of: (i) a temperature prediction step, and (ii) a verification and correction step in which the predicted temperatures are checked for consistency against the enthalpy–temperature curve and corrected if necessary. This method was introduced as one of the alternative numerical algorithms allowing phase-change simulation in ESP-r, a whole-building energy simulation program, (Sadasivam et al., 2011).

TABLE 3.4.2
Numerical Methods Used in Best-Known Numerical Tools Which Can Be Used for Phase-Change Simulations in Buildings

Whole-Building Computer Tool	Numerical Method	Discretization	Time Stepping	References
ESP-r	Effective heat capacity	Finite volume	Explicit	Heim and Clarke (2004)
TRNSYS type 204, plus type 56	Effective heat capacity	Finite element	Crank–Nicolson	Jokisalo et al. (2000)
TRNSYS type 222, plus type 56	Indirect calculations			Ibanez et al. (2005)
TRNSYS type 241, plus type 56	Enthalpy method	Finite difference		Schranzhofer et al. (2006)
TRNSYS type 260, plus type 56	Effective heat capacity	Finite difference	Explicit	Kuznik et al. (2010)
TRNSYS type 399, plus type 56	Two different methods available based on the heat capacity approach	Finite element	Crank–Nicolson	Dentel and Stephan (2013)
MATLAB	Enthalpy method	Finite volume	Crank–Nicolson	Sadasivam et al. (2011)
EnergyPlus	Enthalpy method	Finite difference	Implicit	Pedersen (2007)

Improved temperature-based equivalent heat capacity method: (Cao and Faghri, 1990; Zhanhua and Yuwen, 2006). After a series of enhancements, this numerical model has been used in a number of projects—(Zeng and Faghri, 1994a, b; Zhanhua and Yuwen, 2006). Today, this method is not in common use; however it offers an alternative to the apparent heat capacity method.

In large containers, natural convection in the liquid phase may impact overall system effectiveness. A study by Ahmad et al. (2006) demonstrated that complexity of thermal models does not always yield improvements in simulation accuracy. In this work, numerical predictions generated by a complex thermal model considering a solid–liquid interface and results of a simpler model using the effective heat capacity method were compared. Recorded results showed that a simpler heat capacity approach was more accurate. In another similar study, finite-element computer simulations were performed to compare accuracies of the enthalpy and heat capacity methods, (Lamberg et al., 2004). When compared to experimental data, better agreement was obtained with the heat capacity method.

A list of numerical methods used in the most popular whole-building energy simulation tools, with the capability of modeling phase changes, is given in Table 3.4.2.

3.5 MASS TRANSFER

Anthony F. Mills

Introduction

Mass transfer may occur in a gas mixture, a liquid solution, or a solid solution. There are several physical mechanisms that can transport a chemical species through a phase and transfer it across phase boundaries. The two most important mechanisms are ordinary diffusion and convection. Mass diffusion is analogous to heat conduction and occurs whenever there is a gradient in the concentration of a species. Mass convection is essentially identical to heat convection: a fluid flow that transports heat may also transport a chemical species. The similarity of mechanisms of heat transfer and mass transfer results in the mathematics often being identical, a fact that can be exploited to advantage. But there are some significant differences between the subjects of heat and mass transfer. One difference is the much greater variety of physical and chemical processes that require mass transfer analysis. Another difference is the extent to which the essential details of a given process may depend on the particular chemical system involved, and on temperature and pressure.

In the next subsection, concentrations, velocities, and fluxes are defined, and special attention is paid to phase interfaces where the concentration of a chemical species is almost always discontinuous. Fick's law of ordinary diffusion is introduced in the third section, where other diffusion phenomena are also discussed. The fourth section presents various forms of the species conservation equation. Results for diffusion in a stationary medium are given in the fifth section, and include steady diffusion across a plane wall, transient diffusion in a semi-infinite solid, and diffusion in a porous catalyst. Results for diffusion in a moving medium are given in the sixth section, and the Stefan flow is introduced for diffusion with one component stationary. Also considered are particle combustion, droplet evaporation, and combustion of a volatile liquid hydrocarbon fuel droplet. The last section deals with mass convection. Low mass transfer rate theory is presented and how to exploit the analogy between convective heat and mass transfer is shown. Particular attention is given to situations involving simultaneous heat and mass transfer associated with evaporation or condensation. The section closes by presenting high mass transfer rate theory for convection, and gives engineering calculation methods for boundary layer flows that account for variable property effects.

Concentrations, Velocities, and Fluxes

Definitions of Concentrations

In a gas mixture, or liquid or solid solution, the local *concentration* of a mass species can be expressed in a number of ways. The *number density* of species i in a mixture or solution of n species is defined as

$$\begin{aligned}\text{Number density of species } i &\equiv \text{Number of molecules of } i \text{ per unit volume} \\ &\equiv \mathcal{N}_i \text{ molecules}/\text{m}^3\end{aligned} \tag{3.5.1}$$

Alternatively, if the total number of molecules of all species per unit volume is denoted as $\mathcal{N}$, then we define the *number fraction* of species i as

$$n_i \equiv \frac{\mathcal{N}_i}{\mathcal{N}}; \quad \mathcal{N} = \sum \mathcal{N}_i \tag{3.5.2}$$

where the summation is over all species present, $i = 1,2, \ldots, n$. Equations 3.5.1 and 3.5.2 describe *microscopic* concepts and are used, for example, when the kinetic theory of gases is used to describe transfer processes.

Whenever possible, it is more convenient to treat matter as a continuum. Then the smallest volume considered is sufficiently large for macroscopic properties such as pressure and temperature to have their usual meanings. For this purpose we also require *macroscopic* definitions of concentration. First, on a mass basis,

$$\begin{aligned}\text{Mass concentration of species } i &\equiv \text{partial density of species } i \\ &\equiv \rho_i \text{ kg/m}^3\end{aligned} \tag{3.5.3}$$

The total mass concentration is the total mass per unit volume, that is, the density $\rho = \Sigma\rho_i$. The *mass fraction* of species i is defined as

$$m_i = \frac{\rho_i}{\rho} \tag{3.5.4}$$

Second, on a molar basis,

$$\begin{aligned}\text{Molar concentration of species } i &\equiv \text{number of moles of } i \text{ per unit volume} \\ &\equiv c_i \text{ kmol/m}^3\end{aligned} \tag{3.5.5}$$

If M_i (kg/kmol) is the molecular weight of species i, then

$$c_i = \frac{\rho_i}{M_i} \tag{3.5.6}$$

The total molar concentration is the molar density $c = \Sigma c_i$. The *mole fraction* of species i is defined as

$$x_i \equiv \frac{c_i}{c} \tag{3.5.7}$$

A number of important relations follow directly from these definitions. The mean molecular weight of the mixture of solution is denoted by M and may be expressed as

$$M = \frac{\rho}{c} = \sum x_i M_i \tag{3.5.8a}$$

or

$$\frac{1}{M} = \sum \frac{m_i}{M_i} \tag{3.5.8b}$$

There are summation rules

$$\sum m_i = 1 \tag{3.5.9a}$$

$$\sum x_i = 1 \tag{3.5.9b}$$

It is often necessary to have the mass fraction of species i expressed explicitly in terms of mole fractions and molecular weights; this relation is

$$m_i = \frac{x_i M_i}{\sum x_j M_j} = x_i \frac{M_i}{M} \tag{3.5.10a}$$

and the corresponding relation for the mole fraction is

$$x_i = \frac{m_i / M_i}{\sum m_j / M_j} = m_i \frac{M}{M_i} \tag{3.5.10b}$$

Dalton's law of partial pressures for an ideal gas mixture states that

$$P = \sum P_i, \quad \text{where} \quad P_i = \rho_i R_i T \tag{3.5.11}$$

Dividing partial pressure by total pressure and substituting $R_i = \mathcal{R}/M_i$ gives

$$\frac{P_i}{P} = \frac{\rho_i}{M_i}\frac{\mathcal{R}T}{P} = c_i \frac{\mathcal{R}T}{P} = x_i \frac{c\mathcal{R}T}{P} = x_i \tag{3.5.12}$$

Thus, for an ideal gas mixture, the mole fraction and partial pressure are equivalent measures of concentration (as also is the number fraction).

A commonly used specification of the composition of dry air is 78.1% N_2, 20.9% O_2, and 0.9% Ar, by volume. (The next largest component is CO_2, at 0.3%.) Since equal volumes of gases contain the same number of moles, specifying composition on a volume basis is equivalent to specifying mole fractions, namely,

$$x_{N_2} = 0.781; \quad x_{O_2} = 0.209; \quad x_{Ar} = 0.009$$

The corresponding mass fractions are calculated to be

$$m_{N_2} = 0.755; \quad m_{O_2} = 0.231; \quad m_{Ar} = 0.014$$

Concentrations at Interfaces

Although temperature is continuous across a phase interface, concentrations are usually discontinuous. In order to define clearly concentrations at interfaces, we introduce imaginary surfaces, denoted *u* and *s*, on both sides of the real interface, each indefinitely close to the interface, as shown in Figure 3.5.1 for water evaporating into an airstream. Thus, the liquid-phase quantities at the interface are subscripted u, and gas-phase quantities are subscripted s. If we ignore the small amount of air dissolved in the water, $x_{H_2O,u} = 1$. Notice that the subscript preceding the comma denotes the chemical species, and the subscript following the comma denotes location. To determine $x_{H_2O,s}$ we make use of the fact that, except in extreme circumstances, the water vapor and air mixture at the s-surface must be in thermodynamic equilibrium with water at the u-surface. Equilibrium data for this system are found in conventional steam tables: the saturation vapor pressure of steam at the water temperature, T_s, ($T_s = T_u$), is the required partial pressure $P_{H_2O,s}$. With the total pressure P known, $x_{H_2O,s}$ is calculated as $P_{H_2O,s} / P$. If $m_{H_2O,s}$ is required, Equation 3.5.10a is used.

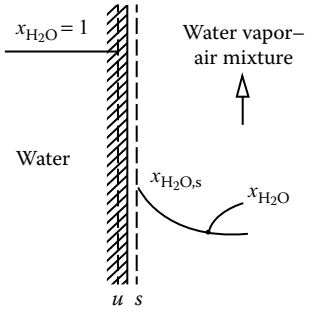

FIGURE 3.5.1 Concentrations at a water-air interface.

For example, at $T_s = 320$ K, the saturation vapor pressure is obtained from steam tables as 0.10535×10^5 Pa. If the total pressure is 1 atm $= 1.0133 \times 10^5$,

$$x_{H_2O,s} = \frac{0.10535 \times 10^5}{1.0133 \times 10^5} = 0.1040$$

$$m_{H_2O,s} = \frac{(0.1040)(18)}{(0.1040)(18) + (1 - 0.1040)(29)} = 0.06720$$

For a gas or solid dissolving in a liquid, equilibrium data are often referred to simply as solubility data, found in chemistry handbooks. Many gases are only sparingly soluble, and for such dilute solutions solubility data are conveniently represented by *Henry's law*, which states that the mole fraction of the gas at the s-surface is proportional to its mole fraction in solution at the u-surface, the constant of proportionality being the *Henry number*, He. For species *i*,

$$x_{i,s} = \mathrm{He}_i x_{i,u} \tag{3.5.13}$$

The Henry number is inversely proportional to total pressure and is also a function of temperature. The product of Henry number and total pressure is the *Henry constant*, C_{He}, and for a given species is a function of temperature only:

$$\mathrm{He}_i P = C_{\mathrm{He}_i}(\mathrm{T}) \tag{3.5.14}$$

Solubility data are given in Table 3.5.1.

For example, consider absorption of carbon dioxide from a stream of pure CO_2 at 2 bar pressure into water at 310 K. From Table 3.5.1, $C_{He} = 2170$ bar; thus

$$\mathrm{He}_{CO_2} = \frac{2170}{2} = 1085; \quad x_{CO_2,u} = \frac{1}{1085} = 9.22 \times 10^{-4}$$

Dissolution of gases into metals is characterized by varied and rather complex interface conditions. Provided temperatures are sufficiently high, hydrogen dissolution is reversible (similar to CO_2 absorption into water); hence, for example, titanium-hydrogen solutions can exist only in contact with a gaseous hydrogen atmosphere. As a result of hydrogen going into solution in atomic form, there is a characteristic square root relation

$$m_{H_2,u} \alpha P_{H_2,s}^{1/2}$$

TABLE 3.5.1
Henry Constants C_{He} for Dilute Aqueous Solutions at Moderate Pressures ($P_{i,s}/x_{i,u}$ in atm, or in bar $= 10^5$ Pa, within the Accuracy of the Data)

Solute	290 K	300 K	310 K	320 K	330 K	340 K
H_2S	440	560	700	830	980	1,140
CO_2	1,280	1,710	2,170	2,720	3,220	—
O_2	38,000	45,000	52,000	57,000	61,000	65,000
H_2	67,000	72,000	75,000	76,000	77,000	76,000
CO	51,000	60,000	67,000	74,000	80,000	84,000
Air	62,000	74,000	84,000	92,000	99,000	104,000
N_2	16,000	89,000	101,000	110,000	118,000	124,000

The constant of proportionality is strongly dependent on temperature, as well as on the particular titanium alloy: for Ti-6Al-4V alloy it is twice that for pure titanium. In contrast to hydrogen, oxygen dissolution in titanium is irreversible and is complicated by the simultaneous formation of a rutile (TiO_2) scale on the surface. Provided some oxygen is present in the gas phase, the titanium-oxygen *phase diagram* (found in a metallurgy handbook) shows that $m_{O_2,u}$ in alpha-titanium is 0.143, a value essentially independent of temperature and O_2 partial pressure. Dissolution of oxygen in zirconium alloys has similar characteristics to those discussed above for titanium.

All the preceding examples of interface concentrations are situations where thermodynamic equilibrium can be assumed to exist at the interface. Sometimes thermodynamic equilibrium does not exist at an interface: a very common example is when a chemical reaction occurs at the interface, and temperatures are not high enough for equilibrium to be attained. Then the concentrations of the reactants and products at the *s*-surface are dependent both on the rate at which the reaction proceeds—that is, the *chemical kinetics*—as well as on mass transfer considerations.

Definitions of Fluxes and Velocities

The mass (or molar) flux of species *i* is a vector quantity giving the mass (or moles) of species *i* that pass per unit time through a unit area perpendicular to the vector (Figure 3.5.2). We denote the absolute mass and molar fluxes of species *i*, that is, relative to stationary coordinate axes, as $\boldsymbol{n}_i$ (kg/m^{2s}) and $\boldsymbol{N}_i$ (kmol/m^{2}s), respectively. The absolute mass flux of the mixture (mass velocity) is

$$\boldsymbol{n} = \sum \boldsymbol{n}_i \tag{3.5.15}$$

and the local mass-average velocity is

$$\boldsymbol{v} = \frac{\boldsymbol{n}}{\rho}\,\text{m/s} \tag{3.5.16}$$

The velocity *v* is the velocity that would be measure by a Pitot tube and corresponds to the velocity used in considering pure fluids. On a molar basis, the absolute molar flux of the mixture is

$$\boldsymbol{N} = \sum \boldsymbol{N}_i \tag{3.5.17}$$

and the local molar-average velocity is

$$\boldsymbol{v}^* = \frac{\boldsymbol{N}}{c}\,\text{m/s} \tag{3.5.18}$$

The absolute fluxes of species *i* have two components. On a mass basis we write

$$\boldsymbol{n}_i = \rho_i \boldsymbol{v} + \boldsymbol{j}_i \tag{3.5.19}$$

where $\rho_i \boldsymbol{n}$ is transport of species *i* by bulk motion of the fluid at velocity $\boldsymbol{v}$ and is the *convective* component. Thus, $\boldsymbol{j}_i$ is transport of species *i* relative to the mass average velocity; it is called the

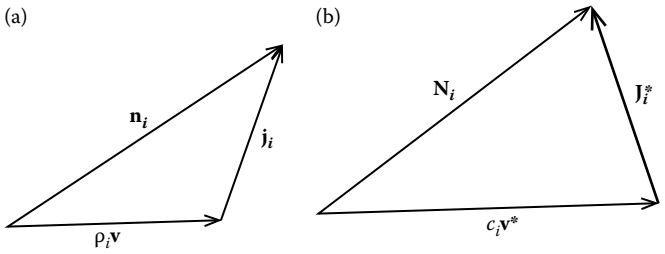

FIGURE 3.5.2 Flux vectors: (a) mass basis and (b) molar basis.

diffusive component because most commonly it is due to ordinary (concentration) diffusion of the species. On a molar basis the corresponding relation is

$$\boldsymbol{N}_i = c_i \boldsymbol{v}^* + \boldsymbol{J}_i^* \tag{3.5.20}$$

Some important relations follow from these definitions:

$$\sum \boldsymbol{j}_i = \sum \boldsymbol{J}_i^* = 0 \tag{3.5.21}$$

$$\boldsymbol{N}_i = \frac{\boldsymbol{n}_i}{M_i} \tag{3.5.22}$$

$$\boldsymbol{n}_i = \rho_i \boldsymbol{v} + \boldsymbol{j}_i = m_i \sum \boldsymbol{n}_i + \boldsymbol{j}_i \tag{3.5.23a}$$

$$\boldsymbol{N}_i = c_i \boldsymbol{v}^* + \boldsymbol{J}_i^* = x_i \sum \boldsymbol{N}_i + \boldsymbol{J}_i^* \tag{3.5.23b}$$

Mechanisms of Diffusion

Ordinary Diffusion

Fick's law of ordinary diffusion is a linear relation between the rate of diffusion of a chemical species and the local concentration gradient of that species. It is exact for a binary gas mixture, for which the kinetic theory of gases gives

$$\boldsymbol{j}_1 = -\rho D_{12} \nabla m_1 \text{ kg/m}^2 \text{ s} \tag{3.5.24a}$$

on a mass basis, and

$$\boldsymbol{J}_1^* = -c D_{12} \nabla x_1 \text{ kg/m}^2 \text{ s} \tag{3.5.24b}$$

on a molar basis; D_{12} (m^2/s) is the binary diffusion coefficient (or mass diffusivity), and $D_{21} = D_{21}$. Equations 3.5.24a and 3.5.24b are mathematically equivalent; however, notice that it is incorrect to write

$$\boldsymbol{j}_1 = -D_{12} \nabla \rho_1 \tag{3.5.25}$$

since $\nabla \rho_1 \neq \rho \nabla m_1$ in general. Fick's law in the form of Equations 3.5.24a and 3.5.24b is also valid for dilute liquid and solid solutions, for which it is often possible to assume ρ (or c) constant, and then Equation 3.5.25 or its molar equivalent are good approximations.

Ordinary diffusion in multicomponent systems is described by the Stefan–Maxwell equations (Hirschfelder et al., 1954). These equations are difficult to use for engineering analysis. In gas mixtures containing species that do not have widely varying molecular weights, it is possible to model approximately the diffusion process by using an effective binary diffusion coefficient in Fick's law. This coefficient is a suitable average over the species in the mixture, and may be calculated from

$$D_{1m} = \frac{(1 - x_1)}{\sum_{i=2}^{n} (x_i / D_{1i})}; \quad x_1 \ll 1 \tag{3.5.26}$$

This equation works well for most mixtures of combustion gases (except those containing appreciable concentrations of H or H_2).

Binary diffusion coefficients at 300 K are of the order of 10^{-5} m^2/s in gases at 1 atm, 10^{-9} m^2/s in aqueous solutions, and 10^{-10} to 10^{-13} m^2/s in solids. However, the product ρD or (cD) is, at most, one order of magnitude different for gases and liquids. Data for diffusion coefficients may be found in Tables 3.5.2 through 3.5.5.

Molecules in a gas mixture, and in a liquid or solid solution, can diffuse by mechanisms other than ordinary diffusion governed by Fick's law. *Thermal diffusion* is diffusion due to a temperature gradient and is often called the *Soret effect*. Thermal diffusion is usually negligible compared with ordinary diffusion, unless the temperature gradient is very large. However, there are some important processes that depend on thermal diffusion, the most well known being the large-scale separation of uranium isotopes. *Pressure diffusion* is diffusion due to a pressure gradient and is also usually negligible unless the pressure gradient is very large. Pressure diffusion is the principle underlying

2000	4.80	3.94	4.87	2.06	18.0	4.48	3.360	16.6

Note: Owing to the practical importance of water vapor-air mixtures, engineers have used convenient empirical formulas for $D_{H_2O\,air}$. A formula that has been widely used for many years is

$$D_{H_2O\,air} = 1.97\times10^{-5}\left(\frac{P_0}{P}\right)\left(\frac{T}{T_0}\right)^{1.685}\ \text{m}^2/\text{s};\quad 273\,\text{K} < T < 373\,\text{K}$$

where $P_0 = 1$ atm; $T_0 = 256$ K. More recently, the following formula has found increasing use. (Marrero, T.R. and Mason, E.A. 1992. Gaseous diffusion coefficients, *J. Phys. Chem. Ref. Data*, 1, 3–118):

$$D_{H_2O\,air} = 1.87\times10^{-10}\frac{T^{2.072}}{P};\quad 280\,\text{K} < T < 450\,\text{K}$$

$$= 2.75\times10^{-9}\frac{T^{1.632}}{P};\quad 450\,\text{K} < T < 1070\,\text{K}$$

for P in atmospheres and T in kelvins. Over the temperature range 290–330 K, the discrepancy between the two formulas is less than 2.5%. For small concentrations of water vapor in air, the older formula gives a constant value of $Sc_{H_2O\,air} = 0.61$ over the temperature range 273–373 K. On the other hand, the Marrero and Mason formula gives values of $Sc_{H_2O\,air}$ that vary from 0.63 at 280 K to 0.57 at 373 K.

Note: Schmidt number $Sc = \mu/\rho D$; since the solutions are dilute, μ and ρ can be taken as pure water values. For other temperatures use $Sc/Sc_{300K} \simeq (\mu^2/\rho T)/(\mu^2\rho T)_{300K}$, where μ and ρ are for water, and T is absolute temperature. For chemically similar solutes of different molecular weights use $Sc_2/Sc_1 \simeq (M_2/M_1)^{0.4}$. A table of $(\mu^2/\rho T)/(\mu^2\rho T)_{300K}$ for water follows.

the operation of a centrifuge. Centrifuges are used to separate liquid solutions and are increasingly being used to separate gaseous isotopes as well. *Forced diffusion* results from an external force field acting on a molecule. Gravitational force fields do not cause separation since the force per unit mass of a molecule is constant. Forced diffusion occurs when an electrical field is imposed on an electrolyte (for example, in charging an automobile battery), on a semiconductor, or on an ionized gas (for example, in a neon tube or metalion laser). Depending on the strength of the electric field, rates of forced diffusion can be very large.

Some interesting diffusion phenomena occur in porous solids. When a gas mixture is in a porous solid, such as a catalyst pellet or silica–gel particle, the pores can be smaller than the mean free path of the molecules. Then, the molecules collide with the wall more often than with other molecules. In the limit of negligible molecule collisions we have *Knudsen diffusion*, also called *free molecule flow* in the fluid mechanics literature. If the pore size approaches the size of a molecule, then Knudsen diffusion becomes negligible and *surface diffusion*, in which adsorbed molecules move along the pore walls, becomes the dominant diffusion mechanism.

Very small particles of 10^{-3} to 10^{-1} μm size—for example, smoke, soot, and mist—behave much like large molecules. Ordinary diffusion of such particles is called *Brownian motion* and is described in most elementary physics texts. Diffusion of particles due to a temperature gradient is called *thermophoresis* and plays an important role for larger particles, typically in the size range 10^{-1} to 1 μm. Diffusion of particles in a gas mixture due to concentration gradients of molecular species is called *diffusiophoresis. Forced diffusion* of a charged particle in an electrical field is similar to that for an ionized molecular species. Thermal and electrostatic precipitators are used to remove particles from power plant and incinerator stack gases, and depend on thermophoresis and forced diffusion, respectively, for their operation. Diffusion phenomena are unimportant for particles of size greater than about 1 μm in air at 1 atm; the motion of such particles is governed by the laws of Newtonian mechanics. Transport of particles is dealt with in the *aerosol science* literature.

Species Conservation Equation

The principle of conservation of a chemical species is used to derive the *species conservation equation*. On a mass basis this equation is

$$\frac{\partial \rho_i}{\partial t} + \nabla \cdot \boldsymbol{n}_i = \dot{r}_i''' \tag{3.5.27}$$

and on a molar basis

$$\frac{\partial c_i}{\partial t} + \nabla \cdot \boldsymbol{N}_i = \dot{R}_i''' \tag{3.5.28}$$

where $\dot{r}_i'''$ and $\dot{R}_i'''$ are the mass and molar rates of production of species i due to chemical reactions. Summing Equation 3.5.27 over all species gives the mass conservation or continuity equation,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot \rho \boldsymbol{v} = 0 \tag{3.5.29}$$

The molar form is

$$\frac{\partial c}{\partial t} + \nabla \cdot c\boldsymbol{v}^* = \sum_i \dot{R}_i''' \tag{3.5.30}$$

since, in general, moles are not conserved in chemical reactions. A useful alternative form to Equation 3.5.27 can be obtained using Equations 3.5.23a and 3.5.29 and is

$$\rho \frac{Dm_i}{Dt} = \nabla \cdot \boldsymbol{j}_i + \dot{r}_i''' \tag{3.5.31}$$

where D/Dt is the substantial derivative operator.

If we consider a binary system of species 1 and 2 and introduce Fick's law, Equation 3.5.24a into Equation 3.5.31, then

$$\rho \frac{Dm_i}{Dt} = \nabla \cdot \left(\rho D_{12} \nabla m_1\right) + \dot{r}_1''' \tag{3.5.32}$$

When working on a mass basis we define a stationary medium as one in which the mass average velocity v is zero everywhere. Substituting in Equation 3.5.32 with no chemical reactions and assuming constant properties,

$$\frac{\partial m_1}{\partial t} = D_{12} \nabla^2 m_1 \tag{3.5.33}$$

which is the diffusion equation, and is the mass transfer analog to Fourier's equation for heat conduction. For steady diffusion, Equation 3.5.33 reduces to Laplace's equation

$$\nabla^2 m_1 = 0 \tag{3.5.34}$$

Notice that since properties have been assumed constant, any measure of concentration can be used in Equations 3.5.33 and 3.5.34, for example ρ_1, c_1, and x_1.

Diffusion in a Stationary Medium

Many problems involving diffusion in a stationary medium are governed by the diffusion equation (Equation 3.5.33). Often solutions may be obtained from their heat conduction analogs. Some important cases follow.

Steady Diffusion through a Plane Wall

The mass flow of species 1 across a plane wall of thickness L and cross-sectional area A is

$$\dot{m}_1 = \frac{\rho D_{12} A}{L}\left(m_{1,u} - m_{1,u'}\right) \text{kg/m}^2\text{s} \tag{3.5.35}$$

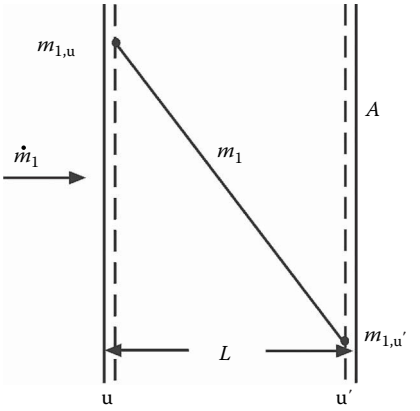

FIGURE 3.5.3 Steady diffusion across a plane wall.

where the u- and u′-surfaces are shown in Figure 3.5.3. Solubility data are required to relate the u- and u′-surface concentrations to s- and s′-surface concentrations. Alternatively for systems that obey Henry's law, a solubility S can be defined as the volume of solute gas (at STP of 0°C and 1 atm) dissolved in unit volume when the gas is at a partial pressure of 1 atm. Then, defining permeability p_{12} as the product $D_{12}S$, the volume flow of species 1 is

$$\dot{V}_1 = \frac{p_{12}A}{L}\left(P_{1,s} - P_{1,s'}\right)\mathrm{m}^3(\mathrm{STP})/\mathrm{s} \tag{3.5.36}$$

where the partial pressures P_1 are in atmospheres. The SI units for permeability are m^3 (STP)/m^2 s (atm/m). Permeability and solubility data are given in Table 3.5.6. For example, consider helium at 10^5 Pa contained in a 7056-glass vessel with a 1-mm-thick wall at 680 K. For a surface area of 0.01 m^2, the leakage rate into ambient air is

$$\dot{V} = \frac{\left(1.0\times10^{-12}\right)\left(0.01\right)}{\left(0.001\right)}\left(10^5 - 0\right) = 1.0\times10^{-6}\ \mathrm{m}^3(\mathrm{STP})/\mathrm{s}$$

where the value p_{12} was obtained from Table 3.5.6.

[a] Solubility S = volume of solute gas (0°C, 1 atm) dissolved in unit volume of solid when the gas is at 1 atm partial pressure. Solubility coefficient $S'=c_{1,u}/c_{1,s}$.

[b] Permeability $p_{12}=D_{12}S$.

In general, mass fractions are discontinuous across phase interfaces. Hence, Equation 3.5.35 cannot be generalized to a number of walls in series by simply adding diffusion resistances. However, equilibrium partial pressures P_1 are continuous, and for two walls A and B, Equation 3.5.36 becomes

$$\dot{V}_1 = \frac{P_{1,s} - P_{1,s'}}{\dfrac{L_A}{P_{1A}A} + \dfrac{L_B}{P_{1B}A}} \text{ m}^3 \text{ (STP)/s} \tag{3.5.37}$$

Transient Diffusion in a Semi-Infinite Solid

The typically low diffusion coefficients characterizing solids result in many situations where concentration changes are limited to a thin region near the surface (of thickness $\delta_c \sim (D_{12}t)^{1/2}$). Examples include case-hardening of mild steel and coloring of clear sapphires. Details of the geometry are then unimportant and semi-infinite solid model can be used (Figure 3.5.4). For an initial concentration $m_{1,0}$ and a u-surface concentration suddenly changed to $m_{1,u}$ at time $t=0$, the concentration distribution $m_1(z,t)$ is

$$\frac{m_1 - m_{1,0}}{m_{1,u} - m_{1,0}} = \text{erfc}\frac{z}{\left(4D_{12}t\right)^{1/2}} \tag{3.5.38}$$

and the dissolution rate is

$$\dot{m}_1 = j_{1,u}A = \rho A\left(\frac{D_{12}}{\pi t}\right)^{1/2}\left(m_{1,u} - m_{1,0}\right) \text{kg/s} \tag{3.5.39}$$

For example, consider a Pyrex glass slab at 800 K suddenly exposed to helium at 10^4 Pa. The molar equivalent to Equation 3.5.39 for an assumed constant solid phase molar concentration c is

$$\frac{\dot{M}_1}{A} = \left(\frac{D_{12}}{\pi t}\right)^{1/2}\left(c_{1,u} - c_{1,0}\right)$$

From Table 3.5.6, $S' = c_{1,u}/c_{1,s} \cong 0.024$; hence, $c_{1,u} = (0.024)(10^4)/(8314)(800) = 3.61\times10^{-5}$ kmol/m^3. From Table 3.5.4, $D_{12} = 4.76\times10^{-8}\exp[-(2.72\times10^4)(10^3)/(8314)(800)] = 7.97\times10^{-10}$ m^2/s. Hence,

$$\frac{\dot{M}_1}{A} = \left(\frac{7.97\times10^{-10}}{\pi t}\right)^{1/2}\left(3.61\times10^{-5} - 0\right) = 5.75\times10^{-10}/t \text{ kmol/s}$$

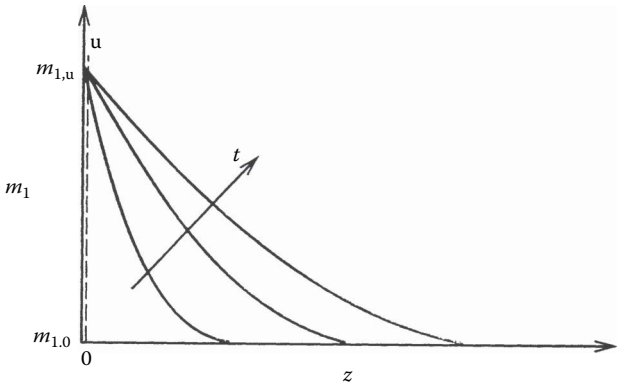

FIGURE 3.5.4 Transient diffusion in a plane slab.

Transient Diffusion in Slabs, Cylinders, and Spheres

Transient heat conduction in slates, cylinders, and spheres with surface convection is dealt with in Section 3.1. The analogous mass diffusion problem for the slab $-L < z < L$ is now considered. On a molar basis the governing differential equation is

$$\frac{\partial x_1}{\partial t} = D_{12} \frac{\partial^2 x_1}{\partial z^2} \tag{3.5.40}$$

with initial condition $x_1 = x_{1,0}$ at $t=0$. Boundary conditions are $\partial x_1/\partial z = 0$ at $z=0$, and at the surface $z=L$,

$$-cD_{12} \left.\frac{\partial x_1}{\partial z}\right|_{z=L} = G_{m1}\left(y_{1,s} - y_{1,e}\right) \tag{3.5.41}$$

The convective boundary condition is of the same form as Newton's law of cooling, and defines the mole transfer conductance G_{m1} (kmol/m^{2}s) (see also the section on mass and mole transfer conductances). Also, we have followed chemical engineering practice and denoted mole fraction x in the solid (or liquid) phase and y in the liquid (or gas) phase, to emphasize that generally mole fraction is not continuous across a phase interface. For example, consider absorption of a sparingly soluble gas into a liquid for which Henry's law, Equation 3.5.13, applies: then $y_{1,s} = \mathrm{He}\, x_{1,u}$.

In using heat conduction charts for mass diffusion problems, particular care must be taken with the evaluation of the Biot number. For heat conduction $\mathrm{Bi} = h_c L/k$, where k is the solid conductivity. For mass diffusion the Biot number accounts for the discontinuity in concentration across the phase interface. Using gas absorption into a plane layer of liquid, for example, when Equation 3.5.41 is put into an appropriate dimensionless form, the mass transfer Biot number is seen to be

$$\mathrm{Bi}_m = \frac{G_{m1}\mathrm{He}L}{cD_{12}} \tag{3.5.42}$$

For sparingly soluble gases, e.g., O_2 or CO_2 in water, He, and hence Bi_m, are very large, and the absorption process is liquid-side controlled; that is, a uniform gas-phase composition can be assumed. Often interface equilibrium data are in graphical or tabular form; then an effective Biot number at the concentration of concern must be used.

For example, consider a 2-mm-diameter droplet of water at 300 K entrained in an air flow at 1 atm pressure containing 1% by volume CO_2. From Table 3.5.5, $\mathrm{He} = C_{\mathrm{He}} = 1710$. The liquid phase molar density can be approximated by the pure water value of $c = \rho/M = 996/18 = 55.3$ kmol/m^3. The liquid phase diffusion coefficient is obtained from Table 3.5.4 as $D_{12} = \nu_{H_2O}/\mathrm{Sc}_{12} = 0.87\times10^{-6}/420 = 2.07\times10^{-9}$ m^2/s. For negligible relative motion between the droplet and gas, the Sherwood number (see the section on dimensionless groups) is approximately 2.0, and hence the gas phase mole transfer conductance is $G_{m1} = 2cD_{12}/D$. For the gas phase, the molar density $c = P/RT = (1.0133\times10^5)/(8314)(300) = 0.0406$ kmol/m^3 and $D_{12} = 0.157\times10^{-4}$ m^2/s from Table 3.5.2. Thus,

$$G_{m1} = \frac{(2)(0.0406)\left(0.157\times10^{-4}\right)}{(0.002)} = 6.37\times10^{-4} \text{ kmol/m}^2\text{s}$$

From Equation 3.5.42 with $L = R$ the droplet radius, the mass transfer Biot number is

$$\mathrm{Bi}_m = \frac{\left(6.37\times10^{-4}\right)(1710)(0.001)}{(55.3)\left(2.07\times10^{-9}\right)} = 9520$$

Thus, even for a small droplet with a relatively large gas-side mole transfer conductance, the absorption process is liquid-side controlled.

Diffusion in a Porous Catalyst

Porous catalysts are used to give a large surface area per unit volume of catalyst surface. Current practice for automobile catalytic convertors is to use a ceramic matrix as a support for a thin porous alumina layer that is impregnated with the catalyst (called a *washcoat*). A typical matrix has passages of hydraulic diameter 1 mm, and the washcoat may be about 20 μm thick. Pore sizes are of the order of 1 μm for which ordinary and Knudsen diffusion resistances are important. A simple model for diffusion in a porous catalyst is

$$J_1 = -cD_{1,\text{eff}} \cdot \nabla x_1 \text{ kmol/m}^2\text{s} \tag{3.5.43}$$

where the subscript eff denotes an effective diffusivity that accounts for the presence of the solid material. Assuming additive resistances,

$$\frac{1}{D_{1,\text{eff}}} = \frac{1}{D_{12,\text{eff}}} + \frac{1}{D_{\text{K1,eff}}} \tag{3.5.44}$$

and

$$D_{12,\text{eff}} = \frac{\varepsilon_v}{\tau} D_{12}; \quad D_{\text{K1,eff}} = \frac{\varepsilon_v}{\tau} D_{\text{K1,eff}} \tag{3.5.45}$$

where ε_v is the volume void fraction and τ is the tortuosity factor (usually between 4 and 8). From the kinetic theory of gases the Knudsen diffusion coefficient is

$$D_{\text{K1}} = 97 r_e \left(T/M_1\right)^{1/2} \text{ m}^2/\text{s} \tag{3.5.46}$$

for effective pore radius r_e in meters and T in kelvins.

When a chemical reaction takes place within a porous layer, a concentration gradient is set up, and surfaces on pores deep within the pellet are exposed to lower reactant concentrations than surfaces near the pore openings. For a first-order reaction, it is straightforward to obtain the concentration distribution. The results of such an analysis are conveniently given in the form of an effectiveness η_p, which is defined as the actual consumption rate of the reactant divided by that for an infinite diffusion coefficient. For a layer of thickness L exposed to reactants on one side, as shown in Figure 3.5.5.

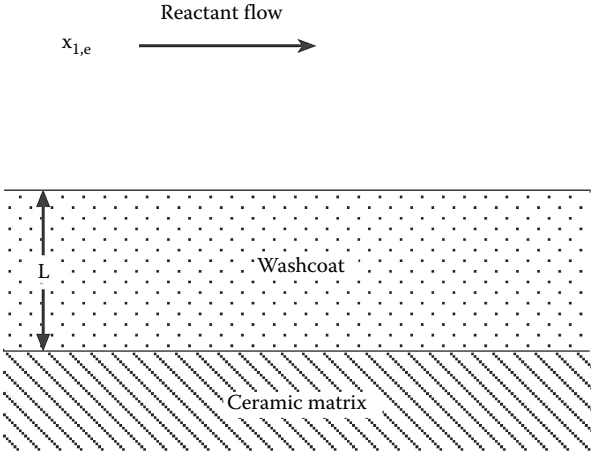

FIGURE 3.5.5 A catalyst layer.

$$\eta_p = \frac{\tanh bL}{bL}; \quad b = \left(\frac{k'' a_p}{D_{1,\text{eff}}} \right)^{1/2} \tag{3.5.47}$$

where k'' (m/s) is the rate constant for a first-order reaction and a_p (m^{-1}) is the catalyst area per unit volume. Notice that this effectiveness is analogous to the efficiency of a heat transfer fin.

For example, consider a 30-μm-thick porous alumina washcoat with a volume void fraction $\varepsilon_v = 0.8$, a tortuosity factor $\tau = 4.0$, average pore radius $r_e = 1$ μm, and catalytic surface area per unit volume $a_p = 7.1 \times 10^5$ cm^2/cm^3. For carbon monoxide oxidation by copper oxide at 800 K, 1 atm, the rate constant is approximately 4.2×10^{-4} m^2/s. To calculate the effectiveness of the washcoat, we first need to calculate the effective diffusion coefficient $D_{1,\text{eff}}$:

$$D_{12,\text{eff}} = \frac{\varepsilon_v}{\tau} D_{12} = \frac{0.8}{4.0}\left(1.06 \times 10^{-4}\right) = 2.12 \times 10^{-5} \text{ m}^2/\text{s}$$

where D_{12} is approximated as the CO-air value from Table 3.5.2.

$$D_{\text{K}1,\text{eff}} = \frac{\varepsilon_v}{\tau} D_{12} = \frac{0.8}{4.0}(97)\left(1 \times 10^{-6}\right)\left(800/28\right)^{1/2} = 1.04 \times 10^{-4} \text{ m}^2/\text{s}$$

$$\frac{1}{D_{1,\text{eff}}} = \frac{1}{2.12 \times 10^{-5}} + \frac{1}{1.04 \times 10^{-4}}; \quad D_{1,\text{eff}} = 1.76 \times 10^{-5} \text{ m}^2/\text{s}$$

$$b = \left[\frac{\left(4.2 \times 10^{-4}\right)\left(7.1 \times 10^5\right)\left(10^2\right)}{1.76 \times 10^{-5}} \right]^{1/2} = 4.2 \times 10^4 \text{ m}^{-1}; \quad bL = \left(4.2 \times 10^4\right)\left(30 \times 10^{-6}\right) = 1.236$$

$$\eta_p = \frac{\tanh 1.236}{1.236} = 68.3\%$$

In an automobile catalytic convertor, Equation 3.5.47 applies to the catalyst washcoat. However, the mass transfer problem also involves a convective process for transport of reactants from the bulk flow. Referring to Figure 3.5.6 there are two mass transfer resistances in series, and the consumption rate of species 1 per unit surface area of the washcoat is

$$J_{1,s} = \frac{-x_{1,e}}{\dfrac{1}{L\eta_p k'' c} + \dfrac{1}{G_{m1}}} \text{ kmol/m}^2\text{ s} \tag{3.5.48}$$

where G_{m1} is the mole transfer conductance describing convective transport to the washcoat surface (see the section on mass and mole transfer conductances). Notice that when $G_{m1} \ll L\eta_p k'' c$ the reaction rate is controlled by mass transfer from the gas stream to the washcoat surface; when

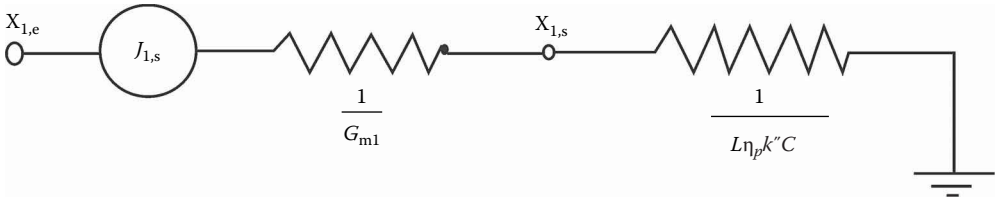

FIGURE 3.5.6 Equivalent circuit for mass transfer in an automobile catalytic converter.

$L\eta_p k'' c <<< G_{m1}$, the reaction rate is controlled by diffusion within the washcoat and the kinetics of the reaction.

Diffusion in a Moving Medium

Net mass transfer across a surface results in a velocity component normal to the surface, and an associated convective flux in the direction of mass transfer. This convective flow is called a *Stefan flow*. The solutions of a number of mass transfer problems, involving a Stefan flow induced by the mass transfer process itself, follow. When necessary to obtain an analytical result, properties are assumed constant. Thus, use of these results requires evaluation of properties at a suitable reference state.

Diffusion with One Component Stationary

As an example, consider the simple heat pipe shown in Figure 3.5.7 with the evaporator and condenser located at the ends only (a bad design!). Then, if the working fluid is species 1, and a noncondensable gas is species 2, the concentration distribution is

$$\left(\frac{1-x_1}{1-x_{1,s}}\right)=\left(\frac{1-x_{1,e}}{1-x_{1,s}}\right)^{z/L} \tag{3.5.49}$$

and the vapor flux along the heat pipe is

$$N_1=\frac{cD_{12}}{L}\ln\frac{1-x_{1,e}}{1-x_{1,s}}\,\text{kmol/m}^2\text{s} \tag{3.5.50}$$

Notice that $N_2=0$; that is, the gas is stationary. The rate of heat flow for a heat pipe of cross-sectional area of A_c is $\dot{Q}=N_1M_1h_{fg}A_c$. Evaluation of the cD product at a reference temperature $T_r=(1/2)(T_s+T_e)$ is adequate for most applications. Equation 3.5.50 applies to any situation where a one-dimensional model of mass transport is appropriate.

Heterogeneous Combustion

As an example, consider a small carbon particle entrained in a high-temperature airstream, as shown in Figure 3.5.8. The surface reaction is $2C+O_2 \rightarrow 2CO$ and there are no reactions in the gas phase. The stoichiometric ratio for the reaction is $r=4/3$ kg oxygen/kg carbon. The reaction is diffusion controlled at the temperatures under consideration, that is, $m_{O_2,s} \simeq 0$. The mass transfer rate is n_s, which we give the distinctive symbol $\dot{m}''$ since it is usually the desired result of an analysis; in this situation $\dot{m}''=n_{C,u}$ is the combustion rate of carbon, and for a spherical particle of radius R is given by

$$\dot{m}''=\frac{\rho D_{O_2,m}}{R}\ln\left[1+\frac{m_{O_2,e}-m_{O_2,s}}{m_{O_2,s}+4/3}\right]=0.160\,\frac{\rho D_{O_2,m}}{R}\,\text{kg/m}^2\text{s} \tag{3.5.51}$$

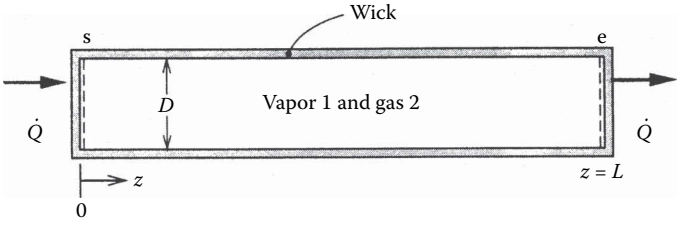

FIGURE 3.5.7 A simple heat pipe with the evaporator and condenser located at its ends.

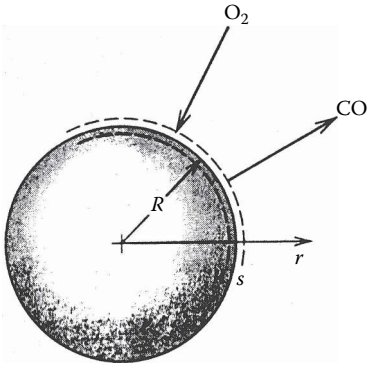

FIGURE 3.5.8 Combustion of a carbon particle in high-temperature air. The surface reaction is $2C+O_2 \rightarrow 2CO$.

The carbon particle temperature depends on its radius, and it is required to evaluate the property product ρD at an appropriate reference temperature: an energy balance on the particle should be performed for this purpose. The resulting particle lifetime τ is

$$\tau = \frac{\rho_{\text{solid}} D_0^2}{1.28\left(\rho D_{O_2,m}\right)_r} \text{ s} \tag{3.5.52}$$

for an initial particle diameter of D_0. Air properties at an average mean film temperature can be used to evaluate $\rho D_{O_2,m}$.

Consider a 10-μm-diameter carbon particle ignited in an airstream at 1500 K and 1 atm. An energy balance on the particle (including radiation to surroundings at 1500 K) shows that the average temperature of the particle is approximately 2550 K, and, thus, $T_r=(1/2)(1500+2550)=2025$ K or $\rho \simeq \rho_{\text{air}}=0.175\,\text{kg/m}^3$ and $D_{O_2,m} \simeq D_{O_2,\text{air}} = 4.89\times10^{-4}\,\text{m}^2/\text{s}$ (from Table 3.5.1). Then

$$\tau = \frac{(1810)\left(10\times10^{-6}\right)^2}{(1.28)(0.175)\left(4.89\times10^{-4}\right)} = 1.65\times10^{-3}\,\text{s}$$

Droplet Evaporation

Consider a small droplet of species 1 entrained in a gas stream, species 2 (Figure 3.5.9). This is a simultaneous heat and mass transfer problem, and the mass transfer rate can be obtained by solving simultaneously

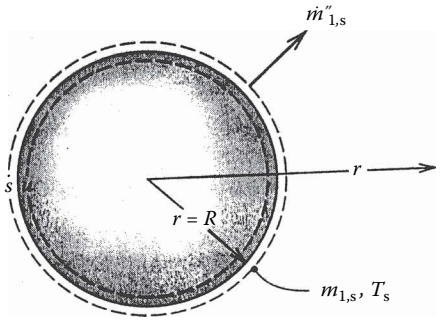

FIGURE 3.5.9 Evaporation of a droplet.

$$\dot{m}'' = \frac{\rho D_{12}}{R} \ln\left(1 + \frac{m_{1,e} - m_{1,s}}{m_{1,s} - 1}\right) = \frac{k/c_{p1}}{R} \ln\left(1 + \frac{c_{p1}(T_e - T_s)}{h_{fg}}\right) \text{kg/m}^2\,\text{s} \tag{3.5.53a}$$

$$m_{1,s} = m_{1,s}(T, P) \quad \text{(from vapor–pressure data)} \tag{3.5.53b}$$

Temperature T_s is the adiabatic vaporization temperature and is essentially the psychrometric wet-bulb temperature. Properties can be evaluated at mean film temperature and composition; alternatively, c_{p1} can be set equal to the reference specific heat and all properties evaluated using Hubbard's 1/3, rule, namely,

$$m_{1,r} = m_{1,s} + (1/3)(m_{1,e} - m_{1,s}) \tag{3.5.54a}$$

$$T_r = T_s + (1/3)(T_e - T_s) \tag{3.5.54b}$$

Droplet Combustion

Figure 3.5.10 shows a schematic of a volatile liquid hydrocarbon fuel droplet burning in air at zero gravity. The flame diameter is typically four to six times the droplet diameter. Heat is transferred from the flame to the droplet and serves to vaporize the fuel. In the flame, the vapor reacts with oxygen to form gaseous products, primarily CO_2 and H_2O. When a fuel droplet ignites, there is a short initial transient during which the droplet heats up, until further conduction into the droplet is negligible and the droplet attains a steady temperature (approximately the wet-bulb temperature, which is very close to the boiling point for a typical hydrocarbon fuel). The reaction in the flame can be modeled as a single-step reaction with a constant stoichiometric ratio, r, and heat of combustion Δh_c J/kg of fuel.

The burning (mass transfer) rate of the droplet is given by the Godsave–Spalding formula,

$$\dot{m}'' = \frac{k/c_p}{R} \ln[1 + B] \text{ kg/m}^2\text{s} \tag{3.5.55}$$

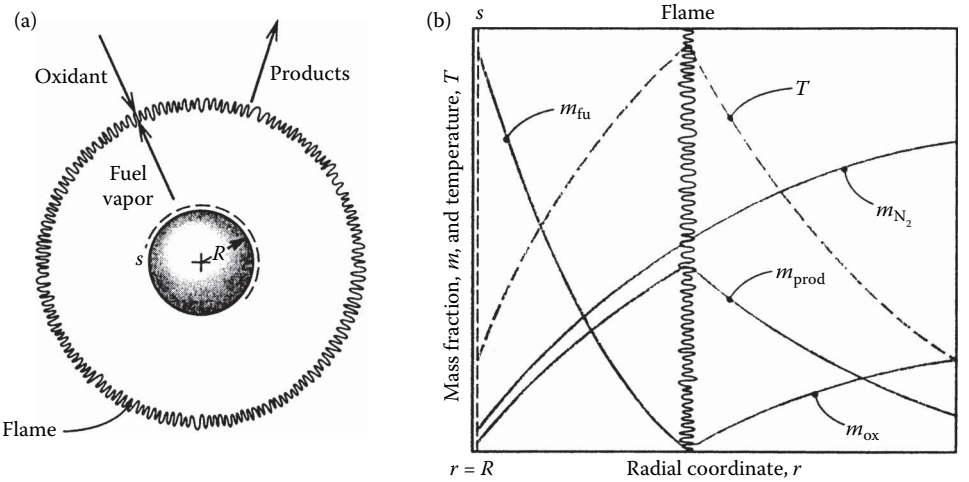

FIGURE 3.5.10 Combustion of a volatile fuel droplet burning in air: (a) schematic showing the flame and (b) concentration and temperature profiles.

where

$$B = \frac{m_{\text{ox,e}}\Delta h_{\text{c}} / r + c_{\text{p}}(T_{\text{e}} - T_{\text{s}})}{h_{\text{fg}}}$$

is the *mass transfer driving force* (or *transfer number*). The droplet lifetime is then

$$\tau = \frac{\rho_l D_0^2}{8(k / c_{\text{p}})\ln(1+B)}(\text{s}) \tag{3.5.56}$$

Based on experimental data for alkane droplets burning in air, Law and Williams (1972) recommend that properties be evaluated at a reference temperature $T_{\text{r}}=(\text{l}/2)(T_{\text{BP}}+T_{\text{flame}})$ where T_{flame} is the adiabatic flame temperature. The reference specific heat is $c_{\text{pr}}=c_{\text{pfu}}$, and the reference thermal conductivity is $k_{\text{r}}=0.4k_{\text{fu}}+0.6k_{\text{air}}$. Radiation has been ignored in the analysis leading to Equation 3.5.55 but is accounted for in using the Law and Williams reference-property scheme.

For example, consider a 1-mm-diameter *n*-octane droplet burning in air at 1 atm and 300 K, at near zero gravity. For *n*-octane (*n*-C_8H_{18}), $\rho_{\text{l}}=611\,\text{kg/m}^3$, $h_{\text{fg}}=3.03\times10^5\,\text{J/kg}$, $\Delta h_{\text{c}}=4.44\times10^7\,\text{J/kg}$, and $T_{\text{BP}}=399$ K. The flame temperature is $T_{\text{flame}}=2320$ K. At a reference temperature of (1/2) $(T_{\text{flame}}+T_{\text{BP}})=1360$ K, property values of *n*-octane vapor include $k=0.113$ W/m K, $c_{\text{p}}=4280\,\text{J/kg K}$. The reaction is

$$C_8H_{18}+12.5O_2 \rightarrow 8CO_2+9H_2O$$

Hence, the stoichiometric ratio $r=400/114.2=3.50$. Also $m_{\text{ox,e}}=0.231$ and $T_{\text{s}} \simeq T_{\text{BP}}=399$ K. Thus, the transfer number is

$$B = \frac{(0.231)\left(4.44\times10^7\right)/(3.50)+4280(300-399)}{3.03\times10^5} = 8.27$$

At $T_{\text{r}}=1360$ K, $k_{\text{air}}=0.085$ W/m K. Hence,

$$k_{\text{r}} = 0.4k_{\text{fu}}+0.6k_{\text{air}} = (0.4)(0.113)+(0.6)(0.085) = 0.096\,\text{W/m K}$$

and the droplet lifetime is

$$\tau = \frac{(611)\left(1\times10^{-3}\right)^2}{(8)(0.096/4280)\ln(1+8.27)} = 1.53\,\text{s}$$

Mass Convection

The terms *mass* convection or *convective mass transfer* are generally used to describe the process of mass transfer between a surface and a moving fluid, as shown in Figure 3.5.11. The surface may be that of a falling water film in an air humidifier, of a coke particle in a gasifier, or of a silica-phenolic heat shield protecting a reentry vehicle. As is the case for heat convection, the flow can be *forced* or *natural, internal* or *external*, and *laminar* or *turbulent*. In addition, the concept of whether the mass transfer rate is *low* or *high* plays an important role: when mass transfer rates are low, there is a simple analogy between heat transfer and mass transfer that can be efficiently exploited in the solution of engineering problems.

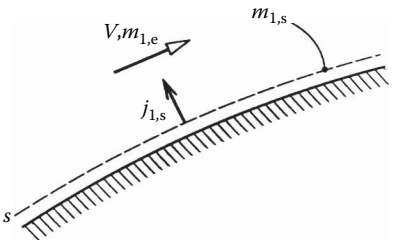

FIGURE 3.5.11 Notation for convective mass transfer into an external flow.

Mass and Mole Transfer Conductances

Analogous to convective heat transfer, the rate of mass transfer by convection is usually a complicated function of surface geometry and s-surface composition, the fluid composition and velocity, and fluid physical properties. For simplicity, we will restrict our attention to fluids that are either binary mixtures or solutions, or situations in which, although more than two species are present, diffusion can be adequately described using effective binary diffusion coefficients, as was discussed in the section on ordinary diffusion. Referring to Figure 3.5.11, we define the *mass transfer conductance* of species 1, g_{m1}, by the relation

$$J_{1,s} = g_{m1} \cdot \Delta m_1;\ \Delta m_1 = m_{1,s} - m_{1,e} \tag{3.5.57}$$

and the units of g_{m1} are seen to be the same as for mass flux (kg/m^{2}s). Equation 3.5.57 is of a similar form to Newton's law of cooling, which defines the heat transfer coefficient h_c. Why we should not use a similar name and notation (e.g., mass transfer coefficient and h_m) will become clear later. On a molar basis, we define the *mole transfer conductance* of species 1, G_{m1}, by a corresponding relation,

$$J_{1,s} = G_{m1} \cdot \Delta x_1;\ \Delta x_1 = x_{1,s} - x_{1,e} \tag{3.5.58}$$

where G_{m1} has units (kmol/m^{2}s).

Low Mass Transfer Rate Theory

Consider, as an example, the evaporation of water into air, as shown in Figure 3.5.12. The water–air interface might be the surface of a water reservoir, or the surface of a falling water film in a cooling tower or humidifier. In such situations, the mass fraction of water vapor in the air is relatively small; the highest value is at the s-surface, but even if the water temperature is as high as 50°C, the corresponding value of $m_{H_2O,s}$ at 1 atm total pressure is only 0.077. From Equation 3.5.54, the driving potential for diffusion of water vapor away from the interface is $\Delta m_1 = m_{1,s} - m_{1,e}$, and is small compared to unity, even if the free-stream air is very dry such that $m_{1,e} \simeq 0$. We then say that the mass transfer rate is *low* and the rate of evaporation (kg/s) of the water can be approximated as $j_{1,s}$; for a surface area A,

$$\dot{m}_1 = \left(m_{1,s} n_s + j_{1,s}\right) A \simeq j_{1,s} A \tag{3.5.59}$$

In contrast, if the water temperature approaches its boiling point, $m_{1,s}$ is no longer small, and of course, in the limit of $T_s = T_{BP}$, $m_{1,s} = 1$. The resulting driving potential for diffusion Δm_1 is then large, and we say that the mass transfer rate is *high*. Then, the evaporation rate cannot be calculated from Equation 3.5.59, as will be explained in the section on high mass transfer rate theory. For water evaporation into air, the error incurred in using low mass transfer rate theory is approximately (1/2) Δm_1, and a suitable criterion for application of the theory to engineering problems is $\Delta m_1 < 0.1$ or 0.2.

A large range of engineering problems can be adequately analyzed assuming low mass transfer rates. These problems include cooling towers and humidifiers as mentioned above, gas absorbers for

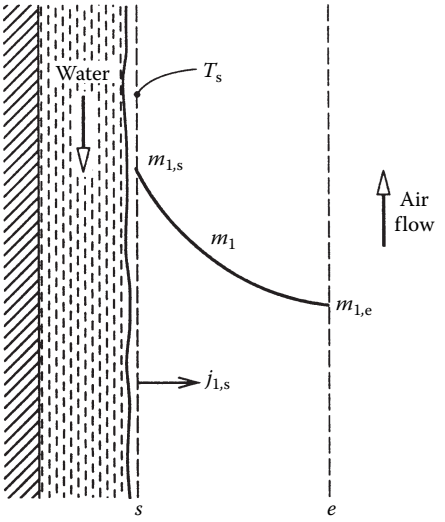

FIGURE 3.5.12 Evaporation of water into an air flow.

sparingly soluble gases, and catalysis. In the case of catalysis, the *net* mass transfer rate is actually zero. Reactants diffuse toward the catalyst surface and the products diffuse away, but the catalyst only promotes the reaction and is not consumed. On the other hand, problems that are characterized by high mass transfer rates include condensation of steam containing a small amount of noncondensable gas, as occurs in most power plant condensers; combustion of volatile liquid hydrocarbon fuel droplets in diesel engines and oil-fired power plants, and ablation of phenolic-based heat shields on reentry vehicles.

Dimensionless Groups

Dimensional analysis of convective mass transfer yields a number of pertinent dimensionless groups that are, in general, analogous to dimensionless groups for convective heat transfer. The most important groups are as follows.

1. The Schmidt number, $\mathrm{Sc}_{12}=\mu/\rho D_{12}$, which is a properties group analogous to the Prandtl number. For gas mixtures, $\mathrm{Sc}_{12}=O(1)$, and for liquid solutions, $\mathrm{Sc}_{12}=O(100)$ to $O(1000)$. There are not fluids for which $\mathrm{Sc}_{12} \ll 1$, as is the case of Prandtl number for liquid metals.
2. The Sherwood number (or mass transfer Nusselt number). $\mathrm{Sh}=g_{m1}L/\rho D_{12}$ $(=G_{m1}L/cD_{12})$ is a dimensionless conductance.
3. The mass transfer Stanton number $\mathrm{St}_m=g_{m1}/\rho V$ $(=G_{m1}/cV)$ is an alternative dimensionless conductance.

As for convective heat transfer, forced convection flows are characterized by a Reynolds number, and natural convection flows are characterized by a Grashof or Rayleigh number. In the case of Gr or Ra it is not possible to replace $\Delta\rho$ by $\beta\Delta T$ since density differences can result from concentration differences (and both concentration and temperature differences for simultaneous heat and mass transfer problems).

Analogy between Convective Heat and Mass Transfer

A close analogy exists between convective heat and convective mass transfer owing to the fact that conduction and diffusion in a fluid are governed by physical laws of identical form, that is, Fourier's

and Fick's laws, respectively. As a result, in many circumstances the Sherwood or mass transfer Stanton number can be obtained in a simple manner from the Nusselt number or heat transfer Stanton number for the same flow conditions. Indeed, in most gas mixtures Sh and St_m are nearly equal to their heat transfer counterparts. For dilute mixtures and solutions and low mass transfer rates, the rule for exploiting the analogy is simple: The *Sherwood or Stanton number is obtained by replacing the Prandtl number by the Schmidt number in the appropriate heat transfer correlation*. For example, in the case of fully developed turbulent flow in a smooth pipe

$$\mathrm{Nu_D} = 0.023\mathrm{Re_D^{0.8}Pr^{0.4}}; \quad \mathrm{Pr} > 0.5 \tag{3.5.60a}$$

which for mass transfer becomes

$$\mathrm{Sh_D} = 0.023\mathrm{Re_D^{0.8}Sc^{0.4}}; \quad \mathrm{Sc} > 0.5 \tag{3.5.60b}$$

Also, for natural convection from a heated horizontal surface facing upward,

$$\overline{\mathrm{Nu}} = 0.54\left(\mathrm{Gr_L Pr}\right)^{1/4}; \quad 10^5 < \mathrm{Gr_L Pr} < 2\times 10^7 \text{ (laminar)} \tag{3.5.61a}$$

$$\overline{\mathrm{Nu}} = 0.14\left(\mathrm{Gr_L Pr}\right)^{1/3}; \quad 2\times 10^7 < \mathrm{Gr_L Pr} < 3\times 10^{10} \text{ (turbulent)} \tag{3.5.61b}$$

which for isothermal mass transfer with $\rho_s < \rho_e$ become

$$\overline{\mathrm{Sh}} = 0.54\left(\mathrm{Gr_L Sc}\right)^{1/4}; \quad 10^5 < \mathrm{Gr_L Sc} < 2\times 10^7 \text{(laminar)} \tag{3.5.62a}$$

$$\overline{\mathrm{Sh}} = 0.14\left(\mathrm{Gr_L Sc}\right)^{1/3}; \quad 2\times 10^7 < \mathrm{Gr_L Sc} < 3\times 10^{10} \text{(turbulent)} \tag{3.5.62b}$$

With evaporation, the condition, $\rho_s < \rho_e$ will be met when the evaporating species has a smaller molecular weight than the ambient species, for example, water evaporating into air. Mass transfer correlations can be written down in a similar manner for almost all the heat transfer correlations given in Section 3.2. There are some exceptions: for example, there are no fluids with a Schmidt number much less than unity, and thus there are no mass transfer correlations corresponding to those given for heat transfer to liquid metals with $\mathrm{Pr} \ll 1$. In most cases it is important for the wall boundary conditions to be of analogous form, for example, laminar flow in ducts. A uniform wall temperature corresponds to a uniform concentration $m_{1,s}$ along the s-surface, whereas a uniform heat flux corresponds to a uniform diffusive flux $j_{1,s}$. In chemical engineering practice, the analogy between convective heat and mass transfer is widely used in a form recommended by Chilton and Colburn in 1934, namely, $\mathrm{St}_m/\mathrm{St} = (\mathrm{Sc/Pr})^{-2/3}$. The Chilton–Colburn form is of adequate accuracy for most external forced flows but is inappropriate for fully developed laminar duct flows.

For example, air at 1 atm and 300 K flows inside a 3-cm-inside-diameter tube at 10 m/s. Using pure-air properties the Reynolds number is $VD/\nu = (10)(0.03)/15.7\times 10^{-6} = 1.911\times 10^4$. The flow is turbulent. Using Equation 3.5.60b with $\mathrm{Sc_{12}} = 0.61$ for small concentrations of H_2O in air,

$$\mathrm{Sh_D} = (0.023)\left(1.911\times 10^4\right)^{0.8}(0.61)^{0.4} = 50.2$$

$$g_{m1} = \rho D_{12}\mathrm{Sh}/D = \rho\nu\mathrm{Sh}/\mathrm{Sc_{12}}D = \frac{(1.177)\left(15.7\times 10^{-6}\right)(50.2)}{(0.61)(0.03)} = 5.07\times 10^{-2} \text{ kg/m}^2\,\text{s}$$

Further insight into this analogy between convective heat and mass transfer can be seen by writing out Equations 3.5.60a and 3.5.60b as, respectively,

$$\frac{(h_c/c_p)D}{k/c_p} = 0.023 Re_D^{0.8} \left(\frac{\mu}{k/c_p} \right)^{0.4} \tag{3.5.63a}$$

$$\frac{g_m D}{\rho D_{12}} = 0.023 Re_D^{0.8} \left(\frac{\mu}{\rho D_{12}} \right)^{0.4} \tag{3.5.63b}$$

When cast in this form, the correlations show that the property combinations k/c_p and ρD_{12} play analogous roles; these are *exchange coefficients* for heat and mass, respectively, both having units kg/m s, which are the same as those for dynamic viscosity μ. Also, it is seen that the ratio of heat transfer coefficient to specific heat plays an analogous role to the mass transfer conductance, and has the same units (kg/m^{2}s). Thus, it is appropriate to refer to the ratio h_c/c_p as the *heat transfer conductance,* g_h, and for this reason we should not refer to g_m as the mass transfer *coefficient*.

Simultaneous Heat and Mass Transfer

Often problems involve simultaneous convective heat and mass transfer, for which the surface energy balance must be carefully formulated. Consider, for example, evaporation of water into air, as shown in Figure 3.5.13. With H_2O denoted as species 1, the steady-flow energy equation applied to a control volume located between the u- and s-surfaces requires that

$$\dot{m}(h_{1,s} - h_{1,u}) = A(q''_{cond} - q''_{conv} - q''_{rad}) \tag{3.5.64}$$

where it has been recognized that only species 1 crosses the u- and s-surfaces. Also, the water has been assumed to be perfectly opaque so that all radiation is emitted or absorbed between the u-surface and the interface.

If we restrict our attention to conditions for which low mass transfer rate theory is valid, we can write $\dot{m}/A \simeq j_{1,s} = g_{m1}(m_{1,s} - m_{1,e})$. Also, we can then calculate the convective heat transfer as if there were no mass transfer, and write $q_{conv} = h_c(T_s - T_e)$. Substituting in Equation 3.5.64 with $q_{conv} = -k\,\partial T / \partial y|_u$, $h_{1,s} - h_{1,u} = h_{fg}$, and rearranging, gives

$$-k \left. \frac{\partial T}{\partial y} \right|_u = h_c(T_s - T_e) + g_{m1}(m_{1,s} - m_{1,e}) h_{fg} + q''_{rad} \quad \text{W/m}^2 \tag{3.5.65}$$

It is common practice to refer to the convective heat flux $h_c(T_s - T_e)$ as the *sensible* heat flux, whereas the term $g_{m1}(m_{1,s} - m_{1,e})\,h_{fg}$ is called the *evaporative* or *latent* heat flux. Each of the terms in Equation 3.5.65 can be positive or negative, depending on the particular situation. Also, the evaluation of the conduction heat flux at the u-surface, $-k\partial T/\partial y|_u$, depends on the particular situation. Four examples are shown in Figure 3.5.13. For a water film flowing down a packing in a cooling tower (Figure 3.5.13b), this heat flux can be expressed in terms of convective heat transfer from the bulk water at temperature T_L to the surface of the film, $-k\partial T/\partial y|_u = h_{cL}(T_L - T_s)$. If the liquid-side heat transfer coefficient h_{cL} is large enough, we can simply set $T_s \simeq T_L$, which eliminates the need to estimate h_{cL}. The evaporation process is then *gas-side controlled*. Figure 3.5.13c shows film condensation from a steam-air mixture on the outside of a vertical tube. In this case we can write $k\partial T/\partial y|_u = U(T_s - T_c)$, where T_c is the coolant bulk temperature. The overall heat transfer coefficient U includes the resistances of the condensate film, the tube wall, and the coolant. Sweat cooling is shown in Figure 3.5.13d, with water from a reservoir (or *plenum chamber*) injected through a porous wall at a rate just sufficient to keep the wall surface wet. In this case, the conduction across the u-surface can be related to the reservoir conditions by application of the steady-flow energy equation to a control

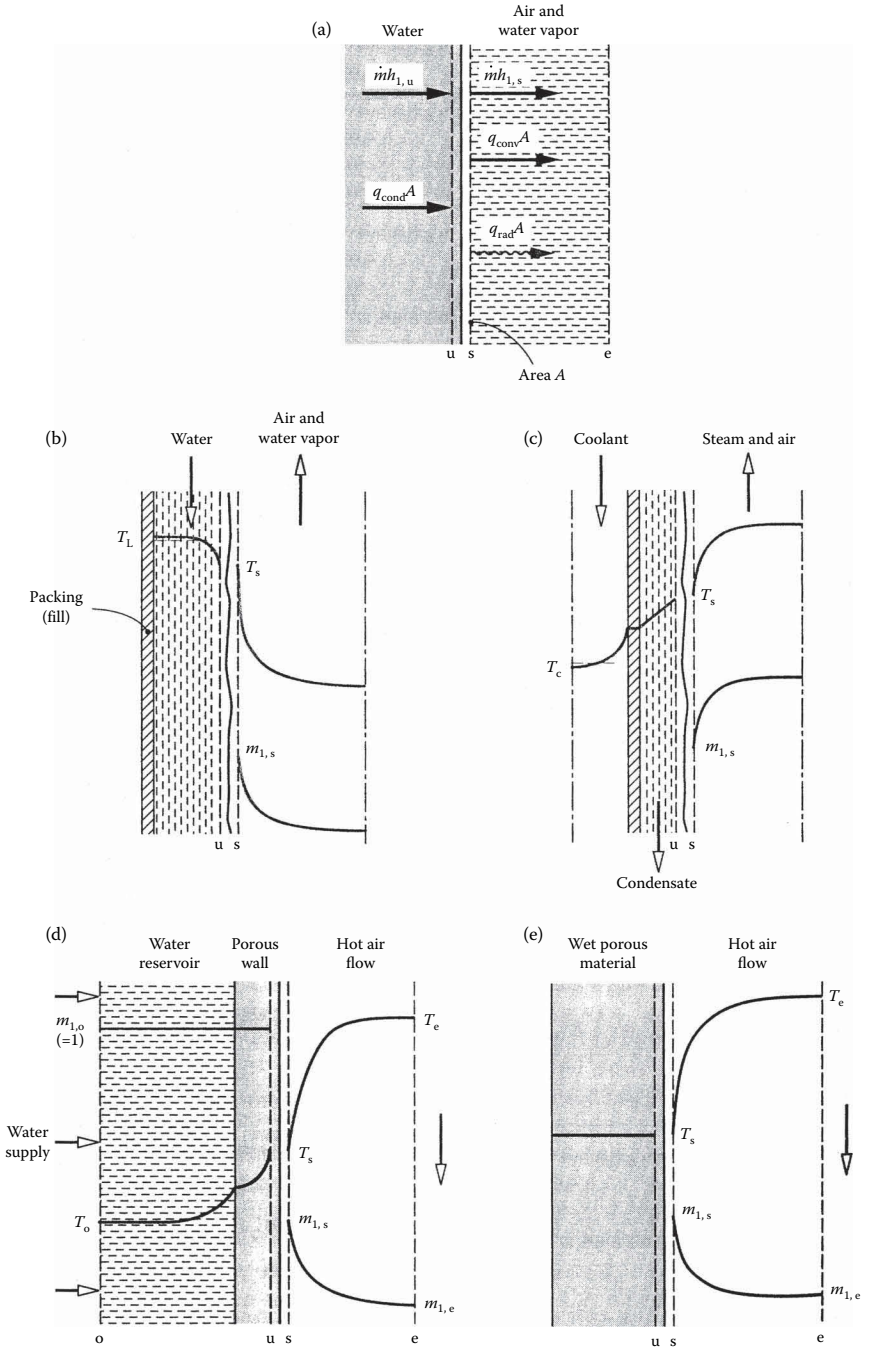

FIGURE 3.5.13 The surface energy balance for evaporation of water into an air stream.

volume located between the o- and u-surfaces. Finally, Figure 3.5.13e shows drying of a wet porous material (e.g., a textile or wood). During the constant-rate period of the process, evaporation takes place from the surface with negligible heat conduction into the solid; then $-k\partial T/\partial y|_u \simeq 0$. The term *adiabatic vaporization* is used to describe evaporation when $q_{cond}=0$; constant-rate drying is one example, and the wet-bulb psychrometer is another.

Consider a 1-m-square wet towel on a washline on a day when there is a low overcast and no wind. The ambient air is at 21°C, 1 atm, and 50.5% RH. In the constant-rate drying period the towel temperature is constant, and $q_{cond}=0$. An iterative calculation is required to obtain the towel temperature using correlations for natural convection on a vertical surface to obtain h_c and g_{m1}; q_{rad} is obtained as $q_{rad}=\sigma\varepsilon\left(T_s^4-T_e^4\right)$ with $\varepsilon=0.90$. The results are $T_s=17.8°C$, $h_c=1.69\,W/m^2\,K$, $g_{m1}=1.82\times10^{-3}\,kg/m^2s$, and the energy balance is

$$q_{cond}=h_c(T_s-T_e)+g_{m1}(m_{1,s}-m_{1,e})h_{fg}+q_{rad}$$

$$0=-5.4+21.7-16.3\,W/m^2$$

Evaluation of composition-dependent properties, in particular the mixture specific heat and Prandtl number, poses a problem. In general, low mass transfer rates imply small composition variations across a boundary layer, and properties can be evaluated for a mixture of the free-stream composition at the mean film temperature. In fact, when dealing with evaporation of water into air, use of the properties of dry air at the mean film temperature gives results of adequate engineering accuracy. If there are large composition variations across the boundary layer, as can occur in some catalysis problems, properties should be evaluated at the mean film composition and temperature.

The Wet- and Dry-Bulb Psychrometer

The wet- and dry-bulb psychrometer is used to measure the moisture content of air. In its simplest form, the air is made to flow over a pair of thermometers, one of which has its bulb covered by a wick whose other end is immersed in a small water reservoir. Evaporation of water from the wick causes the wet bulb to cool and its steady-state temperature is a function of the air temperature measured by the dry bulb and the air humidity. The wet bulb is shown in Figure 3.5.14. In order to determine the water vapor mass fraction $m_{1,e}$, the surface energy balance Equation 3.5.66 is used with conduction into the wick and q''_{rad} set equal to zero. The result is

$$m_{1,e}=m_{1,s}-\frac{c_p}{h_{fg}}\left(\frac{Pr}{Sc_{12}}\right)^{-2/3}(T_e-T_s) \tag{3.5.66}$$

Usually $m_{1,e}$ is small and we can approximate $c_p=c_{p\,air}$ and $(Pr/Sc_{12})^{-2/3}=1/1.08$. Temperatures T_s and T_e are the known measured wet- and dry-bulb temperatures. With T_s known, $m_{1,s}$ can be obtained

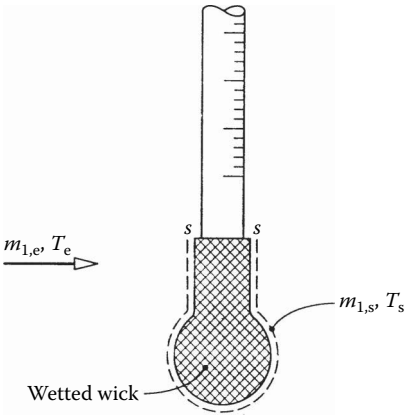

FIGURE 3.5.14 Wet bulb of a wet- and dry-bulb psychrometer.

using steam tables in the usual way. For example, consider an air flow at 1000 mbar with measured wet- and dry-bulb temperatures of 305.0 and 310.0 K, respectively. Then $P_{1,s}=P_{sat}(T_s)=P_{sat}(305.0\text{ K})=4714$ Pa from steam tables. Hence, $x_{1,s}=P_{1,s}/P=4714/10^5=0.04714$, and

$$m_{1,s}=\frac{0.04714}{0.04714+(29/18)(1-0.04714)}=0.02979$$

Also, $h_{fg}(305\text{ K})=2.425\times10^6$ J/kg, and $c_{p\ air}=1005$ J/kg K; thus

$$m_{1,e}=0.02979-\frac{1005}{(1.08)(2.425\times10^6)}(310-305)=0.02787$$

$$x_{1,e}=\frac{0.02787}{0.02787+(18/29)(1-0.02787)}=0.04415$$

$$P_{1,e}=x_{1,e}P=(0.04415)(10^5)=4412\text{ Pa}$$

By definition, the relative humidity is $RH=P_{1,e}/P_{sat}(T_e)$; $RH=4415/6224=70.9\%$.

In the case of other adiabatic vaporization processes, such as constant-rate drying or evaporation of a water droplet, $m_{1,e}$ and T_e are usually known and Equation 3.5.66 must be solved for T_s. However, the thermodynamic wet-bulb temperature obtained from psychrometric charts or software is accurate enough for engineering purposes.

High Mass Transfer Rate Theory

When there is net mass transfer across a phase interface, there is a convective component of the absolute flux (Kg/m^{2}s) of a species across the *s*-surface. From Equation 3.5.23a for species 1,

$$n_{1,s}=\rho_{1,s}v_s+j_{1,s} \tag{3.5.67}$$

During evaporation the convection is directed in the gas phase, with a velocity normal to the surface v_s. When the convective component cannot be neglected, we say that the mass transfer rate is *high*. There are two issues to consider when mass transfer rates are high. First, the rate at which species 1 is transferred across the *s*-surface is not simply the diffusive component $j_{1,s}$ as assumed in low mass transfer rate theory, but is the sum of the convective and diffusive components shown in Equation 3.5.67. Second, the normal velocity component v_s has a *blowing* effect on the concentration profiles, and hence on the Sherwood number. The Sherwood number is no longer analogous to the Nusselt number of conventional heat transfer correlations, because those Nusselt numbers are for situations involving impermeable surfaces, e.g., a metal wall, for which $v_s=0$.

Substituting for $j_{1,s}$ from Equation 3.5.57 into Equation 3.5.67 gives

$$\dot{m}''=g_{m1}\frac{m_{1,e}-m_{1,s}}{m_{1,s}-n_{1,s}/\dot{m}''}=g_{m1}B_{m1} \tag{3.5.68}$$

where $\dot{m}''=n_s$ is the mass transfer rate introduced in the section on heterogeneous combustion and B_{m1} is the *mass transfer driving force*. In the special case where only species 1 is transferred, $n_{1,s}/\dot{m}''=1$, for example, when water evaporates into air, and dissolution of air in the water is neglected. It is convenient to rewrite Equation 3.5.68 as

$$\dot{m}''=g_{m1}^*\left(g_{m1}/g_{m1}^*\right)B_{m1}\ \ (\text{kg/m}^2\text{s}) \tag{3.5.69a}$$

where

$$g_{m1}^{*} = \lim_{B_m \to 0} g_{m1} \tag{3.5.69b}$$

Now g_{m1}^{*} is the limit value of g_{m1} for zero mass transfer (i.e., $v_s = 0$), and Sh* can be obtained from conventional heat transfer Nusselt number correlations for impermeable surfaces. The ratio $\left(g_{m1}/g_{m1}^{*}\right)$ is termed as a *blowing factor* and accounts for the effect of v_s on the concentration profiles. Use of Equation 3.5.69 requires appropriate data for the blowing factor. For the constant-property laminar boundary layer on a flat plate, Figure 3.5.15 shows the effect of the Schmidt number on the blowing factor. The abscissa is a *blowing parameter* $B_m = \dot{m}''/g_m^{*}$.

The blowing velocity also affects the velocity and temperature profiles, and hence the wall shear stress and heat transfer. The curve for Sc = 1 in Figure 3.5.15 also gives the effect of blowing on shear stress as τ_s/τ_s^{*}, and the curve for Sc = 0.7 gives the effect of blowing on heat transfer for air injection into air as h_c/h_c^{*} (since Pr = 0.7 for air).

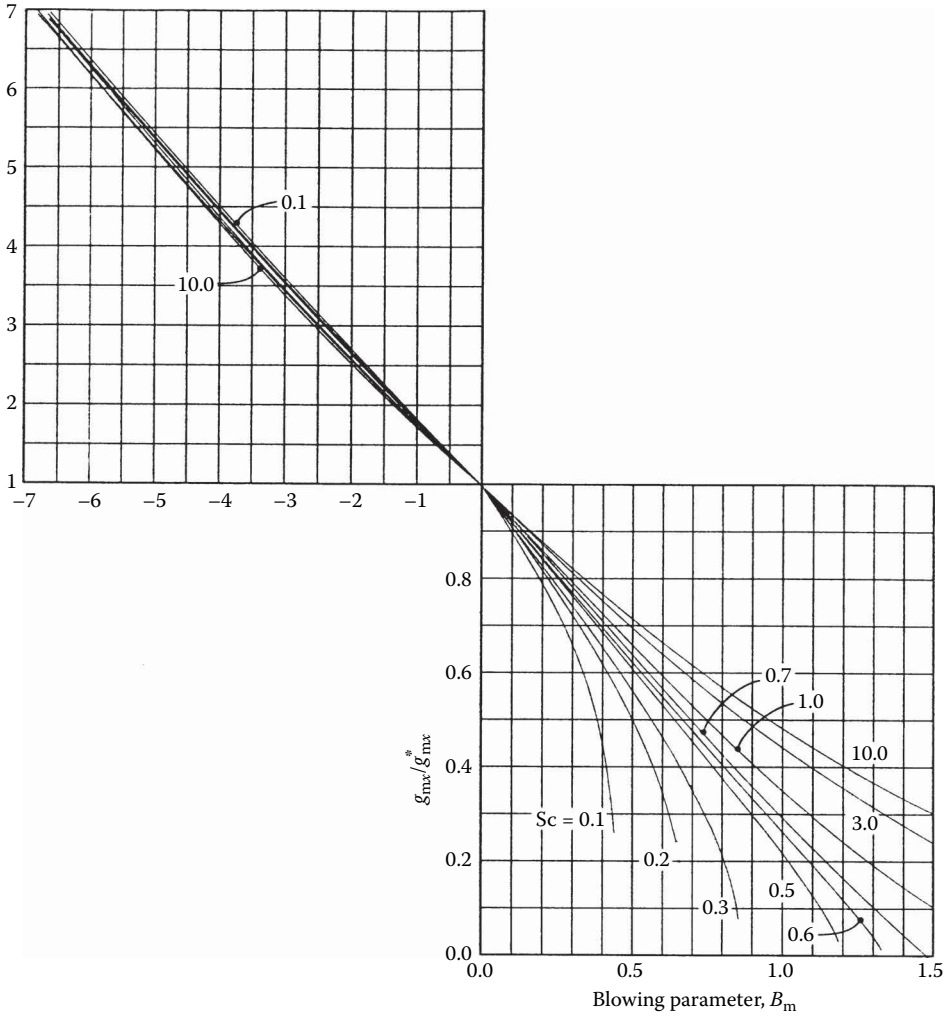

FIGURE 3.5.15 Effect of mass transfer on the mass transfer conductance for a laminar boundary layer on a flat plate: g_m/g_m^{*} vs. blowing parameter $B_m = \dot{m}''/g_m^{*}$.

Variable Property Effects of High Mass Transfer Rates

High mass transfer rate situations are usually characterized by large property variations across the flow, and hence property evaluation for calculating g_m and h_c is not straightforward. An often-encountered situation is transfer of a single species into an inert laminar or turbulent boundary layer flow. The effect of variable properties can be very large as shown in Figure 3.5.16 for laminar boundary layers, and Figure 3.5.17 for turbulent boundary layers.

A simple procedure for correlating the effects of flow type and variable properties is to use weighting factors in the exponential functions suggested by a constant-property Couette-flow model (Mills, 1995). Denoting the injected species as species *i*, we have

$$\frac{g_{m1}}{g_{m1}^*} = \frac{a_{mi}B_{mi}}{\exp(a_{mi}B_{mi})-1}; \quad B_{mi} = \frac{\dot{m}''}{g_{mi}^*} \tag{3.5.70a}$$

or

$$\frac{g_{m1}}{g_{mi}^*} = \frac{\ln(1+a_{mi}B_{mi})}{a_{mi}B_{mi}}; \quad B_{mi} = \frac{\dot{m}''}{g_{mi}} = \frac{m_{i,e}-m_{i,e}}{m_{i,s}-1}$$

$$\frac{\tau_s}{\tau_s^*} = \frac{a_{fi}B_f}{\exp(a_{fi}B_f)-1}; \quad B_f = \frac{\dot{m}''u_e}{\tau_s^*} \tag{3.5.70b}$$

$$\frac{h_c}{h_c^*} = \frac{a_{hi}B_h}{\exp(a_{hi}B_h)-1}; \quad B_h = \frac{\dot{m}''c_{pe}}{h_c^*} \tag{3.5.70c}$$

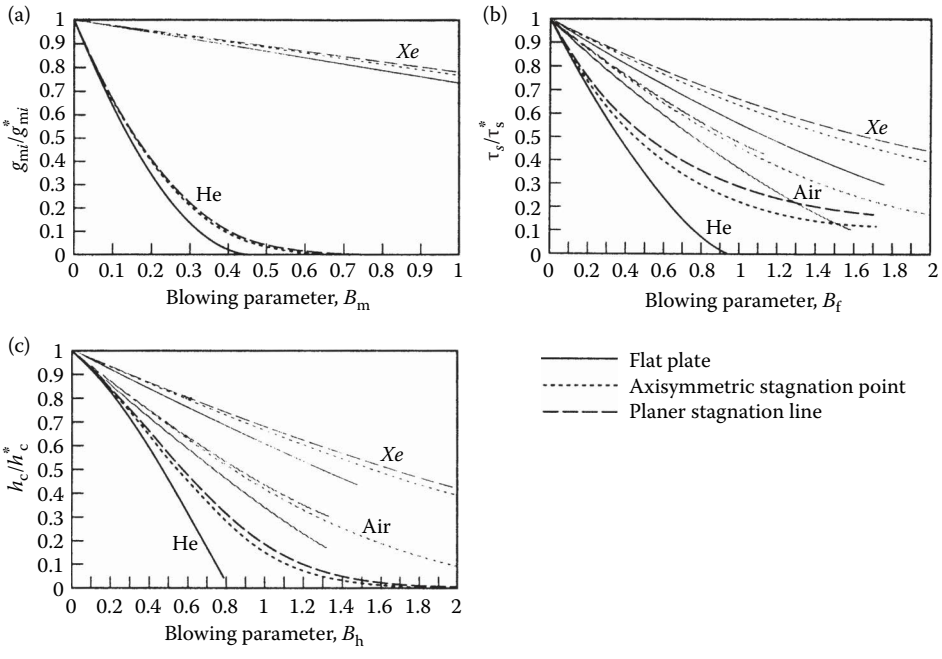

FIGURE 3.5.16 Numerical results for the effect of pressure gradient and variable properties on blowing factors for laminar boundary layers: low-speed air flow over a cold wall (T_s/T_e=0.1) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, and (c) heat transfer coefficient. (From Wortman, A., Mass transfer in self-similar boundary-layer flows, Ph.D. dissertation, University of California, 1969. With permission.)

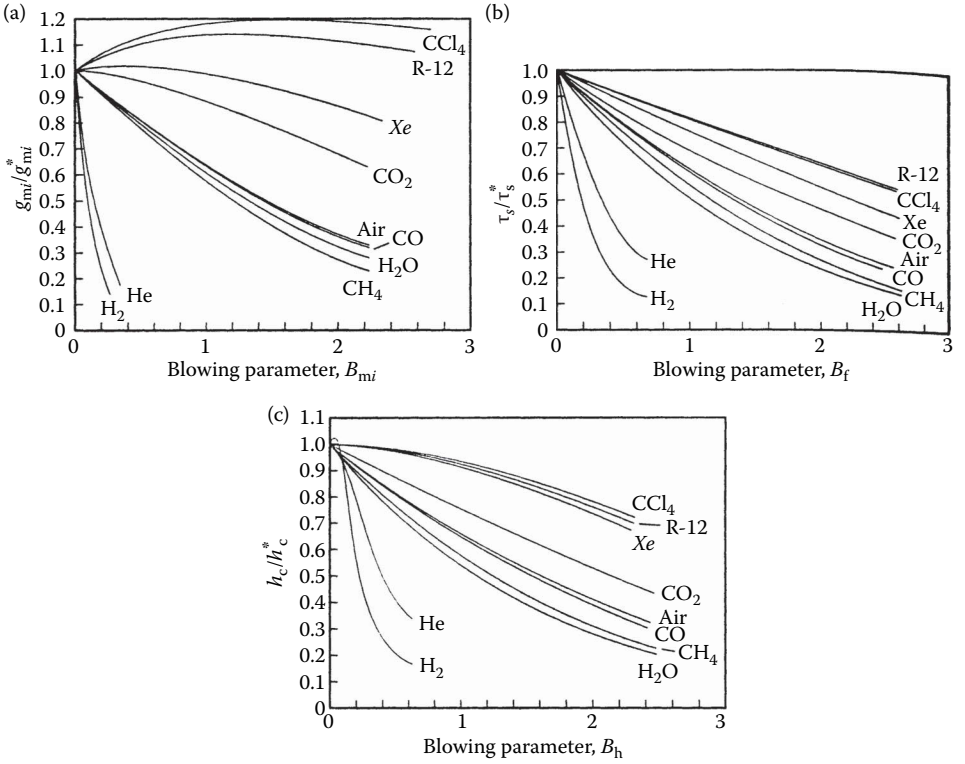

FIGURE 3.5.17 Numerical results for the effect of variable properties on blowing factors for a low-speed turbulent air boundary layer on a cold flat plate ($T_s/T_e=0.2$) with foreign gas injection: (a) mass transfer conductance, (b) wall shear stress, and (c) heat-transfer coefficient. (From Landis, R.B., Numerical solution of variable property turbulent boundary layers with foreign gas injection, Ph.D. dissertation, University of California, 1972. With permission.)

Notice that $g^*_{mi}, \tau^*_s, h^*_c$, and c_{pe} are evaluated using properties of the free-stream gas at the mean film temperature. The weighting factor a may be found from exact numerical solutions of boundary layer equations or from experimental data. Some results for laminar and turbulent boundary layers follow.

1. *Laminar boundary layers.* We will restrict our attention to low-speed air flows, for which viscous dissipation and compressibility effects are negligible, and use exact numerical solutions of the self-similar laminar boundary layer equations (Wortman, 1969). Least-squares curve fits of the numerical data were obtained using Equations 3.5.70c. Then, the weighting factors for axisymmetric stagnation-point flow with a cold wall ($T_s/T_e=0.1$) were correlated as

$$a_{mi} = 1.65\left(\frac{M_{\text{air}}}{M_i}\right)^{10/12} \tag{3.5.71a}$$

$$a_{\text{fi}} = 1.38\left(\frac{M_{\text{air}}}{M_i}\right)^{5/12} \tag{3.5.71b}$$

$$a_{\text{hi}} = 1.30\left(\frac{M_{\text{air}}}{M_i}\right)^{3/12}\left[\frac{c_{pi}}{\left(2.5\mathcal{R}/M_i\right)}\right] \tag{3.5.71c}$$

Notice that $c_{pi}/2.5\,\mathcal{R}/M_i)$ is unity for a monatomic species. For the planar stagnation line and the flat plate, and other values of the temperature ratio T_s/T_e, the values of the species weighting factors are divided by the values given by Equations 3.5.71a through 3.5.71c to give correction factors G_{mi}, G_{fi}, and G_{hi}, respectively. The correction factors are listed in Table 3.5.7.

The exponential relation blowing factors cannot accurately represent some of the more anomalous effects of blowing. For example, when a light gas such as H_2 is injected, Equation 3.5.70c indicates that the effect of blowing is always to reduce heat transfer, due to both the low density and high specific heat of hydrogen. However, at very low injection rates, the heat transfer is actually increased, as a result of the high thermal conductivity of H_2. For a mixture, $k \approx \Sigma x_i k_i$ whereas $c_p = \Sigma m_i c_{pi}$. At low rates of injection, the mole fraction of H_2 near the wall is much larger than its mass fraction; thus, there is a substantial increase in the mixture conductivity near the wall, but only a small change in the mixture specific heat. An increase in heat transfer results. At higher injection rates, the mass fraction of H_2 is also large, and the effect of high mixture specific heat dominates to cause a decrease in heat transfer.

TABLE 3.5.7
Correction Factors for Foreign Gas Injection into Laminar Air Boundary Layers

		$G_{mi}\ T_s/T_e$			$G_{fi}\ T_s/T_e$			$G_{hi}\ T_s/T_e$

Source: Based on numerical data of Wortman, A., Mass transfer in self-similar boundary-layer flows, Ph.D. dissertation, School of Engineering and Applied Science, University of California, 1969. Correlations developed by Dr. D.W. Hatfield.

2. *Turbulent boundary layers*. Here we restrict our attention to air flow along a flat plate for Mach numbers up to 6, and use numerical solutions of boundary layer equations with a mixing length turbulence model (Landis, 1972). Appropriate species weighting factors for $0.2 < T_s/T_e < 2$ are

$$a_{mi} = 0.79\left(\frac{M_{\text{air}}}{M_i}\right)^{1.33} \tag{3.5.72a}$$

$$a_{\text{fi}} = 0.91\left(\frac{M_{\text{air}}}{M_i}\right)^{0.76} \tag{3.5.72b}$$

$$a_{\text{hi}} = 0.86\left(\frac{M_{\text{air}}}{M_i}\right)^{0.76} \tag{3.5.72c}$$

In using Equation 3.5.70, the limit values for $\dot{m}''=0$ are elevated at the same location along the plate. Whether the injection rate is constant along the plate or varies as $x^{-0.2}$ to give a self-similar boundary layer has little effect on the blowing factors. Thus, Equation 3.5.72 has quite general applicability. Notice that the effects of injectant molecular weight are greater for turbulent boundary layers than for laminar ones, which is due to the effect of fluid density on turbulent transport. Also, the injectant specific heat does not appear in a_{hi} as it did for laminar flows. In general, c_{pi} decreases with increasing M_i and is adequately accounted for in the molecular weight ratio.

Reference state schemes. The reference state approach, in which constant-property data are used with properties evaluated at some reference state, is an alternative method for handling variable-property effects. In principle, the reference state is independent of the precise property data used and of the combination of injectant and free-stream species. A reference state for a boundary layer on a flat plate that can be used in conjunction with Figure 3.5.14 is (Knuth, 1963)

$$m_{1,\text{r}} = 1 - \frac{M_2}{M_2 - M_1}\frac{\ln\left(M_\text{e}/M_\text{s}\right)}{\ln\left(m_{2,\text{e}}M_\text{e}/m_{2,\text{s}}M_\text{s}\right)} \tag{3.5.73}$$

$$T_\text{r} = 0.5\left(T_\text{e} + T_\text{s}\right) + 0.2r^*\left(u_\text{e}^2/2c_{\text{pr}}\right) + 0.1\left[B_{\text{hr}} + \left(B_{\text{hr}} + B_{\text{mr}}\right)\frac{c_{\text{p1}} - c_{\text{pr}}}{c_{\text{pr}}}\right]\left(T_\text{s} - T_\text{e}\right) \tag{3.5.74}$$

where species 1 is injected into species 2 and r^* is the recovery factor for an impermeable wall. Use of the reference state method is impractical for hand calculations: a computer program should be used to evaluate the required mixture properties.

4.1 HEAT EXCHANGERS FOR THE PROCESS AND ENERGY INDUSTRIES

Joshua D. Ramsey and Ken Bell

Introduction

A heat exchanger is a device to provide for the transfer of internal thermal energy (enthalpy) between two or more fluids, between a solid surface and a fluid, or between solid particulates and a fluid, in thermal contact without external heat interactions. The fluids may be single components or mixtures, and they may be single phase or multiphase. Typical applications involve heating or cooling of a fluid stream of concern, vaporization or condensation of a single- or multicomponent fluid stream, or heat recovery or rejection from a system. In other cases, the objective may be to sterilize, pasteurize, distill, fractionate, concentrate, or crystallize the process fluid. Some heat exchangers use internal mechanical devices such as rotating blades to enhance the heat-transfer process.

In most heat exchangers, the fluids are separated by a solid wall through which heat is transferred by conduction. There may also be unwanted solid deposits on the wall, commonly referred to as "fouling." These deposits can arise from corrosion of the wall material, chemical degradation of the fluid by thermal action, deposition of suspended solid material in the fluid, or freezing of the fluid by excessive cooling. Some heat-transfer devices operate by direct contact between two immiscible fluid streams, which are subsequently separated by gravitational settling or centrifugation; these are not treated in this section.

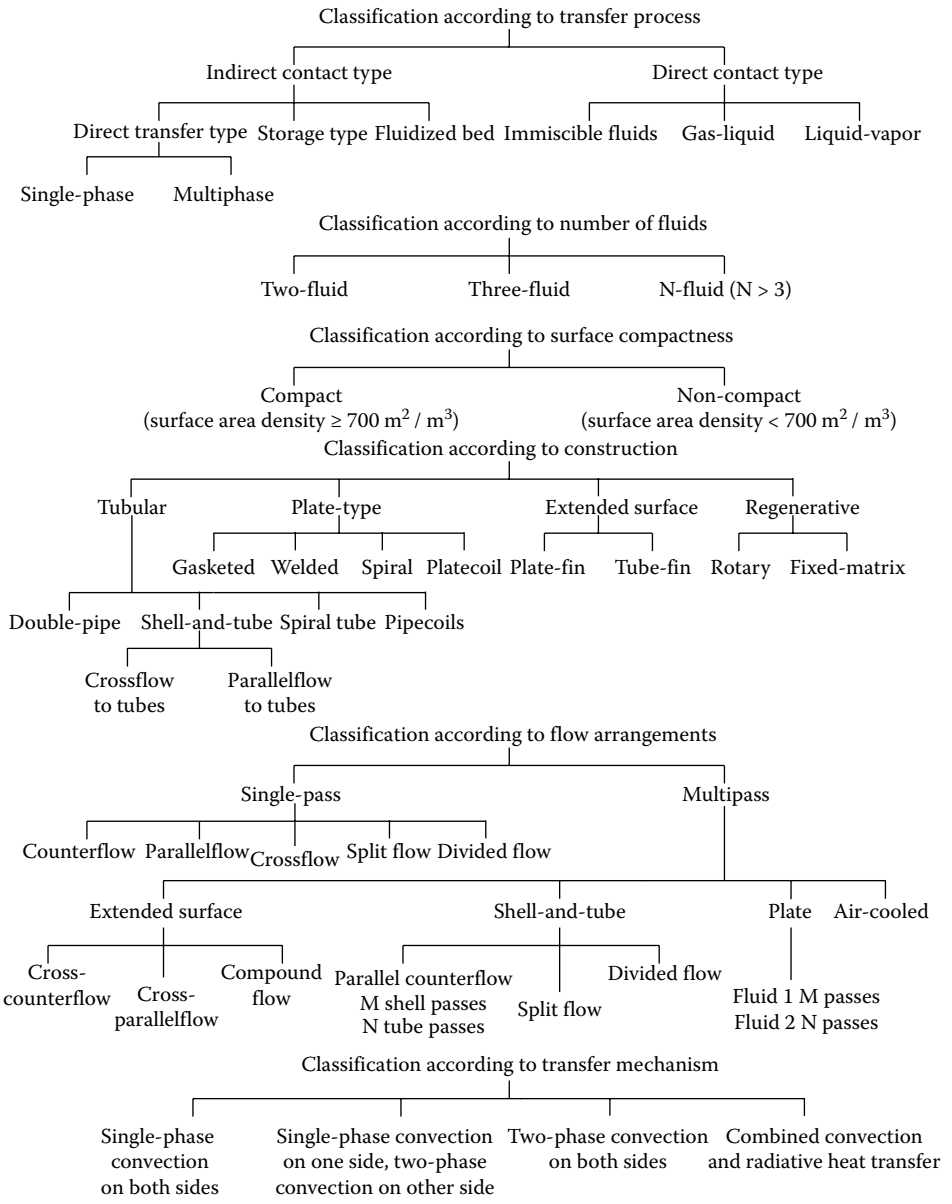

FIGURE 4.1.1 Classification of heat exchangers.

There are several ways to classify heat exchangers—by function, construction, heat-transfer mechanisms, etc. Figure 4.1.1 diagrams several of these classifications. Another important distinction is according to the ultimate market for the exchanger—mass utilization of a given product (as in automotive exchangers, residential and commercial environmental control, refrigeration, etc.), or custom applications (as in process plants, petroleum refineries, and thermal energy plants).

Typically, for mass utilization, a number of feasible configurations are constructed and tested over the plausible range of operating conditions for the application. Based on the test results and the manufacturability analysis, the final selection is made and large numbers of nominally identical units are then produced, with emphasis upon quality control. For most of these applications, a critical consideration in developing the test items is "compactness"—providing a high ratio of

heat-transfer surface area per unit of volume. A "compact" heat exchanger is usually defined as having greater than 700 m^2/m^3 (213 ft^2/ft^3) of surface area on at least one side of the heat-transfer surface, typically in contact with a gas. These heat exchangers are discussed in the second part of this section under the heading of *Compact Heat Exchangers.* The latter section is written by R. K. Shah.

This section deals with custom applications and with three types of heat exchangers commonly used in the process and energy industries: double pipe, shell-and-tube, and air-cooled. The starting point for design is a set of stated requirements, provided by the process engineer, giving the inlet fluid data (composition, flow rate, temperature, pressure) for each stream and the desired exit conditions at least for the process stream. Then an "optimum" design is developed to meet the stated requirements, with due allowance for possible future process changes and for design uncertainties. Construction is typically "one-off," unless multiple units are to be used side-by-side in a given plant. Equal emphasis is given to the "robustness" of the design process, construction quality, and maintainability under often severe operating conditions.

Double pipe exchangers are simple to design and construct from readily available components, and usually adaptable to high pressures and temperatures. However, they are relatively expensive per unit area of heat-transfer surface and are typically employed for smaller heat duties. The subsection titled "Principles of Heat Exchanger Design" introduces the basic design equations for all heat exchangers, using the double pipe as an example.

The most widely used heat exchanger type in the typical process plant is the shell-and-tube exchanger. Rugged, with a wide range of design/construction options and well-developed thermal/hydraulic and mechanical design procedures, these exchangers are described in more detail in the subsection titled, "Shell-and-Tube Heat Exchangers."

Wherever cooling and/or condensation to near atmospheric temperatures are required, the ready-to-hand solution may be an air-cooled exchanger. While air is a poor heat-transfer medium, it is available in generous supply anyplace one is likely to build a process or energy plant. The features and options of air-cooled exchangers are discussed in the subsection titled, "Air-cooled Heat Exchangers."

The most comprehensive literature source on heat exchangers is the five-volume "Heat Exchanger Design Handbook" (Hewitt 2008), available also through online subscription. Several excellent textbooks are available, especially Hewitt et al. (1994) and Serth and Lestina (2014). Many computer-based rating/design programs are available commercially, but no design program output—whether hand-calculated or computer-based—should be accepted until it has been vetted by one skilled in the art.

Principles of Heat Exchanger Design

In general, there are two basic approaches for heat exchanger design. One method is based on the known mean temperature difference (MTD) and is used to calculate the required area for heat transfer. This approach is used for custom design of a heat exchanger and is the typical approach used in the process and energy industries. The second approach is based on the number of transfer units (NTU) and is sometimes referred to as the effectiveness method. The NTU approach is used to determine outlet conditions for a given heat exchanger area. This approach is often thought of in terms of rating rather than designing, but for engineers working in industries where a standard, off-the-shelf configuration is selected or developed for a mass market (e.g., air conditioning systems), the NTU approach is used to determine the suitability of a standard configuration for a newly designed application. The focus here is on the MTD approach, but the reader is directed to other references for comprehensive coverage of the NTU approach (Çengel and Ghajar 2011).

MTD Approach

The MTD approach is used for custom design of a heat exchanger and is specifically used to calculate the area required for heat transfer. The approach requires knowledge of inlet and outlet conditions for each stream, which distinguishes it from the NTU approach. The MTD approach is

based on the local rate equation that relates the differential heat-transfer rate (dq) to a differential heat-transfer area (dA) *at a specific location*,

$$dq = U^* dA^* \left(T_h - T_c\right) \tag{4.1.1}$$

where dq is the differential heat-transfer rate, W (Btu/h); U is the overall heat-transfer coefficient, W/m^2·K (Btu/h·ft^2·°F); dA is the differential area, m^2 (ft^2); and T_h and T_c are the local temperatures of the hot (h) and cold (c) streams, K (°F), respectively. The superscript* on A* and U* simply indicates that a consistent basis must be used when defining each term. For example, for an exchanger with plain tubes, it is customary to use the total outside heat-transfer area of all of the tubes in the exchanger, A_o, as the reference area, and then U_o is the overall heat-transfer coefficient referenced to A_o. If the exchanger has low-finned tubes, A* may refer either to the total outside area including fins or to the inside tube heat-transfer area; the choice is optional, but must be spelled out.

The total required area (A) can be found by rearranging and integrating the local rate Equation 4.1.1,

$$A^* = \int_0^{q_T} \frac{dq}{U^*\left(T_h - T_c\right)} \tag{4.1.2}$$

where q_T is the total heat-transfer rate needed to achieve the desired outlet conditions. Solving the integral expression for the required area is complicated by the fact that the overall convective heat-transfer coefficient and the temperature difference between the hot and cold streams change during flow through the heat exchanger. The expression can be simplified, however, if we assume each term is constant and can be represented by an average value. In the case of the overall convective heat-transfer coefficient, U is calculated using physical properties (e.g., density, viscosity, thermal conductivity, and specific heat capacity) that also vary with temperature (and pressures for gases) and therefore with their position within the heat exchanger. The overall convective heat-transfer coefficient is typically calculated using properties of the streams at their average temperature. The under and overestimation of the physical properties tend to cancel one another leading to a reasonable estimate of U. Similarly, an average temperature difference based on $(T_h - T_c)$ over the length of the heat exchanger is substituted in place of the local temperature difference between the hot and cold streams. The assumption that U and $(T_h - T_c)$ can be represented by a constant, average value leads to

$$A^* = \frac{q_T}{U^* \cdot \mathrm{MTD}} \tag{4.1.3}$$

where MTD is the mean temperature difference between the hot and cold streams, K (°F).

To calculate the MTD, the inlet and outlet conditions of both streams must be known. For one stream, for example, the "hot stream," the inlet and outlet conditions are often set based on process constraints. For this stream, the heat transfer required to meet the outlet conditions can be determined from

$$q_T = \dot{m}_h \, c_{p,h}\left(T_{h,i} - T_{h,o}\right) = \dot{m}_c \, c_{p,c}\left(T_{c,o} - T_{c,i}\right) \tag{4.1.4}$$

where $\dot{m}$ is the mass flow rate kg/h (lb/h), c_p is the specific heat capacity of the respective stream J/kg·K (BTU/lb·°F), and T_i and T_o are the inlet and outlet temperatures, K (°F), respectively. As previously mentioned, the specific heat capacity is typically evaluated at the average temperature based on the inlet and outlet temperatures.

For the cold stream, the inlet and outlet conditions may also be set by process constraints, such as the supply and return temperatures of a utility stream. An overall energy balance requires that the heat-transfer rate for the cold stream equal that calculated for the hot stream (Equation 4.1.4), which in turn requires an appropriate mass flow rate for the given temperature change of the cold stream. Alternatively, it may be the mass flow rate that is fixed, in which case the exit temperature of the cold stream can be calculated using Equation 4.1.4 for the given mass flow rate and heat transfer rate.

The MTD can be calculated once the inlet and outlet conditions of the hot and cold streams are known. For pure countercurrent flow, where the hot and cold streams always move in directions opposite to one another, the MTD is the logarithmic mean temperature difference (LMTD), where

$$\text{MTD} = \text{LMTD}_{\text{countercurrent}} = \frac{\left(T_{\text{h,i}} - T_{\text{c,o}}\right) - \left(T_{\text{h,o}} - T_{\text{c,i}}\right)}{\ln\left(\dfrac{T_{\text{h,i}} - T_{\text{c,o}}}{T_{\text{h,o}} - T_{\text{c,i}}}\right)} \tag{4.1.5}$$

Very occasionally, cocurrent flow is specified, with the two streams flowing in the same direction. Cocurrent flow is often used when one wants to limit the local temperature of the tube wall. For cases with cocurrent flow, the MTD is again the LMTD, but the expression for the LMTD takes on a slightly different form,

$$\text{MTD} = \text{LMTD}_{\text{cocurrent}} = \frac{\left(T_{\text{h,i}} - T_{\text{c,i}}\right) - \left(T_{\text{h,o}} - T_{\text{c,o}}\right)}{\ln\left(\dfrac{T_{\text{h,i}} - T_{\text{c,i}}}{T_{\text{h,o}} - T_{\text{c,o}}}\right)} \tag{4.1.6}$$

Equations 4.1.5 and 4.1.6 apply to heat exchanger configurations with either countercurrent or cocurrent flow, such as that encountered in a double-pipe heat exchanger (Figure 4.1.2). Many heat exchangers, however, have configurations that produce a combination of countercurrent, cocurrent, and/or crossflow within a single heat exchanger. In these situations, the MTD approach must be altered to account for a corrected MTD, where

$$\text{MTD} = F \cdot \text{LMTD}_{\text{countercurrent}} \tag{4.1.7}$$

$\text{LMTD}_{\text{countercurrent}}$ is calculated from Equation 4.1.5, and F is the "configuration correction factor" for the particular flow configuration involved. F can be mathematically derived as a function of dimensionless temperature ratios for most flow configurations of interest and is given for some common cases in the next two subsections. Correction factors for numerous other flow configurations can be found in many heat-transfer references (e.g., TEMA 2007; Hewitt 2008, Vol. 1). F is equal to unity for pure countercurrent flow and is less than unity for all other cases, except for pure cocurrent

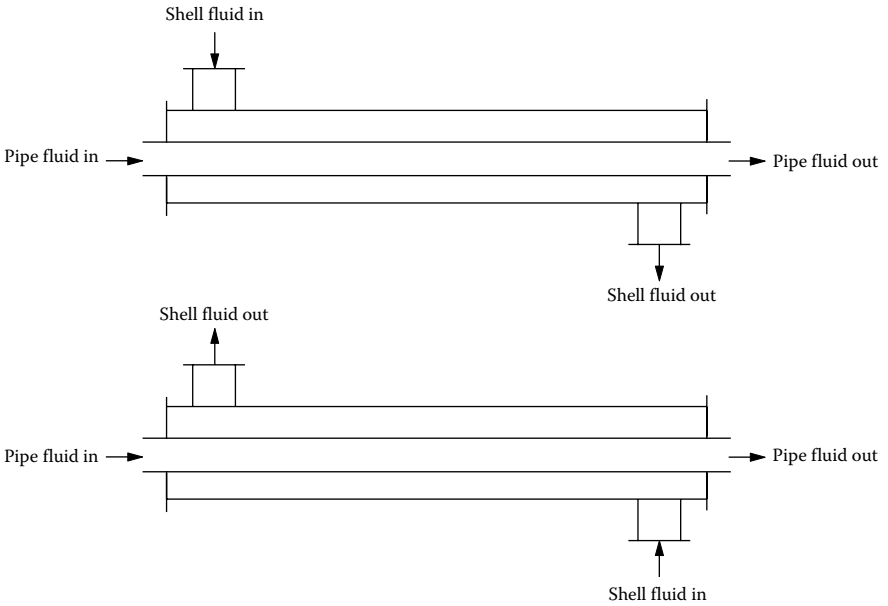

FIGURE 4.1.2 Double pipe heat exchangers with cocurrent flow (top) and countercurrent flow (bottom).

flow, where Equation 4.1.6 applies. Practical considerations usually limit the range of interest to values of F above 0.7 at the lowest and more comfortably to values above 0.8. Values of zero or below indicate conditions that violate the Second Law of Thermodynamics.

The remaining term needed to solve for the required area in Equation 4.1.3 is the overall heat-transfer coefficient, U^*. How the overall heat-transfer coefficient is related to the area, the individual (film) heat-transfer coefficients of the hot and cold streams, the fouling factors associated with both streams, and the construction material is based on the heat exchanger configuration. For example, the overall heat transfer coefficient for heat transfer through a flat wall is related to the other terms by

$$U^* = \frac{1}{\frac{1}{h_h} + R_{fh} + \frac{x_w}{k_w} + R_{fc} + \frac{1}{h_c}} \tag{4.1.8}$$

where h_h and h_c are, respectively, the hot and cold stream film heat transfer coefficients, W/m²·K (Btu/h ft² °F); R_{fh} and R_{fc} are the corresponding fouling resistances, m²·K/W (h ft² °F/Btu); x_w is the wall thickness, m (ft); and k_w is the thermal conductivity of the wall, W/m·K (Btu/h·ft·°F). The overall heat transfer coefficient for heat transfer between two fluids separated by a cylindrical wall has the relationship,

$$U^* = \frac{1}{\frac{A^*}{h_i A_i} + R_{fi}\frac{A^*}{A_i} + \frac{A^* \ln(d_o / d_i)}{2\pi L k_w} + R_{fo}\frac{A^*}{A_o} + \frac{A^*}{h_o A_o}} \tag{4.1.9}$$

where L is the length of the tube, m (ft), and k_w is the thermal conductivity of the tube wall, W/m·K (Btu/h·ft·°F). Notice, it is now more convenient to refer to the *inside* and *outside* of the tube, indicated by subscripts *i* and *o*, respectively, instead of referring to the hot and cold streams.

The equation for the overall heat transfer coefficient has introduced additional terms that are needed before the required area can be calculated. These terms, the film heat transfer coefficients and fouling factors, are addressed in detail in the next two subsections. For estimating purposes, however, it is convenient to assign typical values based on major classes of service (see Table 4.1.1).

TABLE 4.1.1
Typical Film Heat Transfer Coefficients for Shell-and-Tube Heat Exchangers

Fluid Conditions		h, W/m² K[a,b]	Fouling resistance, m² K/W[a]
	Sensible Heat Transfer		
Water[c]	Liquid	5000–7500	$1–2.5\times10^{-4}$
Ammonia	Liquid	6000–8000	$0–1\times10^{-4}$
Light organics[d]	Liquid	1500–2000	$0–2\times10^{-1}$
Medium organics[e]	Liquid	750–1500	$1–4\times10^{-4}$
Heavy organics[f]	Liquid		
	Heating	250–750	$2–10\times10^{-4}$
	Cooling	150–400	$2–10\times10^{-4}$
Very heavy organics[g]	Liquid		
	Heating	100–300	$4–30\times10^{-3}$
	Cooling	60–150	$4–30\times10^{-3}$

[a] Heat transfer coefficients and fouling resistances are based on area in contact with fluid. Ranges shown are typical, not all encompassing. Temperatures are assumed to be in normal processing range; allowances should be made for very high or low temperatures.

[b] Allowable pressure drops on each side are assumed to be about 50–100 kN/m² except for (1) low-pressure gas and two-phase flows, where the pressure drop is assumed to be about 5% of the absolute pressure; and (2) very viscous organics, where the allowable pressure drop is assumed to be about 150–250 kN/m².

[c] Aqueous solutions give approximately the same coefficients as water.

[d] Light organics include fluids with liquid viscosities less than about 0.5×10^{-3} Ns/m², such as hydrocarbons through C_8, gasoline, light alcohols and ketones, etc.

(Continued)

[e] Medium organics include fluids with liquid viscosities between about 0.5×10^{-3} and 2.5×10^{-1} Ns/m^2, such as kerosene, straw oil, hot gas oil, and light crudes.

[f] Heavy organics include fluids with liquid viscosities greater than 2.5×10^{-3} Ns/m^2, but not more than 50×10^{-3} Ns/m^2, such as cold gas oil, lube oils, fuel oils, and heavy and reduced crudes.

[g] Very heavy organics include tars, asphalts, polymer melts, greases, etc., having liquid viscosities greater than about 50×10^{-3} Ns/m^2. Estimation of coefficients for these materials is very uncertain and depends strongly on the temperature difference, because natural convection is often a significant contribution to heat transfer in heating, whereas congelation on the surface and particularly between fins can occur in cooling. Since many of these materials are thermally unstable, high surface temperatures can lead to extremely severe fouling.

[h] Values given for gases apply to such substances as air, nitrogen, carbon dioxide, light hydrocarbon mixtures (no condensation), etc. Because of the very high thermal conductivities and specific heats of hydrogen and helium, gas mixtures containing appreciable fractions of these components will generally have substantially higher heat transfer coefficients.

[i] Superheat of a pure vapor is removed at the same coefficient as for condensation of the saturated vapor if the exit coolant temperature is less than the saturation temperature (at the pressure existing in the vapor phase) and if the (constant) saturation temperature is used in calculating the MTD. But see note k for vapor mixtures with or without noncondensable gas.

[j] Steam is not usually condensed on conventional low-finned tubes; its high surface tension causes bridging and retention of the condensate and a severe reduction of the coefficient below that of the plain tube.

[k] The coefficients cited for condensation in the presence of noncondensable gases or for multicomponent mixtures are only for very rough estimation purposes because of the presence of mass transfer resistances in the vapor (and to some extent, in the liquid) phase. Also, for these cases, the vapor-phase temperature is not constant, and the coefficient given is to be used with the MTD estimated using vapor-phase inlet and exit temperatures, together with the coolant temperatures.

[l] As a rough approximation, the same relative reduction in low-pressure condensing coefficients due to noncondensable gases can also be applied to higher pressures.

[m] Absolute pressure and noncondensables have about the same effect on condensing coefficients for medium and heavy organics as for light organics. For large fractions of noncondensable gas, interpolate between pure component condensation and gas cooling coefficients.

[n] Narrow condensing range implies that the temperature difference between dew point and bubble point is less than the smallest temperature difference between vapor and coolant at any place in the condenser.

[o] Medium condensing range implies that the temperature difference between dew point and bubble point is greater than the smallest temperature difference between vapor and coolant, but less than the temperature difference between inlet vapor and outlet coolant.

[p] Boiling and vaporizing heat transfer coefficients depend very strongly on the nature of the surface and the structure of the two-phase flow past the surface in addition to all of the other variables that are significant for convective heat transfer in other modes. The flow velocity and structure are very much governed by the geometry of the equipment and its connecting piping. Also, there is a maximum heat flux from the surface that can be achieved with reasonable temperature differences between surface and saturation temperatures of the boiling fluid; any attempt to exceed this maximum heat flux by increasing the surface temperature leads to partial or total coverage of the surface by a film of vapor and a sharp decrease in the heat flux.

Therefore, the vaporizing heat transfer coefficients given in this table are only for very rough estimating purposes and assume the use of plain or low-finned tubes without special nucleation enhancement. $\Delta T_{SH,max}$ is the maximum allowable temperature difference between surface and saturation temperature of the boiling liquid. No attempt is made in this table to distinguish among the various types of vapor-generation equipment, since the major heat transfer distinction to be made is the propensity of the process stream to foul. Severely fouling streams will usually call for a vertical thermosiphon or a forced-convection (tube-side) reboiler for ease of cleaning.

[q] Subcooling heat load is transferred at the same coefficient as latent heat load in kettle reboilers, using the saturation temperature in the MTD. For horizontal and vertical thermosiphons and forced-circulation reboilers, a separate calculation is required for the sensible heat transfer area, using appropriate sensible heat transfer coefficients and the liquid temperature profile for the MTD.

[r] Aqueous solutions vaporize with nearly the same coefficient as pure water if attention is given to boiling point elevation, if the solution does not become saturated, and if care is taken to avoid dry wall conditions.

[s] For boiling of mixtures, the saturation temperature (bubble point) of the final liquid phase (after the desired vaporization has taken place) is to be used to calculate the MTD. A narrow-boiling-range mixture is defined as one for which the difference between the bubble point of the incoming liquid and the bubble point of the exit liquid is less than the temperature difference between the exit hot stream and the bubble point of the exit boiling liquid. Wide-boiling-range mixtures require a case-by-case analysis and cannot be reliably estimated by these simple procedures.

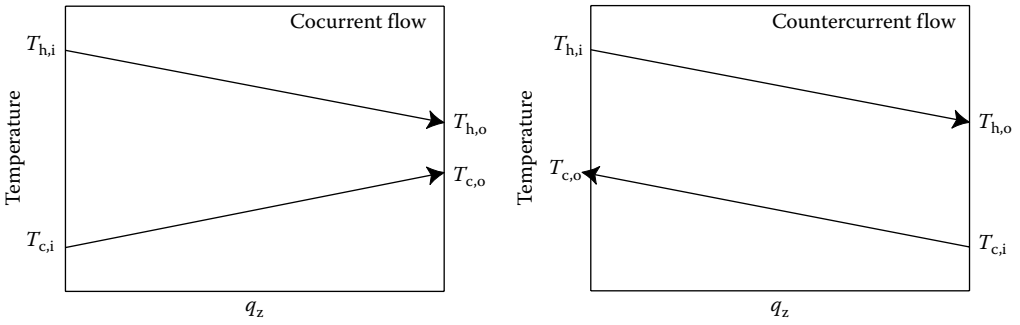

FIGURE 4.1.3 Example of temperature profiles within a cocurrent (left) and countercurrent (right) heat exchanger.

While not elaborated on earlier, it is important to appreciate the assumptions that have gone into deriving the equations so that their suitability can be determined for a particular application. One basic assumption is that heat is not transferred to or from the surroundings, but instead, all of the heat transferred from the hot stream is used to heat the cold stream (Equation 4.1.4). Another assumption related to Equation 4.1.4 is that the specific heat capacities of the streams are relatively constant and can be approximated by the properties of the stream at the average temperature. The assumption of constant specific heat capacity is important for Equation 4.1.4 and is also a major assumption in the derivation of the LMTD equations (Equations 4.1.5 and 4.1.6), which was not shown. The reason the constant specific heat assumption affects the LMTD derivation is because of the additional assumption that the variation in temperature (T) and position (z) within the heat exchanger (or T vs. q_z) is linearly related (Figure 4.1.3). This relationship is affected by the specific heat capacity and can also be affected by assumptions of constant temperature during boiling or condensation. Boiling and condensation, however, do not always occur isothermally due to pressure drop down the length of the heat exchanger or with phase change of multicomponent mixtures. Consequently, significant variations in the specific heat capacity or problems with assumptions regarding the linear relationship between temperature and position (or q_z) will introduce error in the calculation of the MTD.

In addition to constant specific heat capacity, it was also assumed that the overall heat transfer coefficient could be treated as constant if its average value was used in solving Equation 4.1.2. This assumption, however, is often not reasonable, especially when a phase change occurs. In cases where the variation in the overall heat transfer coefficient is a concern, the integral form of the area calculation (Equation 4.1.2) can be used to calculate the total area by dividing the heat exchanger into smaller sections. The iterative approach to finding a solution involves calculating the overall heat transfer coefficient for each section using the properties of the streams at their average temperature for the section. Modern computational tools have greatly simplified this approach.

Considering the limiting assumptions and the approximations often used with the LMTD method, one may wonder how it has been used to successfully design heat exchangers that function quite well in industrial service. The answer is not particularly reassuring. In many cases, the novice process engineer has been fortunate in that overly conservative estimates have offset poor estimates made through inexperience. While this is not meant to discourage the typical process engineer from generating an approximate design, it should serve as a caution to know when one needs to involve a technical expert because of a particular system that pushes the limits of the assumptions that are a part of the MTD approach.

Example of MTD Method Applied to a Double Pipe Heat Exchanger

The MTD method can be better understood by seeing it applied to an example. A countercurrent, double-pipe heat exchanger provides one of the simplest configurations to analyze. Consider the following example.

Problem statement. Determine the length of a double-pipe heat exchanger used to cool 11,905 lb_m/h (1.5 kg/s) kerosene from 140°F to 95°F (60°C–35°C) using cooling water that has a supply temperature of 86°F (30°C) and a maximum return temperature of 122°F (50°C). Cooling water passes through the internal pipe, which is 1.5 in. Schedule 40 carbon steel (ID = 1.61 in. or 40.9 mm; OD = 1.90 in. or 48.3 mm), and kerosene flows countercurrent through the annular region created by a larger pipe that is 2.5 in. Schedule 40 carbon steel (ID = 2.47 in. or 62.2 mm) (Figure 4.1.4). Assume that the thermal conductivity of carbon steel is 31.9 Btu/h ft °F (55 W/m K).

Stream properties

	Kerosene (118°F)	Water (104°F)
Density (lb_m/ft^3)	44.4	61.9
Viscosity (cP)	0.574	0.678
Specific heat (Btu/lb_m °F)	0.548	0.998
Thermal conductivity (Btu/h ft °F)	0.071	0.362

Solution. The general approach is to use Equation 4.1.3 to calculate the required area, from which one can easily determine the length. Before Equation 4.1.3 can be used, however, the heat exchanger duty (q_T), MTD, and overall convective heat transfer coefficient (U) must be determined.

Heat exchanger duty (q_T). The required heat transfer can be determined from Equation 4.1.4, where kerosene has been designated as the hot stream,

$$q_T = (11{,}905\ \text{lb}_m/\text{h})(0.548\ \text{Btu}/\text{lb}_m\ °\text{F})(140°\text{F} - 95°\text{F}) = 293{,}577\ \text{Btu/h} = 86{,}903\ \text{W}$$

Since q_T must be equal for both the kerosene and water streams, Equation 4.1.4 can be rearranged to solve for the mass flow rate of water,

$$\dot{m}_{\text{water}} = \frac{(293{,}577\ \text{Btu}/\text{h})}{(0.998\ \text{Btu}/\text{lb}_m\ °\text{F})(122°\text{F} - 86°\text{F})} = 8{,}171\ \text{lb}_m/\text{h} = 1.03\ \text{kg}/\text{s}$$

Mean temperature difference. The expression to determine the MTD for countercurrent flow was given earlier as Equation 4.1.5. Substituting the inlet and outlet temperatures for the kerosene (hot) and water (cold) streams results in the following MTD,

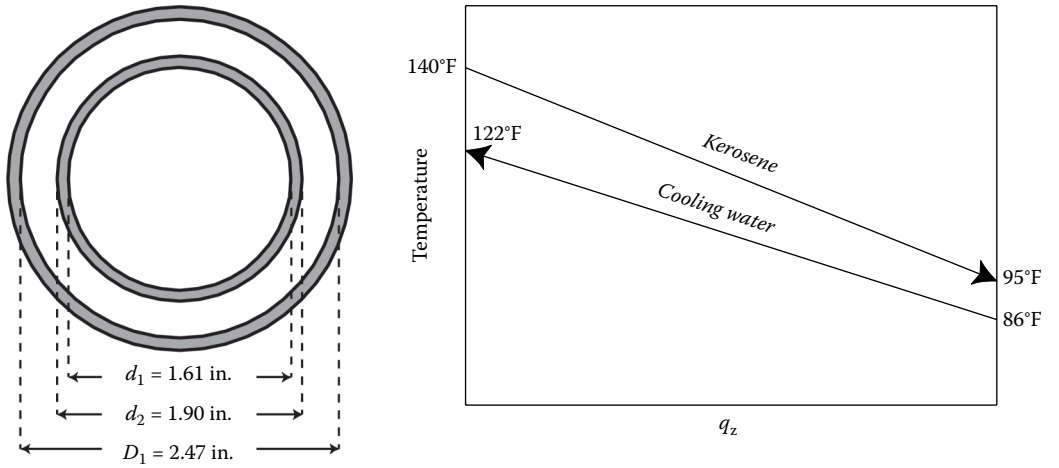

FIGURE 4.1.4 Cross-sectional profile of the double-pipe heat exchanger showing tube diameters (left) and temperature profiles within the heat exchanger.

$$\text{MTD} = \text{LMTD}_{\text{countercurrent}} = \frac{(140°\text{F} - 122°\text{F}) - (95°\text{F} - 86°\text{F})}{\ln\left(\frac{(140°\text{F} - 122°\text{F})}{(95°\text{F} - 86°\text{F})}\right)} = 13°\text{F} = 7.2°\text{C}$$

Notice that no correction factor is needed since the double-pipe configuration does not involve a combination of countercurrent, cocurrent, or crossflow.

Overall convective heat transfer coefficient (U_o). As discussed earlier, the basis of A^* and U^* is optional but must be stated. In this example, the basis will be the outside area ($A^* = A_o$) of the inner pipe. The expression for the overall convective heat transfer coefficient, Equation 4.1.9, can be simplified and written in terms of the provided pipe diameters,

$$U_o = \frac{1}{\frac{d_2}{h_i d_1} + R_{fi}\frac{d_2}{d_1} + \frac{d_2 \ln(d_2/d_1)}{2k_w} + R_{fo} + \frac{1}{h_o}} \tag{4.1.10}$$

Typical fouling factors for water (R_{fi}) and kerosene (R_{fo}) are provided in Table 4.1.1:

Inner fouling R_{fi}	0.0006 h ft² °F/Btu	1.0×10^{-4} m² K/W
Outer fouling R_{fo}	0.0011 h ft² °F/Btu	2.0×10^{-4} m² K/W

The remaining challenge is to calculate the film heat transfer coefficients on the interior (h_i) and exterior (h_o) of the inner pipe. For this example, the Dittus–Boelter correlation will be used,

$$\text{Nu}_D \equiv \frac{hD_h}{k} = 0.023\text{Re}_D^{0.8}\text{Pr}^n \tag{4.1.11}$$

The dimensionless Nusselt number (Nu_D) is defined by the convective heat transfer coefficient, the mean hydraulic diameter (D_h), and the thermal conductivity (k) of the fluid. The Dittus–Boelter correlation (Equation 4.1.11) can be used to calculate the Nusselt number if the Reynolds (Re_D) and Prandtl (Pr) numbers are known. The value of n depends on whether a fluid is being heated ($n = 0.4$) or cooled ($n = 0.3$). The subscript D on the Nusselt and Reynolds numbers indicates that the dimensionless numbers are based on a particular hydraulic diameter, which in this case may be either the hydraulic diameter of the inner pipe ($D_h = d_1$) or the mean hydraulic diameter of the annular region ($D_h = D_1 - d_2$). It is important to note that the Dittus–Boelter correlation is only valid for $\text{Re} \geq 10{,}000$ and $0.6 \leq \text{Pr} \leq 160$. The correlation is also only valid for smooth pipe surfaces, which is not exactly the case in this example. Finally, error is introduced if there are large differences between the pipe wall and the mean temperature of the fluid, which was used to evaluate the fluid properties. Multiple iterations can be used to solve for the wall temperature or other correlations may be useful in minimizing these errors.

For the tube-side fluid,

$$v = \frac{\dot{m}_{\text{water}}}{\rho\left(\frac{\pi d_1^2}{4}\right)} = \frac{(8{,}171\ \text{lb}_m/\text{h})(\text{h}/3600\ \text{s})}{(61.9\ \text{lb}_m/\text{ft}^3)\left(\frac{\pi}{4}\right)(1.61\ \text{in.})^2(\text{ft}/12\ \text{in.})^2} = 2.59\ \text{ft/s} = 0.75\ \text{m/s}$$

$$\text{Re}_{d_1} = \frac{\rho v d_1}{\mu} = \frac{(61.9\ \text{lb}_m/\text{ft}^3)(2.59\ \text{ft/s})(1.61\ \text{in.})(\text{ft}/12\ \text{in.})}{(0.678\ \text{cP})\left(\frac{6.72 \times 10^{-4}\ \text{lb}_m/\text{ft s}}{\text{cP}}\right)} = 47{,}210$$

$$\mathrm{Pr} = \frac{c_p \mu}{k} = \frac{(0.998\ \mathrm{Btu/lb_m\,°F})(0.678\ \mathrm{cP})\left(\frac{6.72 \times 10^{-4}\ \mathrm{lb_m/ft\,s}}{\mathrm{cP}}\right)}{(0.362\ \mathrm{Btu/h\,ft\,°F})(\mathrm{h}/3600\ \mathrm{s})} = 4.52$$

Note that the Reynolds and Prandtl numbers are within the range required for the Dittus–Boelter correlation. Also the tube-side fluid, cooling water, is being heated so $n=0.4$. Using the Dittus–Boelter correlation, the Nusselt number is calculated to be

$$\mathrm{Nu}_{d_1} = 0.023(47{,}210)^{0.8}(4.52)^{0.4} = 230.7$$

The Nusselt number can now be rearranged to solve for the film heat transfer coefficient within the tube,

$$h_i = \mathrm{Nu}_{d_1}\left(\frac{k}{d_1}\right) = (230.7)\left(\frac{(0.362\ \mathrm{Btu/h\,ft\,°F})}{(1.61\ \mathrm{in.})(\mathrm{ft}/12\ \mathrm{in.})}\right) = 622\ \mathrm{Btu/h\,ft^2\,°F} = 3{,}534\ \mathrm{W/m^2\,°C}$$

A similar approach is used for the annular fluid, except the velocity must be calculated using the cross-sectional area of the annular region,

$$v = \frac{\dot{m}_{\mathrm{kerosene}}}{\rho\left(\frac{\pi D_1^2}{4} - \frac{\pi d_2^2}{4}\right)} = \frac{(11{,}905\ \mathrm{lb_m/h})(\mathrm{h}/3600\ \mathrm{s})}{(44.4\ \mathrm{lb_m/ft^3})\left[(\pi/4)(2.47\ \mathrm{in.})^2 - (\pi/4)(1.90\ \mathrm{in.})^2\right](\mathrm{ft}/12\ \mathrm{in.})^2}$$

$$= 5.48\ \mathrm{ft/s} = 1.67\ \mathrm{m/s}$$

Additionally, the mean hydraulic diameter of the annular region is now the difference between the inner diameter of the outer pipe and the outer diameter of the inner pipe,

$$D_h = D_{\mathrm{annular}} = D_1 - d_2 = 2.47\ \mathrm{in.} - 1.90\ \mathrm{in.} = 0.57\ \mathrm{in.}$$

The Reynolds and Prandtl numbers are

$$\mathrm{Re}_{D_{\mathrm{annular}}} = \frac{\rho v D_{\mathrm{annular}}}{\mu} = \frac{(44.4\ \mathrm{lb_m/ft^3})(5.48\ \mathrm{ft/s})(0.57\ \mathrm{in.})(\mathrm{ft}/12\ \mathrm{in.})}{(0.574\ \mathrm{cP})\left(\frac{6.72 \times 10^{-4}\ \mathrm{lb_m/ft\,s}}{\mathrm{cP}}\right)} = 29{,}962$$

and

$$\mathrm{Pr} = \frac{c_p \mu}{k} = \frac{(0.548\ \mathrm{Btu/lb_m\,°F})(0.574\ \mathrm{cP})\left(\frac{6.72 \times 10^{-4}\ \mathrm{lb_m/ft\,s}}{\mathrm{cP}}\right)}{(0.071\ \mathrm{Btu/h\,ft\,°F})(\mathrm{h}/3600\ \mathrm{s})} = 10.7$$

Again, it is important to check that the Reynolds and Prandtl numbers fall within the required range of the Dittus–Boelter correlation, which they do. With this condition met, the Dittus–Boelter correlation can now be used to calculate the Nusselt number for the annular fluid. Since the annular fluid, kerosene, is being cooled, $n=0.3$ and

$$\mathrm{Nu}_{D_{\mathrm{annular}}} = 0.023(29{,}962)^{0.8}(10.7)^{0.3} = 178.6$$

Rearranging the defined expression for the Nusselt number to solve for the film heat transfer coefficient,

$$h_o = \mathrm{Nu}_{D_{\mathrm{annular}}}\left(\frac{k}{D_{\mathrm{annular}}}\right) = (178.6)\left(\frac{(0.071\ \mathrm{Btu/h\,ft\,°F})}{(0.57\ \mathrm{in.})(\mathrm{ft}/12\ \mathrm{in.})}\right)$$

$$h_o = 267 \text{ Btu / h ft}^2 \text{ °F} = 1{,}516 \text{ W/m}^2 \text{ °C}$$

The overall convective heat transfer coefficient can now be calculated,

$$U_o = \left[\left(\frac{1}{622 \text{ Btu / h ft}^2 \text{ °F}} \right) \left(\frac{1.90 \text{ in.}}{1.61 \text{ in.}} \right) + \left(0.0006 \text{ h ft}^2 \text{ °F/ Btu} \right) \left(\frac{1.90 \text{ in.}}{1.61 \text{ in.}} \right) + \left(\frac{(1.90 \text{ in.})(\text{ft} / 12 \text{ in})}{2 \cdot (31.9 \text{ Btu / h ft °F})} \right) \right.$$

$$\left. \ln \left(\frac{1.90 \text{ in.}}{1.61 \text{ in.}} \right) + \left(0.0011 \text{ h ft}^2 \text{ °F / Btu} \right) + \left(\frac{1}{267 \text{ Btu / h ft}^2 \text{ °F}} \right) \right]^{-1}$$

$$U_o = 127 \text{ Btu / h ft}^2 \text{ °F} = 722 \text{ W / m}^2 \text{ °C}$$

Heat exchanger area and length. Equation 4.1.3 can now be used to calculate the required area and the length of the heat exchanger,

$$A_o = \frac{q_T}{U_o \cdot \text{MTD}} = \frac{(293{,}577 \text{ Btu / h})}{(127 \text{ Btu / h ft}^2 \text{ °F})(13 \text{ °F})} = 178 \text{ ft}^2 = 16.5 \text{ m}^2$$

$$L = \frac{A_o}{\pi \cdot d_2} = \frac{(178 \text{ ft}^2)}{\pi (1.90 \text{ in.})(\text{ft} / 12 \text{ in.})} = 358 \text{ ft} = 109 \text{ m}$$

A 358 ft double-pipe heat exchanger would be needed to cool the kerosene stream from 140°F to 95°F using cooling water. The calculated length, however, is much too long for a single double-pipe heat exchanger and would require multiple units connected in series. This example, however, demonstrates how the basic design equations can be used for the custom sizing of a double-pipe heat exchanger.

Shell-and-Tube Heat Exchangers

A shell-and-tube heat exchanger is essentially a bundle of tubes enclosed in a shell and so arranged that one fluid flows through the tubes and another fluid flows across the outside of the tubes, heat being transferred from one fluid to the other through the tube wall. A number of other mechanical components are required to guide the fluids into, through, and out of the exchanger, to prevent the fluids from mixing, and to ensure the mechanical integrity of the heat exchanger. A typical shell-and-tube heat exchanger is shown in Figure 4.1.5 (TEMA 2007), but the basic design allows many modifications and special features, some of which are described later.

Nomenclature of Heat Exchanger Components

For the purpose of establishing standard terminology, Figure 4.1.5 illustrates a typical shell-and-tube heat exchanger. Typical parts and connections, for illustrative purposes only, are numbered for identification:

1. Stationary Head—Channel
2. Stationary Head Bonnet
3. Stationary Head Flange—Channel or Bonnet
4. Channel Cover

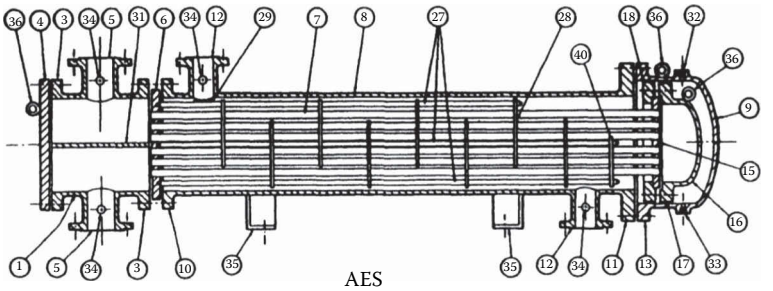

FIGURE 4.1.5 Longitudinal section of a typical shell-and-tube heat exchanger (TEMA AES) with nomenclature. (Modified from TEMA Standards 9th ed., Tubular Exchanger Manufacturers Association, Tarrytown, NY, 2007.)

5. Stationary Head Nozzle
6. Stationary Tubesheet
7. Tubes
8. Shell
9. Shell Cover
10. Shell Flange—Stationary Head End
11. Shell Flange—Rear Head End
12. Shell Nozzle
13. Shell Cover Flange
14. Expansion Joint on Shell (not shown)
15. Floating Tubesheet
16. Floating Head Cover
17. Floating Head Cover Flange
18. Floating Head Backing Device
19. Split Shear Ring
20. Slip-on Backing Flange
21. Floating Head Cover—External
22. Floating Tubesheet Skirt
23. Packing Box
24. Packing
25. Packing Gland
26. Lantern Ring
27. Tierods and Spacers
28. Transverse Baffles or Support Plates
29. Impingement Plates
30. Longitudinal Baffle
31. Pass Partition
32. Vent Connection
33. Drain Connection
34. Instrument Connection
35. Support Saddle
36. Lifting Lug
37. Support Bracket
38. Weir
39. Liquid Level Connection
40. Floating Head Support

Shell-and-tube heat exchangers have been constructed with heat transfer areas from less than 0.1 m^2 (1 ft^2) to over 100,000 m^2 (1,000,000 ft^2), for pressures from deep vacuum to over 1000 bar (15,000 psi), for temperatures from near 0 to over 1400 K (2000°F), and for all fluid services including single-phase heating and cooling and multiphase vaporization and condensation. The key to such flexibility is the wide range of materials of construction, forming and joining methods, and design features that can be built into these exchangers (see Hewitt 2008, Vol. 4; Saunders 1988; and Yokell 1990). Most shell-and-tube heat exchangers are manufactured in conformity with TEMA *Standards* (2007) and the *ASME Boiler and Pressure Vessel Code* (latest edition), but other codes and standards may apply. In the design process, it is important to consider the mechanical integrity under varying operational conditions and the maintainability (especially cleaning) of the exchanger as equally important with the thermal–hydraulic design.

Construction Features

Tubes. Tubes used in shell-and-tube exchangers range from 6.35 mm (1/4 in.) to 50.8 mm (2 in.) and above in outside diameter, with the wall thickness usually being specified by the Birmingham wire gauge (BWG). Tubes are generally available in any desired length up to 30 m (100 ft) or more for plain tubes. While plain tubes are widely used, a variety of internally and/or externally enhanced tubes is available to provide special heat transfer characteristics when economically justified (see subsection on enhancement in Section 4.16). Low-fin tubes having circumferential fins typically 0.8–1.6 mm (0.032–0.062 in.) high, spaced 630–1260 fins/m (16–32 fins/in.) are often employed, especially when the shell-side heat transfer coefficient is substantially smaller than the tube-side coefficient. The outside heat transfer area of a low-fin tube is three to six times the inside area, resulting in a smaller heat exchanger shell for the same service, which may offset the higher cost of the tube per unit length.

The tubes are inserted into slightly oversized holes drilled (or, occasionally, punched) through the tubesheets (items 6 and 15 in Figure 4.1.5). The tubes are secured by several means, depending upon the mechanical severity of the application and the need to avoid leakage between the streams. In some low-severity applications, the tubes are roller-expanded into smooth holes in the tubesheet. For a stronger joint, two shallow circumferential grooves are cut into the wall of the hole in the tubesheet and the tube roller-expanded into the grooves; to eliminate the possibility of leakage, a seal weld can be run between the outer end of the tube and the tubesheet. Alternatively, the tubes may be strength-welded into the tubesheet.

Tube supports. It is essential to provide periodic support along the length of the tubes to prevent sagging and destructive vibration caused by the fluid flowing across the tube bank. A secondary role played by the tube supports is to guide the flow back and forth across the tube bank, increasing the velocity and improving the heat transfer on the shell side (but also increasing the pressure drop). The tube support is usually in the form of single segmental baffles (item 28 in Figure 4.1.5)—circular plates with holes drilled to accommodate the tubes and with a segment sheared off to form a "window" or "turnaround" to allow the shell-side fluid to pass from one crossflow section to the next. The baffles must overlap at least one full row of tubes to give the bundle the necessary rigidity against vibration. When minimizing shell-side pressure drop is not a priority, a baffle cut of 15%–25% of the shell inside diameter is customary. Baffle spacing is determined first by the necessity to avoid vibration and secondarily to approximately match the free crossflow area between adjacent baffles to the flow area in the window; that is, small baffle cuts correspond to closer baffle spacing.

In situations such as low-pressure gas flows on the shell side where pressure drop is severely limited, double segmental and strip baffle arrays can be used. A helical baffle arrangement has been introduced (Kral et al. 1996; Zhang et al. 2010) which causes the shell-side fluid to spiral through the exchanger giving improved heat transfer versus pressure drop characteristics. More recently, tubes with an external longitudinal spiral configuration have been offered. The shell-side fluid flows in a spiral path down the length of the tubes. In addition, the tubes can be bundled in such a way that they are supported by surrounding tubes, thereby eliminating the need for baffles. Where vibration prevention and/or minimum pressure drop are the main concerns, grids of rods or strips can be used

(Gentry et al. 1982). The rod baffle design is also advantageous in shell-side thermosiphon vaporizer applications because it minimizes phase separation, slugging, and vibration.

Shells. The shell is the cylinder which confines the shell-side fluid (item 8 in Figure 4.1.5), fitted with nozzles for fluid inlet and exit. Diameters range from less than 50 mm (2 in.) to 3.05 m (10 ft) commonly, and at least twice that value for special applications. In diameters up to 610 mm (24 in.), shells are usually made from standard pipe or tubular goods by cutting to the desired length; in larger sizes, metal plates are rolled to the desired diameter and welded.

A variety of nozzle arrangements are used for special purposes, and TEMA has a standard code to identify the major types, as well as the various front and rear head configurations on the tube side. Figure 4.1.6 shows these configurations with the corresponding code letters.

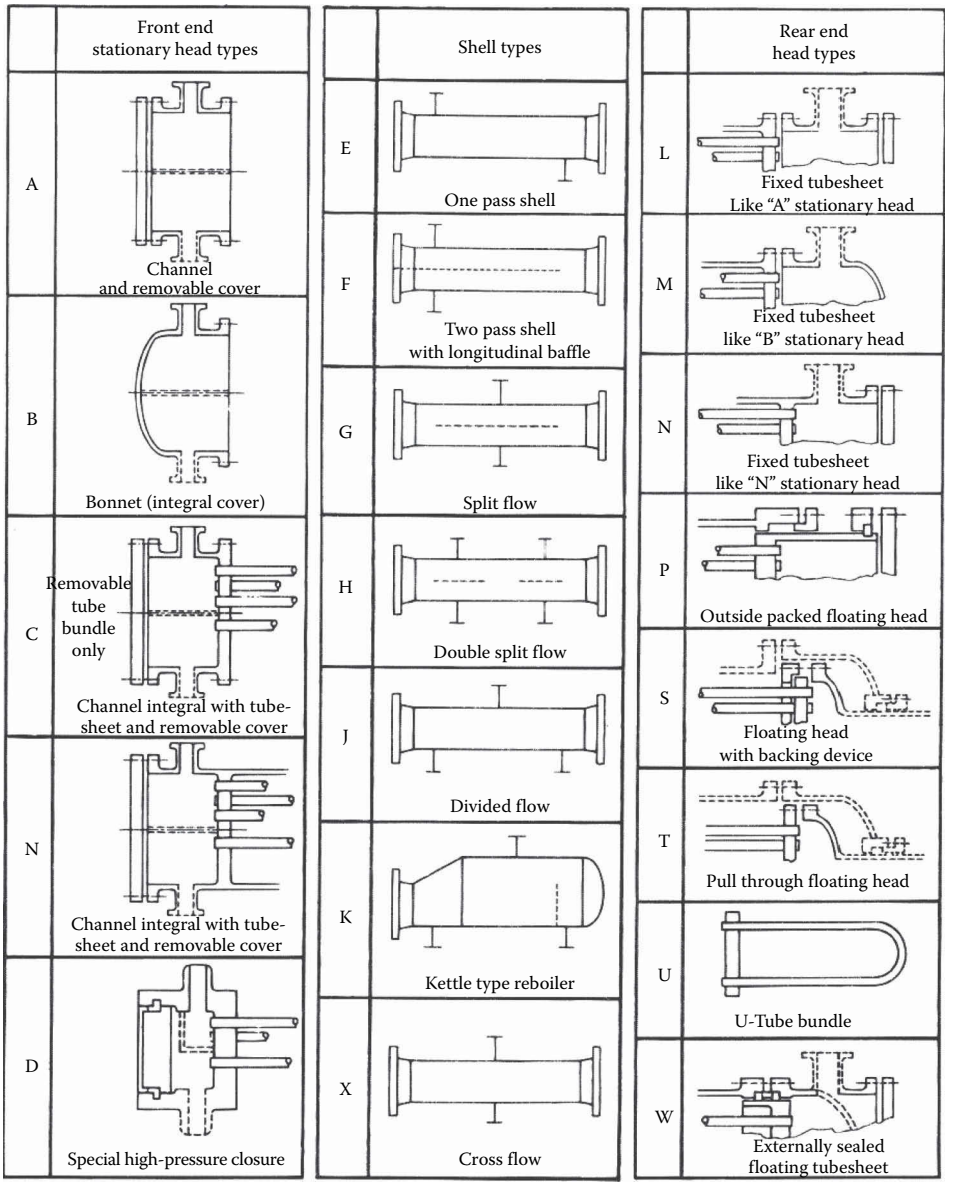

FIGURE 4.1.6 TEMA nomenclature for shell-and-tube configurations. (From TEMA Standards 9th ed., Tubular Exchanger Manufacturers Association, Tarrytown, NY, 2007. With permission.)

The E shell (center column, top) has the nozzles on opposite ends of the shell and is the most common configuration. It is used for any of the thermal services (single-phase heating or cooling, vaporization, and condensation). The nozzles may be on opposite sides of the shell as shown or on the same side; the choice is largely determined by plumbing convenience. The E shell allows countercurrent flow (shown later) of the two streams if there is one tube-side pass (i.e., the tube-side fluid flows through all of the tubes in parallel).

The F shell has both nozzles at one end of the shell and uses a longitudinal baffle on the shell side (shown dashed in the drawing) to force the shell-side fluid to flow to the far end of the heat exchanger and then back to the exit nozzle on the other side of the longitudinal baffle. Ideally, this allows countercurrent flow of the two streams if there are two tube-side passes (i.e., the tube-side fluid flows through half of the tubes in one direction, is turned around in the rear head, and returns through the other half of the tubes—see discussion of head types). However, the longitudinal baffle must be carefully sealed to the shell to prevent leakage of the shell-side fluid across it; this is done by welding the longitudinal baffle to the shell and front tubesheet (which limits some design options) or by using mechanical seals. The F shell is mainly used for sensible heat transfer services.

The G shell has both nozzles at the center of the shell, with a centrally located longitudinal baffle to force the fluid to the ends of the shell before returning. While the G shell is used for all services, its main application is as a shell-side vaporizer with either forced or natural (thermosiphon) convection of the boiling fluid; in the latter service, limited leakage across the baffle generally does not greatly degrade the thermal performance and the longitudinal baffle does not need to be perfectly sealed against the shell.

The H shell is effectively a double G shell and is employed in the same services. It is considered when the calculated shell-side pressure drop for a G arrangement is too high and threatens to limit the circulation rate or cause maldistribution of the flow.

The J shell, with one nozzle on top of the shell and two on the bottom, or vice versa, is commonly used in vacuum-condensing applications because of its low-pressure drop. Two J shells (one inverted) may be mated in series for long-condensing-range mixtures. The nozzles are usually different diameters, with the large diameter accommodating the inlet vapor. The baffles are vertically cut.

The K shell (or kettle reboiler or flooded chiller) is exclusively intended for vaporization of liquid on the shell side, with a condensing vapor (usually steam) or a hot liquid on the tube side as the heating medium. The tubesheet diameter is large enough to accommodate the tube bundle, but the shell transitions to a larger diameter to allow the vapor to disengage from the liquid pool and exit from the top nozzle. A weir or other level control is used to maintain the liquid level, usually just above the top tubes in the bundle.

The X shell is intended to provide a well-distributed crossflow of the shell-side fluid, the fluid usually entering at the top and exiting at the bottom but occasionally used for upflow or horizontal crossflow. To obtain good distribution, multiple nozzles from a properly designed manifold may be required. Alternatively, the upper tubes in the bundle may be omitted to allow internal redistribution, or a large plenum chamber may be welded to the top of the shell ("vapor dome" or "bathtub nozzle"), or a diverging transition section may be placed between the inlet piping and the top of the shell. The tube supports may be complete circles since there is little or no longitudinal shell-side flow. The X shell gives the lowest shell-side pressure drop of any configuration and is often used for low-pressure vapor condensers.

Front head. TEMA recognizes several front head designs as shown in the first column of Figure 4.1.6. Any of these designs will get the tube-side fluid into the tubes, but each has special features which recommend it to meet special needs. In Figure 4.1.6, the dashed lines indicate optional features depending upon need.

The A head, a channel with removable cover, bolts directly to the shell flange as shown in Figure 4.1.5, the tubesheet in that case being held between them and sealed with gaskets. Alternatively, the tubesheet may be integral with the shell (see the L rear head in Figure 4.1.6). A removable channel cover permits inspection, cleaning, removal, and replacement of tubes without disturbing the piping. The dashed lines at the center and the lower nozzle indicate that a pass partition plate may be welded

in the channel (and gasketed against the tubesheet and channel cover) to provide for two tube-side passes (as shown in Figure 4.1.5 and required by the F shell design). Additional pass partitions may be provided to allow four, six, or any even number of tube-side passes. This permits the designer to utilize the available tube-side pressure drop to increase velocity, improve the heat transfer coefficient, and possibly reduce fouling. A second nozzle is required on the channel for multipass designs.

The B, or bonnet, front head reduces the number of gasketed joints and thus the opportunity for leakage, but it does not permit inspection of the tubes without breaking the piping connection. It is generally less expensive than the A head.

C and N heads retain the removable cover feature of the A head but, respectively, replace the channel-to-tubesheet and the tubesheet-to-shell gasketed connections with welds to minimize leakage possibilities. The N head is particularly used in nuclear services.

The D head is mainly used in feedwater heater applications where tube-side pressures are in the 100–400 bar range. The internal partition (optional) need only withstand the 1–2 bar pressure drop through the tubes so it can be of lightweight construction. The high-pressure closure against the atmosphere uses a shear key ring to lock the main closure in place.

Rear head. A variety of rear head designs are used in shell-and-tube exchangers, primarily because of the need to accommodate thermally induced stresses. During operation, the tubes and the shell have different temperatures and therefore will expand (or try to) different amounts, even if there were no residual stresses in the exchanger before start-up and even if the entire exchanger is made out of the same material. The thermal stress problem is exacerbated if there are residual stresses, or if the exchanger is made of different materials, or during transient operation (including start-up and shutdown). If the temperature differences are small, the structure may be able to accommodate the thermal stresses safely; usually, however, it is necessary to make specific provision to allow the shell and the tubes to expand or contract independently. Failure to do so can result in buckling, bending, or even rupture of the shell or the tubes, or destruction of the tube-to-tubesheet joint.

A simple solution is to incorporate an expansion joint or a bellows into the shell (or in certain special applications, into the tube-side piping internal to the shell cover). However, this solution cannot cover the entire range of pressures and temperature differences encountered in practice. Further, it is usually possible to incorporate other desirable features, such as removable bundles, with thermal stress relief in the variety of rear head designs available. These are shown in the last column of Figure 4.1.6.

The L and M rear heads correspond to the A and B front heads previously described. As shown, they require a fixed tubesheet design; that is, the tubesheets are rigidly fastened to the shell, and thermal stress relief, if necessary, must be provided by a shell-side expansion joint or bellows. The tube bundle cannot be removed for inspection or mechanical cleaning on the shell side. However, the outer tube limit—the diameter of the tube field circumscribing the outermost tubes in the bundle—can be as little as 0.4 in. (10 mm) less than the inside diameter of a pipe shell and 0.5 in. (12.7 mm) for a rolled shell. Therefore, the tube field can be very full, giving more tubes and minimizing bypass flow. Similar comments apply to the N rear head, except that more clearance must be left between the outermost tubes and the shell.

The type P head uses packing between the skirt on the rear tubesheet and the shell extension to seal the shell-side fluid against leakage. The compression on the packing has to be adjusted to prevent excessive leakage on the one hand and to allow limited movement of the tube-side head on the other, so the shell-side fluid must be benign and cheap (not surprisingly, it is often cooling water). On the other hand, leakage between the two fluids can occur only through tube hole leaks. Because of the tubesheet skirt, clearance between the outermost tubes and the shell must increase compared with types L or M; accordingly, fewer tubes are possible in a given shell, and sealing strips to partially block the bundle-to-shell bypass stream are recommended. When the floating head cover and packing gland are removed, the tube bundle can be pulled out of the shell for inspection and cleaning.

The TEMA S split-ring floating head design uses a split backing ring to hold the floating head cover and its gasket to the tubesheet. The split backing ring is bolted to the cover with a bolt circle

outside the diameter of the tubesheet. Therefore, when the split ring is removed, the entire tube bundle may be pulled out of the shell. Tube count is similar to type P design and sealing strips are recommended. Usually, the split-ring floating head is used with an even number of tube passes so that a plain bonnet-type shell cover can be used. However, as shown by the dashed lines in Figure 4.1.6, single tube-side pass design (and countercurrent flow) can be achieved by use of a packing gland on the exit piping through the bonnet; alternatively, a deep bonnet can be used together with an expansion joint or bellows on the tube-side exit piping.

The pull-through floating head, type T, uses a floating head cover that flanges directly to the tubesheet, reducing the possibility of internal leakage compared with type S, but also eliminating more tubes around the periphery. Sealing strips are a virtual necessity. Single tube-side pass design is similar to type S, but is rarely used.

TEMA type U uses a bundle of U tubes and hence requires no rear head at all. The U-tube bundle effectively eliminates the thermal stress problem between shell and tubes, because each tube is free to expand or contract independently. The U bundle is also the cheapest construction because the cost of a second tubesheet is avoided. However, there are a number of drawbacks: Designs must have an even number of tube-side passes, mechanical cleaning of the smaller bend radius tubes in the U bend is impossible, individual tubes cannot be replaced except in the outer row, some tube count is lost because of minimum bend limits, and the U bend must be carefully supported against vibration or kept out of the crossflow stream by placing the shell nozzle upstream of the bend. The tube side in the U bend is susceptible to erosion, especially with two-phase or particulate-containing fluids.

Type W uses two sets of packing, often with a lantern ring in between. This construction is generally limited to benign fluids and low to very moderate pressures and temperatures.

Other features. Numerous other components are necessary or optional to construction of shell-and-tube exchangers. Probably the most complete discussion is given by Yokell (1990).

Principles of Design

Design logic. The design of a shell-and-tube exchanger involves the following steps:

1. Selection of a set of design features that are required for mechanical integrity and ease of maintenance, and which will likely lead to satisfying the thermal requirements within the allowable pressure drops, and at lowest cost.
2. Selection of a set of dimensions for the actual exchanger.
3. For the dimensions selected in (2), calculation of the thermal performance of the heat exchanger and both tube-side and shell-side pressure drops, using available rating procedures.
4. Comparison of the thermal performance calculated in (3) with that required and examination of the pressure drops calculated in (3) to ensure that the allowed pressure drops are reasonably used but not exceeded.
5. Adjustment of the dimensions selected in (2) and repetition of steps (3) and (4) until the criteria are satisfied.
6. Completion of the mechanical design to satisfy code requirements.
7. Cost estimation.

Basic design equations. Some of the basic design equations for a shell-and-tube exchanger in steady-state service were introduced earlier in this chapter in the subsection title, "Principles of Heat Exchanger Design." The approach to designing a shell-and-tube exchanger follows the basic approach outlined in this earlier subsection. Equation 4.1.2 relates the differential heat transfer area to the differential heat that is transferred across the area, the temperature difference $(T_h - T_c)$ across the differential area, and the overall convective heat transfer coefficient (U^*). Since T_h and T_c generally vary with the amount of heat transferred (following the first law of thermodynamics, and excepting isobaric phase transition of a pure component) and U^* may vary with local heat transfer conditions, in principle Equation 4.1.2

must be numerically integrated with T_h, T_c, and U^* calculated along the path of integration, and this process is performed by the most-advanced computer-based design methods.

For many applications, certain reasonable assumptions can be made allowing the analytical integration of Equation 4.1.2 to produce Equation 4.1.3. Depending on the flow configuration, the MTD may be calculated using either Equation 4.1.5 or Equation 4.1.6. Most shell-and-tube exchangers, however, have nozzle and tube pass configurations that lead to mixed countercurrent and cocurrent flow regions (as well as crossflow in the X shell). For these cases, the MTD must be calculated using Equation 4.1.7.

The "configuration correction factor" for the flow configuration involved has been found as a function of dimensionless temperature ratios for most flow configurations of interest and is given in analytical and/or graphical form in many heat transfer references (e.g., Hewitt 2008, Vol. 1). As an example, Figure 4.1.7 shows F, the configuration correction factor, for a shell-and-tube heat exchanger with a single shell pass and an even number of tube passes (i.e., 2, 4, 6, etc.). The correction factor is a function of dimensionless temperatures, P and R, where

$$P = \frac{T_{\text{tube, out}} - T_{\text{tube, in}}}{T_{\text{shell, in}} - T_{\text{tube, in}}} \tag{4.1.12}$$

and

$$R = \frac{T_{\text{shell, in}} - T_{\text{shell,out}}}{T_{\text{tube,out}} - T_{\text{tube, in}}} \tag{4.1.13}$$

Overall heat transfer coefficient. The relationship between the overall heat transfer coefficient U^*, referenced to the heat transfer area A^*, and the individual (film) heat transfer coefficients and the fouling resistances for heat transfer across a single cylinder was presented in Equation 4.1.9. This expression can be adjusted to account for heat transfer across a bundle of tubes,

$$U^* = \frac{1}{\dfrac{A^*}{h_i A_i} + R_{fi}\dfrac{A^*}{A_i} + \dfrac{A^* \ln(d_o/d_i)}{2\pi N_t L K_w} + R_{fo}\dfrac{A^*}{A_o} + \dfrac{A^*}{h_o A_o}} \tag{4.1.14}$$

where N_t is the total number of tubes in the heat exchanger. For the special but important case of plain tubes,

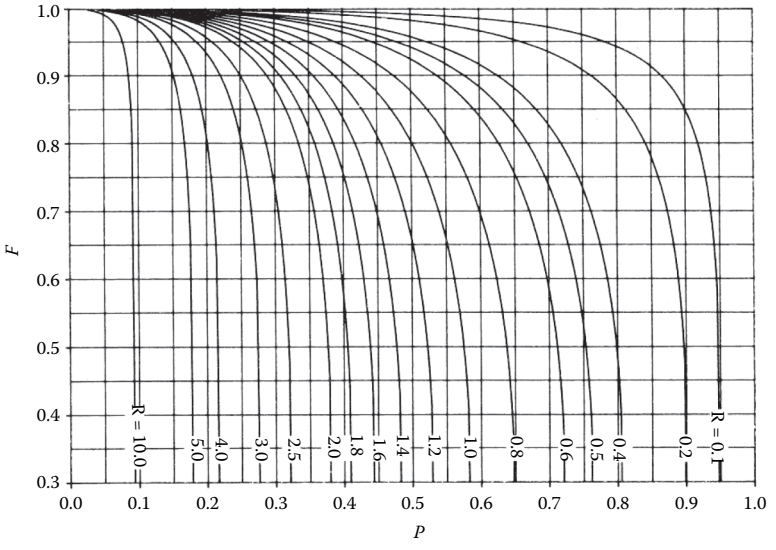

FIGURE 4.1.7 Configuration correction factor for a shell-and-tube heat exchanger with one shell pass and an even number of tube passes. (From Hewitt, G.F., *Heat Exchanger Design Handbook*, Begell House, New York, 2008. With permission.)

$$A^* = A_o = N_t(\pi d_o L) \tag{4.1.15}$$

and Equation 4.1.14 reduces to

$$U_o = \frac{1}{\frac{d_o}{h_i d_i} + R_{fi}\frac{d_o}{d_i} + \frac{d_o \ln(d_o/d_i)}{2K_w} + R_{fo} + \frac{1}{h_o}} \tag{4.1.16}$$

If finned tubes are used, the root diameter d_r of the fins replaces d_o in Equation 4.1.16 and A_o includes the surface area of the fins as well as the bare tube surface between the fins; it is also necessary to include a fin efficiency (typically about 0.8–0.95) multiplier in the numerators of the last two terms on the right side of Equation 4.1.16 to account for resistance to conduction in the fins. The treatment of fin efficiency is fully developed in Kern and Kraus (1972).

Film heat transfer coefficients. Calculation of single-phase tube-side heat transfer coefficients for plain tubes is discussed in Section 3.2.3; special correlations are required for internally enhanced tubes, see discussion of enhancement in Section 4.16. Intube condensation and vaporization are covered in the subsection on boiling and condensation in Section 3.4.1.

Shell-side heat transfer calculations are more complex owing to the large number and range of design variables and process conditions that can occur. The most accurate methods are proprietary and computer based. The best known of these methods are those of Heat Transfer Research, Inc. (HTRI), Navasota, TX, although there are other proprietary software packages available to and used by manufacturers. For single-phase flow, the Delaware method appears to be the best in the open literature, and it is feasible for both hand and computer use; various presentations of the method appear in many references, including Hewitt (2008) Vol. 3 and Hewitt et al. (1994). These references also give methods for shell-side vaporizing and condensing design. An approximate design procedure is given in the next subsection.

Fouling. Fouling is the formation of any undesired deposit on the heat transfer surface, and it presents an additional resistance to the flow of heat. Several different types of fouling are recognized:

Sedimentation: deposition of suspended material on the surface.
Crystallization: precipitation of solute from supersaturated solutions.
Corrosion: formation of corrosion products of the heat exchanger components.
Thermal degradation/polymerization: formation of insoluble products by oxidation, charring, and/or polymerization of a process stream.
Biofouling: growth of large organisms (e.g., barnacles) that interfere with flow to or past a heat transfer surface ("macrobiofouling") or small organisms (e.g., algae) that form a fouling layer on the surface ("microbiofouling").

The effect of fouling on design is twofold: Extra surface must be added to the heat exchanger to overcome the additional thermal resistance, and provision must be made to allow cleaning either by chemical or mechanical means. The fouling resistances included in Equation 4.1.16 result in requiring extra surface by reducing U^* (though they do not properly account for the time-dependent nature of fouling) and should be chosen with care. Prior experience with a given service is the best source of values. Ranges of typical values for major classes of service are included in Table 4.1.1.

Other things being equal, a fouling stream that requires mechanical cleaning should be put in the tubes because it is easier to clean the tube side. If this is not possible or desirable, then a removable bundle with a rotated square tube layout should be chosen to facilitate cleaning by mechanical, hydraulic (typically high-velocity water jets), or chemical means.

Pressure drop. Tube-side pressure drop in plain tubes is discussed in Section 2.4. These calculations are straightforward and quite accurate as long as the tubes are smooth and clean; however, even a small amount of roughening due to corrosion or fouling (sometimes with a significant reduction of flow area) can double or triple tube-side pressure drop. Special correlations are required for internally enhanced tubes.

Calculation of shell-side pressure drop is implicit in the design methods mentioned previously for heat transfer. Roughness has less effect on shell-side pressure drop than on the tube side, but fouling still may have a very substantial effect if the deposits fill up the clearances between the baffles and the shell and between the tubes and the baffles, or if the deposits are thick enough to narrow the clearances between adjacent tubes. Existing design methods can predict these effects if the thickness of the fouling layer can be estimated.

Limitations of design. It should be recognized that even under the best of conditions—new, clean exchangers with conventional construction features—heat exchanger design is not highly accurate. The best methods, when compared with carefully taken test data, show deviations of ±20% on overall heat transfer and ±40% on shell-side pressure drop (e.g., Palen and Taborek 1969). These ranges are considerably worsened in fouling services. In these cases, the thermal *system* should be designed for operational flexibility, including carefully chosen redundancy of key components, and easy maintenance.

Approximate Design Method

Because of the complexity of rigorous design methods, it is useful to have an estimation procedure that can quickly give approximate dimensions of a heat exchanger for a specified service. Such a method is given here for purposes of preliminary cost estimation, plant layout, or checking the results of computer output. This method is based upon Equation 4.1.3 with $A^* = A_o$ and $U^* = U_o$ and depends upon rapidly estimating values for q_T, MTD, and U_o. The procedure is as follows:

Estimation of q_T. For sensible heat transfer, q_T can be found using Equation 4.1.4. For isothermal phase change,

$$q_T = \dot{m} h_{fg} \tag{4.1.17}$$

where $\dot{m}$ is the mass rate of condensation or vaporization and h_{fg} is the latent heat of phase transformation.

For more complex cases, such as partial or multicomponent condensation, more elaborate analyses are required, although this method can still be used with care to give rough estimates.

Estimation of MTD. The first step is to calculate or estimate $\text{LMTD}_{\text{countercurrent}}$ from Equation 4.1.5 and then estimate F as follows:

1. If the two streams are in countercurrent flow, $F = 1$.
2. If the two streams are in a combination of countercurrent and cocurrent flows (i.e., multiple tube passes) and the outlet temperatures of the two streams are equal, $F = 0.8$.
3. If the exchanger has multiple passes and $T_{h,o} > T_{c,o}$, then $0.8 < F < 1.0$, with the actual value depending upon the temperature ranges of the two streams and $(T_{h,o} - T_{c,o})$. It is usually sufficiently accurate to take $F = 0.9$.
4. Design of a multiple tube pass exchanger with $T_{h,o} < T_{c,o}$ (i.e., a temperature cross) leads to $F < 0.8$, which is inefficient, of uncertain inaccuracy, and perhaps even thermodynamically impossible. The problem can be handled with multiple shells in series.
5. Then, $\text{MTD} = F(\text{LMTD})_{\text{countercurrent}}$, (Equation 4.1.7).

Estimation of U_o. The best way to estimate U_o is to use Equation 4.1.16, together with values of h_o, h_i, $R_{f,o}$, and $R_{f,i}$, chosen from Table 4.1.1. This table includes ranges of values that are typical of the fluids and services indicated, assuming normally allowable pressure drops, exchanger construction, and fouling. However, care should be taken in selecting values to consider possible unusual conditions, for example, especially high or low velocities (implying correspondingly high or low allowable pressure drops) and especially fouling. In selecting values from the table, the user should carefully read the footnotes for each entry.

Calculation of A_o. The total outside tube heat transfer area required in the heat exchanger is now found from Equation 4.1.3.

Estimation of exchanger dimensions. Figure 4.1.8 shows the relationship among A_o, effective tube length L, and inside shell diameter for a fully tubed, fixed tubesheet heat exchanger with one tube-side pass, with 3/4 in. (19.05 mm) plain tubes on a 15/16 in. (23.8 mm) pitch equilateral triangular tube layout. These curves are constructed using tube count tables (e.g., Saunders 1988). The dashed lines marked 3:1, 6:1, 8:1, 10:1, and 15:1 indicate ratios of tube length to shell inside diameter for guidance in selection. Exchangers of less than 3:1 ratio are expensive because of the large-diameter shell and tubesheet, with more holes to be drilled and tubes rolled and/or welded, and shell-side flow distribution is likely to be poor and lead to excessive fouling. Exchangers greater than 15:1 ratio are probably beyond the point of saving money by reducing shell diameter and number of tubes and may require excessive clear way for pulling the bundle; the bundles may be springy and difficult to handle during maintenance. Most heat exchangers fall into the 5:1–10:1 range.

Figure 4.1.8 is a very specific case that is used as a reference. In order to extend its usefulness to other tube diameters, layouts, bundle constructions, etc., Equation 4.1.18 is used:

$$A_o' = A_o F_1 F_2 F_3 \tag{4.1.18}$$

where A_o' is the value to be used with Figure 4.1.8, A_o is the required area calculated from Equation 4.1.3, and

F_1 is the correction factor for the tube layout. $F_1 = 1.00$ for 3/4 in. (19.05 mm) outside diameter tubes on a 15/16 in. (23.8 mm) triangular pitch. Values of F_1 for other tube diameters and pitches are given in Table 4.1.2.

F_2 is the correction factor for the number of tube-side passes. $F_2 = 1.00$ for one tube-side pass, and Table 4.1.3 gives values of F_2 for more passes.

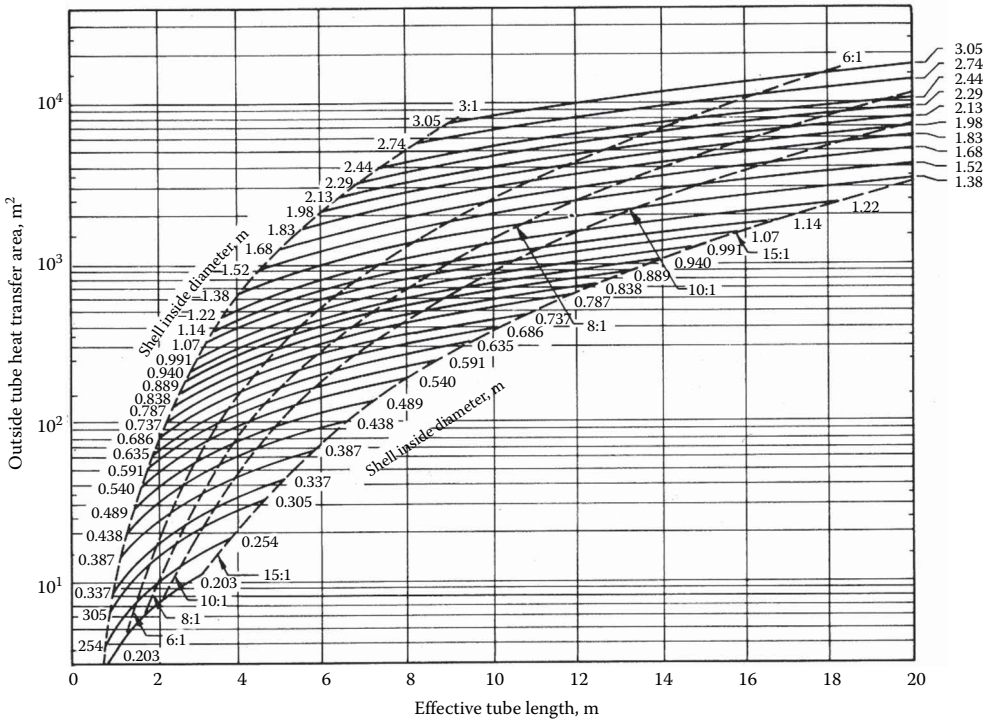

FIGURE 4.1.8 Heat transfer area as a function of shell inside diameter and effective tube length for 19.05 mm (3/4 in.) tubes on a 23.8 mm (15/16 in.) equilateral triangular tube layout, fixed tubesheet, one tube-side pass, fully tubed shell. (From Hewitt, G.F., *Heat Exchanger Design Handbook*, Begell House, New York, 1998. With permission.)

F_3 is the correction factor for shell construction/tube bundle configuration. $F_3 = 1.00$ for fixed tubesheet, fully tubed shells, and Table 4.1.4 gives values of F_3 for the standard TEMA types.

TABLE 4.1.2
Values of F_1 for Various Tube Diameters and Layouts

Tube Outside Diameter, in. (mm)		Tube Pitch, in. (mm)		Layout	F_1
5/8	(15.88)	13/16	(20.6)		0.90
5/8	(15.88)	13/16	(20.6)		1.04
3/4	(19.05)	15/16	(23.8)		1.00
3/4	(19.05)	15/16	(23.8)		1.16
3/4	(19.05)	1	(25.4)		1.14
3/4	(19.05)	1	(25.4)		1.31
1	(25.4)	1 1/4	(31.8)		1.34
1	(25.4)	1 1/4	(31.8)		1.54

$$F_1 = \frac{(\text{Heat transfer area/cross-sectional area of unit cell})\,\text{Reference}}{(\text{Heat transfer area/cross-sectional area of unit cell})\text{New Case}}$$

This table may also be used for low-finned tubing in the following way. The value estimated for h_o from Table 4.1.1 should be multiplied by the fin efficiency (usually between 0.75 and 1 for a good application; 0.85 is a good estimate) and used in Equation 4.1.14 with $A^* = A_o$, the total outside heat transfer area including fins. Then this value of A_o is divided by the ratio of the finned tube heat transfer area to the plain tube area (per unit length). The result of this calculation is used as A_o in Equation 4.1.17 to find A'_o to enter Figure 4.1.8.

[a] Since U-tube bundles must always have at least two passes, use of this table is essential for U-tube bundle estimation. Most floating head bundles also require an even number of passes.

TABLE 4.1.4
F_3 for Various Tube Bundle Constructions

[a] Since U-tube bundles must always have at least two tube-side passes, it is essential to use Table 4.1.3 also for this configuration.

Once a value of A_o' has been calculated from Equation 4.1.18, enter the ordinate of Figure 4.1.8 at that value and move horizontally, picking off the combinations of shell inside diameter and tube length that meet that requirement. The final choice can then be made from among those possibilities.

Example of the Approximate Design Method

Problem statement. Estimate the dimensions of a shell-and-tube heat exchanger to cool 100,000 lb_m/h (12.6 kg/s) of liquid toluene from 250°F to 110°F (121.1°C–43.3°C) using cooling tower water available at 80°F (26.7°C). Use split-ring floating head construction (TEMA S) with 3/4 in. (19.05 mm) outside diameter × 14 BWG (0.083 in. = 2.11 mm wall) low-carbon steel tubes on 15/16 in. (23.8 mm) equilateral triangular pitch. This construction implies one shell-side pass and an even number of tube-side passes—assume two for the present. Choose cooling water exit temperature of 100°F (37.8°C). Specific heat of toluene is 0.52 Btu/lb_m °F (2177 J/kg K) and viscosity at 180°F (82.2°C) is 0.82 lb_m/ft h (0.34×10^{-3} N·s/m^2 or 0.34 cP).

Solution.

$$q_T = \left(100{,}000 \text{ lb}_m / \text{h}\right)\left(0.52 \text{ Btu} / \text{lb}_m \,^\circ\text{F}\right)\left(250 - 110\right)^\circ\text{F}$$

$$= 7.28 \times 10^6 \text{ Btu} / \text{h} = 2.14 \times 10^6 \text{ W}$$

$$\text{LMTD}_{\text{countercurrent}} = \frac{(250 - 100) - (110 - 80)}{\ln \dfrac{250 - 100}{110 - 80}} = 74.6^\circ\text{F} = 41.4^\circ\text{C}$$

Since there are at least two tube-side passes, flow is not countercurrent, and $T_{h_o} > T_{c_o}$, estimate $F \approx 0.9$. Therefore, MTD = 0.9 (74.6°F) = 67.1°F = 37.3°C.

Estimation of U_o. Light organic liquid cooled by liquid water. (Note that 1 Btu/h ft² °F = 5.678 W/m^2 K.)

Water (in tubes) h_i	1000 Btu/h ft² °F	5700 W/m^2 K
Toluene (in shell) h_o	300 Btu/h ft² °F	1700 W/m^2 K
Tube-side fouling R_{f_T}	0.001 h ft² °F/Btu	1.8×10^{-4} m^2 K/W
Shell-side fouling R_{f_o}	0.0005 h ft² °F/Btu	8.8×10^{-5} m^2 K/W

Tube wall resistance (for estimation purposes, this term can be approximated by x_w/k_w, where x_w is the wall thickness):

$$\frac{x_w}{k_w} = \frac{0.083 \text{ in.}}{(12 \text{ in.} / \text{ft})(26 \text{ Btu} / \text{h ft} \,^\circ\text{F})} = 2.7 \times 10^{-4} \text{ h ft}^2 \,^\circ\text{F} / \text{Btu} = 4.6 \times 10^{-5} \text{ m}^2 \text{ K} / \text{W}$$

Then,

$$U_o = \frac{1}{\frac{0.750}{1000(0.584)} + \frac{0.001(0.750)}{0.584} + 2.7\times10^{-4} + 0.0005 + \frac{1}{300}}$$

$$= 150 \text{ Btu / h ft}^2\,^\circ\text{F} = 848 \text{ W / m}^2 \text{ K}$$

$$A_o = \frac{7.28\times10^6 \text{ Btu/h}}{(150 \text{ Btu /h ft}^2\,^\circ\text{F})\,(67.1^\circ\text{F})} = 723 \text{ ft}^2 = 67.7 \text{ m}^2$$

Correct for changes in construction features (preliminary examination of Figure 4.1.8 indicates shell inside diameter will be in the range of 500 mm, or 20 in.):

F_1:F_1 = 1.00 since the same tube size and layout is used
F_2:F_2 = 1.04, assuming two passes
F_3:F_3 = 1.15, TEMA S construction

$$A_o' = \left(723 \text{ ft}^2\right)(1.00)(1.04)(1.15) = 865 \text{ ft}^2 = 81 \text{ m}^2$$

From Figure 4.1.8, entering at A_o' pick off the following combinations of shell inside diameter and tube length:

Shell Inside Diameter		Effective Tube Length		L/D_s
in.	mm	ft	m	
27	686	6.6	2.0	2.9
25	635	7.5	2.3	3.6
23¼	591	9.2	2.8	4.7
21¼	540	10.8	3.3	6.1
19¼	489	13.1	4.0	8.2
17¼	438	16.7	5.1	11.6

Any of these combinations would supply the desired area; the 21¼ in. (540 mm) and 19¼ in. (489 mm) would appear to be likely choices.

Air-Cooled Heat Exchangers

Chemical process plants as well as steam power plants require the rejection of large quantities of heat at low temperatures. The traditional sink has been supplies of natural water, either on a once-through basis where a large river, lake, or ocean was available, or on a recycle basis through a cooling tower operation. With the decreasing number of suitable sites available for providing cooling water with the increasing restrictions on the thermal and chemical quality of water returned to natural sources, there has been greater interest in the use of air as a cooling medium. In fact, air has always been of interest in special applications where water was very scarce or nonexistent or where the temperature levels of heat rejection were such as to render the use of water inadvisable from a fouling standpoint. However, there has been an enormous growth in the use of air, and particularly in the use of air for rejection of heat at fairly low-temperature levels, on the order of 120°F or so.

The main reason for using air cooling is that air is always available wherever a process plant may be located on the surface of the earth, but one can argue also that air is essentially noncorrosive and nonfouling for the usual range of process applications. There are many reasons against using air. It has poor physical properties from the standpoint of the heat exchanger designer. It has low-thermal conductivity, low density, and a modest specific heat. The low-thermal conductivity and low density combine to produce a low heat transfer coefficient while the low density implies that very large volumes of air will be required to pick up a reasonable amount of heat. The low density and large volume flow rate also mean that, within reasonable pumping power limitations, the equipment available to move the air can only sustain very low pressure drops and, therefore, can only provide low velocities. The low velocity in turn further reduces the possibilities for a high heat transfer coefficient. If large quantities of water were available with no more than reasonable restrictions on the temperature at which that water could be discharged into the environment, air cooling would seldom be used in processing equipment.

Considering the disadvantages of using air, it is not surprising that the equipment designed for using air for cooling purposes has some very special features. Because of the low heat transfer coefficient on the air side, there is great incentive for using high-finned tubes with a ratio of total outside heat transfer area to inside heat transfer area up to 25. This helps to even out the product of heat transfer coefficient and the heat transfer area for the air side as compared to the process (tube) side, that is, $h_o A_o \rightarrow h_i A_i$. However, for a wide variety of processes, such as condensing stream or cooling aqueous streams, the controlling resistance to heat transfer will still be on the air side of the heat exchanger.

The combination of large volume flow rates with low allowable pressure drop combines to fix the geometrical configuration of the air-cooled equipment into the form of large flow area, shallow tube banks. The provision of air from the surrounding atmosphere to these tube banks requires not only large surface areas in the heat exchangers but large, open areas adjacent to the heat exchangers in which atmospheric air may flow in to supply the requirements of the heat exchangers. Quite literally, one may talk in terms of acres of air-cooled heat exchangers being required to provide the heat dissipation requirements of even modest-sized process plants and power plants. The industrial standard for air-cooled heat exchangers is largely set by API 661 (API 2013).

Equipment Configurations

Finned tube type. Various finning constructions of high-finned tubes are diagrammed in Figure 4.1.9. The basic problem is to provide the dense spacing of the fins on the outside of the base tube, to provide reasonable mechanical integrity of those fins, and to provide good thermal contact between the base of the fins and the tube.

1. The cheapest configuration is the so-called edge-wound or tension-wound fin, which is simply a thin strip of metal wound in tension around the outside of the plain base tube. One purpose of the tension is to keep the base of the fin in good contact with the base tube. The fin must be tightly secured to the tube at least at each end or it will tend to coil up like a giant Slinky toy.

   The tube and the fin need not be the same metal, though there may be some accelerated corrosion problems as the result of electrochemical cells being formed in damp atmospheres if the two metals are different. Very commonly, the fins are aluminum and the base tube is low carbon steel. The performance of these tubes tends to deteriorate substantially with time, as differential expansion takes place between the aluminum fins and the base tube as a result of operating temperature transients. The fins, being at a lower temperature, may tend to be expanded by the outward pressure of the tube on the inside, causing the fins to deform plastically and fail to fit as tightly as they did originally. Rough physical handling can accomplish the same thing. Corrosion and/or dirt deposits establishing themselves at the base of the fins may also impede heat flow from the base tube into the fins.

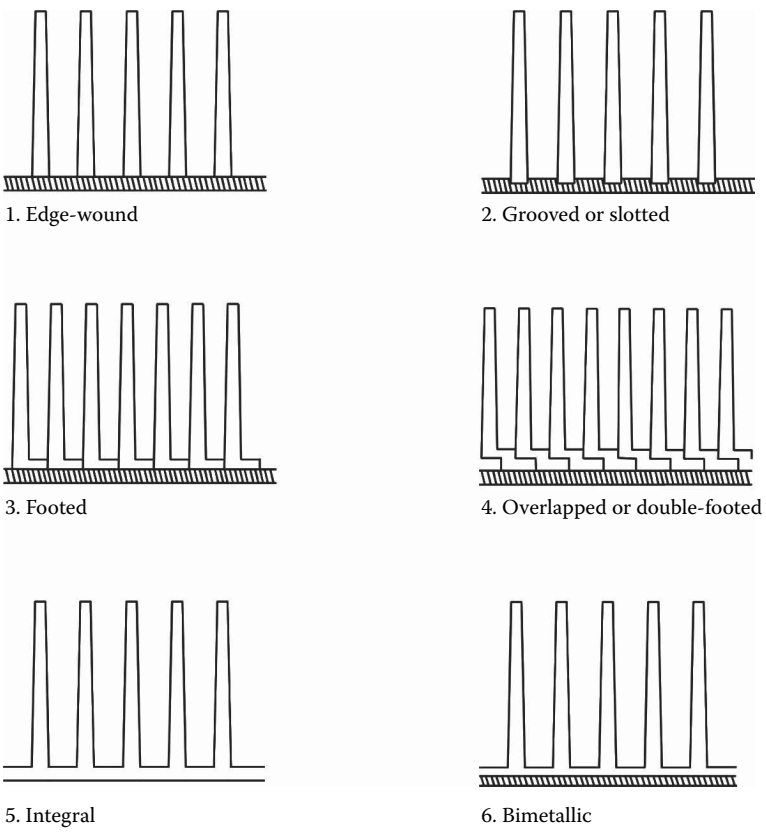

FIGURE 4.1.9 Schematic diagram of various configurations for finned tubes for air-cooled exchangers.

2. An improved version (compared to (1)) is made by tension-winding the finned strip into grooves or slots in the tube, followed by a roller tool to deform the upset metal of the slot back over the base of the fin in order to give an improved mechanical bond between fin and tube. To some extent the groove protects the fin from the atmosphere and reduces the possibilities of accelerated corrosion and/or dirt deposition at the base of the fin as well as making the fin mechanically more strongly bonded to the tube. This construction, of course, costs somewhat more than the simple edge-wound finned tube.
3. The footed fin differs from the above in having a portion of the fin bent at right angles to the main portion of the fin so as to form a small foot which is held in contact upon the base tube by the tension in the fin. If the fin and tube materials are compatible, the fin foot can be spot or continuously welded to the tube. This construction also tends to minimize the possibilities of corrosion and dirt deposition and to provide better thermal contact between the fin and the bare tube. Deterioration over time of the contact between the foot and the tube still occurs as a result of thermal cycling and penetration of atmospheric moisture into the space between the foot of one fin and the adjacent fin.
4. The next improvement is shown in the figure as the overlapped or double-footed fin in which each fin rests upon the foot of the fin immediately adjacent to it, giving further protection against penetration of atmospheric moisture and dirt and providing good thermal contact between the fin and the tube. All of the cases so far discussed may have fins of quite different material from the bare tube (unless welding of fin to tube is intended).
5. The integral fin is formed by a series of machining operations that raise the fin from the original thick-walled plain tube, leading to a fin that is now mechanically integral with the

base tube. This operation can only be performed on fairly soft, mechanically workable material such as aluminum or copper. The advantage is that there is now no possibility of thermal contact resistance developing between the fin and the base tube inasmuch as they are both the same piece of metal. The possibilities of corrosion are very much reduced as well as the penetration of fouling material into the area of the base of the fin. Also, this fin arrangement is much less susceptible to mechanical damage and stripping of the fins than the separately finned tubes mentioned earlier. The disadvantages of this tube are that firstly, it is more expensive, and secondly, the base tube must be of the same metal as the fin and construction is restricted to only a very few metals. If one is trying to cool a substance in the tube that is not compatible with one of the metals from which the integrally finned tube configuration can be made, this configuration cannot be used.

6. The "ultimate" refinement of the finned tube is the bimetallic tube. In this case, a close-fitting liner of essentially any metal required by the corrosive properties of the in-tube fluid may be placed inside the outer tube which is then swaged onto the liner and upset to form the fins. The outer tube is almost always aluminum for its high workability, high thermal conductivity, and low cost. The liner tube may be essentially any metal and may be of whatever wall thickness is required to provide protection against high pressure on the tube side and/or penetration of the tube wall by a pitting-type corrosion action. The disadvantages of the bimetallic tube are that firstly, they are relatively expensive, and secondly, a thermal contact resistance has been introduced between the liner and the finned outer of the tube. The tubes, as originally produced, ordinarily show very low thermal resistance at the contact surface. However, as time goes on, and the tube goes through many thermal cycles, the effect will be generally to develop a possibly very appreciable contact resistance. This problem has been studied at length by Kulkarni and Young (1966).

The choice of which finned tube to select is strongly dependent upon the particular circumstance of the application. In critical or especially severe applications, it will be necessary to go to a better construction at a higher price.

Tube-bank layouts. As shown in Figure 4.1.10, high-finned tubes may be arranged either as equilateral triangular layouts or as rotated square arrangements, though the latter are rather less common than the triangular ones. The tubes are ordinarily spaced very closely together, typically between 1/8 and 1/4 in. being allowed between the outer fins of adjacent tubes. It is necessary to leave some fin-tip-to-fin tip clearance to avoid contact of the fins during the minor vibration that will occur in field applications; yet, one does not wish to place the tubes so far apart that the air can flow through between the fin tips without mixing thoroughly with the air flowing across the fins.

In-line square arrangements are never used with high-finned tubes. It has been conclusively demonstrated (Weierman et al. 1978) that the air will tend to flow in the channels between the fin tips from the inlet to the tube bank to the exit, with little mixing occurring between this air and the air that has actually penetrated in between the fins and taken part in the heat transfer process. The net result is a severe deterioration in the apparent heat transfer coefficient on the fins of the tubes. In fact, this is a classic example of internal flow bypassing (Bell and Kegler 1978).

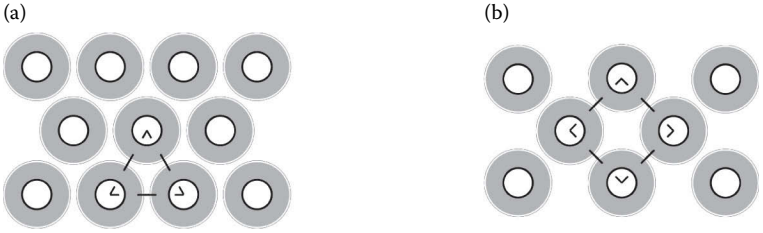

FIGURE 4.1.10 Finned tube unit cell geometries: (a) Equilateral triangular layout and (b) rotated square.

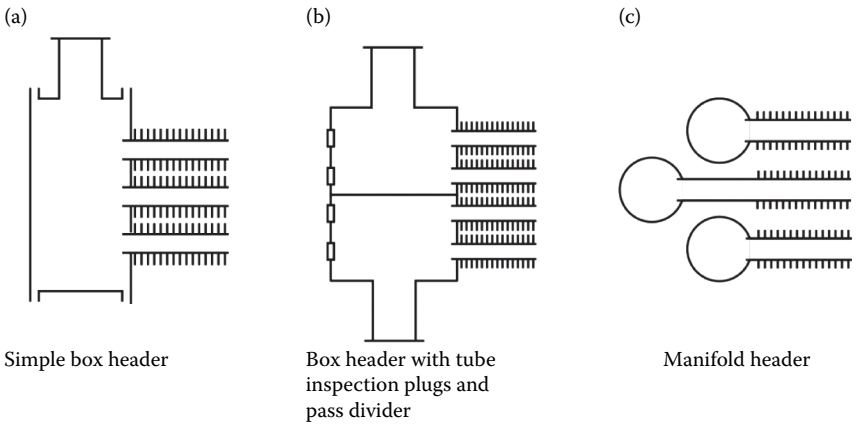

FIGURE 4.1.11 Header configurations for high-finned tubes.

Tube-bank construction. The tubes are commonly inserted into box headers, as shown in Figure 4.1.11. The tubes can be expanded into place if leakage of the tube-side fluid is not serious and if the tube-side fluid is flowing at relatively low pressures. However, the more common construction is for the tubes to be welded to the tubesheet portion of the header. The box header may be closed on the face opposite the tubesheet by a flanged cover with suitable gasketing if the pressure is not too great, or by a welded cover if greater mechanical integrity is required. If a welded cover is used, it is customary to use plugs opposite each tube as shown in Figure 4.1.11, to permit inspection and, if necessary, tube-side cleaning without cutting apart the header.

For high-pressure tube-side fluids, it is common to use a pipe header into which the tubes are inserted and then welded. In this design, inspection of the tube interior is not possible, and tube replacement is considerably more difficult than with the box-header configuration.

The box headers may have one or more pass partition as shown in Figure 4.1.12 in order to provide two or more passes through the tubes in series. When this is done, it is customary for the hot tube-side fluid to enter at the top of the header and flow downward through the consecutive passes, resulting in some approximation to countercurrent flow of air and process fluid and an improved MTD.

Air-cooled heat exchanger arrangement. There are two basic air-cooled heat exchanger arrangements as shown in Figure 4.1.13. The first configuration, called the forced-draft arrangement, has the fan underneath the tube-bank pushing air across the bank of finned tubes and discharging into the atmosphere above. The other arrangement, induced draft, has the fan located above the bank of tubes, drawing air across the tube bank and then discharging it through an upper plenum back into the atmosphere.

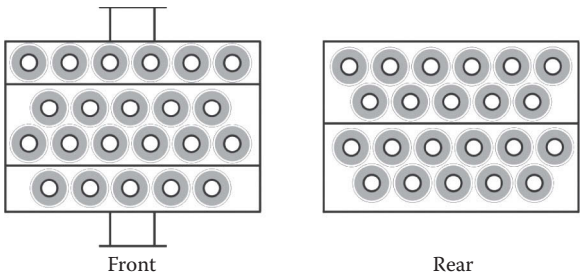

FIGURE 4.1.12 Front and rear header arrangements for a four rows, four pass air cooler.

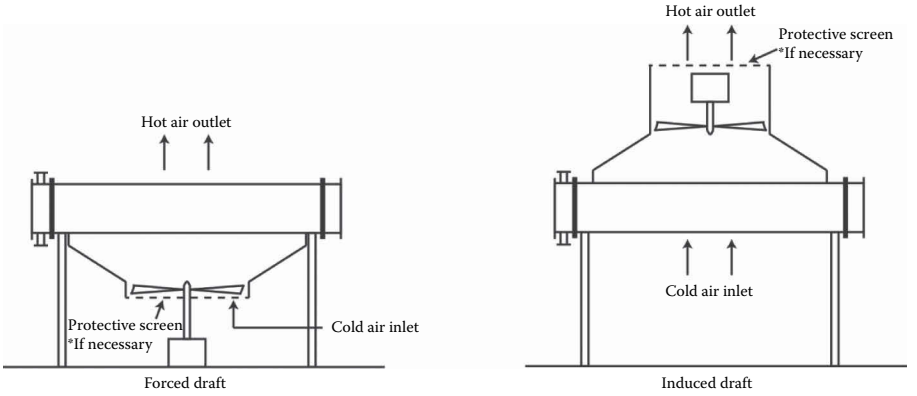

FIGURE 4.1.13 Forced-draft and induced-draft arrangements of air-cooled heat exchangers.

The forced-draft arrangement has the advantage of putting the fan and driver underneath the tube bank where they can be easily reached for maintenance and repair. The driver and fan are both operating in and with atmospheric temperature air, leading to fewer maintenance problems, a higher fan efficiency, and a wider choice of less expensive materials of construction for the fan. Among the disadvantages of this kind of construction are as follows: (1) the fan is exposed to places where operating personnel may walk and there is therefore a greater danger to the personnel; (2) the fan is more likely to ingest trash and debris, damaging the fan; (3) the discharge velocity from the fan is not very uniform and leads to a wide range of actual local air flow velocities across the tube bank, slightly reducing the thermal efficiency, especially in applications for close-temperature approach between the air and the tube-side fluid; (4) the air is discharged from the top of the heat exchanger at fairly low velocities and can mix with the incoming fresh air, giving rise to partial recirculation of the hot air and an increase in the inlet air temperature to the heat transfer surface; and (5) the top of the heat exchanger is exposed to the weather and mechanical damage and may suffer degradation and corrosion.

The induced-draft arrangement has advantages where the forced-draft exchanger has disadvantages and vice versa. That is, the fan and driver on the induced-draft exchanger are located above the heat exchanger where they are difficult to service and where they are exposed to the hot air coming off of the heat exchanger, possibly requiring selection of special materials of construction to satisfy the operating temperature limits. The fan, operating on the heated, less-dense air, tends to be less efficient in moving air. On the other hand, the fan is above the heat exchanger where it is not likely to constitute a danger to even careless personnel. A more nearly uniform air flow occurs across the tube bank, and the discharge plenum can produce a reasonably high-velocity plume of hot air, discharging it high into the atmosphere where there is much less likelihood of recirculation, and consequently deterioration of the inlet temperature difference.

One variant that has its own combination of advantages and disadvantages is to mount the driver for the fan underneath the heat exchanger with a long shaft extending up through the tube bundle to the fan above. The driver is out of the hot air and down where it can be more readily maintained. The fan, however, must be connected to the driver by a long shaft which must be supported against shaft whip and similar instabilities. The penetration of the shaft through the tube field may produce a local inhomogeneity in the tube field (i.e., an internal bypass area), which will at least locally reduce the efficiency of heat transfer in the heat exchanger.

Other configurations of air-cooled exchangers are used for special situations. The A-frame exchanger (Figure 4.1.14) provides more heat transfer surface for a given ground area. For steam and geothermal power plants, the A-frame configuration provides a shorter run for the low-pressure exhaust steam lines. Smaller A-frame exchangers have been used as condensers at the top of distillation columns.

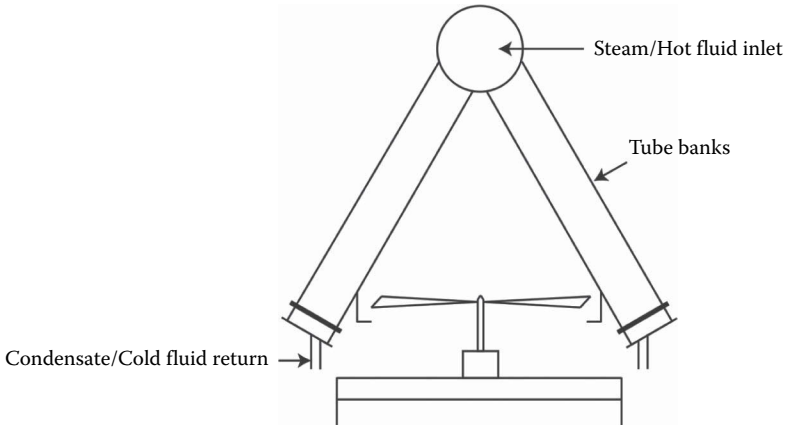

FIGURE 4.1.14 A-frame air-cooled heat exchanger.

Air-cooled exchangers are often used in areas in which the ambient air temperature is well below freezing conditions for the fluid (often water) being cooled and/or condensed. The solution is to provide a means of controlling the inlet air temperature by deliberately and controllably recirculating a portion of the exit hot air from the exchanger. A typical configuration is shown in Figure 4.1.15. By controlling the blowers on the outlet and exit air streams and the recirculating interval flow, the inlet air temperature to the tube bundle can be adjusted to the desired operational condition.

Another variant often used in natural gas production areas is shown in Figure 4.1.16. This unit, typically mounted on a concrete pad with a natural gas fueled diesel engine and a natural gas compressor, provides a variety of cooling services, including condensation of heavy components in the natural gas, interstage cooling of the compressed natural gas, and cooling the gas engine and compressor coolant.

The fan is driven by the gas engine. The several cooling services (1–5) share a common fan but are individually designed as to tube size, number, and tube-bank configuration. Since not all of the tube sections receive the same air throughput (taking into account inherent air flow maldistribution off of the fan and the differences in "exposed" tube length among the different services), allowance must be made in the actual heat transfer surface allocated to each.

Again, the final choice of the proper configuration depends very much upon the particular circumstances operating in each particular case.

Fans for air-cooled heat exchangers. The selection of fans for air-cooled heat exchangers is a rather complex art and the reader is referred to the literature for a more detailed treatment of this

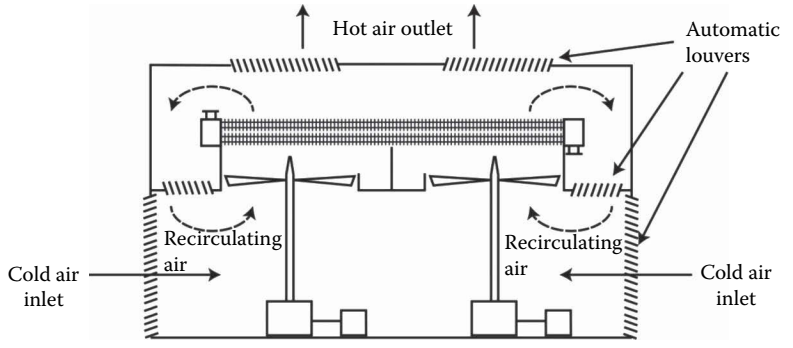

FIGURE 4.1.15 Recirculating air-cooled heat exchanger.

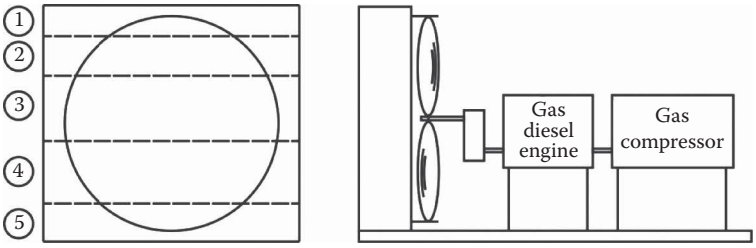

FIGURE 4.1.16 Schematic of skid-mounted well head gas compression unit. (1) Engine jacket water cooler, (2) compressor jacket water cooler, (3) compressor intercooler, (4) compressor aftercooler, and (5) lube oil cooler.

subject (Glass 1978). The fans are rather large diameter, multibladed, fairly low-speed propeller types. The pressure rise capability of these fans is limited to little more than 1 in., which must move the large quantities of air across the banks of finned tubes. A typical design value is on the order of 1/2 in. frictional pressure drop across the tube bank. This limitation allows face velocities (that is the approach velocity of the air to the face of the heat exchanger, assuming a uniform velocity) of about 300–900 ft/min. It may be noted that such air velocities are not greatly different from typical ambient wind velocities at many locations where air-cooled exchangers will be used. (For example, the average annual velocity in Oklahoma City is on the order of 11 or 12 miles/h, or about 1000 ft/min.) This must be taken into account in designing and laying out air-cooled heat exchangers so as to minimize the effect of atmospheric wind currents on the performance of the exchangers.

Basic Equations for Design of Air-Cooled Heat Exchangers

Heat transfer correlations for banks of high-finned tubes. A commonly recommended correlation for heat transfer to banks of high-finned tubes and which is sensitive to the geometrical parameters of the tube is due to Briggs and Young (1963). This equation is:

$$\frac{h_o D_r}{k} = 0.134\left(\frac{D_r \rho V_{max}}{\mu}\right)^{0.68} P_r^{1/3}\left(\frac{H}{S}\right)^{-0.2}\left(\frac{Y}{S}\right)^{-0.12} \tag{4.1.19}$$

The geometrical quantities H, S, and Y are defined in Figure 4.1.17.

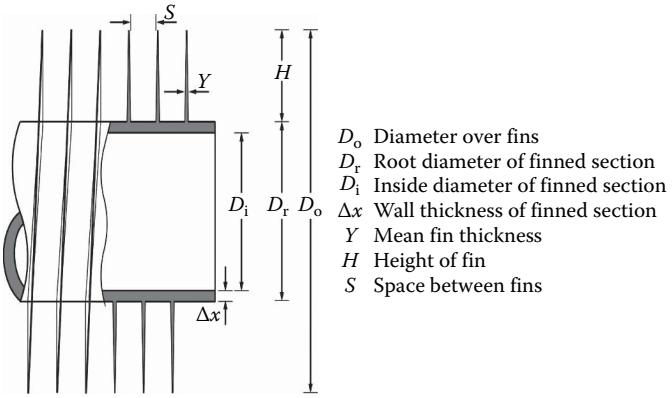

FIGURE 4.1.17 Definition of geometrical parameters for high-finned tubes.

Friction factor correlation for banks of high-finned tubes. The pressure drop for a flow of air across banks of high-finned tubes is usually correlated in terms of a friction factor defined by Equation 4.1.20:

$$f_r = \frac{\Delta P g_c}{n\rho V_{max}^2} \tag{4.1.20}$$

In Equation 4.1.20, n is equal to the number of tube rows crossed by the air.

The best generally available correlation for tubes laid out in an equilateral triangular arrangement is by Robinson and Briggs (1965):

$$f_r = 18.93\left(\frac{D_r \rho V_{max}}{\mu}\right)^{-0.316}\left(\frac{P_t}{D_r}\right)^{-0.927} \tag{4.1.21}$$

where P_t is the transverse pitch between centers of adjacent tubes in the same row. For tubes laid out in an isosceles triangular or rotated square arrangement, the friction factor equation, again from Robinson and Briggs, is

$$f_r = 18.93\left(\frac{D_r \rho V_{max}}{\mu}\right)^{-0.316}\left(\frac{P_t}{D_r}\right)^{-0.927}\left(\frac{P_t}{P_l}\right)^{0.52} \tag{4.1.22}$$

where P_l is the longitudinal pitch between centers of adjacent tubes in different rows measured along the diagonal. It will be noted that when $P_t = P_l$ as it does for an equilateral triangular arrangement, Equation 4.1.22 reduces to Equation 4.1.21.

Fin efficiency. In dealing with heat transfer in finned tubes, it is necessary to take into account the thermal resistance encountered due to flow of the heat through the length of the fin. This results in a reduction of the temperature at the tip of the fin compared to the value at the base of the fin. A sketch of these temperature relationships is shown in Figure 4.1.18.

There are several ways in which this effect may be taken into account, the most common one in the literature being the fin efficiency concept. The fin efficiency, η, is defined as the heat that would be transferred from a real fin (composed of metal having a finite thermal conductivity) divided by the amount of heat that would be transferred by that fin if it were everywhere at its base temperature (i.e., if the fin thermal conductivity were infinite). There has been a great deal of work done on the mathematical analysis of fin efficiency in the literature; much of this work is summarized by Kern

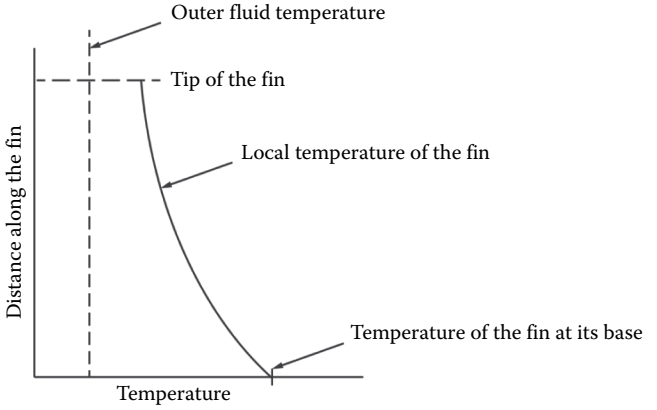

FIGURE 4.1.18 Typical temperature distribution in a fin.

and Kraus (1972). For fins of nearly constant cross section and of dimensions similar to those used in high-fin tubing, there are two approximate expressions sufficient for present purposes. The first set of equations are given as Equations 4.1.23, 4.1.24, and 4.1.25:

$$\eta = \frac{\tanh(H_c B)}{H_c B} \tag{4.1.23}$$

$$B = \left(\frac{2h_o}{k_f Y}\right)^{1/2} \tag{4.1.24}$$

$$H_c = \frac{D_r}{2}\left[\left(\frac{D_o}{D_r} - 1\right)\left(1 + 0.35 \ln \frac{D_o}{D_r}\right)\right] \tag{4.1.25}$$

The other set of equations, which is somewhat more convenient to use, are given in Equations 4.1.26 and 4.1.27:

$$\eta = \frac{1}{1 + \frac{m^2}{3}\sqrt{\frac{D_o}{D_r}}} \tag{4.1.26}$$

$$m = H \sqrt{\frac{2}{\left(\frac{1}{h_o} + R_{fo}\right) k_f Y}} \tag{4.1.27}$$

where R_{fo} is the fouling resistance on the fin surface, usually taken to be zero for air-cooled heat exchangers.

A further concept related to fin efficiency is the fin resistance that incorporates the total thermal resistance of the fin into an equation which can be computed once and for all for a wide variety of cases and used directly in the defining expression for the overall heat transfer coefficient. The fin resistance, R_{fin}, is given by Equation 4.1.28:

$$R_{fin} = \left[\frac{1 - \eta}{\frac{A_{root}}{A_{fin}} + \eta}\right]\left[\frac{1}{h_o} + R_{fo}\right] \tag{4.1.28}$$

where A_{fin} is the heat transfer area of all fins on a unit length of tube, and A_{root} is the surface area of a unit length of plain tube of diameter equal to the root diameter of the finned tube; that is,

$$A_{root} = \pi D_r N_f S = \pi D_r \left(\frac{S}{S + Y}\right) \tag{4.1.29}$$

R_{fin} is shown in Table 4.1.5 as a function of the outside heat transfer coefficient and fouling resistance for a variety of high-finned tubes used in air-cooled tubes used in heat exchangers.

Overall heat transfer coefficient. The overall heat transfer coefficient, based upon the total outside surface area of a heat exchanger with high-finned tubes, is given in terms of the individual coefficients and resistances in Equation 4.1.30.

$$\frac{1}{U_o} = \frac{1}{h_o} + R_{fo} + R_{fin} + \frac{\Delta x}{k_w}\frac{A_o}{A_m} + \left(R_{fi} + \frac{1}{h_i}\right)\frac{A_o}{A_i} \tag{4.1.30}$$

Explanation: All of the tubes shown are Wolverine Trufin Type H/R manufactured of 3003 Aluminum. The important geometrical parameters are given. The values of m, ϕ, and R_{fin} are given for $h_o = 5$, 10, and 15 Btu/h ft² °F. The number in brackets in the R_{fin} columns is the reciprocal of R_{fin}, i.e., the effective heat transfer coefficient corresponding to the fin resistance in Btu/h ft² °F.

In addition to the terms shown in Equation 4.1.30, it is necessary to add a term for the contact resistance between the fin and the tube if the fin is not integrally bonded to the tube, and also a contact resistance between the finned tube and a liner if using a bimetallic tube. The contact resistance between the fin and the tube can only be estimated from experience. The contact resistance between a finned tube and a liner has been studied analytically and to a very limited degree experimentally, with the results being reported in quantitative form in Kulkarni and Young (1966).

Mean temperature difference. In crossflow heat exchangers, the MTD is related to the LMTD as calculated for countercurrent flow in the usual way, as shown by Equation 4.1.31:

$$\text{MTD} = F(\text{LMTD})_{\text{countercurrent}} = F\left(\frac{(T_1 - t_2) - (T_2 - t_1)}{\ln\left(\frac{T_1 - t_2}{T_2 - t_1}\right)}\right) \tag{4.1.31}$$

The temperature definitions for a single tube-side pass (all tubes are treated as being in parallel) are shown in Figure 4.1.19. The correction factors for this configuration have been analyzed for the case of a single tube-side pass with the tube-side fluid and the air-side fluid each unmixed as they flow through the tube bank and are shown in Figure 4.1.20. The correction factors for two tube-side passes in series with the general flow arrangement being countercurrent to the flow of the air have

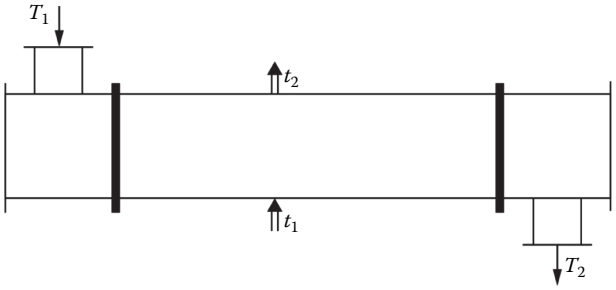

FIGURE 4.1.19 Temperature definitions for a single pass air-cooled heat exchanger.

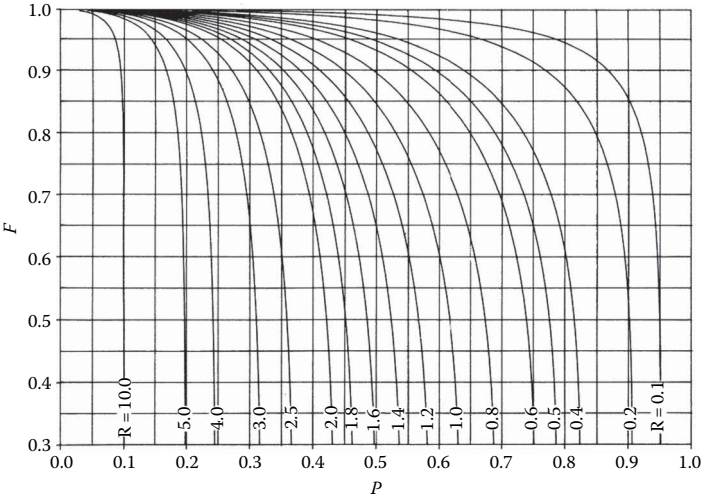

FIGURE 4.1.20 MTD configuration correction factor for crossflow with one tube-side pass. (From Hewitt, G.F., *Heat Exchanger Design Handbook*, Begell House, New York, 2008. With permission.)

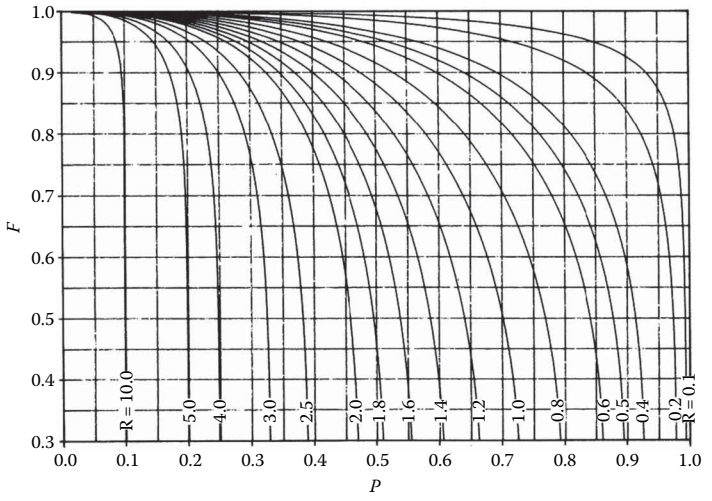

FIGURE 4.1.21 MTD configuration correction factor for crossflow with two tube-side passes. (From Hewitt, G.F., *Heat Exchanger Design Handbook*, Begell House, New York, 2008. With permission.)

been computed as well and are shown in Figure 4.1.21. For more than two tube-side passes, the correction factor F is essentially equal to 1, indicating that this situation results in a flow configuration very close to purely countercurrent flow.

Design Envelope

The possible range of construction and operational parameters for air-cooled heat exchangers is bounded by three limitations which, taken together, constitute the design envelope. The first of these limitations is due to the limited ability of the fan to provide high-pressure drops and will be referred to as the pumping limitation. The second is the thermodynamic limitation, which requires that a certain mass of air be circulated through the heat exchanger in order to remove the heat within the temperature limitations imposed on the air side. The third boundary condition is the rate limitation; that is, the heat transfer area provided must be sufficient that the heat may be transferred into the air with the overall coefficient and the MTD provided for in the design of the heat exchanger. In the following sections, we will examine each of these limitations to see how it tends to fix a fairly narrow range of operating conditions and design parameters for an exchanger for any given service.

Pumping limitation. The maximum design pressure drop obtainable from a typical fan used for air-cooled heat exchangers is on the order of 1 in. H_2O (approximately 0.04 psi). A commonly used design value is on the order of ½ in. H_2O or 0.02 psi. This pressure drop corresponds to a set of values of design face velocities and number of rows of tubes as given in Table 4.1.6.

While the above correspondence is only approximate, it will be found that any attempt to significantly increase the face velocity above the values shown will result in exceeding the allowable pressure that can be developed by the fan. Conversely, a lower velocity than that will tend to result in an excessively large heat exchanger face areas required and less than optimum design of the exchanger from a cost standpoint.

Thermodynamic limitation. The thermodynamic limitation refers to the fact that the weight of the air blown past the heat transfer surface is related to the heat that can be removed and the temperature change on the air side by the following equation:

$$\dot{m}_{\text{air}} = \frac{q_{\text{T}}}{C_{\text{p, air}}\left(t_2 - t_1\right)} \tag{4.1.32}$$

The face area required to satisfy the thermodynamic limitation is given by Equation 4.1.33.

TABLE 4.1.6
Typical Combinations of Number of Tube Rows and Design Face Velocities in Air-Cooled Heat Exchangers

n	V_{face} (ft/min)
3	900
4	800
5	700
6	600
8	500

$$\left(A_{face}\right)_T = \frac{\dot{m}_{air}}{\rho_{air} V_{face}} \tag{4.1.33}$$

in which $\left(A_{face}\right)_T$ is the total face area of the heat exchanger (that is, the length of the tubes×the width of the tube field) required to move the required mass of air at a given face velocity,V_{face}. We can combine Equations 4.1.32 and 4.1.33 to give

$$\frac{\left(A_{face}\right)_T}{q_T} = \frac{1}{c_{p,\,air}\left(t_2 - t_1\right)\rho_{air} V_{face}} \tag{4.1.34}$$

The significance of this equation is illustrated by the following example: 100,000 lb_m/h of water is to be cooled from 180 °F to 120 °F, using air at 90 °F. If the air is to be heated to 140 °F, what face area is required?

Solution:

$$\frac{\left(A_{face}\right)_T}{q_T} = \frac{1}{\left(0.240\ \frac{Btu}{lb_m\,°F}\right)(140-90)°F\left(0.0737\ \frac{lb_m}{ft^3}\right)\left(V_{face,}\frac{ft}{min}\right)\left(60\frac{min}{h}\right)} = \left[\frac{0.01885}{V_{face,}\frac{ft}{min}}\right]\frac{ft^2}{Btu/h}$$

$$q_T = \left(100{,}000\frac{lb_m}{h}\right)\left(1\frac{Btu}{lb_m\,°F}\right)(180-120)°F = 6\times10^6\ Btu/h$$

n	$V_{face}\left(\frac{ft}{min}\right)$	$\frac{\left(A_{face}\right)_T}{q_T}\left(\frac{ft^2}{Btu/\,h}\right)$	$\left(A_{face}\right)_T\left(ft^2\right)$
3	900	2.09×10^{-5}	126
4	800	2.36×10^{-5}	141
5	700	2.69×10^{-5}	162
6	600	3.14×10^{-5}	189
8	500	3.77×10^{-5}	226

Rate limitation. The basic rate equation was presented earlier (Equation 4.1.3). Also, we may write the relationship between the face area required for heat transfer and the number of rows of tubes and the total finned tube heat transfer area:

$$\left(A_{face}\right)_{HT} = \frac{A_o}{nA_{HT}^*} \tag{4.1.35}$$

where A_{HT}^* is the total finned tube heat transfer area per unit face area and per row of tubes. This quantity must be calculated for a given tube geometry and tube layout. Combining Equations 4.1.3 and 4.1.35, we obtain Equation 4.1.36:

$$\frac{\left(A_{\text{face}}\right)_{\text{HT}}}{q_{\text{T}}} = \frac{1}{n\ A^{*}_{\text{HT}} U_{\text{o}}\ (\text{MTD})} \tag{4.1.36}$$

Carrying this out for the example stated in the previous section, we obtain the following results:

n	No. of Tube Passes	F	MTD (°F)	V_{face} (ft/min)	U_{o}	$\frac{(A_{\text{face}})_{\text{HT}}}{q_{\text{T}}}$	$(A_{\text{face}})_{\text{HT}}$ (ft²)
3	1	0.82	28.5	900	12	5.84×10^{-5}	350
4	2	0.91	31.7	800	11	4.29×10^{-5}	258
5	2	0.91	31.7	700	10	3.78×10^{-5}	227
6	3	1.00	34.8	600	9	3.19×10^{-5}	191
8	4	1.00	34.8	500	8	2.69×10^{-5}	161

Resolution of the design. Using the results from the previous three sections, we can determine the combination of number of rows of tubes, the design face velocity, and the required face area for an air-cooled heat exchanger to carry out this service. In Figure 4.1.22, we plot the face area required by the thermodynamic limitation on the left-hand ordinate versus the number of tube rows in the design. On the other ordinate of Figure 4.1.22, we plot the face area required for the heat transfer rate versus the number of tube rows.

The point at which these two curves cross is the design that will satisfy both the thermodynamic limitation and the rate limitation. We can read off directly from Figure 4.1.22 the face area and the number of tube rows required. Note that the pumping limitation is satisfied for all of the points shown by virtue of respecting the relationship between the number of tube rows and the design face velocity as outlined earlier (the subsection *Pumping Limitation*). We see, for the example problem, that the main design features are

$n=6$ rows of tubes
$A_{\text{face}}=190$ ft², or approximately a layout of 10 ft tube field width × 20 ft tube length
$V_{\text{face}}=600$ ft/min

To complete the design, it is, of course, necessary to do a detailed check on the air-side heat transfer coefficient, the fin resistance term, the inside heat transfer coefficient, the overall coefficient, the required heat transfer area, pressure drops on both sides, etc., and rationalize these dimensions to a standard configuration.

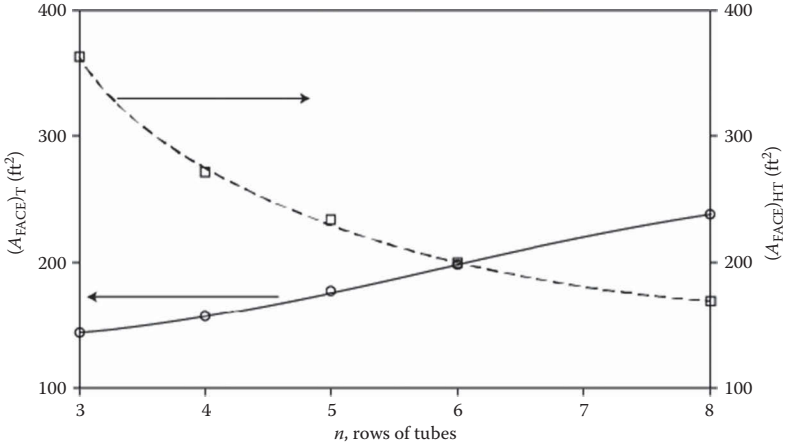

FIGURE 4.1.22 Resolution of the air cooler design.

Nomenclature

A	Total heat transfer area on one fluid side of a heat exchanger, m^2 (ft^2)
$(A_{face})_{HT}$	Total face area of an air-cooled heat exchanger required to satisfy the heat transfer limitation, m^2 (ft^2)
$(A_{face})_T$	Total face area of an air-cooled heat exchanger required to accommodate the air flow rate needed to satisfy the thermodynamic limitation, m^2 (ft^2)
A_{fin}	Heat transfer area of all fins on a unit length of tube, m^2 (ft^2)
A^*_{HT}	Total finned tube heat transfer area per unit face area and per row of tubes
A_m	Logarithmic mean heat transfer area of the bare tube well, m^2 (ft^2)
A'_o	Corrected outside tube heat transfer area used with Figure 4.1.8, ft^2
A_{root}	Surface area of a unit length of plain tube of diameter equal to the root diameter of the finned tube, m^2 (ft^2)
c_p	Specific heat capacity, J/kg·K (Btu/lb·°F)
D_h	Hydraulic diameter, m (in.)
D_I	Inside diameter of fin section, m (in.)
D_o	Diameter over fins, m (in.)
D_r	Root diameter of fin section, m (in.)
d	Tube diameter, m (in.)
d_A	Differential area, m^2 (ft^2)
d_q	Differential heat transfer rate, W (Btu/h)
F	Configuration correction factor, dimensionless
F_1	Correction factor for the tube layout
F_2	Correction factor for the number of tube-side passes
F_3	Correction factor for shell construction/tube bundle configuration
f_r	Friction factor for flow of air across banks of high-finned tubes
g_c	Proportionality constant in Newton's second law of motion, gc = 1 and dimensionless in SI units
H	Height of fin, m (in.)
h	Film heat transfer coefficient, W/m^2·K (Btu/h ft^2 °F)
h_{fg}	Latent heat of phase transformation, J/g (Btu/lb)
K	Fluid thermal conductivity, W/m·K (Btu/h·ft·°F)
k_f	Thermal conductivity of fin material, W/m·K (Btu/h·ft·°F)
k_w	Thermal conductivity of wall material, W/m·K (Btu/h·ft·°F)
L	Tube length, m (ft)
LMTD	Logarithmic mean temperature difference, K (°F)
MTD	Mean temperature difference between the hot and cold streams, K (°F)
$\dot{m}$	Mass flow rate, kg/h (lb/h)
N_f	Number of fins per unit length, m^{-1} (ft^{-1})
N_t	Total number of tubes in the heat exchanger
Nu	Nusselt number, hDh/k, dimensionless
n	Number of tube rows
P	Temperature effectiveness of one fluid, dimensionless
Pr	Prandtl number, μcp/k, dimensionless
P_l	Longitudinal pitch between centers of adjacent tubes in different rows, m (in.)
P_t	Transverse pitch between centers of adjacent tubes in the same row, m (in.)
q_T	Total heat transfer rate, W (Btu/h)
R	Temperature change ratio (also heat capacity rate ratio), dimensionless
Re	Reynolds number, ρvd/μ, dimensionless
R_f	Fouling resistance, m^2·K/W (h ft^2 °F/Btu)
R_{fin}	Fin resistance, m^2·K/W (h ft^2 °F/Btu)
S	Distance between adjacent fins, m (in.)
T_c	Local temperature of the cold stream, K (°F)
T_h	Local temperature of the hot stream, K (°F)
U	Overall heat transfer coefficient, W/m^2·K (Btu/h·ft^2·°F)

V_{face}	Face velocity of air through a air-cooled heat exchanger, m/min (ft/min)
V_{max}	Maximum air velocity across a bank of high-finned tubes, m/min (ft/min)
v	Fluid velocity, m/s (ft/s)
x_w	Wall thickness, m (ft)
Y	Mean fin thickness, m (in.)
ΔP	Pressure drop across a bank of high-finned tubes, Pa
Δx	Wall thickness of finned section, m (in.)
η	Fin efficiency, dimensionless
μ	Fluid dynamic viscosity, Pa·s (cP)
ρ	Fluid density, kg/m^3 (lb/ft^3)
Subscripts	
C	Cold fluid side
H	Hot fluid side
I	Inlet to the exchanger (or inside of tube)
o	Outlet to the exchanger (or outside of tube)
w	Wall or properties at the wall temperature
1	One section (inlet or outlet) of the exchanger
2	Other section (outlet or inlet) of the exchanger

COMPACT HEAT EXCHANGERS

Ramesh K. Shah

As noted earlier, a gas-to-fluid heat exchanger is referred to as a compact heat exchanger if it incorporates a heat transfer surface having a surface area density above about 700 m^2/m^3 (213 ft^2/ft^3) on at least one of the fluid sides that usually has gas flow, see Figure 4.1.1. It is referred to as a laminar flow heat exchanger if the surface area density is above about 3000 m^2/m^3 (914 ft^2/ft^3), and as a micro heat exchanger if the surface area density is above about 10,000 m^2/m^3 (3050 ft^2/ft^3). A liquid/two-phase heat exchanger is referred to as a compact heat exchanger if the surface area density on any one fluid side is above about 400 m^2/m^3 (122 ft^2/ft^3). A typical process industry shell-and-tube exchanger has a surface area density of less than 100 m^2/m^3 on one fluid side with plain tubes, and two to three times that with the high-fin density low-finned tubing. Plate-fin, tube-fin, and rotary regenerators are examples of compact heat exchangers for gas flows on one or both fluid sides, and gasketed and welded plate heat exchangers (PHEs) are examples of compact heat exchangers for liquid flows.

Types and Description

Gas-to-Fluid Exchangers

The important design and operating considerations for compact extended surface exchangers are (1) usually at least one of the fluids is a gas or specific liquid that has low h; (2) fluids must be clean and relatively noncorrosive because of small hydraulic diameter (D_h) flow passages and no easy techniques for mechanically cleaning them; (3) the fluid pumping power (i.e., pressure drop) design constraint is often equally as important as the heat transfer rate; (4) operating pressures and temperatures are somewhat limited compared with shell-and-tube exchangers as a result of the joining of the fins to plates or tubes such as brazing, mechanical expansion, etc.; (5) with the use of highly compact surfaces, the resultant shape of a gas-to-fluid exchanger is one having a large frontal area and a short flow length (the header design of a compact heat exchanger is thus important for a uniform flow distribution among the very large number of small flow passages); and (6) the market potential must be large enough to warrant the sizable manufacturing research and tooling costs for new forms to be developed.

Some advantages of plate-fin exchangers over conventional shell-and-tube exchangers are as follows. Compact heat exchangers, generally fabricated from thin metallic plates, yield large heat transfer surface area per unit volume (β), typically up to 10 times greater than the 50–100 m^2/m^3 provided by a shell-and-tube exchanger for general process application and from 1000 to 6000 m^2/m^3 for highly compact gas-side surfaces. Compact liquid or two-phase side surfaces have a β ratio ranging from 500 to 600 m^2/m^3. A compact exchanger provides a tighter temperature control; thus it is useful for heat-sensitive materials, improves the product (e.g., refining fats from edible oil) and its quality (such as a catalyst bed). Also, a compact exchanger could provide rapid heating or cooling of a process stream, thus improving the product quality. The plate-fin exchangers can accommodate multiple (up to 12 or more) fluid streams in one exchanger unit with proper manifolding, thus allowing process integration and cost-effective compact solutions.

Fouling is one of the potential major problems in compact heat exchangers (except for plate-and-frame heat exchangers), particularly those having a variety of fin geometries or very fine circular or noncircular flow passages that cannot be cleaned mechanically. Chemical cleaning may be possible; thermal baking and subsequent rinsing is possible for small-size units. Hence, extended surface compact heat exchangers may not be used in heavy fouling applications.

Liquid-to-Liquid Exchangers

Liquid-to-liquid and phase-change exchangers are plate-and-frame and welded PHEs, spiral plate, and printed circuit exchangers; some of them are described next in some detail along with other compact heat exchangers and their applications.

Plate-Fin Heat Exchangers

This type of exchanger has "corrugated" fins or spacers sandwiched between parallel plates (referred to as plates or parting sheets) as shown in Figure 4.1.23. Sometimes fins are incorporated in a flat tube with rounded corners (referred to as a formed tube), thus eliminating a need for the side bars. If liquid or phase-change fluid flows on the other side, the parting sheet is usually replaced by a flat tube with or without inserts/webs. Other plate-fin constructions include drawn-cup (see Figure 4.1.24) or tube-and-center configurations. Fins are die- or roll-formed and are attached to the plates by brazing, soldering, adhesive bonding, welding, mechanical fit, or extrusion. Fins may be used on both sides in gas-to-gas heat exchangers. In gas-to-liquid applications, fins are usually used

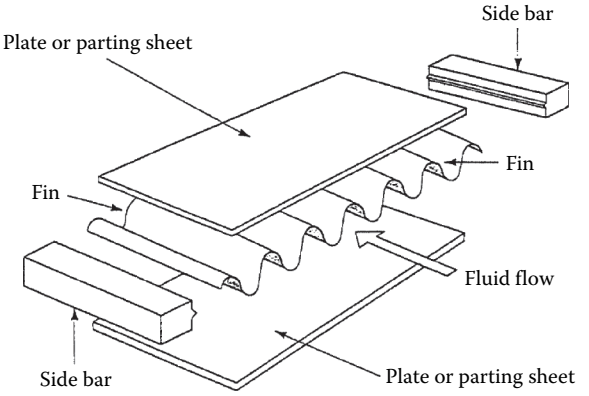

FIGURE 4.1.23 Typical components of a plate-fin exchanger.

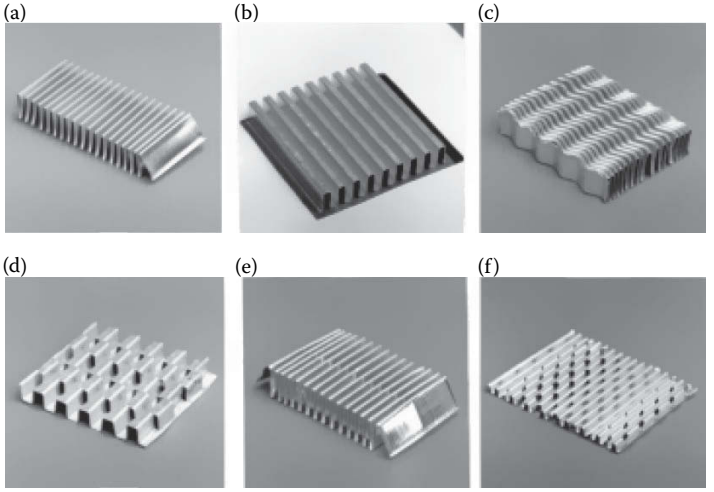

FIGURE 4.1.25 Fin geometries for plate-fin heat exchangers: (a) plain triangular fin, (b) plain rectangular fin, (c) wavy fin, (d) offset strip fin, (e) multilouver fin, and (f) perforated fin.

only on the gas side; if employed on the liquid side, they are used primarily for structural strength and flow-mixing purposes. Fins are also sometimes used for pressure containment and rigidity.

Plate fins are categorized as (1) plain (i.e., uncut) and straight fins, such as plain triangular and rectangular fins; (2) plain but wavy fins (wavy in the main fluid flow direction); and (3) interrupted fins such as offset strip, louver, and perforated. Examples of commonly used fins are shown in Figure 4.1.25.

Plate-fin exchangers have been built with a surface area density of up to about 5900 m^2/m^3 (1800 ft^2/ft^3). There is a total freedom of selecting fin surface area on each fluid side, as required by the design, by varying fin height and fin density. Although typical fin densities are 120–700 fins/m (3–18 fins/in.), applications exist for as many as 2100 fins/m (53 fins/in.). Common fin thicknesses range from 0.05 to 0.25 mm (0.002–0.010 in.). Fin heights range from 2 to 25 mm (0.08–1.0 in.). A plate-fin exchanger with 600 fins/m (15.2 fins/in.) provides about 1300 m^2 (400 ft^2/ft^3) of heat transfer surface area per cubic meter volume occupied by the fins. Plate-fin exchangers are manufactured in virtually all shapes and sizes, and made from a variety of materials.

Tube-Fin Heat Exchangers

In this type of exchanger, round and rectangular tubes are the most common, although elliptical tubes are also used. Fins are generally used on the outside, but they may be used on the inside of the tubes in some applications. They are attached to the tubes by a tight mechanical fit, tension winding, adhesive bonding, soldering, brazing, welding, or extrusion. Fins on the outside of the tubes may be categorized as follows: (1) normal fins on individual tubes, referred to as individually finned tubes or simply as *finned tubes*, as shown in Figures 4.1.26a and 4.1.27; (2) flat or continuous (plain, wavy, or interrupted) external fins on an array of tubes, as shown in Figures 4.1.26b and 4.1.28; (3) longitudinal fins on individual tubes. The exchanger having flat (continuous) fins on tubes has also been referred to as a *plate-fin and tube* exchanger in the literature. In order to avoid confusion with plate-fin surfaces, we will refer to it as a tube-fin exchanger having flat (plain, wavy, or interrupted) fins. Individually finned tubes are probably more rugged and practical in large tube-fin exchangers. Shell-and-tube exchangers sometimes employ low-finned tubes to increase the surface area on the shell side when the shell-side heat transfer coefficient is low compared with the tube-side coefficient. The exchanger with flat fins is usually less expensive on a unit heat transfer surface area basis because of its simple and mass production-type construction features. Longitudinal fins are generally used in condensing applications and for viscous fluids in double-pipe heat exchangers.

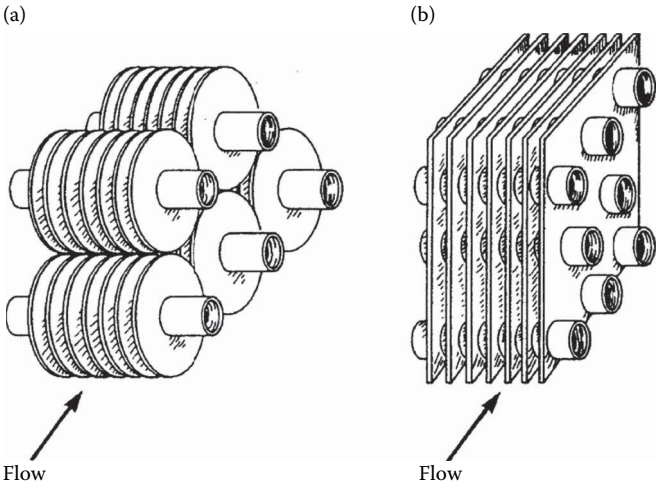

FIGURE 4.1.26 (a) Individually finned tubes, (b) flat or continuous fins on an array of tubes.

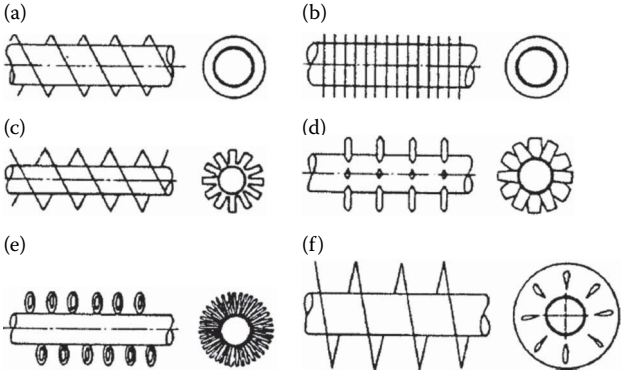

FIGURE 4.1.27 Individually finned tubes: (a) helical, (b) annular disk, (c) segmented, (d) studded, (e) wire loop, and (f) slotted helical.

Tube-fin exchangers can withstand high pressures on the tube side. The highest temperature is again limited by the type of bonding, the materials employed, and the material thickness. Tube-fin exchangers with an area density of about 3300 m^2/m^3 (1000 ft^2/ft^2) are commercially available. On the fin side, the desired surface area can be employed by using the proper fin density and fin geometry. The typical fin densities for flat fins vary from 250 to 800 fins/m (6–20 fins/in.), fin thicknesses vary from 0.08 to 0.25 mm (0.003–0.010 in.), and fin flow lengths from 25 to 250 mm (1–10 in.). A tube-fin exchanger having flat fins with 400 fins/m (10 fins/in.) has a surface area density of about 720 m^2/m^3 (220 ft^2/ft^3). These exchangers are extensively used as condensers and evaporators in air-conditioning and refrigeration applications, as condensers in electric power plants, as oil coolers in propulsive power plants, and as air-cooled exchangers (also referred to as a fin-fan exchanger) in process and power industries.

Regenerators

The regenerator is a storage-type exchanger. The heat transfer surface or elements are usually referred to as a matrix in the regenerator. In order to have continuous operation, either the matrix must be moved periodically into and out of the fixed streams of gases, as in a *rotary* regenerator (Figure 4.1.29a), or the gas flows must be diverted through valves to and from the fixed matrices as in a *fixed-matrix* regenerator (Figure 4.1.29b). The latter is also sometimes referred to as a

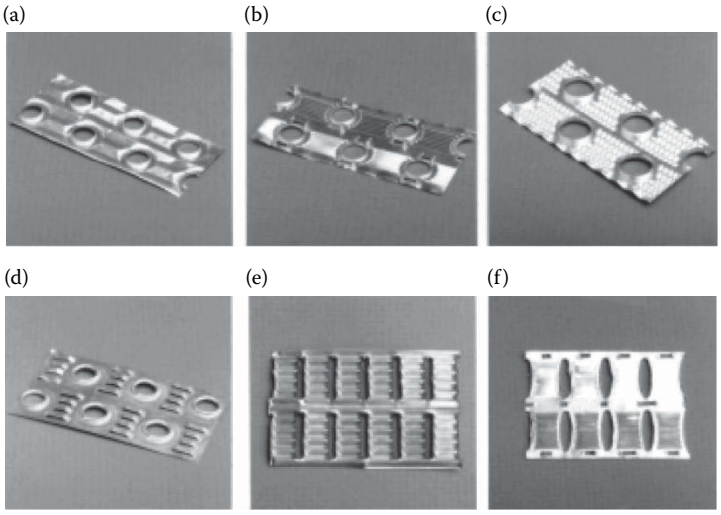

FIGURE 4.1.28 Flat or continuous fins on an array of tubes: On round tubes: (a) wavy fin, (b) multilouver fin, (c) fin with structured surface roughness (dimples), (d) parallel louver fin, (e) louver fin on flat tubes, and (f) multilouver fin on elliptical tubes.

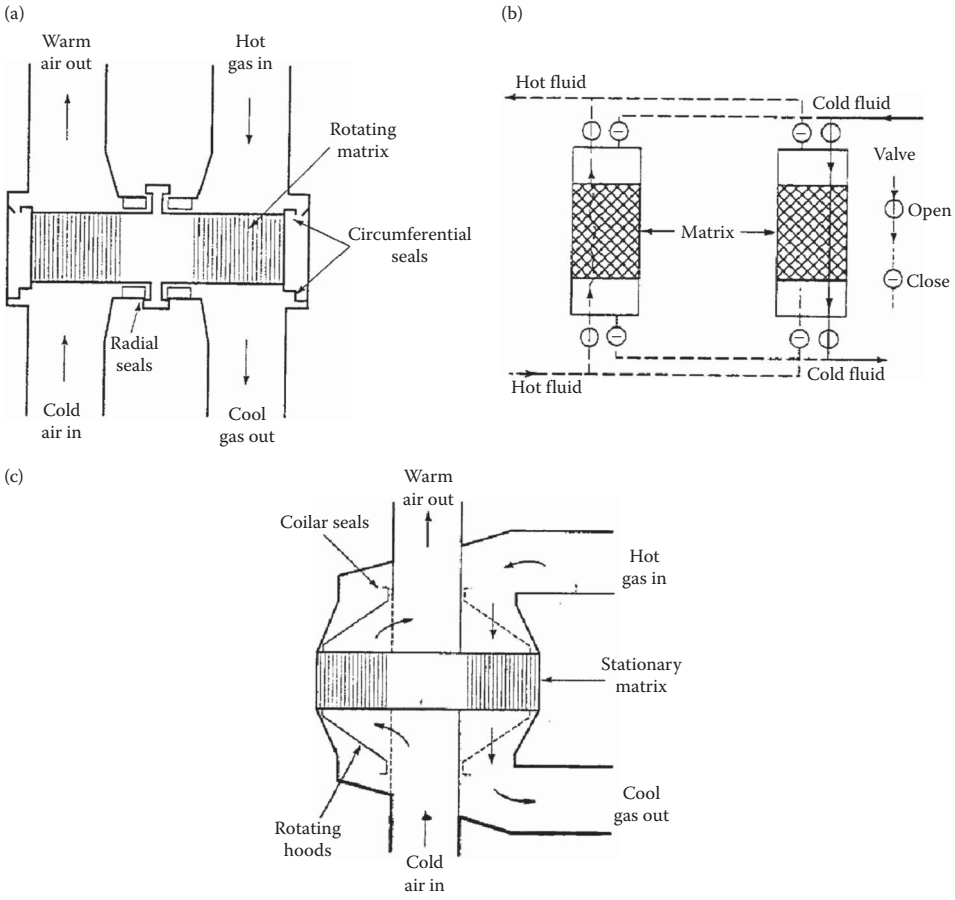

FIGURE 4.1.29 Regenerators: (a) rotary, (b) fixed-matrix, and (c) Rothemuhle.

periodic-flow regenerator or a *reversible heat accumulator.* A third type of regenerator has a fixed matrix (in the disk form) and the fixed stream of gases, but the gases are ducted through rotating hoods (headers) to the matrix as shown in Figure 4.1.29c. This Rothemuhle regenerator is used as an air preheater in some power-generating plants. The thermodynamically superior counterflow arrangement is usually employed in regenerators.

The *rotary regenerator* is usually a disk type in which the matrix (heat transfer surface) is in a disk form and fluids flow axially. It is rotated by a hub shaft or a peripheral ring gear drive. For a rotary regenerator, the design of seals to prevent leakage of hot to cold fluids and vice versa becomes a difficult task, especially if the two fluids are at significantly differing pressures. Rotating drives also pose a challenging mechanical design problem.

Major advantages of rotary regenerators are the following. For a highly compact regenerator, the cost of the regenerator surface per unit of heat transfer area is usually substantially lower than that for the equivalent recuperator. A major disadvantage of a regenerator is an unavoidable carryover of a small fraction of the fluid trapped in the passage to the other fluid stream just after the periodic flow switching. Since fluid contamination (small mixing) is prohibited with liquids, the regenerators are used exclusively for gas-to-gas heat or energy recovery applications. Cross-contamination can be minimized significantly by providing a purge section in the disk and using double-labyrinth seals.

Rotary regenerators have been designed for a surface area density of up to about 6600 m^2/m^3 (2000 ft^2/ft^3), and exchanger effectivenesses exceeding 85% for a number of applications. They can employ thinner stock material, resulting in the lowest amount of material for a given effectiveness and pressure drop of any heat exchanger known today. The metal rotary regenerators have been designed for continuous inlet temperatures up to about 790°C (1450°F) and ceramic matrices for higher-temperature applications; these regenerators are designed up to 400 kPa or 60 psi pressure differences between hot and cold gases. Plastic, paper, and wool are used for regenerators operating below 65°C (150°F) inlet temperature of the hot gas and 1 atm pressure. Typical regenerator rotor diameters and rotational speeds are as follows: up to 10 m (33 ft) and 0.5–3 rpm for power plant regenerators, 0.25–3 m (0.8–9.8 ft) and up to 10 rpm for air-ventilating regenerators, and up to 0.6 m (24 in.) and up to 18 rpm for vehicular regenerators. Refer to Shah (1994) for the description of *fixed-matrix regenerator*, also referred to as a *periodic-flow, fixed bed, valved*, or *stationary* regenerator.

Plate-Type Heat Exchangers

These exchangers are usually built of thin plates (all prime surface). The plates are either smooth or have some form of corrugations, and they are either flat or wound in an exchanger. Generally, these exchangers cannot accommodate very high pressures, temperatures, and pressure and temperature differentials. These exchangers may be further classified as plate, spiral plate, lamella, and plate-coil exchangers as classified in Figure 4.1.1. The PHE, being the most important of these, is described next.

The *plate-and-frame or gasketed PHE* consists of a number of thin rectangular corrugated or embossed metal plates sealed around the edges by gaskets and held together in a frame as shown in Figure 4.1.30. The plate pack with fixed and movable end covers is clamped together by long bolts, thus compressing the gaskets and forming a seal. Sealing between the two fluids is accomplished by elastomeric molded gaskets (typically 5 mm or 0.2 in. thick) that are fitted in peripheral grooves mentioned earlier. The most conventional flow arrangement is one pass to one pass counterflow with all inlet and outlet connections on the fixed end cover. By blocking flow through some ports with proper gasketing, either one or both fluids could have more than one pass. Also more than one exchanger can be accommodated in a single frame with the use of intermediate connector plates such as up to five "exchangers" or sections to heat, cool, and regenerate heat between raw milk and pasteurized milk in a milk pasteurization application.

Typical PHE dimensions and performance parameters are given in Table 4.1.7 (Shah, 1994). Any metal that can be cold-worked is suitable for PHE applications. The most common plate materials are stainless steel (AISI 304 or 316) and titanium. Plates made from Incoloy 825, Inconel 625, and

Hastelloy C-276 are also available. Nickel, cupronickel, and Monel are rarely used. Carbon steel is not used because of low corrosion resistance for thin plates. The heat transfer surface area per unit volume for plate exchangers ranges from 120 to 660 m^2/m^3 (37–200 ft^2/ft^3).

In PHEs, the high turbulence due to plates reduces fouling from about 10%–25% of that of a shell-and-tube exchanger. High thermal performance can be achieved in plate exchangers because the high degree of counterflow in PHEs makes temperature approaches of up to 1°C (2°F) possible. The high thermal effectiveness (up to about 93%) makes low-grade heat recovery economical. PHEs are most suitable for liquid–liquid heat transfer duties.

Welded PHEs. One of the limitations of gasketed PHE is the presence of the gaskets which restricts the use to compatible fluids and which limits operating temperatures and pressures. In order to overcome this limitation, a number of welded PHE designs have surfaced with a welded pair of plates for one or both fluid sides. However, the disadvantage of such design is the loss

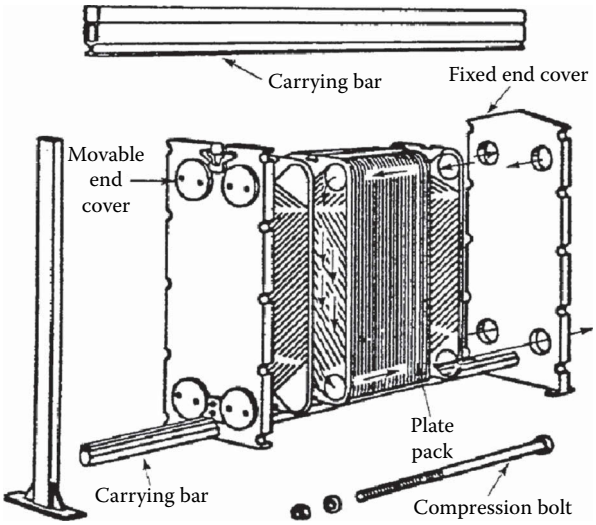

FIGURE 4.1.30 A plate-and-frame or gasketed PHE.

TABLE 4.1.7
Some Geometric and Operating Condition Characteristics of Plate-and-Frame Heat Exchangers

Unit		Operation	
Maximum surface area	2500 m^2	Pressure	0.1–2.5 MPa
Number of plates	3–700	Temperature	–40°C to 260°C
Port size	Up to 400 mm	Maximum port velocity	6 m/s
Plates		Channel flow rates	0.05–12.5 m^3/h
Thickness	0.5–1.2 mm	Maximum unit flow rate	2500 m^3/h
Size	0.03–3.6 m^2	*Performance*	
Spacing	1.5–5 mm	Temperature approach	As low as 1°C
Width	70–1200 mm	Heat exchanger efficiency	Up to 93%
Length	0.6–5 m	Heat transfer coefficients for water–water duties	3000–7000 $W/m^2 K$

of disassembling flexibility on the fluid side where the welding is done. Essentially, welding is done around the complete circumference where the gasket is normally placed. A *stacked plate heat exchanger* is another welded PHE design from Pacinox in which rectangular plates are stacked and welded at the edges. The physical size limitations of PHEs (1.2 m wide × 4 m long max, 4 × 13 ft) are considerably extended to 1.5 m wide × 20 m long (5 × 66 ft) in this exchanger. A maximum surface area of 10,000 m^2 or over 100,000 ft^2 can be accommodated in one unit. The potential maximum operating temperature is 815°C (1500°F) with an operating pressure of up to 20 MPa (3000 psig) when the stacked plate assembly is placed in a cylindrical pressure vessel. For operating pressures below 2 MPa (300 psig) and operating temperatures below 200°C (400°F), the plate bundle is not contained in a pressure vessel, but is bolted between two heavy plates. Some of the applications of this exchanger are catalytic reforming, hydrosulfurization, crude distillation, synthesis converter feed effluent exchanger for methanol, propane condenser, etc.

A number of other PHE constructions have been developed to address some of the limitations of the conventional PHEs. A double-wall PHE is used to avoid mixing of the two fluids. A wide-gap PHE is used for fluids having high fiber content or coarse particles. A graphite PHE is used for highly corrosive fluids. A flow-flex exchanger has plain fins on one side between plates and the other side has conventional plate channels, and is used to handle asymmetric duties (flow rate ratio of 2:1 and higher).

A vacuum *brazed PHE* is a compact PHE for high-temperature and high-pressure duties, and it does not have gaskets, tightening bolts, frame, or carrying and guide bars. It simply consists of stainless-steel plates and two end plates. The brazed unit can be mounted directly on piping without brackets and foundations.

Printed circuit heat exchangers. This exchanger, as shown in Figure 4.1.31, has only primary heat transfer surfaces as PHEs. Fine grooves are made in the plate by using the same techniques as those employed for making printed electrical circuits. High surface area densities (650–1350 m^2/m^3 or 200–400 ft^2/ft^3 for operating pressures of 500–100 bar respectively) are achievable. A variety of materials including stainless-steel, nickel, and titanium alloys can be used. It has been successfully used with relatively clean gases, liquids and phase-change fluids in chemical processing, fuel processing, waste heat recovery, and refrigeration industries. Again, this exchanger is a new construction with limited special applications currently.

Exchanger Heat Transfer and Pressure Drop Analysis

In this subsection, starting with the thermal circuit associated with a two-fluid exchanger, ε-NTU, P-NTU, and MTD methods used for an exchanger analysis are presented, followed by the fin efficiency concept and various expressions. Finally, pressure drop expressions are outlined for various single-phase exchangers.

Two energy conservation differential equations for a two-fluid exchanger with any flow arrangement are (see Figure 4.1.32 for counterflow) as follows:

$$dq = q''\, dA = -C_h dT_h = \pm C_c dT_c \tag{4.1.37}$$

where the ± sign depends upon whether dT_c is increasing or decreasing with increasing dA or dx. The local overall rate equation is

$$dq = q''\, dA = U\left(T_h - T_c\right)\text{local}\, dA = U\Delta T dA \tag{4.1.38}$$

As shown earlier, integration of Equations 4.1.37 and 4.1.38 across the exchanger surface area results in

$$q = C_h\left(T_{h,i} - T_{h,o}\right) = C_c\left(T_{c,o} - T_{c,i}\right) \tag{4.1.39}$$

and

$$q = UA\Delta T_m = \Delta T_m / R_o \tag{4.1.40}$$

where ΔT_m is the true MTD that depends upon the exchanger flow arrangement and degree of fluid mixing within each fluid stream. The inverse of the overall thermal conductance UA is referred to as the overall thermal resistance R_o as follows (see Figure 4.1.33).

$$R_o = R_h + R_{s,h} + R_w + R_{s,c} + R_c \tag{4.1.41}$$

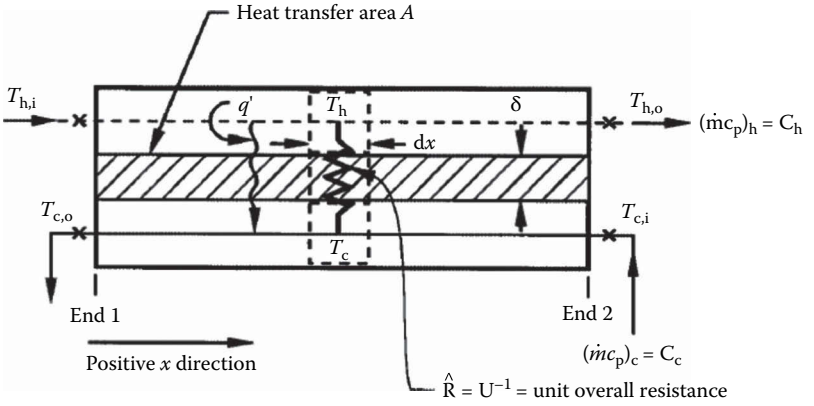

FIGURE 4.1.32 Nomenclature for heat exchanger variables.

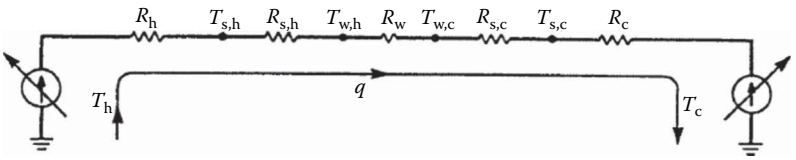

FIGURE 4.1.33 Thermal circuit for heat transfer in an exchanger.

where the subscripts *h*, *c*, *s*, and *w* denote hot, cold, fouling (or scale), and wall, respectively. In terms of the overall and individual heat transfer coefficients, Equation 4.1.41 is represented as

$$\frac{1}{UA}=\frac{1}{\left(\eta_o hA\right)_h}+\frac{1}{\left(\eta_o h_s A\right)_h}+R_w+\frac{1}{\left(\eta_o h_s A\right)_c}+\frac{1}{\left(\eta_o hA\right)_c} \tag{4.1.42}$$

where η_o=the overall surface efficiency of an extended (fin) surface and is related to the fin efficiency η_f, fin surface area A_f, and the total surface area A as follows:

$$\eta_o=1-\frac{A_f}{A}\left(1-\eta_f\right) \tag{4.1.43}$$

The wall thermal resistance R_w of Equation 4.1.41 is given by

$$R_w=\begin{cases}\delta/A_w k_w & \text{for a flat wall}\\ \dfrac{\ln\left(d_o/d_j\right)}{2\pi k_w L N_t} & \text{for a circular tube with a single-layer wall}\\ \dfrac{1}{2\pi L N_t}\left[\displaystyle\sum_j \frac{\ln\left(d_{j+1}/d_j\right)}{k_{wj}}\right] & \text{for a circular tube with a multiple-layer wall}\end{cases} \tag{4.1.44}$$

If one of the resistances on the right-hand side of Equation 4.1.41 or 4.1.42 is significantly higher than the other resistances, it is referred to as the *controlling thermal resistance*. A reduction in the controlling thermal resistance will have much more impact in reducing the exchanger surface area (*A*) requirement compared with the reduction in *A* as a result of the reduction in other thermal resistances.

The overall conductance *UA* of Equation 4.1.42 may be defined in terms of hot or cold fluid side surface area or wall conduction area as

$$UA=U_h A_h=U_c A_c=U_w A_w \tag{4.1.45}$$

When R_w is negligible, $T_{w,h}=T_{w,c}=T_w$ of Figure 4.1.33 is computed from

$$T_w=\frac{T_h+\left[\left(R_h+R_{s,h}\right)/\left(R_c+R_{s,c}\right)\right]T_c}{1+\left[\left(R_h+R_{s,h}\right)/\left(R_c+R_{s,c}\right)\right]} \tag{4.1.46}$$

When $R_{s,h}=R_{s,c}=0$, Equation 4.1.46 reduces to

$$T_w=\frac{T_h/R_h+T_c/R_c}{1/R_h+1/R_c}=\frac{\left(\eta_o hA\right)_h T_h+\left(\eta_o hA\right)_c T_c}{\left(\eta_o hA\right)_h+\left(\eta_o hA\right)_c} \tag{4.1.47}$$

ε-*NTU, P-NTU, and MTD methods*. If we consider the fluid outlet temperatures or heat transfer rate as dependent variables, they are related to independent variable/parameters of Figure 4.1.32 as follows.

$$T_{h,o}, T_{c,o}, \text{ or } q=f\left\{T_{h,j}, T_{c,i}, C_c, C_h, U, A, \text{ flow arrangement}\right\} \tag{4.1.48}$$

Six independent and three dependent variables of Equation 4.1.48 for a given flow arrangement can be transferred into two independent and one dependent dimensionless groups; three different methods are presented in Table 4.1.8 based on the choice of three dimensionless groups. The relationship among

TABLE 4.1.8
General Functional Relationships and Dimensionless Groups for ε-NTU, P-NTU, and MTD Methods

ε-NTU Method	P-NTU Method[a]	MTD Method[a]
$q=\varepsilon C_{\min}(T_{\mathrm{h,i}}-T_{\mathrm{c,i}})$	$q=P_1C_1\lvert T_{1,\mathrm{i}}-T_{2,\mathrm{i}}\rvert$	$q=UAF\Delta T_{\mathrm{lm}}$
$\varepsilon=\phi$ (NTU, C^*, flow arrangement)	$P_1=\phi$ (NTU1, R_1, flow arrangement)	$F=\phi$ (P, R, flow arrangement)[b]
$\varepsilon=\dfrac{C_{\mathrm{h}}\left(T_{\mathrm{h,i}}-T_{\mathrm{h,o}}\right)}{C_{\min}\left(T_{\mathrm{h,i}}-T_{\mathrm{c,i}}\right)}=\dfrac{C_{\mathrm{c}}\left(T_{\mathrm{c,o}}-T_{\mathrm{c,i}}\right)}{C_{\min}\left(T_{\mathrm{h,i}}-T_{\mathrm{c,i}}\right)}$	$P_1=\dfrac{T_{1,\mathrm{o}}-T_{1,\mathrm{i}}}{T_{2,\mathrm{i}}-T_{1,\mathrm{i}}}$	$F=\dfrac{\Delta T_{\mathrm{m}}}{\Delta T_{\mathrm{lm}}}$
$\mathrm{NTU}=\dfrac{UA}{C_{\min}}=\dfrac{1}{C_{\min}}\displaystyle\int_A U\ \mathrm{d}A$	$\mathrm{NTU}_1=\dfrac{UA}{C_1}=\dfrac{\lvert T_{1,\mathrm{o}}-T_{1,\mathrm{i}}\rvert}{\Delta T_{\mathrm{m}}}$	$\mathrm{LMTD}=\Delta T_{\mathrm{lm}}=\dfrac{\Delta T_1-\Delta T_2}{\ln\left(\Delta T_1/\Delta T_2\right)}$
$C^*=\dfrac{C_{\min}}{C_{\max}}=\dfrac{\left(\dot{m}c_{\mathrm{p}}\right)_{\min}}{\left(\dot{m}c_{\mathrm{p}}\right)_{\max}}$	$R_1=\dfrac{C_1}{C_2}=\dfrac{T_{2,\mathrm{i}}-T_{2,\mathrm{o}}}{T_{1,\mathrm{o}}-T_{1,\mathrm{i}}}$	$\Delta T_1=T_{\mathrm{h,i}}-T_{\mathrm{c,o}};\ \Delta T_2=T_{\mathrm{h,o}}-T_{\mathrm{c,i}}$

[a] Although P, R, and NTU are defined on fluid side 1, it must be emphasized that all the results of the P-NTU and MTD methods are valid if the definitions of P, NTU, and R are consistently based on C_c, C_s, C_h, or C.

[b] P and R are defined in the P-NTU method.

three dimensionless groups is derived by integrating Equations 4.1.37 and 4.1.38 across the surface area for a specified exchanger flow arrangement. Such expressions are presented later in Table 4.1.10 for the industrially most important flow arrangements. Now we briefly describe the three methods.

In *the ε-NTU method*, the heat transfer rate from the hot fluid to the cold fluid in the exchanger is expressed as

$$q = eC_{\min}\left(T_{\mathrm{h,j}}-T_{\mathrm{c,j}}\right) \tag{4.1.49}$$

Here, the exchanger effectiveness ε is an efficiency factor. It is a ratio of the actual heat transfer rate from the hot fluid to the cold fluid in a given heat exchanger of any flow arrangement to the maximum possible heat transfer rate $q_{\max}$ thermodynamically permitted. The $q_{\max}$ is obtained in a *counterflow* heat exchanger (recuperator) of *infinite surface area* operating with the fluid flow rates (heat capacity rates) and fluid inlet temperatures equal to those of an actual exchanger (constant fluid properties are idealized). As noted in Table 4.1.7, the exchanger effectiveness ε is a function of NTU and C^* in this method. The NTU is a ratio of the overall conductance UA to the smaller heat capacity rate $C_{\min}$. NTU designates the dimensionless "heat transfer size" or "thermal size" of the exchanger. Other interpretations of NTU are given by Shah (1983). The heat capacity rate ratio C^* is simply a ratio of the smaller to the larger heat capacity rate for the two fluid streams. Note that $0\le\varepsilon\le1$, $0\le\mathrm{NTU}\le\infty$ and $0\le C^*\le1$.

The P-NTU method represents a variant of the ε-NTU method. The ε-NTU relationship is different depending upon whether the shell fluid is the $C_{\min}$ or $C_{\max}$ fluid in the (stream unsymmetric) flow arrangements commonly used for shell-and-tube exchangers. In order to avoid possible errors and to avoid keeping track of the $C_{\min}$ fluid side, an alternative is to present the temperature effectiveness P as a function of NTU and R, where P, NTU, and R are defined consistently either for Fluid 1 side or Fluid 2 side; in Table 4.1.8, they are defined for Fluid 1 side (regardless of whether that side is the hot or cold fluid side), and Fluid 1 side is clearly identified for each flow arrangement in Table 4.1.10; it is the shell side in a shell-and-tube exchanger. Note that

$$q = P_1C_1\left|T_{1,\mathrm{i}}-T_{2,\mathrm{i}}\right| = P_2C_2\left|T_{2,\mathrm{i}}-T_{1,\mathrm{i}}\right| \tag{4.1.50}$$

$$P_1 = P_2 R_2;\ P_2 = P_1 R_1 \tag{4.1.51}$$

$$\mathrm{NTU}_1 = \mathrm{NTU}_2 R_2; \mathrm{NTU}_2 = \mathrm{NTU}_1 R_1 \tag{4.1.52}$$

and

$$R_1 = 1 / R_2 \tag{4.1.53}$$

In *the MTD method*, the heat transfer rate from the hot fluid to the cold fluid in the exchanger is given by

$$q = UA\Delta T_m = UAF\Delta T_{lm} \tag{4.1.54}$$

where ΔT_m the LMTD, and F the LMTD correction factor, a ratio of true (actual) MTD to the LMTD, where

$$\mathrm{LMTD} = \Delta T_{lm} = \frac{\Delta T_1 - \Delta T_2}{\ln\left(\Delta T_1 / \Delta T_2\right)} \tag{4.1.55}$$

Here, ΔT_1 and ΔT_2 are defined as

$$\Delta T_1 = T_{h,i} - T_{c,o} \text{ and } \Delta T_2 = T_{h,o} - T_{c,i} \quad \text{for all flow arrangements except for parallel flow} \tag{4.1.56}$$

$$\Delta T_1 = T_{h,i} - T_{c,j} \quad \Delta T_2 = T_{h,o} - T_{c,o} \quad \text{for parallel flow} \tag{4.1.57}$$

The LMTD represents a true MTD for a counterflow arrangement under the idealizations listed later. Thus, the LMTD correction factor F represents a degree of departure for the MTD from the counterflow LMTD; it does not represent the effectiveness of a heat exchanger. It depends on two dimensionless group P_1 and R_1 or P_2 and R_2 for a given flow arrangement.

The relationship among the dimensionless groups of the ε-NTU, P-NTU, and MTD methods are presented in Table 4.1.9. The closed-form formulas for industrially important exchangers are presented in terms of P_1, NTU_1, and R_1 in Table 4.1.10. These formulas are valid under idealizations that include (1) steady-state conditions; (2) negligible heat losses to the surrounding; (3) no phase changes in the fluid streams flowing through the exchanger, or phase changes (condensation or boiling) occurring at constant temperature and constant effective specific heat; (4) uniform velocity and temperature at the entrance of the heat exchanger on each fluid side; (5) the overall extended surface efficiency η_o is uniform and constant; (6) constant individual and overall heat transfer coefficients; (7) uniformly distributed heat transfer area on each fluid side; (7) the number of baffles as large in shell-and-tube exchangers; (8) no flow maldistribution; and (9) negligible longitudinal heat conduction in the fluid and exchanger wall.

The overall heat transfer coefficient can vary as a result of variations in local heat transfer coefficients due to two effects: (1) change in heat transfer coefficients in the exchanger as a result of changes in the fluid properties or radiation due to rise or drop of fluid temperatures and (2) change in heat transfer coefficients in the exchanger due to developing thermal boundary layers; it is referred to as the *length effect*. The first effect due to fluid property variations (or radiation) consists of two components: (1) distortion of velocity and temperature profiles at a given flow cross section due to fluid property variations—this effect is usually taken into account by the so-called property ratio method, with the correction scheme of Equations 4.1.91 and 4.1.92—and (2) variations in the fluid temperature along the axial and transverse directions in the exchanger depending upon the exchanger flow arrangement—this effect is referred to as the *temperature effect*. The resultant axial

TABLE 4.1.9
Relationships between Dimensionless Groups of the P-NTU and LMTD Methods and Those of the ε-NTU Method

$$P_1 = \frac{C_{\min}}{C_1}\varepsilon = \begin{cases} \varepsilon & \text{for} \quad C_1 = C_{\min} \\ \varepsilon C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$R_1 = \frac{C_1}{C_2} = \begin{cases} C^* & \text{for} \quad C_1 = C_{\min} \\ 1/C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$\mathrm{NTU}_1 = \mathrm{NTU}\frac{C_{\min}}{C_1} = \begin{cases} \mathrm{NTU} & \text{for} \quad C_1 = C_{\min} \\ \mathrm{NTU}\, C^* & \text{for} \quad C_1 = C_{\max} \end{cases}$$

$$F = \frac{\mathrm{NTU}_{\mathrm{cf}}}{\mathrm{NTU}} = \frac{1}{\mathrm{NTU}\left(1 - C^*\right)} \ln\left[\frac{1 - C^*\varepsilon}{1 - \varepsilon}\right] \xrightarrow[C^*=1]{} \frac{\varepsilon}{\mathrm{NTU}\left(1 - \varepsilon\right)}$$

$$F = \frac{1}{\mathrm{NTU}_1\left(1 - R_1\right)} \ln\left[\frac{1 - RP_1}{1 - P_1}\right] \xrightarrow[R_1=1]{} \frac{P_1}{\mathrm{NTU}_1\left(1 - P_1\right)}$$

changes in the overall mean heat transfer coefficient can be significant; the variations in U_{local} could be nonlinear, dependent upon the type of the fluid. The effect of varying U_{local} can be taken into account by evaluating U_{local} at a few points in the exchanger and subsequently integrating U_{local} values by the Simpson or Gauss method (Shah, 1993). The temperature effect can increase or decrease mean U slightly or significantly, depending upon the fluids and applications. The length effect is important for developing laminar flows for which high heat transfer coefficients are obtained in the thermal entrance region. However, in general, it will have less impact on the overall heat transfer coefficient because the other thermal resistances in series in an exchanger may be controlling. The length effect reduces the overall heat transfer coefficient compared with the mean value calculated conventionally (assuming uniform mean heat transfer coefficient on each fluid side). It is shown that this reduction is up to about 11% for the worst case (Shah, 1993).

Shah and Pignotti (1997) have shown that the following are the specific number of baffles beyond which the influence of the finite number of baffles on the exchanger effectiveness is not significantly larger than 2%: $N_b \geq 10$ for 1-1 TEMA E counterflow exchanger; $N_b \geq 6$ for 1-2 TEMA E exchanger for $\mathrm{NTU}_s \leq 2$, $R_s \leq 5$; $N_b \geq 9$ for 1-2 TEMA J exchanger for $\mathrm{NTU}_s \leq 2$, $R_s \leq 5$; $N_b \geq 5$ for 1-2 TEMA G exchanger for $\mathrm{NTU}_s \leq 3$, all R_s; $N_b \geq 11$ for 1-2 TEMA H exchanger for $\mathrm{NTU}_s \leq 3$, all R_s. Various shell-and-tube heat exchangers (such as TEMA E, G, H, J, etc.) are classified by the Tubular Exchanger Manufacturers' Association (TEMA, 1988).

If any of the basic idealizations are not valid for a particular exchanger application, the best solution is to work directly with either Equations 4.1.37 and 4.1.38 or their modified form by including a particular effect, and to integrate them over a small exchanger segment numerically in which all of the idealizations are valid.

Fin Efficiency and Extended Surface Efficiency

Extended surfaces have fins attached to the primary surface on one or both sides of a two-fluid or a multifluid heat exchanger. Fins can be of a variety of geometries—plain, wavy, or interrupted—and can be attached to the inside, outside, or both sides of circular, flat, or oval tubes, or parting sheets. Fins are primarily used to increase the surface area (when the heat transfer coefficient on that fluid side is relatively low) and consequently to increase the total rate of heat transfer. In addition, enhanced fin geometries also increase the heat transfer coefficient compared to that for a plain fin.

[a] In this table, all variables, except P_1, R_1, NTU, and F, are local or dummy variables not necessarily related to similar ones defined in the nomenclature and the text.

Fins may also be used on the high heat transfer coefficient fluid side in a heat exchanger primarily for structural strength purposes (e.g., for high-pressure water flow through a flat tube) or to provide a thorough mixing of a highly viscous liquid (such as for laminar oil flow in a flat or a round tube). Fins are attached to the primary surface by brazing, soldering, welding, adhesive bonding, or mechanical expansion, or they are extruded or integrally connected to the tubes. Major categories of extended surface heat exchangers are plate-fin (Figures 4.1.23 through 4.1.25) and tube-fin (Figures 4.1.26 through 4.1.28) exchangers. Note that shell-and-tube exchangers sometimes employ individually finned tubes—low-finned tubes (similar to Figure 4.1.26a but with low-height fins) (Shah, 1985).

The concept of fin efficiency accounts for the reduction in temperature potential between the fin and the ambient fluid due to conduction along the fin and convection from or to the fin surface depending upon the fin cooling or heating situation. The fin efficiency is defined as the ratio of the actual heat transfer rate through the fin base divided by the maximum possible heat transfer rate through the fin base which would be obtained if the entire fin were at the base temperature (i.e., its material thermal conductivity were infinite). Since most of the real fins are "thin," they are treated as one-dimensional (1-D) with standard idealizations used for the analysis (Huang and Shah, 1992). This 1-D fin efficiency is a function of the fin geometry, fin material thermal conductivity, heat transfer coefficient at the fin surface, and the fin tip boundary condition; it is not a function of the fin base or fin tip temperature, ambient temperature, and heat flux at the fin base or fin tip in general. Fin efficiency formulas for some common fins are presented in Table 4.1.11 (Shah, 1985). Huang and Shah (1992) also discuss the influence on η_f if any of the basic idealizations used in the fin analysis are violated.

The fin efficiency for flat fins (Figure 4.1.26b) is obtained by a sector method (Shah, 1985). In this method, the rectangular or hexagonal fin around the tube (Figures 4.1.28a, b) or its smallest symmetrical section is divided into n sectors (Figure 4.1.34). Each sector is then considered as a circular fin with the radius $r_{e,i}$ equal to the length of the centerline of the sector. The fin efficiency of each sector is subsequently computed using the circular fin formula of Table 4.1.11. The fin efficiency η_f for the whole fin is then the surface area weighted average of $\eta_{f,i}$ of each sector.

$$\eta_f = \frac{\sum_{i=1}^{n} \eta_{f,i} A_{f,i}}{\sum_{i=1}^{n} A_{f,i}} \tag{4.1.58}$$

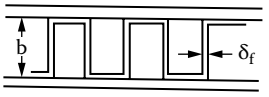
TABLE 4.1.11
Fin Efficiency Expressions for Plat-Fin and Tube-Fin Geometries of Uniform Fin Thickness

Geometry | **Fin Efficiency Formula**

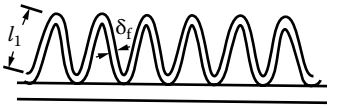


Plain, wavy, or offset strip fin of rectangular cross section

$$m_i = \left[\frac{2h}{k_j\delta_i}\left(1+\frac{\delta_t}{l_f}\right)\right]^{1/2};\ E_1 = \frac{\tanh(m_i l_i)}{m_i t_1}\ i = 1,2$$

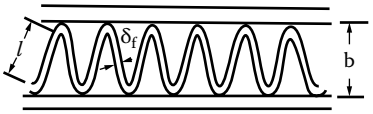
$$\eta_f = E_1$$

$$l_1 = \frac{b}{2} - \delta_1;\ \delta_1 = \delta_f$$



Triangular fin heated from one side

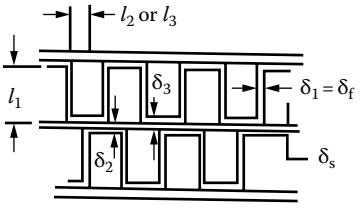
$$\eta_f = \frac{hA_1(T_0 - T_a)\dfrac{\sinh(m_1 l_1)}{m_1 l_1} + q_e}{\cosh(m_1 l_1)\left[hA_1(T_0 - T_a) + q_e\dfrac{T_0 - T_a}{T_1 - T_a}\right]}$$



Plain, wavy, or louver fin of triangular cross section

$$\eta_f = E_1$$

$$l_1 = \frac{l}{2};\ \delta_1 = \delta_f$$

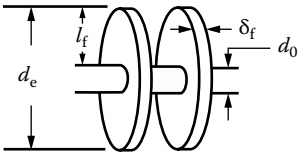


Double sandwich fin

$$\eta_f = \frac{E_1 l_1 + E_2 t_2}{l_1 + l_2}\frac{1}{1 + m_1^2 E_1 E_2 l_1 l_2}$$

$$\delta_1 = \delta_f;\ \delta_2 = \delta_3 = \delta_f + \delta_s$$

$$l_1 = b - \delta_f + \frac{\delta_s}{2};\ l_2 = l_3 = \frac{p_f}{2}$$



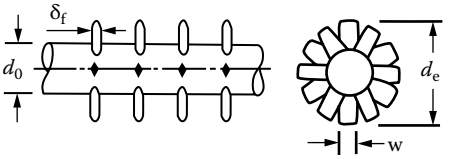
Circular fin

$$\eta_j = \begin{cases} a(ml_e)^{-b} & \text{for } \Phi > 0.6 + 2.257(r^*)^{-0.445} \\ \dfrac{\tanh\Phi}{\Phi} & \text{for } \Phi \le 0.6 + 2.257(r^*)^{-0.445} \end{cases}$$

$$a = (r^*)^{-0.246};\ \Phi = ml_e(r^*)^{\exp(0.13ml_e - 1.3863)}$$

$$b = \begin{cases} 0.9107 + 0.0893r^* & \text{for } r^* \le 2 \\ 0.9706 + 0.17125\ln r^* & \text{for } r^* > 2 \end{cases}$$

$$m = \left(\frac{2h}{k_f\delta_f}\right)^{1/2};\ l_e = l_j + \frac{\delta_f}{2};\ r^* = \frac{d_e}{d_o}$$



Studded fin

$$\eta_j = \frac{\tanh(ml_e)}{ml_e}$$

$$m = \left[\frac{2h}{k_f\delta_f}\left(1+\frac{\delta_f}{w}\right)\right]^{1/2};\ l_e = l_f + \frac{\delta_f}{2};\ l_f = \frac{(d_e - d_o)}{2}$$

Since the heat flow seeks the path of least thermal resistance, actual η_f will be equal to or higher than that calculated by Equation 4.1.58; hence, Equation 4.1.58 yields a somewhat conservative value of η_f.

The η_f values of Table 4.1.11 or Equation 4.1.58 are not valid in general when the fin is thick, when it is subject to variable heat transfer coefficients or variable ambient fluid temperature, or when it has a temperature depression at the fin base. See Huang and Shah (1992) for details. For a thin rectangular fin of constant cross section, the fin efficiency as presented in Table 4.1.11 is given by

$$\eta_f = \frac{\tanh(ml)}{ml} \tag{4.1.59}$$

where $m = \left[2h\left(1+\delta_f l_f\right)/k_f\delta_f\right]^{1/2}$. For a thick rectangular fin of constant cross section, the fin efficiency (a counterpart of Equation 4.1.59) is given by (Huang and Shah, 1992)

$$\eta_f = \frac{\left(\mathrm{Bi}^+\right)^{1/2}}{K\mathrm{Bi}} \tanh\left[K\left(\mathrm{Bi}^+\right)^{1/2}\right] \tag{4.1.60}$$

where $\mathrm{Bi}^+ = \mathrm{Bi}/(1+\mathrm{Bi}/4)$, $\mathrm{Bi} = (h\delta_f/2k_f)^{1/2}$, $K = 2l/\delta_f$. Equation 4.1.59 is accurate (within 0.3%) for a "thick" rectangular fin having $\eta_f > 80\%$; otherwise, use Equation 4.1.60 for a thick fin.

In an extended-surface heat exchanger, heat transfer takes place from both the fins ($\eta_f < 100\%$) and the primary surface ($\eta_f = 100\%$). In that case, the total heat transfer rate is evaluated through a concept of extended surface efficiency η_o defined as

$$\eta_o = \frac{A_p}{A} + \eta_f \frac{A_f}{A} = 1 - \frac{A_f}{A}\left(1-\eta_f\right) \tag{4.1.61}$$

where A_f is the fin surface area, A_p is the primary surface area, and $A = A_f + A_p$. In Equation 4.1.61, heat transfer coefficients over the finned and unfinned surfaces are idealized to be equal. Note that $\eta_o \geq \eta_f$ and η_o is always required for the determination of thermal resistances of Equation 4.1.41 in heat exchanger analysis.

Pressure Drop Analysis

Usually a fan, blower, or pump is used to flow fluid through individual sides of a heat exchanger. Due to potential initial and operating high cost, low fluid pumping power requirement is highly desired for gases and viscous liquids. The fluid pumping power $\wp$ is approximately related to the core pressure drop in the exchanger as (Shah, 1985)

$$\wp = \frac{\dot{m}\Delta p}{\rho} \approx \begin{cases} \dfrac{1}{2g_c}\dfrac{\mu}{\rho^2}\dfrac{4L}{D_h} f\mathrm{Re} & \text{for laminar flow} \quad (4.1.62) \\ \dfrac{0.046}{2g_c}\dfrac{\mu^{0.2}}{\rho^2}\dfrac{4L}{D_h}\dfrac{\dot{m}^{2.8}}{A_0^{1.8}D_h^{0.2}} & \text{for turbulent flow} \quad (4.1.63) \end{cases}$$

It is clear from Equations 4.1.62 and 4.1.63 that the fluid pumping power is strongly dependent upon the fluid density ($\wp \propto 1/\rho^2$) particularly for low-density fluids in laminar and turbulent flows, and upon the viscosity in laminar flow. In addition, the pressure drop itself can be an important consideration when blowers and pumps are used for the fluid flow since they are head limited. Also for condensing and evaporating fluids, the pressure drop affects the heat transfer rate. Hence, the pressure drop determination in the exchanger is important.

The pressure drop associated with a heat exchanger consists of (1) core pressure drop and (2) the pressure drop associated with the fluid distribution devices such as inlet and outlet manifolds, headers, tanks, nozzles, ducting, and so on, which may include bends, valves, and fittings. This second Δp component is determined from Idelchik (1994) and Miller (1990). The core pressure drop may consist of one or more of the following components depending upon the exchanger construction: (1) friction losses associated with fluid flow over heat transfer surface (this usually consists of skin friction, form (profile) drag, and internal contractions and expansions, if any); (2) the momentum effect (pressure drop or rise due to fluid density changes) in the core; (3) pressure drop associated with sudden contraction and expansion at the core inlet and outlet; and (4) the gravity effect due to the change in elevation between the inlet and outlet of the exchanger. The gravity effect is generally negligible for gases. For vertical flow through the exchanger, the pressure drop or rise ("static head") due to the elevation change is given by

$$\Delta p = \pm \frac{\rho_m g L}{g_c} \tag{4.1.64}$$

Here, the "+" sign denotes vertical upflow (i.e., pressure drop), the "–" sign denotes vertical downflow (i.e., pressure rise). The first three components of the core pressure drop are now presented for plate-fin, tube-fin, plate, and regenerative heat exchangers.

Plate-fin heat exchangers. For the plate-fin exchanger (Figure 4.1.23), all three components are considered in the core pressure drop evaluation as follows:

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c}\frac{1}{p_i\rho_i}\left[\left(1-\sigma^2+K_c\right)+f\frac{L}{r_h}\rho_i\left(\frac{1}{\rho}\right)_m+2\left(\frac{\rho_i}{\rho_o}-1\right)-\left(1-\sigma^2-K_e\right)\frac{\rho_i}{\rho_o}\right] \tag{4.1.65}$$

where f is the Fanning friction factor, K_c and K_e are flow contraction (entrance) and expansion (exit) pressure loss coefficients (see Figure 4.1.35), and σ is a ratio of minimum free flow area to frontal area. K_c and K_e for four different entrance flow passage geometries are presented by Kays and London (1998). The entrance and exit losses are important at low values of σ and L (short cores), high values of Re, and for gases, they are negligible for liquids. The values of K_c and K_e apply to long tubes for which flow is fully developed at the exit. For partially developed flows, K_c and K_e are higher than that for fully developed flows. For interrupted surfaces, flow is never a fully developed boundary layer type. For highly interrupted fin geometries, the entrance and exit losses are generally small compared to the core pressure drop and the flow is well mixed; hence, K_c and K_e for Re $\rightarrow \infty$ should represent a good approximation. The mean specific volume v_m or $(1/\rho)_m$ in Equation 4.1.65 is given as follows. For liquids with any flow arrangement, or for a perfect gas with $C^*=1$ and any flow arrangement (except for parallel flow),

$$\left(\frac{1}{\rho}\right)_m = v_m = \frac{v_i+v_o}{2} = \frac{1}{2}\left(\frac{1}{\rho_i}+\frac{1}{\rho_o}\right) \tag{4.1.66}$$

where ν is the specific volume in m^3/kg. For a perfect gas with $C^*=0$ and any flow arrangement,

$$\left(\frac{1}{\rho}\right)_m = \frac{\tilde{R}}{p_{ave}}T_{lm} \tag{4.1.67}$$

Here $\tilde{R}$ is the gas constant in J/(kg K), $p_{ave}=(p_i+p_o)/2$, and $T_{lm}=T_{const}+\Delta T_{lm}$, where T_{const} is the mean average temperature of the fluid on the other side of the exchanger; the LMTD ΔT_{lm} is defined in Table 4.1.8. The core frictional pressure drop in Equation 4.1.65 may be approximated as

$$\Delta p \approx \frac{4fLG^2}{2g_cD_h}\left(\frac{1}{\rho}\right)_m \tag{4.1.68}$$

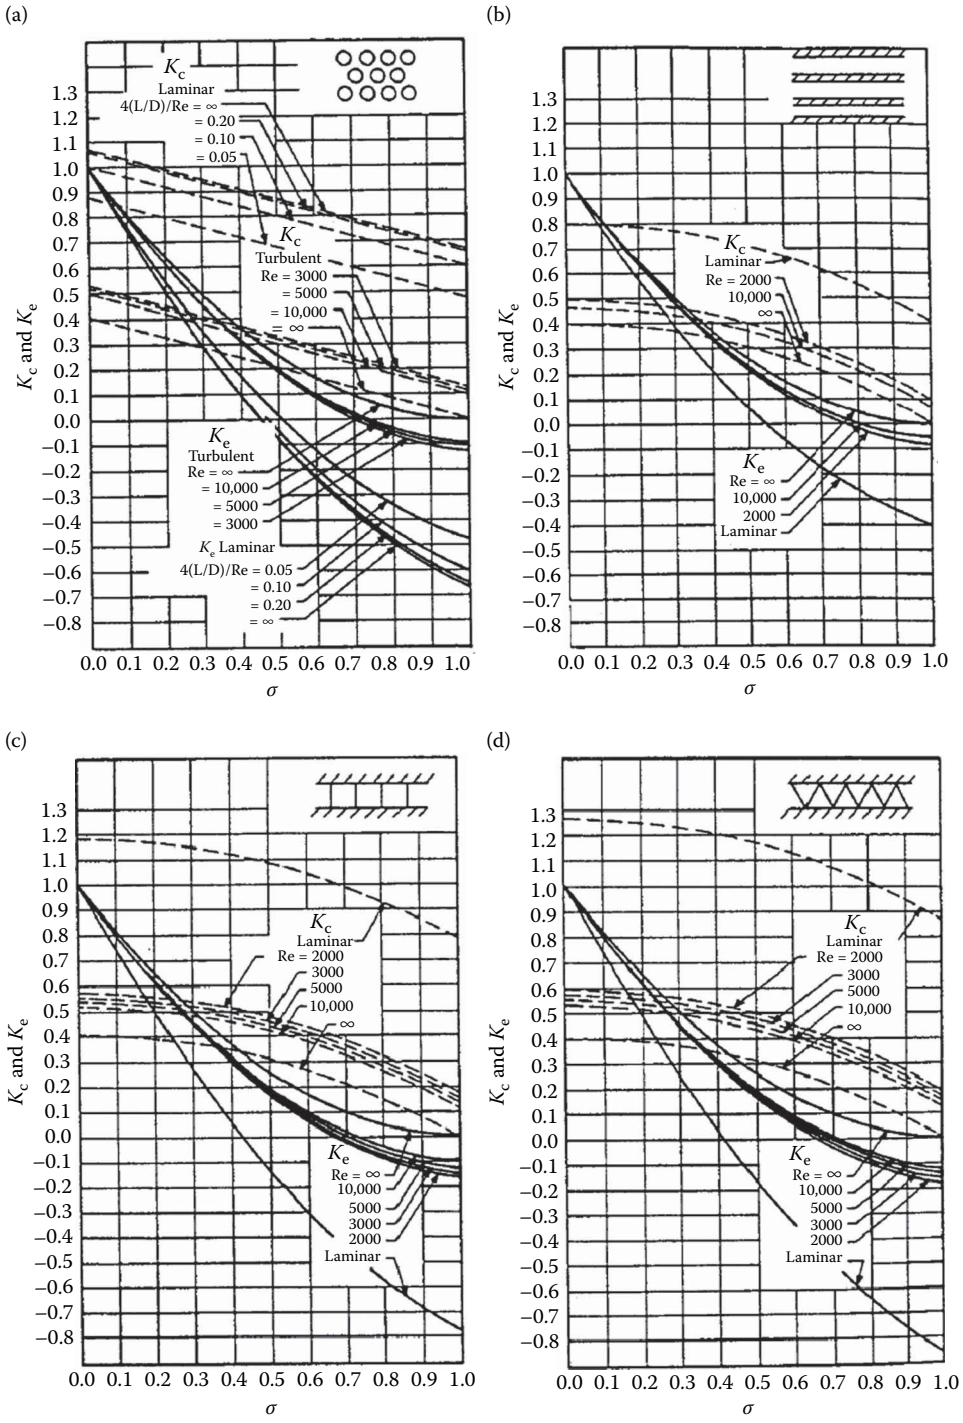


FIGURE 4.1.35 Entrance and exit pressure loss coefficients: (a) circular tubes, (b) parallel plates, (c) square passages, and (d) triangular passages. (From Kays, W.M. and London, A.L., *Compact Heat Exchangers*, 3rd ed., McGraw-Hill, New York, 1998. With permission.) For each of these flow passages, shown in the inset, the fluid flows perpendicular to the plane of the paper into the flow passages.

Tube-fin heat exchangers. The pressure drop inside a circular tube is computed using Equation 4.1.65 with proper values of f factors, and K_c and K_e for circular tubes using the method outlined in section 2.4.

For flat fins on an array of tubes (see Figure 4.1.26b), the components of the core pressure drop (such as those in Equation 4.1.65) are the same with the following exception: The core friction and momentum effect take place within the core with $G = \dot{m} / A_0$, where A_0 is the minimum free-flow area within the core, and the entrance and exit losses occur at the leading and trailing edges of the core with the associated flow area A_0' such that

$$\dot{m} = GA_o = G'A_o' \quad \text{or} \quad G'\sigma' = G\sigma \tag{4.1.69}$$

where σ' is the ratio of free-flow area to frontal area at the fin leading edges. The pressure drop for flow normal to a tube bank with flat fins is then given by

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c}\frac{1}{p_i\rho_i}\left[f\frac{L}{r_h}\rho_i\left(\frac{1}{\rho}\right)_m + 2\left(\frac{\rho_i}{\rho_o}-1\right)\right] + \frac{G'^2}{2g_c}\frac{1}{p_i\rho_i}\left[\left(1-\sigma'^2-K_c\right)-\left(1-\sigma'^2-K_e\right)\frac{\rho_i}{\rho_o}\right] \tag{4.1.70}$$

For individually finned tubes as shown in Figure 4.1.26a, flow expansion and contraction take place along each tube row, and the magnitude is of the same order as that at the entrance and exit. Hence, the entrance and exit losses are generally lumped into the core friction factor. Equation 4.1.65 then reduces for individually finned tubes to

$$\frac{\Delta p}{p_i} = \frac{G^2}{2g_c}\frac{1}{p_i\rho_i}\left[f\frac{L}{r_h}\rho_i\left(\frac{1}{\rho}\right)_m + 2\left(\frac{\rho_i}{\rho_o}-1\right)\right] \tag{4.1.71}$$

Regenerators. For regenerator matrices having cylindrical passages, the pressure drop is computed using Equation 4.1.65 with appropriate values of f, K_c, and K_e. For regenerator matrices made up of any porous material (such as checkerwork, wire, mesh, spheres, copper wools, etc.), the pressure drop is calculated using Equation 4.1.71 in which the entrance and exit losses are included in the friction factor f.

Plate heat exchangers. Pressure drop in a PHE consists of three components: (1) pressure drop associated with the inlet and outlet manifolds and ports, (2) pressure drop within the core (plate passages), and (3) pressure drop due to the elevation change. The pressure drop in the manifolds and ports should be kept as low as possible (generally <10%, but it is found as high as 25%–30% or higher in some designs). Empirically, it is calculated as approximately 1.5 times the inlet velocity head per pass. Since the entrance and exit losses in the core (plate passages) cannot be determined experimentally, they are included in the friction factor for the given plate geometry. The pressure drop (rise) caused by the elevation change for liquids is given by Equation 4.1.64. Hence, the pressure drop on one fluid side in a PHE is given by

$$\Delta p = \frac{1.5G^2N_p}{2g_c\rho_i} + \frac{4fLG^2}{2g_cD_e}\left(\frac{1}{\rho}\right)_m + \left(\frac{1}{\rho_o}-\frac{1}{\rho_i}\right)\frac{G^2}{g_c} \pm \frac{\rho_m gL}{g_c} \tag{4.1.72}$$

where N_p is the number of passes on the given fluid side and D_e is the equivalent diameter of flow passages (usually twice the plate spacing). Note that the third term on the right-hand side of the equality sign of Equation 4.1.72 is for the momentum effect which is generally negligible in liquids.

Heat Transfer and Flow Friction Correlations

Accurate and reliable surface heat transfer and flow friction characteristics are a key input to the exchanger heat transfer and pressure drop analyses or to the rating and sizing problems (Shah,

1985). Some important analytical solutions and empirical correlations are presented next for selected exchanger geometries.

The heat transfer rate in laminar duct flow is very sensitive to the thermal boundary condition. Hence, it is essential to identify carefully the thermal boundary condition in laminar flow. The heat transfer rate in turbulent duct flow is insensitive to the thermal boundary condition for most common fluids ($Pr > 0.7$); the exception is liquid metals ($Pr < 0.03$). Hence, there is generally no need to identify the thermal boundary condition in turbulent flow for all fluids except liquid metals.

Fully developed laminar flow analytical solutions for some duct shapes of interest in compact heat exchangers are presented in Table 4.1.12 for three important thermal boundary conditions denoted by the subscripts $H1$, $H2$, and T (Shah and London, 1978; Shah and Bhatti, 1987). Here, $H1$

[b] Interpolated values.

denotes constant axial wall heat flux with constant peripheral wall temperature, *H*2 denotes constant axial and peripheral wall heat flux, and *T* denotes constant wall temperature. The entrance effects, flow maldistribution, free convection, property variation, fouling, and surface roughness all affect fully developed analytical solutions. In order to account for these effects in real plate-fin plain fin geometries having fully developed flows, it is best to reduce the magnitude of the analytical Nu by at least 10% and to increase the value of the analytical *f*Re by 10% for design purposes.

The initiation of transition flow, the lower limit of the critical Reynolds number ($\mathrm{Re}_{\mathrm{crit}}$), depends upon the type of entrance (e.g., smooth vs. abrupt configuration at the exchanger flow passage entrance). For a sharp square inlet configuration, $\mathrm{Re}_{\mathrm{crit}}$ is about 10%–15% lower than that for a rounded inlet configuration. For most exchangers, the entrance configuration would be sharp. Some information on $\mathrm{Re}_{\mathrm{crit}}$ is provided by Ghajar and Tam (1994).

Transition flow and fully developed turbulent flow Fanning friction factors (within ±2% accuracy) are given by Bhatti and Shah (1987) as

$$f = A + B\mathrm{Re}^{-1/m} \tag{4.1.73}$$

where

$$A = 0.0054, \quad B = 2.3\times10^{-8}, \quad m = -2/3, \quad \text{for } 2100 \le \mathrm{Re} \le 4000$$

$$A = 0.00128, \quad B = 0.1143, \quad m = 3.2154, \quad \text{for } 4000 \le \mathrm{Re} \le 10^7$$

The transition flow and fully developed turbulent flow Nusselt number correlation for a circular tube is given by Gnielinski as reported in Bhatti and Shah (1987) as

$$\mathrm{Nu} = \frac{(f/2)(\mathrm{Re}-1000)\mathrm{Pr}}{1+12.7(f/2)^{1/2}\left(\mathrm{Pr}^{2/3}-1\right)} \tag{4.1.74}$$

which is accurate within about ±10% with experimental data for $2300 \le \mathrm{Re} \le 5\times10^6$ and $0.5 \le \mathrm{Pr} \le 2000$.

A careful observation of accurate experimental friction factors for all noncircular smooth ducts reveals that ducts with laminar *f*Re < 16 have turbulent *f* factors lower than those for the circular tube, whereas ducts with laminar *f*Re > 16 have turbulent *f* factors higher than those for the circular tube (Shah and Bhatti, 1988). Similar trends are observed for the Nusselt numbers. Within ±15% accuracy, Equations 4.1.73 and 4.1.74 for *f* and Nu can be used for noncircular passages with the hydraulic diameter as the characteristic length in *f*, Nu, and Re; otherwise, refer to Bhatti and Shah (1987) for more accurate results for turbulent flow.

For hydrodynamically and thermally developing flows, the analytical solutions are boundary condition dependent (for laminar flow heat transfer only) and geometry dependent. The hydrodynamic entrance lengths for developing laminar and turbulent flows are given by Shah and Bhatti (1987) and Bhatti and Shah (1987) as

$$\frac{L_{\mathrm{hy}}}{D_{\mathrm{h}}} = \begin{cases} 0.0565\mathrm{Re} & \text{for laminar flow}\left(\mathrm{Re} \le 2100\right) \quad (4.1.75) \\ 1.359\mathrm{Re}^{1/4} & \text{for turbulent flow}\left(\mathrm{Re} \ge 10^4\right) \quad (4.1.76) \end{cases}$$

Analytical results are useful for well-defined constant cross-sectional surfaces with essentially unidirectional flows. The flows encountered in heat exchangers are generally very complex having flow separation, reattachment, recirculation, and vortices. Such flows significantly affect Nu and *f* for the specific exchanger surfaces. Since no analytical or accurate numerical solutions are available, the information is derived experimentally. Kays and London (1998) and Webb (1994) present most of

the experimental results reported in the open literature. In the following, empirical correlations for only some important surfaces are summarized due to space limitations.

Plate-Fin Extended Surfaces

Offset strip fins. This is one of the most widely used enhanced fin geometries (Figure 4.1.36) in aircraft, cryogenics, and many other industries that do not require mass production. This surface has one of the highest heat transfer performances relative to the friction factor. The most comprehensive correlations for j and f factors for the offset strip fin geometry are provided by Manglik and Bergles (1995) as follows:

$$j = 0.6522\mathrm{Re}^{-0.5403}\left(\frac{s}{h'}\right)^{-0.1541}\left(\frac{\delta_f}{l_f}\right)^{0.1499}\left(\frac{\delta_f}{s}\right)^{-0.0678} \times\left[1+5.296\times10^{-5}\mathrm{Re}^{1.340}\left(\frac{s}{h'}\right)^{0.504}\left(\frac{\delta_f}{l_f}\right)^{0.456}\left(\frac{\delta_f}{s}\right)^{-1.055}\right]^{0.1} \tag{4.1.77}$$

$$f = 9.6243\mathrm{Re}^{-0.7422}\left(\frac{s}{h'}\right)^{-0.1856}\left(\frac{\delta_f}{l_f}\right)^{0.3053}\left(\frac{\delta_f}{s}\right)^{-0.2659} \times\left[1+7.669\times10^{-8}\mathrm{Re}^{4.429}\left(\frac{s}{h'}\right)^{0.920}\left(\frac{\delta_f}{l_f}\right)^{3.767}\left(\frac{\delta_f}{s}\right)^{0.236}\right]^{0.1} \tag{4.1.78}$$

where

$$D_h = 4A_o/\left(A/l_f\right) = 4sh'l_f/\left[2\left(sl_f + h'l_f + \delta_f h'\right) + \delta_f s\right] \tag{4.1.79}$$

Geometric symbols in Equation 4.1.79 are shown in Figure 4.1.36.

These correlations predict the experimental data of 18 test cores within ±20% for $120 \le \mathrm{Re} \le 10^4$. Although all the experimental data for these correlations are obtained for air, the j factor takes into consideration minor variations in the Prandtl number, and the above correlations should be valid for $0.5 < \mathrm{Pr} < 15$.

Louver fins. Louver or multilouver fins are extensively used in the auto industry because of their mass production manufacturability and hence lower cost. The louver fin has generally higher j and f factors than those for the offset strip fin geometry, and also the increase in the friction factors is in general higher than the increase in the j factors. However, the exchanger can be designed for higher

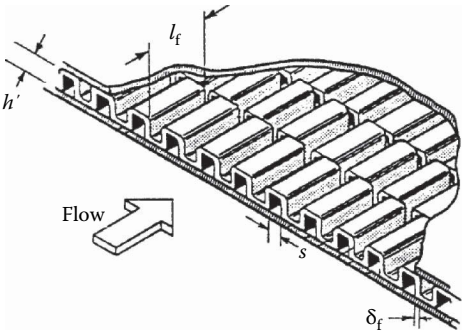

FIGURE 4.1.36 An offset strip fin geometry.

heat transfer and the same pressure drop compared to that with the offset strip fins by a proper selection of exchanger frontal area, core depth, and fin density. Published literature and correlations on the louver fins are summarized by Webb (1994) and Cowell et al. (1995), and the understanding of flow and heat transfer phenomena is summarized by Cowell et al. (1995). Because of the lack of systematic studies reported in the open literature on modern louver fin geometries, no correlation can be recommended for the design purpose.

Tube-Fin Extended Surfaces

Two major types of tube-fin extended surfaces as shown in Figure 4.1.26 are (1) individually finned tubes and (2) flat fins (also sometimes referred to as plate fins) with or without enhancements/interruptions on an array of tubes. An extensive coverage of the published literature and correlations for these extended surfaces are provided by Webb (1994), Kays and London (1998), and Rozenman (1976). Empirical correlations for some important geometries are summarized later.

Individually finned tubes. This fin geometry, helically wrapped (or extruded) circular fins on a circular tube as shown in Figure 4.1.26a, is commonly used in process and waste heat recovery industries. The following correlation for *j* factors is recommended by Briggs and Young (see Webb 1994) for individually finned tubes on staggered tube banks:

$$j = 0.134\mathrm{Re}_d^{-0.319}\left(s/l_f\right)^{0.2}\left(s/\delta_f\right)^{0.11} \tag{4.1.80}$$

where l_f is the radial height of the fin, δ_f the fin thickness, $s = p_f - \delta_f$ is the distance between adjacent fins and p_f is the fin pitch. Equation 4.1.80 is valid for the following ranges: $1100 \le \mathrm{Re}_d \le 18{,}000$, $0.13 \le s/l_f \le 0.63$, $1.01 \le s/\delta_f \le 6.62$, $0.09 \le l_f/d_o \le 0.69$, $0.011 \le \delta_f/d_o \le 0.15$, $1.54 \le X_t/d_o \le 8.23$, fin root diameter d_o between 11.1 and 40.9 mm, and fin density N_f (= $1/p_f$) between 246 and 768 fin/m. The standard deviation of Equation 4.1.80 with experimental results was 5.1%.

For friction factors, Robinson and Briggs (see Webb 1994) recommended the following correlation:

$$f_{tb} = 9.465Re_d^{-0.316}\left(X_t/d_o\right)^{-0.927}\left(X_t/X_d\right)^{0.515} \tag{4.1.81}$$

Here $X_d = \left(X_t^2 + X_l^2\right)^{1/2}$ is the diagonal pitch, and X_t and X_l are the transverse and longitudinal tube pitches, respectively. The correlation is valid for the following ranges: $2000 \le \mathrm{Re}_d \le 50{,}000$, $0.15 \le s/l_f \le 0.19$, $3.75 \le s/\delta_f \le 6.03$, $0.35 \le l_f/d_o \le 0.56$, $0.011 \le \delta_f/d_o \le 0.025$, $1.86 \le X_t/d_o \le 4.60$, $18.6 \le d_o \le 40.9$ mm, and $311 \le N_f \le 431$ fin/m. The standard deviation of Equation 4.1.81 with correlated data was 7.8%

For crossflow over low-height finned tubes, a simple but accurate correlation for heat transfer is given by Ganguli and Yilmaz (1987) as

$$j = 0.255\mathrm{Re}_d^{-0.3}\left(d_e/s\right)^{-0.3} \tag{4.1.82}$$

A more accurate correlation for heat transfer is given by Rabas and Taborek (1987). Chai (1988) provides the best correlation for friction factors:

$$f_{tb} = 1.748\mathrm{Re}_d^{-0.233}\left(\frac{l_f}{s}\right)^{0.552}\left(\frac{d_o}{X_t}\right)^{0.599}\left(\frac{d_o}{X_l}\right)^{0.1738} \tag{4.1.83}$$

This correlation is valid for $895 < \mathrm{Re}_d < 713{,}000$, $20 < \theta < 40°$, $X_t/d_o < 4$, $N \ge 4$, and θ is the tube layout angle. It predicts 89 literature data points within a mean absolute error of 6%; the range of actual error is from –16.7 to 19.9%.

Flat plain fins on a staggered tubebank. This geometry, as shown in Figure 4.1.26b, is used in air-conditioning/refrigeration industry as well as where the pressure drop on the fin side prohibits

the use of enhanced/interrupted flat fins. An inline tubebank is generally not used unless very low fin side pressure drop is the essential requirement. Heat transfer correlation for Figure 4.1.26b flat plain fins on staggered tubebanks is provided by Gray and Webb (see Webb 1994) as follows for four or more tube rows.

$$j_4 = 0.14\mathrm{Re}_\mathrm{d}^{-0.328}\left(X_\mathrm{t}/X_l\right)^{-0.502}\left(s/d_\mathrm{o}\right)^{0.031} \tag{4.1.84}$$

For the number of tube rows N from 1 to 3, the j factor is lower and is given by

$$\frac{j_\mathrm{N}}{j_4} = 0.991\left[2.24\mathrm{Re}_\mathrm{d}^{-0.092}\left(N/4\right)^{-0.031}\right]^{0.607(4-N)} \tag{4.1.85}$$

Gray and Webb (see Webb 1994) hypothesized the friction factor consisting of two components: one associated with the fins and the other associated with the tubes as follows.

$$f = f_\mathrm{f}\frac{A_\mathrm{f}}{A} + f_\mathrm{t}\left(1-\frac{A_\mathrm{f}}{A}\right)\left(1-\frac{\delta_\mathrm{f}}{p_\mathrm{f}}\right) \tag{4.1.86}$$

where

$$f_\mathrm{f} = 0.508\mathrm{Re}_\mathrm{d}^{-0.521}\left(X_\mathrm{t}/d_\mathrm{o}\right)^{1.318} \tag{4.1.87}$$

and f_t (defined the same way as f) is the Fanning friction factor associated with the tube and can be determined using the charts available in Zukauskas (1987) as $f_\mathrm{t}=\mathrm{EuN}(X_\mathrm{t}-d_\mathrm{o})/\pi d_\mathrm{o}$. Equation 4.1.86 correlated 90% of the data for 19 heat exchangers within ±20%. The range of dimensionless variables of Equations 4.1.86 and 4.1.87 are $500 \le \mathrm{Re}_\mathrm{d} \le 24{,}700$, $1.97 \le X_\mathrm{t}/d_\mathrm{o} \le 2.55$, $1.7 \le X_\mathrm{t}/d_\mathrm{o} \le 2.58$, and $0.08 \le s/d_\mathrm{o} \le 0.64$.

Exchanger Design Methodology

The problem of heat exchanger design is complex and multidisciplinary (Shah, 1991). The major design considerations for a new heat exchanger include process/design specifications, thermal and hydraulic design, mechanical design, manufacturing and cost considerations, and trade-offs and system-based optimization, as shown in Figure 4.1.37 with possible strong interactions among these considerations as indicated by double-sided arrows. The thermal and hydraulic design methods are mainly analytical, and the structural design is analytical to some extent. Most of the other major design considerations involve qualitative and experience-based judgments, trade-offs, and compromises. Therefore, there is no unique solution to designing a heat exchanger for given process specifications. Further details on this design methodology are given by Shah (1991).

Two important heat exchanger design problems are the rating and sizing problems. Determination of heat transfer and pressure drop performance of either an existing exchanger or an already sized exchanger is referred to as the rating problem. The objective here is to verify vendor's specifications or to determine the performance at off-design conditions. The rating problem is also sometimes referred to as the performance problem. In contrast, the design of a new or existing type of exchanger is referred to as the sizing problem. In a broad sense, it means the determination of the exchanger construction type, flow arrangement, heat transfer surface geometries and materials, and the physical size of an exchanger to meet the specified heat transfer and pressure drops. However, from the viewpoint of quantitative thermal–hydraulic analysis, we will consider that the selection of the exchanger construction type, flow arrangement, and materials has already been made. Thus, in the sizing problem, we will determine the physical size (length, width, height) and surface areas on each side of the exchanger. The sizing problem is also sometimes referred to as the design problem.

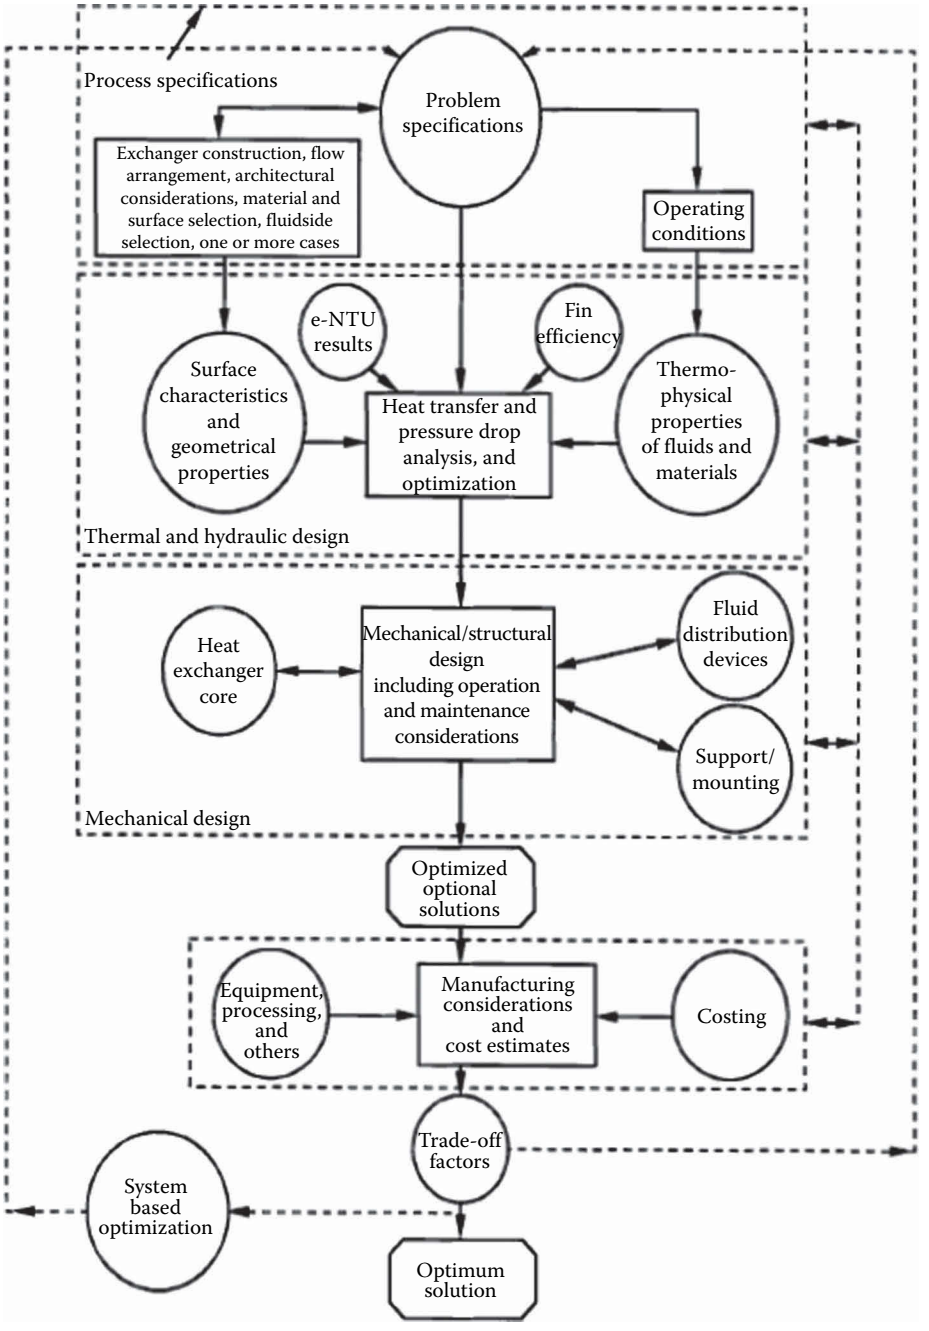

FIGURE 4.1.37 Heat exchanger design methodology.

The step-by-step solution procedures for the rating and sizing problems for counterflow and crossflow single-pass plate-fin heat exchangers have been presented with a detailed illustrative example by Shah (1981). Shah (1988a) presented further refinements in these procedures as well as step-by-step procedures for two-pass cross-counterflow plate-fin exchangers, and single-pass crossflow and two-pass cross-counterflow tube-fin exchangers. Also, step-by-step solution procedures for the rating and sizing problems for rotary regenerators (Shah 1988b), heat pipe heat exchangers (Shah, and

Giovannelli, 1988), and PHEs (Shah and Wanniarachchi, 1991) are available. As an illustration, the step-by-step solution procedures will be covered here for a single-pass crossflow exchanger.

Rating Problem for a Crossflow Plate-Fin Exchanger

Following is a step-by-step procedure for rating a crossflow plate-fin exchanger. Inputs to the rating problem for a two-fluid exchanger are the exchanger construction, flow arrangement and overall dimensions, complete details on the materials and surface geometries on both sides including their nondimensional heat transfer and pressure drop characteristics (j and f vs. Re), fluid flow rates, inlet temperatures, and fouling factors. The fluid outlet temperatures, total heat transfer rate, and pressure drops on each side of the exchanger are then determined as the rating problem solution.

1. Determine the surface geometric properties on each fluid side. This includes the minimum free-flow area A_o, heat transfer surface area A (both primary and secondary), flow lengths L, hydraulic diameter D_h, heat transfer surface area density β, the ratio of minimum free-flow area to frontal area σ, fin length l_f, and fin thickness δ for fin efficiency determination, and any specialized dimensions used for heat transfer and pressure drop correlations.
2. Compute the fluid bulk mean temperature and fluid thermophysical properties on each fluid side. Since the outlet temperatures are not known for the rating problem, they are estimated initially. Unless it is known from past experience, assume an exchanger effectiveness as 60%–75% for most single-pass crossflow exchangers or 80%–85% for single-pass counterflow exchangers. For the assumed effectiveness, calculate the fluid outlet temperatures.

$$T_{h,o} = T_{h,i} - e\left(C_{min} / C_h\right)\left(T_{h,i} - T_{c,i}\right) \tag{4.1.88}$$

$$T_{c,o} = T_{c,i} - e\left(C_{min} / C_c\right)\left(T_{h,i} - T_{c,i}\right) \tag{4.1.89}$$

   Initially, assume $C_c/C_h = \dot{m}_c/\dot{m}_h$ a gas-to-gas exchanger, or $C_c/C_h = \dot{m}_c c_{p,c}/\dot{m}_h c_{p,h}$ for a gas-to-liquid exchanger with very approximate values of c_p for the fluids in question.

   For exchangers with $C^* > 0.5$ (usually gas-to-gas exchangers), the bulk mean temperatures on each fluid side will be the arithmetic mean of the inlet and outlet temperatures on each fluid side (Shah, 1981). For exchangers with $C^* > 0.5$ (usually gas-to-gas exchangers), the bulk mean temperature on the C_{max} side will be the arithmetic mean of inlet and outlet temperatures; the bulk mean temperature on the C_{min} side will be the log-mean average temperature obtained as follows:

$$T_{m,C_{min}} = T_{m,C_{max}} \pm \Delta T_{lm} \tag{4.1.90}$$

   where ΔT_{lm} is the LMTD based on the terminal temperatures (see Equation 4.1.55). Use the plus sign if the C_{min} side is hot; otherwise, use the negative sign.

   Once the bulk mean temperature is obtained on each fluid side, obtain the fluid properties from thermophysical property books or from handbooks. The properties needed for the rating problem are μ, c_p, k, Pr, and ρ. With this c_p, one more iteration may be carried out to determine $T_{h,o}$ or $T_{c,o}$ from Equation 4.1.88 or 4.1.89 on the C_{max} side, and subsequently T_m on the C_{max} side, and refine fluid properties accordingly.

3. Calculate the Reynolds number $\mathrm{Re} = GD_h/\mu$ and/or any other pertinent dimensionless groups (from the basic definitions) needed to determine the nondimensional heat transfer and flow friction characteristics (e.g., j or Nu and f) of heat transfer surfaces on each side of the exchanger. Subsequently, compute j or Nu and f factors. Correct Nu (or j) for variable fluid property effects (Shah, 1981) in the second and subsequent iterations from the following equations.

$$\text{For gases}: \quad \frac{\mathrm{Nu}}{\mathrm{Nu}_{cp}} = \left[\frac{T_w}{T_m}\right]^{n'}; \quad \frac{f}{f_{cp}} = \left[\frac{T_w}{T_m}\right]^{m'} \tag{4.1.91}$$

$$\text{For liquids}: \quad \frac{\text{Nu}}{\text{Nu}_{cp}} = \left[\frac{\mu_w}{\mu_m}\right]^{n'}; \quad \frac{f}{f_{cp}} = \left[\frac{\mu_w}{\mu_m}\right]^{m'} \tag{4.1.92}$$

where the subscript cp denotes constant properties, and m' and n' are empirical constants provided in Table 4.1.13. Note that T_w and T_m in Equations 4.1.91 and 4.1.92 and in Tables 4.1.13a and b and are absolute temperatures.

4. From Nu or j, compute the heat transfer coefficients for both fluid streams.

$$h = \text{Nu}\ k / D_h = jGc_p\text{Pr}^{-2/3} \tag{4.1.93}$$

Subsequently, determine the fin efficiency η_f and the extended surface efficiency η_o

$$\eta_f = \frac{\tanh ml}{ml} \quad \text{where} \quad m^2 = \frac{h\tilde{p}}{k_f A_k} \tag{4.1.94}$$

[a] Valid for $2 \le \text{Pr} \le 140$, $10^4 \le \text{Re} \le 1.25 \times 10^5$.

[b] Valid for $1.3 \le \text{Pr} \le 10$, $10^4 \le \text{Re} \le 2.3 \times 10^5$.

where $\tilde{P}$ is the wetted perimeter of the fin surface.

$$\eta_o = 1 - \frac{A_f}{A}\left(1 - \eta_f\right) \tag{4.1.95}$$

Also calculate the wall thermal resistance $R_w = \delta/A_w k_w$. Finally, compute the overall thermal conductance UA from Equation 4.1.42 knowing the individual convective film resistances, wall thermal resistances, and fouling resistances, if any.

5. From the known heat capacity rates on each fluid side, compute $C^* = \boldsymbol{C}_{min}/C_{max}$. From the known UA, determine NTU $= UA/C_{min}$. Also calculate the longitudinal conduction parameter λ. With the known NTU, $\boldsymbol{C}^*$, λ, and the flow arrangement, determine the exchanger effectiveness ε from either closed-form equations of Table 4.1.10 or tabular/graphical results from Kays and London (1998).
6. With this ε, finally compute the outlet temperatures from Equations 4.1.88 and 4.1.89. If these outlet temperatures are significantly different from those assumed in Step 2, use these outlet temperatures in Step 2 and continue iterating Steps 2–6, until the assumed and computed outlet temperatures converge within the desired degree of accuracy. For a gas-to-gas exchanger, most probably one or two iterations will be sufficient.
7. Finally, compute the heat duty from

$$q = \varepsilon C_{min}\left(T_{h,i} - T_{c,i}\right) \tag{4.1.96}$$

8. For the pressure drop calculations, first we need to determine the fluid densities at the exchanger inlet and outlet (ρ_i and ρ_o) for each fluid. The mean specific volume on each fluid side is then computed from Equation 4.1.66.

Next, the entrance and exit loss coefficients, K_c and K_e, are obtained from Figure 4.1.35 for known σ, Re, and the flow passage entrance geometry.

The friction factor on each fluid side is corrected for variable fluid properties using Equation 4.1.91 or 4.1.92. Here, the wall temperature T_w is computed from

$$T_{w,h} = T_{m,h} - (R_h + R_{s,h})\,q \tag{4.1.97}$$

$$T_{w,c} = T_{m,c} + \left(R_c + R_{s,c}\right)q \tag{4.1.98}$$

where the various resistance terms are defined by Equation 4.1.42.

The core pressure drops on each fluid side are then calculated from Equation 4.1.65. This then completes the procedure for solving the rating problem.

Sizing Problem for a Crossflow Plate-Fin Exchanger

As defined earlier, we will concentrate here to determine the physical size (length, width, and height) of a single-pass crossflow exchanger for specified heat duty and pressure drops. More specifically, inputs to the sizing problem are surface geometries (including their nondimensional heat transfer and pressure drop characteristics), fluid flow rates, inlet and outlet fluid temperatures, fouling factors, and pressure drops on each side.

For the solution to this problem, there are four unknowns—two flow rates or Reynolds numbers (to determine correct heat transfer coefficients and friction factors) and two surface areas—for the two-fluid crossflow exchanger. The following four equations—Equations 4.1.99, 4.1.101, 4.1.102 and 4.1.103—are used to solve iteratively the surface areas on each fluid side: UA in Equation 4.1.99 is

determined from NTU computed from the known heat duty or ε and C^*; G in Equation 4.1.101 represents two equations, for Fluids 1 and 2 (Shah, 1988a); and the volume of the exchanger in Equation 4.1.103 is the same based on the surface area density of Fluid 1 or Fluid 2.

$$\frac{1}{UA} \approx \frac{1}{(\eta_o hA)_h} + \frac{1}{(\eta_o hA)_c} \tag{4.1.99}$$

Here, we have neglected the wall and fouling thermal resistances. This equation in nondimensional form is given by

$$\frac{1}{\text{NTU}} = \frac{1}{\text{ntu}_h (C_h/C_{\min})} + \frac{1}{\text{ntu}_c (C_c/C_{\min})} \tag{4.1.100}$$

$$G_i = \left[\frac{2 g_c \Delta p}{\text{Deno}}\right]_i^{1/2} \qquad i = 1,2 \tag{4.1.101}$$

where

$$\text{Deno}_i = \left[\frac{f}{j}\frac{\text{ntu}}{\eta_o}\text{Pr}^{2/3}\left(\frac{1}{\rho}\right)_m + 2\left(\frac{1}{\rho_o} - \frac{1}{\rho_i}\right) + \left(1-\sigma^2+K_c\right)\frac{1}{\rho_i} - \left(1-\sigma^2-K_e\right)\frac{1}{\rho_o}\right]_i \tag{4.1.102}$$

$$V = \frac{A_1}{\alpha_1} = \frac{A_2}{\alpha_2} \tag{4.1.103}$$

In the iterative solutions, the first time one needs ntu_h and ntu_c to start the iterations. These can be either determined from the past experience or by estimations. If both fluids are gases or both fluids are liquid, one could consider that the design is "balanced," that is, that the thermal resistances are distributed approximately equally on the hot and cold sides. In that case, $C_h = C_c$, and

$$\text{ntu}_h \approx \text{ntu}_c \approx 2\,\text{NTU} \tag{4.1.104}$$

Alternatively, if we have liquid on one side and gas on the other side, consider 10% thermal resistance on the liquid side, that is,

$$0.10\left(\frac{1}{UA}\right) = \frac{1}{(\eta_o hA)_{\text{liq}}} \tag{4.1.105}$$

Then, from Equations 4.1.99 and 4.1.100 with $C_{\text{gas}} = C_{\min}$, we can determine the ntu values on each side as follows:

$$\text{ntu}_{\text{gas}} = 1.11\text{NTU}, \qquad \text{ntu}_{\text{liq}} = 10C^*\text{NTU} \tag{4.1.106}$$

Also note that initial guesses of η_o and *j/f* are needed for the first iteration to solve Equation 4.1.102. For a good design, consider $\eta_o = 0.80$ and determine an approximate value of *j/f* from the plot of *j/f* vs. Re curve for the known *j* and *f* vs. Re characteristics of each fluid side surface. The specific step-by-step design procedure is as follows:

1. In order to compute the fluid bulk mean temperature and the fluid thermophysical properties on each fluid side, determine the fluid outlet temperatures from the specified heat duty

$$q = (\dot{m}c_p)_h (T_{h,i} - T_{h,o}) = (\dot{m}c_p)_c (T_{c,o} - T_{c,i}) \tag{4.1.107}$$

or from the specified exchanger effectiveness using Equations 4.1.88 and 4.1.89. For the first time, estimate the values of c_p.

For exchangers with $C^* \geq 0.5$, the bulk mean temperature on each fluid side will be the arithmetic mean of inlet and outlet temperatures on each side. For exchangers with $C^* < 0.5$, the bulk mean temperature on the C_{max} side will be the arithmetic mean of the inlet and outlet temperatures on that side and the bulk mean temperature on the C_{min} side will be the log-mean average as given by Equation 4.1.90. With these bulk mean temperatures, determine c_p and iterate one more time for the outlet temperatures if warranted. Subsequently, determine μ, c_p, k, Pr, and ρ on each fluid side.

2. Calculate C^* and ε (if q is given), and determine NTU from the ε-NTU expression, tables, or graphical results for the selected flow arrangement (in this case, it is unmixed–unmixed crossflow, Table 4.1.10). The influence of longitudinal heat conduction, if any, is ignored in the first iteration since we do not know the exchanger size yet.
3. Determine ntu on each side by the approximations discussed with Equations 4.1.104 and 4.1.106 unless it can be estimated from past experience.
4. For the selected surfaces on each fluid side, plot *j*/*f* vs. Re curve from the given surface characteristics and obtain an approximate value of *j*/*f*. If fins are employed, assume $\eta_o = 0.80$ unless a better value can be estimated.
5. Evaluate G from Equation 4.1.101 on each fluid side using the information from Steps 1–4 and the input value of Δp.
6. Calculate Reynolds number Re, and determine j and f on each fluid side from the given design data for each surface.
7. Compute h, η_f, and η_o using Equations 4.1.93 through 4.1.95. For the first iteration, determine U_1 on Fluid 1 side from the following equation derived from Equations 4.1.42 and 4.1.103.

$$\frac{1}{U_1} = \frac{1}{(\eta_o h)_1} + \frac{1}{(\eta_o h_s)_1} + \frac{\alpha_1/\alpha_2}{(\eta_o h_s)_2} + \frac{\alpha_1/\alpha_2}{(\eta_o h)_2} \tag{4.1.108}$$

where $\alpha_1/\alpha_2 = A_1/A_2$, $\alpha = A/V$, V is the exchanger total volume, and subscripts 1 and 2 denote Fluid 1 and 2 sides. For a plate-fin exchanger, α terms are given by Shah (1981) and Kays and London (1998):

$$\alpha_1 = \frac{b_1\beta_1}{b_1 + b_2 + 2a}; \qquad \alpha_2 = \frac{b_2\beta_2}{b_1 + b_2 + 2a} \tag{4.1.109}$$

Note that the wall thermal resistance in Equation 4.1.108 is ignored in the first iteration. In second and subsequent iterations, compute U_1 from

$$\frac{1}{U_1} = \frac{1}{(\eta_o h)_1} + \frac{1}{(\eta_o h_s)_1} + \frac{\delta A_1}{k_w A_w} + \frac{A_1/A_2}{(\eta_o h_s)_2} + \frac{A_1/A_2}{(\eta_o h_2)_2} \tag{4.1.110}$$

where the necessary geometry information A_1/A_2 and A_1/A_w is determined from the geometry calculated in the previous iteration.

8. Now calculate the core dimensions. In the first iteration, use NTU computed in Step 2. For subsequent iterations, calculate longitudinal conduction parameter λ (and other dimensionless groups for a crossflow exchanger). With known ε, C^*, and λ, determine the correct value of NTU using either a closed-form equation or tabular/graphical results (Kays and London 1998). Determine A_1 from NTU using U_1 from the previous step and known C_{min}.

$$A_1 = \text{NTU}\, C_{min} / U_1 \tag{4.1.111}$$

and hence

$$A_2 = (A_2 / A_1)A_1 = (\alpha_2 / \alpha_1)A_1 \tag{4.1.112}$$

A_o from known $\dot{m}$ and G is given by

$$A_{o,1} = (\dot{m}/G)_1; \quad A_{o,2} = (\dot{m}/G)_2 \tag{4.1.113}$$

so that

$$A_{fr,1} = A_{o,1} / \sigma_1; \quad A_{fr,2} = A_{o,2} / \sigma_2 \tag{4.1.114}$$

where σ_1 and σ_2 are generally specified for the surface or can be computed for plate-fin surfaces from Shah (1981) and Kays and London (1998):

$$\sigma_1 = \frac{b_1\beta_1 D_{h,1}/4}{b_1 + b_2 + 2\delta}; \quad \sigma_2 = \frac{b_2\beta_2 D_{h,2}/4}{b_1 + b_2 + 2\delta} \tag{4.1.115}$$

Now compute the fluid flow lengths on each side (see Figure 4.1.38) from the definition of the hydraulic diameter of the surface employed on each side.

$$L_1 = \left(\frac{D_h A}{4A_o}\right)_1; \quad L_2 = \left(\frac{D_h A}{4A_o}\right)_2 \tag{4.1.116}$$

Since $A_{fr,1} = L_2L_3$ and $A_{fr,2} = L_1L_3$, we can obtain

$$L_3 = \frac{A_{fr,1}}{L_2} \quad \text{or} \quad L_3 = \frac{A_{fr,2}}{L_1} \tag{4.1.117}$$

Theoretically, L_3 calculated from both expressions of Equation 4.1.117 should be identical. In reality, they may differ slightly because of the round-off error. In that case, consider an average value for L_3.

9. Finally, compute the pressure drop on each fluid side, after correcting f factors for variable property effects, in a manner similar to Step 8 of the Rating Problem for a Crossflow Plate Fin Exchanger.

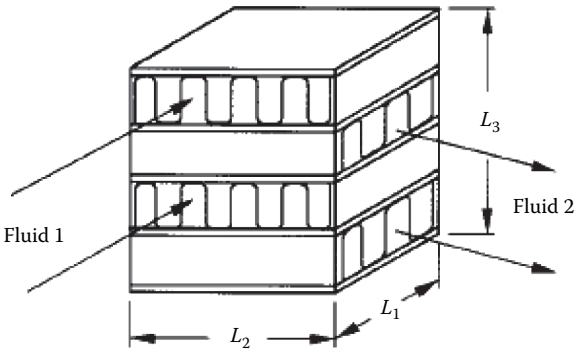

FIGURE 4.1.38 A single-pass crossflow exchanger.

10. If the calculated values of Δp are within and close to input specifications, the solution to the sizing problem is completed. Finer refinements in the core dimensions, such as integer numbers of flow passages, etc., may be carried out at this time. Otherwise, compute the new value of G on each fluid side using Equation 4.1.65 in which Δp is the input-specified value, and f, K_c, K_e, and geometric dimensions are from the previous iteration.
11. Repeat (iterate) Steps 6–10 until both heat transfer and pressure drops are met as specified. It should be emphasized that since we have imposed no constraints on the exchanger dimensions, this procedure will yield L_1, L_2, and L_3 for the selected surfaces such that the design will meet exactly the heat duty and pressure drops on both fluid sides.

Flow Maldistribution

In the previously presented heat transfer (ε-NTU, MTD, etc. methods) and pressure drop analyses, it is presumed that the fluid is uniformly distributed through the core. In practice, flow maldistribution does occur to some extent and often severely, and may result in a significant reduction in exchanger heat transfer performance and an increase in the pressure drop. Hence, it may be necessary for the designer to take into account the effect of flow maldistribution causing undesirable performance deterioration up front while designing a heat exchanger.

Some maldistributions are geometry-induced (i.e., the result of exchanger fabrication conditions, such as header design or manufacturing tolerances, or the duct geometry/structure upstream of the exchanger), and other maldistributions are the result of exchanger operating conditions. Gross, passage-to-passage, and manifold-induced flow maldistributions are examples of the former category, while viscosity, natural convection, and density-difference-induced flow maldistributions are of the latter category. Flow maldistributions associated with two-phase and multiphase flow are too complex, with only limited information available in the literature. The analysis methods and results for some of the above flow maldistributions for single-phase flows are given by Shah (1985), Mueller and Chiou (1987), and Putnam and Rohsenow (1985).

Fouling in Heat Exchangers

Fouling, Its Effect, and Mechanisms

Fouling refers to undesired accumulation of solid material (by-products of the heat transfer processes) on heat exchanger surfaces which results in additional thermal resistance to heat transfer, thus reducing exchanger performance. The fouling layer also blocks the flow passage/area and increases surface roughness, thus either reducing the flow rate in the exchanger or increasing the pressure drop or both. The foulant deposits may be loose such as magnetite particles or hard and tenacious such as calcium carbonate scale; other deposits may be sediment, polymers, coking or corrosion products, inorganic salts, biological growth, etc. Depending upon the fluids, operating conditions, and heat exchanger construction, the maximum fouling layer thickness on the heat transfer surface may result in a few hours to a number of years.

Fouling could be very costly depending upon the nature of fouling and the applications. It increases capital costs: (1) oversurfacing heat exchanger, (2) provisions for cleaning, and (3) use of special materials and constructions/surface features. It increases maintenance costs: (1) cleaning techniques, (2) chemical additives, and (3) troubleshooting. It may cause a loss of production: (1) reduced capacity and (2) shutdown. It increases energy losses: (1) reduced heat transfer, (2) increased pressure drop, and (3) dumping dirty streams. Fouling promotes corrosion, severe plugging, and eventual failure of uncleaned heat exchangers. In a fossil-fired exhaust environment, gas-side fouling produces a potential fire hazard in heat exchangers.

The following are the major fouling mechanisms:

- Crystallization or precipitation fouling results from the deposition/formation of crystals of dissolved substances from the liquid onto heat transfer surface due to solubility changes with temperature beyond the saturation point. If the deposited layer is hard and tenacious, it is often referred to as scaling. If it is porous and mushy, it is called sludge.
- Particulate fouling results from the accumulation of finely divided substances suspended in the fluid stream onto heat transfer surface. If the settling occurs as a result of gravity, it is referred to as sedimentation fouling.
- Chemical reaction fouling is defined as the deposition of material produced by chemical reaction (between reactants contained in the fluid stream) in which the heat transfer surface material does not participate.
- Corrosion fouling results from corrosion of the heat transfer surface that produces products fouling the surface and/or roughens the surface, promoting attachment of other foulants.
- Biological fouling results from the deposition, attachment, and growth of biological organisms from liquid onto a heat transfer surface. Fouling due to microorganisms refers to microbial fouling and fouling due to macroorganisms refers to macrobial fouling.
- Freezing fouling results from the freezing of a single-component liquid or higher-melting-point constituents of a multicomponent liquid onto a subcooled heat transfer surface.

Biological fouling occurs only with liquids since there are no nutrients in gases. Also crystallization fouling is not too common with gases since most gases contain few dissolved salts (mainly in mists) and even fewer inverse-solubility salts. All other types of fouling occur in both liquid and gas. More than one mechanism is usually present in many fouling situations, often with synergetic results. Liquid-side fouling generally occurs on the exchanger side where the liquid is being heated, and gas-side fouling occurs where the gas is being cooled; however, reverse examples can be found.

Importance of Fouling

Fouling in liquids and two-phase flows has a significant detrimental effect on heat transfer with some increase in pressure drop. In contrast, fouling in gases reduces heat transfer somewhat (5%–10% in general) in compact heat exchangers, but increases pressure drop significantly up to several hundred percent. For example, consider $U = 1400\,\mathrm{W/m^2\,K}$ as in a process plant liquid-to-liquid heat exchanger. Hence, $R = 1/U = 0.00072\,\mathrm{m^2\,K/W}$. If the fouling factors $(r_{s,h} + r_{s,c})$ together amount to 0.00036 (considering a typical TEMA value of the fouling factor as 0.00018), 50% of the heat transfer area requirement A for given q is chargeable to fouling. However, for gas flows on both sides of an exchanger, $U \approx 280\,\mathrm{W/m^2\,K}$, and the same fouling factor of 0.00036 would represent only about 10% of the total surface area. Thus, one can see a significant impact on the heat transfer surface area requirement due to fouling in heat exchangers having high $\boldsymbol{U}$ values (such as having liquids or phase-change flows).

Considering the core frictional pressure drop (Equation 4.1.68) as the main pressure drop component, the ratio of pressure drops of fouled and cleaned exchangers is given by

$$\frac{\Delta P_F}{\Delta p_C} = \frac{f_F}{f_C}\left(\frac{D_{h,C}}{D_{h,F}}\right)\left(\frac{u_{m,F}}{u_{m,C}}\right)^2 = \frac{f_F}{f_C}\left(\frac{D_{h,C}}{D_{h,F}}\right)^5 \tag{4.1.118}$$

where the term after the second equality sign is for a circular tube and the mass flow rates under fouled and clean conditions remain the same. Generally, $f_F > f_c$ due to the fouled surface being rough. Thus, although the effect of fouling on the pressure drop is usually neglected, it can be significant, particularly for compact heat exchangers with gas flows. If we consider $f_F = f_c$, and the reduction in the tube inside diameter due to fouling by only 10% and 20%, the resultant pressure drop increase

will be 69% and 205%, respectively, according to Equation 4.1.118 regardless of whether the fluid is liquid or gas!

Accounting of Fouling in Heat Exchangers

Fouling is an extremely complex phenomenon characterized by a combined heat, mass, and momentum transfer under transient condition. Fouling is affected by a large number of variables related to heat exchanger surfaces, operating conditions, and fluids. Fouling is time dependent, zero at $\tau = 0$; after the induction or delay period τ_d, the fouling resistance is either pseudolinear, falling rate, or asymptotic.

Fouling is characterized by all or some of the following sequential events: initiation, transport, attachment, removal, and aging (Epstein, 1983). Research efforts are concentrated on quantifying these events by semitheoretical models (Epstein, 1978) with very limited success on specific fouling situations. Hence, the current heat exchanger design approach is to use a constant (supposedly an asymptotic) value of the fouling factor $r_s = 1/h_s$. Equation 4.1.42 presented earlier includes the fouling resistances on the hot and cold sides for a nontubular extended-surface exchanger. Here $1/h_s = r_s$ is generally referred to as the *fouling factor.* Fouling factors for some common fluids are presented in Tables 4.1.14 and 4.1.15. Also see Section 4.4 in this Handbook.

The specification of fouling effects in a process heat exchanger is usually represented in the following form, wherein the combined fouling factor $r_{s,t}$ is the sum of the fouling factors on the hot and cold sides:

$$\text{Combined fouling factor} \qquad r_{s,t} = \frac{1}{U_C} - \frac{1}{U_F} \tag{4.1.119}$$

$$\text{Cleanliness factor CF} = U_F / U_C \tag{4.1.120}$$

$$\text{Percentage oversurface} \quad \%\text{OS} = \left(\frac{A_F}{A_C} - 1 \right) 100 \tag{4.1.121}$$

Here the subscripts *F* and *C* denote fouled and clean exchanger values. From Equation 4.1.42 with $A_h = A_c = A$, $\eta_o = 1$, $\Delta T_{m,F} = \Delta T_{m,C}$, it can be shown that

$$\frac{A_F}{A_C} = \frac{U_C}{U_F} = 1 + U_C r_{s,t} \tag{4.1.122}$$

where $r_{s,t} = r_{s,h} + r_{s,c}$. In heat exchanger design, constant (supposedly an asymptotic) values of $r_{s,h}$ and $r_{s,c}$ are used. Accordingly, extra heat transfer surface area is provided to take into account the deleterious effect of fouling. Thus, the heat exchanger will be "oversized" for the initial clean condition, "correctly sized" for asymptotic fouling (if it occurs in practice), and "undersized" just before the cleaning operation for nonasymptotic fouling.

Influence of Operating and Design Variables

Based on operational experience and research over the last several decades, many variables have been identified that have a significant influence on fouling. The most important variables are summarized next.

Flow velocity. Flow velocity is one of the most important variables affecting fouling. Higher velocities increase fluid shear stress at the fouling deposit–fluid interface and increase the heat transfer coefficient; but, at the same time, increased pressure drop and fluid pumping power may erode the surface and may accelerate the corrosion of the surface by removing the protective oxide layer. The fouling buildup in general is inversely proportional to $u_m^{1.5}$. For water, the velocity should be kept above 2 m/s to suppress fouling, and the absolute minimum should be above 1 m/s to minimize fouling.

TABLE 4.1.14
Fouling Factors for Various Fluid Streams Used in Heat Exchangers

Water Type	Fouling Factors (m^2 K)/W
Seawater (43°C maximum outlet)	0.000275–0.00035
Brackish water (43°C maximum outlet)	0.00035–0.00053
Treated cooling tower water (49°C maximum outlet)	0.000175–0.00035

[a] Depending on charge characteristics and storage history, charge fouling resistance may be many times this value.

[b] American Petroleum Institute.

Surface temperature. Higher surface temperatures promote chemical reaction, corrosion, crystal formation (with inverse solubility salts), and polymerization, but reduce biofouling for temperatures above the optimum growth, avoid potential freezing fouling, and avoid precipitation of normal-solubility salts. It is highly recommended that the surface temperature be maintained below the reaction temperature; it should be kept below 60°C for cooling tower water.

Tube material. The selection of the tube material is important from the corrosion point of view which in turn could increase crystallization and biological fouling. Copper alloys can reduce certain biofouling, but their use is limited by environmental concerns with river, ocean, and lake waters.

There are many other variables that affect fouling. It is beyond the scope here, but the reader may refer to TEMA (1988).

Fouling Control and Cleaning Techniques

Control of fouling should be attempted first before any cleaning method is attempted. For gas-side fouling, one should verify that fouling exists, identify the sequential event that dominates the foulant accumulation, and characterize the deposit. For liquid-side fouling, fouling inhibitors/additives should be employed while the exchanger is in operation; for example, use antidispersant polymers to prevent sedimentation fouling, "stabilizing" compounds to prevent polymerization and chemical reaction fouling, corrosion inhibitors to prevent corrosion fouling, biocide/germicide to prevent biofouling, softeners, acids, and polyphosphates to prevent crystallization fouling.

If the foulant control is not effective, the exchanger must be cleaned either online or off-line. Online cleaning includes flow-driven brushes/sponge balls inside tubes, power-driven rotating brushes inside tubes, acoustic horns/mechanical vibrations for tube banks with gases, soot blowers, and shutting off of the cold gas supply, flowing hot gas, or reversing of the fluids. Off-line cleaning methods, without dismantling the exchanger include chemical cleaning (circulate acid/detergent solutions), circulating of particulate slurry (such as sand and water), and thermal melting of frost layers. Off-line cleaning with a heat exchanger opened includes high-pressure steam or water cleaning, and thermal baking of an exchanger and then rinsing for small heat exchanger modules removed from the container of the modular exchangers.

Nomenclature

A	Total heat transfer area (primary + fin) on one fluid side of a heat exchanger, A_p: primary surface area, A_f: fin surface area, m^2
A_{fr}	Frontal area on one side of an exchanger, m^2
A_k	Total wall cross-sectional area for heat conduction in fin or for longitudinal conduction in the exchanger, m^2

A_o	Minimum free-flow area on one fluid side of a heat exchanger, m^2
b	Plate spacing, $h'+\delta_f$, m
C	Flow stream heat capacity rate with a subscript c or h, $\dot{m}c_p$, W/°C
C^*	Heat capacity rate ratio, C_{min}/C_{max}, dimensionless
c_p	Specific heat of fluid at constant pressure, J/kg K
D_h	Hydraulic diameter of flow passages, $4A_oL/A$, m
d_e	Fin tip diameter of an individually finned tube, m
d_i, d_o	Tube inside and outside diameters, respectively, m
Eu	N-row average Euler number, $\Delta p/(\rho\, \mu_m^2\, N/2g_c)$, $\rho\Delta p g_c/(NG^2/2)$, dimensionless
F	Log-mean temperature difference correction factor, dimensionless
f	Fanning friction factor, $\rho\Delta p g_c D_h/(2LG^2)$, dimensionless
f_{tb}	Fanning friction factor per tube row for crossflow over a tube bank outside, $\rho\Delta p g_c/(2NG^2)$
G	Mass velocity based on the minimum free flow area, $\dot{m}/A_o$, kg/m^2s
g	Gravitational acceleration, m^2/s
g_c	Proportionality constant in Newton's second law of motion, $g_c=1$ and dimensionless in SI units
H	Fin length for heat conduction from primary surface to either fin tip or midpoint between plates for symmetric heating, m
h	Heat transfer coefficient, W/m^2 K
h'	Height of the offset strip fin (see Figure 4.1.36), m
j	Colburn factor, $NuPr^{-1/3}/Re$, $StPr^{2/3}$, dimensionless
k	Fluid thermal conductivity, W/m K
k_f	Thermal conductivity of the fin material, W/m K
k_w	Thermal conductivity of the matrix (wall) material, W/m K
L	Fluid flow (core or tube) length on one side of an exchanger, m
l	Fin length for heat conduction from primary surface to the midpoint between plates for symmetric heating, see Table 4.1.11 for other definitions of l, m
l_f	Offset trip fin length or fin height for individually finned tubes, l_f represents the fin length in the fluid flow direction for an uninterrupted fin with $l_f=L$ in most cases, m
m	Fin parameter, 1/m
N	Number of tube rows, dimensionless
N_f	Number of fins per meter, 1/m
N_t	Total number of tubes in an exchanger, dimensionless
NTU	Number of heat transfer units, UA/C_{min}, it represents the total number of transfer units in a multipass unit, $NTU_s=UA/C_{shell}$, dimensionless
Nu	Nusselt number, hD_h/k, dimensionless
ntu_c	Number of heat transfer units based on the cold side, $(\eta_o hA)_c/C_c$, dimensionless
ntu_h	Number of heat transfer units based on the hot side, $(\eta_o hA)_h/C_h$, dimensionless
$\dot{m}$	Mass flow rate, kg/s
P	Temperature effectiveness of one fluid, dimensionless
$\wp$	Fluid pumping power, W
Pr	Fluid Prandtl number, $\mu c_p/k$, dimensionless
p	Fluid static pressure, Pa
Δp	Fluid static pressure drop on one side of heat exchanger core, Pa
P_f	Fin pitch, m
q	Heat duty, W
$\boldsymbol{q_e}$	Heat transfer rate (leakage) at the fin tip, W
q''	Heat flux, W/m^2
R	Heat capacity rate ratio used in the P-NTU method, $R_1=C_1/C$, $R_2=C_2/C_1$, dimensionless
R	Thermal resistance based on the surface area A, compare Equations 4.1.41 and 4.1.42 for definitions of specific thermal resistances, K/W
Re	Reynolds number, GD_h/μ, dimensionless

Re_d	Reynolds number, $\rho u_m d_o/\mu$, dimensionless
r_h	Hydraulic radius, $D_h/4$, $A_o L/A$, m
r_s	Fouling factor, $1/h_s$ m² K/W
St	Stanton number, h/Gc_p, dimensionless
s	Distance between adjacent fins, $p_f - \delta_f$, m
T	Fluid static temperature to a specified arbitrary datum, °C
T_a	Ambient temperature, °C
T_o	Fin base temperature, °C
T_l	Fin tip temperature, °C
U	Overall heat transfer coefficient, W/m² K
u_m	Mean axial velocity in the minimum free flow area, m/s
V	Heat exchanger total volume, m³
X_d	Diagonal tube pitch, m
X_l	Longitudinal tube pitch, m
X_t	Transverse tube pitch, m
α	Ratio of total heat transfer area on one side of an exchanger to the total volume of an exchanger, A/V, m²/m³
β	Heat transfer surface area density, a ratio of total transfer area on one side of a plate-fin heat exchanger to the volume between the plates on that side, m²/m³
ε	Heat exchanger effectiveness, it represents an overall exchanger effectiveness for a multipass unit, dimensionless
δ	Wall thickness, m
δ_f	Fin thickness, m
η_f	Fin efficiency, dimensionless
η_o	Extended surface efficiency, dimensionless
λ	Longitudinal wall heat conduction parameter based on the total conduction area, $\lambda = k_w A_{k,t}/C_{min}L$; $\lambda_c = k_w A_{k,c}/C_c L$, $\lambda_h = k_w A_{k,h}/C_h L$, dimensionless
μ	Fluid dynamic viscosity, Pa·s
ρ	Fluid density, kg/m³
σ	Ratio of free flow area to frontal area, A_o/A_{fr}, dimensionless

Subscripts

C	Clean surface value
c	Cold fluid side
F	Fouled surface value
f	Fin
h	Hot fluid side
i	Inlet to the exchanger
o	Outlet to the exchanger
s	Scale or fouling
w	Wall or properties at the wall temperature
1	One section (inlet or outlet) of the exchanger
2	Other section (outlet or inlet) of the exchanger

Further Information

Heat exchangers play a crucial and dominant role in many developments related to energy conservation, recovery, utilization, economic development of new energy sources, and environmental issues such as air and water pollution control, thermal pollution, waste disposal, etc. Many new and innovative heat exchangers have been developed for these and many other applications worldwide. A broad overview is provided for various heat exchangers and basic design theory for single-phase heat exchangers. For further details and study, the reader may refer to the following references: Kakaç et al. (1981, 1983, 1988, 2012), Taylor (1987), Shah et al. (1988, 1990), Shah and Sekulic (2003), Foumeny and Heggs (1991), Kakaç (1991), Roetzel et al. (1991), Shah and Hashemi (1993), Shah et al. (1997), Hesselgreaves (2001), Klemes et al. (2015), Thulukkanam (2013) and Zohuri (2016).

4.2 APPLICATION OF NANOFLUIDS IN HEAT EXCHANGERS: PERFORMANCE AND CHALLENGES

Bengt Sundén and Zan Wu

Introduction

The focus of this section is performance and challenges of nanofluids in heat exchanger applications. Heat exchangers are equipment being used for transfer of heat between two or more fluids at different temperatures (Sundén, 2012). Heat exchangers play an important role in the reduction of greenhouse gas emissions and for achieving clean and sustainable development. They are widely used in many applications including power plants, automotives, space heating, refrigeration and air-conditioning systems, chemical plants, petrochemical processes, electronic cooling, environment engineering, etc. (Sundén and Wu, 2015). Due to advancement in manufacturing processes, various heat-transfer enhancement techniques have been routinely used in different types of heat exchangers to improve their thermal efficiency. Heat-transfer enhancement techniques can be classified either as passive (no external power needed) or as active (external power required). Passive techniques employ special surface geometries (e.g., fins, corrugations, insert devices, curved tubing, and surface coatings) or additives (e.g., particles, phase change materials, and surfactants) for heat-transfer enhancement. Interested readers can refer to Webb and Kim (2005) for more details about these enhancement techniques.

Due to recent progress in nanotechnology, thermal conductivity values can be increased by adding nanometer-sized structures (e.g., nanoparticles, nanofibers, and nanotubes) in conventional heat-transfer fluids to form the so-called nanofluids. As shown in Table 4.2.1, conventional heat-transfer fluids such as water, ethylene glycol, and engine oil have relatively low-thermal conductivity values, which thus limit the heat-transfer rates. The thermal conductivity of these fluids can be enhanced by adding solid particles of high thermal conductivities. There are several advantages by using nanoparticles instead of microparticles. Nanoparticles are more stable and stay suspended much longer than microparticles if well prepared, with relatively little particle settling, channel erosion, and clogging. The nanoparticle settling velocity due to gravity can be obtained from a balance of the buoyancy and viscous forces (Buongiorno, 2006):

$$\frac{\pi}{6} d_p^3 \left(\rho_p - \rho_f\right) g = 3\pi d_p u_p \mu \Rightarrow u_p = \frac{d_p^2 \left(\rho_p - \rho_f\right) g}{18\mu}, \tag{4.2.1}$$

where the viscous resistance is calculated by the Stokes law. The settling velocity u_p is $<1.6 \times 10^{-8}$ m/s for nanoparticles with size <100 nm. Besides, the surface area per unit volume of nanoparticles is much larger than that of microparticles, allowing them to absorb and transfer heat more efficiently. Furthermore, there might be additional nanoparticle/fluid slip mechanisms in nanofluids, such as Brownian motion and thermophoresis, which can lead to further heat-transfer enhancement. Nanofluids have promising potential in nanomedicine, electronics, chemistry, optics, and various transport processes.

Nanoparticle additions increase the thermal conductivity, which is beneficial for convective heat transfer. Viscosity is also increased in nanofluids, which is not favorable especially taking the pumping power into account. In general, the increase in viscosity is higher than the increase in thermal conductivity.

Convective heat-transfer performance of nanofluids in straight smooth tubes has been extensively investigated, for example, Xuan and Li (2003), Ding et al. (2006), Heris et al. (2007), Williams et al. (2008), Yu et al. (2008), Choi (2009), Bianco et al. (2011), Haghighi et al. (2014), and Huang et al. (2015). However, there is considerable disagreement about whether addition of nanoparticles could enhance the convective heat transfer (Sergis and Hardalupas, 2011). On one hand, it is very

TABLE 4.2.1
Thermal Conductivity of Typical Materials at 300 K (Han, 2008; Pop et al., 2012)

Solids/Liquids	Material	Thermal Conductivity (W m^{-1} K^{-1})
Metallic solids	Silver	429
	Copper	401
	Gold	318
	Aluminum	237
Nonmetallic solids	Suspended graphene without substrate	Up to 4000
	Diamond	Up to 3300
	Carbon nanotube	Up to 3000
	Silicon	148
	Alumina (Al_2O_3)	40
Conventional heat-transfer fluids	Water	0.611
	Ethylene glycol (EG)	0.258
	Engine oil	0.145

important to choose appropriate performance comparison criteria (i.e., figures of merit) to compare the performance of nanofluids over their base fluids. Inappropriate comparison criteria such as heat-transfer coefficient ratios based on the constant Reynolds number may give misleading results because the net result for the constant Reynolds number basis is a combination of the nanofluid property effect and the flow velocity effect (Wu et al., 2013; Vanapalli and ter Brake, 2013; Sundén and Wu, 2015). Due to the higher viscosity of the nanofluid, the flow velocity in the nanofluid is generally higher than that of the base fluid at the same Reynolds number, which provides an advantage for the nanofluid over the base fluid. Therefore, more appropriate comparison criterion such as comparison of heat-transfer enhancement based on equal flow velocity and equal pumping power should be used to evaluate the benefit of nanofluids over their base fluids.

On the other hand, as indicated in Prabhat et al. (2011) and Wu and Sundén (2016), there seems no anomalous heat-transfer enhancement in the fully developed laminar flow and turbulent flow. Previous single-phase correlations can accurately reproduce the fully developed convective heat-transfer behavior of nanofluids in tubes by adopting the measured temperature- and loading-dependent thermal conductivities and viscosities of the nanofluids in the analysis. However, anomalous heat transfer could be obtained during the developing laminar flow (Liu, 2012).

So far, there are few studies on heat-transfer characteristics of nanofluids in complex geometries (e.g., helically coiled tubes and corrugated plates) and heat exchangers. Seyf and Mohammadian (2011) numerically simulated laminar nanofluid flow in a counterflow microchannel heat exchanger and suggested that nanofluid can enhance the heat exchanger effectiveness by nanoparticle Brownian motion. A single-phase approach was used for nanofluid modeling, and arbitrary thermal conductivity and viscosity values were adopted in the simulation. Pandey and Nema (2012) experimentally observed higher heat-transfer coefficients of Al_2O_3/water nanofluids than water in a corrugated plate heat exchanger (PHE). Heat-transfer coefficient decreases when the nanoparticle volume concentration increases from 2.0% to 4.0%. The pressure drop of nanofluids increased with increasing nanoparticle volume concentrations and was higher than that of water. Prasad et al. (2015) experimentally studied turbulent convective heat transfer and friction of alumina/water nanofluids flowing through a concentric tube U-bend heat exchanger with and without helical tape inserts. In these works, usually the thermal performance of nanofluids was evaluated by comparing the Nusselt number or the heat-transfer coefficient based on the Reynolds number. However, this comparison criterion is misleading. Besides, property correlations were used in most of these experimental and numerical studies rather than the measured nanofluid properties, which confuses researchers further to get a uniform opinion.

To provide a clearer view of the application of nanofluids in heat exchangers, our previous experimental investigations on the thermal performance of various nanofluids in different types of heat exchangers have been presented in this chapter. As the thermal performance of nanofluids is dependent on the thermophysical properties, nanofluid preparation, characterization, and property correlations have also been reported.

Nanofluid Preparation and Characterization

Preparation of nanofluids has an important influence on nanofluid thermophysical properties and stability. There are two main types of methods to produce nanofluids: single-step method and two-step method. The single-step method is a process that simultaneously makes and disperses the nanoparticles into base fluids, for which the nanoparticles are directly prepared by physical vapor deposition or a liquid chemical method. In the single-step method, the processes of drying, storage, transportation, and dispersion of nanoparticles are avoided, so the agglomeration of nanoparticles is minimized and the stability of fluids is increased (Li et al., 2009). To prevent oxidation of metallic particles, the single-step method is always preferable for synthesizing nanofluids containing metal particles. One disadvantage of the single-step method is that only low-vapor-pressure fluids are compatible with the process. Another disadvantage is that the single-step method is difficult to scale-up due to high cost and its demand for a vacuum.

The two-step method is a process that first generates nanoparticles and subsequently disperses the nanoparticles into base liquids. Nanoparticles, nanofibers, or nanotubes used in the two-step method are produced as a dry powder by suitable techniques such as inert gas condensation, chemical vapor deposition, and mechanical alloying. An advantage of the two-step method is that the inert gas condensation technique has already been scaled up to commercial nano-powder production (Wang and Fan, 2010). Besides, the particle concentration and size distribution could be manipulated. A deficiency of the two-step method is particle agglomeration during drying, storage and transportation of nanoparticles, and dispersion of nanoparticles in the base fluids. The nanoparticles tend to form agglomerations of different size due to the van der Waals attractive forces. Severe agglomeration might not only result in particle settlement and channel clogging, but also alter the thermal properties. Addition of surfactants, pH adjustment, and ultrasonic or microwave vibrations can reduce the size of the agglomerates substantially but are not able to break the agglomerates into primary particles.

Characterization of nanofluids includes colloidal stability, particle agglomerations, size distribution, and nanofluid properties (e.g., thermal conductivity and viscosity). One very easy and rough way to detect nanofluid stability is to see if there is any sedimentation. More accurately, the nanofluid stability can be characterized by the microscale agglomerations, size distributions, or property changes. For example, Figure 4.2.1 shows the change of the averaged thermal conductivity for each day with elapsed time for an alumina/water nanofluid with a nanoparticle volume fraction of 7.82% at 20°C. In general, thermal conductivity decreases with elapsed time. A 7.0% reduction in thermal conductivity averaged for each day was observed after 55 days. Therefore, the nanofluid is unstable with elapsed time even if the nanofluid looks nearly the same to the naked eye. It suggests that the microscale agglomerations in the nanofluid change with elapsed time.

Transmission electron microscopy (TEM) can be used to verify particle dimensions and to identify agglomerations. The electron beam can be used to see features on the nanometer level. One major disadvantage to use TEM is that the nanoparticle samples must be dried out of the nanofluids in order to be attached to the carbon matrix for observation under vacuum conditions. There is always a risk that the nanoparticles might have agglomerated in a different way when it has dried. One alternative is to cryo-plunge nanoparticles with the nanofluids in the aqueous state down to liquid nitrogen temperature. The resolution becomes lower by this method. For the two-step nanofluid preparation, TEM images can be obtained for the dry powder produced by

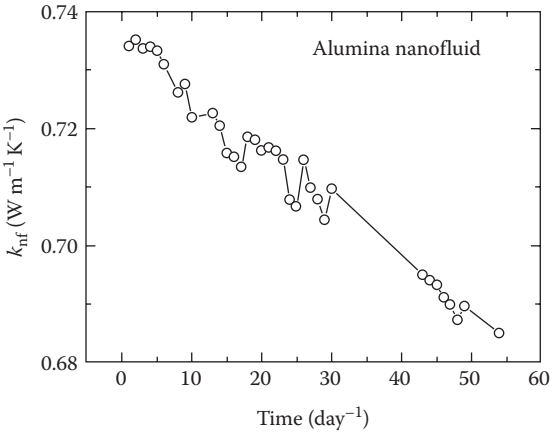

FIGURE 4.2.1 Change in thermal conductivity averaged for each day with elapsed time for an alumina/water nanofluid (7.82% volume fraction) at 20°C. (From Wu, Z. et al., *Front. Heat Mass Transfer*, 5, 18, 2014.)

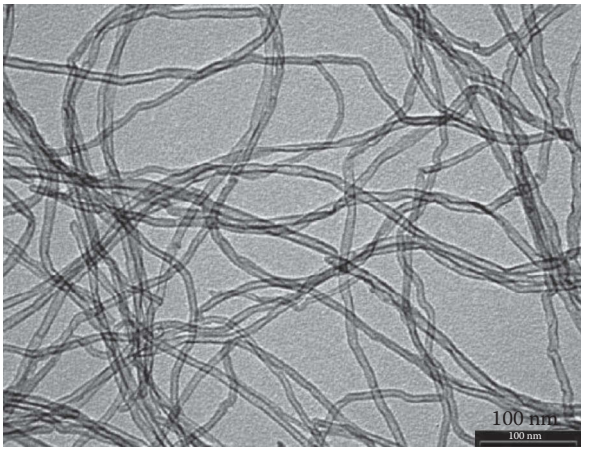

FIGURE 4.2.2 TEM characterization of MWCNTs. (From Wu, Z. et al., *Appl. Therm. Eng.*, 96, 364–371, 2016.)

the first step. Figure 4.2.2 shows an example of TEM characterization of multiwalled carbon nanotubes (MWCNTs). Apparently, the MWCNTs are aggregated and entangled before dispersion into the base fluid. Please note that the microscale structures formed by nanoparticles in the nanofluid will be different from dry powder observations.

The dynamic light scattering (DLS) technique can be used to observe the effective particle size distribution in a dilute nanofluid. When light from a laser passes through the nanofluid, the light will scatter uniformly from particles with a size less than about 250 nm. The particle size can be determined by the time measurements of the scattered light intensity. The time variation of the intensity can be correlated to the hydrodynamic radius of the particles in the nanofluid. For example, Figure 4.2.3 shows the particle size distributions by DLS of two MWCNT/water nanofluids of weight concentrations 0.05 and 0.1 wt%, respectively. The two nanofluids give similar particle size distributions and have a peak, about 200 nm for 0.05 wt% and 220 nm for 0.1 wt%. One drawback of DLS is that it can only be used for dilute nanofluids. Special care must be taken when diluting the nanofluids, for example, to maintain the nanofluid pH stable during dilution. Another drawback of DLS is that the size measurement of very polydisperse systems might be misleading.

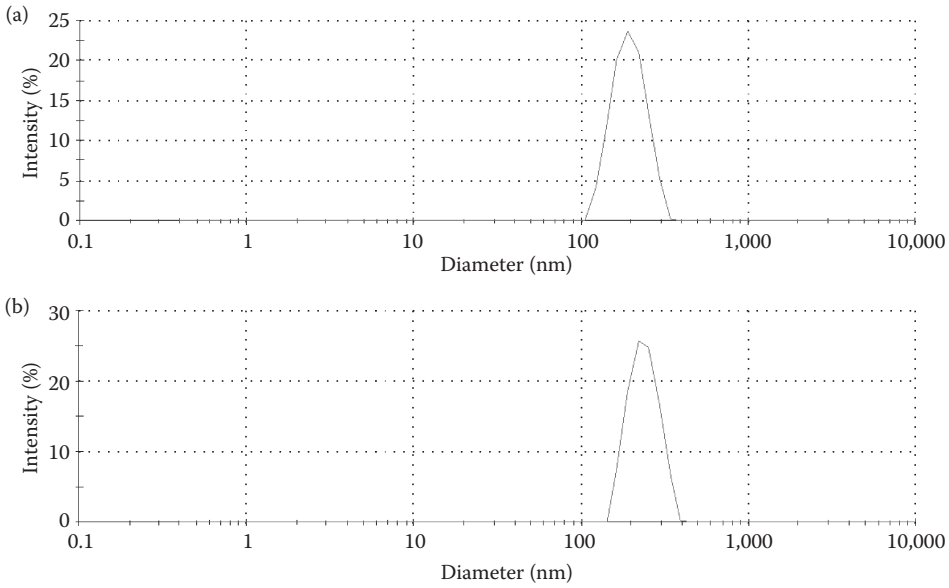

FIGURE 4.2.3 The particle size distributions by DLS of two MWCNT/water nanofluids: (a) 0.05 wt% and (b) 0.1 wt%. (From Wu, Z. et al., *Appl. Therm. Eng.*, 96, 364–371, 2016.)

Shear viscosities of the nanofluid can be measured using rotational viscometers/rheometers of cone and plate geometries. Rotational viscometers use the idea that the force required to turn an object in a fluid can indicate the viscosity of that fluid. Thermal conductivities of the nanofluid can be measured by a transient hot wire method or a transient plane source method. Please refer to Healy et al. (1976) and Gustafsson (1991) for detail descriptions of the transient hot wire technique and the transient plane source technique, respectively.

Properties of Nanofluids

Heat-transfer performance of nanofluids is mainly affected by the physical properties of nanofluids. Physical properties, such as density, specific heat, viscosity, and thermal conductivity, are decided by nanoparticles (e.g., particle size and shape, concentration, and material), the base fluid (e.g., fluid type, additives), and preparation methods, as shown in Figure 4.2.4. Property characterization of nanofluids has received intensive attention, especially viscosity and thermal conductivity. Please refer to reviews such as Fan and Wang (2011), Kleinstreuer and Feng (2011), and Taylor et al. (2013) for more details. It is generally accepted that the density of the nanofluid can be calculated by the mixing theory (volume-weighted average).

$$\rho_{nf} = (1-\varphi)\rho_f + \varphi\rho_p, \tag{4.2.2}$$

where φ is the nanoparticle volume concentration. Subscripts nf, f, and p indicate the nanofluid, the base fluid, and the particle, respectively. Properties of surfactant additives should be considered when evaluating the properties of the base fluid.

The specific heat of the nanofluid cannot be calculated from the volume-weighted average as the volume-weighted average deviated very significantly from the experimental data (O'Hanley et al., 2012). Assuming that the base fluid and the nanoparticles are in thermal equilibrium, the following expression can predict the specific heat of nanofluids accurately:

$$\rho_{nf} c_{p,nf} = (1-\varphi)\rho_f c_{p,f} + \varphi\rho_p c_{p,p}. \tag{4.2.3}$$

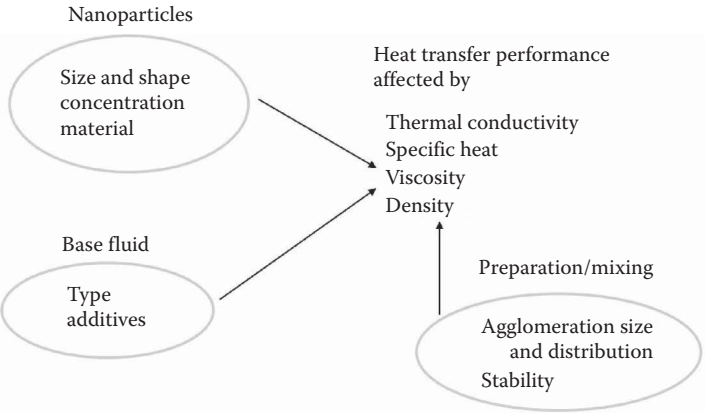

FIGURE 4.2.4 Properties of nanofluids.

Given its sound theoretical basis, this equation is generally applicable. Small discrepancies between the data and predictions might occur because properties (density and specific heat) may differ if the material is in nanoparticle form versus bulk form.

Up to now, there are no general correlations to predict the thermal conductivity and viscosity of nanofluid. Thermal conductivity and viscosity of nanofluids are strongly dependent on parameters such as particle concentration, particle size and shape, the presence of agglomerations (i.e., nanoclusters and aggregates), the nature of the base fluid, temperature, and nanofluid stability. Due to attractive van der Waals forces, nanoparticles tend to agglomerate in nanofluids to form the so-called aggregate-laden nanofluids.

Existence of nanoparticle agglomerations has already been recognized by DLS and SEM/TEM observations in the literature, for example, Keblinski et al. (2002), Hong et al. (2006), Prasher et al. (2006), Karthikeyan et al. (2008), and Anoop et al. (2009). Aggregation affects the nanofluid properties such as thermal conductivity and viscosity and further affects the heat-transfer performance. On one hand, agglomeration tends to enhance nanofluid viscosity due to the immobilized fluid trapped in the particle clusters and thus a higher effective volume fraction than the actual solid volume fraction. Anoop et al. (2009) considered the viscosity increase to be primarily due to the agglomeration of particles in water-based and ethylene-based nanofluids. On the other hand, fractal agglomerations or aggregates can lead to thermal conductivity enhancement due to the ability of the heat to move rapidly along the backbone of the clusters. Note that relatively large packed clusters may deteriorate thermal conductivity as it may induce sedimentation and therefore decrease the particle volume fraction.

Previous correlations for viscosity and thermal conductivity were given in the literature, for example, Chen et al. (2009), Philip and Shima (2012), and Wu et al. (2014). Classical models such as the Einstein model (Einstein, 1906), the Maxwell model (Maxwell, 1881), and the Hamilton–Crosser model (Hamilton and Crosser, 1962) might not be able to predict the nanofluid properties accurately. Most of the developed correlations for nanofluids are based on very limited experimental data, and mainly depend on the properties of the base fluid and the nanoparticle, particle volume concentration, temperature, and aspect ratio for nonspherical particles. Effects of the microscopic aggregates are not considered in most of these correlations. However, the microscale structures in the nanofluid affect macroscopic thermophysical properties, especially viscosity and thermal conductivity. Here we suggest correlations which include effects of aggregation and interfacial thermal resistance. The bulk effective dynamic viscosity for nanofluids including fractal aggregates can be calculated by the modified Krieger–Dougherty model (1959):

$$\frac{\mu_{nf}}{\mu_f} = \left(1 - \frac{\varphi_a}{\varphi_m}\right)^{-[\mu]\varphi_m} = \left(1 - \frac{\varphi/\varphi_{in}}{\varphi_m}\right)^{-[\mu]\varphi_m}, \tag{4.2.4}$$

where φ_m is the maximum particle packing fraction, which is 0.61 for rigid spherical particles at high shear rates. φ_{in} and φ_a denote the volume fraction of the particles in the aggregates and the volume fraction of the aggregates in the entire nanofluid, respectively. φ_{in} can be calculated by

$$\varphi_{in} = \left(\frac{d_a}{d_p}\right)^{D-3}. \tag{4.2.5}$$

The parameter [μ] is the intrinsic viscosity with a typical value of 2.5 for spherical nanoparticles. The fractal index D ranges from 2.4 to 1.8, depending on aggregate formations (Gharagozloo and Goodson, 2010). Normally, for spherical particles, D is 1.8. The normalized viscosity data of ethylene glycol (EG)-based and EG-water based SiO_2 nanofluids with reference to the viscosity of base fluids are presented in Figure 4.2.5. The well-known Einstein equation (Einstein, 1906) and the Batchelor equation (Batchelor, 1977) underestimate the nanofluid viscosity data by a large margin. Feng and Li (2013) showed in Figure 4.2.5 that the Krieger–Dougherty model can estimate their viscosity data relatively well if the values of φ_{in} are in the range of 5.5–16.5%.

The lower and upper limits of the nanofluid thermal conductivity can be completely determined by the serial mode and the parallel mode (Nielsen, 1978) only using volume fractions and thermal conductivities of the two phases, respectively. Hashin and Shtrikman (1963) proposed strict bounds based on the classical effective medium theory, given below for the case of $k_p/k_f > 1$:

$$k_f\left(1+\frac{3\varphi(k_p-k_f)}{3k_f+(1-\varphi)(k_p-k_f)}\right) \le k_{nf} \le k_p\left(1-\frac{3(1-\varphi)(k_p-k_f)}{3k_p-\varphi(k_p-k_f)}\right). \tag{4.2.6}$$

At the lower bound, nanoparticles are well-dispersed in the base fluid. The lower bound is basically applicable for dilute suspensions of well-dispersed noninteracting spherical particles. At the upper bound, the nanoparticles form a continuous phase with linear or chainlike particle morphologies,

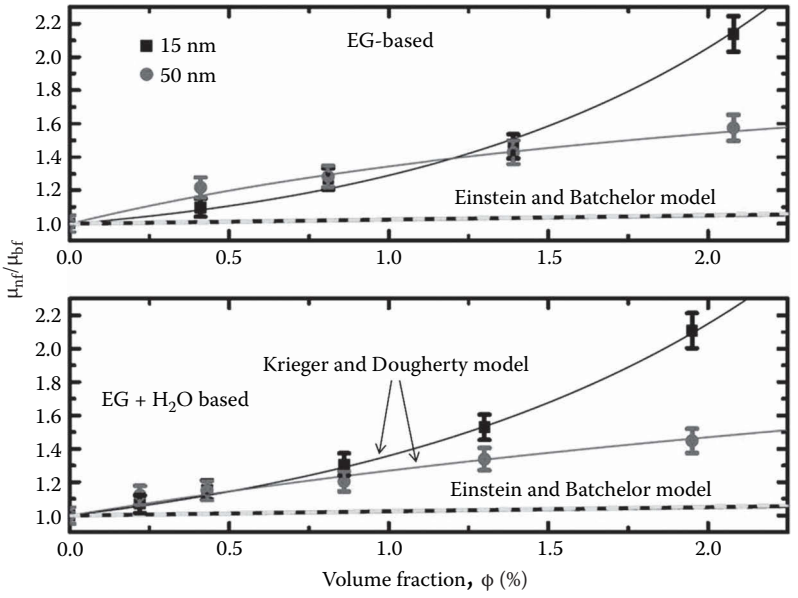

FIGURE 4.2.5 Evaluation of the Krieger–Dougherty model by EG-based and EG-water-based SiO_2 nanofluids at 20°C. The Einstein equation and the Batchelor equation are shown for comparison. (From Feng, Z.Z. and Li, W. *Int. J. Heat Mass Transfer*, 65, 919–927, 2013.)

and the base fluid becomes a dispersed phase. Figure 4.2.6 evaluates the lower and upper bounds and the Bruggeman model (Bruggeman, 1935) by the literature and experimental data of alumina/water nanofluids. The literature data from Kim et al. (2007), Timofeeva et al. (2007), and Williams et al. (2008) are shown for comparison. The primary diameter of the alumina nanoparticles is approximately 40 nm. As shown in Figure 4.2.6, considering the measurement uncertainty range, most of the data points are located near the lower bound. The thermal conductivity enhancement of Timofeeva et al. (2007) is even lower than the lower bound. One of the possible reasons might be particle cluster deposition, which decreases the nanoparticle volume fraction in the nanofluid and accordingly decreases the thermal conductivity. Figure 4.2.6 suggests that there is still a lot of room for thermal conductivity improvement by nanoparticles.

Besides the agglomeration morphology described earlier, liquid layering at the liquid–particle interface, Brownian motion, and coupled transport can also influence the thermal conductivity values (Fan and Wang, 2011). Using X-ray reflectivity, Mo et al. (2005) observed the presence of an ordered liquid layer near a nanoparticle surface by which the atomic structure of the liquid near the surface is significantly more ordered than that of bulk liquid. The thermal conductivity of ordered liquid layers tends to be larger than that of the bulk base fluid. Therefore, ordered liquid layers may enhance the effective thermal conductivity of the nanofluid by augmenting the particle effective volume fraction. Wang and Fan (2011) suggested the liquid layers offer insignificant conductivity enhancement for water-based nanofluids containing spherical particles as the liquid film thickness is only 0.28 nm for aqueous nanofluids. For nanoparticle size of the order of 10 nm, the increase in effective volume fraction induced by ordered liquid layers is only 0.1%, which contributes little. However, their presence may facilitate formation of interconnected particle agglomerations by relaxing the requirement of particle physical contact with each other. In addition, the liquid layering at the liquid–particle interface may present interfacial thermal resistance at the particle–fluid interface and among the particle–particle interface due to different nature of thermal conduction in nanoparticles and the base fluid, and thus decrease thermal conductivity enhancement.

Brownian motion can enable direct interparticle transport of heat from one particle to another and induce surrounding fluid flow and thus so-called micro-convection. The ratio of the contribution to thermal conductivity by Brownian motion and micro-convection (k_{BM}) to the base fluid conductivity (k_f) was estimated based on the kinetic theory by Evans et al. (2006).

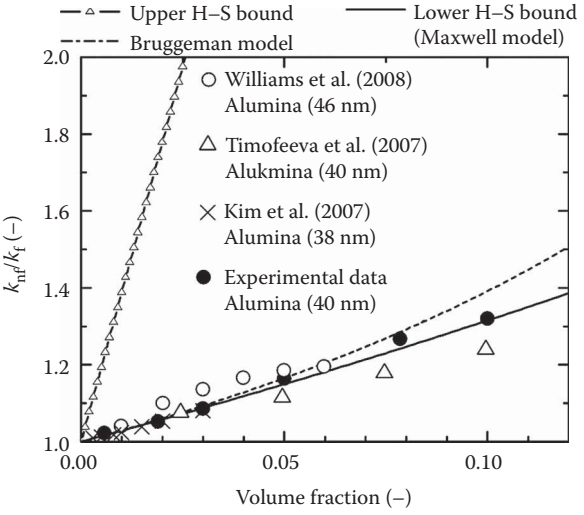

FIGURE 4.2.6 Evaluation of the lower and upper H–S bounds (Hashin and Shtrikman, 1963) and the Bruggeman model (Bruggeman, 1935) by the literature and experimental data (Wu et al., 2014) for alumina/water nanofluids.

$$\frac{k_{BM}}{k_f} = \frac{\rho_p c_{p,f} \varphi k_B T}{3\pi\mu_f d_p k_f} + \frac{k_B T}{3\pi\mu_f d_p \alpha_f}. \tag{4.2.7}$$

The contribution of Brownian motion of nanoparticles is not always important. For example, for alumina/water nanofluids with an average nanoparticle diameter of 40 nm, the contribution of Brownian motion and micro-convection can be negligible at room temperatures according to the abovementioned equation. Brownian motion becomes more important at higher temperatures for smaller particles. However, for nanofluids with surfactant additives, the operating temperature of the nanofluid is generally limited because the surfactants lose their effectiveness at high temperatures (e.g., 60°C).

Eapen et al. (2010) believed that both the Soret effect (also known as thermodiffusion or thermophoresis) and the Dufour effect (an induced heat flow caused by the concentration gradient) do not directly influence the nanofluid thermal conductivity by analyzing the orders of magnitude, but the coupled or crossed transport between them or other transport processes might affect the thermal conductivity. Wang and Fan (2011) stated that the coupled transport could change the nature of heat conduction in nanofluids from a diffusion process to a wave process, thus giving a nanofluid thermal conductivity enhancement as high as 10%.

The nanofluid thermal conductivity can be calculated by the procedure proposed by Evans et al. (2008), as shown in Figure 4.2.7. The Evans et al. procedure was later modified by Wu and Sundén (2016) to consider the effects of interfacial thermal resistance. Figure 4.2.7 briefly illustrates the calculation procedure. Aggregate consists of a few approximately linear chains (black circles) and dead ends (gray circles). The linear chains that span the whole cluster are called the backbone. The other particles are called dead ends. To calculate the nanofluid thermal conductivity, the aggregate is decomposed into dead ends with the fluid and the backbone. Thermal conductivity of the aggregate with only dead end particles, denoted as k_{nc}, can be calculated by the modified Bruggeman model:

$$\begin{aligned}\frac{k_{nc}}{k_f} = {} & \frac{1}{4}\left[\left(-2+3\varphi_{in,nc}\right)\left(\frac{k_p}{k_f\left(1+\mathrm{Bi}\right)}-1\right)+\frac{k_p}{k_f\left(1+\mathrm{Bi}\right)}\right] \\ & +\frac{1}{4}\sqrt{\left[\left(-2+3\varphi_{in,nc}\right)\left(\frac{k_p}{k_f\left(1+\mathrm{Bi}\right)}-1\right)+\frac{k_p}{k_f}\right]^2+8\frac{k_p}{k_f\left(1+\mathrm{Bi}\right)}},\end{aligned} \tag{4.2.8}$$

where the nanoparticle Biot number, $\mathrm{Bi} = 2R_k k_f/d_p$, accounts for the interfacial thermal resistance R_k. $\varphi_{in,nc}$ indicates the volume fraction of the dead end nanoparticles. By assuming that the backbone

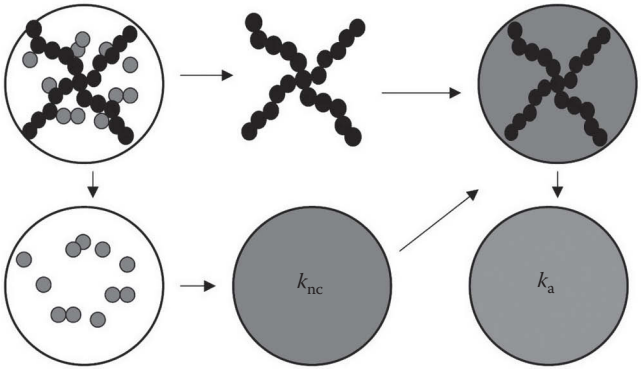

FIGURE 4.2.7 Illustrations of an aggregate and the calculation procedure for thermal conductivity proposed by Evans et al. (2008). (From Evans, W. et al., *Int. J. Heat Mass Transfer*, 51(5), 1431–1438, 2008.)

is embedded in a medium with an effective conductivity of k_{nc}, the effective thermal conductivity of the aggregate including both dead ends and linear chains can be calculated by the Nan et al. model (Nan et al., 2003).

$$\frac{k_a}{k_{nc}} = \frac{3+\varphi_{in,c}\left[2\beta_x\left(1-L_x\right)+\beta_z\left(1-L_z\right)\right]}{3-\varphi_{in,c}\left[2\beta_x L_x+\beta_z L_z\right]}, \tag{4.2.9}$$

where $\varphi_{in,c}$ is the volume fraction of the linear chains. Please refer to Evans et al. (2008) for details to determine $\varphi_{in,nc}$ and $\varphi_{in,c}$. The volume fraction of the nanoparticles in the aggregates (φ_{in}) is the addition of the volume fraction of the dead end particles in the aggregate ($\varphi_{in,nc}$) and the volume fraction of the linear chains in the aggregate ($\varphi_{in,c}$):

$$\varphi_{in} = \varphi_{in,nc} + \varphi_{in,c}. \tag{4.2.10}$$

The parameters β_x and β_z are calculated by

$$\beta_x = \frac{k_x - k_{nc}}{k_{nc} + L_x\left(k_p - k_{nc}\right)}, \tag{4.2.11}$$

$$\beta_z = \frac{k_z - k_{nc}}{k_{nc} + L_z\left(k_p - k_{nc}\right)}, \tag{4.2.12}$$

$$k_x = \frac{k_p}{1+\left(2+1/p\right)\mathrm{Bi}\cdot L_x k_p / k_f}, \tag{4.2.13}$$

$$k_z = \frac{k_p}{1+\left(2+1/p\right)\mathrm{Bi}\cdot L_z k_p / k_f}, \tag{4.2.14}$$

$$L_x = \frac{p^2}{2\left(p^2-1\right)} - \frac{p}{2\left(p^2-1\right)^{3/2}}\cosh^{-1} p \quad \text{for } p>1, \tag{4.2.15}$$

where p is the aspect ratio. For aggregate linear chains, the aspect ratio is given as $p = d_a/d_p$:

$$L_z = 1-2L_x. \tag{4.2.16}$$

Finally, the effective thermal conductivity of the whole nanofluid is calculated by the Maxwell–Garnet model (Levy and Stroud, 1997), as given below:

$$\frac{k_{nf}}{k_f} = \frac{k_a + 2k_f + 2\varphi_a\left[k_a - k_f\right]}{k_a + 2k_f - \varphi_a\left(k_a - k_f\right)}. \tag{4.2.17}$$

Besides, macroscopic properties such as viscosity and thermal conductivity can give some information about the microscopic aggregates. Specifically, from the modified Bruggeman model and the viscosity data, information of φ_{in} (i.e., the volume fraction of the particles in the aggregates) can be obtained. Based on φ_{in}, the modified Evans et al. model, and the thermal conductivity data, the interfacial thermal resistance can be estimated.

Properties of Nanofluids in Heat Exchangers

This part aims to briefly present our experimental investigations on heat transfer and pressure drop characteristics of nanofluids in complex geometries and heat exchangers. A schematic of the experimental setup is shown in Figure 4.2.8. Please refer to Wu et al. (2013) for a detailed description of the

test rig. It consists of two loops, for the cold and hot fluids, respectively. The hot water or nanofluid runs in the hot closed loop, while cold water is forced in the cold open loop. Water or nanofluid is heated in a 50-L reservoir by an imbedded electric heater of 6 kW fixed at the bottom of the reservoir. Each loop has two rotameters of small and large ranges for accurate flow rate measurement. A differential pressure transducer with an accuracy of ±0.075% of the set span was used to measure the pressure drop of the nanofluid side. All rotameters were calibrated for water and nanofluids of different type and concentrations at different temperatures by using a stopwatch and measuring cylinders. The inlet and outlet temperatures of the inner tube and the annulus were measured by four calibrated copper–constantan thermocouples with an accuracy of ±0.1 K, respectively. Three heat exchangers were tested, that is, one double-pipe helical heat exchanger and two chevron PHEs. The heat exchangers were thermally insulated to reduce heat losses to the ambient. Geometrical parameters of the helically coiled tube and the corrugated plate are detailed in Table 4.2.2. Uncertainties of all relevant parameters are listed in Table 4.2.3.

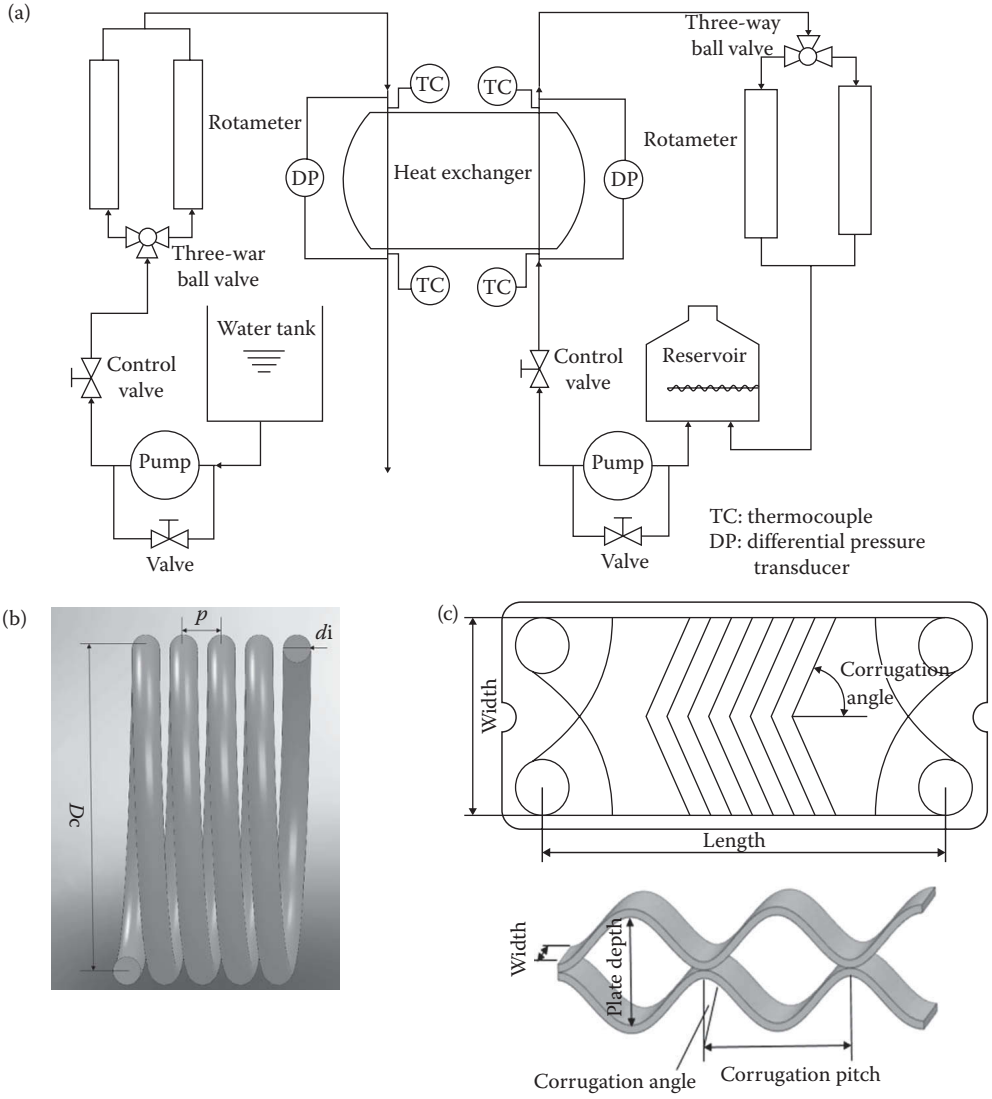

FIGURE 4.2.8 Schematics of (a) the test rig, (b) helically coiled tube, and (c) corrugated plate.

TABLE 4.2.2
Geometrical Parameters of the Tested Double-Pipe Helical Heat Exchanger and the Two Chevron Plate Heat Exchangers

Parameters	Values	
	Helical Heat Exchanger	
Inside diameter of the inner tube	13.28 mm	
Inside diameter of the outer tube	26.0 mm	
Number of turns	4.5	
Coil diameter of curvature (D_c)	254 mm	
Pitch of the helical coil (p)	34.5 mm	
Tube length	3.591 m	
	PHE I	**PHE II**
Plate length, L	0.154 m	0.154 m
Plate width, w	0.07 m	0.07 m
Plate depth, $2b_c$	0.004 m	0.00382 m
Plate thickness, δ	0.0003 m	0.00025 m
Heat-transfer area per plate	0.0132 m^2	0.0132 m^2
Corrugation pitch	0.006 m	0.007 m
Corrugation angle	60°	65°
Number of plates	20	10
Surface enlargement ratio	1.2375	1.22

TABLE 4.2.3
Uncertainties Estimation of Relevant Parameters

Primary measurements	
Diameter	±0.05 mm
Length/Width	±0.2 mm
Temperature	±0.1 K
Dependent quantities	
Mass flow rate m, kg s^{-1}	±2.0%
Heat flux q, W m^{-2}	±5.2%
LMTD, K	±1.5%
Apparent Darcy friction factor f_{app}	±3.5%
Heat-transfer coefficient h, W m^{-2} K^{-1}	±5.4%

Three types of nanofluids were tested, that is, γ-Al_2O_3/water nanofluids of six concentrations, multiwalled carbon nanotube (MWCNT)/water nanofluids of three concentrations, and a hybrid γ-Al_2O_3 + MWCNT/water nanofluid. Untreated concentrated γ-Al_2O_3/water nanofluid with spherical alumina nanoparticles of 40-nm mean diameter was purchased from a commercial company (Nanophase Technologies Corporation, US). No surfactants were added in the nanofluid. Different amounts of concentrated nanofluid were diluted in water to obtain nanofluids with low concentrations. The diluted nanofluid mixture was mechanically stirred for 0.5 h followed by ultrasonic vibration for 3 h. The pH value of the prepared alumina nanofluid is about 3–3.5, which is far away from the isoelectric point of alumina nanofluid to maintain colloidal stability.

An aqueous MWCNT suspension of 1.0% mass fraction was purchased from a commercial company (Nanocyl, Belgium). The suspension consists of thin MWCNTs dispersed in deionized (DI) water (97% mass fraction) and surfactant sodium dodecyl benzene sulfonate (SDBS, 2.0% mass fraction).

TABLE 4.2.4
Measured Thermal Conductivity and Viscosity of the Ten Nanofluids

Nanofluids	Volume Concentration (Weight Concentration)	Thermal Conductivity Enhancement (%)	Viscosity Enhancement (%)
γ-Al_2O_3/water nanofluid	0.2 vol% (0.78 wt%)	0.96	0.15
	0.56 vol% (2.18 wt%)	2.25	0.59
	1.02 vol% (3.89 wt%)	3.25	5.68
	1.5 vol% (5.68 wt%)	4.31	11.11
	1.88 vol% (7.04 wt%)	5.16	13.68
	2.84 vol% (10.56 wt%)	8.1	20
MWCNT/water nanofluid	0.0111 vol% (0.02 wt%)	0.07	12.99
	0.0278 vol% (0.05 wt%)	0.2	15.87
	0.0555 vol% (0.1 wt%)	0.42	20.66
Hybrid Al_2O_3+MWCNT/water nanofluid	1.89 vol% Al_2O_3/water + 0.0111 vol% MWCNT/water at a volume ratio of 1:2.5	4.4	10.8

The MWCNT, produced via the catalytic carbon vapor deposition process, has an average length of 1.5 μm and an average diameter of 9.5 nm, with an average aspect ratio of 158. The surface area of the MWCNT is 250–300 m^2/g. The carbon purity of the MWCNTs is 90%, while the remaining 10% is metal oxide. Similar to alumina nanofluid, different amounts of concentrated nanofluid were diluted in water to obtain MWCNT/water nanofluids with different fractions. The diluted nanofluid mixture was mechanically stirred for 10 min followed by ultrasonic vibration for 1 h. The pH values of the prepared MWCNT/water nanofluids are in the range 7.0–8.0.

The hybrid nanofluid mixture was obtained by mixing the 1.89 vol.% Al_2O_3/water nanofluid and the 0.0111 vol.% MWCNT/water nanofluid at a volume ratio of 1:2.5 and ultrasonically vibrated for 3 h. The equivalent volume concentration of Al_2O_3 nanoparticles in the hybrid nanofluid mixture is 1.48%. Each prepared nanofluid was immediately tested in the heat exchanger within 2 days after the nanofluid preparation.

The thermal conductivity (λ) and viscosity (μ) of the 10 nanofluids were experimentally measured. A thermal constants analyzer (TPS 2500S from Hot Disk AB, Sweden) using the transient plane source method (TPS) was employed to measure the thermal conductivity. The thermal conductivity uncertainty was estimated, from the standard deviations of experimental data and departures from literature data, to be lower than 3.0%. A rotational rheometer HAAKE RS6000 (Thermo Fisher Scientific Inc., US) was used to measure the rheology behavior of those nanofluids. The standard deviation of the measured dynamic viscosity data of water (the base fluid) and departures from the literature data is <3.0%. The measured thermal conductivity and viscosity data of the nanofluids are listed in Table 4.2.4.

Results of Nanofluids in a Double-Pipe Helical Heat Exchanger

Figure 4.2.9 shows the relationship between the apparent Darcy friction factor f_{app} and the Reynolds number Re_b for water and eight nanofluids. The subscript "b" indicates that the properties were calculated at the average bulk temperature. The average bulk temperature was estimated from the inner-tube inlet and outlet temperatures. The apparent Darcy friction factor was calculated by the following equation:

$$x_{1,2} = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}. \tag{4.2.18}$$

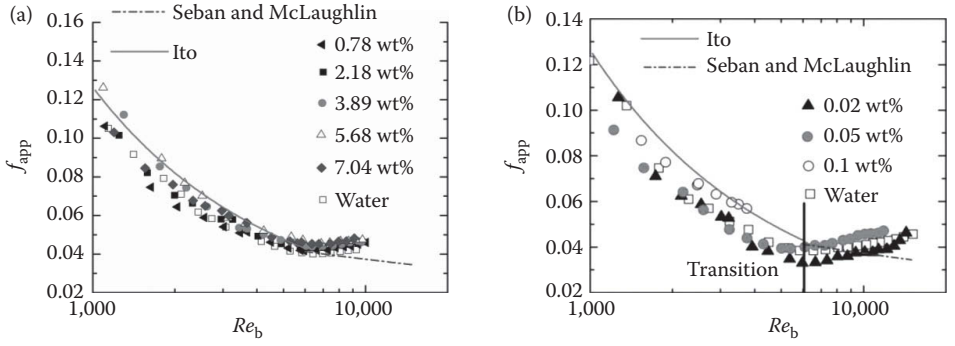

FIGURE 4.2.9 The f_{app}–Re_b relationship for water and the tested alumina/water and MWCNT/water nanofluids. The Ito (1969) equation and the Seban and McLaughlin (1963) equation were drawn for comparison. (a) Alumina nanofluid and (b) MWCNT nanofluid. (Data from Wu, Z. et al., *Appl. Therm. Eng.*, 60(1), 266–274, 2013; Wu, Z. et al., *Appl. Therm. Eng.*, 96, 364–371, 2016.)

The apparent friction factor decreases with Re_b when $Re_b < 6000$, while it increases slowly when $Re_b > 6000$. The transitional Reynolds number from laminar flow to turbulent flow is approximately 6000 for water and the nanofluids. Therefore, the transitional velocity of the nanofluids will be larger than that of water due to the larger viscosity of the former compared to the latter. It suggests that nanoparticles might stabilize the flow in helically coiled tubes. No obvious difference exists among the five alumina nanofluids, especially in laminar flow. For MWCNT/water nanofluid in laminar flow, the apparent friction factor for the 0.1 wt% nanofluid is the largest among the three tested MWCNT nanofluids mainly due to its higher increase in viscosity. As shown in Figure 4.2.9, the Ito (1969) equation and the Seban and McLaughlin (1963) equation can predict the experimental data relatively well for laminar flow and turbulent flow, respectively. For turbulent flow, the Seban and McLaughlin equation predicts a decreasing trend with Reynolds number, while our data points show an increasing trend. A possible reason might be that the data points are still located in the transition region. Besides, the Seban and McLaughlin equation also underestimates the friction factor for water in the previous literature for turbulent flow.

Figure 4.2.10 demonstrates the relationship between $Nu_b(Pr_b)^{-0.4}$ and the inner tube Dean number De_b ($=Re_b(d_i/D_c)^{0.5}$) for laminar flow. All properties used in the dimensionless numbers were calculated at the average bulk temperature. The measured nanofluid properties were used.

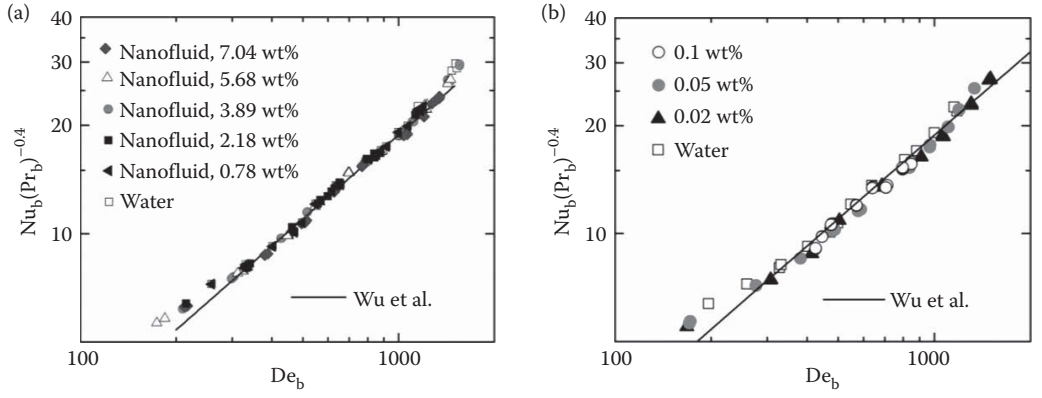

FIGURE 4.2.10 $Nu_b(Pr_b)^{-0.4}$ vs. De_b for laminar flow against the Wu et al. (2013) correlation. (a) Alumina nanofluid and (b) MWCNT nanofluid. (Data from Wu, Z. et al., *Appl. Therm. Eng.*, 60(1), 266–274, 2013; Wu, Z. et al., *Appl. Therm. Eng.*, 96, 364–371, 2016.)

Temperature effects were accounted for in the Prandtl number Pr_b. As shown in Figure 4.2.10, the Nusselt number increases with the Dean number. Water, the five alumina nanofluids, and the three MWCNT nanofluids present very similar heat-transfer characteristics. This indicates that the net effect of nanoparticles (alumina or MWCNT) on the heat-transfer performance in helically coiled tubes is probably insignificant. The thermal conductivity increase by nanoparticles is beneficial for heat transfer, whereas the secondary flow intensity induced by centrifugal forces might be mitigated by nanoparticles due to the larger viscosity and density of the nanofluid compared to those of the base fluid. Besides, the Wu et al. (2013) correlation, originally developed based on water and alumina/water nanofluid data in helically coiled tubes, can also predict the heat-transfer performance of MWCNT/water nanofluid very well.

Figure 4.2.11 presents the relationship between $Nu_b(Pr_b)^{-0.4}$ and the inner tube Reynolds number Re_b for the turbulent flow. It is clear that $Nu_b(Pr_b)^{-0.4}$ increases with Re_b and the eight nanofluids and water show very similar trends. The Seban and McLaughlin (1963) correlation can predict the thermal behavior of water and nanofluids very accurately, with a mean absolute error and a standard deviation of 2.63 and 3.25%, respectively. The existing correlation can accurately reproduce the turbulent convective heat-transfer behavior of nanofluids in helically coiled tubes by adopting the measured properties of the nanofluids in the analysis. Based on our experimental analysis, no anomalous heat-transfer enhancement exists in our cases for both laminar flow and turbulent flow.

Heat-transfer enhancement comparison for nanofluids over their base fluids based on equal Reynolds number can be misleading and tends to overestimate the actual heat-transfer enhancement largely. Figure 4.2.12 demonstrates two performance comparison criteria for the tested alumina nanofluids, that is, based on equal Reynolds number and equal flow velocity. The viscosity in the Reynolds number of Figure 4.2.12a was calculated by the Williams et al. (2008) correlation. Over 40% heat-transfer enhancement can be obtained for the 7.04% wt. nanofluid compared to water for the equal Reynolds number basis, as shown in Figure 4.2.12a. However, from Figure 4.2.12b at the same flow velocity, the heat-transfer enhancement of nanofluids over the base fluid is much less than that based on the equal Reynolds number. Thus, the anomalous heat-transfer enhancement shown in Figure 4.2.12a is just an analysis artifact. The method based on the equal Reynolds number comparison should not be used. Figure 4.2.13 shows heat-transfer coefficient comparisons for water and MWCNT nanofluids using two criteria: the fixed flow velocity and the fixed pumping power. Pumping power is calculated by the product of ΔP and the volume flow rate. The heat transfer was not enhanced by addition of MWCNTs based on the two criteria. On the contrary, the h_{nf} values are $<h_f$ except at very low flow velocities.

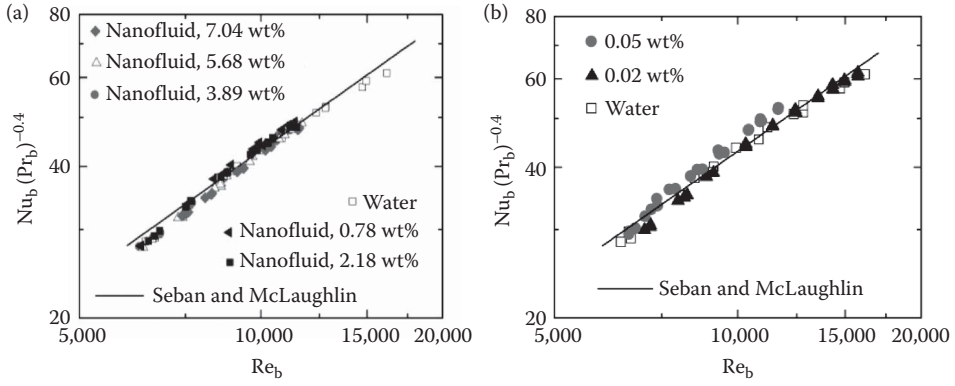

FIGURE 4.2.11 $Nu_b(Pr_b)^{-0.4}$ vs. Re_b for turbulent flow against the Seban and McLaughlin (1963) equation. (a) Alumina nanofluid and (b) MWCNT nanofluid. (Data from Wu, Z. et al., *Appl. Therm. Eng.*, 60(1), 266–274, 2013; Wu, Z. et al., *Appl. Therm. Eng.*, 96, 364–371, 2016.)

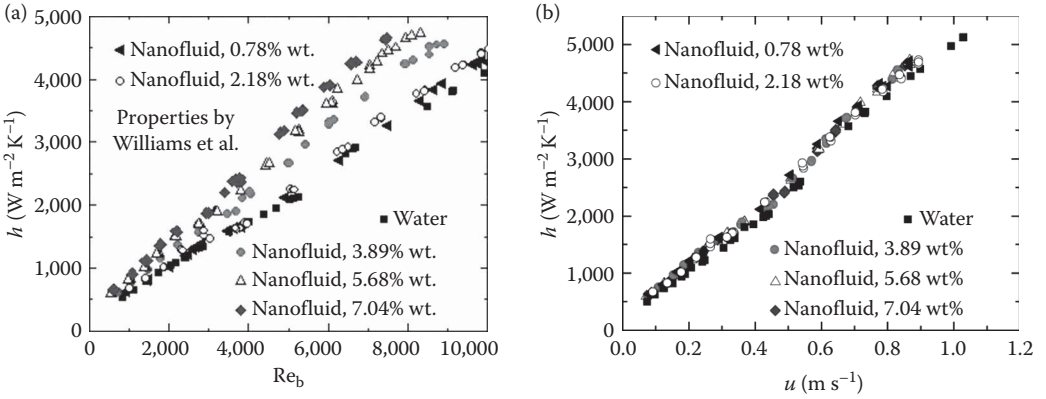

FIGURE 4.2.12 Heat-transfer coefficient comparisons: (a) h vs. Re_b for the constant Reynolds number basis, with dynamic viscosity calculated by the Williams et al. (2008) equation and (b) h vs. u for the constant flow velocity basis. (From Wu, Z. et al., *Appl. Therm. Eng.*, 60(1), 266–274, 2013.)

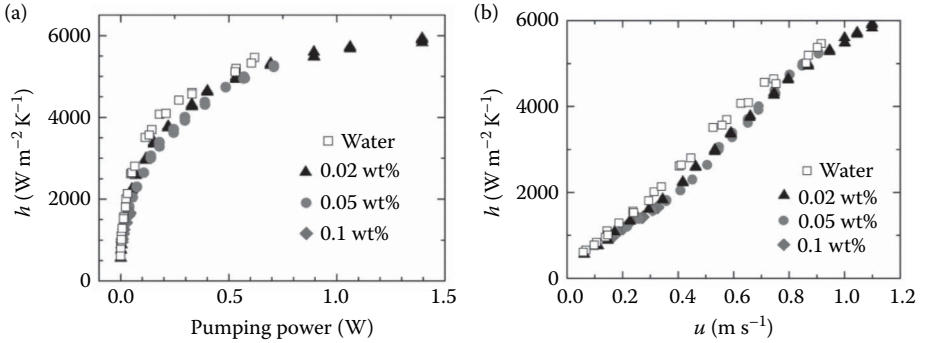

FIGURE 4.2.13 Heat-transfer coefficient comparison for water and MWCNT nanofluids at (a) a fixed flow velocity and (b) a fixed pumping power. (From Wu, Z. et al., *Appl. Therm. Eng.*, 96, 364–371, 2016.)

The heat transfer degradation in the tested MWCNT nanofluids is mainly due to the low enhancement of the thermal conductivity and the high increase of the viscosity.

Results of Nanofluids in a PHE

The relationship between the measured pressure drop (ΔP) across the PHE I and the volume flow rate for nanofluids and water is depicted in Figure 4.2.14. The pressure drop is related to the thermophysical properties, flow velocity, and the geometry of the PHE I. As shown in Figure 4.2.14, the pressure drop of nanofluids is a little bit larger than that of water and seems to increase with increasing particle volume concentrations due to the increase in viscosity. However, there is no much difference between the pressure drop of nanofluids and that of water as the particle volume concentration is low. In Figure 4.2.15, the friction factor f is plotted versus the dimensionless number Re_e for both nanofluids and water. A correlation for predicting the friction factor is found to be: $f = 20.202Re_e^{-0.191}$, where the dimensionless number Re_e is based on the equivalent diameter, $D_e = 2b_c$. It shows that all the experimental data are located within the ±10% error band. The correlation is in good agreement with the experimental data and can predict the friction factor of nanofluids flowing in PHEs. Pantzali et al. (2009) experimentally investigated the heat-transfer performance of CuO–water nanofluids in a chevron-type PHE. The experimental friction factor

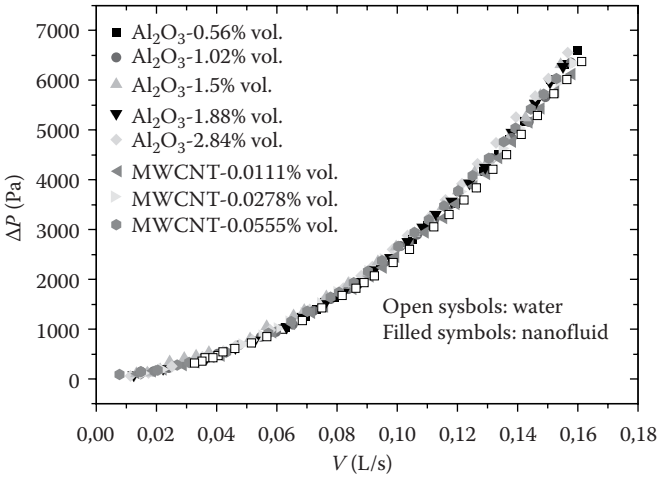

FIGURE 4.2.14 Measured pressure drop vs. the volumetric flow rate. (From Huang, D. et al., *Int. Commun. Heat Mass Transfer*, 63, 54–61, 2015.)

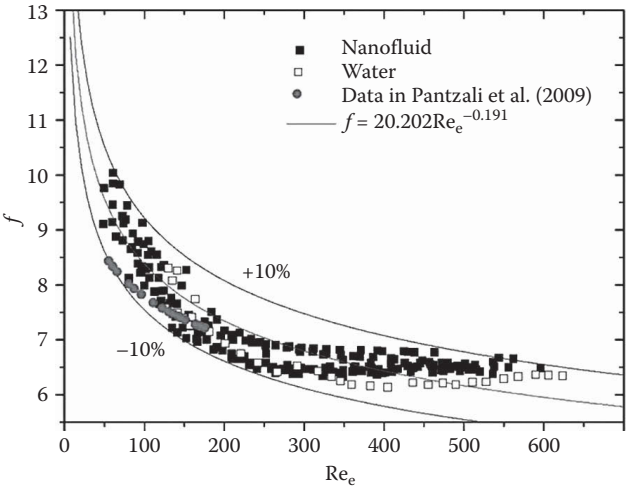

FIGURE 4.2.15 Comparison between experimental and predictive f values. (From Huang, D. et al., *Int. Commun. Heat Mass Transfer*, 63, 54–61, 2015.)

values of Pantzali et al. (2009) are also presented in Figure 4.2.15 for comparison. It shows that data of Pantzali et al. (2009) are also within the ±10% error band.

Figures 4.2.16 and 4.2.17 depict the heat-transfer performances of Al_2O_3–water nanofluids and MWCNT/water nanofluids versus Re_e and u, respectively. The Nusselt number increases with increasing Re_e. The heat-transfer coefficient increases with increasing u. Nanofluids of different volume concentrations show similar heat-transfer performances. When compared based on the equal Reynolds number, Figures 4.2.16a and 4.2.17a show that the nanofluids can always enhance heat transfer. However, the heat transfer is not improved at all if the comparison is based on a constant flow velocity. Besides, the heat transfer deterioration increases as flow velocity increases. One possible reason is that the increase in viscosity by nanoparticle additives will suppress the turbulence at high flow velocity, while the relatively small increase in thermal conductivity is not able to compensate this suppression. Also, the specific heat (c_p) decreases by adding nanoparticles. Thus the heat-transfer coefficient of nanofluids is lower than that of water at a constant flow velocity.

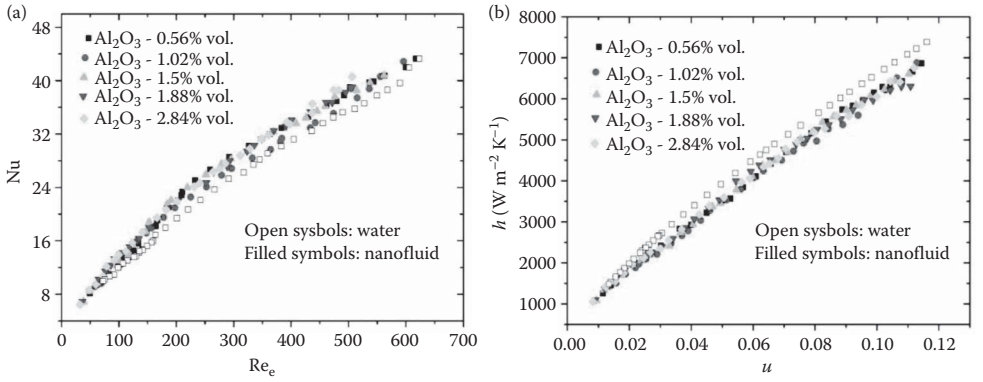

FIGURE 4.2.16 Heat-transfer performance of alumina/water nanofluids in PHE I (a) variation of Nusselt number with Reynolds number (b) variation of Heat-Transfer Coefficient (HTC) with flow velocity. (From Huang, D. et al., *Int. Commun. Heat Mass Transfer*, 63, 54–61, 2015.)

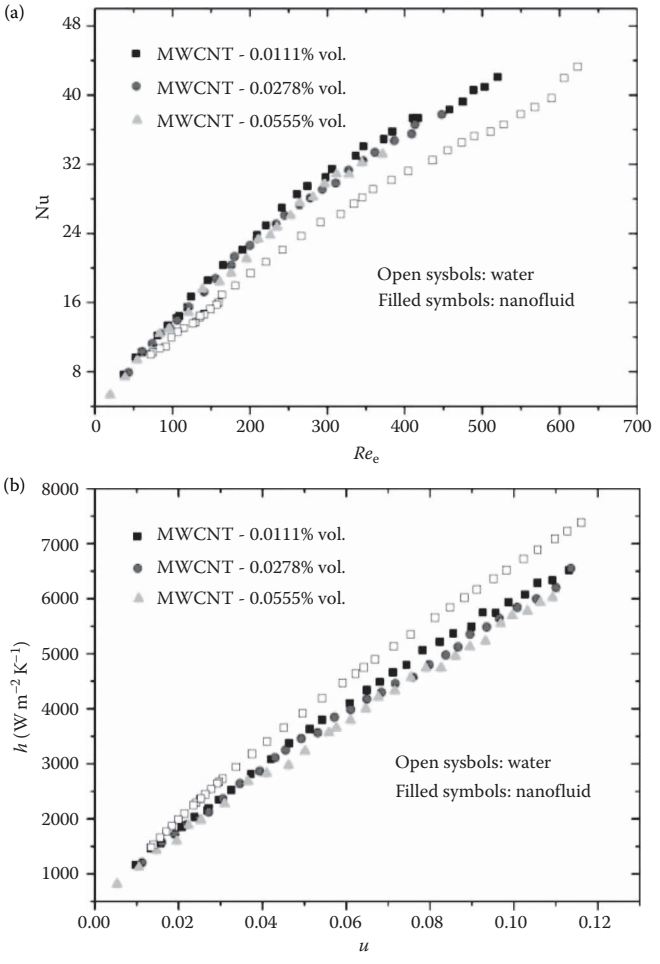

FIGURE 4.2.17 Heat-transfer performance of MWCNT/water nanofluids in PHE I (a) variation of Nusselt number with Reynolds number and (b) variation of heat-transfer coefficient with flow velocity. (From Huang, D. et al., *Int. Commun. Heat Mass Transfer*, 63, 54–61, 2015.)

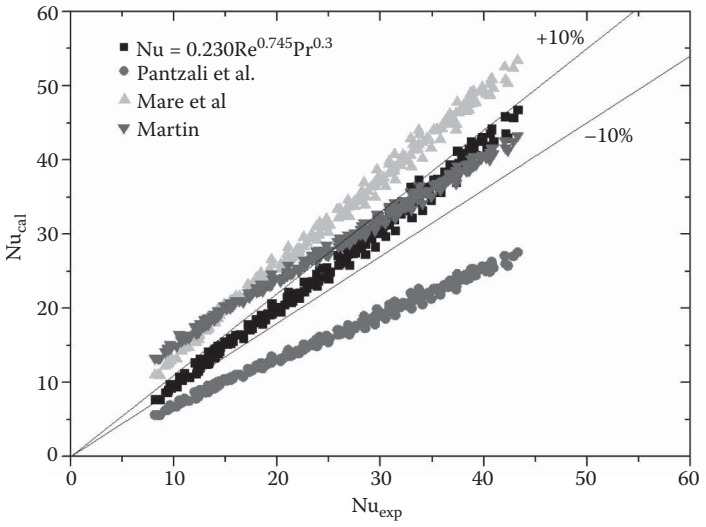

FIGURE 4.2.18 Comparison of the new correlation and three existing correlations. (From Huang, D. et al., *Int. Commun. Heat Mass Transfer*, 63, 54–61, 2015.)

A new correlation was proposed based on the experimental data. Comparison of the experimental Nu values with the predicted Nu values based on the newly proposed correlation (Huang et al., 2015) is given in Figure 4.2.18. Another three empirical correlations, Martin (1996), Pantzali et al. (2009), and Maré et al. (2011) are also shown for comparison. The newly developed correlation provides the best prediction as all the experimental data points are located within the ±10% error band. Martin (1996) predicts the experimental data very well especially at high Nusselt numbers, while the deviation is very large at low Nusselt numbers, as the correlation proposed by Martin (1996) was obtained at a Reynolds number range of $60 < Re < 30000$. The correlations proposed by Pantzali et al. (2009) and Maré et al. (2011) show large deviations from the experimental data, with the Pantzali et al. correlation underestimating the experimental data and the Maré et al. correlation overestimating the experimental data. The over- or underestimation may be caused by the different geometrical parameters and manufacturing variations of PHEs.

Results of Hybrid Nanofluids in a PHE

Hybrid nanofluid is a new kind of nanofluid, including two different types of nanoparticles. Han et al. (2007) proposed a hybrid sphere/carbon nanotube (CNT) particle, consisting of numerous CNTs attached to an alumina/iron oxide sphere, for applications in nanofluids. In such hybrid nanoparticles, heat is expected to transport rapidly from one CNT to another through the center sphere and thus leading to less thermal contact resistance between CNTs when compared to simple CNTs dispersed in fluids. CNTs have an extremely high thermal conductivity, but thermal resistance between the CNTs and the fluid has limited their performance in nanofluids. The proposed hybrid sphere/CNT particles are synthesized by spray pyrolysis followed by catalytic growth of CNTs. The spheres are about 70 nm in diameter on average, and the attached CNTs have a length up to 2 μm. The mass fraction of each component in these hybrid sphere/CNT particles is as follows: CNT ~ 3 wt%, alumina ~ 32 wt%, and iron oxide ~ 65 wt%. These hybrid nanoparticles are dispersed to poly-alpha-olefin with sonication and a small amount of surfactants to form stable nanofluids. The thermal conductivity of the fluids has been measured by a 3ω-wire method over a temperature range of 10–90°C. The results indicate that the effective thermal conductivity of the fluids is increased by about 21% at room temperature for a particle volume fraction of 0.2%.

Suresh et al. (2011) synthesized nanocrystalline alumina–copper hybrid powder by a thermochemical synthesis method. The hybrid nanofluids were prepared by dispersing the hybrid powder into deionized water. Sodium lauryl sulpfate (SLS) was used as a dispersant to get a stable suspension. The Al_2O_3–Cu/water nanofluids behave as Newtonian fluids. Figure 4.2.19 presents the thermal conductivity and viscosity data of the hybrid nanofluids compared to those of alumina nanofluids at the same concentration. Both thermal conductivity and viscosity increase with increasing nanoparticle volume fractions. The hybrid nanofluids have higher thermal conductivity and viscosity values than the alumina nanofluids.

As hybrid nanofluids seem to give a significant enhancement in thermal conductivity, the heat-transfer performance of hybrid nanofluids was experimentally investigated in PHE II. Preparation and properties of the alumina + MWCNT/water hybrid nanofluid were given earlier. As shown in Figure 4.2.20, the heat-transfer coefficient increases with increasing flow velocity. The heat-transfer

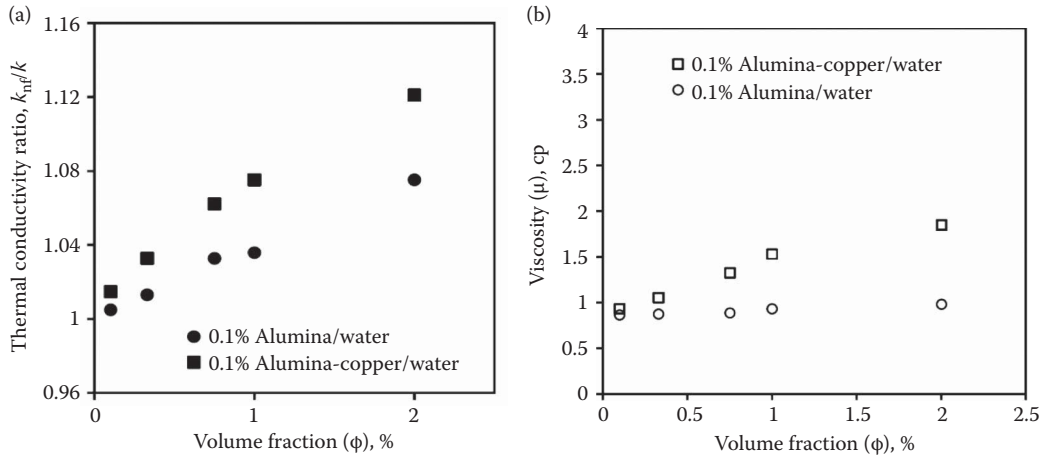

FIGURE 4.2.19 (a) Thermal conductivity and (b) viscosity of the alumina–copper/water hybrid nanofluids as a function of particle volume concentration. (From Suresh, S. et al., *Colloids Surf. A*, 388(1), 41–48, 2011.)

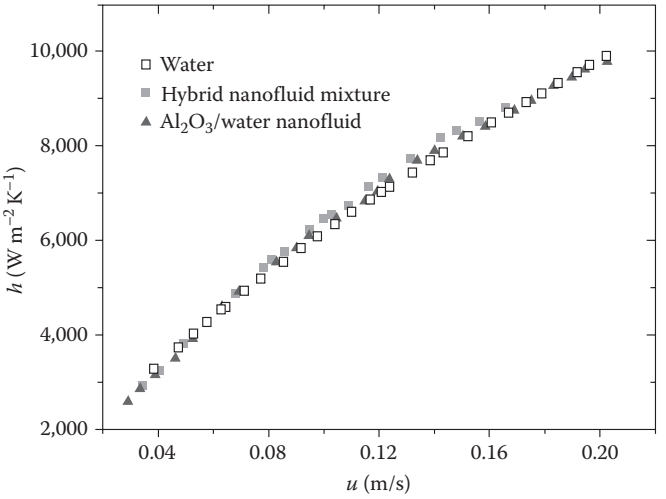

FIGURE 4.2.20 Variation of HTC versus flow velocity for hybrid nanofluids. (From Huang, D. et al., *Exp. Therm. Fluid Sci.*, 72, 190–196, 2016.)

coefficient of the hybrid nanofluid mixture seems to be slightly larger than that of the Al_2O_3/water nanofluid and water, indicating an enhanced heat transfer by using hybrid nanofluid mixture. However, it should be noted that the heat-transfer enhancement is less than that reported in Sundar et al. (2014) and Madhesh et al. (2014) and the increase in heat transfer is within the error range. This might be due to the different preparation methods of nanofluids: the hybrid nanofluid mixture was prepared by mixing the Al_2O_3/water nanofluid and MWCNT/water nanofluid in this work. Thus the alumina particles and MWCNTs might not be able to combine perfectly, and accordingly the thermal resistance between the nanostructures and fluids could not be reduced effectively.

The relationship between the measured pressure drop (ΔP) across the PHE II and the volumetric flow rate for the hybrid nanofluid mixture, Al_2O_3/water nanofluid and water is depicted in Figure 4.2.21. The pressure drop is related to the thermophysical properties, flow velocity, and the geometry of the PHE. As shown in Figure 4.2.21, pressure drop of the hybrid nanofluid is slightly less than that of the Al_2O_3/water nanofluid and slightly higher than that of water. The nanoparticle clusters in the hybrid nanofluid mixture might increase the hydrodynamic diameter of nanoparticles and thus cause the increase in viscosity and the increase in pressure drop. When evaluating the effects of nanofluids in PHEs, a comparison in terms of the pumping power and heat-transfer coefficient is necessary. The relationship between heat-transfer coefficient and pumping power is presented in Figure 4.2.22. It is observed that the hybrid nanofluid mixture seems to exhibit the highest heat-transfer coefficient at a given power consumption. This indicates that the hybrid nanofluid mixture might be a promising working fluid in heat-transfer applications as it has better heat-transfer performance than water and the Al_2O_3/water nanofluid but only with a small pressure drop penalty.

From our experimental studies in heat exchangers, it seems that nanofluid is not favorable for heat-transfer enhancement in heat exchangers when taking the pumping power into account. The primary reason is the significant increase in viscosity and only a moderate increase in thermal conductivity of the nanofluids compared to base fluids. In addition, the intensity of the turbulence produced by the complex or enhanced geometries in heat exchangers might be mitigated by nanoparticles due to their large inertia. Besides, the slip mechanisms such as Brownian diffusion and thermophoresis are relatively unimportant compared to convective transport in these applications. New types of nanofluids such as hybrid nanofluids need to be developed in order to benefit the thermal performance of heat exchangers.

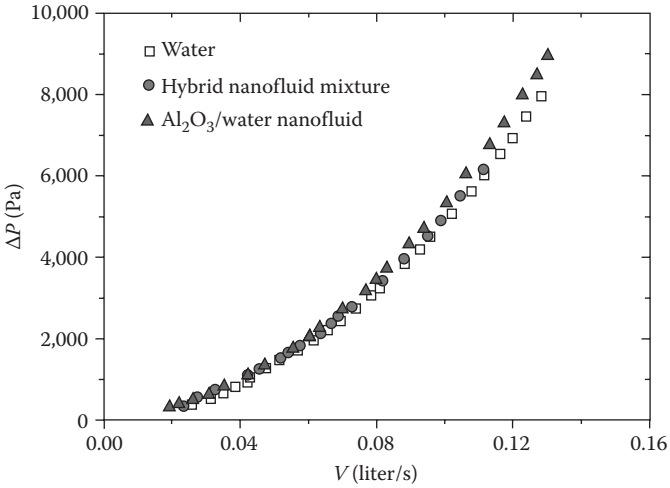

FIGURE 4.2.21 Measured pressure drop vs. the volumetric flow rate for hybrid nanofluids. (From Huang, D. et al., *Exp. Therm. Fluid Sci.*, 72, 190–196, 2016.)

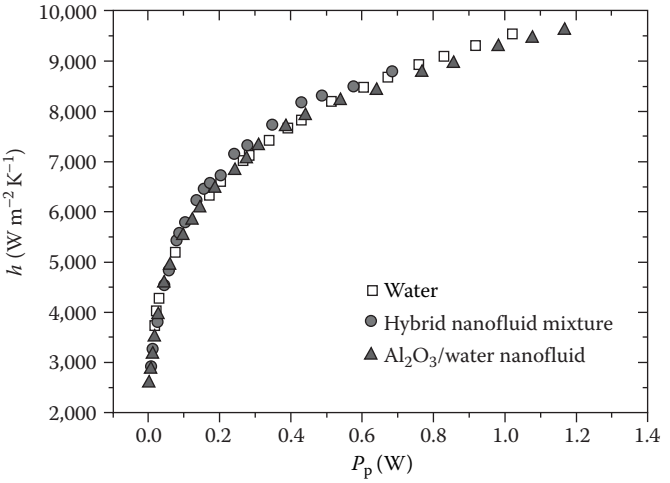

FIGURE 4.2.22 Heat-transfer coefficient vs. pumping power for hybrid nanofluids. (From Huang, D. et al., *Exp. Therm. Fluid Sci.*, 72, 190–196, 2016.)

Performance of Nanofluids in Heat Pipe Evaporators

The earlier results are for nanofluid flow in heat exchangers without phase change. Nanofluid boiling and evaporation has shown potential to increase heat transfer and critical heat flux (Coursey and Kim, 2008; Kim et al., 2010; Kwark et al. 2012; Sayahi and Bahrami, 2016). One likely mechanism for enhancement is the formation of nanoparticle deposition layers during the boiling/evaporation process, which provide more nucleation sites and also modify the surface wettability (Wu and Sundén, 2014). Up to now, there are only very few works on nanofluid boiling/evaporation in heat exchangers. Heat pipes are heat-transfer devices that combine the principles of both thermal conductivity and phase transition to efficiently manage the transfer of heat between two solid interfaces. They can easily be implemented as heat exchangers in many heat-transfer processes. Studies (e.g., Ma et al., 2006; Liu et al., 2007; Kang et al., 2009; Do and Jang, 2010; Hung et al., 2013; Kole and Dey, 2013; Karthikeyan et al., 2014; Putra et al., 2015) suggest that nanofluid can significantly enhance the thermal performance of heat pipes.

Qu et al. (2010) investigated the effects of spherical Al_2O_3 nanoparticles of 56 nm in diameter on the thermal performance of an oscillating heat pipe (OHP) charged with base water. The experimental rig is shown in Figure 4.2.23. The tested OHP was made of a bending stainless steel capillary tube with inner and outer diameters of 2 and 3 mm, respectively. The vertically oriented OHP consists of evaporation, adiabatic, and condensation sections with 50, 105, and 70 mm in length, respectively. The evaporation section (evaporator) was electrically heated, and the condensation section (condenser) was cooled by water which pumped from the cold bath. Figure 4.2.24 shows the thermal resistance (R) of the alumina nanofluid-charged OHP as a function of the power input (Q). The thermal resistance in Figure 4.2.24 is calculated by

$$R = \frac{T_{\text{evap}} - T_{\text{cond}}}{Q}, \tag{4.2.19}$$

where T_{evap} and T_{cond} denote the average wall temperatures of the evaporator and condenser, respectively. It can be seen that: (1) the thermal resistance apparently decreased for nanofluids, that is, the addition of alumina nanoparticles enhanced the heat transport capability of the OHP; (2) the thermal resistance depended greatly on the filling ratio (FR), and the lower FR led to a smaller thermal resistance; and (3) the thermal resistance decreased with increasing weight concentrations

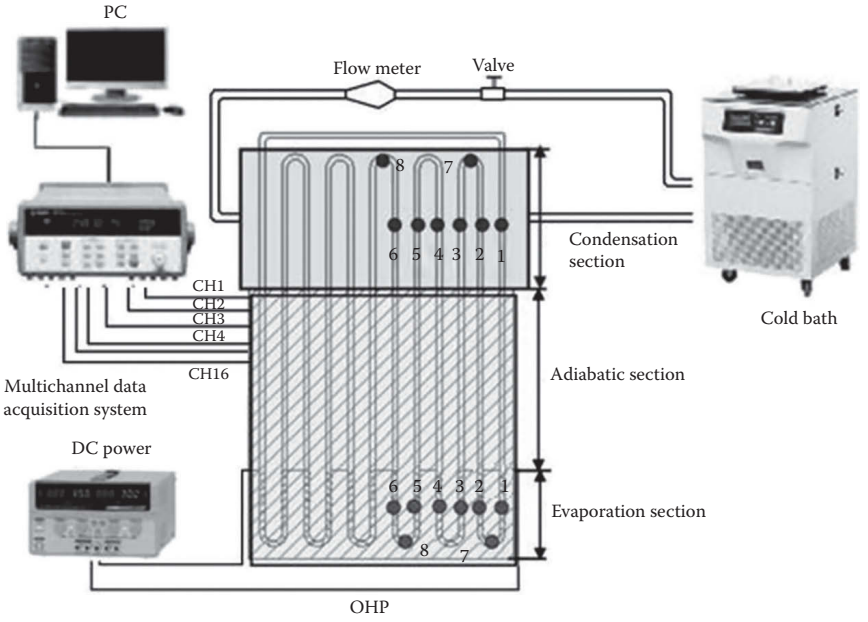

FIGURE 4.2.23 Experimental rig for nanofluids in an OHP. (From Qu, J. et al., *Int. Commun. Heat Mass Transfer*, 37(2), 111–115, 2010.)

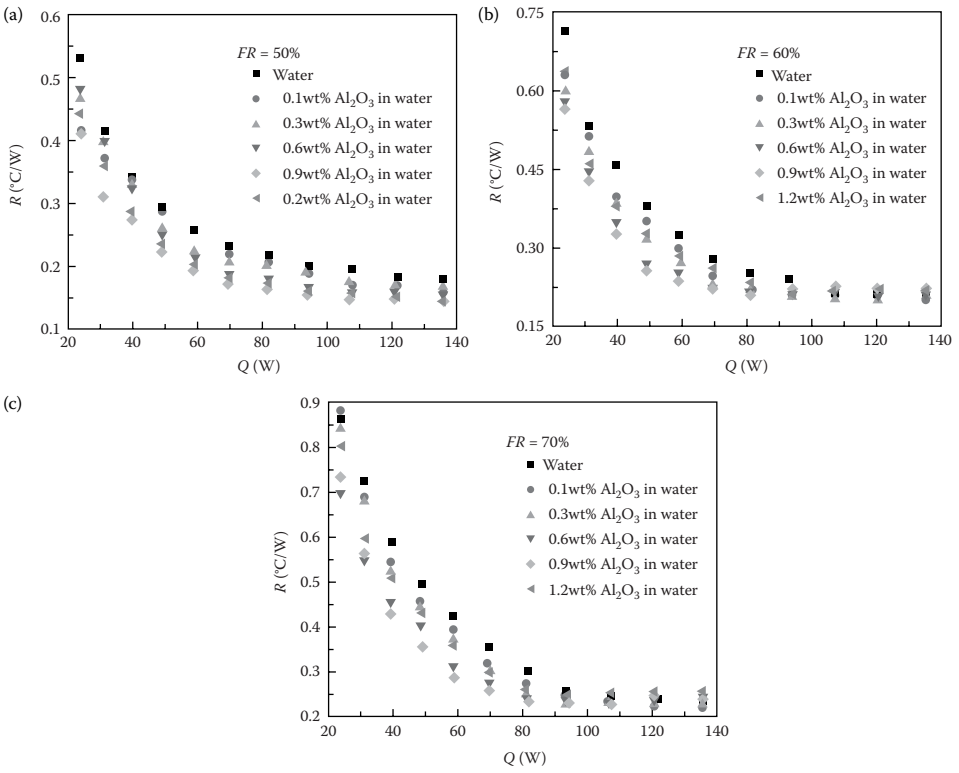

FIGURE 4.2.24 Thermal resistance comparison for the OHP charged with water and alumina nanofluids at FRs of (a) 50%, (b) 60%, and (c) 70%. (From Qu, J. et al., *Int. Commun. Heat Mass Transfer*, 37(2), 111–115, 2010.)

of nanoparticles from 0 wt% (i.e., pure water) to 0.9 wt%, but it increased when the weight concentration reached 1.2 wt%. At the optimal value of 0.9 wt%, the maximal decrease of the thermal resistance was about 0.14°C/W (or 32.5%) as compared with pure water, which occurred at 70% FR when the power input was 58.8 W. Thus, the addition of alumina nanoparticles in the base fluid enhanced the thermal performance of the OHP.

Generally, the active nucleation site density is related to the surface condition and roughness. Figure 4.2.25 shows the 2-D atomic force microscope images of the surface morphology for clean substrate and alumina nanoparticle-deposited substrate of the evaporator, respectively. As can be seen from Figure 4.2.25b, the alumina nanostructure completely modified the surface of the evaporator. The cavities of the clean surface were on the magnitude of about 2–3 μm as shown in Figure 4.2.25a, so they are one or two orders of magnitude larger than the size of nanoparticles deposited on the evaporator surface. As a result, when the smaller nanoparticles sit on nucleation sites, they can create more new active nucleation sites by splitting a single nucleation site into multiple ones, and thus enhance the boiling heat transfer (Das et al., 2008). In addition, the irregular nanopores formed between the deposited alumina nanoparticles which created the nano-roughness within the micrometer-roughened surface would affect the bubble release diameter and frequency. The bubble generation on the nanomicroroughened hierarchical surface was different from that of a clean surface. Within the cavities through the nanopore network, the nanobubbles may be continuously generated and feed the nucleation and growth of larger bubbles at the microscale cavities (Li et al., 2008). This enables stable nucleation with increasing bubble release frequency.

Kole and Dey (2013) added stable copper/water nanofluids instead of water in screen mesh wick heat pipes and found that the average evaporator wall temperature of the heat pipe using nanofluids is reduced compared to those with water. Figure 4.2.26 shows heat pipe thermal resistance as a function of nanoparticle concentration for 10 and 100 W respectively inclined at different angles. As shown in Figure 4.2.26, vertical heat pipes are found to perform better than at other inclinations. It may be noted that the total thermal resistance decreases both with the increasing Cu concentration in nanofluid and also with increase in the input power. High thermal resistance observed for low heat loads is due to the formation of a solid/liquid film on the evaporator section. On the other hand, nucleate boiling which is more important at high heat loads brings in a rapid decrease in the thermal resistance.

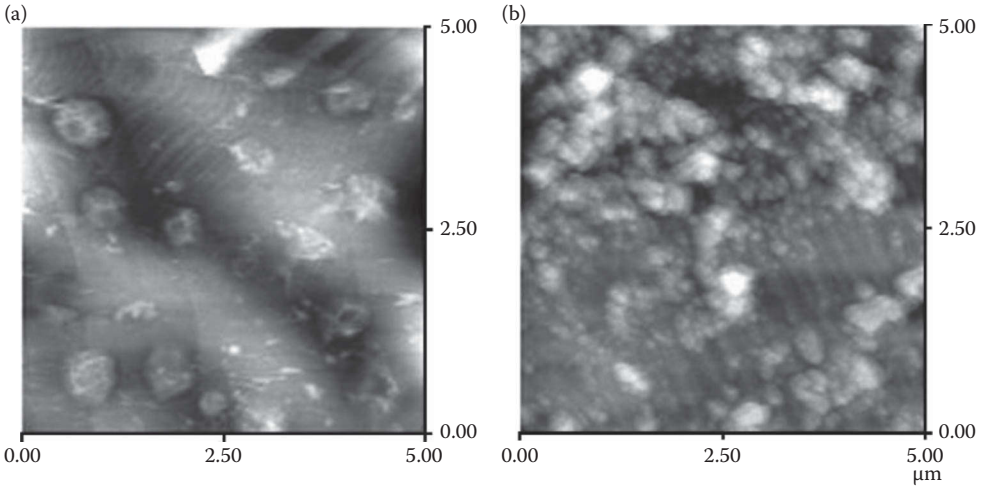

FIGURE 4.2.25 2-D atomic force microscope images of (a) a clean substrate boiled in pure water and (b) a nanoparticle-deposited substrate at the evaporator. (From Qu, J. et al., *Int. Commun. Heat Mass Transfer*, 37(2), 111–115, 2010.)

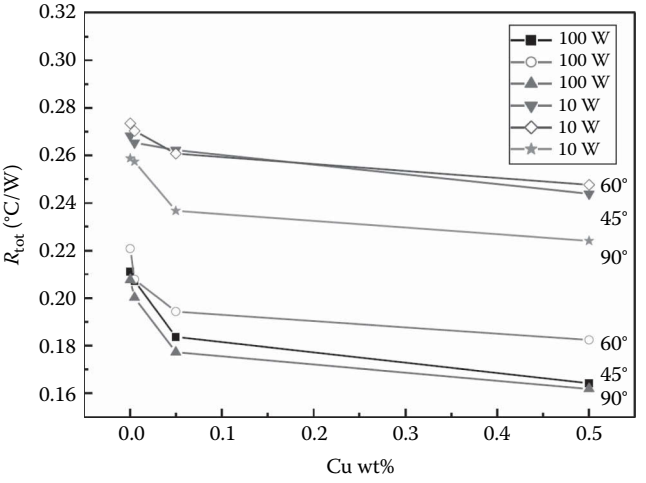

FIGURE 4.2.26 Heat pipe thermal resistance as a function of nanoparticle concentrations for 10 and 100 W, respectively, inclined at different angles. (From Kole, M. and Dey, T.K. *Appl. Therm. Eng.*, 50(1), 763–770, 2013.)

Challenges of Nanofluids in Heat Exchangers

Many efforts are needed to target the following challenges towards application of nanofluids in heat exchangers.

There is still a lot of room for thermal conductivity enhancement of nanofluids. Further thermal conductivity enhancement can be obtained by manipulating the nanostructure morphology in nanofluids to form elongated and/or percolated aggregates. More investigations should be conducted to achieve large thermal conductivity enhancement with relatively low viscosity increase, for example, by modifying the nanostructure morphology in nanofluids. Nanofluids with compact nanoparticles of different size or with hybrid or multicomponent nanoparticles might be promising as they generally present larger thermal conductivities.

New kinds of nanofluids, such as hybrid nanofluids, might be promising for heat-transfer augmentation. However, if not properly synthesized, the hybrid nanofluids will not be superior to common nanofluids. Cost-effective manufacturing and preparation methods need to be developed.

Nanofluid stability is always a problem for application of nanofluids. More investigations on the lift cycle of nanofluids should be performed.

Nanofluids of relatively large particle volume fractions or nanoparticles of nonspherical shape (e.g., nanorod, nanotube) present non-Newtonian behavior, which may cause problems for heat exchangers designed for Newtonian fluids.

For rod-like nanoparticles and nanoparticle agglomerations, the thermal conductivity enhancement at flowing conditions may be lower than that at static conditions. As shown in Figure 4.2.27, the randomly oriented agglomerations (might be percolated) at static conditions tend to be parallel with the flow direction at flowing conditions due to the liquid inertia. The long axis of the agglomeration is prone to be perpendicular to the temperature gradient under flowing conditions, and therefore it degrades the thermal conductivity enhancement.

Nanofluid boiling and evaporation has potential to increase heat transfer and critical heat flux in heat pipes and evaporators. However, it is hard to control the nanoparticle deposition process. Thick nanoparticle deposition is unfavorable as the deposition layer adds an additional resistance to heat transfer. For flow boiling in heat exchangers such as PHEs, the nanoparticle deposition process is even harder to control as the nanoparticle deposition is tempo-spatial variable in the heat exchanger. Besides, some nanofluids use surfactants to increase nanofluid stability. However, these surfactants might also affect the boiling/evaporation process (Feng et al., 2016).

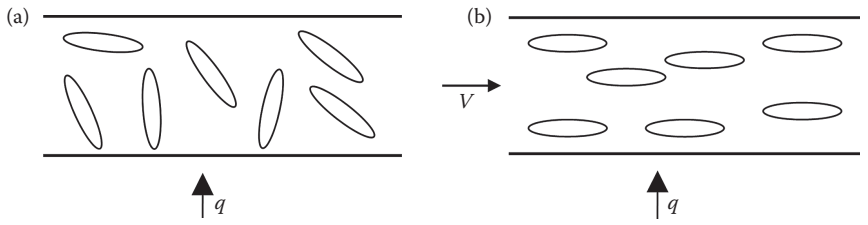

FIGURE 4.2.27 Possible agglomeration morphology at (a) static conditions and (b) flowing conditions. (From Wu, Z. et al., *Front. Heat Mass Transfer*, 5, 2014.)

Summary

Nanofluid and its application in various heat exchangers have been discussed in this chapter. Influential parameters of nanofluids on the thermal performance have been identified such as nanofluid stability, viscosity, and thermal conductivity. Reliable correlations for nanofluid properties (density, specific heat, viscosity, and thermal conductivity) have also been given.

For nanofluid flow without phase change, nanofluids are more favorable for developing flow than developed flow, and more favorable for laminar flow compared to turbulent flow.

Based on our experimental investigations on the thermal performance of alumina/water and MWCNT/water nanofluids and hybrid alumina + MWCNT/water nanofluid mixture in a helical heat exchanger and PHEs, the nanofluids and base fluid show very similar heat-transfer performances, which indicates that the net effect of nanoparticles on the thermal performance in heat exchangers is probably insignificant. When the measured nanofluid properties were used for calculation, conventional heat-transfer correlations can reproduce the thermal behaviors of the tested nanofluids for laminar flow and turbulent flow very well. Heat-transfer comparison with the base fluid at a constant Reynolds number can be misleading and should not be used to evaluate heat-transfer enhancement. Based on the fixed flow velocity and the fixed pumping power, no heat transfer enhancement can be achieved by nanoparticle additions because the increase in viscosity is generally much larger than the increase in thermal conductivity.

Nanofluid additives are very effective to enhance the thermal performance of heat pipe evaporators due to the formation of nanoparticle deposition layers during the boiling or evaporation process, which provide more nucleation sites and modify the surface wettability.

Nomenclature

Bi	Particle Biot number, $2R_k k_f/d_p$
c_p	Specific heat at constant pressure (J kg^{-1} K^{-1})
D_c	Coil diameter of curvature (m)
d	Diameter (m)
De	Dean number, $Re_b(d_i/D_c)^{0.5}$
f	Friction factor
h	Heat-transfer coefficient (W m^{-2} K^{-1})
k	Thermal conductivity (W m^{-1} K^{-1})
L	Length (m)
LMTD	Logarithmic mean temperature difference (K)
Nu	Nusselt number, hd/k
ΔP	Pressure drop (Pa)
p	Pitch of the helical coil (m); aspect ratio
Pr	Prandtl number, $c_p\mu/k$

Q	Power (W)
q	Heat flux (W m^{-2})
R_k	Interfacial thermal resistance (m^2 K W^{-1})
Re	Reynolds number, $\rho ud/\mu$
T	Temperature (K)
u	Velocity (m s^{-1})
V	Volume flow rate (m^3 s^{-1})
w	Plate width (m)
Greek symbols	
μ	Dynamic viscosity (Pa s)
ρ	Density (kg m^{-3})
φ	Volume fraction
Subscripts	
a	Agglomeration
app	Apparent
cond	Condenser
evap	Evaporator
f	Base fluid
Nf	Nanofluid
P	Nanoparticle

4.3 CONVECTION HEAT TRANSFER IN CONDUITS WITH NANOFLUIDS

Clement Kleinstreuer and Zelin Xu

Introduction

For convection heat transfer in conduits, according to Newton's law of cooling ($Q = kA\Delta T$), the heat transfer rate is proportional to the thermal conductivity of the fluid k, the heat transfer area A, and the temperature difference ΔT, being the "driving force." This implies that, next to larger heat transfer areas, fluids with enhanced k values would effectively increase the heat transfer rate (see also Book Section 3.2.3). This can be achieved by dispersing nanometer-size solid particles in liquids, called *nanofluids*, which elevates the effective thermal conductivity of the mixture. Advancements in nanotechnology allow the fabrication of such spheres, ellipsoids, tubes, or fibers with diameters less than 100 nm. This new class of heat transfer fluids is a suspension of nanoparticles (NPs) with typically high thermal conductivity in the base fluid at low volume fractions, say, less than 6%. In nanofluids, Brownian agitation of nanoparticles overcomes particle sedimentation, resulting in mixture properties that are determined by characteristics of both the NPs and the base fluid. The NPs that have been investigated include, but are not limited to, oxides such as Al_2O_3, CuO, TiO_2, Fe_3O_4, and ZnO, metallic solids such as Cu and Ag, nonmetallic solids such as diamond, SiC, as well as carbon nanotubes. Typical base fluids include water, oil, and ethylene glycol (EG). The thermal conductivities of different nanoparticle materials are shown in Table 4.3.1, while a few examples of nanofluids as well as dispersed NPs are shown in Figure 4.3.1.

The nanofluid-flow concept can be further expanded to develop additional applications; for example, to include inhaled toxic/therapeutic nanosize aerosols or nanodroplet–vapor–air mixtures, as well as nanodrugs infused into the blood stream to combat cancer.

The term "nanofluid" was first used by Choi (1995) to refer to the fluid–nanoparticle mixture. Later experimental results showed that adding a small amount of nanoparticles (usually less than 6%) to the base fluids measurably increased the thermal conductivity of the particle suspensions in batch processes (Kleinstreuer and Feng, 2011). For heat transfer in conduits, adding NPs to the base fluid also increased the convection heat transfer coefficient and the Nusselt number (Kleinstreuer, 2016; see also Section 4.2). While the initial applications of nanofluids have been driven primarily by the potential to significantly improve convective heat transfer performances, presently much broader applications are being implemented. Specifically, its unique properties are being explored in drug delivery (Peer et al., 2007; Kleinstreuer and Childress, 2015), mass transport (Fang et al., 2009; Veilleux and Coulombe, 2011), boiling phenomena (Kim et al., 2007; Kwark et al., 2010), absorption and conversion of radiation (Otanicar et al., 2010; Xu and Kleinstreuer, 2014a), optics (Liu et al., 2006; Taylor et al., 2011), surfaces and catalysts (Taylor et al., 2013), and lubrication (Hu et al., 2015).

Preparation of Nanofluids

The preparation of nanofluids is more involved than just mixing the nanoparticles into the base fluid. Chemically inert NPs usually agglomerate due to the van der Waals force. Metal NPs oxidize easily in air due to their large surface-to-volume ratio and high surface reactivity. Even after the particles are dispersed in the carrier fluid, it is difficult to keep the mixture stable and uniform for a long time. Therefore, special procedures are necessary in the preparation of stable nanofluids.

Synthesis

There are primarily two methods to prepare nanofluids: two-step preparation and one-step preparation. In the two-step method, nanoparticles are first produced as dry powders via chemical or physical methods, and then mixed with a base fluid. Aggregation may occur because of the strong van der Waals force acting among adjacent nanoparticles. Hence, ultrasonic vibration or high-shear mixing

TABLE 4.3.1
Thermal Conductivities of Common Liquids and Nanoparticles

Coolants		Metals		Metal Oxides		Nonmetallic	
Material	**k (W/m·K)**	**Material**	**k (W/m·K)**	**Material**	**k (W/m·K)**	**Material**	**k (W/m·K)**
Water	0.61	Cu	401	CuO	77	SiO_2	1.4
EG	0.25	Al	237	ZnO	89	Si	148
Mineral Oil	0.15	Zn	120	Al_2O_3	36	SiC	120

over extended periods of time is usually employed to stir nanopowders and form well-dispersed suspensions. This is the most economical method and is more suitable for preparing nanofluids with oxide NPs than those with metallic NPs.

The more advanced one-step technique simultaneously produces and disperses nanoparticles in fluids. There are several specific methods in this category. For example, in the direct evaporation and condensation method, metals are vaporized and cooled into solids to obtain nanofluids. This technique has better control of the NP morphology and can greatly reduce aggregation. However, it is not suitable for large-scale syntheses. Also, there may be residuals remaining due to incomplete reaction.

Stabilization

Nanofluid stability is essential for practical applications, avoiding particle agglomeration with severe effects. For example, the thermophysical properties of nanofluids will change and any enhanced heat transfer deteriorates as a result. The aggregates may settle and hence deposit on the conduit wall, adding interface thermal resistance and possibly clogging microchannels or filters. Furthermore, due to strong van der Waals interactions between nanoparticles, it may be difficult to maintain a stable suspension in practical applications. Specifically, the attractive potential is proportional to the particle diameter d_p, the material (or Hamaker) constant A_H, and is inversely proportional to the distance of separation, h:

$$\psi_{LD} = -\frac{A_H}{12}\left[\frac{1}{x(x+2)} + \frac{1}{(x+1)^2} + 2\ln\frac{x(x+2)}{(x+1)^2}\right] \tag{4.3.1}$$

where $x = h/d_p$. For small particle separations ($h \ll d_p$), this reduces to

$$\psi_{LD} = -\frac{A_H d_p}{24h} \tag{4.3.2}$$

The average (minimum) separation distance between two spheres in a well-dispersed suspension can be obtained via

$$h = \frac{d_p}{2}\left[\left(\frac{0.64}{\varphi}\right)^{\frac{1}{3}} - 1\right] \tag{4.3.3}$$

where φ is the NP volume fraction. According to Equation 4.3.3, the average particle distance scales with the particle diameter and hence becomes very small for NPs.

There are two main methods of stabilizing nanofluids, that is, steric stabilization, where adsorbed polymeric molecules separate nanoparticles away from each other, and electrostatic or charge stabilization, where electrical double layers are formed at particles surfaces to generate a repulsive force.

Adding surfactants to the nanofluids also enhances the stability of NPs in aqueous suspensions. The reason is that the hydrophobic surfaces of nanoparticles/nanotubes are modified to become hydrophilic and *vice versa* for nonaqueous liquids. This causes steric repulsion between NPs. However, surfactant functionality may deteriorate under high temperatures when the bonds between the polymer molecules and the NPs weaken. The stability can also be improved by altering the pH value of the mixture. The repulsive forces overcome the van der Waals force and keep the particles from aggregating. Figure 4.3.2 illustrates the two stabilization mechanisms.

The potential of the electrostatic repulsive force can be expressed as

$$\psi_{EDL} = 32\pi d_p \kappa_B T \kappa^{-2} \rho_{el} \tanh^2\left(\frac{\sigma e \phi_0}{4\kappa_B T}\right)\exp(-\kappa h) \tag{4.3.4}$$

where κ_B is the Boltzmann constant, σ is the valence of the ions, κ is the inverse of the Debye length, ρ_{el} is the concentration of electrons, e is the electric charge, and ϕ_0 is the electric double layer (EDL) potential at the surface of the nanoparticles. The sum of the potentials due to the van der Waals attraction and the electrostatic repulsion determines the stability of the nanofluid. Higher potentials lead to bigger potential barriers for aggregation. The interaction potentials at different pH-values are shown in Figure 4.3.3a.

Because pH is a measure of the electrostatic charge on the particle surface, it has a significant influence on the thermal property and convection heat transfer performance of nanofluids (see Figure 4.3.3b). Generally, pH must be far from the IEP (isoelectric point, the pH at which the particle carries no net electrical charge) to maintain good nanofluid stability.

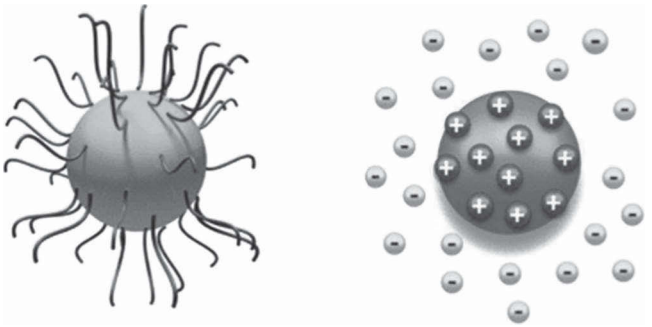

FIGURE 4.3.2 Stabilization methods. (From Yu, W. and Xie, H., *J. Nanomater.*, 1, 2012.)

Thermophysical Properties of Nanofluids

The basic particle–fluid mixture properties are greatly a function of the particle volume fraction. If particles are assumed to be spherical, monodisperse, and forming a homogeneous dilute suspension, the nanofluid density and heat capacity in the case of low NP-volume fractions can be expressed as

$$\rho_{nf} = \varphi\rho_p + (1-\varphi)\rho_{bf} \tag{4.3.5a}$$

$$(\rho c_p)_{nf} = \varphi(\rho c_p)_p + (1-\varphi)(\rho c_p)_{bf} \tag{4.3.5b}$$

where the subscripts bf and p indicate base fluid and particle, respectively.

For the effective thermal conductivity k_{nf} and effective viscosity μ_{nf} of nanofluids, classical mixture theories fail to predict accurate values.

Thermal Conductivity of Nanofluids

Certain nanofluids have shown significantly enhanced thermal conductivities over their base fluids. It has been shown that the effective thermal conductivity of the mixture k_{nf} increases with the NP volume fraction and temperature and with the decrease of particle size (see Figure 4.3.4). In addition, particle shape, pH, and aggregation also have significant effects on k_{nf}. As can be observed from Figure 4.3.4, the percentages of enhancement in thermal conductivity cover a wide range.

Originally, an expression for k_{nf} of a two-phase mixture with relatively large spheres has been derived by Maxwell in 1881. It assumes that the increase in mixture thermal conductivity is due to the high thermal conductivity of the particles. In this case, the effective thermal conductivity depends only on the particle volume fraction. Assuming a monodisperse mixture with spherical particles, the effective thermal conductivity is given as

$$k_{eff} = k_{bf} \cdot \left(1 + \frac{3\left(\frac{k_a}{k_{bf}} - 1\right)\varphi}{\left(\frac{k_a}{k_{bf}} + 2\right) - \left(\frac{k_a}{k_{bf}} - 1\right)\varphi} \right) \tag{4.3.6}$$

where k_{bf} and k_a are the thermal conductivities of the base fluid and the nanoparticle material, respectively. The Maxwell model predicts the k_{eff} of mixtures with particle sizes greater than 1 μm. However, it significantly underestimates the effective thermal conductivity of nanofluids.

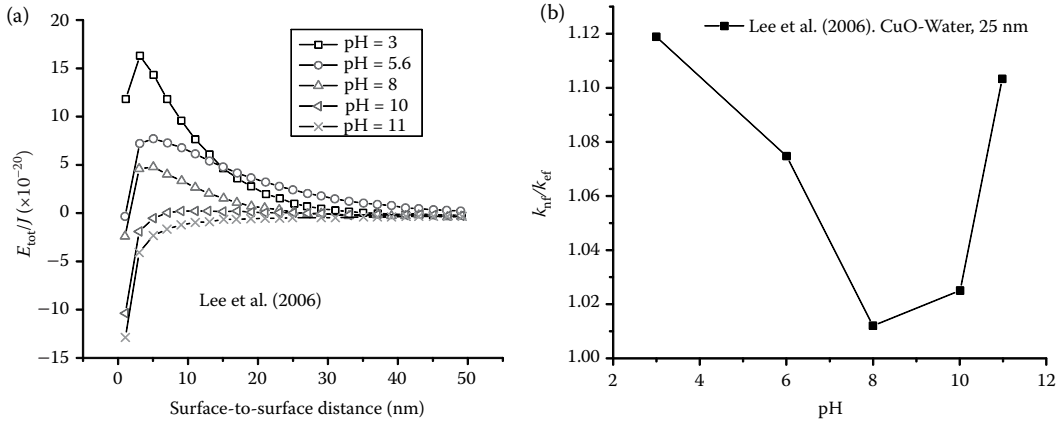

FIGURE 4.3.3 Electrostatic stabilization: (a) The interaction potentials at various pH values as a function of interparticle distance and (b) effect of pH on the effective thermal conductivity of CuO–water nanofluid.

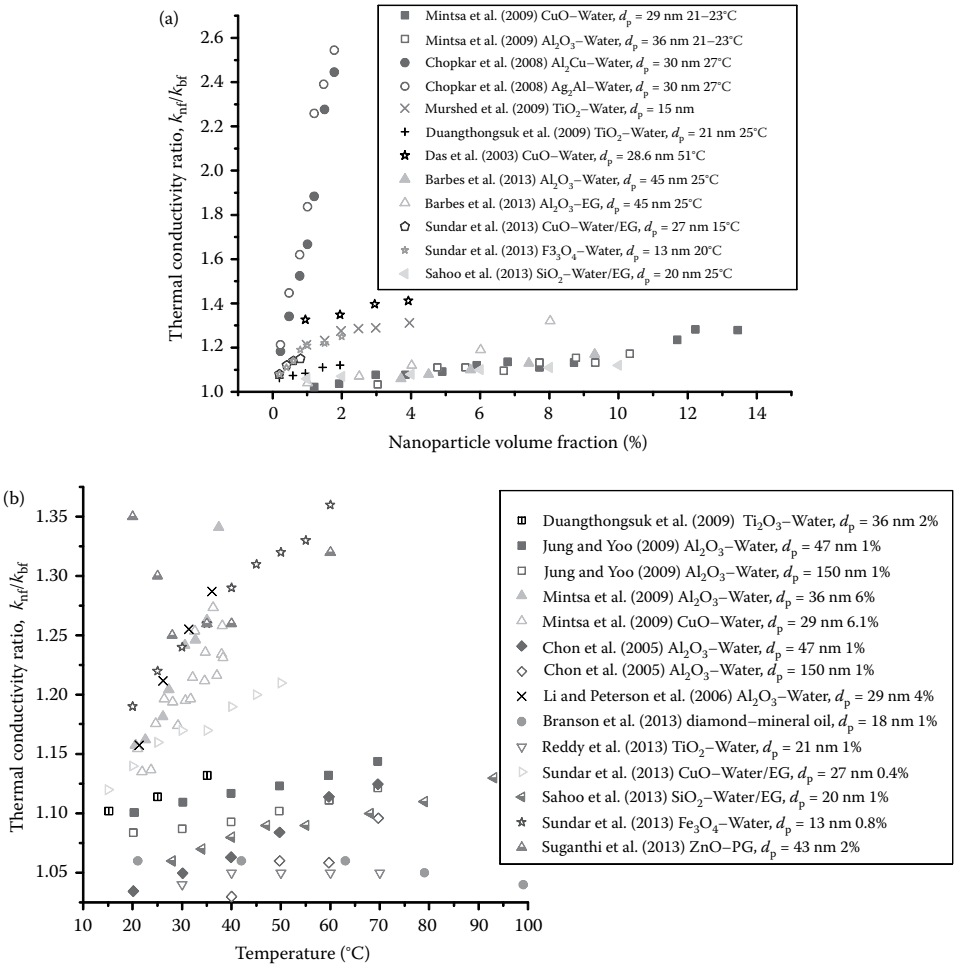

FIGURE 4.3.4 Nanofluid thermal conductivity as a function of (a) volume fraction ϕ and (b) temperature.

To explain this discrepancy, a number of models have been proposed. For example, Brownian motion and particle aggregation are arguably the most fundamental effects that characterize nanofluids. Nanoparticles undergo vigorous Brownian motion due to the random bombardment of liquid molecules, carrying with them relatively large volumes of surrounding liquid. This microscale interaction may occur between hot and cold regions of the fluid, resulting in micromixing effects and causing an enhanced effective thermal conductivity. The randomly moving particles may collide with each other at high frequency, forming locally small cluster-like structures. Such NP clusters can form thermal pathways and augment heat transfer, resulting in enhanced k_{nf}-values (see Figure 4.3.5).

For example, Kleinstreuer and Feng (2012) proposed a model based on Brownian motion-induced microconvection. It divides the thermal conductivity k_{nf} of the nanofluid into two parts: a static part, k_{static}, similar to Maxwell's model, and a micromixing part, k_{mm}, due to Brownian motion of nanoparticles. However, this model does not consider NP clustering, which may be also important. So, Xu and Kleinstreuer (2014a) enhanced the F-K model to include the local clustering effect as well as the interfacial thermal resistance effect. The modified model has the same basic form $k_{nf} = k_{static} + k_{mm}$; however, with a different k_{mm} expression:

$$k_{mm} = 19631 \cdot C_c \varphi \frac{\kappa_B \tau_a}{m_a} \left(\rho c_p\right)_{nf} \left(\overline{T} \cdot \ln \overline{T} - \overline{T}\right) \tag{4.3.7}$$

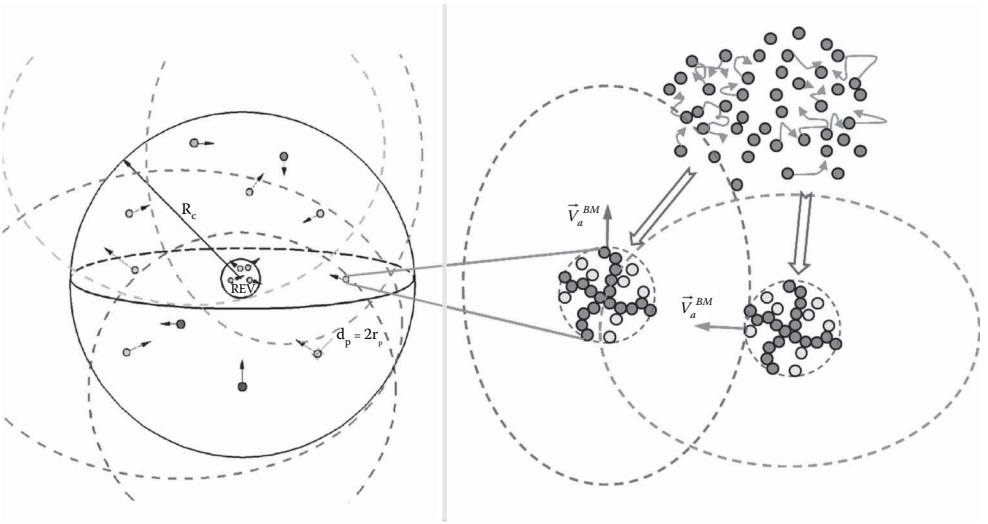

FIGURE 4.3.5 Mechanisms causing enhanced thermal conductivity of nanofluids: nanoparticle interaction and clustering due to Brownian motion. (From Xu, Z., An improved thermal conductivity model for nanofluids with applications to concentration photovoltaic-thermal systems. MS Thesis, North Carolina State University, 2014.)

Now, the NP thermal conductivity in the original Maxwell model is replaced by the effective thermal conductivity of particle aggregate unit k_a:

$$k_a = k_{de} \cdot \frac{3+\varphi_b\left[2\beta_{11}\left(1-L_{11}\right)+\beta_{33}\left(1-L_{33}\right)\right]}{3-\varphi_b\left(2\beta_{11}L_{11}+\beta_{33}L_{33}\right)} \tag{4.3.8}$$

where

$$\begin{aligned} k_{de} &= (3\varphi_{de}-1)k_{peff}+(2-3\varphi_{de})k_{bf} \\ &+\sqrt{[(3\varphi_{de}-1)k_{peff}]^2+[(2-3\varphi_{de})k_{bf}]^2+2[2+9\varphi_{de}(1-\varphi_{de})]k_{peff}k_{bf}} \end{aligned} \tag{4.3.9}$$

The effective thermal conductivity of the NPs including the thermal contact resistance, k_{peff}, is given as

$$k_{peff} = \frac{k_p}{1+R_K k_p/d_p} \tag{4.3.10}$$

In these equations, k_{de} is the effective thermal conductivity of the mixture of base fluid and dead-end particles, φ_{de} is the volume fraction of dead-end particles in an aggregate unit, φ_b is the volume fraction of backbone particles in an aggregate unit, L_{ii} and β_{ii} are parameters appearing in the derivation of the effective thermal conductivity of arbitrary isotropic particulate composites with interfacial thermal resistance. The readers are referred to Xu (2014) Section 2.5 for a complete explanation of the meanings of these parameters. Moreover, R_K is the Kapitza resistance, ρ is the density, c_p is the specific heat capacity, and $\overline{T}$ is the time-averaged temperature. The subscripts p and a denote nanoparticle and aggregate unit, respectively. C_c is a correction factor that differs among different NP–base fluid pairings, but the value is around unity. For example, for Al_2O_3–water nanofluids, $C_c = 1.1$. The characteristic time interval τ_a is expressed as

$$\tau_a = \frac{m_a}{3\pi\mu_{bf}R_g} \tag{4.3.11}$$

where R_g is the average radius of the aggregate units:

$$R_g = 2.5 d_p \sqrt{\frac{\varphi}{0.01}} \cdot \sqrt{\frac{T_0}{T}} \tag{4.3.12}$$

Here, d_p is the nanoparticle diameter, and $T_0 = 273\,\mathrm{K}$ is the reference temperature.

In light of experimental evidence, this model is suitable for several types of metal oxide nanoparticles in water with volume fractions up to 10% and mixture temperatures below 350 K (see Figure 4.3.6).

A few different mechanisms have been proposed to explain the anomalous enhancement of the mixture thermal conductivity. For example, the base-fluid molecules form layered structures at the particle surface, acting as thermal bridge between the liquid and the solid particles, and thus enhance the k_{nf} (Yu and Choi, 2003). However, there are strong debates about whether they are really important to the enhanced thermal conductivity.

Viscosity of Nanofluids

Apart from thermal conductivity, the viscosity of nanofluids, μ_{nf}, is also important in the evaluation of heat transfer performance, influencing both the necessary power supply as well as the convective heat transfer coefficient. Specifically, measurements of the rheological properties of nanofluids show that particle loading, temperature, particle shape and size, surfactants, and pH have direct impacts on the viscosity of nanofluids. For example, viscosity increases with higher particle volume fractions, while it decreases with elevated temperatures (see Figure 4.3.7). Still, at low particle volume concentrations, most nanofluids behave as Newtonian-fluid mixtures (Mahbubul et al., 2012; Kleinstreuer, 2014). Due to the aggregation effect of NPs, it is difficult to determine how the particle size would affect the effective viscosity. Surfactants and pH affect μ_{nf} mainly through enhancing the dispersion of nanoparticles.

Einstein (1906) developed a formula for the effective viscosity of fluids containing spherical particles at low volume fractions (<2%). It shows a linear increase in viscosity with particle volume fraction:

$$\frac{\mu_{eff}}{\mu_{bf}} = 1 + 2.5\varphi \tag{4.3.13}$$

where μ_{efl} and μ_b are the viscosities of the mixture and the base fluid, respectively. Brinkman (1952) extended this model to consider moderate particle concentrations up to 4%:

$$\frac{\mu_{eff}}{\mu_{bf}} = (1-\varphi)^{2.5} \tag{4.3.14}$$

Comparison with experimentally measured data showed that the Einstein model and the Brinkman model both tend to underestimate the viscosity of nanofluids. The reasons are that these two models only account for the effect of particle loading on the mixture viscosity, but neglect other important influencing factors such as temperature, particle size, and pH. In addition, newly proposed theoretical formulas are not able to accurately predict the effective viscosity for a wide range of nanofluids (Mahbubul et al., 2012). Theoretical models for the viscosity of the mixture usually rely on the homogeneous-dispersion assumption, which makes it nearly impossible to derive a general correlation that accurately predicts μ_{nf}, given that the aggregation of nanoparticles almost always lead to a heterogeneous mixture. Still, due to the substantial difference among the available experimental data of μ_{nf}, specific empirical correlations are only applicable to one or a few types of nanofluids within specific ranges of pertinent parameters. For example, Corcione (2011) obtained an empirical correlation for μ_{nf} with NP ranges in diameter from 25 to 200 nm, volume fraction 0.01%–7.1%, and temperature 293–333 K. The correlation reads:

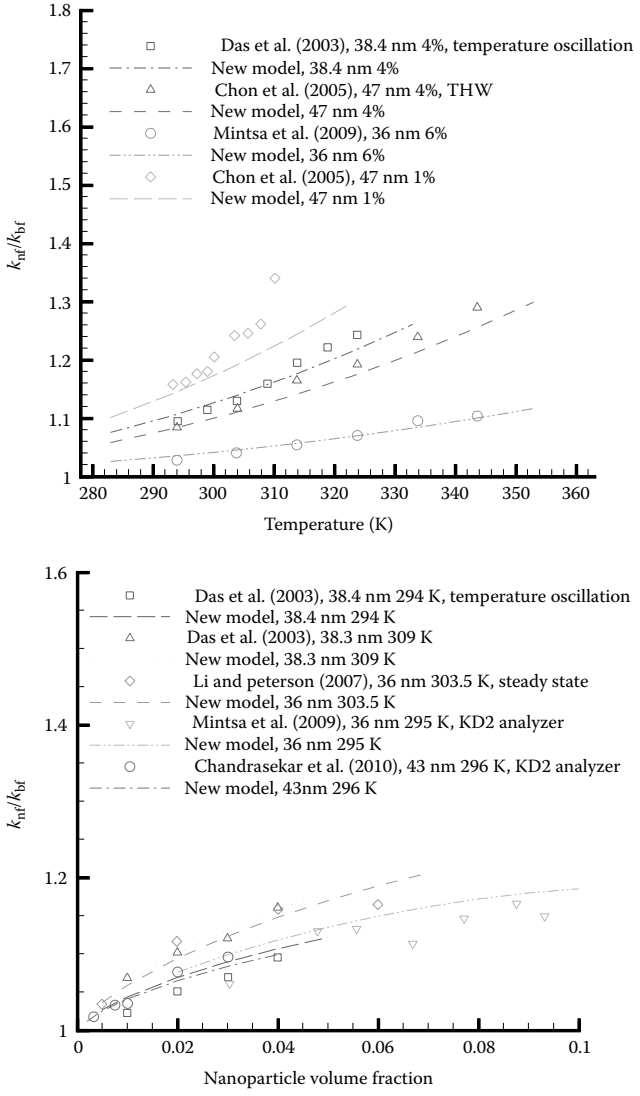

FIGURE 4.3.6 Model prediction of nanofluid thermal conductivity as a function of temperature and particle loading, and comparison with measurements. (Xu, Z. and Kleinstreuer, C., *Energy Convers. Manage.*, 87: 504–512, 2014a.)

$$\mu_{nf} = \frac{\mu_{bf}}{1 - 34.87\left(d_p/d_{bf}\right)^{-0.3}\varphi^{1.03}} \tag{4.3.15}$$

where d_{bf} is the equivalent diameter of a base fluid molecule, given by

$$d_{bf} = \left(\frac{6M}{N\pi\rho_{bf0}}\right)^{1/3} \tag{4.3.16}$$

in which M is the molecular weight of the base fluid, N is the Avogadro number, and ρ_{bf0} is the mass density of the base fluid calculated at temperature $T_0 = 293$ K.

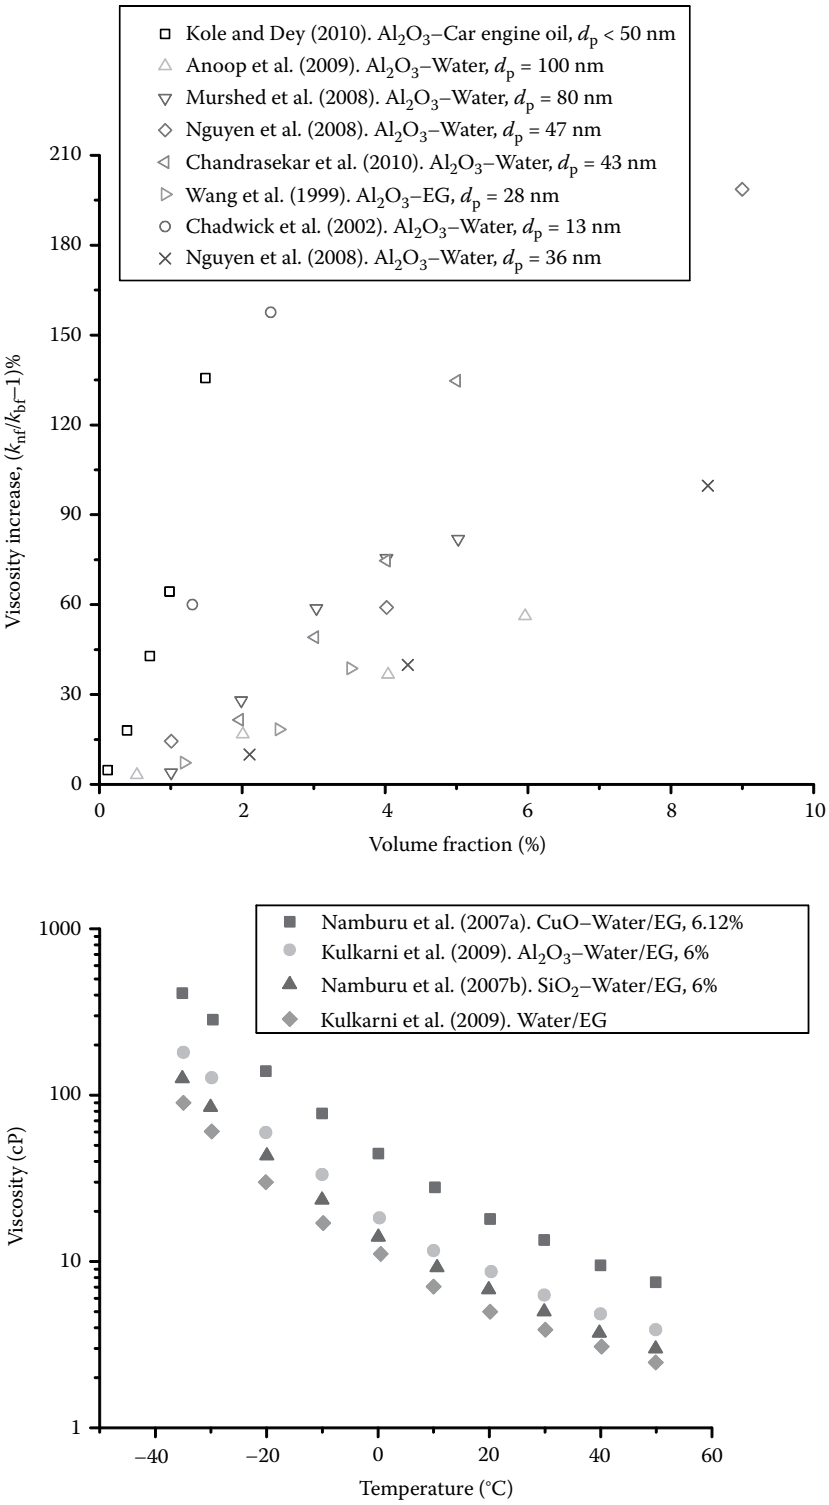

FIGURE 4.3.7 Nanofluid viscosity as a function of particle concentration and temperature.

As mentioned, the implication of elevated viscosities is that higher pressure drops are needed to power nanofluid flows. This drawback may eliminate the gain of enhanced heat transfer in some cases.

Heat Transfer in Nanofluid Flow

For thermal nanofluid flow in conduits, convection heat transfer performance is the most important issue. Heat transfer performance for Fourier-type processes is characterized by the convective heat transfer coefficient or the Nusselt number, that is,

$$h = \frac{q_w}{T_w - T_f} \tag{4.3.17}$$

while

$$\mathrm{Nu}_x = \frac{h \cdot x}{k} \tag{4.3.18}$$

where q_w is the local wall heat flux, and Nu_x is the Nusselt number at location x.

Experimental Evidence

Laminar Flow

The Nusselt number increases with the Reynolds number and the Prandtl number, hence the thermal Peclet number (i.e., $\mathrm{Re} \cdot \mathrm{Pr}$) as well as NP volume fraction (see figures in Book Section 7.1). The enhancement is especially significant in the entrance region, where the nonuniform local particle concentration may be the reason. The heat transfer enhancement reported in many studies ranges from 5% to 45% for spherical nanoparticles; however, for nanofluids with high aspect ratios, such as carbon nanotubes, the enhancement can be much greater (Ding et al., 2006).

It should be noted that the enhancement of the heat transfer coefficient is often found to be larger than that of the thermal conductivity for the same NP-volume fraction. Especially in laminar flows, particle migration effects, for example, thermophoresis, Brownian motion, shear stresses, and/or viscosity gradients are the reasons for the enhanced heat transfer performance. Again, focusing on the entrance region, the thermal conductivity in the wall-shear layer is the main parameter that affects the convection heat transfer rate. Thus, locally enhanced thermal conductivities of nanofluids due to particle migration can substantially increase the convection heat transfer rates. Also, such developing flow fields feature nonuniform thermal conductivity and viscosity profiles as well as reduced boundary layer thicknesses.

Turbulent Flow

For turbulent convective heat transfer, elevated, unchanged, and reduced h_{nf} values, in comparison to h_{bf} values, have all been reported. So, whether the dispersion of nanoparticles in the base fluid enhances the convective heat transfer is still under debate, although the number of studies that observed increased convective heat transfer coefficients with Reynolds number, implied random NP dispersion, and particle volume fraction are in the majority (Kleinstreuer and Feng, 2011; Kleinstreuer and Xu, 2015). Another widely recognized character is the NP size effect on the convective heat transfer coefficient. Larger particles seem to give better h_{nf} results for the same particle volume fraction, possibly due to greater particle slip caused by higher inertia effects. Also, thermophoresis as well as Brownian diffusion of nanoparticles may lead to increased particle–fluid slip, which enhances the convective heat transfer. In the boundary layer, the particle concentration is smaller than in the bulk due to radial flow, which reduces the viscosity and the thickness of the boundary layer, hence promoting heat transfer. Still, some argue that at high Reynolds numbers the

heat transfer is dominated by convection, implying that NPs provide only a small contribution to the overall heat transfer.

The Nusselt number excludes the effect of increased pumping cost due to the dispersion of NPs in the base fluid. Hence, to measure the performance of thermal nanofluid flow, the thermal performance factor may be used:

$$\eta = \frac{\mathrm{Nu}_{\mathrm{nf}}/\mathrm{Nu}_{\mathrm{bf}}}{\left(f_{\mathrm{nf}}/f_{\mathrm{bf}}\right)^{\frac{1}{3}}} \tag{4.3.19}$$

Convection Heat Transfer Correlations

As mentioned, nanofluids have potentially shown superior heat transfer capabilities than the base fluid in both laminar and turbulent regimes. The heat transfer coefficient appears to increase more than the thermal conductivity. The friction factor correlations developed for pure fluids may still be used for nanofluids in both laminar and turbulent flow regimes, given that the corresponding nanofluid properties are used. However, it is under debate whether the conventional correlations for Nusselt number can accurately predict the nanofluid heat transfer characteristics using the measured nanofluid properties (Sarkar, 2011; Sundar and Singh, 2013). New correlations have been proposed to fit the experimental data for Nusselt numbers of nanofluids. Unfortunately, in both laminar and turbulent flow regimes, strong disagreements have been observed between proposed correlations. For forced convection in conduits, the heat transfer coefficient may be an alternative parameter to evaluate nanofluids. For example, Yu et al. (2012) reviewed experimental data sets for turbulent heat transfer of nanofluids in horizontal tubes. They concluded that if properly compared, the actual heat transfer enhancement of nanofluids over their base fluids can be predicted quite accurately using the Dittus–Boelter equation, that is,

$$\mathrm{Nu} = 0.023\mathrm{Re}^{4/5}\mathrm{Pr}^{n} \tag{4.3.20}$$

where $n = 0.4$ for heating (wall hotter than the bulk fluid) and $n = 0.33$ for cooling. It should be noted that while using Equation 4.3.20, the nanofluid properties have to be used to calculate the Reynolds number and the Prandtl number.

Numerical Studies

Numerical simulations of nanofluids allow to depict fluid flow and heat transfer characteristics under different scenarios. The numerical methods used in the literature can be categorized into two groups, that is, the macroscale continuum approach and the meso/microscale approach (see selectively Book Sections 5.1 through 5.9). The continuum approach can be further divided into a single-phase and two-phase approach. The meso/microscale models for nanofluid flow simulations require much smaller length scales, and hence are computationally much more expensive. Examples include the lattice Boltzmann method (LBM), molecular dynamics (MD) simulations, direct numerical simulation (DNS), and dissipative particle dynamics (DPD) (as discussed in Karimipour et al., 2015; Sun et al., 2011; Yang et al., 2014; Abu-Nada, 2015).

Continuum Mechanics Analyses

Single-Phase Approach

In the single-phase approach, it is assumed that the suspended nanoparticles are in thermal equilibrium with the liquid phase, and that the relative velocity between the two phases is negligible. The reasoning is that NPs are so small, say, $d_{\mathrm{p}} < 100$ nm, that they closely follow the fluid streamlines, making the nanofluid to behave like a homogeneous mixture (Kleinstreuer, 2014; among others). Thus, the set of governing equations for pure fluids can be used with the effective thermophysical properties of nanofluids replacing the fluid properties.

Continuity equation:

$$\frac{\partial \rho_{\mathrm{nf}}}{\partial t}+\frac{\partial}{\partial x_i}(\rho_{\mathrm{nf}}u_i)=0 \tag{4.3.21}$$

Momentum equation:
(Laminar flow)

$$\frac{\partial(\rho_{\mathrm{nf}}u_i)}{\partial t}+\frac{\partial}{\partial x_j}(\rho_{\mathrm{nf}}u_iu_j)=-\frac{\partial p}{\partial x_i}+\frac{\partial}{\partial x_j}\left[\mu_{\mathrm{nf}}\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)\right] \tag{4.3.22}$$

(Turbulent flow)

$$\frac{\partial(\rho_{\mathrm{nf}}u_i)}{\partial t}+\frac{\partial}{\partial x_j}(\rho_{\mathrm{nf}}u_iu_j)=-\frac{\partial p}{\partial x_i}+\frac{\partial}{\partial x_j}\left[\mu_{\mathrm{nf}}\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)-\rho_{\mathrm{nf}}\overline{u_iu_j}\right] \tag{4.3.23}$$

Energy equation:
(Laminar flow)

$$\frac{\partial(\rho_{\mathrm{nf}}h)}{\partial t}+\frac{\partial}{\partial x_i}\left[(\rho c_{\mathrm{p}})_{\mathrm{nf}}u_iT\right]=\frac{\partial}{\partial x_i}\left(k_{\mathrm{nf}}\frac{\partial T}{\partial x_i}\right)+\mu_{\mathrm{nf}}\Phi \tag{4.3.24}$$

(Turbulent flow)

$$\frac{\partial(\rho_{\mathrm{nf}}h_{\mathrm{tot}})}{\partial t}+\frac{\partial}{\partial x_i}(\rho_{\mathrm{nf}}u_ih_{\mathrm{tot}})=\frac{\partial}{\partial x_i}\left(k_{\mathrm{nf}}\frac{\partial T}{\partial x_i}-\rho_{\mathrm{nf}}\overline{u_ih}\right)+\mu_{\mathrm{nf}}\Phi-\frac{\partial u_j}{\partial x_i}(\rho_{\mathrm{nf}}\overline{u_iu_j}) \tag{4.3.25}$$

where $h = u + pv$ is the enthalpy, and Φ is the energy dissipation term, that is,

$$\Phi=\left(\frac{\partial u_i}{\partial x_j}+\frac{\partial u_j}{\partial x_i}\right)\frac{\partial u_i}{\partial x_j} \tag{4.3.26}$$

Clearly, the single-phase approach is easier to implement, requires less computational time, and achieves comparison with selected experimental data sets. However, the results depend strongly on the selected thermophysical property models, especially for the thermal conductivity and viscosity. As mentioned, particle migration can significantly affect the heat transfer results by creating nonuniform concentration fields. They occur most prominently in entrance regions and boundary layers, especially when the Peclet number, $\mathrm{Pe} = \mathrm{Re} \cdot \mathrm{Pr}$, is large.

To improve the single-phase model, some modifications have been applied to include the slip between particles and the base fluid by adding a virtual term in the thermal conductivity expression (Mokmeli and Saffar-Awal, 2010). Also, solving the NP-mass transfer equation together with the momentum and energy equations to account for nonuniform concentration distributions can also increase the accuracy (Kamyar et al., 2012).

Two-Phase Approach

Though ultrafine particles may easily be uniformly suspended, several factors like Brownian motion, thermophoresis, and aggregation can significantly change the relative particle motion, leading to velocity differences between the two phases. Hence, two-phase models, which solve one set of governing equations for each of the phases, may be more suitable (see Book Section 2.8). Most of the

numerical studies used the so-called Eulerian–Eulerian approach to investigate the fluid flow and heat transfer characteristics of nanofluids, where both phases are considered as "fluids" with volume fractions summing up to unity. Specifically, the governing equations for phase α are as follows.

Continuity equation:

$$\frac{\partial(\varphi_\alpha \rho_\alpha)}{\partial t} + \nabla(\varphi_\alpha \rho_\alpha u_\alpha) = 0 \tag{4.3.27}$$

Momentum equation:

$$\frac{\partial}{\partial t}(\varphi_\alpha \rho_\alpha u_\alpha) + \nabla(\varphi_\alpha \rho_\alpha u_\alpha u_\alpha) = -\varphi_\alpha \nabla p + \nabla\left[\varphi_\alpha \mu_\alpha \left(\nabla u_\alpha + (\nabla u_\alpha)^T\right)\right] + F_\alpha \tag{4.3.28}$$

Energy equation:

$$\frac{\partial(\varphi_\alpha \rho_\alpha h)}{\partial t} + \nabla\left[\varphi_\alpha \rho_\alpha u_\alpha h_\alpha\right] = \nabla\left(k_\alpha \nabla T_\alpha\right) + Q_\alpha \tag{4.3.29}$$

where F_α is the surface force due to the existence of another phase and Q_α is the interface heat transfer term. Aside from the inclusion of volume fraction φ, the differences of Equations 4.3.27 through 4.3.29 from Equations 4.3.21 through 4.3.26 are due to interfacial momentum and energy change. Specifically, the interfacial forces that may apply to nanofluid flow are drag, lift, wall lubrication, interphase turbulent dispersion, Brownian diffusion, Magnus, and thermophoresis forces. The rate of interface heat transfer between the nanoparticles (α) and the fluid (β) reads:

$$Q_{\alpha,\beta} = h_{\alpha,\beta} A_{\alpha,\beta}(T_\alpha - T_\beta) \tag{4.3.30}$$

where $A_{\alpha,\beta}$ is the interfacial area per unit volume.

Alternatively, the Eulerian–Lagrangian framework can be employed, which tracks the particles in the fluid phase. Still, a mixture model that introduces a term due to drift of NPs into the momentum equation of the base fluid is feasible (Behroyan et al., 2016). However, the comparisons between different two-phase models suggest no obvious winner in terms of prediction accuracy. Hence the Eulerian two-phase model is favored due to ease of use and low computational cost. It should be noted that although the two-phase models are capable of capturing the nonuniform concentration fields, most studies assumed that the turbulence of the fluid phase is not directly affected by the presence of the nanoparticle phase.

Meso- and Microscale Analyses

High-resolution methods of present research interest are the lattice Boltzmann method, molecular dynamics simulation, and direct numerical simulation. Here, only a brief summary is provided as additional discussions may be found in Book Section 2.8.

Lattice Boltzmann method. In addition to the classical numerical methods, an alternative approach to analyze thermal nanofluid flow is the lattice Boltzmann method (LBM), which fills the gap between microscopic and macroscopic phenomena (Kamyar et al., 2012). In LBM, the discrete Boltzmann equation is solved to simulate nanofluid flow with a suitable particle collision model. This computational fluid dynamics-method is advantageous for systems with complex geometric boundaries and for massive parallel processing. Despite the high computational cost, LBM has shown satisfactory results in thermal nanofluid flow applications. Due to the limited studies available, more research may be needed using this method to see the applicability as well as accuracy.

Molecular dynamics simulation. Molecular Dynamics simulation solves Newton's equation of motion for a system of particles interacting with a prescribed potential. It is able to directly calculate the movement of particles at the atomic level, providing insights from the microscopic scale through statistical processing (Sun et al., 2011). Therefore, MD simulation can be used to directly calculate

the thermal conductivity of nanofluids. Assuming that the micromixing effect is the main reason for the enhanced thermal conductivity of nanofluids, MD simulations show that k_{nf} strongly depends on the shear rate, γ. For large shear rates, the rotation of the particles, being subjected to strong velocity gradients, will be higher. Also, k_{nf} increases with the particle Peclet number, where $\mathrm{Pe} = \gamma d^2/\alpha$, and $\alpha = k/\rho c_p$ is the thermal diffusivity (Sun et al., 2011). The thermal conductivity ratios obtained from such simulations significantly exceed unity. As can be expected, the increase in thermal conductivity ratio with shear rate is less for higher particle loadings due to slower particle rotation.

Direct numerical simulation. Direct numerical simulation can resolve the flow field down to the smallest temporal and spatial scales, even for turbulent flows. Hence, it can directly simulate the forces and interactions between individual NPs as well as the coupling between the particles and the fluid, provided that the mesh spacing is finer than the nanoparticles. This eliminates many of the simplifications made for the theoretical closure models and provides a better understanding to the mechanisms of heat transfer enhancement in nanofluids. For example, the Brownian force, thermophoresis force, and van der Waals force experienced by nanoparticles (and the resulting NP aggregates), as well as the two-way temperature coupling between the continuous phase and the discrete phase can be directly simulated (Kondaraju et al., 2010). Thus, the effective thermal conductivity of the nanofluid can be directly calculated.

Natural Convection Heat Transfer with Nanofluids

As discussed, in *forced* convection applications, nanofluids have generally shown superior heat transfer performance when compared to their base fluids. In *natural* convection, however, the thermal performance of nanofluids is limited. In fact, experimental evidence shows that adding NPs to the base fluid deteriorates natural convection heat transfer either systematically or when a critical particle concentration is used (Haddad et al., 2012). For example, the Nusselt number of nanofluid natural convection decreases with increasing particle concentration for a given Rayleigh number Ra, where $\mathrm{Ra} = g\beta_{nf}\Delta T L^3/\nu_{nf}\alpha_{nf}$, with β being the thermal expansion coefficient, ΔT the temperature difference between the heat transfer surface and the fluid, L a characteristic length, ν the kinematic viscosity, and α the thermal diffusivity. This effect was attributed to a number of factors, including sedimentation of NPs, particle–fluid slip, and modifications of the dispersion properties. Clearly, according to its definition, the Rayleigh number is reduced by an increase in the mixture kinematic viscosity. Owning to this effect, the stress–strain relation of the nanofluid will have a substantial influence on the natural convection heat transfer of nanofluids. This can be seen from the results of numerical studies concerning nanofluid natural convection heat transfer. In computer simulations of single phase natural convection, nanofluids have been shown to be more stable (i.e., delayed onset of convection), exhibiting higher heat transfer rates at least for low Ra numbers than the base fluids. The Nu number increases with NP volume fraction up to a critical Ra number. Hence, using an accurate μ_{nf} model is critical when simulating single-phase nanofluid natural convection. On the other hand, some studies adopted a two-phase mixture model for numerical evaluation of nanofluid natural convection. For example, the model developed by Buongiorno (2006) considers particle–fluid slip caused by Brownian diffusion and thermophoresis. The critical Rayleigh number of nanofluids (i.e., when flow instability occurs) is shown to be much lower than that of the base fluids.

Entropy Generation in Thermal Nanofluid Flow

The use of thermal nanofluid flow for enhanced heat transfer has been the major focus for most studies. However, for efficient removal of high heat fluxes and proper optimization of thermal systems, not only the heat transfer has to be maximized but the increase in entropy generation has to be minimized as well. Entropy generation is the measure of process irreversibility caused by both heat transfer and friction effects. It can be employed as a criterion to assess the performance of thermal devices. For convection heat transfer, the local entropy-generation rate (S_{gen} in W/K) can be expressed as (Bejan, 1996; Kleinstreuer, 2014; among others):

$$S_{\text{gen}} = S_{\text{gen}}(\text{thermal}) + S_{\text{gen}}(\text{friction}) \tag{4.3.31}$$

Clearly, Equation 4.3.31 encapsulates the irreversibility due to heat transfer and frictional effects, where

$$S_{\text{gen}}(\text{thermal}) = \frac{k}{T^2}\left[\left(\frac{\partial T}{\partial x}\right)^2 + \left(\frac{\partial T}{\partial y}\right)^2 + \left(\frac{\partial T}{\partial z}\right)^2\right] \tag{4.3.32a}$$

and

$$\begin{aligned} S_{\text{gen}}(\text{frictional}) &= \frac{\mu\Phi}{T} = \frac{\mu}{T}\left(\overline{\Phi} + \Phi'\right) \\ &= \frac{\mu}{T}\left[\left(\frac{\partial \overline{u_i}}{\partial x_j} + \frac{\partial \overline{u_j}}{\partial x_i}\right)\frac{\partial \overline{u_i}}{\partial x_j} + \overline{\frac{\partial u_i}{\partial x_j}\frac{\partial u_i}{\partial x_j}}\right] \end{aligned} \tag{4.3.32b}$$

Bejan (1996) pointed out that for turbulent flow the dissipation due to mean flow is roughly the same as that due to turbulent fluctuation. In fact, the frictional entropy generation rate accounts for a negligible part of S_{gen}, unless the Reynolds number becomes very large. It should be noted that when using the previous equations for nanofluids, the corresponding nanofluid properties should be used.

Adding nanoparticles to the base fluid reduces entropy generation in the laminar regime of nanofluid flow in conduits, with an optimal volume fraction corresponding to minimized entropy generation (Li and Kleinstreuer, 2010). Also, a nanofluid decreases the total generated entropy of the system without significantly increasing the required pumping power (Feng and Kleinstreuer, 2010). Although adding NPs to the base fluid increases both k and μ in Equation 4.3.32, it also reduces the temperature and velocity gradients, which leads to a reduction in S_{gen} (Xu and Kleinstreuer, 2014b). Thus, from a perspective of the second law of thermodynamics, adding NPs to the base fluid can be very beneficial. It simply decreases the entropy generation rate, especially in the low-to-medium Reynolds number regime. When the Reynolds number is very high, the part of frictional entropy generation contributes more to the total entropy generation than the thermal part, pushing up the entropy generation rate due to the augmented nanofluid viscosity (Mahian et al., 2013). Clearly, the thermophysical properties of nanofluids play an important role in determining the entropy generation rate.

Discrepancies among Enhanced Heat Transfer Studies Using Nanofluids

Flow of nanofluids is a relatively new concept, and experimental/theoretical research efforts are still ongoing. As a result, there have been strong debates on almost all aspects of nanofluid-flow studies when applied to enhanced heat transfer (Prabhat et al., 2012). Perhaps the most notable one is the International Nanofluid Property Benchmark Exercise (Buongiorno et al., 2009), in which the thermal conductivities of identical samples of stable nanofluids were measured by more than 30 organizations worldwide, using a variety of measurement techniques. They found that when normalized to the measured base fluid thermal conductivity, the thermal conductivity of the nanofluid can be well predicted by the effective medium theory (Maxwell, 1881), suggesting no anomalous enhancement of thermal conductivity. In addition, controversies can be found over nanofluid viscosity, heat transfer coefficient, Nusselt number, and pressure drop. During the first few years, experimental studies often showed enhanced values for the thermal conductivity and heat transfer coefficient (Kleinstreuer and Xu, 2015; Mohamad, 2015). However, in recent years, a lot of studies reported that there is negligible increase of these parameters, occasionally even a decrease when adding nanoparticles to liquids. The controversy over nanofluid viscosity is especially noticeable. For example, some studies found positive relationships between particle diameter and viscosity, and some found negative ones. Even theoretical analyses focusing on the same mechanisms resulted

in contradictory conclusions. Though Brownian motion and aggregation are considered the most important characteristics of nanofluids, *how* they influence the thermophysical properties and hence the heat transfer performance of nanofluids is still under debate.

Nanofluid Flow Applications

Nanofluids have abundant potential applications in a variety of thermal processes occurring in conduits. It would be impractical to exhaust the list here; therefore, only a few important applications are discussed in this section. Clearly, nanofluids were first investigated to achieve enhanced heat transfer for cooling purposes. Hence, the heat transfer performance of a nanofluid in a double-tube heat exchanger will be presented as an example (see also Book Section 4.2). In contrast, magnetic nanofluids have great potential in certain unique thermal applications due to its distinctive properties. Novel applications of nanofluids pertaining to internal flow thermal processes occur in biomedical engineering, as demonstrated with discussions of two state-of-the-art research directions.

Nanofluid Flow in a Heat Exchanger

Thermal nanofluid flow in a double-tube heat exchanger is presented to evaluate the heat transfer performance of an alumina–water nanofluid. The configuration is depicted in Figure 4.3.8 as part of a novel solar collector system (Kleinstreuer and Xu, 2015). Hot water flows in the annular, cold nanofluid flowing in the inner tube exchanges heat with water through a copper wall in between. The convectional dynamic viscosity model by Brinkman (1952) and the empirical model by Corcione (2011) were compared. The effective thermal conductivity model developed by Xu and Kleinstreuer (2014a) was employed, which relied on the single-phase approach for simulations.

Figure 4.3.9 compares the pressure gradients at different Reynolds numbers for water and nanofluids with different NP volume fractions. The conventional Brinkman viscosity model underestimates the pressure drop, especially when the NP loading is high. On the other hand, the nanofluid yields a higher heat transfer coefficient than pure water at the same Reynolds number. Meanwhile, the heat transfer coefficient predicted using the Corcione model is higher than that using the Brinkman model.

Magnetic Nanofluids

Magnetic nanofluids (MNFs) or ferrofluids are nanofluids that consist of a nonmagnetic base fluid and magnetic nanoparticles. The NPs are made from ferromagnetic materials such as iron, nickel, and cobalt, or their oxides such as spinel-type ferrites, and magnetite (Fe_3O_4). In order to prevent the coagulation, particles are coated with surfactants, either long chained molecules, or an electrostatic layer. In the absence of a magnetic field, the fluid behaves as a normal single component fluid. When an external magnetic field is applied, the fluid is magnetized, and the apparent fluid properties such as viscosity or thermal conductivity may be changed (see Figure 4.3.10). In fact, the properties of magnetic nanofluids may be controlled and tuned based on application requirements

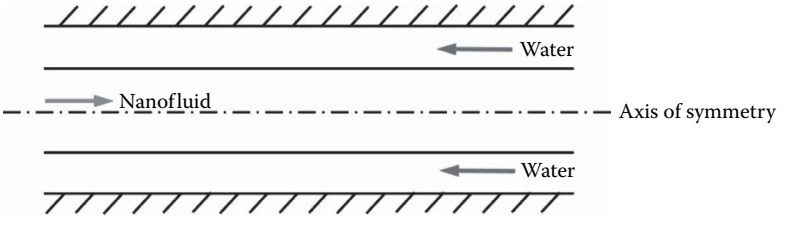

FIGURE 4.3.8 Schematics of a counterflow, double-tube heat exchanger.

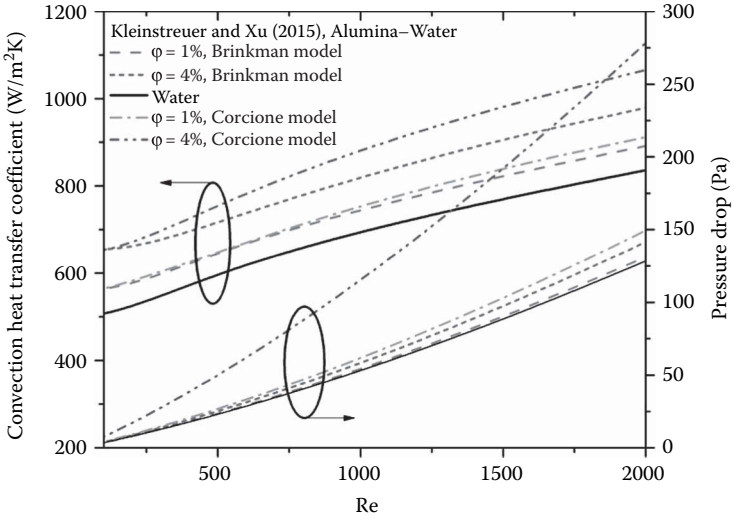

FIGURE 4.3.9 Pressure drop and convection heat transfer coefficient as a function of Re number.

(Shima et al., 2009). The magnetic field can be applied in a number of different ways depending on application requirements (see Figure 4.3.11).

Magnetic nanofluid behaves like a paramagnetic material. In the absence of magnetic field, the magnetic moments of particles are randomly orientated due to the Brownian motion, and the fluid has no net magnetization. When an external magnetic field is applied, the magnetic moments align along the magnetic field direction, generating net magnetization to the fluid. In the presence of a magnetic field, the governing equations of the fluid flow and heat transfer need to be modified to include the Lorentz force and the corresponding energy. The continuity equation remains unchanged, while the momentum equation becomes

$$\rho\frac{D\vec{v}}{Dt}=-\nabla p+\nabla\cdot\vec{\vec{\tau}}+\rho\vec{g}+\vec{J}\times\vec{B} \tag{4.3.33}$$

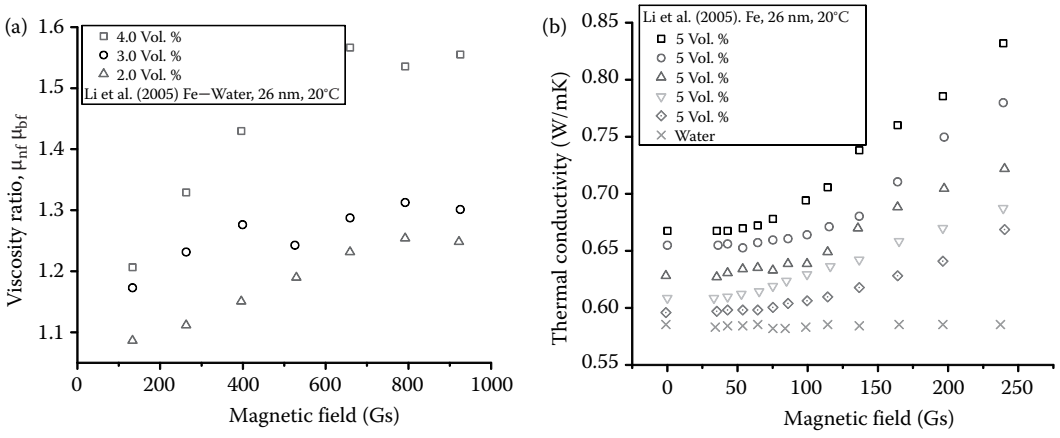

FIGURE 4.3.10 Properties of MNFs: (a) Relative viscosity of Fe–water magnetic fluid parallel to the magnetic field; and (b) thermal conductivity of Fe–water magnetic fluid in the magnetic field parallel to temperature gradient.

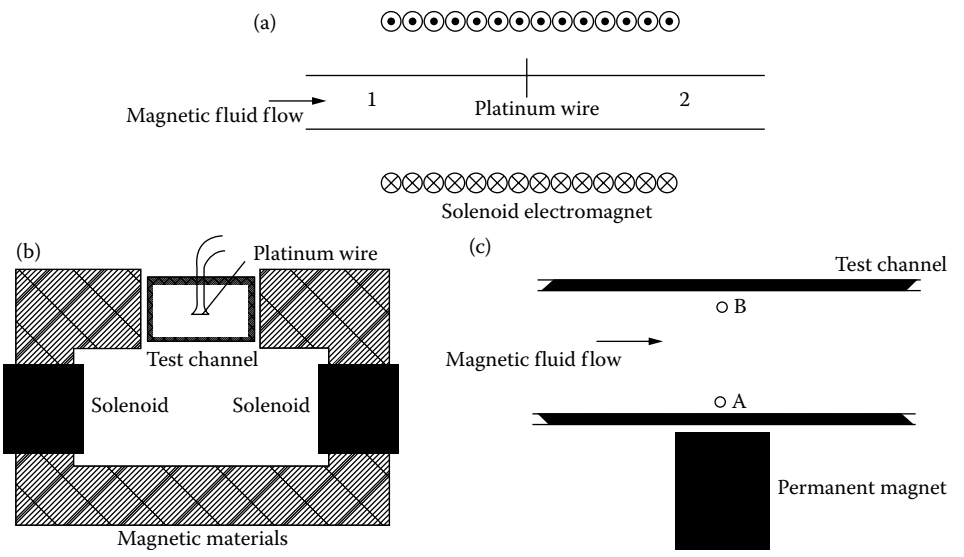

FIGURE 4.3.11 Schematic diagram of magnetic system (*not in scale*): (a) Solenoid electromagnet (parallel field); (b) electromagnet (perpendicular field); and (c) permanent magnet (perpendicular field). (From Li, Q. and Xuan, Y., *Exp. Therm. Fluid Sci.*, 33 (4): 591–596, 2009.)

where $\vec{v}$ is the velocity field, p is the pressure, D/Dt is the total derivative, $\vec{g}$ is the gravitational acceleration, $\vec{\vec{\tau}}$ is the deviatoric stress tensor, $\vec{J}$ is the electric current density, and $\vec{B}$ is the magnetic flux density. Owing to Ampere's law, the Lorentz force term $\vec{J}\times\vec{B}$ can be written in the form

$$\vec{J}\times\vec{B}=\frac{(B\cdot\nabla)B}{\mu_0}-\nabla\left(\frac{B^2}{2\mu_0}\right) \tag{4.3.34}$$

The energy equation has the form

$$\left[\rho c_V-\mu_0\vec{H}\cdot\left(\frac{\partial M}{\partial T}\right)\right]\left(\frac{\partial T}{\partial t}+\vec{v}\cdot\nabla T\right)+\mu_0 T\left(\frac{\partial M}{\partial T}\right)\cdot\frac{\partial\vec{H}}{\partial T}=k_{\mathrm{nf}}\nabla^2 T+\mu_{\mathrm{nf}}\Phi \tag{4.3.35}$$

where $\mu_0=4\pi\times10^{-7}\,\mathrm{H}\cdot\mathrm{m}^{-1}$ is the magnetic constant, $\vec{H}$ is the magnetic field intensity, M is the magnetization of the fluid, and $\mu_{\mathrm{nf}}\Phi$ is the viscous dissipation term. As such, the fluid flow and heat transfer of magnetic nanofluids can be manipulated by applying different magnetic fields.

The thermophysical properties of MNFs are different with and without the presence of a magnetic field. In addition, the strength and orientation of the applied magnetic field affect the properties (see Figure 4.3.12). For example, applying a magnetic field parallel to the temperature gradient will significantly enhance the thermal conductivity along that direction (Bahiraei and Hangi, 2015). This is probably due to the particle alignment and chain-like structure formation in that direction. Moreover, the thermal conductivity increases with the magnetic field strength.

MNF-convection heat transfer in conduits can be controlled by applying magnetic fields to all or a specific section of the flow field, which provides great flexibility. This influence is due both to the modified thermophysical properties of the MNFs and to the motion and migration of nanoparticles under the magnetic field. Using alternating and nonuniform magnetic fields to tune the heat transfer characteristics of MNFs is feasible. For example, increasing the frequency of the alternating magnetic field can lead to greater heat transfer enhancement, as shown in Figure 4.3.12b. Applying a magnetic field such that the field gradient is along the main flow will enhance the convection heat transfer, while a field gradient apposite to the main stream suppresses the heat transfer (see Figure 4.3.12a).

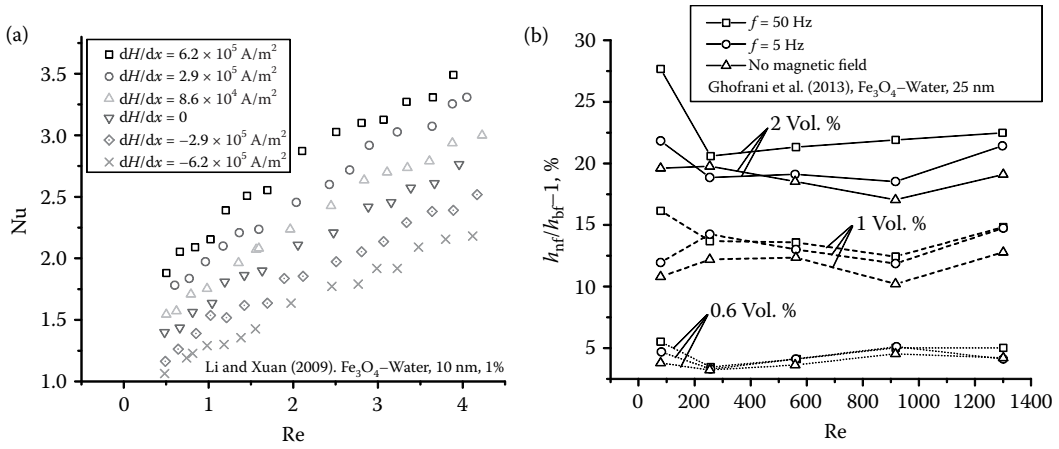

FIGURE 4.3.12 Heat transfer performance of MNFs (a) Nusselt numbers as a function of the Re number with the magnetic field gradient along or opposite to the main flow direction of the magnetic fluid, and (b) variation of the enhancement of heat transfer coefficient with Reynolds number as a function of the frequency of the alternating magnetic field and nanoparticle volume concentration.

Meanwhile, using a magnetic field with negative gradient along the flow stream requires a higher pumping power, while a magnetic field with positive gradient acts as a pump (Aminfar et al., 2011).

Aside from thermal engineering, magnetic nanofluids have also broad applications in biomedical engineering (Kleinstreuer et al., 2008, 2014; Sharifi et al., 2012; Lin et al., 2013; Miaskowski and Sawicki, 2013) and electronics (Li et al., 2008). An interesting application of MNFs is due to the unique characteristics of a specific type of MNF, that is, temperature-sensitive magnetic fluids whose magnetization is dependent on temperature. This property gives rise to thermomagnetic convection, where the MNF continuously circulates in the conduits without additional energy consumption. This is particularly useful in cases where pressure-driven flows are not feasible or inadequate, as the driving force here is the magnetic force induced by a temperature difference. Hence, higher heat load will result in greater velocity and higher heat transfer coefficient (Mukhopadhyay et al., 2005). An important biomedical application is external magnetic field-guided delivery of nanodrugs in either the pulmonary tract (Dames et al., 2007; Azarmi et al., 2008; Pourmhran, et al. 2015) or the cardiovascular system (Arruebo et al., 2007; Veiseh et al., 2010). Another example is cancer treatment taking advantage of magnetic nanofluid hyperthermia (Lin et al., 2013).

It should be noted that in the applications using MNFs, the long-term stability of the suspension is of uttermost importance, because formation of aggregates can lead to unexpected instabilities and system failure.

Nanodroplet–Vapor–Air Mixture Dynamics in Models of Human Lung Airways

As discussed, nanofluids have broad applications in biomedical engineering. For instance, *direct* nanodrug delivery has been extensively studied in recent years, believing to be a major future treatment option for many diseases. A specific application is the convection heat transfer with phase change of inhaled nanodroplets in lung airways (see Figure 4.3.13). Examples include administered drug-aerosols using inhalers, fume- or mist-nanodroplet inhalation from fuel handling, welding operation, spray processes as well as smoke-aerosol inhalation from conventional cigarettes and electronic cigarettes. Their transport and conversion phenomena involve complex physical and thermodynamic interactions between air, vapors, and nanodroplets with their therapeutic (or toxic) compounds and the respiratory tract walls. This is an area of interdisciplinary applications of modern thermal internal nanofluid-flow engineering. A basic mathematical model can be outlined as follows.

Any given air–vapor mixture is described as a single continuous phase, that is, the conservation laws for mass, momentum, and energy, describing the air–vapor mixture transport and the advection-diffusion equation describing vapor-species transport. Droplet–vapor interactions, that is, liquid–vapor mass change due to evaporation or condensation, are implemented by: (1) introducing source terms into the energy equation and vapor-species transport equations (see Equations 4.3.36 through 4.3.39); and (2) employing the local vapor-mass fraction in the droplet mass conservation equation (see Equation 4.3.41). Specifically, the energy equation of the air–vapor mixture reads:

$$\frac{\partial\left(\rho c_p T\right)_{a-v}}{\partial t}+\frac{\partial\left(\rho c_p u_j T\right)_{a-v}}{\partial x_j}=$$

$$\frac{\partial}{\partial x_j}\left[\left(k_{a-v}+\frac{\rho_{a-v}c_{a-v,p}\nu_T}{\mathrm{Pr}_T}\right)\frac{\partial T_{a-v}}{\partial x_j}\right]+\Phi+\frac{\partial}{\partial x_j}\left[\sum_{s=1}^{N}h_s\rho_{a-v}\left(\tilde{D}_{a-v}+\frac{\nu_T}{\mathrm{Sc}_T}\right)\frac{\partial Y_{v,s}}{\partial x_j}\right]+S_{v-d}^{(E)} \quad (4.3.36)$$

where the energy source term $S_{v-d}^{(E)}$ is due to the latent heat of evaporation or condensation, which is released or absorbed by the droplets per local mesh cell:

$$S_{v-d}^{(E)}=\sum_{s=1}^{4}S_{v-d,s}^{(E)}=\left\{\sum_{i=1}^{N_{d,\mathrm{cell}}}\left[\left(\sum_{s=1}^{4}L_s\overline{j_s}\right)A_d\right]_i\right\}/V_{\mathrm{cell}} \quad (4.3.37)$$

where $N_{d,\mathrm{cell}}$ is the total droplet number in a specified mesh cell.

The governing equation for advection and diffusion of the sth vapor species is expressed as

$$\frac{\partial(\rho_{a-v}Y_{v,s})}{\partial t}+\frac{\partial}{\partial x_j}\left(\rho_{a-v}u_jY_{v,s}\right)=\frac{\partial}{\partial x_j}\left[\rho_{a-v}\left(\tilde{D}_{a-v,s}+\frac{\nu_T}{\mathrm{Sc}_T}\right)\frac{\partial Y_{v,s}}{\partial x_j}\right]+S_{v-d,s}^{(Y)} \quad (4.3.38)$$

where $\mathrm{Sc}_T=0.9$ is the turbulence Schmidt number for $Y_{v,s}$, ν_T is the turbulent viscosity, and $\tilde{D}_{a-v,s}$ is the molecular diffusivity of the sth vapor species in the air–vapor mixture. The local vaporized/condensed vapor-mass flow rate of the aerosol components are added to its advection-diffusion equation as a source term $S_{v-d,s}^{(Y)}$ (kg m^{-3} s^{-1}), that is,

$$S_{v-d,s}^{(Y)}=\int_{t_{i,\mathrm{start}}}^{t_{i,\mathrm{start}}+\Delta t_f}\left(\sum_{i=1}^{N_{d,\mathrm{cell}}}\left(\overline{j_s}A_d\right)_i\right)dt_d\,/\left(V_{\mathrm{cell}}\Delta t_f\right) \quad (4.3.39)$$

where $\overline{j_s}$ is the average evaporation/condensation mass flux normal to the droplet surface of the sth component (i.e., $\overline{j_s}>0$ for evaporation and $\overline{j_s}<0$ for condensation), and A_d is the droplet surface area. Also, $\mathrm{d}t_\mathrm{d}$ represents the droplet phase time differential and Δt_f is the flow time step.

For the multicomponent droplet size change and transport, the governing equations for discrete droplets are the translational equation as well as the mass and energy conservation laws.

Newton's second law of motion states:

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(m_d u_{d,i}\right)=F_i^D+F_i^L+F_i^{BM}+F_i^G \quad (4.3.40)$$

where F_i^D, F_i^L, F_i^{BM}, and F_i^G are the drag force, lift force, Brownian motion-induced force, and gravity, respectively.

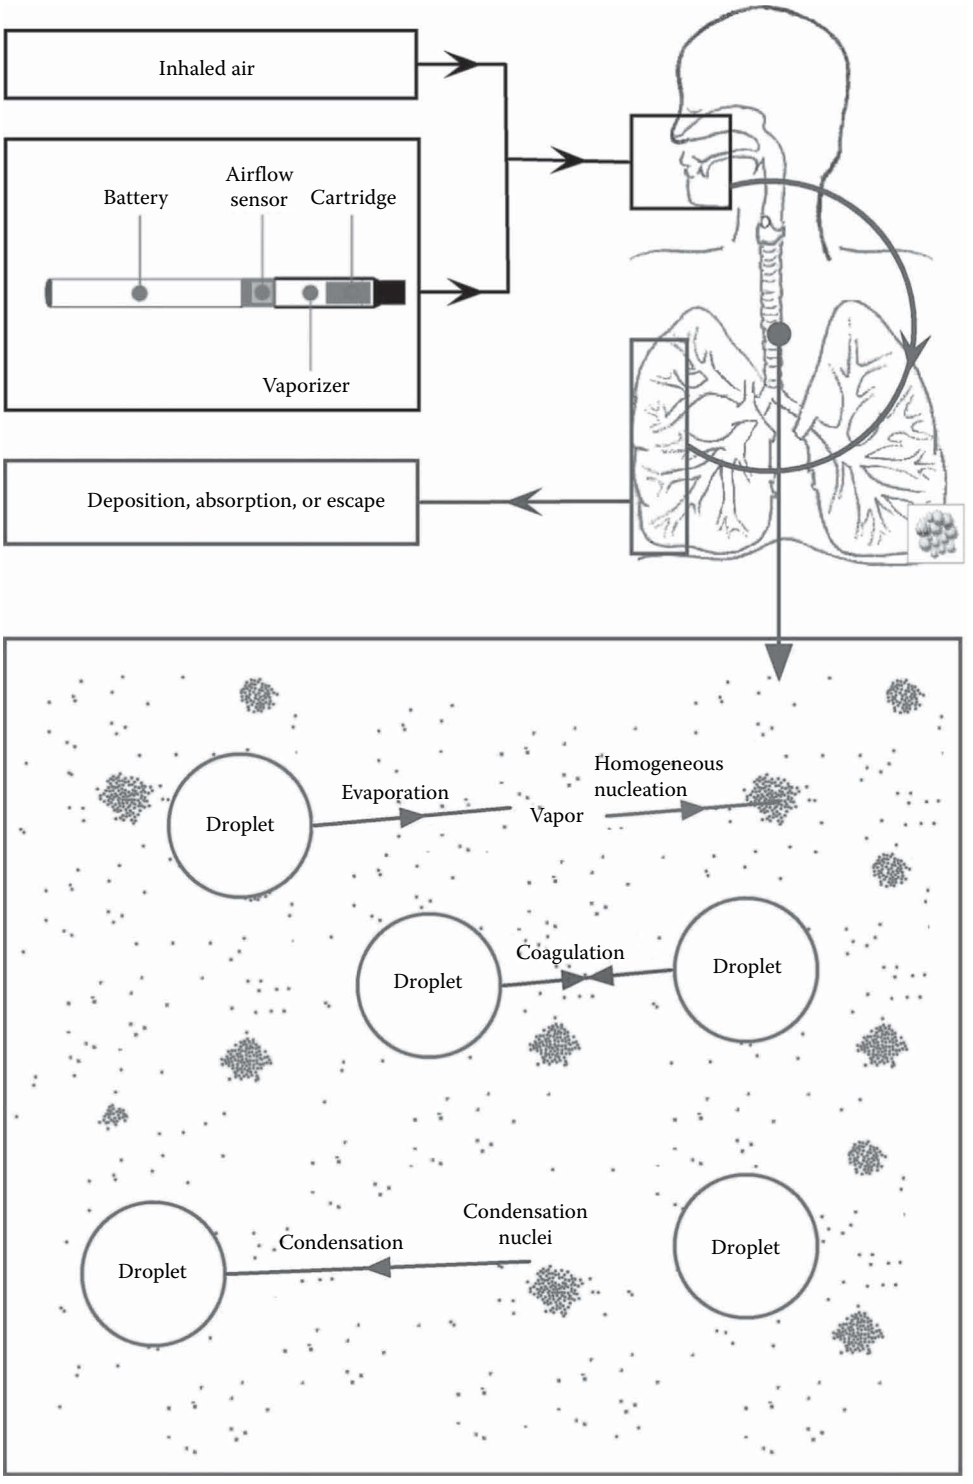

FIGURE 4.3.13 Illustration of inhalation of multicomponent droplet–vapor mixtures and their fate in human lung airways. (From Feng, Y. and Kleinstreuer, C., A novel computational fluid-particle dynamics model for the simulation of multicomponent droplet-vapor transport/deposition in an idealized human upper airway configuration. In *2015 Annual Meeting of the Biomedical Engineering Society*, Tampa, FL, 2015.)

Droplet mass changes due to condensation/evaporation can be described as

$$\frac{\mathrm{d}m_d}{\mathrm{d}t} = -\sum_{s=1}^{m} \int_{\text{surf}} j_s \, dA \approx -\sum_{s=1}^{m} (\overline{j_s} \cdot A_d) \tag{4.3.41}$$

where the average mass flux $\overline{j_s}$ is given by Turns (1996):

$$\overline{j_s} = \rho_{a-v} \cdot C_m \cdot \mathrm{Sh} \cdot \tilde{D}_{a-v,s} \cdot d_d^{-1} \ln\left[\left(1 - Y_{v,s,\,\text{cell}}\right) / \left(1 - Y_{v,s,\,\text{surf}}\right)\right] \tag{4.3.42}$$

Here, Sh is the Sherwood number (see the Nomenclature for definition), while $Y_{v,s,\text{surf}}$ and $Y_{v,s,\text{cell}}$ are the mass fractions of the sth vapor phase at the droplet surface and at the center of the cell, where the droplet currently resides. The correction factor C_m for submicron droplets, considering noncontinuum effects, can be expressed as

$$C_\text{m} = \frac{1 + \mathrm{Kn}}{1 + \left(\dfrac{4}{3\alpha_\text{m}} + 0.377\right)\mathrm{Kn} + \dfrac{4}{3\alpha_\text{m}}\mathrm{Kn}^2} \tag{4.3.43}$$

where Kn is the Knudsen number, $\mathrm{Kn} = 2\lambda_{a-v}/d_d$, in which λ_{a-v} is the mean free path of the air–vapor mixture surrounding the droplet, and α_m is the mass accommodation coefficient, where $\alpha_\text{m} = 1$ was used in the present study (Hinds, 1999). The derivation of Equation 4.3.42 is based on the assumption that the distance between the droplet mass center and the mesh cell center is much larger than the droplet radius. Specifically, $Y_{v,s,\text{cell}}$ is determined by the advection-diffusion equation (see Equation 4.3.38), while $Y_{v,s,\text{surf}}$ can be calculated by

$$Y_{v,s,\,\text{surf}} = \frac{\rho_{v,s,\,\text{surf}}}{\rho_{a-v}} = \frac{\left(P_{v,s,\,\text{surf}} / \Re_s T_d\right)}{\rho_{a-v}} = \frac{\gamma_s \cdot K_s \cdot X_{s,d} \cdot P_{v,s,\text{sat}}(T_d)}{\rho_{a-v}\left(\Re / M_s\right) T_d} \tag{4.3.44}$$

Here, $P_{v,s,\text{surf}}$ is the equivalent density of vapor species s in the air–vapor mixture at the droplet surface; γ_s is the activity coefficient of species s, which is a correction of the evaporation/condensation characteristics of a certain liquid component due to the molecular bonding changes in the pure droplets and in the multicomponent droplets (Tu and Ray, 2005); $X_{s,d}$ is the mole fraction of the sth component in the droplet; $\Re_s$ is the species gas constant; T_d is the droplet temperature; and $P_{v,s,\text{sat}}$ is the temperature-dependent saturation pressure of the pure sth species. Clearly, parameters γ_s and γ_s serve as corrections to the vapor pressure at the surface of multicomponent droplets (Raoult's law), while K_s is the correction factor for the Kelvin effect (Hinds, 1999):

$$K_s = \exp[4\sigma_s M_s / (\Re \rho_s d_d T_d)] \tag{4.3.45}$$

where σ_s is the surface tension of component s at the droplet surface.

The droplet heat transfer equation takes the form:

$$m_d c_{p,d}\left(\frac{\mathrm{d}T_d}{\mathrm{d}t}\right) = C_T\left(k_{a-v} \cdot \frac{\mathrm{Nu}}{d_d}\right)(T_{a-v,\text{cell}} - T_d)A_d - \left(\sum_{s=1}^{N} L_s \overline{j_s}\right)A_d \tag{4.3.46}$$

where L_s is the latent heat of liquid–vapor phase transition of the sth species (L_s is always larger than zero). Also, C_T is the correction factor for submicron droplets:

$$C_T = \frac{1 + \mathrm{Kn}}{1 + \left(\dfrac{4}{3\alpha_T} + 0.377\right)\mathrm{Kn} + \dfrac{4}{3\alpha_T}\mathrm{Kn}^2} \tag{4.3.47}$$

where α_T is the thermal accommodation coefficient with the value of $\alpha_T = 1$ (Hinds, 1999).

The governing equations of the transport and phase change of the multicomponent droplet–vapor mixtures can be solved using computational fluid-particle dynamics (CF-PD) methods (Kleinstreuer, 2014). For example, the transient transport and conversion phenomena of electronic cigarette aerosol under nonisothermal conditions leading to local particle/droplet/vapor depositions and possible species mass transfer into systemic regions was studied by Feng and Kleinstreuer (2015). The transient puff topography is shown in Figure 4.3.14, whereas the deposition patterns of both the droplets and the vapor are shown in Figure 4.3.15.

Future Work

Nanofluids have been studied for more than two decades, especially for enhanced cooling applications (see also Book Section 4.20). However, there are still a lot of questions that remain to be answered. Specifically, the fundamental physics underlying its anomalous characteristics, if any, and the reliability and robustness of its applicability require further attention.

Because contradictory results have been reported, partially due to different preparation methods and measurement procedures adopted, standardized methods for synthesis and characterization of nanofluids are needed to prove reliability and repeatability.

The macroscale characteristics of nanofluids are due to microscale effects that are still elusive to a certain extent. Hence, to understand and predict the behavior of nanofluids, the microscale physics need to be recognized. This requires more experimental studies and high-fidelity simulations that can reveal the interactions between nanoparticles and the base fluid that may give rise to any anomalous behavior of nanofluids in forced convection heat transfer.

A major issue in real systems and engineering applications with nanofluids is instability, which is difficult to model and predict theoretically. The instabilities are often absent when systems are studied using idealized models. The reason is that the unstable behavior of a complex system is often caused by secondary effects, which are neglected in simplified models. Therefore, more experimental measurements and theoretical analyses are needed to determine the most important effects that need to be considered in modeling efforts.

Nanofluid-flow applications with heat transfer in biomedical engineering and toxicology have enormous potential, as indicated in this section. Proof-of-concepts have been so far the focus of

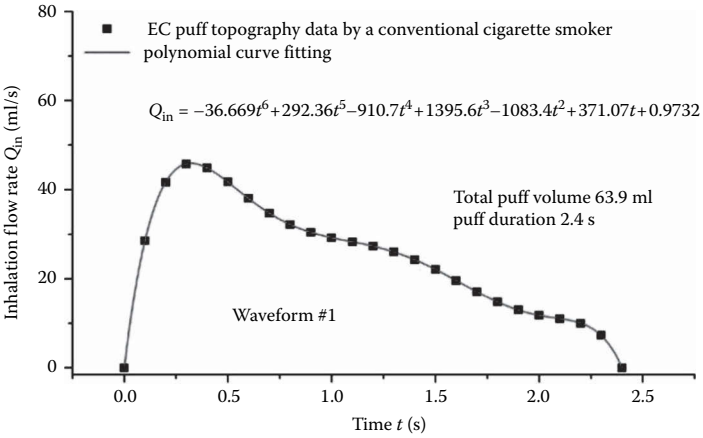

FIGURE 4.3.14 Transient puff topographies. most studies. To evaluate real-world performance and applicability of internal thermal nanofluid flow in various scenarios, basic experimental, theoretical, and numerical studies are most desirable.

Conclusions

Nanofluid flow in conduits has shown remarkable convective heat transfer performance mainly due to the small particle size. Brownian motion and nanoparticle aggregation may be the two most important effects that give rise to potentially superior thermal properties of nanofluid flow. Additional factors include nanoparticle loading, particle–liquid slip, temperature, particle size and shape, pH, and favorable aggregation. However, long-term stability of nanofluids is difficult to achieve due to random aggregation effects. Nanofluid flow is still an active field of study, partly because of the contradictory results concerning its most important characteristics. These controversial studies put the effectiveness of nanofluids as coolants in debate and cast a doubt on its engineering applicability. Hence, high-resolution studies are needed to better understand nanofluid flow dynamics and to determine its effectiveness in enhanced cooling or heating.

In contrast, thermal internal nanofluid-flow applications in biomedical engineering and toxicology are, without doubt, one of the important research areas in modern thermal fluid-particle dynamics.

4.4 FOULING IN CRUDE OIL AND FOOD RELATED HEAT-TRANSFER EQUIPMENT

D. Ian Wilson and Graham T. Polley

Introduction: The Major Unresolved Problem in Heat Transfer

Fouling is the unwanted accumulation of material on the surface of process equipment to form deposit layers, which impose additional resistances to heat transfer. These fouling layers can also affect the flow of the fluid, increasing surface roughness and/or pressure drop. As a result, the thermal and hydraulic performance of the unit will deteriorate over time.

Fouling occurs because species in the fluid being processed form the layers in response to being heated or cooled. This section addresses fouling and its mitigation in the food processing sector and crude oil refining operations, where fouling is commonly encountered. The chapter *does not* deal with water scaling, particulate fouling from gases, or biofouling: the reader is advised to consult Bott (1995), ESDU (2003, 2008), Bott (2008), and the proceedings of the conferences on fouling and cleaning in heat exchangers at http://www.heatexchanger-fouling.com/ for detailed information on these topics to complement the general points made here.

Fouling is a dynamic phenomenon and requires consideration at each stage of a heat exchanger's life in design, commissioning, and during operation. Fouling requires active management. Many problems with fouling arise because it is treated as a steady-state phenomenon at the design stage, or the heat exchanger is not operated in a manner which will mitigate fouling.

Quantitative Impact of Fouling

The thermal resistance of a deposit layer is usually lower than that of the volume of moving fluid it displaces, so the overall resistance to heat transfer increases. For heat transfer across a tube of inner and outer radii r_i and r_o, respectively, the clean overall heat transfer coefficient is given by

$$1/U_{j,\text{clean}}r_j = 1/r_i h_i + \ln\left(r_o/r_i\right)/k_{\text{wall}} + 1/r_o h_o . \tag{4.4.1}$$

Here j can be either i or o. The presence of fouling layers adds further terms. Where fouling layers are thin, the thermal resistance can be approximated as that of a thin slab with thermal conductivity k_f and thickness l_f. The overall heat transfer coefficient is then

$$\begin{aligned} 1/U_j r_j &= 1/U_{j,\text{clean}}r_j + l_{f,o}/r_o k_{f,o} + l_{f,i}/r_i k_{f,i} \\ &= 1/U_{j,\text{clean}}r_j + R_{f,o}/r_o + R_{f,i}/r_i , \end{aligned} \tag{4.4.2}$$

where R_f is the fouling resistance and subscripts o and i denote the surface on which the fouling layer is formed. If a fouling layer is not thin, the slab approximation will be inaccurate and the film heat transfer coefficient is also likely to change. A rough deposit layer will also change the film heat transfer coefficient, causing it to increase: this can result in an apparently negative fouling resistance if the impact of roughness on $U_{j,\text{clean}}$ is not considered. The pressure drop will, however, increase: this is one of the reasons why pressure drop as well as thermal performance should be monitored on heat exchangers subject to fouling.

In practice, it is not possible to distinguish where in a heat exchanger a deposit is formed on the basis of steady state thermal measurements alone, and a single term is used to quantify the additional resistance due to fouling:

$$1/U_j = 1/U_{j,\text{clean}} + R_{f,j} . \tag{4.4.3}$$

In several texts, $R_{f,j}$ is called the *fouling factor*. It follows that

$$U_j = \frac{U_{j,clean}}{\left(1 + R_{f,j} U_{j,clean}\right)}. \tag{4.4.4}$$

The group $R_{f,j}\ U_{j,clean}$ is dimensionless and is sometimes called the fouling Biot number. Another measure used for the impact of fouling is the cleanliness factor, CF, defined as

$$\begin{aligned} CF &= 100 \times U_j / U_{j,clean} \\ &= 100 / (1 + R_{f,j} U_{j,clean}). \end{aligned} \tag{4.4.5}$$

Both U_j and CF decrease as the fouling resistance increases.

In the rest of this chapter, the j subscript on U is no longer used.

Equation 4.4.4 shows that the impact of fouling depends on the magnitude of the clean heat transfer coefficient. Figure 4.4.1 shows the effect of a linear increase in fouling resistance with time on the overall heat transfer coefficient for two values of U_{clean}. When U_{clean} is large, a small fouling resistance has a significant effect, whereas if U_{clean} is small, the effect of fouling will not be noticed, or measurable in practical terms, until R_f is large. In the latter case, the effect of fouling on pressure drop and/or flow rate is likely to be noticed before that on heat transfer (see Figure 4.4.4).

It is also important to note that the definition of R_f in Equation 4.4.3 includes the inaccuracy in the calculation of the clean heat transfer coefficient and any uncertainty in its estimation. In practice, the thermophysical properties of the fluids are seldom known accurately, or may be specified wrongly. Differences in heat transfer performance can then be incorrectly attributed to fouling.

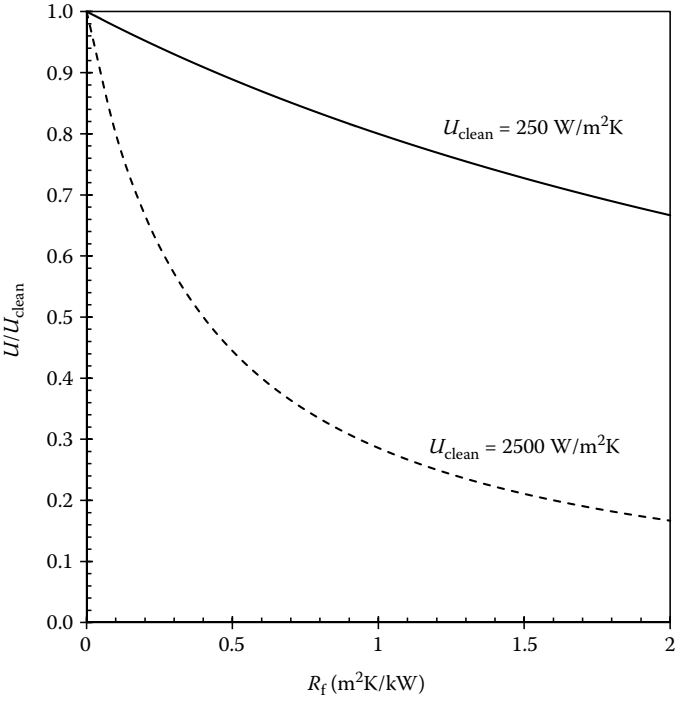

FIGURE 4.4.1 Effect of fouling resistance on overall heat transfer coefficient for two values of U_{clean}.

Robust Design

The impact of fouling on a heat exchanger depends on the unit's design: some designs are more *robust* toward the impact of fouling. It must be stressed that this does not mean that they mitigate fouling by reducing the occurrence of fouling or the rate of fouling layer deposition: it refers to the effect of fouling on the unit's performance. Fouling changes the local heat fluxes and temperature driving forces within a unit and the total heat duty, q, is determined by the contacting arrangement.

This is illustrated in Figure 4.4.2 for the case of a single-pass countercurrent heat exchanger. Recall that the heat exchanger effectiveness (see NTU-effectiveness method, Chapter 4.1) is determined by the contacting arrangement and the number of transfer units, NTU = UA/C, where A is the heat transfer area, and C is the smaller heat capacity rate. If the approach temperatures are constant, q is proportional to the effectiveness ε, given by

$$\varepsilon = \frac{\left(1 - \exp\left(-\mathrm{NTU}\left(1 - C_r\right)\right)\right)}{\left(1 - C_r \exp\left(-\mathrm{NTU}\left(1 - C_r\right)\right)\right)}, \tag{4.4.6}$$

where C_r is the ratio of the heat capacity rates. Figure 4.4.2 shows that ε is more sensitive to NTU when NTU is less than about 3. Fouling reduces U, the reduction in ε (and q) depending on C_r and the initial value of NTU, that is, the surface area of the exchanger and U_{clean}. A robust design would either start with a large value of NTU or be configured so that there is little fouling.

All four variables in Equation 4.4.6, namely U, A, C, and C_r, are determined by the unit design. The *historical* method for designing for fouling service has been to set C and C_r at the values determined by the process design (with neither recycle nor bypass modifying a flow rate) and to calculate U_{clean} based on clean performance (via Equation 4.4.1). The U value used for the design is then calculated via Equation 4.4.2, using estimates of fouling resistance expected to be experienced in practice for $R_{f,i}$ and $R_{f,o}$. These are often referred to as fouling factors. The heat exchanger area is

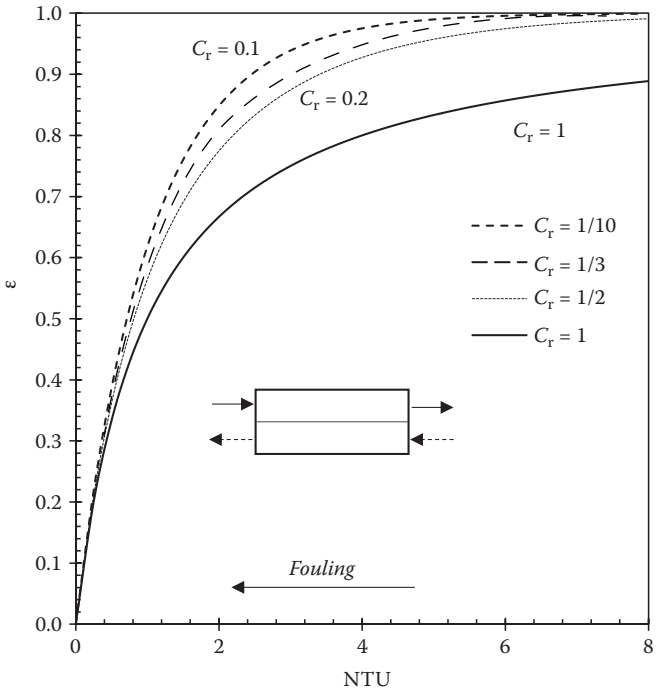

FIGURE 4.4.2 Effect of fouling, via NTU, on the effectiveness of a simple countercurrent heat exchanger for different values of capacity rate ratio. Fouling causes NTU to decrease, reducing ε.

then larger than that required for the clean case: excess area has to be added. NTU is then greater than required, and Figure 4.4.2 shows that the design is then apparently more robust. Initially, however, it will overperform and some control action (typically involving bypassing) will be needed to adjust the duty to its target value.

Tables of "fouling factors" are available in many sources, including the web, design handbooks (e.g., Saunders, 1988; Kakaç and Liu, 2002), as well as those based on local experience. If the historical method is to be used, the latter source is to be preferred.

Equation 4.4.4 shows that injudicious selection of such fouling factors can lead to large amounts of excess area, with associated penalties in terms of cost, pressure drop, and even promotion of fouling resulting in a "self-fulfilling prophecy" (see Bott, 1995; Ishiyama et al., 2008). An alternative rule of thumb used elsewhere is the "no-foul" approach whereby fouling factors are not used, and the excess area added for fouling and uncertainty in the calculation of heat transfer coefficients is limited to a fixed percentage, for example, 20% (Gilmour, 1965; Bennett and Nesta, 2004).

Other contacting arrangements give different relationships between ε and NTU, and therefore different sensitivity to fouling. The contacting arrangement also determines the distribution of surface temperatures within the heat exchanger: for fouling processes that are sensitive to surface temperature, this will determine the rate of deposition and is discussed further in the "Use of Fouling Models in Exchanger Design" section.

Fouling Dynamics

The rate of fouling is determined by the supply of precursors in the fluid, flow rates, bulk and surface temperatures, and the physical and chemical properties of the heat transfer surface. The factors particular to food processing and crude oil are discussed further in "Fouling in Food Processing" and "Crude Oil Fouling" sections, respectively.

The inset in Figure 4.4.3 shows two characteristic fouling behaviors that are often observed in practice: (1) linear fouling, where the fouling resistance increases at a constant or near-constant rate over time, and (2) asymptotic fouling, where the rate of increase decreases over time and may approach an asymptotic value, labelled $R_{f,\infty}$. The fouling resistances are plotted as the product $R_f U_{clean}$, and the effect on heat transfer performance of a simple countercurrent unit, expressed as the effectiveness, is shown for two values of NTU. It can be seen that a linear increase in R_f over time gives a nonlinear change in effectiveness (and thus duty). After extended time, the performance of the linear fouling case is poor, and consideration should be given to taking the unit offline for cleaning.

The asymptotic trend has the same initial behavior as the linear case but approaches a steady value of fouling resistance and effectiveness over time. This is the basis for the design approach based on fouling factors, which assumes that the fouling resistance will reach an asymptotic limit and the unit is designed on this basis. The figure highlights the pitfalls associated with this approach: asymptotic fouling behavior is often observed with cooling water systems but is less common in refinery crude oil and continuous food processing applications.

Both trends show an initial period in which there is no measured change in fouling resistance, called the *induction period*. This is often associated with the modification of the original, clean surface to a form that supports the attachment of fouling layers. It can involve surface oxidation, corrosion, or adsorption of precursors. Once the original surface is coated with a fouling layer, the nature of the surface plays little role in deposition (apart from heat transfer considerations), but it can influence the rate of cleaning. Surface modification to prolong induction periods and thereby mitigate fouling is the subject of ongoing research (e.g., Gomes da Cruz et al., 2015).

Timescales

The length of time over which fouling occurs varies between applications. *Acute* fouling, where the overall heat transfer coefficient changes strongly over a relatively short period, is associated with fouling precursors being present in the bulk fluid in high concentration. *Chronic* fouling is

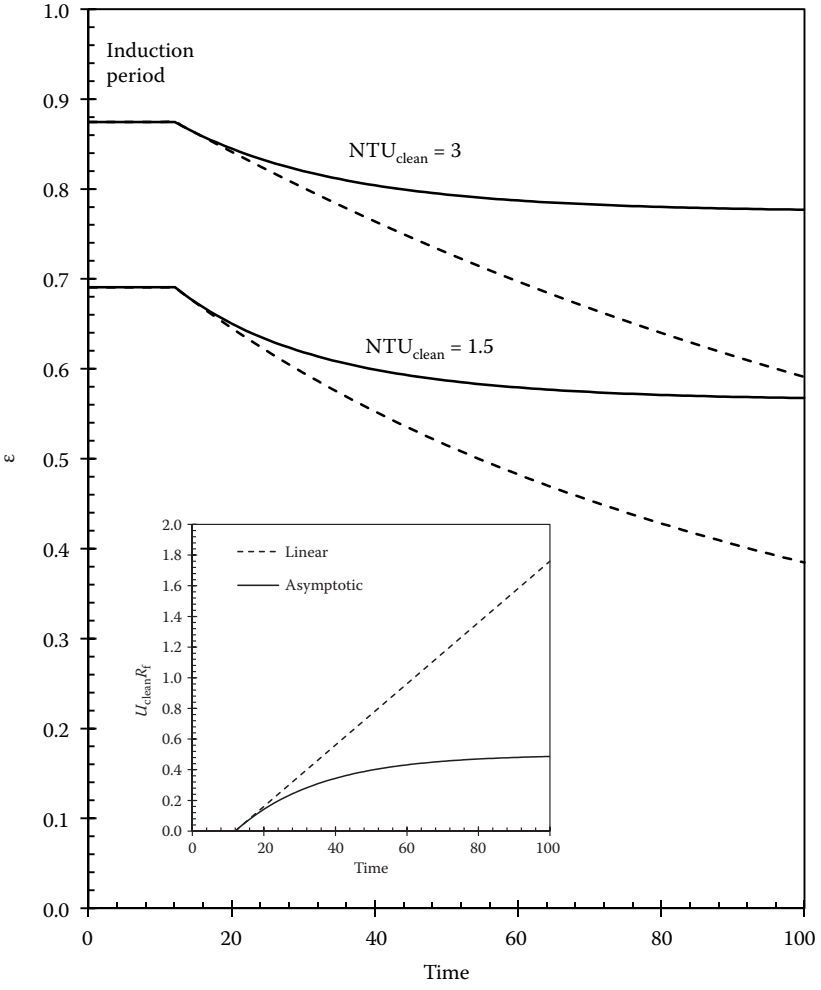

FIGURE 4.4.3 Effect of linear and asymptotic fouling on effectiveness of a simple countercurrent heat exchanger (see Figure 4.4.2). Inset shows evolution of $U_{clean}R_f$, which is dimensionless. Time is in arbitrary units.

associated with fouling precursors being present in low concentration, or being formed in the heated or cooled region near the heat transfer surface. Operations that normally operate subject to chronic fouling can experience acute fouling when process conditions or bulk chemistry are perturbed, such as when large amounts of material from a slop tank are added to the crude oil fed to a refinery preheat train or when incompatibility problems arise in blends of crude oils.

Pressure Drop

Fouling affects pressure drop by changing the roughness of the surface and by narrowing the cross-sectional area of the duct for flow. The effect of fouling on pressure drop can be estimated from the following simple model if the thermal conductivity of the fouling layer is known (or can be calculated). Assume that fraction x of the overall fouling resistance is caused by a layer of uniform thickness l_f and thermal conductivity k_f, on the side (hot or cold) under consideration. The thickness of the layer, assuming the thin slab approximation, is given by

$$l_f = xk_f R_f . \tag{4.4.7}$$

The hydraulic diameter of the duct, and thus the pressure drop, can then be calculated.

This is illustrated here for a shell-and-tube unit with no fouling on the shell side. Only the tube side pressure drop is then affected. For the tube side, $x=1$ and the internal diameter of the fouled tube, d_f, is given by

$$d_f = d_i - 2l_f = d_i - 2\ k_f R_f . \tag{4.4.8}$$

The pressure drop along the tube is proportional to the friction factor, C_f, and mean velocity, with the latter proportional to V/d_f^2. If the volumetric flow rate V is held constant, the ratio of the pressure drop under fouled and clean conditions is given by

$$\frac{\Delta P_{\text{fouled}}}{\Delta P_{\text{clean}}} = \frac{C_{\text{f,fouled}}}{C_{\text{f,clean}}} \times \frac{1}{\left(1 - 2k_f R_f / d_i\right)^4} . \tag{4.4.9}$$

Figure 4.4.4 plots the effect of fouling on pressure drop, given by Equation 4.4.9, against the effect of fouling on the overall heat transfer coefficient, Equation 4.4.4, for different values of the ratio of friction factors, U_{clean} and k_f/d_i. The U_{clean} values and the range in R_f are those used in Figure 4.4.1.

Over time the pressure drop increases and the overall heat transfer coefficient decreases. It can be seen that (1) the pressure drop is very sensitive to changes in roughness, and (2) the relationship between pressure drop and heat transfer coefficient depends on the value of U_{clean}. This is because a thin fouling layer has a significant effect if U_{clean} is large, but the effect on pressure drop is small. If U_{clean} is small, the fouling resistance (and thus the change in duct dimension) must be large in order to affect the heat transfer coefficient.

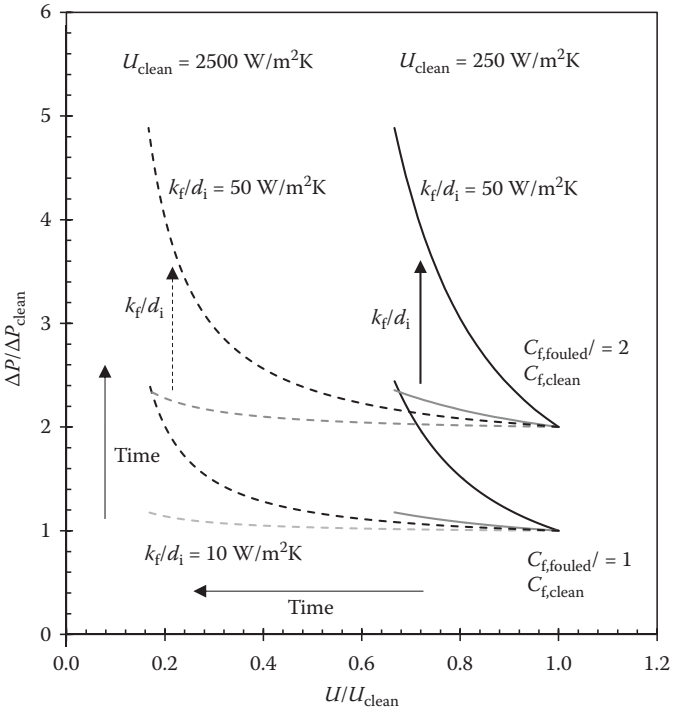

FIGURE 4.4.4 Effect of fouling on pressure drop, expressed as $\Delta P/\Delta P_{\text{clean}}$, and thermal performance, expressed as U/U_{clean}, for different values of U_{clean} and friction coefficient C_f. Line patterns indicate different values of k_f/d_i.

Fouling and Cleaning

A heat exchanger subject to fouling is likely to require cleaning in order to restore its performance or to avoid phenomena promoted by the presence of fouling layers such as microbial growth (in the food sector) and corrosion of the heat transfer surface. It is essential that cleaning is considered at the design stage, as certain configurations of heat exchanger are not compatible with some cleaning methods. A description of cleaning technologies can be found in Müller-Steinhagen and Zettler (2011). The aim of a cleaning operation is to remove any fouling deposit present and to restore the surface to its original condition. Ineffective cleaning will leave residues of foulant, which will promote fouling growth, so that the induction period will be very short or nonexistent (see Figure 4.4.3).

Cleaning also needs to be considered when selecting the materials of construction, seals, and pump sizing so that these can handle the chemical agents, conditions, and flow rates required for effective cleaning. In the food sector, the design must also consider the agents used for disinfection such as live steam.

Where cleaning is performed regularly, there is often an optimal run time between cleaning actions. Mathematical algorithms for scheduling cleaning operations have been developed for individual exchangers (see Cosado, 1990; Sheikh et al., 1996; Ishiyama et al., 2011). These rely on the availability of models describing the change in heat duty over time. The calculations for isolated exchangers can be performed on spreadsheets. Scheduling cleaning for units in networks requires detailed simulation of the network (see Ishiyama et al., 2009) and commercial software tools for this purpose have been developed (e.g., SmartPM from IHS; Studio from Hexxcell).

If the process is continuous and a unit cannot be taken offline for cleaning, it is common practice to split the unit into several smaller units, one of which is cleaned and is then available on standby.

Fouling Mechanisms

Fouling layers are often classified in terms of the mechanism by which they are formed, as this determines the nature of the deposit and the steps controlling the rate of formation. The latter information is important for heat exchanger design and control as it can guide how design and operating parameters can be selected to reduce fouling rates or possibly avoid fouling altogether.

The classification reported by Epstein (1983) is as follows:

Crystallization fouling is the formation and growth of crystalline deposits from species in solution. Crystallization occurs when the concentration of solute exceeds the equilibrium value, which is usually strongly related to temperature. A hot or cold surface can result in the local equilibrium concentration being lower than the bulk value, promoting crystallization at the surface. The equilibrium concentration increases with temperature for normal solubility species, such as fats, which leads to fats forming fouling layers on chilled surfaces. It decreases with temperature for inverse solubility salts such as calcium and magnesium carbonates and sulfates, and also calcium phosphates: the latter is responsible for the fouling of the higher temperature milk heaters in dairy ultra-high temperature (UHT) processing.

Particulate fouling occurs when solid particulates present in the bulk fluid are transported to the heat transfer surface where they attach. Particulates can be conveyed into the exchanger in the process steam or generated in the bulk by a chemical reaction such as crystallization.

Chemical reaction fouling occurs when species present in solution undergo a chemical transformation at the surface to form a fouling layer. The surface may catalyze the transformation. Surface temperature is an important factor, and this parameter will determine which reactions take place and their rate. Chemical reaction, like crystallization, can also occur in the bulk fluid and can lead to the formation of insoluble species which deposit by a particulate fouling mechanism.

Corrosion fouling is where the heat transfer surface undergoes a transformation under the operating conditions to form corrosion products with increased heat transfer resistance. Corrosion products can also spall off, generating particulates which deposit elsewhere in the exchanger or in a unit downstream.

Biofouling is the formation of fouling layers by organisms. Heat transfer surfaces provide environments which favor the attachment of macroorganisms such as shellfish as well as colonization by biofilm-forming microorganisms. Biofouling is rarely seen in crude oil processing but is encountered in food processing operations due to the availability of nutrients in aqueous solution.

Many fouling layers in practice are generated by a mixture of fouling mechanisms. Biofouling can promote corrosion fouling when anaerobic bacteria generate acidic conditions at the exchanger surface; a particulate fouling layer can become harder to remove owing to crystallization, chemical reaction, or biofouling "cementing" particulates in the deposit.

Table 4.4.1 shows where the different fouling mechanisms arise in the food and crude oil processing sectors.

The rate of fouling is related to the concentration of precursors entering the system. This can be subject to natural variations, for example, seasonal changes in foodstuffs and lactation cycles for milk. In processing crude oil, refineries often blend crudes together so the nature and concentration of fouling precursors can vary regularly: in these systems, it is important to avoid combining so-called incompatible crudes to give a mixture in which some components are insoluble. Those components then precipitate in the bulk fluid and the heat exchangers are subject to acute particulate fouling (Wiehe, 2008).

Many deposits undergo *ageing*, where the initially deposited species are transformed over time owing to exposure to the temperature and flow conditions active at the heat transfer surface. This is the equivalent to baking the layer to give a harder deposit. Wax and fat layers can similarly harden over time on cold surfaces. Ageing can create problems for cleaning, in which case cleaning should be performed earlier and thus more often. Ageing also disguises the identity of the fouling precursors responsible for deposit growth. Where fouling does occur, it is recommended that samples of the fouling layer are obtained intact for analysis in order to identify the precursor(s) and mechanism(s) involved.

TABLE 4.4.1
Fouling Mechanisms Encountered in the Food and Crude Oil Processing Sectors

Fouling Mechanism	Food Processing	Crude Oil
Crystallization	Fats—gelation on cold surfaces	Waxes in chiller units
	Calcium phosphate in UHT milk processing (milk stone)	Upstream of a desalter and downstream of a poorly operated desalter
	Heating and cooling water	Heating and cooling water
Particulate	Suspensions	Iron sulfide and rust particles introduced during crude storage and transport
	Protein aggregates formed in milk heated above the protein denaturation temperature	Sediments
		Sand particles
		Asphaltene precipitates arising from blending of incompatible crudes
Chemical reaction	Protein solutions heated above the protein denaturation temperature (e.g., milk and egg)	Degradation of asphaltenes
		Polymerization of unsaturated compounds (both in the presence and absence of oxygen)
	Unsaturated fats exposed to air (autoxidative polymerization, e.g., in fryers)	Condensation reaction products
		Pyrolysis and coking reactions (high temperature)
	Viscous sauces	
Corrosion	Avoid by material selection: can be caused by cleaning solutions	Acidic crudes
Biofouling	Heating and cooling water	Heating and cooling water
	Many dilute aqueous solutions	

Designing for Fouling Service

Fouling can be avoided or controlled to a low level in some circumstances by the addition of antifoulant chemicals. This is often only economically feasible for closed-loop systems and is unlikely to be acceptable in food processing operations. Surface treatments that deter the attachment of fouling deposits are available for some niche applications but have yet to reach widespread use in the food and crude oil sectors.

A second option is to employ an antifouling exchanger or fouling mitigation measures. Table 4.4.2 lists some of the devices available. These incur additional capital cost and can also require additional pressure drop in order to handle a given throughput. Design of such units is specialized and require liaison with the device manufacturer.

The final option is to utilize a conventional heat exchanger and select a combination of surface temperatures, flow velocity, and contacting arrangement which will reduce the rate of fouling. Fouling is still likely to occur so the design specification must include targets for the heat duty and maximum allowable pressure drop across the unit in the fouled state, noting that fouling will increase the pressure drop for a given flow rate.

The time for which the unit is to be available, before cleaning or switching to a standby unit, must also be specified. This sets an acceptable fouling rate. If fouling models are available for estimating the effect of flow velocity, bulk and surface temperature on the fouling rate, the heat exchanger design can be optimized to mitigate fouling. This is considered further for crude oil applications in Section 4.5.

Some general guidelines for designing shell-and-tube heat exchangers for fouling service presented by Gilmour in 1965 are summarized in Table 4.4.3 and still apply to these and other configurations. Many of his recommendations focus on ensuring that flow patterns are close to theoretical. One point which Gilmour made 50 years ago and still applies is that poor exchanger design is often attributed, wrongly, to fouling: according to Equation 4.4.3, R_f includes all errors in estimating U_{clean}.

The choice of exchanger type should include cleaning considerations, including (1) the requirements of the likely cleaning method; (2) the ability to access both sides of the heat transfer surface if fouling occurs on both; and (3) whether blockage caused by fouling layers will render the unit difficult to clean. Plate and frame exchangers, which can be disassembled to expose individual plates for cleaning and inspection, are good in this regard but care must be taken to maintain the integrity of the seals. In contrast, tube inserts may need to be removed and replaced in order to achieve effective cleaning.

Particular care should be taken when selecting shell-and-tube configurations. It is conventional with shell-and-tube designs for the process stream more prone to fouling to be on the tube side, particularly if cleaning required mechanical action such as pigging. Some tube pitch patterns render the shell-side surface difficult to access by water jets, while U-bend tubes are not suitable for a range of cleaning technologies. More details about configurations and cleaning are given in Müller-Steinhagen and Zettler (2011).

Control

The information used to design the exchanger should also determine the control strategy.

When an exchanger is designed with excess area in order to mitigate the effect of fouling, it will overperform when clean. The standard control technique for a unit exchanging heat between two process streams is to bypass a fraction of one of the streams in order to maintain the exit temperatures at the target values. If one of the streams is not prone to fouling, this is the stream that should be manipulated unless other criteria such as boiling will arise (see Figure 4.4.5a). If the fouling stream is manipulated, the initial flow rate (and velocity through the unit) will be lower, reducing the shear stress acting on the surface and the film heat transfer coefficient. The surface temperature will then approach that of the other stream. Both these effects tend to promote fouling, and will result in high initial fouling rates, negating the benefit of the excess area.

TABLE 4.4.2
Fouling Mitigation: Antifouling Heat Exchangers and Devices

Heat Exchanger Type	Origin of Mitigation Action	Comments and Source
Scraped surface	Annular heat exchanger with rotating blades which scrape material off the outer, heat transfer surface	Standard technology in the manufacture of lubricants and ice cream, and for processing of viscous foods Power required for motor
	Solano et al. (2011) report a novel double-pipe device with reciprocating scraper elements	Blades require regular maintenance
Fluidized bed	Scouring particles are fluidized by the passage of the process stream prone to fouling: the particles remove fouling deposits from the heat transfer surface	Specialized units with proven record for streams prone to severe fouling Klaren et al. (2007) Klaren and de Boer (2011) Müller-Steinhagen and Lancefield (2005)
	Shell and Tube	
Taprogge	Abrasive balls are circulated through tubes by fluid flow, captured and reinjected	Widely used in cooling water and power generation applications Not all tubes may be cleaned
	Used intermittently to remove fouling layers	Abradents need replenishment periodically Müller-Steinhagen and Zettler (2011)
Spirelf	Coiled insert for tubes. Fluid flow causes the inset to vibrate, scouring deposit layer	Increases heat transfer and pressure drop Krueger and Pouponnot (2009)
Turbotal	Helical ribbon insert for tubes. Fluid flow causes the insert to rotate, scouring deposit layer	Increases heat transfer and pressure drop Krueger and Pouponnot (2009)
Fixotal	Fixed helical insert for tubes. Promotes turbulence	Does not scour/remove deposit Krueger and Pouponnot (2009)
HITRAN	Coiled wire inserts for tubes, which increase fluid mixing and wall shear stress	Film heat transfer coefficient is increased, accompanied by higher pressure drop Difficult to clean Ritchie et al. (2007) Drögemüller et al. (2013)
Twisted tubes	Tubes are rolled such that they appear to be twisted. They are primarily oval in shape and can be aligned so that they touch intermittently along the length of the bundle. The result is a very rigid structure. Significantly more twisted tubes than plain tubes can be accommodated in a shell of given diameter.	These units cannot be cleaned by standard mechanical means: specialist cleaning is required Most frequently used with crude oil Al-Hadhrami et al. (2010)
Helical baffles	These consist of a series of interlocking plates positioned to provide a screw-type motion along the shell. The spacing of the plates is a function of shell diameter (unlike segmental baffles where the spacing can be changed independently). The larger the shell diameter, the lower the shell side velocity, and the lower the pressure drop. This is accompanied by a lower heat transfer coefficient. Later designs utilized a "double helix" that gave some improvement	In the case of crude oil duties, low heat transfer coefficients usually lead to increased fouling rates. Consequently, the processing of crude on the shell side of such exchangers is not recommended. There is a "niche" application for these units, in the cooling of vacuum and atmospheric residues The viscosity of such residues is generally high (>2 cps). Therefore they benefit from being passed through the shell side of the unit. The crude can be passed through the tubes and inserts used to promote good heat transfer van der Zijden et al. (2013), Brignone et al. (2015)

TABLE 4.4.3
Summary of Gilmour (1965) Recommendations for Designing Shell-and-Tube Heat Exchangers for Fouling Service

Feature	Recommendation	Reason
Flow maldistribution	Site inlets, outlets, and impingement plates in order to ensure uniform flow in tubes (and other channels)	Channels subject to low flow velocity will give poor heat transfer and are also prone to fouling and blockage.
Avoid shell-side bypassing	Use a baffle cut of 20% and never more than 25% Do not use vertical baffle cuts for sensible heat transfer Avoid shell-side bypass streams by insisting on TEMA shell-baffle clearances Use tie rods and spacers to block bypass routes around a shell Use dummy tubes to block central bypass paths Avoid notches for drainage and venting	Bypassing reduces the flow pattern from plug flow to mixed flow, giving poorer heat transfer The associated low velocities promote fouling and deposition in stagnant areas
Materials of construction	Select materials of construction carefully, giving consideration to fluid conditions as well as bimetallic corrosion	Saving money on a one-off capital purchase often proves more expensive over time due to higher operating costs and/or replacement
Viscous streams	Put through the channel that is easier to clean	Some guidelines insist on putting viscous fluids through tubes rather the shell: if the residue is viscous rather than hard, shell-side cleaning can be faster

Alternative control strategies include recycling a fraction of the outlet stream and mixing it with the feed in order to raise the inlet temperature, reducing the maximum heat duty (Figure 4.4.5b). This requires a pumparound and has the advantage of increasing the velocity in the unit, albeit at the cost of a pump. This strategy can also be used to enhance the flow rate when high velocities are required. It is not suitable for many food applications owing to the effect of heating or cooling operations on the product microstructure, or the potential for long residence times to promote microbial growth via the recycle of material.

When one of the process streams is a heating or cooling utility, the inlet temperature of this stream should be manipulated where this is feasible (e.g., by adjusting steam pressure: see Figure 4.4.5c).

Fouling in Food Processing

Fouling is encountered in a wide range of food applications. Many food products are temperature sensitive yet need to be heated for pasteurization or sterilization. Dairy processing units, for example, experience acute fouling primarily due to denaturation of proteins at temperatures below 110°C. At higher temperatures, crystallization of calcium phosphate also contributes, giving a hard protein/mineral deposit sometimes called “milk stone.”

Many foodstuffs are mixtures of species that individually could cause fouling, so deposition can involve several mechanisms. Milk stone is an example, where denatured proteins (chemical reaction fouling) glue together calcium phosphate solids (crystallization fouling). It is advised to determine as part of the design specification whether any temperature conditions should be avoided: this will set a constraint or a guideline for the surface temperatures to be reached in the unit.

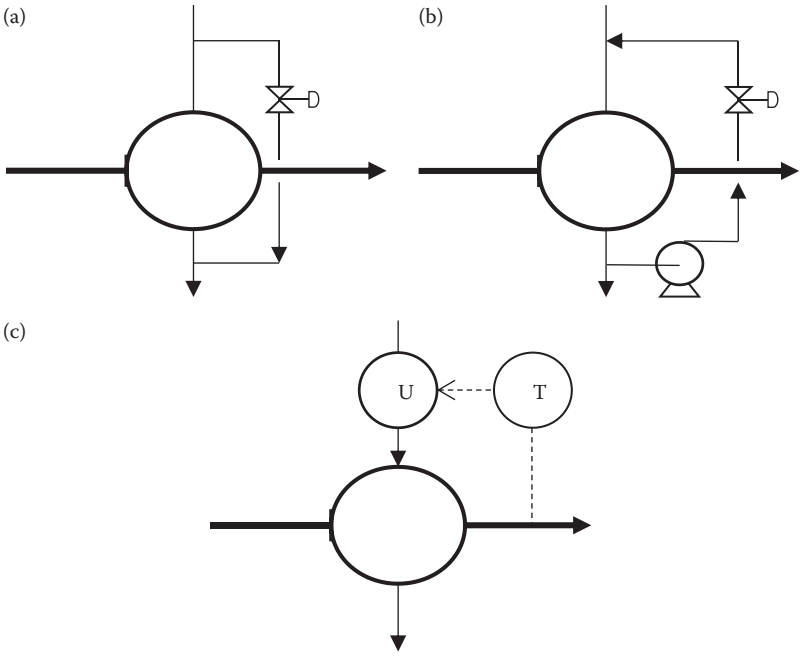

FIGURE 4.4.5 Schematic of control schemes to mitigate fouling. Solid line is stream subject to fouling: (a) bypassing of nonfouling stream, (b) recycle of nonfouling stream (not suitable if extended residence times for this stream in the heat exchanger cause problems), (c) modification of inlet temperature of nonfouling stream using utility (heating or cooling).

Heat exchangers used for food processing must therefore be designed to be cleaned and to be disinfected. The materials of construction must be compatible with the temperatures and pH of the product stream(s), the cleaning solutions (alkali and acids are both used), and the sterilizing/disinfecting agents. Stainless steel is frequently used except where the product contains high levels of salt. Cleaning is required for

1. *Microbiological integrity:* Hygienic operation is critical and units will often be taken offline for cleaning before fouling has reduced process performance in order to minimize microorganism growth. Many food fouling layers promote microorganism attachment and can shield thermophilic bacteria or their spores from cleaning agents.
2. *Product changeover:* Food processing plants often manufacture a range of products, so the units have to be flushed out on a regular basis. This means that the designer must consider a range of fluid properties. It also poses challenges for surface treatments to reduce fouling, as changes in product composition will determine the fouling precursors and mechanisms.
3. *Restoring process performance:* It should be noted that many food products are manufactured in batch mode and the batch run time determines the period over which acceptable process performance must be maintained. Many food fouling layers age to give more tenacious deposits, which are harder to clean. For units running for extended periods, this should be considered in the specification of the cleaning system and protocols.

While the operating period may be set by hygiene or batch manufacturing criteria, it is nevertheless important to minimize fouling in food heat exchangers because cleaning can take a significant length of time, affecting plant productivity. Hygienic operation usually requires cleaning-in-place (CIP), whereby solutions are circulated through a unit for a set length of time or until a monitoring program determines that the end point has been reached. A CIP cycle often includes purging,

TABLE 4.4.4
Heat Exchanger Types Regularly Used in Food Processing Operations

Exchanger Type	Fouling/Cleaning	Examples
Plate and frame	Complex flow patterns: deposition often occurs in regions of slower flow Can be opened for inspection or rigorous cleaning	Widely used in milk processing
Scraped surface	The rotating blade provides a self-cleaning action Start-up and shutdown must be managed to avoid a thick layer building up	Ice cream (water freezes to form ice crystals, which are scraped into the bulk fluid) High viscosity sauces, pastes
Concentric tube (double pipe, triple tube)	Well-defined flow field to minimize dead zones, promoting uniform fouling and uniform access for CIP fluids	Viscous sauces, creams Products containing larger particulates or pieces (this dictates the tube size)
Multiple tube	A small number of tubes with heating utility in a common shell. Careful design of flow manifold required	As above
Evaporators (falling film, rising film)	Concentrations of fouling precursors increase as evaporation occurs, giving regions where fouling starts Uniform distribution of liquid product and CIP solutions is critical to avoid dry patches/hot spots on surface	Concentration units upstream of spray driers
Fryers	Gum formation by oxidation of unsaturated fats/oils	Snack food manufacture, e.g., potato chips, french fries

cleaning, rinsing, disinfection, and clean water stages, which can be reduced in length and resource consumption if there is little fouling.

These considerations result in the range of exchanger types used in heating or cooling food products being quite small, summarized in Table 4.4.4.

In all food processing units, it is important not to create dead zones in the fluid pathway, both to avoid broad residence time distributions (affecting product quality) and inhibiting biofilm formation. These are covered by hygienic design standards. The exchanger specification should include instrumentation for monitoring the performance of the unit during normal operation and a CIP cycle.

Fouling can also occur in sections where there is no driving force for heat transfer such as holding sections, distributors, and headers. Deposition in these cases can be caused by the laydown of species generated by heat treatment upstream, such as protein aggregates, or by particulates created by cooling oils and fats.

Studies of food fouling have tended to focus on the influence of composition and temperature regime on fouling mechanisms, the deposits generated, and on cleaning (e.g., Changani et al., 1997; Visser, 1997; Bansal and Chen, 2006). Most studies of fouling rates, useful for guiding heat exchanger design, are for dairy applications. Most studies have been performed using simple tubular devices, shell and tube, or plate heat exchangers with bulk temperatures below 100°C, where fouling is dominated by the deposition of proteinaceous deposits. One of the models that describes the observed fouling rates is that of Paterson and Fryer (1988), in which the *initial* rate follows

$$\mathrm{d}R_\mathrm{f} / \mathrm{d}t \propto \exp\left(-E_\mathrm{act} / RT_\mathrm{w}\right) / u, \tag{4.4.10}$$

where t is the time, E_act is an apparent activation energy (a positive quantity), T_w is the temperature at the heat transfer surface, and u is the local flow velocity. More detailed models including protein

kinetics have been proposed, for example, Petermeier et al. (2002). Equation 4.4.10 indicates that high surface temperatures and low flow velocities will give high fouling rates so these should be avoided where possible. If the heating utility temperature is kept constant, the temperature at the surface of the deposit in contact with the milk will decrease: in this case, as deposit grows, the fouling rate will change and falling rate or asymptotic fouling behavior may be observed. If the heating utility temperature is adjusted in order to maintain the outlet temperature at its target value, the deposit surface temperature will not change as much and fouling is likely to proceed at a similar rate. The dynamics are, however, complicated by ageing and modification of the flow pattern by deposit buildup.

When an exchanger design features excess area, consideration should thus be given to manipulating the heating (or cooling) utility temperature in order to reduce the initial surface temperature. The excess area will result in the product still reaching the desired outlet temperature. When steam is used as a heating utility, this can be achieved by modifying the steam pressure. As fouling occurs, the utility temperature can be adjusted to maintain the target performance. This control strategy has the added advantage of minimizing ageing of deposit driven by high wall temperatures.

Plate and frame heat exchangers are widely used in dairy applications. These feature heating, holding, and cooling sections within a unit, and the configuration of the exchanger can be manipulated to give temperature distributions that mitigate fouling (see De Jong, 1997). The plate layout (chevron angle, number and spacing of channels, and distributor layout) dictates the flow distribution, pressure drop, and overall heat transfer coefficient (see Picon-Nunez et al., 2010) as well as fouling behavior, and manufacturers may advocate different designs for units in fouling service. Detailed numerical models of plate heat exchangers subject to milk fouling have been developed (e.g., Georgiadis and Macchietto, 2000; Grijspeerdt et al., 2004) but have yet to find widespread use in industrial design.

Crude Oil Fouling

Crude oil is a mixture of many organic components and may contain inorganic species as well as water. The simplest characterization of crudes classifies species by solvency into saturates, aliphatics, resins, and asphaltenes. Crudes vary according to source and transportation history, and the crude oil entering a refinery will often contain a water fraction with dissolved salts as well as suspended solids (sand, clay particles, and minerals such as iron sulfide). No two crudes are the same, and refineries frequently blend batches of crudes to give the required product slate.

Crude oil fouling is therefore complex. The multicomponent nature of a crude or crude blend means that fouling can arise from several mechanisms (see Watkinson and Wilson, 1997). Figure 4.4.6 shows a schematic of a refinery distillation unit preheat train and identifies the regions where different fouling mechanisms occur, which is chiefly determined by the temperature regime.

Two of the phenomena in the figure are related to phase behavior. Most preheat trains feature a desalter to remove water and its dissolved salts because the water will flash off at elevated temperature, giving a vapor phase and an associated high-pressure drop. This deprives the salts of a solvent and they will form crystalline deposits. Poor control of a desalter will promote fouling downstream of the unit. Similarly, if the crude is allowed to vaporize at higher temperatures before it reaches the furnace, this will increase the pressure drop (possibly limiting throughput) and the loss of volatile species from the liquid will change the solubility of some of the species. The solubility of the many species collectively known as asphaltenes is a complex phenomenon (see Wiehe, 2008), and every effort should be made to ensure that these stay in solution before the crude reaches the distillation column.

Crude Oil Fouling Models

The historical method for designing heat exchangers based on fouling factors (see "Quantitative Impact of Fouling" section) is widely used for units in crude oil service and is described in texts

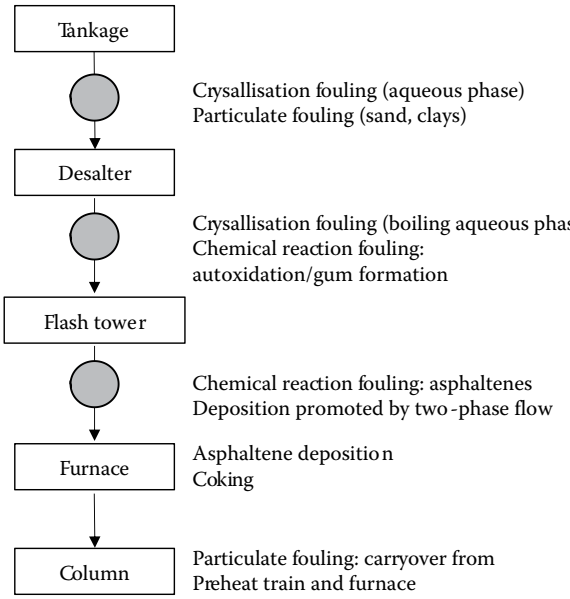

FIGURE 4.4.6 Schematic of crude oil fouling behaviors observed in an oil refinery preheat train.

such as Saunders (1988) and Kakaç and Liu, 2002. Bennett and Nesta (2004) presented an alternative, the "no foul" approach, in which fouling factors are *not* used. They advocated the application of guidelines for exchanger design based on critical velocities and maximum surface temperatures which should preclude significant fouling, and the use of a safety margin (in effect, excess area) to account for uncertainties in predicting heat transfer and a small amount of fouling. Table 4.4.5 is a summary of their "no foul" approach.

Since 1995, considerable attention has been paid to developing quantitative fouling models to provide a means of relating the rate of fouling encountered within a heat exchanger processing crude

TABLE 4.4.5
Summary of Bennett and Nesta (2004) "No Foul" Approach for Shell-and-Tube Units in Liquid Hydrocarbon Service

Parameter	Guideline
Fluid	Liquids with API gravity <45° No heavy particulate matter such as catalyst fines No or low salt content
Fouling factors	Set to zero unless the fluid is outside the scope and is known to foul. A modest safety margin (20% or less excess area, depending on experience) may be used
Tube-side velocity	$u \geq 2$ m/s d_o up to 25.4 mm $u \geq 2.2$ m/s for $d_o \geq 31.75$ mm
Wall temperature	The maximum tube wall temperature should be 300°C
Shell-side design	Single segmental baffles with baffle cut of 20% Spacing shell-side velocity should be at least 0.6 m/s and selected to give a shear stress similar to that for the tube-side guideline if fouling is expected Baffle cut orientation, end spaces, impingement protection, longitudinal baffles: see Bennett and Nesta (2004)
Pressure drop	As required to meet tube-side and shell-side velocity guidelines

oil to its operating condition. This approach is consistent with the Bennet and Nesta guidelines and is discussed here in detail as it is expected to be the subject of future developments in the field.

The purpose of a fouling model is to indicate how the operating conditions in a unit can be specified or changed in order to reduce fouling within the exchanger. It can be used to design a new exchanger, for example, by identifying critical velocities and surface temperatures, and also to predict how an existing exchanger will perform in a revised network.

A variety of models have been proposed for fouling caused by heating of crude oils in refinery preheat train applications. These models have incorporated a variety of considerations, including mass transfer, chemical reaction, physical adhesion rates, and ageing of deposits. Modelling of crude oil fouling was reviewed by Wilson et al. (2017).

To be of practical use, a fouling model must satisfy two requirements. It needs a reasonably sound physical basis and it should have a small number of characterizing parameters. There is a conflict between these requirements, as crude oil fouling is complex and it may not be possible to simplify reality to a small number of parameters. For instance, it is known that the thermal conductivity of asphaltene deposits increase over time as ageing converts the layer to coke. This means that the thermal resistance presented by the deposit will reduce over time. Mathematical models that account for this process have been developed but the model parameters are often obtained by fitting the models to noisy plant data, which are inherently of questionable accuracy as they are subject to instrument error etc. It is difficult to reproduce crude oil fouling conditions in laboratory tests so the methodology described here is based on interrogating plant data sets to identify parameters for simple fouling models, and to apply these to exchanger design and operation. Detailed descriptions of the approach are given in Wilson et al. (2002); Polley et al. (2002a, b), and Yeap et al. (2005).

Three fouling models that fit the abovementioned requirements of reasonable physical basis and small number of parameters are the (1) Ebert–Panchal model (1997) and its variants; (2) the Epstein model (see Epstein, 1994; Yeap et al., 2005); and (3) the asphaltene precipitation model (Polley et al., 2011a; see Wilson et al., 2017). A particular feature of the Epstein model is its capacity to describe fouling controlled by mass transfer or by chemical reaction, such that there can be a maximum in the observed fouling rate as velocity is increased. It does contain more parameters as a result. The Ebert–Panchal model is used here owing to its frequent use in published work at the time of writing. It is recognized that other models have been, and will be, developed over time.

Ebert–Panchal Model

This model has been used widely to relate fouling rate data obtained from plant operating data for exchangers subject to chemical reaction fouling from crude oil streams. It is similar in form to the Paterson and Fryer model, Equation 4.4.10, but includes a second term describing fouling suppression by fluid shear.

$$\mathrm{d}R_\mathrm{f} / \mathrm{d}t = C_1 \exp\left(-E_\mathrm{A} / RT_\mathrm{f}\right) / h - C_2 \tau_\mathrm{w}, \tag{4.4.11}$$

where C_1, C_2, and E_A are fouling model parameters, which have to be identified: h is the relevant film heat transfer coefficient (tube or shell side), τ_w is the local wall shear stress, and T_f is the film temperature, given by

$$T_\mathrm{f} = 0.55\ T_\mathrm{w} + 0.45\ T_\mathrm{bulk}. \tag{4.4.12}$$

The fouling suppression term, $-C_2\ \tau_\mathrm{w}$, is sometimes labelled as a "removal" term. The latter suggests that deposit, once attached, can be removed by fluid shear alone. This has not been confirmed in any systematic study. Equation 4.4.11 does, nevertheless, suggest that an acceptably low fouling rate can be achieved by selecting appropriate combinations of T_f, τ_w, and h. All three quantities are related by the flow velocity (and the design): this is the basis of the "threshold fouling" approach to mitigating fouling described in "Threshold Fouling and the Temperature Field Plot" section. This

extends the critical velocity and critical temperature guidelines of the "no foul" approach in Table 4.4.5 to allow different exchanger designs to be identified and an optimal case selected.

Values of E_A obtained from regression fitting to plant data range from 20 to 80 kJ/mol and particular care needs to be taken in estimating this parameter owing to the sensitivity of the exponential term. Polley et al. (2010) have suggested, following work by Wiehe on the reaction of maltenes to asphaltenes and subsequent deposition, that an E_A value of 44.3 kcal/g mol (185 kJ/mol) should be used for fouling dominated by asphaltene deposition. This is typically at the hot end of a preheat train and in a furnace.

Threshold Fouling and the Temperature Field Plot

The "threshold fouling" concept arises from the form of Equation 4.4.11, which suggests that an acceptable level of fouling (or fouling rate) can be achieved by judicious selection of flow velocity and operating temperatures. The label "fouling threshold" arises from the case where no fouling is observed (i.e., $dR_f/dt = 0$). Rearranging Equation 4.4.11 gives

$$\exp\left(-E_A / RT_f\right) = h / C_1 \times \left(\left[dR_f / dt\right]_{target} + C_2 \tau_w\right), \tag{4.4.13}$$

where $[dR_f/dt]_{target}$ is the acceptable fouling rate. For turbulent flow through a tube, this can be written in terms of the mean velocity, u:

$$\exp\left(-E_A / RT_f\right) \propto u^{0.8} / C_1 \times \left(\left[dR_f / dt\right]_{target} + C_3 u^{1.75}\right) \tag{4.4.14}$$

For a given value of u, the film temperature required can then be calculated if the constants are known. The corresponding wall temperature can then be calculated.

In practice, in a refinery heat exchanger network, the film and surface temperature in a unit are set by the network configuration. Crude oil passing from one exchanger to the next can experience a large change in film temperature owing to the difference in hot stream temperatures. The temperature field plot is a construction that allows the effect of network configuration on fouling behavior to be assessed.

The crude bulk temperature is plotted on the x-axis, which thus represents the location in the network. The hot stream temperature and the film temperature are plotted on the y-axis. Accurate determination of the film temperature requires calculation of the wall temperature, and the rigor which is used to do this depends on the stage of design. For a simple estimate, the film temperature could be taken as the arithmetic average of the hot and cold stream temperatures. Each exchanger is plotted as a line linking the temperature conditions (T_{crude}, T_f) at its inlet and outlet: in Figure 4.4.7, the exchangers are assumed to operate in countercurrent mode. The distance along the x-axis is related to the gain in crude temperature and thus the exchanger duty.

Also plotted are the solutions to Equation 4.4.13 for different values of u, which is set by the number of tubes, passes, and size of tubes in a shell-and-tube exchanger. For each value of T_{crude}, there is a corresponding value of T_f. If the heat exchanger line lies on or below a fouling rate locus, this means that a unit designed with that value of u will be subject to acceptable levels of fouling. The further a heat exchanger line lies above a locus, the larger the fouling rate will be: a higher velocity would be needed to avoid fouling.

Two exchanger lines are plotted on the figure, corresponding to different hot streams for the same crude duty. Match A features lower hot stream temperatures and thus lower T_f values, and requires a lower velocity to avoid fouling. The temperature driving force in this match is smaller so the exchanger would need to be larger, but the pressure drop is likely to be smaller. Critically, the pressure drop is unlikely to change much over time as fouling will be modest. It should be noted that no excess area has been added at this stage. Match B, with higher hot stream temperatures, offers a larger temperature driving force and smaller area but would require higher velocities to avoid fouling. If higher velocities were not allowed, any excess area added to accommodate fouling could offset the difference in areas for the two clean designs.

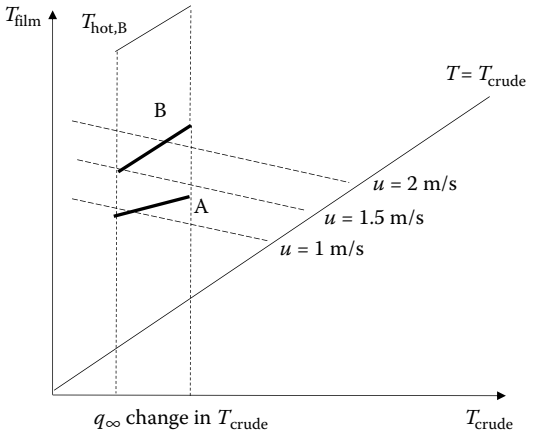

FIGURE 4.4.7 Temperature field plot construction. Dashed lines show T_{film} locus for the acceptable fouling rate for the u value indicated. Solid lines indicate T_{film} values expected in exchangers A and B. Vertical dotted lines show construction for exchanger B, where T_{film} is a weighted average of T_{hot} and T_{crude}. Exchanger A features a cooler hot stream.

The effect of configuration and fouling on pressure drop across the exchanger can also be included in the construction, in the modified temperature field plot (see Wilson et al., 2002).

Figure 4.4.7 provides insights into how fouling should be considered when considering network placement. The temperature field plot can also be used for retrofits and revamps (see Yeap et al., 2005). It can also be seen that as the crude temperature increases, higher velocities are needed (for the use of inserts or alternative designs, which will be described by different fouling model parameters, see "Use of Fouling Models in Exchanger Design" section).

The film temperature, and thus the fouling rate, can differ significantly between the crude inlet and outlet. Since the performance of the unit is determined by an average of the fluxes across the exchanger, an equivalent average fouling rate and fouling resistance is required. Ishiyama et al. (2008) compared different averages for the case where the film temperature increased linearly across the exchanger. Good agreement was obtained for an expression based on the exponential integral which can be evaluated using modern spreadsheets: the geometric average will give a reasonable estimate as long as the fouling rates at each end are non-zero.

Use of Fouling Models in Exchanger Design

Shell-and-tube exchangers are commonly used for crude oil service owing to their ability to handle the process conditions (temperatures and pressures) at the scale required, and the availability of techniques for cleaning fouled tube bundles. This section will therefore focus on the design of shell-and-tube units for refinery preheat train service.

The flow rates in refinery preheat trains are large. It is therefore common to find many trains with exchangers of large diameter (greater than 1 m). This is often the result of arguments based on economy of scale. However, such arguments only apply to the capital cost of the exchanger; the "lifetime" cost of an exchanger is dominated by operational costs, particularly by costs associated with exchanger downtime and reduced productivity. Consideration of fouling needs to be an integral part of exchanger design.

The design process involves the following steps:

a. Specifying the process streams, their properties, inlet temperatures, and any outlet target temperatures. This sets the exchanger duty or range of duties.

b. Specifying the maximum pressure drop for each stream, which may include an absolute pressure to avoid boiling or condensation.
c. Identifying likely exchanger configurations (size, type, and number of tubes; number of tube passes, shell passes, etc.) as well as baffle arrangement.
d. Calculating the heat transfer coefficients and duty for given configurations, including considerations of turndown and process variation.
e. Identifying optimal designs for final selection.

The fouling model approach provides guidance for steps (c) and (d), for use in tandem with computational design tools.

Simple guidelines for step (c) include the following:

Baffle Configuration

Exchanger design software often allows the baffle cut to be specified anywhere within the range 15–45%, and any spacing that will fit within the shell. Little or no guidance is given on how the baffle configuration will affect fouling within the shell. Polley et al. (2011b) and Bouhairie (2012) both used computational fluid dynamics simulations (CFD) to study flow fields within heat exchanger shells and recommended that only geometries providing close to uniform flow be used, confirming Gilmour's advice. This means baffle cuts are in the range 15–25% and a window-to cross flow area ratio in the range 0.8–1.2 (see Tables 4.4.3 and 4.4.5). It is also important that a sufficiently high velocity is maintained within the exchanger shell. Before that advent of computer programs, it was standard practice to ensure that the cross-flow velocity exceeded 0.5 m/s.

Cleaning

The need to clean can preclude some bundle layouts: a square pitch or 45° layout is preferred. It also affects the suitability of U-tube and twisted tube designs as well as other technologies (plate units, plate-and-shell units etc.).

Fouling Maps

"Threshold Fouling and the Temperature Field Plot" section introduced the concept of the "fouling threshold," which is a combination of flow velocity and film temperature which will give little fouling. In many applications, it is not possible to identify a design that will allow operation below the fouling threshold and an acceptable fouling rate, $[\mathrm{d}R_\mathrm{f}/\mathrm{d}t]_\mathrm{target}$ will need to be identified. This provides an indication of how frequently the unit may have to be cleaned and where the installation of tube inserts will be beneficial (see below).

Equation 4.4.13 can then be used to sketch a "fouling map" to compare the designs identified in step (c) that satisfy the pressure drop and heat transfer requirements. The fouling map is a plot of the film temperature which will give the specified fouling rate ($[\mathrm{d}R_\mathrm{f}/\mathrm{d}t]_\mathrm{target}$) for a given tube or shell-side velocity. The latter parameter is set by the flow configuration; the film temperature is determined by the resultant heat transfer calculation.

The calculation method is as follows:

1. From the local flow velocity, u, determine the wall shear stress, τ_w, and the film heat transfer coefficient, h;
2. Solve Equation 4.4.13 to find T_f;
3. For each candidate design, calculate T_f at the inlet and outlet, and other salient points (see below) to see where the design lies on the fouling map. The film temperature is calculated using Equation 4.4.12, with T_w given by

$$T_\mathrm{w} = T_\mathrm{cold} + \left(T_\mathrm{hot} - T_\mathrm{cold}\right) \times \left(1 + r_\mathrm{i} h_\mathrm{i} \ln\left(r_\mathrm{o} / r_\mathrm{i}\right) / k_\mathrm{wall} + r_\mathrm{i} h_\mathrm{i} / r_\mathrm{o} h_\mathrm{o}\right). \tag{4.4.15}$$

Figure 4.4.8 shows an example for an application with fouling on the tube side. For a tube side velocity of 2 m/s and a fouling rate of 10^{-6} m^{2}K/Wh, the critical film temperature is 169°C: for a tube side velocity of 2.5 m/s, the critical film temperature is about 180°C. If the bulk crude temperature is 150°C, the corresponding wall temperatures are 185°C and 205°C, respectively. These values can be compared with T_w calculated using Equation 4.4.15 or generated by the heat exchanger design software using its internal algorithms. The design can then be rejected at this level of fouling, or retained for comparison with others.

The same information can be used in the Poddar plot construction for identifying candidate designs (see Polley et al., 2002b).

It is important to note that the shell configuration determines the wall temperature distribution and thus the location where the largest fouling rate is likely to arise. Figure 4.4.9 summarizes some important differences between standard TEMA (Tubular Manufacturer's Manufacturing Association) configurations. Similarly, for multiple shells, Figure 4.4.10 shows how the flow arrangement can be manipulated to reduce the maximum wall temperature. It is important to note that configurations or arrangements that are favorable in terms of fouling may not be optimal in terms of clean heat transfer (e.g., capital cost), but are more likely to perform reliably over time (e.g., operating cost), when operated correctly.

The fouling model approach can be extended to determine fouling on the shell side of an exchanger as well as tubes fitted with inserts (see Table 4.4.2). In both cases, a component of the pressure drop is associated with form drag in addition to skin friction, and this has to be compensated for in calculating the wall shear stress that appears in the fouling model.

"Self-Cleaning" Inserts

As more heat is recovered in a preheat train, the crude oil bulk temperature reaches levels where the associated wall temperature is too high to be countered by allowed liquid velocities. The fouling rate can be so high that regular cleaning is required to maintain productivity. As a result, bypass exchangers, fluidized bed units, and inserts are regularly employed at the hot end of the preheat train.

The performance of Turbotal inserts has been successfully described by the fouling model approach. These devices feature a rotating element that reduces the rate at which fouling occurs

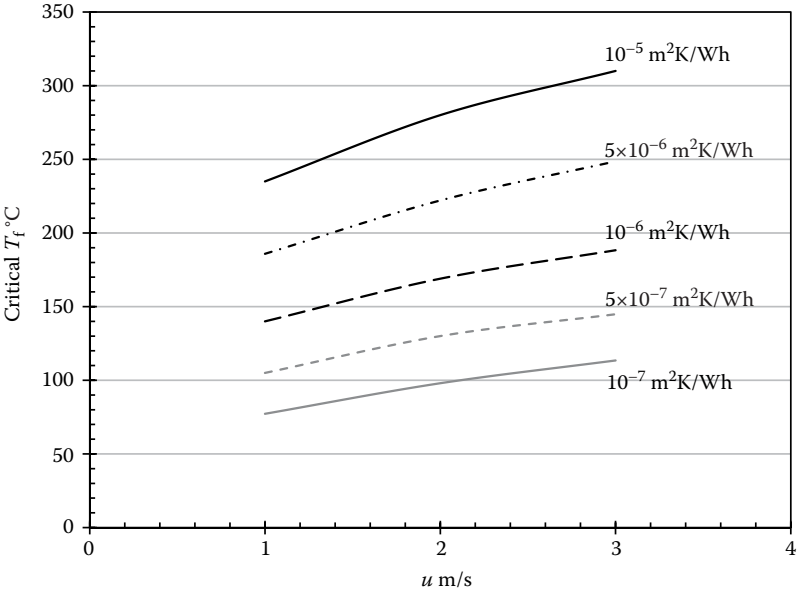

FIGURE 4.4.8 Example of fouling map.

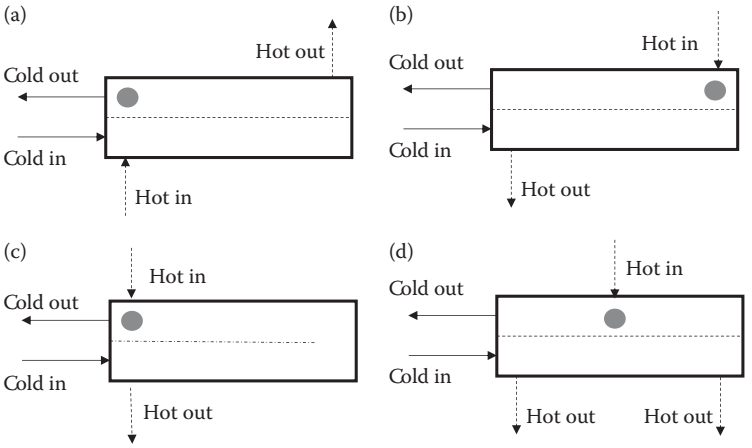

FIGURE 4.4.9 Thermal contacting patterns in single shell, twin tube pass configurations. The designs are equivalent in terms of heat transfer but the T_w distributions differ. The circles indicate regions with high T_w, where the hot stream enters the shell and where the cold stream is warm (After Polley, G.T. et al., *Appl. Therm. Eng.*, 22: 777–788, 2002b.) (a, b) Two tube side pass, one shell side, (c) TEMA F shell, and (d) TEMA J shell (lower shell-side pressure drop than F, less good in terms of fouling propensity).

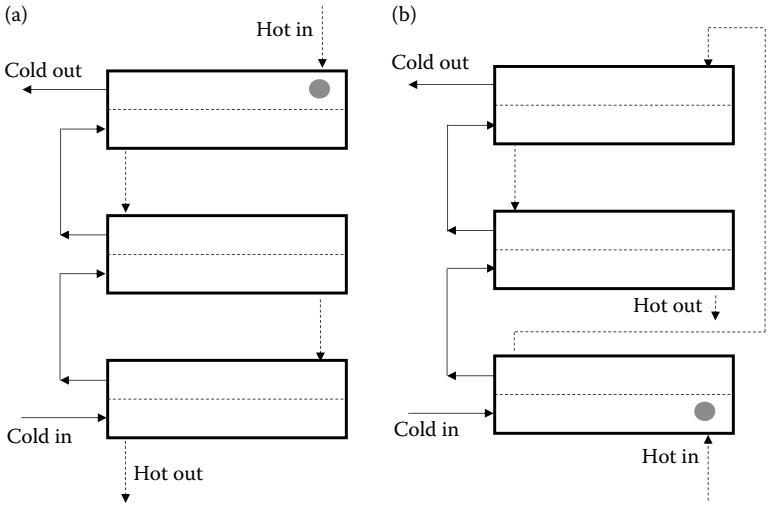

FIGURE 4.4.10 Shells-in-series arrangement: (a) normal pattern and (b) one that reduces fouling. Circles indicate the region of thermal contact where the hot stream enters the shell: T_w differs significantly between the two designs. (After Polley, G.T. et al., *Appl. Therm. Eng.*, 22: 777–788, 2002b.)

compared to a plain tube and subsequently control the thickness of the deposit formed such that the fouling resistance is maintained at a constant value. Aquino et al. (2007) and Polley and Gonzales-Garcia (2009) presented a modified form of the Ebert–Panchal model for the prediction of the initial fouling rates in tubes fitted with inserts:

$$\begin{aligned} dR_f / dt &= h_{i,plain} / h_{i,enhanced} \times C_1 Re^{-0.66} Pr^{-0.33} \exp\left(-E_A / RT_f\right) \\ &\quad - 0.7\ C_2 \tau_w \times \Delta P_{enhanced} / \Delta P_{plain}. \end{aligned} \tag{4.4.16}$$

The modification is a simple one. The deposition term has been multiplied by the ratio of the plain tube heat transfer coefficient to the enhanced coefficient. This modification quantifies the reduced

thickness of the thermal film, and hence reduction in volume of reacting liquid assumed by Ebert and Panchal. The suppression term has been multiplied by the ratio of the pressure drop encountered in the enhanced tube to that in the plain tube. This term is multiplied by 0.7 to reflect that only 70% of the pressure drop encountered during flow through tubes fitted with inserts is associated with wall friction. The remainder is caused by form drag. These modifications allowed the fouling rate to be estimated.

Eventually, a layer of adherent layer fills the gap between the rotating insert and the wall, and the insert scours any further fresh material. Aquino et al. (2007) found that this gave an asymptotic value of R_f of 0.0035 m^{2}K/W. This was in good agreement with an estimate of R_f based on the insert clearance and a deposit thermal conductivity of 0.43 W/mK (see Watkinson, 1988). Figure 4.4.11 shows how their simulation of the performance of a two-shell unit over 9 months matched the R_f values estimated from plant measurements. Readers unfamiliar with fouling data may find the scatter and uncertainty in this plot disconcerting. It is, however, a feature of many calculations based on plant operating data (see Crittenden et al., 1992; Takemoto et al., 1999).

In considering the use of such inserts, the designer would have to consider the impact of the insert on pressure drop as well as fouling: the absolute pressure at the hot end of the preheat train usually needs to be maintained above the bubble point of the crude in order to avoid flashing of the oil. If there was sufficient pressure drop, a unit could be designed on the basis of the asymptotic fouling resistance. The abovementioned guidance on flow distribution as well as that on operation would still apply.

Further Factors to Consider in Shell-and-Tube Exchanger Design

Effect of Fouling on Shell-Side Flow and Heat Transfer

When fouling does occur on the shell side, the deposits are usually not evenly distributed over the metal surfaces. Deposition is often heaviest down the face of the "trailing" baffle (the one forming

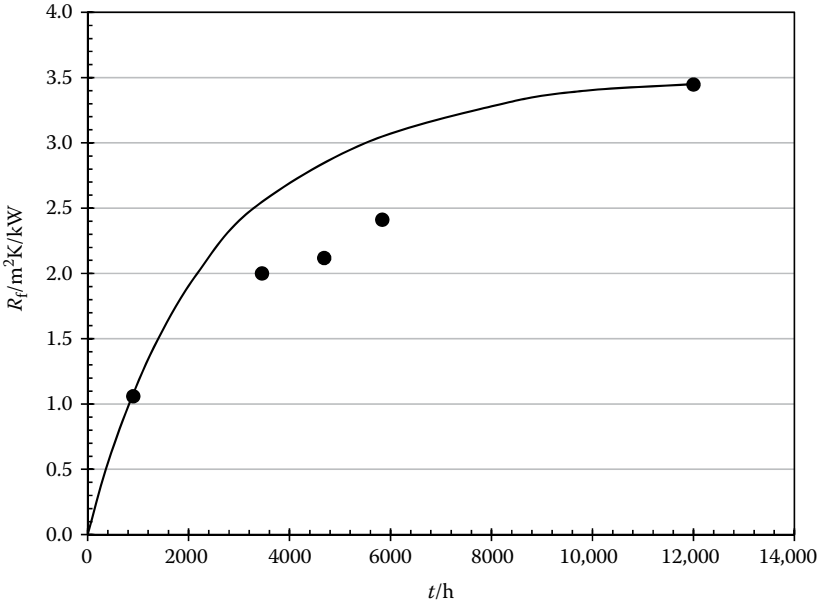

FIGURE 4.4.11 Use of Turbotal insert to mitigate fouling in a crude preheat train exchanger subject to severe fouling. Symbols: R_f estimated from plant measurements: line—predictions of a simulation with fouling predicted using Equation 4.4.16. (Reproduced from Aquino, B. et al., *Proceedings of 7th Engineering Foundation Conference on Heat Exchanger Fouling and Cleaning*, Tomar, Portugal, http://dc.engconfintl.org/heatexchanger2007/51, 2007.)

the window through which flow enters the baffle space), around the perimeter of the baffles, and in the corner between the shell and the baffle diverting the flow into the baffle space. This results in blockage of the clearances between the tubes and the baffle plates and between the baffle plate and the heat exchanger shell.

These blockages result in increased pressure drop but they also lead to an increase in the shell-side heat transfer coefficient. It is this phenomenon that led Gilmour (1965) to state that fouling can be eliminated by putting the fouling stream on the shell side rather than the usual practice of passing it through the tubes. However, this benefit can only be realized if the baffle arrangement provides a good flow field.

Fouling and Cleaning

It is harder for a deposit to grow on a clean surface than on existing deposit: the cleaning methodology influences the speed at which heat exchangers will foul when returned to service.

Chemical cleaning involves the recirculation of solution through the exchanger in order to dissolve the deposit. When strongly aged deposits are present, residual layers are likely to remain and the effectiveness of chemical cleaning will decrease as the number of cleaning cycles increases. For example, gas oil washes are used in some installations but this is unlikely to remove coked material or mineral deposits. Residual layers that will promote fouling are thin (microns thick), as they influence the surface chemistry: it is impossible to determine their presence from flow or heat transfer measurements.

Cleaning methods based on hydraulic forces, termed "mechanical" cleaning, including steam lances and high-pressure water jets, are in widespread use (see Müller-Steinhagen and Zettler, 2011). These techniques do not clean to the microscopic level. More stringent removal is achieved by pigging and by hydro-drilling. Pigging uses high-pressure water to propel a cleaning plug along a tube, driving debris ahead of it before being collected by a basket at the exit. In hydro-drilling, high-pressure water lances fitted with rotating nozzles are passed along the exchanger tube. A very high-speed water jet is then directed onto any deposit. In both cases, the shear forces applied can remove hard deposits and also the outer layers of metal (removing any corrosion deposits that may have initiated fouling in the first instance). Hydro-drilling and pigging are readily applied to straight, empty tubes but cannot be used in every exchanger type. Notably, they cannot be used with twisted tubes or in welded plate units.

The use of acoustic resonance in conjunction with chemical cleaning has proved effective for cleaning badly fouled units in some instances. This requires specialist contractors, and its effectiveness is not guaranteed in every instance.

Fired Heaters and Two-Phase Flow

Preheat trains and their exchangers are often designed to avoid two-phase flow owing to the high-pressure drop associated with the higher volumetric flow rate. Some units do nevertheless operate with flashing of the crude. The Ebert–Panchal fouling model can also be applied to situations in which two-phase flow is occurring within plain tubes: the h value used is that due to two-phase convective heat transfer, and τ_w is taken from the frictional component of the two-phase pressure loss.

Fired heaters are designed to vaporize part of the feed. The wall temperatures are often high enough to promote coking, and it is important to recognize the different requirements of fired heaters designed for coking operations from those preheating distillation column feeds: coke generated in a fired heater can cause significant operating problems for a column.

Fired heater design is complicated as the thermal and hydraulic performance of the unit are intimately linked. The optimization of preheat train fired heaters was studied in detail by Morales-Fuentes et al. (2014). They highlighted one aspect of current fired heater design practice that requires examination. Traditionally, fired heaters consist of two separate sections; a convective section and a radiant section, each with a number of parallel pipes. The crude is fed to the convective section before passing to the hotter radiant section, with the pipes in the convective section feeding a common manifold which feeds the radiant tubes.

In the sections of the convective section where the crude is liquid, the heat transfer coefficient will be low, giving high wall temperatures and high fouling rates. It can lead to excessive fuel consumption as higher wall temperatures will be required for a given duty, and consequently faster fouling. Allowing the crude to vaporize in the convective section will increase heat transfer rates and reduce fouling. However, if the fluid leaving the convective section contains vapor, the two phases are likely to separate in the manifold, and this could give rise to some tubes in the radiant section handling vapor and other liquid. The tubes handling vapor could subsequently fail through excessive wall temperatures. It follows that designers should seek to modify the construction of fired heaters such that a two-phase flow can be generated as early as possible and maintained throughout the unit.

Closing Remarks

Fouling is the major unresolved problem in heat transfer because it is a complex and dynamic phenomenon. This chapter has sought to communicate some simple lessons about fouling, to which local experience and design criteria must be added. The following closing statements by Gilmour in 1965 apply equally well today:

"One could go on and on, citing paradoxical instances in relation to fouling and heat transfer, but it is hoped that by now we have made the point clear that the fouling factor should not be relied upon as the means of combating the fouling problem.

Selling Ideas to Engineers

It has been, of course, impossible for us to condense thirty years of know-how on fouling prevention in this short discourse. It will also be impossible for one to sell these ideas to engineers who have never been in an operating plant, have never evaluated test data, have never issued specification for rebuilding an existing—but inadequately operating—exchanger, and who are concerned only with the inconsistent requisites of lower first cost and highest surface area. It is equally impossible to expect the fabricators to accept these ideas, because their object is to sell lots of surface area, their burden is to guarantee performance on nameless fluids, and their ululation is that they never receive adequate feedback on the performance and maintenance of the heat exchangers they sell. Therefore, they need to use a generous fouling factor to protect their interests.

Foster Dedicated Employees

It follows, therefore, that if a used company desires to reap economic benefits, it behoves that company to foster one or more of their own dedicated employees to become proficient in the design, procurement, testing, and maintenance of heat exchangers for their own requirements. This job entails design, specification, review of vendors' detailed drawings, observance of fabrication and installation, performance testing, and observance of units removed for maintenance."

4.5 BIOHEAT TRANSFER

John A. Pearce, Kenneth R. Diller, and Jonathan W. Valvano

Abstract

Heat transfer plays a major role in many processes in living systems. This chapter presents a brief review of bioheat transfer from the perspective of those aspects, which distinguish it from processes in inanimate systems. Of particular interest are the effects of blood perfusion on temperature distribution, coupling with biorate processes, measurement of thermal transport properties in tissues, therapeutic processes, human thermoregulation, and effects on living tissues of elevated temperatures and subzero temperatures. An extensive compilation of properties for biomaterials is also presented.

Introduction

Analysis and control of heat transfer processes in living systems involve phenomena that are not encountered in systems that are not alive. For example, there is a continuous flow of blood through tissues and organs via a complex network of branching vessels. Heat exchange processes are influenced by vascular geometry, which consists of arteries and veins with countercurrent flow over large portions of the network of pairs. For some physiological conditions, arterial and venous blood temperatures are different, neither is equal to the local tissue temperature, and these temperature differences may vary as a function of many transient physiological and physical parameters. Mechanisms of regulation for the thermal state in tissue are quite nonlinear and have presented a major challenge to understand and model. Nonetheless, thermoregulatory processes are critical to the maintenance of life and must be accounted for in the design of many types of systems that interface with humans and animals.

Although considerable progress has been made in defining and modeling thermal processes in living systems, and especially so over the past 15 years, many important problems remain. This section provides a brief discussion of the present state of knowledge and understanding of some of the more active areas of bioheat transfer. Greater detail and additional areas of application of bioheat transfer may be found among the references cited.

Coupling of Temperature History to Rate Processes

Although the processes of life are observed at the system (macroscopic) and microscopic levels of resolution, the true essence of life lies in the multitudinous biochemical phenomena that occur continuously throughout all organisms. Over the past 50 years, the science of biochemistry has elucidated many of the governing life processes at the molecular level. Today the major frontier of knowledge in the life sciences is associated with molecular biology. Increasingly, bioengineers are collaborating with molecular biologists to understand and manipulate the molecules and biochemical processes that constitute the basis of life. Temperature is a primary controlling parameter in the regulation of these rate processes. The study of thermal biology has identified that the rates of nearly all physiological functions are altered by 6%–10% per degree Celsius over wide range of thermal states produced in response to environmental conditions.[1] Likewise, temperature is often altered during therapeutic or diagnostic procedures to produce or measure a targeted effect, based on the fact that a change in local temperature will have a large effect on biochemical process rates. Thus, knowledge of how temperature can be monitored and/or controlled in living tissues is of great value in both the assessment of normal physiological function and the treatment of pathological states.

In assessing the effects of temperature alterations on biochemical rate processes, two broad categories of state changes can be considered: temperatures both above and below the normal physiological thermal steady state. An extensive review of both of these thermal domains has been published recently,[2] to which the reader is referred for further details and bibliography.

A summary of some of the most important and recent advances in bioheat transfer will be discussed in this section.

Tissue Thermal Transport Properties

The transport of thermal energy in living tissue is a complex process involving multiple phenomenological mechanisms including conduction, convection, radiation, metabolism, evaporation, and phase change. The equilibrium thermal properties presented here were measured after temperature stability had been achieved.

Thermal probe techniques are used frequently to determine the thermal conductivity and the thermal diffusivity of biomaterials.[3–6] Common to these techniques is the use of a thermistor bead either as a heat source or a temperature sensor. Various thermal diffusion probe techniques[7] have been developed from Chato's first practical use of the thermal probe.[3] Physically, for all of these techniques, heat is introduced to the tissue at a specific location and is dissipated by conduction through the tissue and by convection with blood perfusion.

Thermal probes are constructed by placing a miniature thermistor at the tip of a plastic catheter. The volume of tissue over which the measurement occurs depends on the surface area of the thermistor. Electrical power is delivered simultaneously to a spherical thermistor positioned invasively within the tissue of interest. The tissue is assumed to be homogeneous within the milliliter surrounding the probe. The electrical power and the resulting temperature rise are measured by a microcomputer-based instrument. When the initial tissue temperature is just below the freezing point, the thermistor heat is removed both by conduction and by latent heat. In this situation, the instrument measures effective thermal properties that are the combination of conduction and latent heat. By taking measurements over a range of temperatures, the processes of conduction and latent heat can be separated. When the tissue is perfused by blood, the thermistor heat is removed both by conduction and by heat transfer due to blood flow near the probe. *In vivo*, the instrument measures effective thermal properties that are the combination of conductive and convective heat transfer. Thermal properties are derived from temperature and power measurements using equations that describe heat transfer in the integrated probe/tissue system.

The following five complexities make the determination of thermal properties a technically challenging task. First, tissue heat transfer includes conduction, convection, radiation, metabolism, evaporation, and phase change. It is difficult but necessary to decouple these different heat transfer mechanisms. Second, the mechanical and thermal interactions between the probe and tissue are complex, and must be properly modeled to achieve accurate measurements. When the probe is inserted into living tissue a fluid pool may form around the probe because of the mechanical trauma. Because the probe is most sensitive to the tissue closest to it, the presence of a pool of blood and other fluids will significantly alter the results. Tissue damage due to probe insertion may also occur *in vitro*. Third, the tissue structure is quite heterogeneous within each sample. Thus, the probe (which returns a single measurement value) measures a spatial average of the tissue properties surrounding the active elements. Unfortunately, the spatial distribution is very nonuniform.[8] The probe is most sensitive to the tissue immediately adjacent to it. It is important to control this effective measurement volume. If the effective volume is too small, then the measurement is highly sensitive to the mechanical/thermal contact between the probe and tissue. If the effective volume is too large, then the measurement is sensitive to the boundary conditions at the surface of the tissue sample. Fourth, there are significant sample to sample and species to species variabilities. One must be careful when extrapolating results obtained in one situation to different situations. Fifth, tissue handling is critical. Thermal properties are dependent on temperature and water content.[9–12]

Blood flow, extracellular water, and local metabolism are factors that strongly affect heat transfer in living tissue, but are difficult to determine or control experimentally. Once a tissue dies, if handled improperly there will be significant water fluxes which will affect tissue thermal properties. Tissues should be stored on a saline-moistened surgical gauze pad and wrapped in aluminum foil and kept at 4°C to minimize tissue mass transfer: collagenous tissues are especially hydrophilic and will absorb substantial amounts of water if immersed, significantly altering their physical properties.

Currently, there is no method to quantify simultaneously the major three parameters: the intrinsic tissue thermal conductivity, k_m, the tissue thermal diffusivity, α_m, and perfusion, w. Either the knowledge of k_m is required prior to the perfusion measurement, or even when k_m is measured in the presence of perfusion, the thermal diffusivity cannot be measured.[6,13]

Background

There are many good reviews of techniques to measure thermal properties.[10,14–16] Thermophysical Properties of Matter is a ten-volume set that catalogs thermal properties. Volumes 1 and 3 contain thermal conductivity data, and Volume 10 contains thermal diffusivity data. Extensive reviews of measurement techniques exist as prefaces to each volume of the set. Additional thermal property data can be found in Kreith and Bohn.[17] John Chato has written an excellent chapter in Heat Transfer in Medicine and Biology, edited by Shitzer and Eberhart, which reviews techniques to measure thermal properties of biologic materials.[10] Valvano has documented the temperature dependence of tissue thermal properties.[11,12] Duck has written an excellent review chapter on this subject.[18]

The thermal diffusion probe was conceived by Chato.[3,10] Significant developments were obtained by Balasubramaniam, Bowman, Chen, Holmes, and Valvano.[19–27] Patel and Walsh have applied the self-heated thermistor technique to nondestructive surface measurements.[8,24–26] Unfortunately, surface probes are unreliable due to poor probe/tissue contact and uncertain boundary conditions at the tissue surface.[24,27]

Self-heated thermistors have been used to measure perfusion.[4,9,19,20,22–24] Effective thermal conductivity, k_{eff}, is the total ability of perfused tissue to transfer heat in the steady state; k_{eff} is the combination of conduction (due to intrinsic thermal conductivity, k_m) and convection (due to perfusion). Measurements of k_{eff} are very sensitive to perfusion. The limitation of most techniques is that the intrinsic tissue thermal conductivity must be known in order to accurately measure perfusion. Holmes and Chen use a combination of steady-state and transient heating modes to determine perfusion without requiring a no-flow calibration measurement.[13,19,20] The uncertainty of k_m significantly limits the perfusion accuracy.[9]

Measurement of Thermal Conductivity and Diffusivity

Methods

In the constant temperature heating technique, the instrument first measures the baseline tissue temperature, T_0. Then, an electronic feedback circuit applies a variable voltage, $V(t)$, in order to maintain the average thermistor temperature at a predefined constant, T_h. The applied thermistor power includes a steady state and a transient term:

$$P(t) = A + Bt^{-1/2} \tag{4.5.1}$$

where A and B are system constants that depend on the characteristics of the probe and the thermal interaction with the tissue in which it is embedded.

In order to measure thermal conductivity, thermal diffusivity, and tissue perfusion, the relationship between applied thermistor power, P, and resulting thermistor temperature rise, $\Delta T(t) = T_h - T_0$, must be known. In the constant temperature method, ΔT is constant. The thermistor bead is treated

as a sphere of radius "a" embedded in a homogeneous medium. Since all media are considered to have constant parameters with respect to time and space, the initial temperature will be uniform when no power is supplied to the probe.

$$T_b = T_m = T_0 = T_a + \frac{Q_{met}}{wc_{bl}} \quad \text{at } t = 0 \tag{4.5.2}$$

where w is the rate of perfusion of blood through the local tissue (mL blood/mL tissue $- s$) and c_{bl} is the specific heat of blood kJ/(kg K).

Let $\overline{T}$ be the temperature rise above baseline, $\overline{T} = T - T_0$. Both the thermistor bead temperature rise ($\overline{T}_b$) and the tissue temperature rise ($\overline{T}_m$) are initially zero. The subscripts b and m refer, respectively, to the bead and the tissue (i.e., the surrounding medium).

$$\overline{T}_b = \overline{T}_m = 0 \quad \text{at } t = 0 \tag{4.5.3}$$

Assuming the venous blood temperature equilibrates with the tissue temperature and that the metabolic heat is uniform in time and space, the Pennes's bioheat transfer[28] in spherical coordinates is given by

$$\rho_b c_b \frac{\partial \overline{T}_b}{\partial t} = k_b \frac{1}{r^2} \frac{\partial}{\partial r}\left(r^2 \frac{\partial \overline{T}_b}{\partial r} \right) + \frac{A + Bt^{-1/2}}{\frac{4}{3}\pi a^3} \qquad r < a \tag{4.5.4}$$

$$\rho_m c_m \frac{\partial \overline{T}_m}{\partial i} = k_m \frac{1}{r^2} \frac{\partial}{\partial r}\left(r^2 \frac{\partial \overline{T}_m}{\partial r} \right) - wc_{bl} V_m \qquad r > a \tag{4.5.5}$$

Perfect thermal contact is assumed between the finite-sized spherical thermistor and the infinite homogeneous perfused tissue. At the interface between the bead and the tissue, continuity of thermal flux and temperature leads to the following boundary conditions:

$$\overline{T}_b = \overline{T}_m \quad \text{at } r = a \tag{4.5.6}$$

$$k_b \frac{\partial \overline{T}_b}{\partial r} = k_m \frac{\partial \overline{T}_m}{\partial r} \quad \text{at } r = a \tag{4.5.7}$$

The other necessary boundary conditions are at positions $r \to 0$ and $r \to \infty$. Since no heat is gained or lost at the center of the thermistor,

$$\overline{T}_b = \text{finite}\left(\text{or } k_b \frac{\partial \overline{T}_b}{\partial r} = 0 \right) \quad \text{as } r \to 0 \tag{4.5.8}$$

Because the thermistor power is finite and the tissue is infinite, the tissue temperature rise at infinity goes to zero:

$$\overline{T}_m \to 0 \quad \text{as} \quad r \to \infty \tag{4.5.9}$$

It is this last initial condition that allows the Laplace transform to be used to solve the coupled partial differential equations. The Laplace transform converts the partial differential equations into ordinary differential equations that are independent of time t. The steady-state solution allows for the determination of thermal conductivity and perfusion.[20]

$$\bar{T}_b(r) = \frac{A}{4\partial a k_b}\left\{\frac{k_b}{k_m\left(1+\sqrt{z}\right)} + \frac{1}{2}\left[1-\left(\frac{r}{a}\right)^2\right]\right\} \tag{4.5.10}$$

$$\bar{T}_m(r) = \frac{A}{4\partial r k_m}\left(\frac{e^{(1-r/a)\sqrt{z}}}{1+\sqrt{z}}\right) \tag{4.5.11}$$

where z is a dimensionless Pennes's model perfusion term ($wc_{bl}a^2/k_m$). The measured thermistor response, ΔT, is assumed to be the simple volume average of the thermistor temperature:

$$\Delta T = \frac{\int_0^a \bar{T}_b(r) 4\pi r^2 \, dr}{\frac{4}{3}\pi a^3} \tag{4.5.12}$$

Inserting Equation 4.5.10 into Equation 4.5.12 yields the relationship used to measure thermal conductivity, assuming no perfusion.[4]

$$k_m = \frac{1}{\frac{4\pi a \Delta T}{A} - \frac{0.2}{k_b}} \tag{4.5.13}$$

A similar equation allows the measurement of thermal diffusivity, α, from the transient response, again assuming no perfusion.[22]

$$\alpha_m = \left[\frac{a}{\sqrt{\pi}\, B/A\left(1+0.2\frac{k_m}{k_b}\right)}\right]^2 \tag{4.5.14}$$

Rather than using the actual probe radius (a) and probe thermal conductivity (k_b), the following empirical equations are used to calculate thermal properties:

$$k_m = \frac{1}{\frac{c_1 \Delta T}{A} + c_2} \tag{4.5.15}$$

$$\alpha_m = \left[\frac{c_3}{\sqrt{\pi}\, B/A\left(1+0.2\frac{k_m}{c_4}\right)}\right]^2 \tag{4.5.16}$$

The coefficients c_1, c_2, c_3, and c_4 are determined by operating the probe in two materials of known thermal properties. Typically, agar-gelled water and glycerol are used as thermal standards. This empirical calibration is performed at the same temperatures at which the thermal property measurements will be performed.

It is assumed that the baseline tissue temperature, T_0, is constant during the 30-s transient. Patel has shown that if the temperature drift, dT_0/dt, is larger than 0.1°C/min, then significant errors will occur.[8] The electronic feedback circuit forces T_h to a constant. Thus, if T_0 is constant, then ΔT does not vary during the 30-s transient period.

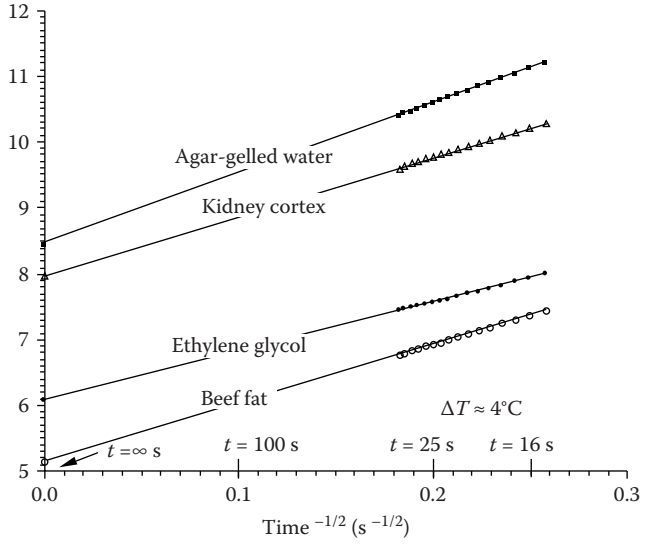

FIGURE 4.5.1 Typical $P/\Delta T$ vs. time$^{-1/2}$ data for the constant temperature heating technique. (From Valvano, J.W., *Optical-Thermal Response of Laser-Irradiated Tissue*, Plenum Press, New York, 1995. With permission.)

The applied power, $P(t)$, varies during the 30-s transient. Linear regression is used to calculate the steady-state and transient terms in Equation 4.5.1. Figure 4.5.1 shows some typical responses. The steady-state response (time equals infinity) is a measure of the thermal conductivity. The transient response (slope) indicates the thermal diffusivity.

The time of heating can vary from 10 to 60 s. Shorter heating times are better for small tissue samples and for situations where there is baseline tissue temperature drift. Another advantage of shorter heating times is the reduction in the total time required to make one measurement. Longer heating times increase the measurement volume and reduce the effect of imperfect thermistor/tissue coupling. Typically, shorter heating times are used *in vivo* because it allows more measurements to be taken over the same time period. On the other hand, longer heating times are used *in vitro* because accuracy is more important than measurement speed.

Probe Design

Thermal probes must be constructed in order to measure thermal properties. The two important factors for the thermal probe are thermal contact and transducer sensitivity. The shape of the probe should be chosen to minimize trauma during insertion. Any boundary layer between the thermistor and the tissue of interest will cause a significant measurement error. The second factor is transducer sensitivity, that is, the slope of the thermistor voltage vs. tissue thermal conductivity. Equation 4.5.13 shows that for a fixed ΔT, k_m, and k_b, the thermistor power (A) increases linearly with probe size (a). Therefore, larger probes are more sensitive to thermal conductivity. Thermometrics P60DA102M and Fenwal 121-102EAJQ01 are glass probe thermistors that make excellent transducers. The glass-coated spherical probes provide a large bead size and a rugged, stable transducer. Thermometrics BR55KA102M and Fenwal 112-102EAJ-B01 bead thermistors also provide excellent results. For large tissue samples multiple thermistors can be wired in parallel, so they act electrically and thermally as one large device. There are two advantages to using multiple thermistors. The effective radius, $a=c_1/4\pi$, is increased from about 0.1 cm for a typical single P60DA102M probe to about 0.5 cm for a configuration of three P60DA102M thermistors. The second advantage is that the three thermistors are close enough to each other that the tissue between the probes will be heated by all three thermistors. This cooperative heating tends to increase the effective measurement volume and

reduce the probe/tissue contact error. Good mechanical/thermal contact is critical. The probes are calibrated after they are constructed, so that the thermistor geometry is incorporated into the coefficients c_1, c_2, c_3, and c_4. The same water bath and probe configuration should be used during the calibration and tissue measurements.

Calibration

Calibration is a critical factor when using an empirical technique. For temperatures below 0°C, ice and ethylene glycol are used as thermal standards. For temperatures between 0°C and 15°C, agar-gelled water and ethylene glycol can be used as thermal standards. For temperatures between 15°C and 75°C, agar-gelled water and glycerol can be used; 1 g of agar per 100 mL of water should be added to reduce convection. The instrument has been used to measure k_m and α_m of various concentrations of agar-gelled water at 37°C. A mixture of water and glycerol can be used to estimate the accuracy of the technique. The mass fraction, m, can be used to determine the true thermal properties of the mixture where k_w and k_g are in mW/(m K):[29]

$$k_m = m\,k_g + (1-m)k_w + 1.4m(m-1)(k_w - k_g - 2) - 0.014m(m-1)(T - 20°C) \tag{4.5.17}$$

$$\alpha_m = m\alpha_g + (1-m)\alpha_w \tag{4.5.18}$$

Estimation of the Convective Heat Transfer Coefficient

Introduction

The heart is an organ in which it is possible to make experimental measurements of convective transport between flowing blood and tissue. The topologies of the inner surfaces of the heart and blood vessels are very complex. Consequently, it is very difficult to model the heat transfer at the wall analytically. Any attempt to estimate the heat transfer coefficient analytically will be inaccurate because of the complex contours of structures like the endocardium. The experimental method presented in this section to estimate the heat transfer coefficient is very appropriate.

The following method can be used to estimate the convective coefficient due to blood flow inside the chambers of the heart. This method can be applied to blood vessels as well. The method to measure the convective coefficient due to blood flow inside the heart is derived from basic heat transfer analysis. Two miniature thermistor (BR11, Thermometrics Inc, Northridge, CA.) probes are inserted at fixed locations near the inner surface of the model. T_1 is the measured temperature nearest the endocardial wall, and T_2 is measured 2 mm inside the myocardial wall. The epicardial surface of the heart is maintained at a steady temperature, T_o. Blood at a different temperature T_f is pumped through the heart. The thermistor probes are used to continuously monitor the spatial temperature gradient in the heart muscle. The basic principle used to estimate the heat transfer coefficient, h, is as follows:

$$h \cdot \left(T_{wall} - T_f\right) = k_s \cdot \left.\frac{dT}{d\hat{n}}\right|_{wall} \tag{4.5.19}$$

where $\hat{n}$ is the direction perpendicular to the surface and k_s is the thermal conductivity of the heart wall. The gradient at the wall of the surface is calculated from the data obtained from the array of thermistors.

Calibration

Ideally, the temperature measured in any experiment should be the temperature of the zero-volume point of interest. But when a measurement is made the temperature sensor has a finite volume and the actual measurement is the volume-averaged measurement of some region around the sensor. Similarly, the gradient measured using two sensors is an estimate of the gradient between the two

sensors. These two errors are responsible for the estimate of the heat transfer coefficient measured using Equation 4.5.19 to be vastly different from the correct value. Hence, the probe assembly is first calibrated by operating the probe in situations where the true convective heat transfer coefficient is known. Two calibration factors, c_1 and c_2, are added to Equation 4.5.19 to adjust for the finite size of the temperature sensors, and for the fact that the measured temperature gradient is not at the wall surface:

$$h = c_1 \exp\left(c_2 \frac{k_s (T_1 - T_2)}{(T_f - T_1)} \right) \tag{4.5.20}$$

where T_1 and T_2 are measured temperatures in the wall. A cylindrical tube made with a material (e.g., silicone) that has thermal properties close to tissue can be used to calibrate the sensor combination. The key to accurate measurements lies in how close the calibration configuration matches the actual experimental conditions.

Verification

The effect of measurement errors on the estimate of the heat transfer coefficient was studied for a tube of inner radius R_i (0.73 cm) and outer radius of R_o (1.33 cm). The temperature distribution inside the tube wall was analytically determined for water flowing inside and the outer wall temperature held at a constant value of 23°C. The heat transfer coefficient was then calculated from the temperature distribution using the relation in Equation 4.5.19. The effect of the measurement errors on the heat transfer coefficient estimate was analyzed by using values for the temperature and the gradient away from the wall of the tube.

The temperature at any point of distance R from the axis of the tube is given by

$$T = T_o - \mathrm{Bi}(T_f - T_w) \ln\left(\frac{R}{R_o} \right), \tag{4.5.21}$$

where the T_w is the inner wall temperature given by

$$T_w = \frac{T_o - \mathrm{Bi} \ln\left(\frac{R_i}{R_o} \right) T_f}{1 - \mathrm{Bi} \ln\left(\frac{R_i}{R_o} \right)} \tag{4.5.22}$$

where T_o is the outer wall temperature, Bi is the Biot number, calculated as (hR_i/k), h is the heat transfer coefficient, and k is the thermal conductivity of the material of the tube.

In Vitro Studies

The first *in vitro* study used two cylindrical tubes. The first tube was used to calibrate the probe and the second to evaluate measurement accuracy. The exact position of the thermistor array for sensing the temperature must be in a similar location relative to the inner wall for both calibration and measurement. Water at 37°C was made to flow through the tube at a rate of L (liters per minute). The flow was measured using a rotameter type flowmeter (accuracy 2%, Omega Engineering Inc, Norwalk, CT.). The temperature gradients were recorded continuously.

The tube was initially maintained at room temperature. For a smooth tube of cylindrical cross section the relation between Nu, Re, and Pr for turbulent flow conditions is given by

$$\mathrm{Nu}_D = \frac{(f/8)(\mathrm{Re}_D - 1000)\mathrm{Pr}}{1 + 12.7(f/8)^{1/2}(\mathrm{Pr}^{2/3} - 1)} \tag{4.5.23}$$

where the friction factor, f, is

$$f = (0.79 \ln\{\mathrm{Re_D}\} - 1.64) - 2 \tag{4.5.24}$$

This correlation is valid for $0.5 < \mathrm{Pr} < 2000$ and $2300 < \mathrm{Re_D} < 5 \times 10^6$. The setup was calibrated with a tube of 1.46 cm diameter and then tested with a tube of 1.27 cm diameter. The flow rates were selected to give a range of h values from 800 to 4000 W/m^2 K. The average accuracy is about 10%.

Temperature-Dependent Thermal Properties

Temperature Dependence of Organ Tissue

When modeling heat transfer in situations where the temperature change exceeds 10°C it is important to consider the temperature dependence of the tissue thermal properties. Valvano measured tissue thermal properties as a function of temperature using the constant ΔT thermistor heating technique.[11,12] The results, shown in Table 4.5.1, were derived from *in vitro* measurements taken at 3°C, 10°C, 17°C, 23°C, 30°C, 37°C, and 45°C.

TABLE 4.5.1
Thermal Properties as a Function of Temperature

The animal tissues were measured from freshly sacrificed dogs, rabbits, and pigs. The normal human tissues were obtained by autopsy. The human cancers were freshly excised. The k_0, k_1, α_0, and α_1 values are the linear fit of the thermal properties as a function of temperature.

$$k = k_0 + k_1 T \tag{4.5.25}$$

$$\alpha = \alpha_0 + \alpha_1 T \tag{4.5.26}$$

The average thermal properties of these data are

$$k = 4.574 + 0.01403T \tag{4.5.27}$$

$$\alpha = 0.001284 + 0.000053T \tag{4.5.28}$$

where conductivity is in mW/(cm °C), diffusivity is in cm²/s, and temperature is in °C.

Temperature Dependence of Human Arterial Tissue

Aortic tissue was obtained from a local pathology lab. The thermal probes were placed on the endothelial surface of the aortic wall, and the tissue/probe combination was wrapped in plastic. The tissue surface was kept wet to improve the thermal contact and to prevent drying. The samples were placed in a beaker of saline and the beaker was put into a temperature-controlled water bath. Thermal conductivity and thermal diffusivity were measured 10 times at each temperature 35°C, 55°C, 75°C, and 90°C. The measurement sequence was varied between 35, 55, 75, 90, 95, 75, 55, 35 75, 90, 55, 35 and 55, 35, 90, 75. Measurements were obtained from both normal and diseased tissue. The plaques were categorized by gross visual observation. The calcified plaques were hard and bony. The fibrous plaques were firm but pliable. The fatty plaques were loose and buttery. The results from 54 tissues are presented in Tables 4.5.2 and 4.5.3. The column n refers to the number of tissue samples. The standard deviation is given in the parentheses.

The two-sample *t*-test with $p = 0.05$ was used to determine significant differences. The tissue thermal properties increased with temperature and were significantly less than those of water. The

measurement order did not affect the measured thermal properties. There was no significant difference between the thermal conductivity of normal aorta, fatty plaque, and fibrous plaque. The thermal conductivity and thermal diffusivity of calcified plaque were slightly higher than normal aorta, fatty plaque, and fibrous plaque.

Temperature Dependence of Canine Arterial Tissue

Carotid and femoral arteries were harvested immediately postmortem. The thermal probes were placed on the endothelial surface of the arterial wall. Thermal conductivity and thermal diffusivity were measured 10 times at each temperature 25°C, 35°C, 45°C, 55°C, 65°C, 75°C, 85°C, and 95°C. Measurements were obtained only from normal tissue. The results from 18 tissue samples are summarized as follows:

Canine Femoral Artery

$$k\text{mW/(cm °C)} = 3.688 + 0.0062014T(°\text{C}) \tag{4.5.29}$$

$$\alpha(\text{cm}^2/\text{s}) = 0.001003 + 0.000001381T(°\text{C}) \tag{4.5.30}$$

Canine Carotid Artery

$$k\text{mW/(cm °C)} = 4.480 + 0.0000164T(°\text{C}) \tag{4.5.31}$$

$$\alpha(\text{cm}^2/\text{s}) = 0.001159 + 0.000003896T(°\text{C}) \tag{4.5.32}$$

The two-sample *t*-test with $p = 0.01$ shows that both thermal conductivity and thermal diffusivity are higher in carotid vs. femoral artery. These results could be explained from the fact that the carotid artery contains more collagen than femoral artery. A tissue with a higher percentage of collagen would have lower thermal properties because collagen is a thermal insulator.

Temperature Dependence of Swine Left Ventricle

Swine myocardial samples were harvested immediately postmortem. The thermal probes were placed on the left ventricular muscle. Thermal conductivity and thermal diffusivity were measured 10 times at each temperature 25°C, 37°C, 50°C, 62°C, and 76°C. Measurements were obtained only from normal tissue. The results are summarized in Tables 4.5.4 and 4.5.5.

Thermal Properties of Frozen Tissue

The thermal properties of frozen tissue are significantly higher than normal tissue. Valvano measured frozen tissue thermal properties using the constant ΔT thermistor heating technique.[30] The results, shown in Table 4.5.6, were derived from *in vitro* measurements taken at –18°C, –5°C, and +0.1°C.

Thermal Properties as a Function of Water and Fat Content

In a global sense, the thermal properties of tissue are determined by the relative concentrations of its constituent parts. Spells found a linear relationship between tissue thermal conductivity and water content:[31]

$$k\text{mW/(cm °C)} = 0.54 + 5.73m_{\text{water}} \text{ for } m_{\text{water}} > 0.2 \tag{4.5.33}$$

where m_{water} is the mass fraction of water in the tissue. Cooper and Trezek found an empirical relationship between thermal conductivity and mass fractions of water, protein, and fat:[32]

$$k\text{mW/(cm °C)} = \rho\sum_n \frac{k_n m_n}{\rho_n} = \rho\left(6.28m_{\text{water}} + 1.17m_{\text{protein}} + 2.31m_{\text{fat}}\right) \tag{4.5.34}$$

Effect of Blood Flow on Temperature

Bioheat transfer processes in living tissues are often influenced by blood perfusion through the vascular network. When there is a significant difference between the temperature of blood and the tissue through which it flows, convective heat transport will occur, altering the temperatures of both the blood and the tissue. Perfusion-based heat transfer interaction is critical to a number of physiological processes such as thermoregulation and inflammation.

The blood/tissue thermal interaction is a function of several parameters including the rate of perfusion and the vascular anatomy, which vary widely among the different tissues, organs of the body, and pathology. Appendix B contains an extensive compilation of perfusion rate data for many tissues and organs and for many species. The literature on mathematical modeling of the influence of blood perfusion on bioheat transfer phenomena has been reviewed recently by Charney,[33] and this reference is highly recommended for readers desiring an in-depth presentation of the topic.

The rate of perfusion of blood through different tissues and organs varies over the time course of a normal day's activities, depending on factors such as physical activity, physiological stimulus, and environmental conditions. Further, many disease processes are characterized by alterations in blood perfusion, and some therapeutic interventions result in either an increase or decrease in blood flow in a target tissue. For these reasons, it is very useful in a clinical context to know what the absolute level of blood perfusion is within a given tissue. There are numerous techniques that have been developed for this purpose over the past several decades. In some of these techniques, the coupling between vascular perfusion and local tissue temperature is applied to advantage to assess the flow through local vessels via inverse solution of equations which model the thermal interaction between perfused blood and the surrounding tissue.

Pennes[28] published the seminal work on developing a quantitative basis for describing the thermal interaction between tissue and perfused blood. His work consisted of a series of experiments to measure temperature distribution as a function of radial position in the forearms of nine human subjects. A butt-junction thermocouple was passed completely through the arm *via* a needle inserted as a temporary guideway, with the two leads exiting on opposite sides of the arm. The subjects were unanesthetized so as to avoid the effects of anesthesia on blood perfusion. Following a period of normalization,

the thermocouple was scanned transversely across the mediolateral axis to measure the temperature as a function of radial position within the interior of the arm. The environment in the experimental suite was kept thermally neutral during the experiments. Pennes's data showed a temperature differential of three to four degrees between the skin and the interior of the arm, which he attributed to the effects of metabolic heat generation and heat transfer with arterial blood perfused through the microvasculature.

Pennes proposed a model to describe the effects of metabolism and blood perfusion on the energy balance within tissue. These two effects were incorporated into the standard thermal diffusion equation, which is written in its simplified form as

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + (\rho c)_b \omega_b (T_a - T) + q_{met} \tag{4.5.37}$$

Metabolic heat generation, q_{met}, is assumed to be homogeneously distributed throughout the tissue of interest as the rate of energy deposition per unit volume. It is assumed that the blood perfusion effect is homogeneous and isotropic and that thermal equilibration occurs in the microcirculatory capillary bed. In this scenario, blood enters capillaries at the temperature of arterial blood, T_a, where heat exchange occurs to bring the temperature to that of the surrounding tissue, T. There is assumed to be no energy transfer either before or after the blood passes through the capillaries, so that the temperature at which it enters the venous circulation is that of the local tissue. The total energy exchange between blood and tissue is directly proportional to the density, ρ_b, specific heat, c_b, and perfusion rate, ω_b, of blood through the tissue, and is described in terms of the change in sensible energy of the blood. This thermal transport model is analogous to the process of mass transport between blood and tissue, which is confined primarily to the capillary bed.

A major advantage of the Pennes model is that the added term to account for perfusion heat transfer is linear in temperature, which facilitates the solution of Equation 4.5.37. Since the publication of this work, the Pennes model has been adapted by many researchers for the analysis of a variety of bioheat transfer phenomena. These applications vary in physiological complexity from a simple homogeneous volume of tissue to thermal regulation of the entire human body.[34,35] As more scientists have evaluated the Pennes model for application in specific physiological systems, it has become increasingly clear that many of the assumptions foundational to the model are not valid. For example, Chato,[36] Chen and Holmes,[37] and Weinbaum et al.[38–50] have demonstrated very convincingly that thermal equilibration between perfused blood and local tissue occurs in the precapillary arterioles, and that by the time blood flows into vessels 60 μm in diameter and smaller, the equilibration process is complete. Therefore, no significant heat transfer occurs in the capillary bed; the exchange of heat occurs in the larger components of the vascular tree. The vascular morphology varies considerably among the various organs of the body, which contributes to the need for specific models for the thermal effects of blood flow (as compared to the Pennes model that incorporates no information concerning vascular geometry). It would appear as a consequence of these physiological realities that the validity of the Pennes model is questionable.

Many investigators have developed alternative models for the exchange of heat between blood and tissue. These models have accounted for the effects of vessel size (Chato,[36] Chen and Holmes,[37] Mooibroek and Lagendijk[51]), countercurrent heat exchange (Baish,[52] Huang et al.,[53] Keller and Seiler,[54] Mitchell and Meyers,[55] Mooibroek and Lagendijk[51]), as well as a combination of partial countercurrent exchange and bleed-off perfusion (Weinbaum and Jiji[38–50]). All of these models provided a larger degree of rigor in the analysis, but at the compromise of greater complexity and reduced generality. Some of these models have been the subject of considerable debate concerning their validity and range of appropriate application (Baish et al.,[56] Weinbaum and Jiji,[57] Wissler[58,59]). These studies also led to an increased appreciation of the necessity for a more explicit understanding of the local vascular morphology as it governs bioheat transfer, which has given rise to experimental studies to measure and characterize the three-dimensional architecture of the vasculature in tissues and organs of interest.

It is quite interesting that, in the context of the above studies to improve on the widely applied but questionable Pennes model, the 50th anniversary of the publication of Pennes's research was

recognized recently.[28] For this occasion, Wissler[59] returned to Pennes's original data and analysis and reevaluated his work. Given the hindsight of 5 decades of advances in bioheat transfer plus greatly improved computational tools and better constitutive property data, Wissler's analysis pointed out further flaws in Pennes's work which had not been appreciated previously. However, he also showed that much of the criticism that has been directed toward the Pennes model is not justified, in that his improved computations with the model demonstrated a good standard of agreement with the experimental data. Thus, Wissler's conclusion is that "those who base their theoretical calculations on the Pennes model can be somewhat more confident that their starting equations are valid." The quantitative analysis of the effects of blood perfusion on the internal temperature distribution in living tissue remains a topic of active research after a half-century of study.

Limitations of Pennes's Model

Pennes's model was the first major effort in quantifying the heat transfer contribution of perfusion. It was developed for describing the transverse temperature profile in the human forearm. The model is unique in that the perfusion is very simple. The "bioheat equation" was previously shown as Equation 4.5.37.

The limitations of this model arise from the erroneous view of the heat transfer process and its anatomical location. Chen and Holmes's analysis of blood vessel thermal equilibration lengths showed that Pennes's concept is incorrect.[37] The thermal equilibration length is defined as the length at which the difference between the blood and the tissue temperature decreases to $1/e$ of the initial value. They indicated that thermal equilibration occurs predominantly within the terminal arterioles and venules, and that blood is essentially equilibrated prior to entering the capillaries. In considering the contribution of perfusion as a nondirectional term, the directional convective mechanism is neglected. Nor does the model account for specific vascular architecture such as countercurrent arteries and veins. The limitations of Pennes's model have motivated subsequent investigators to develop their own models.

Despite its erroneous concept, the perfusion term of Pennes's model has been widely used, and found to be valid for situations other than the forearm. Its wide usage has been mainly due to its simplicity of implementation, especially in analyses where a closed form analytical solution is sought.[22,60] Investigators have obtained good temperature predictions for the following circumstances:

1. The porcine kidney cortex in the absence of large vessels (diameter > 300 μm)[61]
2. The rat liver[5,22]
3. The capillary bleed-off from large vessels[42]

In the last case, Charny compared Weinbaum and Jiji's countercurrent model and Pennes's model against the experimental results of Pennes. The simulations found that Pennes's model is valid in the initial branchings of the largest microvessels from the countercurrent vessels (diameter > 500 μm) in deep tissue. In this case, the microvessel blood temperature is close to arterial temperature. Arkin et al.[62] provide an explanation of the inconsistencies between the two anatomical sites. They suggest that since blood typically travels down successive generations of the vascular branches before equilibrating with the tissue temperature, Charny's claim actually refers to the collective contribution of numerous smaller thermally significant vessels in a region dominated by the large microvessels. The distinction of being thermally significant is based upon the ratio of thermal equilibration length to actual vessel length (ε):

$$\varepsilon = \frac{L_e}{L} \tag{4.5.38}$$

Along with Xu's observations in porcine kidney,[61] Pennes's model appears to be applicable to regions where the vasculature comprises numerous, small, thermally significant vessels ($\varepsilon \approx 1$).

Continuum Models

Among the continuum formulations of bioheat transfer, the Chen–Holmes model is the most developed. Prior to Chen–Holmes model, continuum formulations by Wulff[63] and Klinger[64] addressed the isotropicity of Pennes's perfusion term. However, they did not challenge the Pennes's concept of the site of heat exchange. Chen and Holmes[37] formulated their model after analyzing the significance of blood vessel thermal equilibration length. Through this analysis, they quantitatively showed that the major heat transfer processes occur in the 50- to 500-μm diameter vessels and refuted Pennes's paradigm. In their model, they proposed that larger vessels be modeled separately from smaller vessels and tissue. Larger vessels were distinguished using the ratio of equilibration length to actual vessel length of about one ($\varepsilon \approx 1$) as the criterion. The smaller vessels and tissue were then modeled as a continuum. In a differential control volume of this continuum, they further separated solid tissue from the blood within the vascular space (Figure 4.5.2).

Subsequently, the heat transfer mechanisms can be divided into the contributions from (1) non-equilibrated blood in the thermally significant vessels, (2) blood that has equilibrated with the surrounding tissue, and (3) nearly equilibrated blood. The perfusion term of Pennes is then replaced by three terms:

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + (\rho c)_b \omega^* (T_a^* - T) - (\rho c)_b \bar{u} \cdot \nabla T + \nabla \cdot k_p \nabla T + q_m \tag{4.5.39}$$

The second through the fourth term on the right-hand side arise from each of the three categories described above. The second term, $(\rho c)_b \omega^* (T_a^* - T)$, is similar to Pennes except the perfusion and the arterial temperature are specific to the volume being considered. The $(\rho c)_b \bar{u} \nabla T$ term is a directional convective term due to the net flux of equilibrated blood. Finally, the $\nabla \cdot k_p \nabla T$ term is to account for the contribution of the nearly equilibrated blood in a tissue temperature gradient. The nearly equilibrated blood contributes to small temperature fluctuations within the tissue and the effect is modeled as a tensor "perfusion conductivity":

$$k_p = n(\rho c)_b \pi r_b^2 \bar{V} \cos^2 \gamma \sum_{i=1}^{\infty} \frac{L_e}{L_e^2 \beta_1^2 + 1} \tag{4.5.40}$$

which is a function of local average blood flow velocity vector within the vessel ($\bar{V}$) relative angle (γ) between blood vessel direction and the tissue temperature gradient, the number of vessels (n), and vessel radius (r_b). The Fourier integral spectral wave number (β) can be approximated as the inverse of vessel length. The contribution of this conductivity is minimal except when vessels with large equilibration lengths are considered. However, for this situation, Chen and Holmes recommend that these vessels be treated separately. The assumptions that were made for their model include (1) neglecting the mass transfer between vessel and tissue space, and (2) treating the thermal

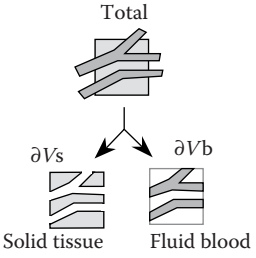

FIGURE 4.5.2 Schematic representation of tissue control volume as used by Chen-Holmes.[37]

conductivity and temperature within the tissue-blood continuum as that of the solid tissue, since the vascular volume is much smaller than that of the solid tissue.

The limitation of this model is that given the detail required, the model is not easy to implement. Also, the perfusion conductivity term is difficult to evaluate, and distinction within the continuum model is not well defined. Furthermore, the model does not explicitly address the effect of closely spaced countercurrent artery–vein pairs. This model has been applied to the porcine kidney and was found to predict temperatures similar to Pennes's model, and thus, given the simplicity of the latter, Xu et al.[61] recommended that Pennes be used. Arkin et al.[62] claim that the Chen–Holmes model can be essentially applied to the same tissue region as that for Pennes.

Vasculature-Based Models

Weinbaum–Jiji–Lemons[38–50]

The modeling of countercurrent vasculature, which was not explicitly addressed by the Chen–Holmes model, developed separately from that of the continuum models.[38–50] Bazett et al.[65] initially presented the countercurrent structure from observations of large arteries and veins in human limbs. The first major quantitative analysis was presented by Mitchell and Myers.[55] It was then followed by the work of Keller and Seiler,[54] which became the predecessor to the Weinbaum–Jiji models. In 1979, Weinbaum and Jiji[43] proposed the initial model of the artery–vein pair as two parallel cylinders of equal diameters with collateral bleed-off in the plane normal to the cylinders. The anatomical configuration is a schematic of an artery and vein pair with branches to the peripheral skin layer (Figure 4.5.3). The contribution of perfusion to heat transfer in tissue was treated as heat transfer in a porous medium. It was considered as a unidirectional convective term normal to the artery–vein pair. Knowledge of vessel density, diameter, and blood velocity was required at the different blood vessel generations.

In 1984, they presented a more thorough model based upon anatomical observations with Lemons.[38,39] This model analyzed three tissue layers of a limb: (1) deep, (2) intermediate, and (3) superficial or cutaneous. For the countercurrent structure of the deep tissue layer, they proposed a system of three coupled equations:

$$(\rho c)_b \pi r_b^2 \overline{V} \cdot \frac{dT_a}{ds} = -q_a \tag{4.5.41}$$

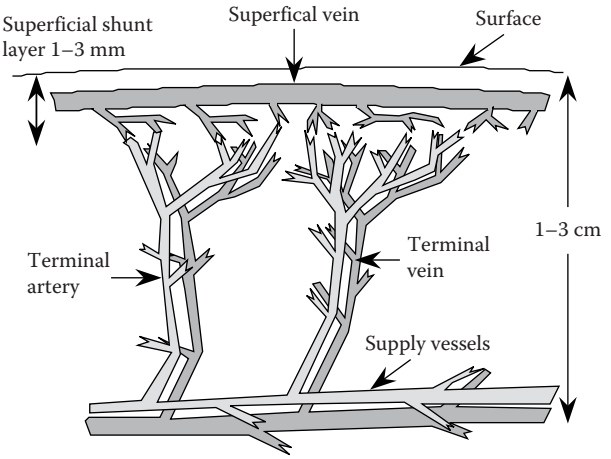

FIGURE 4.5.3 Schematic of artery and vein pair in peripheral skin layer.[43]

$$(\rho c)_b \pi r_b^2 \bar{V} \cdot \frac{dT_v}{ds} = -q_v \tag{4.5.42}$$

$$\rho c \frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + n\, g (\rho c)_b \cdot (T_a - T_v) - n \pi r_b^2 (\rho c)_b \bar{V} \cdot \frac{d(T_a - T_v)}{ds} + q_m \tag{4.5.43}$$

The first two equations describe the heat transfer of the thermally significant artery and vein, respectively. The third equation refers to the tissue surrounding the artery–vein pair. For this equation, the middle two right-hand-side terms represent the capillary bleed-off energy exchange, and the net heat exchange between the tissue and artery–vein pair, respectively. The capillary bleed-off term is similar to Pennes's perfusion term except the bleed-off mass flow (g) is used. Their analysis showed that the major heat transfer is due to the imperfect countercurrent heat exchange between artery–vein pairs. They quantified the effect of perfusion bleed-off associated with this vascular structure, and showed that Pennes's perfusion formulation is negligible due to the temperature differential.

Assumptions Include the Following:

1. Neglecting the lymphatic fluid loss, so that the mass flow rate in the artery is equal to that of the vein.
2. Spatially uniform bleed-off perfusion.
3. Heat transfer in the plane normal to the artery–vein pair is greater than that along the vessels (in order to apply the approximation of superposition of a line sink and source in a pure conduction field).
4. A linear relationship for the temperature along the radial direction in the plane normal to the artery and vein.
5. The artery–vein border temperature equals the mean of the artery and vein temperature.
6. The blood exiting the bleed-off capillaries and entering the veins is at the venous blood temperature.

The last assumption has drawn criticism based on studies that indicate the temperature to be closer to tissue.[58,62] Limitations of this model include the difficulty of implementation, and that the artery and vein diameters must be identical. Both of these issues have led to the development of the models described in subsequent sections. Studies using this model have been applied to the peripheral muscle tissue of a limb,[44–46] and the model is accepted as valid for vasculature with diameters <300 μm and $\varepsilon < 0.3$.[62]

Simplified Weinbaum–Jiji[40]

In response to the criticism that their previous model is too difficult and complex to apply, Weinbaum and Jiji simplified the three-equation model to a single equation:[40]

$$\rho c \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k_{eff} \frac{\partial T}{\partial x} \right) + q_{met} \tag{4.5.44}$$

In their simplification, they derived an equation based on the temperature of tissue only. The imperfect countercurrent heat exchange is embodied in an effective conductivity tensor term.

$$k_{eff} = k \left\{ 1 + \frac{n\left[(\rho c)_b \pi r_b^2 \bar{V} \cos\gamma \right]^2}{\sigma_\Delta \cdot k^2} \right\} + q_{met} \tag{4.5.45}$$

The k_{eff} term has similar parameters to the tissue and artery–vein pair heat exchange term in Equation 4.5.43, and a shape factor term (σ_Δ). In order to eliminate the blood temperature from their previous formulation, two major assumptions (the closure conditions) were used:

1. The mean tissue temperature $=(T_a+T_v)/2$.
2. Heat from a paired artery is mostly conducted to the corresponding vein:

$$q_a \approx q_v \approx \sigma_\Delta k \left(T_a - T_v\right) \tag{4.5.46}$$

Both of these assumptions were based upon studies in rabbit thigh muscle from their previous formulation. However, to respond to criticism of these assumptions, they performed further mathematical analysis on ε and provided insights into the limits for applying these assumptions.[47] An obvious limitation of this model is that the local temperatures along the countercurrent artery and vein cannot be calculated. Another limitation is that the model is applicable only in situations where $L_e / L \ll 1$. In the example of analyzing the peripheral tissue in the arm, L is equal to the characteristic radius of the arm.[48] Weinbaum and Lemons[48] admit that this assumption breaks down under the following conditions: (1) if blood flow rates significantly increased in the larger vessel pairs of the peripheral tissue layer, and (2) if deeper muscle tissue, where the diameter of the countercurrent pair vessels are less than 300 μm, are included. This model has been tested in the porcine[61] and canine kidney,[66] and continues to be verified by the Weinbaum group[41,50] and other investigators.[67]

Small Artery Model[68,69]

The small artery model was developed by Anderson in studies of the canine kidney cortex.[68,69] The model considers the energy balance in a control volume (i, j, k) which contains either an arterial (Q_a) or venous (Q_v) vessel. For a volume with an artery parallel to the "z" coordinate axis, the equation is

$$Q_a = N(VA)_a(\rho c)_b(1+\lambda-2\lambda\xi)\left(\frac{T_z - T_{z-\Delta z}}{\Delta z}\right) \tag{4.5.47}$$

For a volume with a vein,

$$Q_v = M(VA)_v(\rho c)_b(1+\lambda-2\lambda\xi)\left(\frac{T_{z+\Delta z} - T_z}{\Delta z}\right) \tag{4.5.48}$$

where N and M are the densities of the interlobular arteries and veins in the kidney cortex, respectively; ξ refers to the fraction of the total interlobular artery flow within the control volume; in the kidney cortex, $\xi=1$ at the corticomedullary junction and decreases to $\xi=0$ at the outer capsule. The total flow within this region accounts for bleed-off from the interlobular arteries through the λ term, where $\lambda=1$ represents complete bleed-off.

The discrete representation provides for straightforward numerical implementation when the vessel density within the tissue region of interest is known. Model assumptions include the following:

1. Thermal equilibration length within the volume is much less than vessel length.
2. A linear relation between the effect of bleed-off on arterial flow and location along the length of the vessel.
3. Bleed-off is modeled as a change in the arterial flow.
4. Bleed-off heat transfer is negligible.
5. No major thermally significant vessels (i.e., $\varepsilon \ll 1$) in the region of interest.

In its initial formulation, arbitrarily oriented vessels which would cause more than one vessel to occupy a control volume were not considered. Branching vessels are also not addressed. Even though this is not an inherent limitation of the model, implementation would be more difficult.

Due to its discrete representation, the model cannot solve the inverse problem. The model has been shown to be valid in the canine kidney cortex where there is uniformly oriented countercurrent artery–vein architecture of 70-μm diameter.

Hybrid Models

The lack of an encompassing model which can account for the various tissue structures has led researchers to propose and apply hybrid models. The substantial amount of effort related to the application and investigation of the major models discussed has shown that no one model applies to all the different vascular structures in tissue.[58,62] Wissler[58,59] points to the unlikelihood of a single equation being able to provide a complete description of the heat transfer process in tissue, and thus suggests the use of a combination of equations. The realization of this suggestion is found in Charny's work,[42] in which W-J's and Pennes's models are used to describe peripheral and deep muscle tissue, respectively. When the applicability of each of the major models has been conclusively defined, an algorithm which would enable users to arrive at the appropriate choice of equations given the tissue vasculature of interest would be beneficial.

The applicability of the models discussed requires an understanding of the validity and development of each model. A comparison of the models discussed has been summarized by Charney.[33]

Thermal Measurements of Perfusion

Introduction

Perfusion, the transmission of blood in the microcirculation, is an important factor in surgery, tissue transplants, heart disease, and cancer therapy. Despite its importance, no clinical method of measuring perfusion is currently available for a majority of applications. One technique that shows considerable promise involves the use of self-heated thermistors.[6–13] In this method, a miniature thermistor (0.5–2.5 mm in diameter) is placed invasively in the tissue of interest and heated with a predetermined applied power. Since both tissue conduction and perfusion act to carry heat away from the thermistor, the resulting volumetric-average temperature rise in the thermistor bead, ΔT, is related to both the tissue thermal conductivity and perfusion. By knowing the intrinsic tissue conductivity and the apparent conductivity of the tissue (due to both blood flow and conduction), the perfusion rate can be calculated.

At least two difficulties exist with this technique. The first is that the intrinsic tissue conductivity of perfused tissue must be known in order to calculate the perfusion rate. Although one could stop the blood flow to a tissue and measure its conductivity, this is clearly not desirable, nor is it always practical. In order to overcome this problem, Holmes and Chen have proposed techniques that measure perfusion without interrupting blood flow.[13,20]

Perfusion Resolution

The perfusion resolution, δw, is defined as the smallest change in perfusion that can be detected by the instrument. It can be determined theoretically:

$$\delta w = \delta k \cdot \frac{\partial w}{\partial k} \tag{4.5.49}$$

For the constant temperature heating technique using a P60 thermistor, δk is about 0.02 mW/(cm °C), and the sensitivity is about 100 (mL/100 g min)/(mW/cm °C). Using Equation 4.5.49 gives a perfusion resolution of about 2 mL/100 g min. Due to fluctuations in the baseline tissue temperature, the practical resolution is about 10 mL/100 g min. There are so many experimental and tissue variables that it is extremely important to test these techniques in preparations where the perfusion is known.

Measurement Volume

The measurement volume of a thermistor is a complex function of many factors, including the perfusion rate and vascular anatomy of the tissue of interest. One problem with small thermistors is their small measurement volume. A boundary layer (decoupler) between the thermistor and the tissue causes a significant measurement error. This unwanted boundary layer is often caused by the probe itself during insertion. The larger probes exhibit a smaller error, but are likely to cause a larger decoupler because of the increased trauma during insertion.

Temperature Dependence of Perfusion

Perfusion depends on a wide variety of factors, some local to the tissue (pH, temperature, pO_2), some which are external but directly control local flow (parasympathetic, hormones), and some which indirectly affect local flow (heart rate, blood pressure, skin temperature, needs of other organs). A simple experiment studied the effect of local tissue temperature on muscle perfusion. The constant ΔT method was used to measure perfusion in an anesthetized rat. The muscle temperature was manipulated by placing the hind limb into a water bath. Insulation was carefully placed so as to minimize changes to the body temperature. The rectal and neck temperatures were constant while the muscle in the hind limb was heated. Figure 4.5.4 shows the perfusion as a function of tissue temperature for a typical experiment. The dip in perfusion as a function of temperature, as shown in Figure 4.5.4, consistently occurred, but did not always occur at the same temperature. This dip may be due to an anastomotic shunt attempting to regulate the core body temperature.

Figure 4.5.5 presents the averaged results for 10 rats. Because the dip occurred at different temperatures for the various rats, it does not appear in the average. The large standard deviations are due to perfusion differences from one rat to the next. A linear fit to this averaged data gives the following approximation:

$$w = 1.9720(1 + 0.059T) \tag{4.5.50}$$

where w has units of mL/(100 g min) and T has units of °C.

Yuan et al.[70] measured perfusion and temperatures at various locations within each of the four canine prostates subjected to a transurethral microwave (MW) thermal source. The total number of the perfusion sampling points coupled with temperature is 15. Colored microspheres were used to measure perfusion due to their simplicity compared with radioactively labeled microspheres, and because the microsphere trapping method is regarded as a standard. Temperatures were measured using miniature thermistors. The prostate temperatures were raised to 40°C–45°C by 5-W-step increments of the MW power at hourly intervals to 15 W. Temperatures and perfusion were measured at baseline, and at the beginning and end of each heating interval. Thus, the periods between

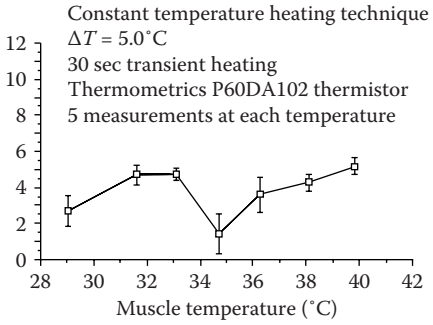

FIGURE 4.5.4 Perfusion vs. muscle temperature during a typical experiment. (From Valvano, J.W., *Optical-Thermal Response of Laser-Irradiated Tissue*, Plenum Press, New York, 1995. With permission.)

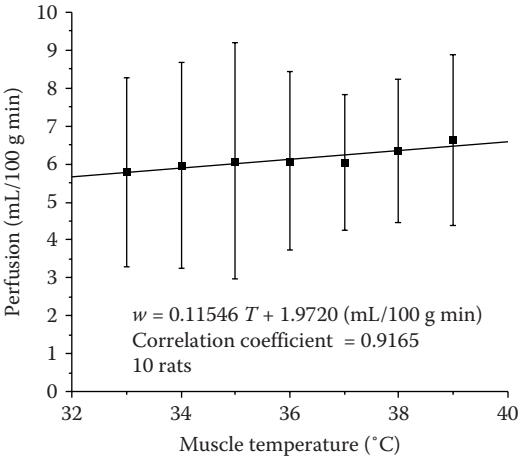

FIGURE 4.5.5 Perfusion vs. muscle temperature averaged over 10 experiments. (From Valvano, J.W., *Optical-Thermal Response of Laser-Irradiated Tissue*, Plenum Press, New York, 1995. With permission.)

perfusion samples were approximately either 5 or 60 min. Under baseline conditions, the temperature fluctuations within the prostate were approximately ±0.3°C. A relative dispersion estimate of 15% was derived from one dog for the fluctuations in baseline perfusion. Thus, changes in absolute perfusion and temperature greater than 15% and 0.3°C, respectively, were considered to be substantial changes.

As heating progressed, a variety of substantial changes were observed, but no uniform pattern emerged. However, the measurements included changes typically expected for hyperthermia:

1. An initial perfusion increase associated with elevating the baseline temperature.
2. A perfusion return towards baseline after this initial increase.
3. A dramatic increase in perfusion at elevated temperatures.

The initial perfusion increases were observed in three dogs when the temperatures exceeded 38°C ± 3°C (mean ± 1 SD, $N = 8$). The perfusion increased 34% from a baseline value of 0.59 ± 0.26 mL/g min over a temperature rise of 1.7°C ± 1.3°C. Half of the measurements in the three dogs subsequently showed a decrease in perfusion ranging from 16% to 25%. In two dogs, dramatic perfusion increases as high as 364% were observed with a corresponding decrease in tissue temperature.

The mean perfusion and temperature measured from all dogs at similar instances during the experimental protocol were calculated. Figure 4.5.6 shows the changes as the experiment progressed from baseline conditions.

The mean behavior indicates no substantial change in perfusion until the tissue temperature exceeded 39.6°C, after which the perfusion increased 17%. This occurred over a 5-min period as the nominal MW power was stepped from 10 to 15 W. The perfusion increased another 35% when the tissue temperature exceeded 41.7°C, and appeared to affect a slight lowering of tissue temperature.

Xu et al.[71] measured perfusion using the pulse-decay self-heated thermistor technique[13,20] in these dog prostates during the same transurethral MW hyperthermia treatments. Interestingly, in the exact same dogs at roughly the same locations, the perfusion response to temperature measured with the thermal technique was roughly linear with temperature as shown in Figure 4.5.7.

The interdependence between perfusion and temperature was observed in these studies: most notably, a decrease in tissue temperature associated with a dramatic increase of perfusion. Such

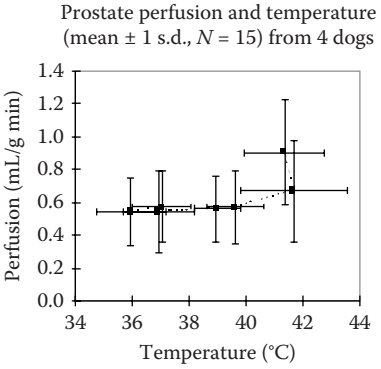

FIGURE 4.5.6 Perfusion vs. prostate temperature.[71]

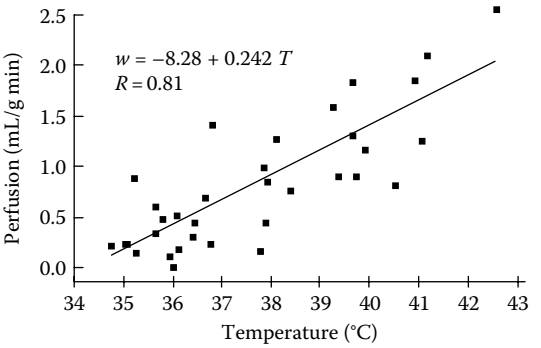

FIGURE 4.5.7 Perfusion vs. prostate temperature.[72]

changes have been modeled previously with Pennes's bioheat equation, using assumed perfusion values and changes for the prostate. The data from this study will provide more realistic estimates of perfusion values and thermoregulation models in hyperthermic canine prostates. Two hypotheses exist that explain the differences between the perfusion responses to hyperthermia as measured by microspheres and the thermal decay probe. The first possibility is that one or both methods have significant measurement errors. A second possibility is that perfusion as measured by spheres trapped in the capillaries is a different parameter than perfusion as measured by enhanced heat transfer within the 70- to 200-μm-diameter vessels.

Human Thermoregulation

Humans possess an elaborate thermal control (thermoregulation) system that ensures maintenance of internal body temperatures near a physiological set point under a large spectrum of environmental conditions and metabolic rate activities. After many years of research, much has been learned of the operation of the human thermoregulatory system and it remains a topic of active investigation. A number of reviews on specific aspects of the physiological basis of thermoregulation are recommended for further background detail.[72–75]

Internal and boundary heat transfer processes are key to thermoregulation. As the operational mechanisms have become better understood, it has been possible to model these functions in an attempt to simulate and predict thermoregulatory behavior and to be able to design systems to interact thermally with the human body (such as an environmental protective garment or a space suit) without compromising the health and safety of the subject.

Physiological Processes of Thermoregulation

The prevailing thermal physiology theory is that the human thermoregulation system operates to maintain the body core temperature at a constant value consistent with that required for regular body function, regardless of the environmental temperature and energy loading. Alternatively, it has been suggested that thermoregulation serves the purpose of maintaining the body's energy balance, with body temperatures being a result, not a cause, of the regulation process.[72,76,77]

Many general observations of the thermal characteristics of human thermoregulation are consistent, even if alternative explanations of the underlying operative mechanisms are proffered. For example, temperature and internal energy storage of the human body vary with time of day, metabolic activity, and individuality of the person.[78] The body incorporates a number of energy production and dissipation mechanisms to preserve thermal homeostasis, many of which are controlled by feedback signals based on specific physiological states. Examples of thermoregulatory processes that are governed by feedback are sweating, shivering, and variable localized blood flow.

According to the theory of thermoregulation by control of the body core temperature, the main control center is located in the hypothalamus of the brain, from which multiple reflex responses operate to maintain the body temperature within a narrow range.[79] The signals that activate the hypothalamic temperature-regulating centers come largely from two sources: the temperature-sensitive cells in the anterior hypothalamus and cutaneous temperature receptors. The cells in the anterior hypothalamus sense the temperature of the body core or, specifically, the temperature of arterial blood which passes through the head.

Webb has presented a theory of thermoregulation to maintain an energy balance within the body, as demonstrated by the existence of temperature sensors at several levels in the skin enabling the sensing of heat flow within and from the body.[77] Evidence also supports neurological sensing of thermal gradients which direct thermoregulation behavior. The hypothesis in support of the theory of energy content regulation based on Webb's experimental observations is:

> Heat (energy) regulation achieves heat (energy) balance over a wide range of heat (energy) loads. Heat flow to or from the body is sensed, and physiological responses defend the body heat (energy) content. Heat (energy) content varies over a range that is related to heat (energy) load. Changes in body heat (energy) content drive deep body temperatures.[77]

The proposed mechanism of energy-driven thermoregulation balances the constantly changing metabolic energy production and the adjustment of heat losses to maintain the body as a system at steady-state. In contrast, the proposed mechanism of temperature-driven thermoregulation affects a coordination of physiological processes to maintain the body core temperature at a set point.

Thermoregulatory Processes

Conservation of energy for the human body must account for internal metabolic energy production plus multiple mechanisms of environmental heat and work exchange.

$$\Delta E = M - (W + Q_{conv} + Q_{cond} + Q_{rad} + Q_{evap} + Q_{resp}) \tag{4.5.51}$$

where ΔE = Rate of energy storage in the body (W)
M = Metabolic energy production (W)
W = External work (W)
Q_{conv} = Surface heat loss by convection (W)
Q_{cond} = Surface heat loss by conduction (W)
Q_{rad} = Surface heat loss by radiation (W)
Q_{evap} = Surface heat loss by evaporation (W)
Q_{resp} = Respiratory heat loss (W)

The human body produces energy, exchanges heat with the environment, and loses heat by evaporation of body fluids. Energy is produced in the body by basal (resting), metabolism defined as the minimal metabolism measured at a temperature of thermal neutrality in a resting homeotherm with normal body temperature several hours after a meal and not immediately after hypothermia, and also at an increased rate due to muscle activity, including physical exercise and shivering, and by food intake. Therefore, the total energy production in the body is determined by the energy needed for basic body processes plus any external work. Since the body operates with less than 100% efficiency, only a fraction of the metabolic rate is applied to work, with the remainder dissipated as heat.[78] The mechanical efficiency, η, associated with metabolic energy utilization, is zero for most activities except when the person is performing external mechanical work such as in walking upstairs, lifting something to a higher level, or cycling on an ergometer.[80] When work transferred from the environment is dissipated as heat in the human body, η is negative. An example of this case is walking downstairs.

Convection, radiation, conduction, and evaporation of sweat at the skin surface all facilitate heat transfer from the body. Heat transfer also occurs via the respiratory tract and lungs, although to a lesser extent in human beings as compared with many mammals and reptiles. Storage of energy takes place whenever there is an imbalance of production and dissipation mechanisms. In many instances, such as astronauts in space suits or military personnel in chemical defense garments, energy storage is forced due to the lack of appropriate heat exchange with the environment.[81]

The human thermoregulatory system is quite complex and behaves mathematically in a highly nonlinear manner. It contains multiple sensors, multiple feedback loops, and multiple outputs.[82] The primary mechanisms by which the body responds to control the storage of energy (positive or negative) include the evaporation of sweat, shivering of the muscles, and vasoconstriction and vasodilation of the blood vessels.

Heat transfer internal to the body is due to the conductance which governs the flow of energy between the core, through the tissue, and to the surface. This transport process is governed significantly by peripheral blood flow, the core-skin temperature gradient, and the conductivity of the various body tissues. Transient blood perfusion provides an effective variable path of peripheral energy transport via convection between blood and tissue and countercurrent heat exchange between the arteries and the veins. Blood flow distribution is controlled according to metabolic needs of the body, local tissue temperature, and the need to maintain the appropriate core temperature. When the core becomes too hot, the blood vessels in the skin dilate to allow increased perfusion to the body surface. The blood is cooled by the environment, and the cooler blood is returned to the core. Increased blood flow to the skin surface also enables greater sweat production, adding to the cooling process. In contrast, when the core becomes too cold, blood flow to the skin is constricted to conserve the body's internal energy. Sweating occurs when the arterial blood is elevated in temperature, causing the hypothalamus to increase nerve impulses to the sweat glands. Shivering, on the other hand, is an involuntary response of the skeletal muscles when passive body cooling exceeds metabolic energy production.[79]

Human thermoregulation mechanisms can be divided into two main categories: autonomic and behavioral.[38] Autonomic thermoregulation is controlled primarily by the hypothalamus, whereas behavioral thermoregulation is controlled consciously by humans and includes active movement and adjustment of clothing. Behavioral thermoregulation is associated with conscious temperature sensation as well as with thermal comfort or discomfort. Some engineered systems are designed to interact with the body to enhance its ability to maintain thermoregulation in harsh or hazardous environments. Examples range from the common HVAC systems encountered in buildings and vehicles to sophisticated garments worn during certain military and space missions.

Wissler Model of Human Thermoregulation

Models that accurately incorporate the transient whole-body behavior during thermoregulation for a wide range of states and environmental challenges may be quite useful in describing and predicting this important human physiological function. Moreover, such a model can be used as a design tool

in the development of systems with which humans must interact for a variety of work, pathological, and recreational circumstances. The development of models of human thermoregulation has proved to be a daunting task that has been addressed by many researchers. The complexity of the coupling among physiological processes involved in thermoregulation and of the control algorithms has dictated that models that incorporate these multiple effects be solved numerically. Thus, the first realistic thermoregulation models appeared in the 1960s and 1970s from the studies of Wissler,[34,83] Stolwijk,[84,85] Mitchell et al.[85,86] Hayward et al.,[87,88] and Kuznetz.[89] An important early application of modeling human thermoregulation was the design and development of active thermal control garments to be worn under the space suit during extravehicular activity.[78,81,90,91] Over the years the Wissler model has been improved and updated on a continuous basis, and it is now applied to a very broad spectrum of human thermal control scenarios.[35,92]

The Wissler human thermoregulation model is a transient-state mathematical formulation used to describe human physiological responses to various levels and combinations of exercise and thermal stress. The model computes thermal, cardiovascular, ventilatory, and metabolic changes that occur during a specified period of time. The values for the independent physiological and environmental variables, such as metabolic rate, environmental conditions, and garment cooling liquid flow rate, are specified as inputs to the model. A finite-difference scheme is applied to numerically compute tissue and blood temperatures throughout the body as a function of time.

The model represents the human body as 15 cylindrical elements for the head, thorax, abdomen, and proximal, medial, and distal portions of each arm and leg. A schematic representation of the multi-element model of the human body is shown in Figure 4.5.8. Each body element is composed of cylindrical shells that are defined by physical and physiological properties for composite layers of viscera, bone, muscle, fat, and skin. In each of the elements metabolic energy may be generated as appropriate due to basal metabolism, exercise, and shivering. The generated energy is either conducted to adjacent body regions, convected to circulating blood, or stored in the element. Each body element contains an arterial and venous pool and a capillary bed. The pools are interconnected serially between adjacent elements. As venous blood is returned to the heart it passes through the lungs for exchange of gases before entering the arterial system.

A number of signal feedback loops are used to account for thermoregulation within the body. Feedback data are the differences between skin and central head temperatures and their respective specified set point values. Error signals specified by these differences drive sweat secretion, shivering, and vasomotion responses. The algorithm equations have the general format of a proportional controller that is activated when a defined threshold condition is satisfied. The control equations do not all have the same level of response to error signals. For example, sweating and vasodilation are more responsive to an increase in central head temperature than to cutaneous temperature, while vasoconstriction is more responsive to cutaneous temperature.

Thermoregulation is also affected via heat exchange during the venous return flow of blood. Venous flow occurs through either deep or superficial veins, thus influencing the rate of countercurrent heat exchange. Modeling of the venous return provides a realistic simulation of the countercurrent heat exchange that takes place in the extremities during exercise in hot environments and immersion in cold water.

Blood flow rates are simulated to satisfy the level of local metabolic need for oxygen in the tissues. Therefore, a lower limit is set for extremity blood perfusion during cold exposure. The model also incorporates material balances for oxygen, carbon dioxide, and lactate as defined for cardiovascular response. In addition to physiological factors, conditions of the environment with which the subject interacts are accounted for. Physical properties of the environmental fluid and characteristics of the flow field in the vicinity of the subject are specified as they determine conductive and convective heat transfer.

The model allows the user to specify layers of clothing described by physical properties of annular shells outside of but interacting with the skin layer. The physical properties of the garments may change with the accumulation of unevaporated sweat, which may saturate the material.

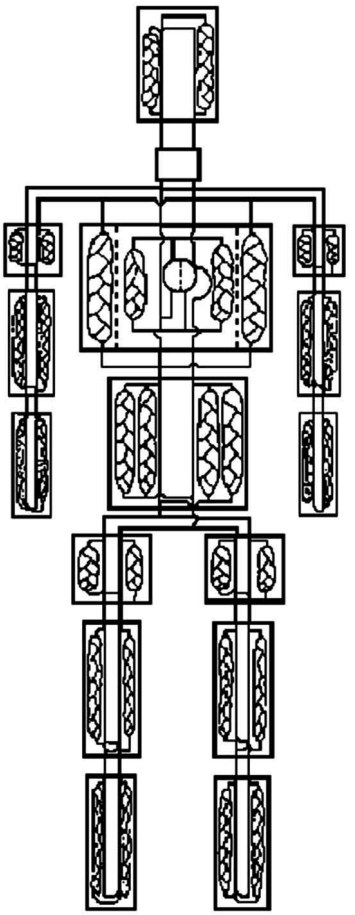

FIGURE 4.5.8 Multielement model representing the human body in the Wissler model. (From Wissler, E.H., *Heat Transfer in Medicine and Biology: Analysis and Applications*, Vol. 1, Plenum Press, New York, 325, 1985. With permission.)

Transient tissue and blood temperatures are calculated during simulated thermal scenarios by Crank-Nicolson-type finite-difference equations. Updated temperatures and other physiological values are computed every 10. The model allows a simulation to be broken down into any number of scenario subintervals, with the following factors being specified in each interval:

- Basal metabolic rate
- Kind and level of exercise being performed
- Environmental conditions (pressure, temperature, dew point, etc.)
- Garment properties
- Use of a fluid-conditioned garment (FCG) (flow rates, inlet temperatures, etc.)

The equations needed to describe a liquid- or air-cooled garment are derived from material and energy balances for the circulating fluid. Sensible heat transfer is treated the same for liquid- and air-cooling situations. However, the evaporation and condensation associated with latent heat transfer must be treated differently for the two fluids. In the case of the liquid-cooled garment, water from sweat and environmental moisture condenses on the cool surface of the garment. On the other hand, air cooling generally facilitates evaporation of sweat by removing water vapor from the garment.

In its early formulation the Wissler model required a large mainframe computer to perform simulations of thermal regulation. However, owing to advances in computational capabilities in recent years, it is now possible to run extensive simulations on a desktop personal computer in an order of magnitude less than real time. The thermoregulation model provides reliable predictions of changes in the human thermal state for many different types of environmental and metabolic stress, and it has been used for the design of new automated personal garments for application in hazardous environments.[92]

Therapeutic Heating

Normal physiologic temperatures range from approximately 30°C to 42°C. The average so-called core (central abdominal) temperature in mammals varies slightly among species between about 36°C and 38°C (37°C for humans, 38°C for most canines). It was noted above that thermal gradients are inherent in metabolically driven open systems at steady state, and measured "core" temperatures will vary slightly depending on the relative metabolic rate, blood flow, and location of the various organs, and from point to point within an organ. Though core temperature is maintained close to a steady-state value, skin surface temperature at rest in a controlled room environment varies between about 30°C and 34°C, depending on climate and season.

Elevation of body, appendage, or organ temperature to between 40°C and 42°C can be used for analgesia (relief of pain) and to provide the most advantageous environment for injury response (wound healing) processes. Note that there is no external intervention that can be claimed to "promote" wound healing—one may only provide the best conditions under which the natural processes will heal wounds. Thermal intervention has been used for many years for these two purposes.

Heat Generation Modalities

Therapeutic heating can be obtained by surface heat transfer means (hot or cold packs), but the effectiveness is limited to surface injury. Nevertheless, contact heating is the method of choice for such injuries as sprains, muscle strain, and postoperative swelling. The standard response to elevated temperatures is to increase the blood flow, and thus perfusion. One applies cold heat sinks to reduce perfusion in the injured area during the first 12–24 h and hot packs or circulating water (up to 45°C) after that to promote perfusion and thus increase the supply of neutrophils and other blood components related to injury response and wound healing.

Deeper injuries require volumetric heating to attain adequate temperatures. The most effective volumetric heating methods to date have been (1) electromagnetic fields at radiofrequencies (RFs) or MW frequencies), and (2) ultrasound (US). Assigned RFs for industrial, scientific, and medical (ISM) use are 6.78, 13.56, 27.12, and 40.68 MHz. Practical ISM frequencies for medical use in the MW range are 915 MHz and 2.45 GHz. Typical ultrasound heating devices operate between about 500 kHz and 10 MHz. In all three cases there is an engineering trade-off among local volumetric heat generation, q''', thermal heat generation field dimensions, and depth of penetration. Higher frequencies have shorter wavelengths and, in general, are absorbed more strongly and thus penetrate less deeply. Tissues are inhomogeneous and, with only a few exceptions, anisotropic. The electrical and acoustic properties of tissues can vary over several orders of magnitude. Consequently, electromagnetic and acoustic boundary conditions often determine the volume generation term in spite of efforts to shape the field by clever applicator design.

For electromagnetic heating in tissues the volume generation term is essentially governed by the electrical conductivity, σ (S/m), the imaginary part of the electric permittivity, ε''—$\varepsilon^* = \varepsilon' - j\varepsilon''$ (F/m)—and the magnitude of the local electric field, $|\mathbf{E}|$:

$$q''' = (\sigma + \omega\varepsilon'')|\mathbf{E}|^2 + \omega\mu''|\mathbf{H}|^2 \tag{4.5.52}$$

where ω is the angular frequency (rad/s). Heating can be due to direct absorption from a magnetic field, $\omega\mu''|\mathbf{H}|^2$ where $\mu^* = \mu' - j\mu''$ is the complex magnetic permeability (H/m). Magnetic field heating is usually negligible except in the case of magnetic "seeds" or magnetic nanoparticles. Yet, RF and MW magnetic fields heat tissue very effectively, too, despite that tissues have the (real) magnetic permeability of free space, μ_0. This is because, by Faraday's law of induction, a time-varying magnetic field will induce an electric field in the tissue, and it is the electric field that actually generates the heat in tissues.

Faraday's Law in integral form:

$$\oint_C \mathbf{E} \cdot d\mathbf{l} = -\frac{\partial}{\partial t}\left[\int \int \mu \mathbf{H} \cdot d\mathbf{S}\right] \tag{4.5.53}$$

in point form:

$$\nabla \times \mathbf{E} = -\mu \frac{\partial \mathbf{H}}{\partial t} \tag{4.5.54}$$

A comprehensive discussion of these properties and effects in materials may be found in the work of Green and Diller.[98] Values of relevant electrical and acoustic properties of tissues are given in Tables 4.5.7[93] and 4.5.8,[94] respectively.

Acoustic waves are highly scattered in many tissues, so simple wave-propagation models are inadequate to predict the local acoustic field strength. Nevertheless, a uniform plane-wave description of the heating field often suffices to explain the distribution of the heat generation with acceptable accuracy. The volume heat generation term is determined by the acoustic absorption coefficient, α (m^{-1}), and the wave power density, U_0 (W/m^2) E, approximately according to Beer's law:

$$q'''(z) = \alpha U_0 e^{-\alpha z} \tag{4.5.55}$$

where U_0 is the surface power density at $z=0$ (W/m^2) and α varies according to the acoustic wave frequency, f: $\alpha \approx f^n$, where $1 < n < 2$. Table 4.5.8 units for α are (cm^{-1}). In other references, α may be reported as dB/cm [dB = 10 $\log_{10}(U_{out}/U_{in})$].

Physiologic Effects of Local Heating

The general physiological effects of local heating comprise a cascade of responses.[95,96] As noted in the previous section, systemic response is controlled from the hypothalamus by both neuronal and hormonal signals. Appendage- and organ-level response to local heat may be spinal-cord-mediated; but local heating can trigger local release of bradykinins that induce vascular dilation or constriction, thus affecting temperature rise.

The increase in tissue temperature is accompanied by an increase in cellular metabolism. The arterioles (microscopic arteries, typically about of 40–200 μm inner diameter[95]) dilate in response to heating under smooth muscle control. The downstream capillary pressure increases above the homeostatic level of about 25 torr. Two consequences are an increased capillary flow and capillary pressure. First, at higher capillary pressures the gaps between the endothelial cells (thin epithelial cells comprising the vessel wall) tend to widen and, at higher pressures, edema may form (an increase in the fluid in the extracellular compartment).[97,98] Second, higher capillary flow results in rapid clearing of cellular metabolites and increases convection heat transfer, delivery of tissue oxygen, cellular nutrients, antibodies, and leukocytes (white blood cells) including monocytes which are necessary in the healing response. Neutrophils are white blood cells that initially release proteolytic enzymes to digest dead tissue and, later, phagocytose (eat) the debris.[99] Monocytes are other leukocytes that remove damaged and dead cells by phagocytosis.

Tissue Effects: Elevated Temperatures

Exposure to temperatures above normal physiologic ranges (>42°C) over time can result in measurable irreversible changes in tissue structure or function. Cell death or tissue alterations may be detrimental—for example, skin burns—or beneficial, as in vessel sealing or tumor destruction. Tissues of the central nervous system are the most thermally sensitive, exhibiting irreversible changes for long-term exposures above about 42°C. The specific pathologic end point may be evaluated histologically, histochemically, and/or physiologically. Most assays of thermal alterations are qualitative in nature; however, several end points that are inherently quantitative lend themselves well to rate process descriptions of their thermal kinetics. Examples of quantitative assays[99] include loss of birefringence, vital stain uptake, fluorescent stains, gene expression, apoptosis, necroptosis, traumatic necrosis, and loss of clonogenicity (in cancer cells). Even for qualitative processes, thermal kinetic models often provide useful descriptions and so provide helpful insights into the underlying principles of tissue thermal damage.

Here we use "damage" in a generic sense to denote all types of irreversible alterations, therapeutic or not. Many damage processes can be modeled as first-order rate processes, Arrhenius models, for which two experimentally derived coefficients are sufficient. First-order Arrhenius analysis applies well to thermal alterations in structural proteins (such as collagen, elastin and actin) and to cell death processes at higher temperatures. Other intrinsic programmed cell death processes (with either intrinsic or extrinsic signal mechanisms), such as apoptosis, necroptosis and, possibly, autophagy involve intricate multipath cascades of functional proteins (chiefly enzyme catalysts) that require much higher-order kinetic models to describe adequately. We will illustrate that the net effect of the higher order chemical kinetics is to introduce a temperature-dependent delay into the cell death process, a so-called shoulder region in a cell survival curve. It turns out that many such processes exhibiting shoulder region behavior can be accurately represented by adding a temperature-dependent time delay to a first-order Arrhenius model.

In the Arrhenius models, irreversible thermal damage is exponentially dependent on temperature and linearly dependent on time of exposure. The first-order rate process models often apply well to

the prediction of damage thresholds and less well as the damage becomes complete or severe since several of the fundamental assumptions are violated. In order to be useful in evaluating thermal insult, the kinetic model must be coupled to quantitative pathological analysis. This subsection describes several quantitative markers of thermal damage and experimental methods for estimating relevant kinetic coefficients both in constant temperature and transient thermal history experiments. As expected, transient *in vivo* thermal history data yield a noisy kinetic plot; however, useful estimates of the appropriate rate coefficients can be made.

Theory of Rate Process Descriptions: The Arrhenius Model

The original work on the application of rate process models to thermal damage was reported by Moritz and Henriques in a series of seminal papers entitled "Studies of Thermal Injury" in 1947.[100–103] They applied flowing water at elevated temperatures to pig skin and measured exposure times required to create first-, second-, and third-degree burns. In their work, the damage was quantified using a single parameter, Ω, which ranges on the positive real axis and is calculated from an Arrhenius integral:

$$\Omega(\tau) = \int_0^{\tau} A e^{\left[\frac{-E_a}{RT}\right]} \mathrm{d}t \tag{4.5.56}$$

where A is a frequency factor (s^{-1}), τ the total heating time (s), E_a an activation energy barrier (J/mol), R the universal gas constant (8.314 J/mol/K), and T the absolute temperature (K).

Over the ensuing 50 years, many subsequent investigators have modeled this process[104–107] and made experimental measurements of threshold burn conditions in human,[108–110] animal,[104,111] and cellular and molecular[112–114] systems. Although a considerable body of literature has accrued, there is by no means a consensus on how to accurately predict the occurrence of thermal injury over the wide range of conditions that cause burns.

One difficulty with this model is that a single damage parameter inherently lumps all damage processes into one global measure. In multiple process cases, such as in the case of a skin burn, the lowest temperature process saturates the damage measure, Ω, early during an exposure. In this discussion, we review the underlying assumptions and origin of the terms in Equation 4.5.56 and recast the traditional thermal damage parameter, Ω, into a form suitable for evaluation of multiple-process thermal damage effects.

Kinetic Models of Reaction Product Formation Rates

The basis for rate process models of thermal damage may be obtained from chemical reaction kinetics (see, e.g., the work of Maron and Lando[115]). In a typical reaction process, thermally active reactants surmount an activation barrier to form products, as illustrated in Figure 4.5.9. In the figure,

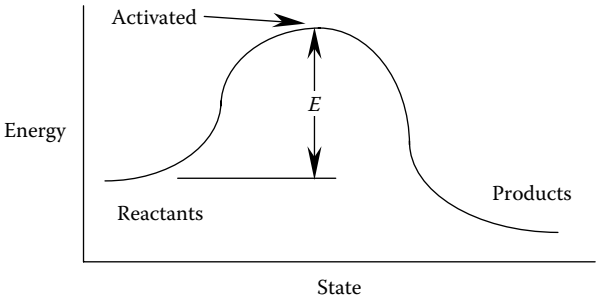

FIGURE 4.5.9 Energy-state diagram of a bimolecular process.

E is the energy barrier in Equation 4.5.56. The collision theory description of ordinary first-order bimolecular reaction kinetics holds that the reactants are activated by collisions; n^* are activated out of n total molecules, and the probability of activation is

$$\frac{n^*}{n} = e^{-\left[\frac{E}{RT}\right]} \tag{4.5.57}$$

In such a process, activated reactants are considered to form an activated "complex" which may either relax to inactivated single reactants or irreversibly progress to form product molecules. The complex has some of the properties of an ordinary molecule and is at least temporarily stable. For reactant molecules *A* and *B*, the sequence of formation is

$$[A]+[B] \underset{k_b}{\overset{k_a}{\rightleftarrows}} [AB^*] \xrightarrow{k} \text{Products} \tag{4.5.58}$$

The overall reaction velocity, k (s^{-1}), determines the rate of formation of product and is related to the equilibrium constant for formation of activated complex, K^*, by

$$k = \frac{RT}{Nh} K^* = \frac{RT}{Nh} e^{-\frac{\Delta G^*}{RT}} \tag{4.5.59}$$

where N is Avogadro's number (6.023×10^{23}), h is Planck's constant (6.627×10^{34} J s), and ΔG^* is the Gibb's free energy of formation of the activated complex. In turn, the free energy of formation is given by

$$\Delta G^* = \Delta H^* - T\Delta S^* \tag{4.5.60}$$

where ΔH^* is the enthalpy (i.e., the total energy) of activation (J/mol) and ΔS^* is the entropy of activation J/(mol K). Employing this relationship results in the Eyring–Polanyi equation.[116,117]

$$k = \frac{RT}{Nh} e^{\left[\frac{\Delta S^*}{R}\right]} e^{-\frac{\Delta H^*}{RT}} \tag{4.5.61}$$

The activation entropy is not calculable except for the simplest reactions in the gas phase, and therefore is usually determined from experimental measurements of the reaction velocity and activation enthalpy. The activation enthalpy, ΔH^*, is determined from the observed activation energy, E_a by

$$\Delta H^* = E_a - iRT \tag{4.5.62}$$

where i is 1 for first-order reactions in solution and gases, 2 for second-order, and 3 for third-order reactions.

Unimolecular Process Descriptions

Thermal damage in tissue is generally a unimolecular process—tissue constituent proteins transition from the native state to the damaged state (Figure 4.5.10). Absolute reaction rate theory can also be used to explain the rate of formation for this process if we assume that a time lag exists between molecular activation and denaturization.[115] During this time lag, the molecules may either denature or relax back to the native state, as illustrated in Figure 4.5.10. Here, ΔH is the enthalpy (internal thermal energy) difference between native state and denatured molecules. The relative barriers are such that, in the thermal damage of tissue, ΔH^* is almost always smaller than ΔH.

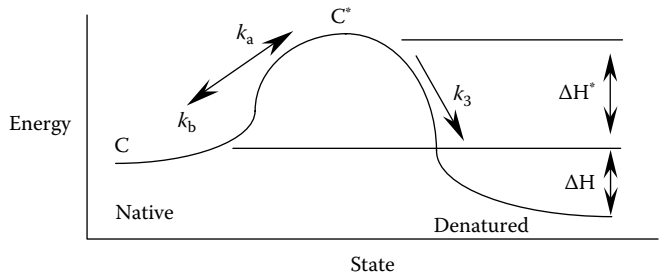

FIGURE 4.5.10 Unimolecular process activation and denaturalization.

So, the activation process may be regarded as reasonably likely, and the probability of denatured tissue relaxing back to native state tissue is near enough to zero that it may be regarded as the impossible event in the absence of an energy-consuming healing process. The rate of damage formation is then proportional to only those molecules that remain activated. For a unimolecular process in the native state C, having an activated state, C^*, with velocity constants k_a, and k_b:

$$[C] \underset{k_b}{\overset{k_a}{\rightleftarrows}} [C] + [C^*] \tag{4.5.63}$$

the activated complex, $[C^*]$ progresses to the damaged state at k_c:

$$[C^*] \xrightarrow{k_c} \text{Damaged state} \tag{4.5.64}$$

so that the rate of disappearance of native state molecules, $[C]$, is given by

$$-\frac{d[C]}{dt} = k_c [C^*] \tag{4.5.65}$$

Generally, $[C^*]$ is neither known nor calculable; however, at sufficiently low concentrations of C^*, the steady-state principle asserts that for short-lived activated states, the rate of formation can be considered equal to the rate of disappearance. The activated state, $[C^*]$, forms at a rate $k_a [C]^2$, relaxes back to inactivated at rate $k_b [C][C^*]$ and denatures at the rate $k_c [C^*]$. Consequently.

$$k_a[C]^2 = k_b[C][C^*] + k_c[C^*] \tag{4.5.66}$$

and so

$$[C^*] = \frac{k_a[C]^2}{k_c + k_b[C]} \tag{4.5.67}$$

We actually need an overall reaction velocity, k, which relates $[C]$ to its rate of disappearance:

$$-\frac{d[C]}{dt} = k[C] \tag{4.5.68}$$

There are two limiting cases for Equation 4.5.67: first, the concentration of remaining undamaged material, $[C]$, may be large enough that deactivation at k_b dominates the k_c pathway, so $[C^*] \cong [C]\, k_a/k_b$ for which the overall formation rate, $k = k_c\, k_a/k_b$ and a first-order process results; and second, if the remaining undamaged material concentration, $[C]$, is small, $k_c \gg k_b\,[C]$ and the process is second order since from Equation 4.5.67 $k = k_a\,[C]$. In liquid-phase systems with appreciable concentrations of native state molecules, the first condition should apply, so the first-order approximation applies.

After a long time of exposure at damaging temperatures such that [C] is very small, $k_c \gg k_b\, C$ and a second-order process results:

$$-\frac{d[C]}{dt} = k[C]^2 \tag{4.5.69}$$

where for simplicity the [C] dependence has been removed from k.

First-Order Solution

Equation 4.5.67, then, is a Bernoulli differential equation with the solution:

$$C(\tau) = C(0)e^{\{-\int k\, dt\}} \tag{4.5.70}$$

Equations 4.5.59 and 4.5.60 may be used to relate k to ΔH^* and ΔS^*. It should be noted at this point that the energy barrier, E_a (Figure 4.5.9) is in fact $\Delta H^* + RT$; however, in practice $\{\Delta H^* \simeq 5\times10^5\} \gg \{RT \cong 3\times10^3\}$, so we may assume that $E_a \simeq \Delta H^*$.

The pre-exponential term in Equation 4.5.59 suggests that it is temperature dependent; however, the linear dependence of A on T is extremely weak compared to the exponential dependence in the final term.

Application of Kinetic Formulations in Thermal Damage and Cell Death Studies

When a quantitative thermal damage phenomenon has been identified, it can be studied as a first-order process. This subsection inspects the more common first-order analysis in some detail and introduces one form of combined process analysis to extend the usefulness of the method. The specific example of Henriques and Moritz original data is also studied. When the damage end point is a qualitative measure, application of these kinetic models is closer to a curve-fitting exercise than to a fundamental study of the underlying phenomena. Therefore, precise identification and strict definition of quantifiable damage end points are required for meaningful analysis.

First-Order Arrhenius Process Analysis

A more useful form of Equation 4.5.56 may be obtained by recasting the result into a volume fraction model. In this formulation, C signifies the remaining concentration of native state (undamaged) tissue constituent. Therefore, the physical significance of the traditional damage measure, Ω, is the logarithm of the ratio of the original concentration of native tissue to the remaining native state tissue:

$$\Omega(\tau) = \ln\left\{\frac{C(0)}{C(\tau)}\right\} = \int_0^\tau k\, dt = \int_0^\tau A e^{-\left[\frac{E_a}{RT}\right]} dt \tag{4.5.71}$$

This form of the damage integral has the advantages that (1) it is easily compared to quantitative pathologic end points such as tissue collagen and muscle birefringence loss, collagen hyaline damage, leakage of fluorescent dyes from dead or dying cells, or some types of cell survival in culture, and (2) multiple thermodynamically independent damage processes may be simultaneously modeled and/or studied in parallel by accumulating separate values for $C(\tau)$. The first-order Arrhenius formulation is effective when the damage process is dominated by irreversible thermal alterations in structural proteins or in cell death processes at higher temperatures—those substantially in excess of the "hyperthermic" range, above about 55°C. Programmed cell death processes often dominate at hyperthermic temperatures—between about 42°C and 50°C; however, whether or not intrinsic processes dominate depends critically on cell type and the particular process studied. Intrinsic cell death processes involve several cascades of functional proteins and require substantially more

sophisticated mathematical formulations to obtain accurate results. Using quantitative damage/death formulations, direct comparisons can be made between computer models of $T(x, y, z, \tau)$ and measured histologic damage.

Confining the discussion to the Arrhenius formulation for the moment, a set of coefficients, A and E_a, is required for each damage process considered in the computer model. For Arrhenius tissue damage processes studied to date, A varies from about 10^{40} to 10^{105} s^{-1}, while E_a usually ranges from about 10^5 to 10^6 J/mol. Each damage process is then allowed to progress in parallel, driven by the calculated thermal field. This formulation assumes that the individual processes are thermodynamically independent, a reasonable description for identifiable thermal damage processes. The concentration of each of the "i" damage markers, $C(\tau)_i$, is accumulated, and a distributed field description of the predicted histologic end point may be generated.

Interestingly, A and E_a are not independent, and comprise a coupled pair. In 2003 two papers appeared that noted this correlation, one by He and Bischof[118] and the other by Neil Wright.[119] The respective correlations are given by Equations 4.5.72 and 4.5.73:

$$\text{He–Bischof: } \ln\{A\} = 3.80\times10^{-4} E_a - 9.236 \tag{4.5.72}$$

$$\text{Wright: } \ln\{A\} = 3.83\times10^{-4} E_a - 10.04 \tag{4.5.73}$$

In these relationships, the units of E_a have been corrected to (J/mol). Over the typical range of E_a, the two relationships are virtually indistinguishable. There has been some controversy regarding the applicability of the correlations. There is support for the correlations in the hypothesis of "Compensation Law" behavior, as presented by Rosenberg et al.[120] Barrie questions the Compensation Law, pointing out that experimental error can result in something that looks like Compensation Law behavior.[121,122] Yelon et al. argue successfully against Barrie's assertion,[123] and the point is finally conceded by Barrie.[124] Wright cited support for the correlation based on a "polymer in a box" construct by Miles and Ghelashvili.[125] Qin et al. argue in favor of the correlation on biochemical grounds.[126] In fact, inspection of the Eyring–Polanyi equation over a fairly narrow temperature range (Equation 4.5.61), as He and Bischof did in 2003, suggests that ΔS^* and ΔH^* should be correlated in some sense. It is also reasonable to expect that a higher energy process would be accompanied by higher entropy.

Functional behavior of the first-order Arrhenius model—The characteristic behavior of the kinetic damage model is that below a threshold temperature the rate of damage accumulation is negligible, but it increases precipitously when this value is exceeded. For purposes of discussion, it is useful to define the critical temperature as the temperature at which the damage accumulation rate, $d\Omega/dt$, is 1.0:

$$T_{crit} = \frac{E_a}{R\ \ln(A)} \tag{4.5.74}$$

A hypothetical damage process with representative coefficients chosen from the approximate center of the He–Bischof line with $E_a = 5\times10^5$ and $A = 3.197\times10^{78}$ has a critical temperature of 59.6°C. Figure 4.5.11 illustrates the damage accumulation rate dependence on temperature for the hypothetical example process.

Constant temperature exposures of the example process will result in a decrease in concentration of native state material depending on the time of exposure. Figure 4.5.12 shows the remaining concentration for this process for constant temperature exposures of $\tau = 0.1$, 1.0, and 10 s; the concentration is seen to gradually decrease with increasing temperature for fixed exposure times, as expected. The strong exponential nature of the process is evident as well. Applying this model framework relies heavily on identifying independent damage processes which can be quantitatively measured. From plots of the form of Figure 4.5.12, estimates of A and E may be made. Each curve will give

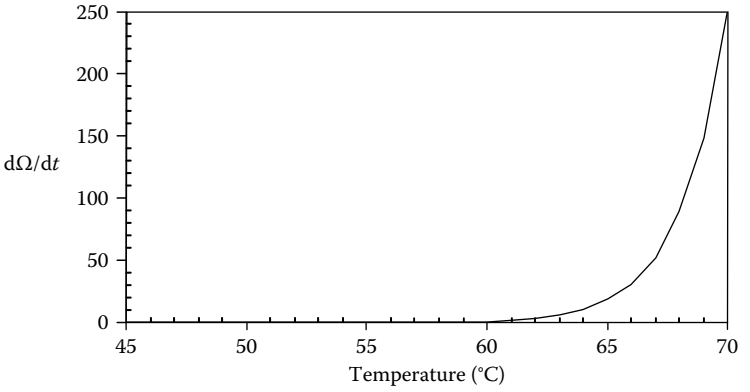

FIGURE 4.5.11 Hypothetical example damage accumulation process has $A = 3.197 \times 10^{78}$ and $E = 5 \times 10^5$ which gives the damage rate, $d\Omega/dt$, shown and a critical temperature of 59.6°C.

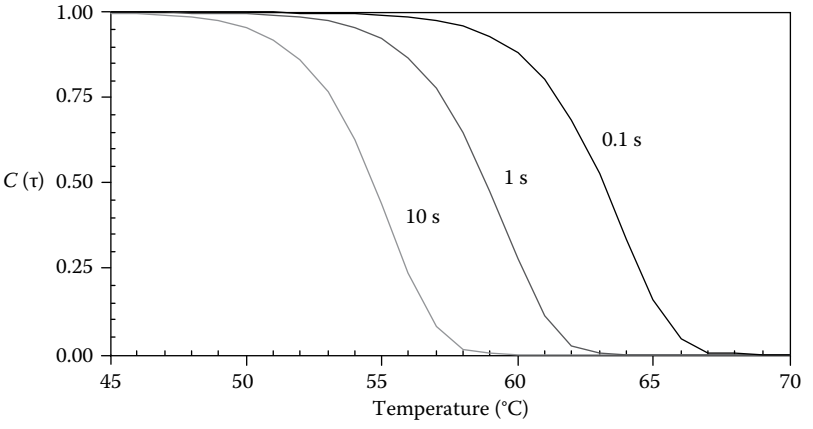

FIGURE 4.5.12 Remaining undamaged concentration vs. temperature at 0.1, 1, and 10 s for the hypothetical example process.

one point on an Arrhenius plot (see above), where $\Omega = 1$. Note the necessity of using exposure times which span several orders of magnitude in order to separate the curves sufficiently to give acceptable accuracy in the determination of the kinetic coefficients.

Though the damage parameter, Ω, cannot be measured directly in histologic section, often a clearer picture of the functional behavior can be obtained from it. The exponential dependence of damage on the inverse of absolute temperature means that the temperature required to obtain comparable damage levels is sensitive to time of exposure. For example, we may define a threshold temperature, T_{TH}, as the temperature at which the damage parameter, Ω, is 1 for a given duration, τ. Assuming a constant temperature exposure, the integral of Equation 4.5.71 reduces to a simple multiplication and the threshold temperature is

$$T_{TH} = \frac{E_a}{R\left[\ln\{\tau\} + \ln\{A\}\right]} \tag{4.5.75}$$

Figure 4.5.13 is a plot of the threshold temperature as a function of duration for the example damage process of Figures 4.5.11 and 4.5.12. Note that threshold temperature is exponentially dependent on

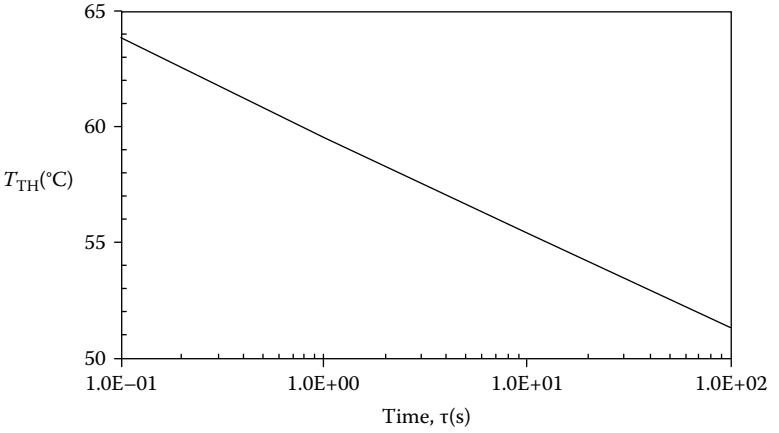

FIGURE 4.5.13 Threshold temperature T_{TH} (where $\Omega = 1$) as a function of duration, τ, for constant temperature exposures for the hypothetical example damage process.

TABLE 4.5.9
Henriques and Moritz Skin Burn Threshold Data ($\Omega = 1$ Means a Second Degree Burn Was Observed)[103]

Exposure Time (s)	Temperature (°C)
25,000	44
11,000	45
5,000	46
2,400	47
1,100	48
570	49
300	50
160	51
90	52
35	54
16	56
5	60
2	65
1	70

duration, as expected, with (in this case) a slope of about −4.58°C per decade. So, while 68.8°C is sufficient to result in $\Omega = 1$ at 0.1 s, 87.1°C would be required for a 1 μs exposure for the hypothetical example process.

Application to the data of Henriques and Moritz[103]—A study of the original skin burn data reported by Henriques and Moritz[100–103] (Table 4.5.9) by Diller and Klutke[127] shows that the fit to a first order process is weak for the higher temperature/shorter exposure time experiments,[127] and that the original values of $A = 3.1 \times 10^{98}$ and $E = 6.27 \times 10^5$ (J/mol)[103] do not fit the data as well as their revised values of $A = 1.3 \times 10^{95}$ and $E = 6.04 \times 10^5$ (for temperatures less than 52°C). In Figure 4.5.14, the skin burn data are also well fit with $A = 8.73 \times 10^{94}$ and $E = 6.03 \times 10^5$ when the last reasonable datum is included (at 52°C).

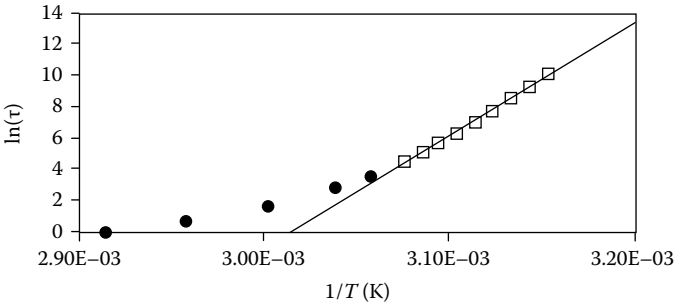

FIGURE 4.5.14 Plot of Henriques and Moritz[107] data on Arrhenius axes with curve fit line for data at 52°C and lower (open diamonds). For the fit $E/R = 72504$ and $\ln\{A\} = 218.61$.

Enzyme Deactivation Model

Xu and Qian[128] presented an enzyme deactivation model for skin burn data that combines some of the first- and second-order aspects into a single calculation. Their method is based on a general simple enzyme-catalyzed reaction sequence from substrate, S, to products, P:

$$E_a + S \underset{k^-}{\overset{k^+}{\rightleftharpoons}} E_aS \xrightarrow{k} E_a + P \tag{4.5.76}$$

and

$$E_a \xrightarrow{k_d} E_i \tag{4.5.77}$$

where here E_a represents activated enzyme, E_i is inactivated denatured enzyme (at velocity k_d), and E_aS is the enzyme–substrate complex. The analysis is completed by assuming that the enzyme inactivation process is slow compared to the main reaction sequence. Nondimensional temperature, z, is used in the analysis, where:

$$z = 1 - \frac{T_0}{T} \tag{4.5.78}$$

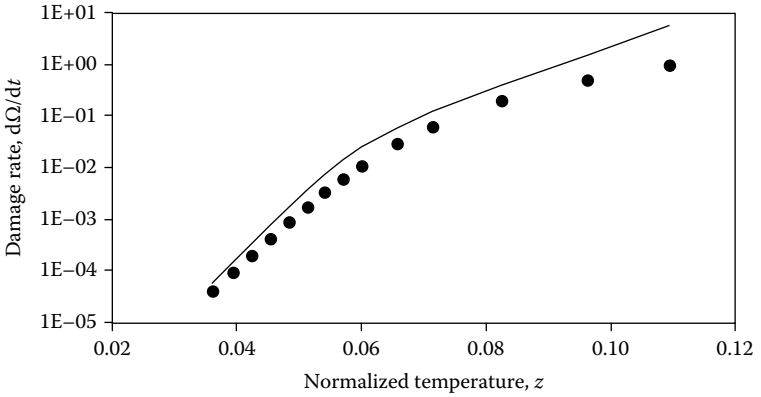

FIGURE 4.5.15 Plot of damage rate for the original Henriques and Moritz data[107] (solid circles) and the enzyme deactivation model of Xu and Qian[128] vs. normalized temperature.

The reference temperature, T_0, as used by Xu and Qian, was representative of the average resting skin temperature: $T_0 = 32.49°C = 305.65$ K.

$$\Omega(\tau) = \ln\left\{\frac{C(0)}{C(\tau)}\right\} = \ln\left\{\frac{E_a(0)}{E_a(\tau)}\right\} = \int_0^{\tau} \frac{Ae^{-\alpha z}}{1 + Be^{-\beta z}}\,dt \tag{4.5.79}$$

This combined formulation fits the data of Henriques and Moritz (Table 4.5.9) well over its entire range if $A = 1.0 \times 10^{-4}$, $\alpha = 100$, $B = 8.0 \times 10^4$, and $\beta = 195$, (see Figure 4.5.15).[128]

Cell Death Processes

Cell death can result in partial or complete death of tissues, organs and, eventually, individuals. The death processes of cells and tissues are divided into two general types: nonprogrammed traumatic cell necrosis and programmed cell death.[136] Nonprogrammed cell necrotic death does not require any premortem genetic activation or expression. It is to be emphasized that any cell can die and undergo postmortem necrosis if presented with a sufficiently severe traumatic injury. On the other hand, programmed cell death processes can only occur in cells that have the specific genes required to initiate and facilitate the mechanisms of cell death.

Nonprogrammed cell and tissue death—Nonprogrammed traumatic necrotic cell death can occur as a result of severe chemical or physical trauma that diffusely and almost instantaneously disrupts all cell function and structure in the targeted volume. As a result, numerous intracellular chemical agents escape into the tissues. These agents include proteases and lipases (digestive enzymes that break down proteins and lipids into small fragments of necrotic debris) and cytokines (small proteins that initiate inflammatory, immune and, later, healing responses to the necrosis). The progression of these postmortem events follows a regular pattern over time (minutes to days) and the resulting necrotic lesions and healing wounds can be described, measured and mapped.

Programmed cell death—Many cells are genetically programmed to die only when a specific chemical or physical stimulus interacts with specific receptors found within or on the surface of the cell. Depending on the receptor type and the cell's genetic programing, these interactions can initiate different cascades of serial catalytic activations of functional proteins, usually enzymes, in the still living cell. However, at some decisive point in a given cascade, a critical activation will occur beyond which the cell will die. Rate analysis and modeling of any cell death process requires the identification of the initiating stimulus/receptor interaction and determination of the critical activation event that leads to the cell death.

Four programmed cell death processes have been identified to date: apoptosis,[99,129] necroptosis,[130,131] autophagy,[132] and pyroptosis.[133] These programmed processes are essential to normal development, maturation and aging, and an individual's response to disease. All consist of signaling, decision-making and execution cascades of functional proteins, usually enzyme catalysts.[99] Catalytic enzymes differ substantially from structural proteins, which derive their function from their molecular formulation and its periodicity.[134] Catalytic enzymes derive their functionality from their geometric conformation: a de-activated enzyme protein is folded in complex ways so that the constituent catalytic segments and binding sites of the long chain protein (which may be separated by many noncatalytic segments) locate closely together in the folded conformation. They may be activated by a slight change in conformation, exposing or assembling the catalytic site.[134]

A comparative description of the processes and their mechanisms was presented by Pearce in 2013.[135] Apoptosis consists of an ordered cleavage of the cell cytoskeleton, DNA, and organelles with bits of nuclear and cytosolic debris completely contained within so-called blebs in the plasma membrane. These "blebs" bud off the cell surface forming "apoptotic bodies" that are soon (on the order of hours) ingested by adjacent phagocytic cells. Apoptosis is identified by the activation of various caspase (i.e., cystic asp.artic protease) enzymes in an intricate and convoluted cascade.[99,129] Additional markers of apoptosis include the microscopic identification

of "apoptotic bodies" or demonstration of endonuclease DNA disruption by gel electrophoresis. The plasma membrane-bound blebs expose "eat me" signals when the normally inactive cytosolic leaflet enzyme "scramblease" is activated and the normally asymmetric membrane proteins distribute uniformly. The symmetrical membrane is a signal for macrophages to consume the bleb. Necroptosis is a sort of ordered cellular explosion marked by receptor interacting proteins (RIP1, RIP3, etc.) in which the cytosolic components are directly released into the extracellular space as random debris.[130,131] In autophagy, malformed or aged proteins and organelles are sequestered into endosomes in the cell cytoplasm. If not too damaged, some of the proteins are repaired. The senescent organelles are digested and compacted into larger, membrane-bound cytoplasmic bodies, the autophagosome, for storage within the cell. Some investigators feel that, in severe cases, the cell may sacrifice itself.[132] However, others (mainly pathologists) think that cell death specifically caused by autophagocytosis has yet to be proven.[136] Pyroptosis is cell death in response to binding of circulating pyrogens–pyrogens, such as interleukins (IL-1, IL-6, etc.) that are produced by host inflammatory and immune cells in response to infections by microorganisms such as pathogenic bacteria, fungi, or viruses.[133]

All of the programmed cell death processes consist of a signaling block, a decision-making block and an executioner block of functional proteins. The best-understood among these processes is apoptosis, so it will be used to illustrate some of the complexity. Apoptosis is of prime interest in the research community because of its implications in embryologic development and maturation, tissue bioengineering, cancer treatment, HIV, and autoimmune diseases. There are tens of thousands of references on apoptosis, the vast majority of which are within the past 15 years. In 2004, Eissing et al.[137] described the decision-making block in apoptosis, including many of the inhibitors and promoters of apoptosis, in an elegant dynamic state-space model. The decision-making block is a bistable switch that introduces a variable delay between signaling and execution depending on the strength of the input signal. Delays between a few minutes and several days may be observed. There are both signaling and executioner caspases among the 14 or so that have been identified. Caspases are numbered in the sequence of their discovery and exist to enzymatically cleave other inactive proenzymes to activated enzymes. Activation of a caspase hetero-tetramer consists of combining the cleaved long and short segments of two pro-caspase molecules after cleaving the *N*-terminus and *C*-terminus.[99]

In Eissing's biochemical model, the initiator (i.e., input signal) caspases (C2, C8, C9, C10, etc.) are represented by activated caspase 8, $C8^*$. There are, of course, many other input signals; for example p52, the "guardian of the genome" and death receptors like FADD (Fas-associated death domain).[129] The executioner caspases (C3, C6, C7, etc.) are represented by activated caspase 3, $C3^*$. Caspase 9 has somewhat of a dual role in that in addition to signaling it participates as the hub of an "apoptosome", a large flower-shaped molecule, with the protein APAF1 forming "petals" tipped with cytochrome *C*.[99,129] There is also intimate coupling between apoptosis and metabolism.[138] Cytochrome *C*, in turn, is a critical participant in the final stages of oxidative phosphorylation on the outer leaflet of the inner membrane of mitochondria, where it is responsible for electron transport between complexes III and IV, immediately upstream of ATP synthase, the final step.[99,129] Presumably, cytochrome *C* plays a similar role at the tips of the apoptosome petals.

The feedback pathways in the decision-making block as modeled by Eissing et al.[137] includes inhibitors of apoptosis proteins (IAPs) and bifunctional apoptosis regulators (BARs), most of which belong to the Bcl2 family.[99,129] This family includes promoters and inhibitors of apoptosis, as well as inhibitors of promoters and inhibitors of inhibitors. The process is an intricate ballet, as it were, in the protein cascade. The feedback system is sketched in Figure 4.5.16. Bid is one of the Bcl2 family, t-Bid is the truncated form, and SMAC is "second mitochondria-derived activator of caspases" (also called DIABLO).

Central to the reaction system describing the feedback pathways are association and dissociation reactions, which are common in all biochemical systems. $C3^*$ is held inactive by binding

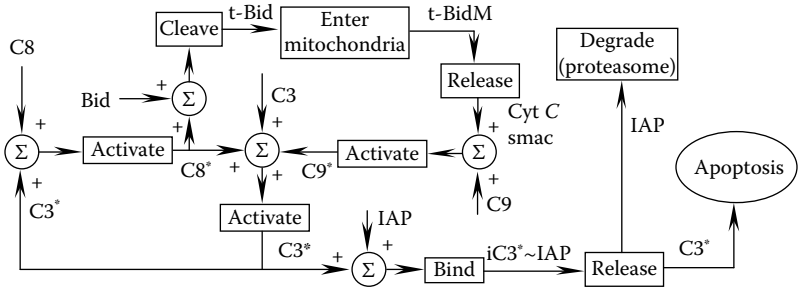

FIGURE 4.5.16 Feedback pathways in the decision block system. (From Pearce, J.A., *Int. J. Hyperthermia*, 29(4), 262, 2013. With permission.)

to IAP, for example, as in *i*C3*~IAP. The four overall governing "law of mass action" reactions are as follows:

$$C8^* + C3 \rightarrow C8^* + C3^* \tag{4.5.80a}$$

$$C8 + C3^* \rightarrow C8^* + C3^* \tag{4.5.80b}$$

$$C3^* + IAP \leftrightarrow iC3^* \sim IAP \tag{4.5.80c}$$

$$C3^* + IAP \rightarrow C3^* \tag{4.5.80d}$$

These four reactions are, in turn, described by a system of eight dynamic state equations. Each of the association and dissociation reactions is a nonlinear component of the state-space system of equations, as presented in the following equations:

$$\frac{d[C8]}{dt} = -k_2[C3^*][C8] - k_9[C8] + k_{-9} \tag{4.5.81a}$$

$$\frac{d[C8^*]}{dt} = -k_2[C3^*][C8] + k_5[C8^*]k_{11}[C8^*][BAR] \tag{4.5.81b}$$

$$\frac{d[C3]}{dt} = -k_1[C8^*][C3] - k_{10}[C3] + k_{-10} \tag{4.5.81c}$$

$$\frac{d[C3^*]}{dt} = k_1[C8^*][C3] - k_3[C3^*][IAP] + k_{-3}[iC3^* \sim IAP] - k_6[C3^*] \tag{4.5.81d}$$

$$\frac{d[IAP]}{dt} = -k_3[C3^*][IAP] + k_{-3}[iC3^* \sim IAP] - k_4[C3^*][IAP] - k_8[IAP] + k_{-8} \tag{4.5.81e}$$

$$\frac{d[C3 \sim IAP]}{dt} = k_3[C3^*][IAP] - k_{-3}[iC3^* \sim IAP] - k_7[iC3^* \sim IAP] \tag{4.5.81f}$$

$$\frac{d[BAR]}{dt} = -k_{11}[C8^*][BAR] + k_{-11}[iC8^* \sim BAR] - k_{12}[BAR] + k_{-12} \tag{4.5.81g}$$

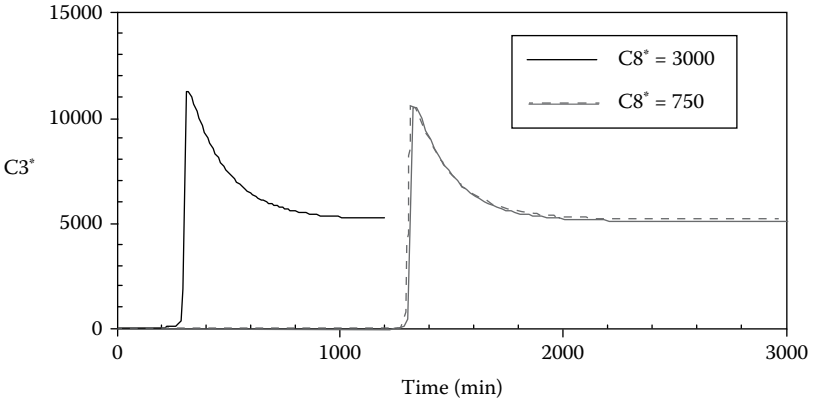

FIGURE 4.5.17 Dynamic response of the biochemical model to two different strengths of input signal, activated caspase 8, C8*, in molecules per cell. The delay in apoptosis varies from 250 to 1300 min (4 to 22 h). (From Pearce, J.A., *Int. J. Hyperthermia*, 29(4), 262, 2013.)

$$\frac{\mathrm{d}\left[C8^{*} \sim \mathrm{BAR}\right]}{\mathrm{d}t} = k_{11}\left[\mathrm{C8}^{*}\right]\left[\mathrm{BAR}\right] - k_{-11}\left[i\mathrm{C8}^{*} \sim \mathrm{BAR}\right] - k_{13}\left[i\mathrm{C8}^{*} \sim \mathrm{BAR}\right] \quad (4.5.81\mathrm{h})$$

where k_i are the reaction velocities, $+i$ for forward reactions, and $-i$ for reverse reactions. The association reactions, negative nonlinear terms, decrease the concentration, while the dissociation reactions, positive nonlinear terms, increase the concentration. The net effect of the nonlinear terms is to cause a variable delay in apoptosis. Figure 4.5.17 illustrates the variable delay in a COPASI model of equations 4.5.81 for inputs of 750 and 3000 molecules/cell of activated caspase 8, C8*. In practice, there may be a delay of as much as a few days in the appearance of apoptosis. However, in health and disease of intact multicellular individuals, biochemical and/or morphological evidence of apoptosis occurs and disappears within 72 h of a single initiating event. But life and death are complicated and numerous waves of programmed cell death may continue as new initiating signals including those for necroptosis and pyroptosis are introduced.

In terms of thermally initiated apoptosis, we might reasonably expect that each of the reaction velocities, k_i, in the system would follow Arrhenius kinetics. If so, we expect the reactions with the higher activation energies would initiate the process since the thermal sensitivity, $\partial k/\partial T$, (ignoring the dependence of A on T) is approximately given by

$$\frac{\partial k}{\partial T} = \left[\frac{E_\mathrm{a}}{RT^2}\right] A e^{\left[\frac{-E_\mathrm{a}}{RT}\right]} \quad (4.5.82)$$

At present, the activation energies of the reaction velocities used by Eissing et al.[137] are not available, however.

The state-space model describes a single cell. In their paper, the authors extend the study by applying a distribution of input signal strengths to simulate a colony of cells. The authors point out that their work was the first attempt to couple an individual cellular response to a colony of cells (Figure 4.5.18).

Modeling Cell Death Processes

The other intrinsic cell death mechanisms are likely to be governed by similarly complex functional protein cascades. Plainly, simpler models are required for practical numerical models. The first-order Arrhenius models are much simpler, but fail to describe these intrinsic processes because they lack sufficient mathematical sophistication (Figure 4.5.19). Arrhenius models work well on structural proteins, and on cell death at higher temperatures, where the intrinsic processes are overwhelmed

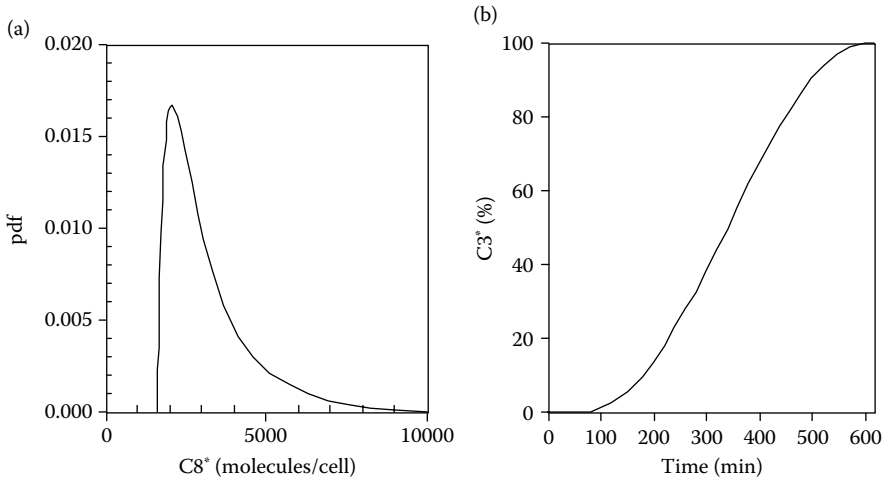

FIGURE 4.5.18. Stochastic response of the biochemical model to distributed input signals, activated caspase 8, C8*, in molecules per cell. (a) The probability density function (pdf) as applied, and (b) the resulting distribution of apoptosis, which may be interpreted as the inverse of a cell survival curve. (From Pearce, J.A., *Int. J. Hyperthermia*, 29(4), 262, 2013. With permission.)

by the applied thermal stress. They fail miserably at hyperthermic temperatures mainly because they initiate immediately and do not have a delay feature. The shoulder region, which typifies many cell survival curves, is bypassed and an unrealistic overestimation of "success" in the form of the irreversible alteration measured results, as in Figure 4.5.19. In the figure, the measured loss of clonogenicity curve at 43°C for Chinese hamster ovary (CHO) cells is compared to the Arrhenius model of equation 4.5.71 using coefficients derived from the constant rate region of the curves. Loss of clonogenicity, strictly speaking, isn't necessarily a cell death process; the cells may simply remain in the G1 phase (i.e., "resting"). However, for cancer cells, such as these are, it amounts to suppressing proliferation and makes a good measure. Since the Arrhenius model initiates immediately without delay, by that measure the "success" is grossly overestimated, a thoroughly unacceptable result.

What is missing, of course, is an appropriate delay. It turns out that by adding a temperature-dependent delay before initiating a first-order decline much more accurate results can be obtained.[140]

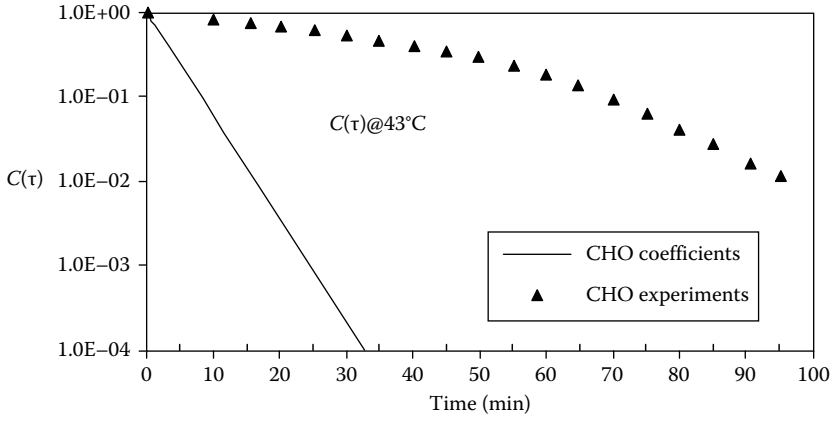

FIGURE 4.5.19 Arrhenius model predictions compared to the cell survival curve at 43°C for the CHO cell loss of clonogenicity from Sapareto and Dewey data.[139] (From Pearce, J.A., *Int. J. Hyperthermia*, 29(4), 262, 2013. With permission.)

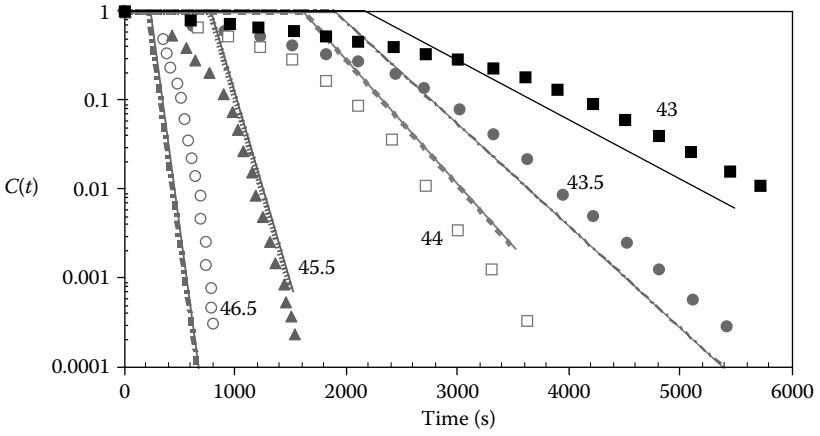

FIGURE 4.5.20 Arrhenius model with temperature-dependent time delay predictions compared to cell survival curves for the CHO loss of clonogenicity from Sapareto and Dewey data.[140] (From Pearce, J.A., *J. Biomech. Eng.*, 137(6), 121006, 2015.)

Looking at the CHO data with an added time delay improves the accuracy substantially, as in Figure 4.5.20. The corrected Arrhenius coefficients for the constant rate region are: $A = 6.355 \times 10^{97}$ and $E_a = 6.102 \times 10^5$ (J/mol). The required time delay from a regression line is given by[140]

$$t_d\,(\text{s}) = 26062 - 555.9T\ (^\circ\text{C}) \quad r^2 = 0.912 \quad T_{max} = 46.9^\circ\text{C} \tag{4.5.83}$$

and the maximum temperature for which a time delay is needed is 46.9°C. The improvement in accuracy is notable, and realistic predictions can now be made with a relatively simple model.

Adding a time delay to the Arrhenius model gives an excellent representation, and thus prediction, of the measurements.

The time delay model also fits other experimental survival curve data with a shoulder region quite well. For example, in a carefully constructed series of experiments on PC3 cells, Feng et al. used propidium iodide (PI) uptake as the cell death measure.[141] PI stains cells that have damaged plasma membranes. The survival curves have a pronounced shoulder region. The required time delay is[140]

$$t_d\ (\text{s}) = 2703 - 49.6T\ (^\circ\text{C}) \quad r^2 = 0.953 \quad T_{max} = 54.5^\circ\text{C} \tag{4.5.84}$$

Elegant and instructive studies of several cell types illustrate that not all death mechanisms require time delays. In 2004, Bhowmick et al. studied the AT1 subline of R3327 benign rat prostate tumor cells with three types of thermal damage assays: calcein fluorescence intensity decay, PI exclusion, and loss of clonogenicity.[142] Of these, only calcein fluorescence decay and loss of clonogenicity and required an added time delay.[140]

AT1 cell calcein fluorescence decay ($E_a = 2.85 \times 10^4$ J/mol and $A = 246.9$ s^{-1}):

$$t_d\,(\text{s}) = 1304 - 18.95T\ (^\circ\text{C}) \quad r^2 = 0.937 \quad T_{max} = 68.8^\circ\text{C} \tag{4.5.85}$$

AT1 cell loss of clonogenicity ($E_a = 5.21 \times 10^5$ J/mol and $A = 5.95 \times 10^{82}$ s^{-1}):

$$t_d\,(\text{s}) = 2436 - 46.1T\ (^\circ\text{C}) \quad r^2 = 0.750 \quad T_{max} = 52.8^\circ\text{C} \tag{4.5.86}$$

The PI uptake studies in AT1 cells were fit very well by the standard Arrhenius model with $E_a = 2.448 \times 10^5$ (J/mol) and $A = 2.99 \times 10^{37}$ (s^{-1}). In another study by the same group, PI uptake was

measured in SN12 human renal carcinoma cells.[143] The standard Arrhenius model also fit the measured data well with no noticeable shoulder region, $E_a = 2.88 \times 10^5$ (J/mol) and $A = 4.46 \times 10^{43}$ (s^{-1}).

These observations present two interesting conundrums. First, the same assay, PI uptake, behaves differently in PC3 (where a time delay is required), in AT1 and in SN12 cells where a standard Arrhenius model fits well. Second, the AT1 cells respond differently to the assays: a time delay is required for calcein fluorescence, but not for PI uptake—both of which assays indicate plasma membrane damage.

In summary, cell survival curves that demonstrate an initial slowly developing shoulder region may be fit by adding a time delay to the standard Arrhenius model.[140] The required time delay is temperature-dependent, and crosses zero typically at some temperature in the range of 46°C–70°C, depending on cell type and particular damage assay. This is in keeping with published observations that the Arrhenius model fits well at higher temperatures. The maximum delay temperature is an indication of the temperature at which intrinsic cell death processes and/or healing responses (such as those involving heat shock proteins) are overwhelmed by the applied thermal stress. Other assays in the same cell line may not require a time delay for adequate accuracy. Of course, this approach discards information in the shoulder region; however, when heating tumors for therapeutic goals the shoulder information is of no interest—except that, of course, the delay time at temperature must be exceeded in order to hope for an effective treatment.

Histologic Markers of Thermal Damage*

Tissue and cell heating produce several pathologic alterations that can be directly attributed to thermal damage mechanisms. Many of these are measurable using quantitative pathologic techniques, and thus are amenable to description by kinetic rate process models. As discussed previously, it is important to recognize that several independent damage processes can be occurring at the same time. Therefore, it is imperative to describe precisely which particular end point will be measured for kinetic analysis. Depending on the tissue, some end points are more easily identified and measured than others. From the pragmatic biological standpoint, cellular and tissue thermal damage end points are divided into two general categories: lethal and nonlethal thermal injury. Details are presented and illustrated by Thomsen and Pearce in several extensive reviews.[144–146]

Nonlethal Low-Temperature Tissue Effects

Most living cells and tissues can tolerate and survive modest temperature elevations for limited time periods depending on the species and the metabolic status of the individual. Recovery after heating is marked by the restoration of normal functions. Most nonlethal thermal injuries of individual cells are secondary either to (1) heat-induced acceleration of metabolism, (2) thermal inactivation of particular enzymes, and/or (3) rupture of cellular membranes. These alterations lead to disruption of several physiologic reactions of which the most critical are respiration and energy-generating metabolic functions.[136,147] The best indicators of reversible, nonlethal thermal injury in the living cell or organism are physiological tests that monitor heat-sensitive biochemical and metabolic changes rather than morphologic alterations.

Immediate effects—Routine light microscopic techniques applied immediately after heating are not useful for the detection of histologic markers of nonlethal thermal injury. However, enzyme histochemistry, a laborious, somewhat capricious methodology, can be used to reveal inactivation of a few heat-labile enzymes.[148] Transmission electron microscopy (TEM) provides sufficient magnification and resolution to show ruptured cellular membranes and distorted organelles; however, it is not quantitative, but subjective, and interrogates only a small tissue region (<1 mm^2). If the ruptures and distortions are infrequently seen, then the damage is not likely lethal. Over time, recovery

*The authors acknowledge the contributions to this subsection by Sharon Thomsen, M.D.; portions excerpted from Pearce, J.A. and Thomsen, S., in Optical-Thermal Response of Laser-Irradiated Tissue, Welch, A.J. and van Germert, M.M.C., eds., Plenum Press, New York, 1995. With permission.

occurs with the synthesis of replacement enzyme proteins and new membranes to patch the holes and reconstitute the normal functions of the organelle and cell.

On the other hand, tissues and organs are composed of a diverse population of cells that have (1) varying levels of heat sensitivity, (2) different types of metabolic functions and repair capabilities, and (3) various contributions to the function of the tissue or organ. Unlike single cells, reversible thermal damage of tissues can and usually does involve some cell death, but it occurs at a level that does not impair the function of the organ or the tissues. Like the situation in single cells, histologic assessment of reversible tissue thermal injury immediately after heating requires enzyme histochemistry and TEM to determine the degree and distribution of thermal damage, because this damage is not detectable with routine light microscopic techniques. The immunofluorescent microscopy based TUNEL (Terminal deoxynucleotidyl transferase dUTP nick end labeling) histochemical reaction reveals endonuclease cleaved ends of DNA but this reaction is fraught with false positive reactions in necrotic lesions.[99]

Delayed effects—Depending on the tissue, intracellular edema, tissue edema, and hyperemia occur within seconds to hours. Delayed effects can only be seen in living, physiologically intact organisms. These are easily identified delayed organismal responses to nonlethal thermal damage in both living single cells and tissues. Intracellular edema is due to abnormal accumulation of fluids secondary to thermally induced metabolic dysfunction, and resolution of the edema upon repair is a marker of healing. Heat-induced tissue edema and transient hyperemia (increased blood flow and blood vessel dilatation) are mediated by the release of vasoactive polypeptides from local inflammatory cells within several seconds of injury. The action of the polypeptides causes blood fluids (primarily plasma) to escape through gaps between the endothelial cells lining the vessel. On the other hand, prolonged hyperemia, like that associated with sunburn, is a delayed response associated with direct endothelial damage. In this case, the histologic indicators of the more severe vascular damage are dilated blood vessels stuffed with red blood cells and, not infrequently, microscopic leakage of the red blood cells through the damaged vessel wall into the adjacent tissue spaces. Recovery, which is secondary to endothelial regeneration and repair, is seen in a few days.[136]

Lethal Low-Temperature Thermal Effects

Nonprogrammed cell and tissue death and postmortem necrosis—Nonprogrammed cell death and subsequent necrosis result when the damage is so severe that the usual repair mechanisms cannot cope and/or the mediators of the repair mechanisms (DNA and RNA transcription enzymes) are thermally destroyed. Again, routine light microscopic techniques cannot be used to identify dead cells immediately after heating, except in the case of severe damage. However, within minutes of lethal thermal damage, TEM reveals the accumulation of chromatin (the DNA-containing chromosomes) at the margins of the nuclei, a recognized TEM marker of cell death, plus more extensive disruption of cellular organelles and limiting cell membranes that are incompatible with survival.[148] Enzyme histochemistry demonstrates enzyme inactivation but, as discussed above, enzyme inactivation by itself cannot be used as a hallmark of cell death. After death, cells and tissues undergo necrosis, which is a natural autolytic process of disintegration that follows a predictable course over time. Tissue necrosis, the "gold standard" marker of death, is easily recognized in light microscopic sections of lesions 24–72 h after the lethal event and, for most tissues, histologic evaluation of the maximal extent of tissue necrosis is seen at about 3–5 days.[149–151] After 5 days, the boundaries of necrosis and other markers of thermal coagulation are obscured by the healing processes and precise measurement of the extent of lethal heating can no longer be done.

In vivo red zone thermal damage—When localized electromagnetic, acoustic, or optical heating results in deep zones of necrosis, as when laser light is delivered through an optical fiber or ultrasound or electromagnetic waves are focused, concentric zones of thermal damage form around the source during heating and immediately thereafter. The boundaries between these zones are often distinct and measurable. Depending on the power density and duration of exposure, the three major zones in the lesion which can be seen by the naked eye are (1) a central ablation hole (at high-power

densities), (2) a whitish zone of coagulation, and (3) when the blood supply is intact, a surrounding peripheral red zone. The red zone is formed as a result of hemostasis, hemorrhage, and hyperemia (increased blood flow). The vascular responses are intermixed; however, hemostasis—due to direct damage to blood cells and vessels—tends to occur at the inner boundary between the surrounding red zone and the more central white coagulation zone. Studies performed in rat liver and goat breast show that the outer boundary of the red zone corresponds to the maximum extent of lethal thermal damage as determined by tissue necrosis evaluated in surviving animals 3 days after treatment.[145,149,150]

Microscopically, additional distinct zones of lethal thermal damage can be detected in the white coagulum. Advancing radially inward from the boundary between the red and white zones, one observes the following quantitative histopathological markers of thermal damage:

1. Lethal cellular injury manifested by cell shrinkage, spindling, and hyperchromasia
2. Collagen hyalinization
3. Collagen birefringence changes.
4. Muscle birefringence changes
5. Water-dominated effects

The changes intensify as the hotter center of the lesion is approached. Additionally, a mass defect created by ablation of the tissue by vaporization and plasma formation is observed in cases of intense heating, but is not considered here.

Thermal Coagulation

As temperatures rise and/or heating times are prolonged, cellular, and tissue structural proteins, which are thermally more stable than the vital, energy-producing enzymes, undergo denaturization and conformational changes—a process defined as thermal coagulation. Coagulation is immediately apparent and always indicates lethal thermal effect. For most tissues, coagulation can be seen with the naked eye as whitening of the tissue associated with increased turgor and opacity. The whitening of the egg white while the egg is being fried is an obvious example of thermal coagulation of protein, in this case, albumin. On the other hand, coagulation of collagen-rich tissues, such as tendon and skin dermis, can be signaled by increasing transparency due, apparently, to decreased optical scattering by the denatured collagen fibrils.

Microscopically, thermal coagulation of cellular and extracellular structural proteins includes an array of morphological alterations that mark a large range of temperatures and exposure times. As tissue temperatures and/or exposure times increase, the coagulative changes become more obvious and light microscopic analysis becomes the investigative tool of choice.

The most useful histologic markers of coagulative thermal damage in tissues are structural alterations of cells and collagens. Thermally coagulated cells and intracellular organelles shrink and undergo characteristic conformational changes. Collagens are a widely dispersed biochemical class of extracellular fibrous proteins that form the supporting scaffolding of nearly all soft tissues and the organic strut system of bone, cartilage, and teeth. These fibrillar proteins swell and form amorphous masses as a unique response to heat.

Cellular shrinkage and conformational changes—Thermally coagulated cells shrink due to denaturation of the elongate cytoplasmic and nuclear proteins that form the three-dimensional scaffolding system of these structures.[144,152] Coagulated surface epithelial cells—such as those that line the gut, bladder, and numerous glands of the body—tend to become elongate (spindle-shaped). The boundary between this change and the normal epithelium can be quite distinct, and thus potentially useful for kinetic analysis.

In contrast, the epithelial cells of the solid organs—such as the liver, pancreas, and kidney—just shrink and do not undergo noticeable conformational change at the light microscopic level. The cellular shrinkage is also due to loss of intracellular water. The coagulated proteins of the desiccated

cells become more densely packed, as reflected by dark cytoplasmic and nuclear staining (hyperchromasia) in routinely prepared histologic sections. Unfortunately, these histologic changes are very subtle and, frequently, cannot be distinguished from technical artifacts due to poor fixation. Therefore, they are not reliable markers of thermal damage, especially in the hands of an inexperienced observer.

Collagen coagulation—Thermal denaturization of extracellular fibrous structural proteins, the collagens, is marked histologically by swelling and an amorphous, glassy transformation of the fibers (hyalinization).[146,149,150,152,153] This transformation is easily seen in those tissues composed of loose networks of collagen fibers, such as the cornea, skin, submucosa of the stomach, intestines, and urinary bladder. However, some collagen fibers, such as those found in arterial media and liver sinusoids, are very thin (reticulin fibers); thus detection of hyalinization is beyond the resolution of the light microscope. And, at the other end of the fiber size spectrum, mild hyalinization and fiber swelling are equally difficult to see in tissues composed of thick, densely packed collagen fibers, such as those found in blood vessel adventitia and dermis. Changes of birefringence of thermally coagulated collagen (described next) are sometimes easier to detect than hyalinization in these circumstances.

Thermally Induced Loss of Birefringence

Birefringence is an optical property of some tissues that rotates incident polarized light. Thermal coagulation is associated with partial and total loss of the native birefringence of muscle tissues and certain fibrillar collagens as revealed by transmission polarizing microscopy (TPM).[144–146,149,153] The birefringence of muscle is due to the very regular arrangement of the fibrillar contractile protein macromolecules, actin and myosin, that form the contractile unit of the muscle. Collagen birefringence is the result of the molecular structure and regimentation of the tropocollagen molecules from which collagen fibrils are built. Tissue birefringence has two components, intrinsic and form birefringence. Intrinsic birefringence is secondary to the α-helical conformation of the polypeptides that form the individual contractile proteins of muscle and tropocollagen molecules and accounts for 12%–30% of the total birefringence of these tissues. The remaining birefringence, form birefringence, is related to the crystalline-like array of the actin and myosin molecules in the sarcomere and the regimented longitudinal array of tropocollagens within the collagen fibrils.[144–146,153–167]

Thermally induced changes of muscle birefringence are associated with dissociation and disruption of the molecules, as revealed by TEM. Partial loss of birefringence in skeletal and cardiac muscle has been identified with the breakdown of the relationships of actin and myosin in the sarcomere (loss of form birefringence). The source of the birefringence of striated muscle is the central portion of the sarcomere, the A or anisotropic band, in which the actin and myosin are arranged in parallel crystalline-like array. The I or isotropic band of the sarcomere includes portions of adjacent sarcomeres that contain actin molecules which are attached to the Z band, an attachment zone for the actin molecules. Total loss of birefringence is associated with increased temperature–time histories and is probably related to the reduction of the individual fibrillar contractile proteins to thermally denatured granular profiles (loss of intrinsic birefringence) as shown in TEM of heated myocardium.[95,168,169]

Thermally induced birefringence changes in collagen involve decreasing intensity of the birefringence image until it is totally lost at higher temperatures. TEM of heated collagens shows a gradual unraveling of the fibers with disappearance of the characteristic periodicity of collagen, reflecting the dissolution of the regimented organization of native collagen as it is heated.[149,167]

The onset of the birefringence changes of collagens varies depending on the experimental conditions, anatomic site, and the age of the organism. Native tissue collagens reside in complex environments of different proteins, glycoproteins, and cells that are greatly influenced by the local and systemic physiology of the living organism. The intimate relationships of the collagens with these tissue constituents are regulated by water and salt concentrations, ionic and covalent bonds, and hormonal and metabolic effects. Collagens extracted from tissues are not in their natural environment,

therefore *in vitro* experiments testing molecular relationships including measurements of birefringence will not predict the native behavior of collagen *in situ* or *in vivo*.[163–165] In addition, as the organism ages, the collagens, especially the Type I collagen found in most tissues, form more molecular cross-links that alter the temperature-time thresholds of fiber dissociation.[164]

TPM can be performed on paraffin sections prepared for routine light microscopy; thus the birefringent images can be correlated directly to the morphologic structure. The intensity of the birefringent images is governed by the thickness of the section, the type of dyes used, and in the case of collagens, the collagen fiber thickness.[150,170]

Collagen Shrinkage

As collagen is heated to denaturing temperatures at which it loses its rope-like native state conformation, it shrinks in length and swells in diameter in an approximately iso-volumic process. An interesting model of the collagen shrinkage process was presented by Chen et al.[171–173] They studied thermally-induced shrinkage in rat *chordae tendineae* between 65°C and 95°C under different levels of applied longitudinal stress between 0 and 650 kPa, and were able to collapse all of their data into a single curve based on a normalized time axis, $\nu = \ln\{t/\tau_2\}$—τ_2 is described in Figure 4.5.22 and Equation 4.5.89. Three nondimensional variables were defined to analyze the data.

The overall shrinkage, ξ (%), is calculated from an interpolation function, $f(\nu)$:

$$\xi = \left(1 - f\left(\nu\right)\right)\left[a_0 + a_1\nu\right] + f\left(\nu\right)\left[b_0 + b_1\nu\right] \tag{4.5.87}$$

where $a_0 = 1.80 \pm 2.25$, $a_1 = 0.983 \pm 0.937$, $b_0 = 42.4 \pm 2.94$, and $b_1 = 3.17 \pm 0.47$ (all in %). The best-fit interpolation function, $f(\nu)$, is given by

$$f\left(\nu\right) = \frac{e^{a(\nu - \nu_m)}}{1 + e^{a(\nu - \nu_m)}} \tag{4.5.88}$$

where $a = 2.48 \pm 0.438$ and $\nu_m = \ln\{\tau_1/\tau_2\} = -0.77 \pm 0.26$. The interpolation function includes all three segments of the shrinkage curve in Figure 4.5.20, excepting the post-heating relaxation curve. And finally, at any temperature, τ_2 is given by

$$\tau_2 = e^{\left[\alpha + \beta P + M/T\right]} \tag{4.5.89}$$

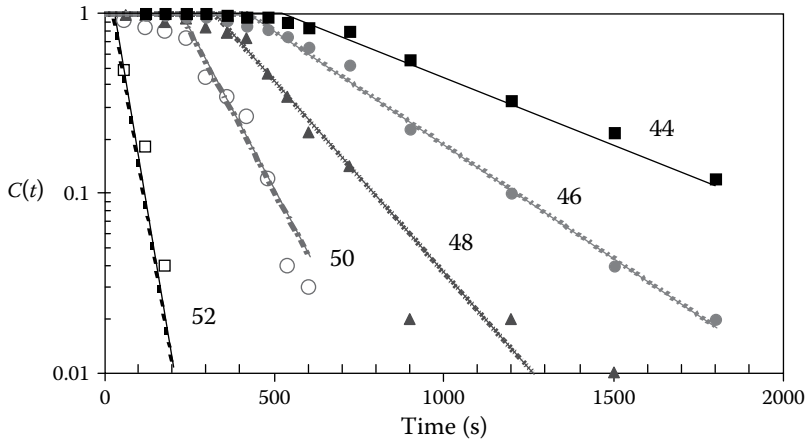

FIGURE 4.5.21 Arrhenius model with temperature-dependent time delay predictions compared to cell survival curves for the PC3 PI uptake assay.[140] (From Pearce, J.A., *J. Biomech. Eng.*, 137(6), 121006, 2015.)

where $\alpha = -152.35$, $\beta = 0.0109$ (kPa^{-1}), P = applied stress (kPa), and $M = 53{,}256$ (K). The exponent in Equation 4.5.89 contains the thermal kinetics of the process: $\alpha = -\ln\{A\}$ and $M = E_a/R$, so the equivalent $A = 1.461 \times 10^{66}$ and $E_a = 4.345 \times 10^5$ (J/mol) for the process (i.e., $T_{crit} = 343$ K = 69.9°C). The signs are reversed compared to Equation 4.5.56 because τ_2 occurs in the denominator of the kinetic equation.

To use the collagen shrinkage model, the equivalent t/τ_2 is accumulated during model execution. That is, at each point in space and time an equivalent value for the increment, $(\Delta t/\tau_2)$ is calculated and accumulated from Equation 4.5.89. Point-specific shrinkage is calculated at selected times by application of Equations 4.5.87 and 4.5.88, respectively.

Water-Dominated Effects

The role of water vaporization becomes dominant as the tissue temperatures approach 100°C. The tissue effects depend on (1) the rate of water vapor formation, (2) the temperature of the water vapor, (3) the rate of diffusion (escape) of the vapor from the tissue, and (4) the tissue mechanical properties.[174–183] All tissues exposed to air will lose water vapor to the atmosphere because of the differences between the partial pressure of water vapor across the tissue/air boundary. Below 100°C water vaporization is a surface phenomenon. As tissues are heated water vapor will be generated and the vapor will diffuse toward the surface to escape. The water vapor is in thermodynamic equilibrium with liquid water and, in the tissues deep to the surface, the relatively low partial pressure gradients favor the liquid over the vapor phase. Meanwhile, at the surface, the tissues dry out as the water vapor escapes leaving the hard, not infrequently brittle, solid tissue components behind.

At or just above 100°C water vapor is generated volumetrically, equilibrium is pushed toward the vapor phase, and, for sufficiently high volume generation rates, q''', more vapor is produced than can escape by simple diffusion. The excess vapor is trapped not only within the cell but also in the extracellular tissue layers forming vacuoles or dissections along planes of mechanical weakness.[183–185] The surface desiccates rapidly because diffusion lengths are short. The temperatures of the tissues that still contain liquid water will either remain close to 100°C or the pressure will rise.

The vapor in the vacuoles will expand quickly compressing the surrounding, rapidly drying tissues that form the vacuolar walls. As the vacuoles expand the walls separating the vapor pockets from each other or the tissue surface become thin. The walls rupture as the force of the increasing pressures of expanding vapor overcomes the mechanical strength of the tissue. The vacuoles coalesce to become larger holes within the tissues or form irregular defects on the surface. When this process takes place over relatively long heating times, the tissue defects are formed as the result of tissue compression, desiccation, and shrinkage, but not to loss of dry mass. On the other hand, rapid heating times result in explosive rupture which causes tissue fragments to be ejected from the surface creating irregular craters formed secondary to dry tissue mass loss. These water-dominated events are the same as those when popcorn is made, hence the tissue changes have been called the "popcorn" effect.[175–179,184,186]

The kinetics of water vaporization will not be treated here; see the discussion of phase change in Chapter 3. Histologically, the zone of water vapor formation manifests as a distinct region populated by vacuoles adjacent to ablation craters formed from volume heat sources. In some experiments, for example, electrosurgical cutting and laser ablation at water-absorbed wavelengths, the vacuolized zone usually has a distinct and measurable border.

Thermal blood vessel sealing—The thermodynamics of tissue water vaporization play an exceedingly important role in RF sealing of large vessels. Hyalinization (gellification) of tissue collagen—which typically occurs between about 60°C and 90°C, depending on heating time—represents the first step in the vessel sealing process. It turns out to be necessary to also thermally denature the vascular elastin, a dominant structural protein in large arteries and in many of the larger veins. This frequently requires temperatures in excess of 140°C, and under ordinary bipolar forceps electrodes explosive boiling destroys tissue structure resulting in a brittle, friable, and unsatisfactory seal. To get a successful seal it is necessary to apply high apposition pressures—at least

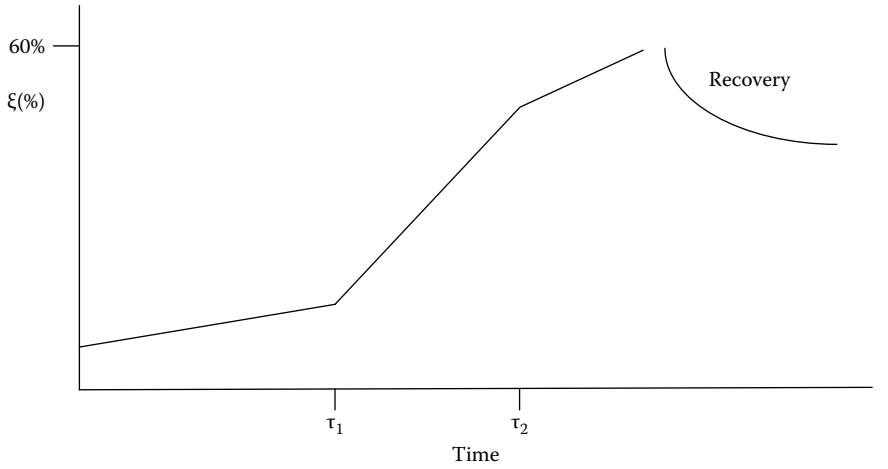

FIGURE 4.5.22 Collagen shrinkage: slow initial shrinkage up to τ_1 followed by rapid shrinkage up to τ_2 and slower shrinkage to a maximum of about 60%. Some relaxation occurs during cooling.

several atmospheres—to raise the equilibrium boiling temperature above the elastin denaturation temperature range. As a result, substantial tissue water is retained, the seal is more pliable, and able to withstand higher burst pressures.

Figure 4.5.23 illustrates the complex anatomy of larger vessels, which is the origin of the vaporization/disruption problem. In Figure 4.5.23a, the cross section of a canine carotid artery at 40× original magnification is shown under Weigert–van Gieson elastin stain. The elastin plates are black, smooth muscle is tan and the adventitial collagen is pink. The internal elastic lamina is at the

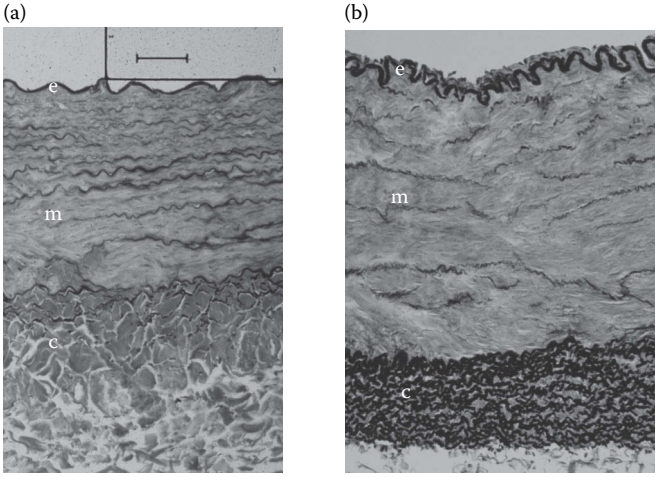

FIGURE 4.5.23 Large vessel anatomical features. (a) Cross section of canine carotid artery. A relatively thick layer of black-staining elastin lamina (e) covers the luminal surface of the artery. The smooth muscle cells (m) form layers between the sheets of elastin in the vessel media. A few black elastin fibers surround the stained collagen fibers (c) in the outer vessel layer, the adventitia. Weigert-van Gieson elastin stain, original magnification 40×, bar = 62 μm. (b) Cross section of porcine femoral artery at the same original magnification with the same stain. By comparison, the femoral arterial structure has the same three layers but the muscle (m) is more abundant in the media and the dense layers of elastin obscure the scant collagen (c) of the adventitia. (Histology provided by Dr. Sharon Thomsen.)

top of the cross-section (the endothelial surface), and the bottom is the adventitia. In Figure 4.5.23b, a porcine femoral artery is shown at the same magnification, and again the internal elastic lamina is at the top (the endothelial surface). Note the different distribution of the elastin layers; this artery has significant elastin in the adventitia and very little collagen by comparison, while the media has a much higher concentration of smooth muscle. In both cases, evolved steam will be trapped in the elastin plates resulting in high internal pressures. Counteracting with high apposition pressures preserves tissue integrity and water retention during *RF* heating.

Damage Rate Process Coefficients

Thermal damage kinetic coefficients are usually determined from constant temperature exposures of relatively long duration. Threshold damage results are selected out of a set of damaged tissue samples for analysis from which estimates of A and E are obtained.

Constant Temperature Exposures

Because of the sensitivity of the damage integral to small changes in temperature, the typical approach in obtaining A and E is to expose the tissue to a constant temperature, identify experiments in which the damage is threshold—i.e., for which $\Omega = 1$, or $C(t) = 36.8\%$ of $C(0)$ — and obtain A from the intercept and E from the slope of an Arrhenius plot of $\ln(t)$ vs. $1/T$ for the threshold experiments. If the temperature is held constant, the integral reduces to a simple multiplication, and $C(\tau) = 0.368\ C(0)$, then Equation 4.5.70 becomes

$$ln\{\tau\} = \frac{E}{R}\frac{1}{T} - \ln\{A\} \tag{4.5.90}$$

The usual experimental method is to expose thin slices of tissue to constant temperature in a water bath, by surface application of heated water,[100–103] or on a heated metallic plate for desired time intervals. Table 4.5.10 lists rate coefficients obtained in various experiments and the relative damage rates ($d\Omega/dt$) are compared for several of them in Figure 4.5.24.

Other experiments in the ensemble for which Ω is not 1 can be included in the estimation of the coefficients by noting that Ω can be included in an equivalent exposure time, τ_{eq}:

$$ln\{\tau\} = \frac{E}{R}\frac{1}{T} - \ln\{A\} + \ln\{\Omega\} \tag{4.5.91a}$$

$$\ln\{\tau_{eq}\} = \ln\{\tau\} - \ln\{\Omega\} = \ln\left\{\frac{\tau}{\Omega}\right\} = \frac{E}{R}\frac{1}{T} - \ln\{A\} \tag{4.5.91b}$$

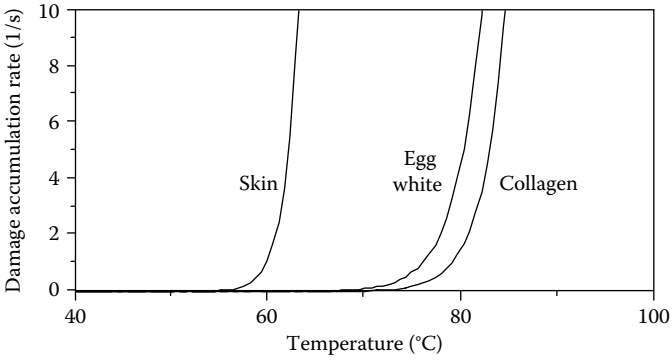

FIGURE 4.5.24 Comparison of selected damage processes from Table 4.5.10: damage rate, $d\Omega/dt$, versus temperature.

TABLE 4.5.10
Experimentally Determined Rate Coefficients

A (s^{-1}) Retina	E (J/mol)	Conditions	
Takata[188]	0	$T \leq 316$ K	
4.3×10^{64}	4.2×10^5	$316 < T \leq 323$	
9.3×10^{104}	6.7×10^5	$T > 323$	
Welch and Polhamus[187]	3.1×10^{99}	6.28×10^5	
Birngruber[189,190]	10^{44}	2.93×10^5	
Skin			
Moritz[103]	3.1×10^{98}	6.27×10^5	Not recommended
Diller and Klutke[127]	8.82×10^{94}	6.03×10^5	$T \leq 53$°C (H&M data)
	1.297×10^{31}	2.04×10^5	$T > 53$°C
Weaver and Stoll[106]	2.2×10^{124}	7.83×10^5	$317 < T < 323$ K
1.8×10^{51}	3.27×10^5	$T \geq 323$	
Egg			
Yang[191]	White 3.8×10^{57}	3.85×10^5	
Yolk 3.05×10^{56}	3.89×10^5		
PI uptake, AT-1 cells			
Bhowmick[142]	2.99×10^{37}	2.448×10^5	
Calcein fluorescence decay, AT-1 cells			
Bhowmick[142]	246.9	2.85×10^4	$300 < T < 328$ K
Time delay: t_d (s) = 1304 – 18.95 T (°C)			
2.7×10^{11}	8.78×10^4	$T > 328$ K	
Loss of clonogenicity, AT-1 cells			
Bhowmick[142]	5.95×10^{82}	5.21×10^5	$300 < T < 328$ K
Time delay: t_d (s) = 2436 – 46.1 T (°C)			
6.11×10^{12}	9.22×10^4	$T > 328$ K	

When using the kinetic models and measured coefficients, it is imperative that an adequate description of the particular end point be given. This is because different end points in the same tissue will have widely varying critical temperatures and damage accumulation rates. For example, in Table 4.5.10 in addition to the variation in tissue, the end points in the various studies differ markedly.

Retina—The measurements of Welch and Polhamus[187] used the diameter of the edge of the visible lesion formed in bovine retina under argon laser irradiation as the end point. The temperatures were not measured directly, but were determined in separate experiments on retinas in which a correlation between temperature and radius was established using microthermocouples (about 5 μm in diameter) advanced from the posterior surface of the eye to a point just below the retina. The correlates were used to estimate the retinal temperature given laser beam power and duration. The critical temperature for these coefficients is 56.0°C. Takata et al.[188] used a similar decision criterion for retinal damage for shorter exposure times. They fit the data with three sets of coefficients because a single first-order model was not sufficient. It would appear that several parallel damage processes were at work in their study, thus a set of coefficients was required. The critical temperature for the high-temperature set of coefficients is 59.9°C. Birngruber et al.[189,190] estimated a frequency factor and activation energy from consideration of the thermodynamics of protein and enzyme denaturization processes. Their estimates have a critical temperature of 74.5°C.

Skin—The end point for $\Omega = 1$ in the original studies of Henriques and Moritz[100–103] corresponded to a continuum of cascaded effects. In their study the skin of pigs was exposed, *in vivo*, to flowing water at a controlled temperature for exposure times varying over several orders of magnitude. They calibrated their coefficients so that $\Omega = 0.53$ corresponded to the onset of erythema (characterized as "first degree" in their paper). Then $\Omega = 1.0$ corresponded to a "second degree", or partial thickness burn, and $\Omega = 104$ to a full thickness, or "third degree" burn. Their coefficients, $A = 3.1 \times 10^{98}$ (s^{-1}) and $E = 6.27 \times 10^5$ (J/mol), have a critical temperature of 59.7°C; however, these coefficients do not fit their data very well and are not recommended despite their having been used by multiple investigators in model studies. In a follow-up study[127] new coefficients were obtained from the original data: $A = 8.82 \times 10^{94}$ (s^{-1}) and $E = 6.03 \times 10^5$ (J/mol) for temperatures below 53°C. These are recommended in place of the original coefficients. Weaver and Stoll[106] used similar criteria to those of Henriques and Moritz and applied two sets of coefficients (the upper values applicable above 50°C, as in the Takata et al. study) to match the experimental data. The critical temperature for their highest temperature coefficient set is 59.4°C.

Egg white and egg yolk—Egg white and yolk were exposed to constant temperature (±0.2°C) in a water bath for varying exposure times.[191] Coagulation was defined as the onset of whiteness (coagulum formation due, apparently, to an increase in scattering in the clear liquid egg white) observed by the naked eye. Water bath temperatures ranged from 60°C to 90°C in 4°C increments. At each temperature, the time to threshold was measured and plotted in accordance with Equation 4.5.22 and rate coefficients determined from linear regression, as described. Approximately 3–5 s were required to obtain whitening in the egg white at 70°C; while in the egg yolk 82°C was required for the same exposure time. The table values have a critical temperature of 76.0°C for egg white and 86.6°C for egg yolk.

The kinetic nature of thermal damage means that the time of exposure is of critical importance when discussing threshold temperatures. For example, it is commonly stated that thermal damage occurs above 45°C—and, in fact, 45°C was identified by Moritz and Henriques as the long-term exposure asymptote for threshold damage. However, at that temperature it would require 9.7 h of exposure to get a burn ($\Omega = 1$). To get a skin burn in 1 s, a temperature of 59°C would be required, and over the 0.1 s typical of the laser activations, 63°C is required. Similarly, using the coefficients for collagen, at 45°C it would require about 73 days of exposure to get $\Omega = 1$ (and that is a huge overprediction since collagen doesn't denature at 45°C); for damage in 1 s, 79°C, and in 0.1 s a constant temperature of 84.5°C is required. So, when comparing the higher temperatures required to obtain collagen denaturization in laser experiments (above about 80°C) to, for example, published values of collagen temperature thresholds (which range from 50°C to 60°C), it is important to note that (1) the times of exposure used in published collagen damage reports are usually in terms of hours and (2) it is entirely likely that collagen in dilute solution has a different set of kinetic coefficients than collagen *in situ* owing to the complex structural interrelationships inherent in the tissue.

Calcein leakage—Bhowmick and Bischof[114] measured calcein leakage rates from type AT-1 prostate tumor cells exposed to elevated temperatures. Calcein is a fluorescent dye that diffuses into cell membranes at varying rates depending on membrane integrity. The coefficients in Table 4.5.10 correspond to a 50% increase in intracellular calcein fluorescence intensity. They also reported cell survival rates (again, for 50% survival). These data are reasonably close to $\Omega = 1$ points (36.8% survival or remaining fluorescence intensity). Many other cell survival studies have been reported in the literature (see, e.g., the works of Mixter et al.[192] and Padanilam[193]).

Transient Thermal History Experiments

Problems with the standard constant temperature approach to determining A and E_a are that

1. With only a very few exceptions, the tissue must be excised to perform the experiments disrupting its blood perfusion and activating autolytic (postmortem degeneration and necrosis) processes.

2. No exposure is truly constant temperature and rise time segments must necessarily be short compared to total exposure time in order to be negligible (restricting one to the study of very slow processes).
3. It is difficult to obtain trustworthy estimates of A since the temperature axis is hyperbolic ($1/T$) and, even if the exposure times vary over several orders of magnitude, small uncertainties in the slope (E_a/R) create very large uncertainties in A.
4. The methods are difficult to use in transient MW, RF or laser damage studies since constant temperature exposures are nearly impossible to obtain.

Working with transient thermal data adds a high level of uncertainty to the damage coefficients since the time of exposure is problematic. Nevertheless, estimates of rate coefficients can be made upon which treatment protocols can be evaluated.

As can be seen from Table 4.5.10, most of the damage processes have activation enthalpies on the order of 10^5 (J/mol). For the hypothetical example damage process, with $E_a = 5.0 \times 10^5$ (J/mol), at 60°C the rate of damage formation would double if the temperature increased to 61.3°C (about 0.4% temperature increase on the absolute scale). If the transient temperature and damage process can be observed as the damage develops, as with fluorescence decay or dye penetration, the reaction velocity is easily determined as a function of temperature and determining the rate coefficients reduces to a curve fitting exercise. If, however, there is only one final observation of the accumulated damage, as in histologic section or a final immunohistochemistry assay, then the most effective approach is to integrate the ensemble of transient temperature records using assumed values for E_a and A from the He-Bischof line evaluated against some sort of "cost" function.

We may rearrange Equation 4.5.71 in which the unknowns are E_a and $\ln\{A\}$:

$$\ln\{A\} = \ln\{\tau\} - \left(\frac{1}{RT}\right)E_a \tag{4.5.92}$$

The value of Ω is calculated for each transient experiment using coefficients from the He–Bischof line and the cost might be some goodness of fit measure such as

$$\text{Cost} = \left| \ln\left\{ \frac{\int_0^{\tau} A\, e^{\left[\frac{-E_a}{RT(t)}\right]} dt}{\Omega(\tau)} \right\} \right| \tag{4.5.93}$$

The He–Bischof line is searched for values that yield minimums (ideally zeroes) in the cost. If the entire E_a and $\ln\{A\}$ plane is searched, the locus of minima is a straight line (a regression line). The solution is where that regression line crosses the He–Bischof line. There should be only one cluster of solution points that fall on the He–Bischof line, so some cluster analysis method may be required.

Summary

First-order kinetic models for tissue damage are useful for predicting trends in damage experiments. Unfortunately, there are only a few damage processes for which the frequency factor and energy have been determined *in situ*—critical temperatures for known processes range from about 50°C to 90°C. Nevertheless, these models can be used to make direct comparisons between numerical predictions of damage and histologic results; something which cannot, as yet, be achieved any other way. A very careful definition of the particular histologic end point is necessary. To avoid the

arbitrariness which characterizes much of the early damage studies, the end point ought to (1) be clearly recognizable and defined, (2) be reproducible under varying experimental conditions, (3) be easily measured, and (4) involve relatively homogeneous and readily available test tissues. For example, thermally induced birefringence image intensity decrease in skeletal and cardiac muscle is easily seen and measured using polarizing microscopy and optical detectors. Beef and pork loin cuts, chicken breasts, and canine or beef hearts can provide the numerous tissue slices required to accumulate adequate data.

In part because of the effects of biologic inhomogeneities and random fluctuations in tissue characteristics, and in part due to the difficulty of resolving small temperature differences, thermal damage data are inherently noisy. Consequently, the prediction of observed damage boundaries in very long-exposure experiments (on the order of minutes to hours) in the presence of substantial spatial thermal gradients may be frustrating. However, in small spot-size exposures of relatively short duration (up to fractions of seconds) the predicted boundaries compare favorably to those observed. This is probably due to the very steep thermal gradients typical of small spot experiments—that is, a rather large error in actual critical temperature may be swamped out by the very steep thermal gradient so that the location of the predicted damage contour may, in fact, agree fairly well with experimental histologic observation. Certainly, even though the results of a particular experiment may eventually prove impossible to duplicate in numerical models, a rather careful analysis of the trends which one would obtain from changing power, contact temperature, spot size, and duration can be studied in detail in the numerical model and on a spatial scale similar to microscopic observation. Also, the numerical model allows dissection of the transient development of thermal damage—something which cannot be achieved in any other way. So, while there are many uncertainties associated with kinetic models of thermal damage, they can be extremely illuminating and helpful in dosimetry planning.

Tissue Effects: Subzero Temperatures

An important area of bioheat transfer application is in the domain of subzero temperatures. As was noted previously, biochemical rate processes are governed by the local system temperature. Lowering the temperature has the effect of reducing reaction rates, and at sufficiently low temperatures a state of suspended animation can be achieved. Owing to the major aqueous component of physiological fluids, temperatures low enough to effect suspended animation normally result in freezing. The freezing of native biomaterials is nearly always lethal to the affected tissue upon thawing. The affected injury can be used beneficially in cryosurgery for the purpose of destroying a target tissue such as cancer. Alternatively, the tissue can be modified prior to freezing by the introduction of a chemical cryoprotective additive (CPA) to afford protection from freeze–thaw injury. Techniques have been developed for the successful long-term cryopreservation of many biomaterials for subsequent applications, including human transplantation. The response of living biomaterials to freezing and thawing is intimately tied to the thermal history during processing, especially at subzero temperatures. Thus, bioheat transfer analysis has played a key role in the design and development of low-temperature bioprocessing protocols.

Cryopreservation

Living tissues may be frozen to deep subzero temperatures to create a state of suspended animation for indefinite periods and recovered with very minimal loss of viability and function. It is necessary to store tissues at below approximately −120°C so the kinetics of chemical reactions and ice nucleation become infinitesimally small. Successful cryopreservation protocols require that subject tissue be modified prior to cooling to subzero (°C) temperatures by addition of a CPA, either to protect against the injurious effects of ice formation or to block the formation of ice so that a glassy state results (vitrification).

Widespread interest has developed in exploiting cryopreservation as a means for reversibly banking a broad spectrum of tissues for transplantation. The seminal paper which first reported this work described the use of glycerol to freeze fowl sperm 67 years ago.[194] Successes were reported in succession for other types of tissues having rather simple cell structures, such as erythrocytes, gametes, and various cells obtained from primary cultures.[195–197] Most of these cryopreservation techniques were derived via largely empirical methods, and starting in the 1970s, it came to be realized that the cryopreservation of more complex systems such as multicellular tissues and whole organs require a more rigorous scientific understanding of the mechanisms of the governing biophysical processes and cellular response to freezing and thawing. Since that time engineers have made significant contributions to the developing science of cryobiology, not the least of which has been to identify some of the key biophysical problems to be solved.[198]

Biophysical Basis of Freezing Processes in Cells

Analysis of cryopreservation by freeze/thaw processes is based on addressing phenomena associated with the solidification of aqueous solutions and their resulting effects on embedded living cells surrounded by semipermeable membranes. When an aqueous solution freezes, water is sequestered into the solid ice phase, resulting in the concentration of solutes in the residual liquid phase solution. If equilibrium is maintained between the liquid and solid phases, the coupling between temperature and solute concentration is described by the phase diagram for the solution. As shown in Figure 4.5.25, as the temperature is depressed below 0°C, the amount of solute in the liquid increases according to a function defined by the liquidus curve until the eutectic state is reached. Thus, cooling a biological tissue until ice is nucleated imposes an osmotic as well as thermal stress.

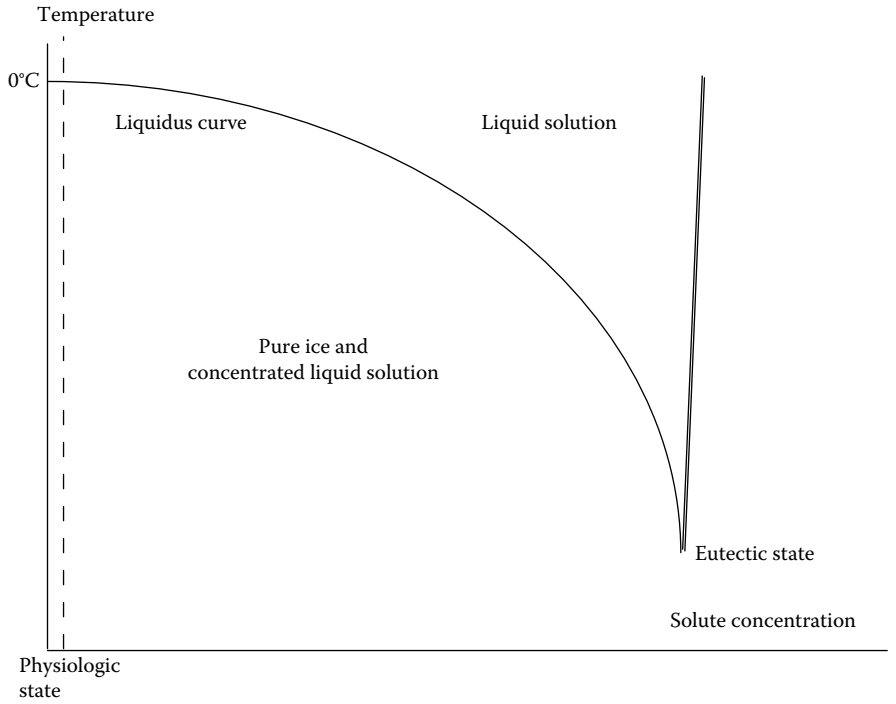

FIGURE 4.5.25 Simplified representation of an aqueous equilibrium phase diagram. Physiological solutions have solute concentrations that are quite small (about 300 mOsm) in comparison with the eutectic state. As freezing progresses, the liquid phase concentration may increase by more than 20-fold, subjecting cells to intense osmotic stress.

A consequence of the osmotic stress is that the individual cells in a tissue will lose intracellular water to the solute-enriched environment. (It is assumed that at subzero temperatures the time scales for transport of other molecular species will be negligible in comparison with that for water.) The rate at which this mass transport occurs across the cell membrane is governed by the membrane permeability to water. This transport process has been modeled as a simple diffusion phenomenon.[199]

$$\frac{\partial \Psi}{\partial T} = -\frac{L_p SBRT}{v} \ln\left(\frac{p_{in}}{p_{ex}}\right) \tag{4.5.94}$$

The Mazur equation predicts the change in the volume, Ψ, of a cell with temperature during freezing at a cooling rate of B in conjunction with the transport of water from within the cell in response to the osmotic differential developed across the membrane as solutes are concentrated during the solidification process, and R is the gas constant. The rate of transport is dependent on the surface area, S, of the cell, the membrane permeability to water, L_p, the molar volume of water, v, and the ratio of intracellular to extracellular vapor pressures of water. Although the latter term is not a rigorous description of the driving potential for the transport process, it is easily replaced by the transmembrane differential in chemical potential or solution concentration.

Dehydration is not the only process by which equilibrium can be achieved between intracellular and extracellular water during freezing. Ice crystals may nucleate within the cell, forming intracellular ice. The occurrence of intracellular ice formation (IIF) is nearly always lethal to cells and is therefore to be avoided during cryopreservation. The balance between equilibration of water across the cell membrane by osmotic dehydration and by IIF is governed primarily by the magnitude of the cooling rate. As depicted in Figure 4.5.26, at rapid cooling rates there is little opportunity for water to escape from the interior of the cell as the extracellular solute concentration increases with progressive freezing. Eventually, the conditions are satisfied for intracellular nucleation of ice

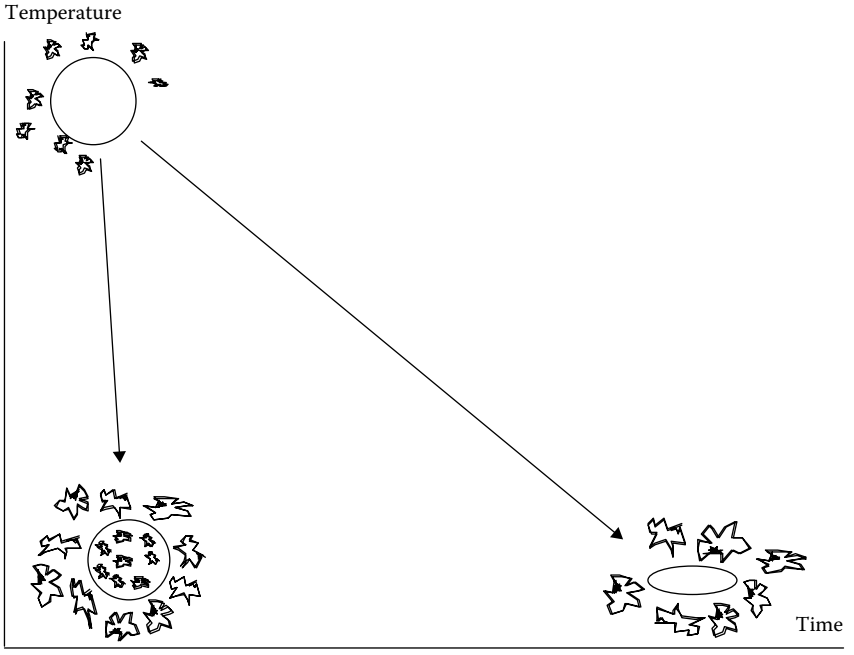

FIGURE 4.5.26 Schematic of the reaction of individual cells to extreme variations in the cooling rate during freezing. At rapid cooling rates, dehydration of the cell is minimal and intracellular ice forms. At slow cooling rates, dehydration is extensive, resulting in loss of intracellular water and morphological distortion.

crystals. At slow cooling rates, the cells are able to dehydrate as the extracellular solute concentration increases, and the intracellular water becomes frozen in the extracellular space. The resulting shrinkage of the cell can give rise to injurious chemical and mechanical stresses. In general, optimal survival from cryopreservation is achieved at intermediate cooling rates, the magnitude of which are dictated by the membrane permeability at subzero temperatures.[200]

Cryoprotective Additives

The sensitivity of cells and tissues to both IIF and osmotic stress and dehydration can be modified substantially by the prefreezing additions of a CPA. As a consequence, virtually all practical cryopreservation procedures are based on the use of a CPA to which the cell membrane is permeable. During both the CPA addition and removal procedures and the freezing and thawing processes, the applied osmotic stress results in coupled transport between the CPA and water. This coupled process is typically described in terms of irreversible thermodynamics using a format defined by Kedem and Katchalsky in which the phenomenological coefficients are related directly to physically measurable properties of a cell membrane.[201,202] These equations are written as

$$J_V = L_p \Delta p - \sum_{i=1}^{n} \sigma_i \Delta \pi_i \tag{4.5.95}$$

$$J_S = C_S (1 - \sigma) J_V + \omega_S \Delta \pi \tag{4.5.96}$$

where L_p is the membrane permeability to water; ω, the permeability to solute (CPA for applications in cryopreservation); and σ, the coupling between the two flows (reflection coefficient). The average concentration of permeable solute between the extracellular and intracellular solutions is given by C_S, and the total volume flux and solute fluxes by J_V and J_S, respectively. Equation 4.5.95 shows a provision for volume flow occurring under the action of multiple solutes.

An alternative, more generalized formulation of this type of phenomenon was also posed by Katchalsky in terms of network thermodynamics.[203] The network thermodynamic model has been applied successfully to the analysis of the cellular response to freezing processes.[204–206] It can readily be applied for inverse solution to quantify the transport coefficients from either freezing data or CPA addition data.[205,207]

Tissues and Organs

The preceding models hold for the analysis of individual cells. However, many important biological systems of interest for cryopreservation consist of organized tissues which have a three-dimensional geometry that exerts a significant effect on the osmotic behavior. For these systems, transport occurs not only across the individual cell membranes, but the interstitial volume is also involved in both the transport and storage of water and CPA. In this case, the model must be expanded to include both parallel and serial transport and storage for all mobile chemical species. Network thermodynamics provides an effective modeling format for describing these processes.

The cryopreservation of whole organs, which is still in the research stage, will demand even more complex coupled thermal and chemical transport analyses. CPAs are added and removed via perfusion through the vascular network, and this hydrodynamic flow is coupled to the osmotic, diffusional, and viscoelastic energy domains of the organ. The network thermodynamic approach to modeling is very well suited to analysis of these coupled multidomain processes and has been applied successfully to the design of CPA perfusion protocols.[208]

Influence of Cell Membrane Permeability

It is well documented that the permeability of cell membranes to water and to CPA is a strong function of the cell species, and that for all species it is a function of temperature.[202] For example,

the water permeability among various species may vary by a factor of 103 or greater. In general, membranes are significantly more permeable to water than to common CPAs, although the opposite case may also occur under unusual conditions.[209] As the temperature is reduced, the permeability is depressed dramatically. For most practical purposes, at temperatures below the range of about –20°C to –30°C the impedance to membrane transport becomes so high that there can be very little molecular exchange between the intracellular and extracellular compartments.

One of the major challenges in applying models for cell membrane transport during freezing has been developing instrumentation to measure the permeability to water and CPAs at subzero temperatures, both in the presence and absence of ice. The approach that has proven to be most successful is to follow visually on a light microscope the transient size of individual cells or tissues when they are subjected to controlled osmotic stress created either by freezing the specimen[210–212] or by changing the chemical environment.[213,214] An effective step change in the concentration of the extracellular solution is produced when ice is nucleated in the extracellular medium and the temperature is subsequently held constant for the duration of the experiment, or when a new bathing medium is perfused rapidly through the specimen chamber on the stage while the cells or tissues are physically immobilized. By both procedures, the concentration of the environmental solution is altered from an initial concentration to a final well-defined state, and the change in cell volume with time can be measured by direct microscopic observation.

The two-dimensional cross-sectional areas of the cells in the micrographs are quantified via digital image analysis and extrapolated to three-dimensional volumes based on an assumption of a consistent geometric morphology throughout the process. These experiments are repeated serially at different temperatures to generate a series of transient volume curves as shown in Figure 4.5.27 for pancreas islets,[215] a multicellular mammalian tissue. A 2 M solution of the CPA dimethyl sulfoxide (Me2SO) was introduced stepwise into the perfusion cryostage to control the osmotic environment of the islets. An initial shrinkage is measured as water leaves the cells more rapidly than the Me2SO can enter. As time progresses the islet reaches a minimum volume and then begins to swell as Me2SO and water enter the cell. The design of protocols for addition and removal of CPAs to tissues is an important and challenging step in developing effective cryopreservation methods. A rational design process is dependent on being able to measure the constitutive transport properties of the tissue of interest and having a model which can be applied to optimize the osmotic process, minimizing stresses (which are potentially lethal) on the cells.

Thus, the utility of the transient volume data is to provide a database from which Equations 4.5.94 through 4.5.96 can be applied to determine the constitutive transport properties for a cell or tissue of interest by inverse solution techniques. Property values are identified at each temperature for which experimental data exist, and the data for each property are used to fit an Arrhenius-type

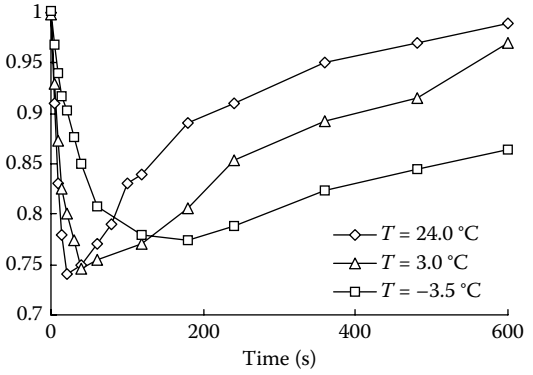

FIGURE 4.5.27 Osmotic response of human pancreas islets to exposure to a 2M solution of dimethyl sulfoxide at the indicated temperatures. (From deFreitas, R.C. et al., *Cryobiology*, 35, 230, 1997. With permission.)

function to characterize the temperature coefficient.[202] Equation 4.5.97 shows a typical formulation used for this purpose.

$$L_p(T) = L_{p,g}(T_g)\exp\left[\frac{\Delta E}{R}\left(\frac{1}{T} - \frac{1}{T_g}\right)\right] \tag{4.5.97}$$

Experiments for many different cell types have shown that the Arrhenius expression provides a model that describes the temperature dependence of the tissue transport properties well.[202]

In order to fully interpret the transient osmotic data described above, it is necessary to determine the fraction of the cell contents which is unable to cross the cell membrane under the types of osmotic stress encountered during cryopreservation. This component of the cytoplasm is often referred to as the osmotically inactive volume. It can be measured by conducting a series of experiments in which cells are exposed to increasing concentrations of impermeable solute and measuring the equilibrium volume at each state. These volumes are then plotted as a function of reciprocal solute concentration and extrapolated to the intercept of the ordinate, which indicates the volume which the cell would assume without injury when exposed to an infinitely large solute concentration. The complementary normalized fraction is a measure of the initial amount of intracellular water which can participate in the response to extracellular osmotic stress. The data are displayed on a Boyle–van't Hoff plot.[216]

A fundamental issue in the analysis of cryopreservation processes that has only recently begun to be addressed via rigorous quantitative modeling is the osmotic behavior of frozen cells during the thawing process. It has now been demonstrated by application of a model based on Equation 4.5.94 that there are combinations of freeze/thaw protocols for which the warming rate may be the governing component of the thermal history in determining the mechanism and extent of injury.[217] The design of optimal cryoprocessing protocols, therefore, may require an analysis of the effect on a tissue of interest of the complete thermal history, including both cooling and warming.

Cryopreservation by Vitrification

Ice nucleation can be avoided by doping the biological specimen with a high concentration of chemicals to induce a vitreous state.[218] The chemicals act to raise the glass transition temperature to a high value which can be reached at cooling rates consistent with standard refrigeration systems. Two major problems involving transport processes remain to be solved before vitrification can be applied to the cryopreservation of whole organs. One is the process by which a 4–5 M solution equilibrates with the entire volume of an organ, including all the constituent cells. Since this high concentration of CPA can be toxic to cells, the addition process is preferably effected at a low temperature, such as 4°C, to reduce the rates of injurious chemical reactions. In addition, the duration of exposure to the CPA prior to further cooling should be minimized to limit the accrued reaction time. However, the trade-off to lowering the temperature is caused by the thermal coefficient of viscosity, which makes it much more difficult to effect the perfusion of CPA solution through the vascular systems of an organ, and the diffusion from the vascular lumen through the interstitial tissue and into the individual cells. Optimal design is dependent upon balancing the coupled hydrodynamic, osmotic, and viscoelastic reaction of the organ to the perfusion process with the biochemical toxic reactions.[218]

Optimization of Heat Transfer during Cryopreservation

The foregoing discussion indicates the importance of the combined osmotic and thermal history at the local cellular level in determining the response to cryopreservation, including the type and extent of injury which may occur. For a given combination of cell type and CPA composition and concentration, the post-thaw viability achieved is governed by the thermal history of the process. The cooling rate determines the frozen state for storage, and the warming rate determines the manifestation of the frozen state on the final level of viability. In general, there are two extremes of

behavior during freezing. For relatively slow cooling rates, the rate at which the extracellular solute concentration increases will have a time scale comparable with that for the osmotic dehydration of the cell at high subzero temperatures. Therefore, the cell will lose a considerable fraction of its water and experience extensive dehydration as indicated in Figure 4.5.25. This large loss of volume is known to damage cells by one or more molecular-level mechanisms which have not been fully identified.[200] Increasing the concentration of CPA will provide an osmotic buffer against this type of dehydration-induced injury, as well as possibly providing other means of protection. Alternatively, when the cooling rate is rapid, the temperature is reduced much more rapidly than the cell can respond osmotically (because the membrane permeability becomes greatly reduced at low temperatures, as will be explained subsequently). Therefore, there is no opportunity for intracellular water to osmotically equilibrate with the extracellular water which is being progressively diminished in concentration. When the transmembrane water disequilibrium (as manifested in terms of liquid phase supercooling) reaches a critical value, the conditions will be satisfied for nucleation of ice in the intracellular volume. It is important to note that the cell membrane acts as a barrier to the growth of a continuous ice phase between the intracellular and extracellular compartments. The crystalline structure of intracellular ice will be considerably smaller than that of extracellular ice owing to the greater extent of supercooling prior to nucleation. Consequently, the propensity for recrystallization will be relatively large in the intracellular volume, and this process has been demonstrated to be nearly universally lethal to cells.

The combination of different injury mechanisms associated with rapid and slow cooling rates during freezing gives rise to a two-factor theory of cryoinjury.[200,219] Between the extremes of rapid and slow cooling there will be a range of intermediate rates at which survival will be maximized. The magnitude and breadth of this range is defined uniquely for each cell type as a function of its membrane permeability and sensitivity to injury. Cryopreservation protocols are targeted to produce a cooling process which lies within the optimal range of this survival signature that will produce the highest possible biological function following thawing. The design of a cryopreservation protocol for a given cell type must take into account the combined effects of the CPA composition and concentration plus the cooling and warming rates.

The above analysis of the freezing process is presented from the perspective of the local thermal history for an individual cell. However, practical cryopreservation procedures are conducted either on tissues and organs of finite macroscopic dimensions or on containers of solutions of cells or microscopic tissue suspensions. The consequence is that although the governing mass transport processes occur across microscopic scale dimensions (a single membrane and the associated boundary layers may be less than 0.1 μm), the governing heat transport occurs on a scale measured in millimeters or centimeters. It is this macroscopic heat transfer that drives all components of the cryopreservation process. Because of the macroscopic dimensions and the restriction that the refrigeration source be applied only at the external boundary of the systems during cooling, there can be significant spatial gradients in cooling rate manifested within the system. Also, in general the cooling rate will not be constant over the entire cooling process. The cooling rate should be defined over the range of temperatures most important to determining the frozen state of a cell. The critical temperature range is defined as that for which transport occurs across the cell membrane and for which IIF is most probable. Analysis of this process involves solution of the classic Stefan moving boundary problem.

For the freezing of biological systems, it is most important to accurately determine the cooling at high subzero temperatures within the mushy zone[220] during which the primary membrane transport processes occur. It is precisely this range of temperatures for which simplifying assumptions concerning the pattern of latent heat release frequently are made in order to render the mathematical solution more tractable. Therefore, it is important to match as well as possible the coupling between temperature and changing solute concentration as defined by the phase diagram. Only when the actual process physics are matched can the cooling rate for the critical temperature range be described accurately. The combination of a nonlinear pattern of latent heat release with temperature

and the often complex system geometry dictates that the governing heat transport equations be solved via numerical methods. The thermal histories calculated may then be correlated with the cooling rates on the survival signature and with the membrane mass transport equations, such as Equation 4.5.94, to predict the biological response of a given tissue to a defined boundary cooling protocol.[221]

Thermal Stress Effects

Another analysis problem to be addressed in cryopreservation is that of thermal stresses in an organ that has been vitrified. Although the constitutive properties are yet to be measured, it is apparent that a biological tissue with dimensions on the order of several centimeters will be subject to fracture at even moderate cooling rates below −120°C after a glass phase has formed.[222] A mechanical fracture of a whole organ will render it useless for subsequent transplantation. It is important to measure the viscoelastic properties of biological materials loaded with high concentrations of CPA over the temperature range between the glass transition and storage temperatures (usually at or near liquid nitrogen temperature at −196°C). Complementary to the property measurements is a need for a thermal stress analysis that can be applied with a versatility of geometric details.

Rubinsky et al.[223] have developed an initial model for how mechanical stresses may develop in the interior of an organ during solidification and the subsequent cooling process. Different organs have widely divergent shapes and sizes, and constitutive property data for frozen and vitrified tissues are practically nonexistent. In addition, an organ is likely to be preserved in a container of fluid with which it will be coupled thermally and mechanically. Factors that can be considered in a process design are manipulation of the boundary thermal protocol, shape of the overall container into which an organ is placed, and coordination of the pattern of distributed internal deposition with cooling at the boundary.

Recent Developments and Innovations

Recent innovative experiments by Fowler and Toner[224] have demonstrated that it is possible at the micro (cellular) scale to melt and recool cells containing intracellular ice at a rate that can produce a vitrified state without the introduction of the CPA to block the initial ice nucleation event. The frozen specimen is irradiated with a laser wavelength that is absorbed preferentially by the cell cytoplasm over the extracellular solution. For a solution of individual cells having characteristic diameters of about 6 μm, warming rates on the order of 1011°C/s can be achieved within the cells, while the extracellular matrix remains frozen. When the heating process is terminated in an approximate step-wise manner after 7 ns, heat transfer from the extracellular matrix to the cells produces an intracellular cooling rate of about 106°C/s, which is adequate to produce a glass state in an aqueous solution. The vitrified cells may then be warmed rapidly to suprafreezing temperatures (>0°C) without nucleation and with no measured injury. If this process is to realize broad clinical or commercial application, there is considerable engineering work to be accomplished in scale-up from these microscopic level processes to applications in larger tissue and organ systems.

Since the initial achievements in the cryopreservation of cells, many applications have been developed in both the biological and medical fields. There are now numerous for-profit concerns that have developed successful techniques for preserving human tissues for subsequent transplantation. Many of these corporations use proprietary processing protocols to preserve specific tissues, and the number of commercial participants in this field has been growing steadily over the past 10 years. In like manner, there are many for-profit and not-for-profit groups which are marketing the cryopreservation of a very broad spectrum of nonhuman tissues. Some of the more prominent applications involve mammalian and amphibian gametes, tissue culture collections, and plant germplasm. A potentially important new area of application will be the cryopreservation of living materials manufactured by the tissue engineering techniques which are being developed.[225] Bioartificial systems such as skin and organs that contain living cells will require a technology for maintaining them in a viable but latent state between the time of manufacture and implementation in a clinical

setting. Cryopreservation provides a tool of suitable potential for meeting this unique need, but the processing protocols will have to be designed to ensure successful storage and recovery for each type of manufactured tissue.

Cryosurgery

All of the foregoing discussion has been devoted to cryopreservation, for which the objective is to maximize the survival of cells from the frozen state to ensure their living function after thawing. The antithesis of this work is cryosurgery, for which the objective is to maximize destruction of a target tissue *in situ*.[226] Cryosurgery has long been practiced as an effective means for killing surface lesions, and recently it has been adopted more widely as a tool for treating internal tumors that are difficult to resect mechanically.[227]

Many of the recent gains in the successful application of cryosurgery are due to the development of new imaging methods that enable the surgeon to follow the growth of the solid-liquid interface, to which the zone of cellular destruction is coupled, in real time during the freezing process. The initial imaging methodology adapted for this purpose was ultrasonography.[228] Subsequently, other imaging modalities that can be coupled to the transient temperature field are being developed, including NMR[229] and spectroscopy.[230] Advances in cryosurgical probes that provide more effective removal of heat from tissues via enhanced thermal transport mechanisms have also contributed to the recent growth in cryosurgery.[231] Finally, over the past decade there has been a steady advance in understanding the mechanisms by which freezing and thawing act to cause tissue death as a function of the thermal parameters of the solidification process and tissue properties. Many of these fundamental advances have resulted from the application of bioengineering analysis of the tissue freezing process,[232–234] which portends the potential for engineering to further contribute to the field of cryosurgery.

A new approach to improving the efficacy of cryosurgery is derived from techniques long applied to enhance cryopreservation processes. Namely, the tissue is modified by addition of chemical agent prior to the initiation of freezing. However, for applications in cryosurgery the desired result is an increased level of cell killing. Antifreeze proteins (AFPs) are proving to be effective for this purpose.[235,236] AFPs are chemical compounds synthesized by many differing types of plants and animals to provide protection against freezing injury at high subzero temperatures.[237,238] It has also been demonstrated that AFPs modify ice crystals to needlelike shapes that can destroy cells during freezing to deeper subzero temperatures.[239]

In summary, clearly there continue to be many opportunities in low-temperature biological heat transfer for contributions with the potential for substantial positive impact on health-care delivery.
