4.6 THERMAL INSULATION

David W. Yarbrough

Introduction

In Fourier's law of steady-state heat conduction in one dimension, $Q = -k \cdot A \cdot (dT/dx)$, k, the material thermal conductivity, relates the flow of heat to the temperature gradient in the material. In many cases, the thermal conductivity is treated as a constant, but for more general cases, it can be a function of temperature, material density, or direction of heat flow. Thermal insulation design is an area of engineering that deals with the minimization of heat flux and control of temperature through proper selection and use of the material thermal conductivity of insulation surrounding or adjacent to a region or body.

Thermal insulation is used either to minimize the energy loss from a body or area such as a building, or to control the surface temperature, for example, of the outer shell of a furnace for safety reasons. It can also be used to control an object's rate of temperature change, for example, biological material, while it is being frozen or thawed.

Thermal insulation is important for all temperature ranges, from near absolute zero in cryogenic applications up to the highest melting point materials which can be used as insulation, ~3000 K. Thermal insulation beyond the highest melting point is no longer a material consideration, since solid materials can no longer exist in that condition and still function as insulators, but rather become purely a heat transfer phenomena involving radiation and convection. This is the case in gas plasmas where temperatures exceed 10,000 K.

The thermal conductivity of materials that could conceivably be used as insulation is shown as a function of temperature in Figure 4.6.1. At very low temperatures, the thermal conductivity approaches zero for all materials. At a few degrees above absolute zero, the thermal conductivity of materials such as pure copper or aluminum exhibits a spike of several thousand W/m·K in the thermal conductivity and then quickly decreases as temperature increases. As the temperature is further increased, the conductivity of metals ranges up to 50–100 W/(m·K). The thermal conductivity of materials can range from 10^{-6} to 1000 W/(m·K). This wide range of thermal conductivity provides the means to control temperatures or heat flows for a wide variety of applications.

Heat Transfer in Thermal Insulation

Efficient use of thermal insulation requires an understanding of the heat transfer that occurs in insulations. Heat transfer occurs by three mechanisms (taken to be independent): conduction through the solid material and interstitial gas in the insulation, gas-phase convection, and thermal radiation. Each will be discussed separately and then combined to give an overall apparent thermal conductivity. Additional discussion can be found in Refs. [1–3].

Solid Conduction

Solid conduction occurs as heat is transferred through the solid portions of the insulation material, from the hot to the cold boundaries. It is characterized by the thermal conductivity of the continuous solid material of the insulation. In a fibrous insulation, such as mineral fiber insulation, this is the conductivity of the material which forms the fibers, the type of contact between the fibers, and the number of fibers per unit volume, i.e., the insulation density. The solid conductivity of the insulation can be modeled by the following equation:

$$k_s = A \cdot k_m \tag{4.6.1}$$

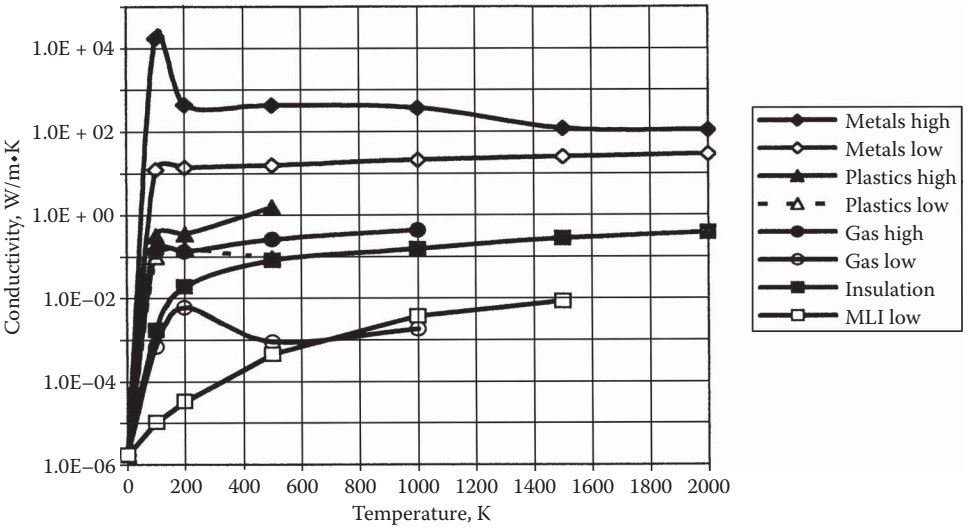

FIGURE 4.6.1 Material thermal conductivity ranges.

where k_s = the thermal conductivity of the insulation material

k_m = the thermal conductivity of the solid-phase material

A = empirical constant which can be related to the load on the insulation, the nature of the contacts or structure of the solid phase, and temperature.

The reader is referred to Refs. [4–6] for models that describe this interaction.

Gas Conduction and Convection

Gas-phase convection is normally suppressed in fibrous or cellular industrial insulation materials because of the insulation density, the closed-cell properties of some solid insulations, or the gas being at a low density in evacuated insulation. In some insulation systems, such as double- or triple-pane windows or low-density open-cell or fibrous insulation, convection can be of importance and will be included in the manufacturers' data sheets showing thermal resistance values. Gas conduction is of importance in most insulations.

Gas conduction at higher pressure ranges will follow a similar equation as solid conduction:

$$k_g = Bk'_g \tag{4.6.2}$$

where k_g = the thermal conductivity of the gas

k'_g = the thermal conductivity of the gas at the mean temperature and pressure of interest

B = an empirical constant.

This shows the insulation conductivity can be reduced by replacing the air in the insulation with a low-conductivity heavy gas such as CO_2, argon, krypton, or high molecular weight hydrocarbons. The thermal conductivity of the insulation can be increased if the air in the insulation is replaced by a high-conductivity gas such as helium or hydrogen. The thermal conductivity ratio of krypton to air is 0.21 while helium to air is 5.7 at STP (273 K and 1 atmosphere).

Trapping a fuel such as hydrogen or a reactant such as oxygen in the insulation can be very dangerous and precautions must be taken to purge or vent the insulation space as a safety measure. In a cryogenic system, there is also the possibility of condensing liquid air in the insulation. The liquid air is enriched in oxygen and will be hazardous if the insulation is combustible.

Equation 4.6.2 is valid as long as the mean free path of the gas is much shorter than the average spacing between solid particles in fibrous or powder insulation or the pore size in a cellular

insulation. In such cases, the gas molecules collide with each other more often than with the insulation surfaces and the gas behaves as if it were at the mean temperature of the insulation. As the gas pressure is reduced, the mean free path of the gas increases and the gas thermal conductivity decreases. At low pressure, k_g is proportional to the gas pressure:

$$k_g = C \cdot k'_g \cdot L \cdot P \tag{4.6.3}$$

where C = a constant which is dependent on the gas at a reference pressure and temperature

L = average distance a gas molecule moves before striking a surface in the porous insulation; this is smaller than the mean free path of the gas.

P = the absolute gas pressure

k'_g = the gas conductivity at the mean insulation temperature and the gas reference pressure, usually taken as 1 atmosphere.

As the gas pressure is lowered, the gas conductivity at some point becomes negligible compared to the radiation and solid conduction components of heat transport. If the insulation interparticle spacing is made smaller than the mean free path of the gas at atmospheric pressure, then the effective gas conductivity in the insulation will be less than the conductivity of the gas at the mean temperature and pressure of the insulation. This is the mechanism by which low-density aerogel insulation or fine particles can attain thermal conductivities less than air at ambient pressure and the mean insulation temperature. More detailed discussions can be found in Refs. [7–9].

Radiation Heat Transfer

The basics of thermal radiation are discussed in Chapter 3 along with the radiation mechanism for insulation containing multiple low-emittance radiation barriers. In powders, cellular or fibrous insulation systems the radiation resistance is provided by reflection, scattering, and absorption.[10,11] The details depend on the optical properties of the material, the size of the particle, and the wavelength of the radiation, which is related to the temperature of the material. In some circumstances, the radiation conductivity for a particulate insulation can be expressed as

$$k_r = \sigma \cdot T^3 / D \tag{4.6.4}$$

where T = absolute temperature (K)

σ = Stefan–Boltzmann constant 5.67×10^{-8} W/m^2·K^4

D = insulation extinction coefficient per unit thickness.

Multilayer insulations consist of multiple low-emissivity metal foils separated by low-conductivity solid spacers. The radiation conductivity for multilayer insulation can be expressed as

$$k_r = \sigma \cdot \varepsilon \cdot T^3 / N \tag{4.6.5}$$

where ε is the emittance of the radiation barrier material, and N is the number of radiation barriers per unit thickness. This shows that in multifoil systems, the radiation heat transfer can be significantly reduced by increasing the number of barrier layers. The emittance for metals at ambient temperature that are used as radiation barriers includes aluminum ($\varepsilon = 0.03$), gold ($\varepsilon = 0.01$–0.02), molybdenum ($\varepsilon = 0.1$), and tantalum ($\varepsilon = 0.05$).

Combined Thermal Conductivity

The combined point thermal conductivity of an insulation can be expressed by

$$k = k_s + k_g + k_r \tag{4.6.6}$$

or

$$k = A \cdot k_{\mathrm{m}} + B \cdot k'_{\mathrm{g}} + \sigma \cdot T^3 / D \tag{4.6.7}$$

The average apparent conductivity of the insulation between two temperatures becomes

$$k_{\mathrm{a}} = A \cdot k_{\mathrm{m}} + B \cdot k'_{\mathrm{g}} + \sigma \cdot \left(T_2^4 - T_1^4\right) / \left(4 \cdot D \cdot \left(T_2 - T_1\right)\right) \tag{4.6.8}$$

Application of this equation to specific types of insulation systems is discussed in the following sections. Most manufacturers report thermal conductivity as the average between two temperatures, typically ambient and a higher or lower temperature. Equation 4.6.9 is the relationship between the point thermal conductivity, $k(t)$, and the average, ka:

$$k_{\mathrm{a}} = \left(\frac{1}{T_2 - T_1}\right) \cdot \int_{T_1}^{T_2} k(t)\mathrm{d}t \tag{4.6.9}$$

Insulation Systems (Nonvacuum and Vacuum)

Powder Systems

Powder insulation consists of particulates such as perlite, vermiculite, beaded Styrofoam, microcellular material, silica, and some types of aerogels. The advantage of this type of insulation is that when poured or blown into the space to be insulated it will flow around obstructions such as piping. Particulates can also be removed by gravity flow, fluidized transfer, or evacuation. This is an advantage in complex process equipment that must be accessible for repair or maintenance. The disadvantage of powder insulation is that a container has to be placed around the region that is to be insulated in order to keep the powder insulation in place and in below ambient temperature systems to eliminate water vapor migration into the powder where it can condense or freeze. If condensation or freezing occurs, the thermal resistance of the insulation will be degraded.

The thermal performance of the insulation is limited by the conduction of the gas filling the pores of the powder. The solid conductivity component is dependent on the multiple point contacts between particles and by selecting a material with low intrinsic solid conductivity. In some powders, the particles are porous rather than solid. Examples are perlite, vermiculite, or agglomerates of smaller particles, such as in fumed silica. Radiation in powder insulation can be reduced through the selection of the proper particle size or the addition of opacifiers such as carbon black or reflective metal flakes of aluminum or copper.[12,13]

Some of the most common powder insulation material properties and thermal conductivities between various temperature ranges are given in Table 4.6.1. Thermal conductivity curves for perlite, vermiculite, and aerogel at various densities are shown in Figure 4.6.2. As shown in Figure 4.6.2, the conductivities of gas-filled perlite and vermiculite powders at the same temperature do not vary greatly from one another since both are dominated by the gas in the insulation pores. The aerogel powder insulation has a pore size approaching the mean free path of the gas, resulting in greatly reduced thermal conductivity.[14,15]

To reduce the conductivity, the gas can be removed from the insulation. This will reduce the apparent thermal conductivity of the insulation by an order of magnitude or more. The level of vacuum which has to be achieved to reduce the gas conductivity to a negligible value is of practical importance. Therefore, the thermal conductivity of various powder insulations is presented as a function of the gas pressure. The evacuated thermal conductivity curves for perlite, aerogel, and microcel with 10% aluminum flakes are shown in Figure 4.6.3. The differences in the powder and the effect of particle size can be seen in these figures.

Handling considerations of powder insulation deserve special mention due to the small particle size of many of the insulations, which can result in airborne dust or respirable hazard while loading

TABLE 4.6.1
Powder Insulation

Materials	Maximum Operating Temperature (K)	Density (kg/m³)	Hot Side Temp (K)	Cold Side Temp (K)	Apparent Thermal Conductivity (W/m·K)
Perlite	1255	112	327	294	0.0418
Vermiculite	1033	144	327	294	0.0677
Silica aerogel	977	80	327	294	0.0303
Silica aerogel with 15 wt% carbon	977	116	327	294	0.0135
Cork	366	208	327	294	0.049
Diatomaceous silica	1144	240	327	294	0.0577

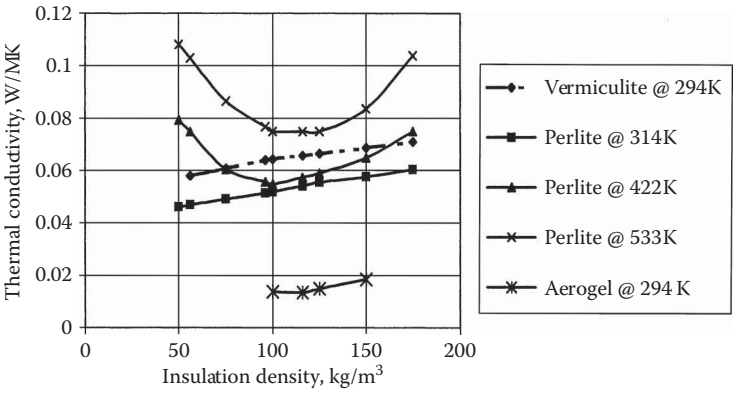

FIGURE 4.6.2 Powder insulation thermal conductivity.

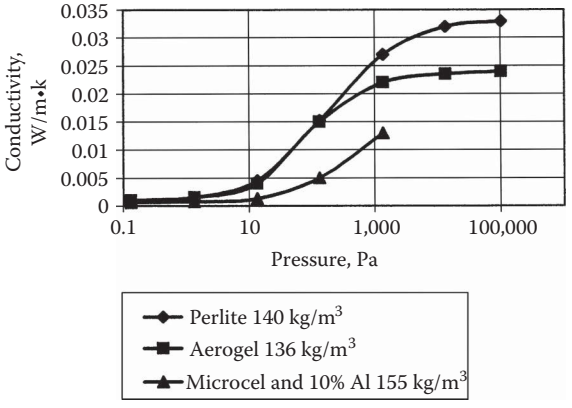

FIGURE 4.6.3 Evacuated powder thermal conductivity from 77 to 300 K.

the insulation powder. If the insulation powder is combustible, the airborne dust can pose an explosion hazard.

Nonvacuum perlite powder insulation is used in cryogenic process cold boxes. Evacuated perlite powder insulation is used in mobile carriers for cryogenic liquid oxygen and nitrogen. Evacuated carbon powder insulation is used in some metal thermos bottles. Powders opacified with metal

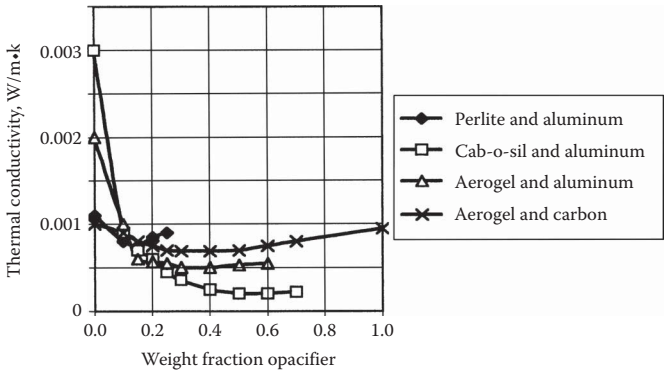

FIGURE 4.6.4 Evacuated opacified powder insulation thermal conductivity.

flakes to reduce radiation heat transfer were used in early small portable liquid oxygen and nitrogen containers, but were later replaced with higher performing evacuated multifoil insulation. The effect of the addition of opacifiers to perlite, Cab-O-Sil (fumed silica), and aerogel is shown in Figure 4.6.4.

Evacuated Multifoil Insulation

Evacuated multifoil insulation has the lowest thermal conductivity of any insulation. This is achieved by removing the gas from the insulation space, using very low solid-conductivity lightweight fiberglass or plastic spacers to separate the radiation shields, and reducing the radiation heat transfer with many low-emittance metal foils or metallized films. This type of insulation has been used successfully from liquid helium temperatures to 1400 K with the correct selection of supporting materials.[16–19]

The selection of material is critical for the insulation to achieve a low-thermal conductivity and to maintain its performance over the life of the system. Problems that can occur are out-gassing or off-gassing of the materials, which can degrade the vacuum or condense on the cooler radiation barrier surfaces and increase the foil emittance. Reactions between the radiation barriers and the spacer material can also increase the solid conduction and reduce the foil emittance. In high-temperature systems, the insulation assembly can be altered to use reduced thermal conductivity materials as the operating temperature decreases. Multifoil insulation systems, which have been used successfully in the past, are listed in Table 4.6.2 along with the operating temperature range.

Commercial Fibrous and Solid Insulation Systems for Moderate and High Temperatures

Introduction

This subsection will deal with systems operating at temperatures above 300 K. Processes operating at moderate or high temperatures are insulated to conserve energy, reduce risk of injury, and control temperature. A variety of products are available for a given temperature range and the thermal properties of a given type of insulation at a given temperature can vary significantly among vendors. It is important, therefore, to verify the temperature limits and the measured thermal conductivity for the specific product under consideration.

Health and Safety

Occupational Safety and Hazard Administration guidelines limit the operating temperatures of accessible surfaces. In some regions, state or local codes may also apply. Safety considerations for systems operating above ambient temperature are often taken to be more crucial than energy savings. The skin damage resulting from hot surface contact depends on a combination of factors such as surface temperature, contact time, and properties of the surface material such as thermal conductivity, specific heat, and density.[20,21] A suggested design for personnel protection is to limit accessible surface temperatures to about 52°C for highly conductive (metal) surfaces and 65°C for nonconductive surfaces.[22]

TABLE 4.6.2
Multifoil Vacuum Insulation

Materials							
Radiation Barrier	Spacer	Maximum Operating Density (K)	Layer Density (layers/cm)	Density (kg/m³)	Hot Side Temp (K)	Cold Side Temp (K)	Apparent Thermal Conductivity (W/m·K)
Aluminum foil	Glass paper	750	24	87	294	77	0.000036
Aluminum foil	Glass mat	750	4	19	294	77	0.00017
Aluminized Mylar	None	370	55	50	294	77	0.000042
Copper foil	Quartz paper	1000	31	339	1000	294	0.00095
Nickel foil	Quartz cloth	1200	42	384	1200	294	0.0021
Molybdenum foil	Zirconia cloth	1600	50	459	1500	294	0.0026

Note: Vacuum level = 0.1 μm.

In some cases, insulating materials contain binders or additives which may volatilize near the upper temperature limit of their range of operation. This upper limit temperature may be approached for the insulation immediately adjacent to a hot surface. The out-gassing is usually limited to the first few hours of heating but must be taken into consideration, especially for insulations used in enclosed areas. The manufacturer's literature should always be examined for warnings about initial off-gassing.

Heat Loss Calculations

Process piping and flat furnace insulations are the most common types of insulation to be considered. Virtually all exposed surfaces operating at temperatures above about 60°C are candidates for thermal insulation. Economic and safety considerations become more important as the temperature increases.

The calculated heat loss from high-temperature surfaces requires consideration of the entire system, inside material to outside air. In many process flow situations, steam lines, for example, the inside heat transfer coefficient is large so the thermal resistance attributable to the inside film coefficient can be neglected. Similarly, the thermal resistance of metal walls and pipes is generally neglected in comparison with the thermal resistance of even a minimal thickness of insulation. The thermal conductivity or thermal resistance of insulation materials to be applied to an outside surface, the external heat transfer coefficient for conduction–convection, and the loss to the surroundings due to radiation are of primary importance.

Discussions of the calculation of heat loss from pipes or flat surfaces at temperatures above ambient are discussed elsewhere in this handbook and in texts on heat transfer. A "standard practice" for calculating heat gain or heat loss complete with supporting computer code has been developed by the American Society for Testing and Materials (ASTM).[23] This Standard Practice published by the ASTM forms the basis for a program entitled "3E Plus, Insulation Thickness Computer Program" and is obtainable from the North American Insulation Manufacturers Association.[24]

The temperature change across moderate or high-temperature insulation can be very large. Since the thermal conductivity of insulations used in such systems increases with temperature, it is necessary to use either mean values for the insulation properties over the range of temperatures to be encountered or use temperature-dependent expressions in Fourier's law for calculating steady-state heat loss from hot systems.

Heat loss calculations require reliable thermal properties for the insulations that are used, exterior surface emittances, and knowledge of the exterior conditions such as air temperature and wind speed. The following discussion contains selected thermal data for a number of materials. Products that are selected for use should be validated by thermal test data obtained in accordance with ASTM C 177,[25] ASTM C 335,[26] ASTM C 518,[27] or C 1033.[28]

The heat transfer through thermal insulations used to reduce heat loss is often described by expressions like Equation 4.5.10 with T being on an absolute temperature scale:

$$k_a(T) = a + b \cdot T + c \cdot T^3 \tag{4.6.10}$$

where the T^3 term is associated with radiative transport, and the linear part of the equation is related to conduction. The radiative term should be written in terms of absolute temperature and the coefficients a, b, and c are positive. Equations 4.6.11–4.6.13 are also used to correlate thermal conductivity with temperature:

$$k_a(T) = a + b \cdot T + c \cdot T^2 \tag{4.6.11}$$

$$k_a(T) = \exp(a + b \cdot T) \tag{4.6.12}$$

$$k_a(T) = a + b \cdot T \tag{4.6.13}$$

Care must be exercised in interpreting laboratory k_a data, especially when large temperature differences are anticipated.[29] Measured k_a are commonly reported as the average of the cold and hot side temperatures. This value is then taken to be a point value for the apparent thermal conductivity. The measurement, however, was actually for the mean value of k_a on the temperature interval of the test. In the case of large measurement intervals, data are best described by an integral method.[30]

Thermal Insulations

A variety of thermal insulating materials are available for use on surfaces operating above 300 K. The maximum allowable temperature for an insulation type is the first consideration in selecting an insulation for a particular application. Table 4.6.3 contains a list of commonly used insulations, an

indication of the maximum application temperature, and a reference to a standard specification. The table contains materials used to insulate pipes, furnaces, and process vessels.

The standard specifications for insulations 1–12 in Table 4.6.3 include sufficient data to determine coefficients for Equation 4.6.10. The coefficients are listed in Table 4.6.4 along with apparent thermal conductivities at selected temperatures.

Table 4.6.5 contains k_a values for calcium silicate and perlite pipe insulation. These data are representative of commercially available products. Table 4.6.6 contains k_a values for several fibrous-type insulations that are representative of commercially available products. Since the data are from various manufacturers, it is not possible to interpolate in density.

Insulation Application

Thermal Insulation Products and Installation

The thermal data contained in the previous paragraphs are representative of the various types of insulation that are available for pipes and flat surfaces. The technical data for a specific product should be consulted before design calculations are completed. The performance of thermal insulations of all types requires installation in accordance with manufacturer's instructions and regular maintenance to remove and replace damaged sections. In general, the thermal resistance of porous or cellular insulation decreases if water is sorbed into the insulation. Thermal insulation is covered with mastics or water impermeable sheathing to prevent water uptake.

Vacuum Maintenance

In order to achieve the design thermal conductivity of a vacuum-insulated system over the life of the system, the vacuum level of the insulation must be maintained at the design value. This is achieved by checking the joints in the enclosure to eliminate air leaks into the vacuum space, calculating the gas permeation through the wall of the enclosure, off-gassing the insulation for a sufficient period of time before sealing the system, and through the addition of active chemical getters and adsorbents.

In cryogenic liquid oxygen, nitrogen, and argon systems, oxygen, nitrogen, and water can be adsorbed using molecular sieves placed on the cold wall of the system. Hydrogen, which will outgas from the metal walls of the enclosure and from the metal radiation foils, will not be adsorbed in significant quantities until the cold side attains a temperature that is below liquid hydrogen. Therefore, an active metal getter has to be placed in the vacuum space. These materials combine chemically

with the reactive gas to remove it from the vacuum space. SAES Getters Inc. produces commercial getters for this purpose.

In ambient and elevated temperature systems, adsorption will not work. The only methods available for vacuum maintenance are chemical getters or very long evacuations combined with high-temperature out-gassing of the insulation, or the use of insulation with very small pore sizes that can tolerate high vacuum levels. Vacuum maintenance materials and temperature levels are given in Table 4.6.7. References 32 and 33 are sources of additional information.

4.7 ENERGY AUDIT FOR BUILDINGS

Moncef Krarti

Introduction

Since the oil embargo of 1973, significant improvements have been made in the efficiency of new buildings. However, the vast majority of the existing stock of buildings are more than a decade old and do not meet current energy-efficient construction standards (EIA, 1991). Therefore, energy retrofits of existing buildings will be required for decades to come if the overall energy efficiency of the building stock is to meet the standards.

Investing to improve the energy efficiency of buildings provides an immediate and relatively predictable positive cash flow resulting from lower energy bills. In addition to the conventional financing options available to owners and building operators (such as loans and leases), other methods are available to finance energy retrofits for buildings. One of these methods that is becoming increasingly common is performance contracting, in which payment for a retrofit project is contingent upon its successful outcome. Typically, an energy service company (ESCO) assumes all the risks for a retrofit project by performing the engineering analysis and obtaining the initial capital to purchase and install equipment needed for energy efficiency improvements. Energy auditing is an important step used by ESCOs to ensure the success of their performance-contracting projects.

Currently, several large industrial and commercial buildings have established internal energy management programs, based on energy audits, to reduce waste in energy use or to comply with the specifications of some regulations and standards. Other building owners and operators take advantage of available financial incentives typically offered by utilities or state agencies to perform energy audits and implement energy conservation measures (ECMs).

In the 1970s, building energy retrofits consisted of simple measures such as shutting off lights, turning down heating temperatures, turning up air-conditioning temperatures, and reducing the hot water temperatures. Today, building energy management infers complete control of the energy systems and consumption within a facility. Therefore, the energy auditor should be aware of key energy issues such as the subtleties of electrical utility rate structures and of the latest building energy efficiency technologies and their applications.

This section describes a general but systematic procedure for energy auditing that is suitable for both commercial buildings and industrial facilities. Some of the commonly recommended ECMs are briefly discussed. A case study for an office building is presented to illustrate the various tasks involved in an energy audit. Finally, an overview is provided to outline the existing methods for measurement and verification of energy savings incurred by the implementation of ECMs.

Types of Energy Audits

The term "energy audit" is widely used and may have different meanings depending on the ESCOs. Energy auditing of buildings can range from a short walk-through of the facility to a detailed analysis with hourly computer simulation. Generally, four types of energy audits can be distinguished as briefly described as follows.

Walk-Through Audit

This audit consists of a short on-site visit of the facility to identify areas where simple and inexpensive actions can provide immediate energy and/or operating cost savings. Some engineers refer to these types of actions as operating and maintenance (O&M) measures. Examples of O&M measures include lowering heating set point temperatures, replacing broken windows, insulating exposed hot water or steam pipes, and adjusting boiler fuel–air ratio.

Utility Cost Analysis

The main purpose of this type of audit is to carefully analyze the operating costs of the facility. Typically, the utility data over several years are evaluated to identify the patterns of energy use, peak demand, weather effects, and the potential for energy savings. To perform this analysis, it is recommended that the energy auditor conducts a walk-through survey to get acquainted with the facility and its energy systems.

It is important that the energy auditor understands clearly the utility rate structure that applies to the facility for several reasons, including the following:

- Checking the utility charges and ensuring that no mistakes were made in calculating the monthly bills. Indeed, the utility rate structures for commercial and industrial facilities can be quite complex, with ratchet charges and power factor penalties.
- Determining the most dominant charges in the utility bills. For instance, peak demand charges can be a significant portion of the utility bill, especially when ratchet rates are applied. Peak usage shaving measures can then be recommended to reduce these demand charges.
- Identifying if the facility can benefit from using other utility rate structures or purchasing cheaper fuel to reduce its operating costs. This analysis can provide a significant reduction in the utility bills, especially with the electrical industry deregulation and the advent of real time pricing (RTP) rate structures.

Moreover, the energy auditor can determine whether or not the facility is prime for energy retrofit projects by analyzing the utility data. Indeed, the energy use of the facility can be normalized and compared to indices (for instance, the energy use per unit of floor area for commercial buildings—or per unit of a product for industrial facilities).

Standard Energy Audit

The standard audit provides a comprehensive analysis of the energy systems of the facility. In addition to the activities described for the walk-through audit and the utility cost analysis described earlier, the standard energy audit includes the development of a baseline for the energy use of the facility and the evaluation of the energy savings and the cost-effectiveness of appropriately selected ECMs. The step-by-step approach of the standard energy audit is similar to that of the detailed energy audit, which is described in the following subsection.

Typically, simplified tools are used in the standard energy audit to develop baseline energy models and to predict the energy savings of ECMs. Among these tools are the degree-day methods and linear regression models (Fels, 1988). In addition, a simple payback analysis is generally performed to determine the cost-effectiveness of ECMs.

Detailed Energy Audit

This is the most comprehensive but also time-consuming energy audit type. Specifically, the detailed energy audit includes the use of instruments to measure energy use for the whole building and/or for some energy systems within the building (for instance, by end uses: lighting, office equipment, fans, chiller, etc.). In addition, sophisticated computer simulation programs are typically employed for detailed energy audits to evaluate and recommend energy retrofits for the facility.

The techniques available to perform measurements for an energy audit are diverse. During an on-site visit, handheld and clamp-on instruments can be used to determine the variance of some building parameters such as the indoor air temperature, the luminance level, and the electrical energy use. When long-term measurements are needed, sensors are typically used and are connected to a data acquisition system so measured data can be stored and be remotely accessible. Recently, nonintrusive load monitoring (NILM) techniques have been proposed (Shaw et al., 1998). The NILM technique can determine the real-time energy use of the significant electrical loads in

a facility by using only a single set of sensors at the facility service entrance. The minimal effort associated with using the NILM technique compared to the traditional multimetering approach (which requires a separate set of sensors to monitor energy consumption for each end use) makes the NILM a very attractive and inexpensive load-monitoring technique for ESCOs and facility owners.

The computer simulation programs used in the detailed energy audit typically provide the energy use distribution by load type (i.e., energy use for lighting, fans, chillers, boilers, etc.). They are often based on dynamic thermal performance of the building energy systems and usually require a high level of engineering expertise and training. These simulation programs range from those based on the bin method (Knebel, 1983) to those that provide hourly building thermal and electrical loads such as DOE-2 (LBL, 1980).

In the detailed energy audit, more rigorous economical evaluation of the ECMs is generally performed. Specifically, the cost-effectiveness of energy retrofits may be determined based on the life-cycle cost (LCC) analysis rather than the simple payback period analysis. LCC analysis takes into account a number of economic parameters such as interest, inflation, and tax rates.

General Procedure for a Detailed Energy Audit

To perform an energy audit, several tasks are typically carried out depending on the type of the audit and the size and function of the building. Some of the tasks may have to be repeated, reduced in scope, or even eliminated based on the findings of other tasks. Therefore, the execution of an energy audit is often not a linear process and is rather iterative. However, a general procedure can be outlined for most buildings.

Step 1: Building and Utility Data Analysis

The main purpose of this step is to evaluate the characteristics of the energy systems and the patterns of energy use for the building. The building characteristics can be collected from the architectural/mechanical/electrical drawings and/or from discussions with building operators. The energy use patterns can be obtained from a compilation of utility bills over several years. Analysis of the historical variation of the utility bills allows the energy auditor to determine any seasonal and weather effects on the building energy usage. Some of the tasks that can be performed in this step are presented as follows, with the key goals expected from each task noted in italics:

- Collect at least 3 years of records of utility data [*to identify a historical energy use pattern*].
- Identify the fuel types used (electricity, natural gas, oil, etc.) [*to determine the fuel type that accounts for the largest energy use*].
- Determine the patterns of fuel use by fuel type [to identify the peak demand for energy use by fuel type].
- Understand utility rate structure (energy and demand rates) [to evaluate if the building is penalized for peak demand and if cheaper fuel can be purchased].
- Analyze the effect of weather on fuel consumption.
- Perform utility energy use analysis by building type and size (building signature can be determined including energy use per unit area [*to compare against typical indices*]).

Step 2: Walk-Through Survey

This step should identify potential energy savings measures. The results of this step are important since they determine if the building warrants any further energy auditing work. Some of the tasks involved in this step are as follows:

- Identify the customer's concerns and needs.
- Check the current O&M procedures.

- Determine the existing operating conditions of major energy use equipment (lighting, heating, ventilating, and air conditioning (HVAC) systems, motors, etc.).
- Estimate the occupancy, equipment, and lighting (energy use density and hours of operation).

Step 3: Baseline for Building Energy Use

The main purpose of this step is to develop a base-case model that represents the existing energy use and operating conditions for the building. This model will be used as a reference to estimate the energy savings due to appropriately selected ECMs. The major tasks to be performed during this step are as follows:

- Obtain and review architectural, mechanical, electrical, and control drawings.
- Inspect, test, and evaluate building equipment for efficiency, performance, and reliability.
- Obtain all occupancy and operating schedules for equipment (including lighting and HVAC systems).
- Develop a baseline model for building energy use.
- Calibrate the baseline model using the utility data and/or metered data.

Step 4: Evaluation of Energy-Saving Measures

In this step, a list of cost-effective ECMs is determined using both energy savings and economic analysis. To achieve this goal, the following tasks are recommended:

- Prepare a comprehensive list of ECMs (using the information collected in the walk-through survey).
- Determine the energy savings due to the various ECMs pertinent to the building by using the baseline energy use simulation model developed in Step 3.
- Estimate the initial costs required to implement the ECMs.
- Evaluate the cost-effectiveness of each ECM using an economical analysis method (simple payback or LCC analysis).

Tables 4.7.1 and 4.7.2 provide summaries of the energy audit procedure recommended, respectively, for commercial buildings and for industrial facilities. Energy audits for thermal and electrical systems are separated since they are typically subject to different utility rates.

Common Energy Conservation Measures

In this subsection, some ECMs commonly recommended for commercial and industrial facilities are briefly discussed. It should be noted that the list of ECMs presented later does not pretend to be exhaustive nor comprehensive. It is provided merely to indicate some of the options that the energy auditor can consider when performing an energy analysis of a commercial or an industrial facility. However, it is strongly advised that the energy auditor keeps abreast of any new technologies that can improve the facility energy efficiency. Moreover, the energy auditor should recommend the ECMs only after he performs an economical analysis for each ECM.

Building Envelope

For some buildings, the envelope (i.e., walls, roofs, floors, windows, and doors) can have an important impact on the energy used to condition the facility. The energy auditor should determine the actual characteristics of the building envelope. During the survey, a sheet for the building envelope should be established to include information such as materials of construction (for instance, the level of insulation in walls, floors, and roofs) and the area and number of various assemblies of

	Reduction of harmonics

the envelope (for instance, the type and the number of panes for the windows should be noted). In addition, comments on the repair needs and recent replacement should be noted during the survey.

Some of the commonly recommended ECMs to improve the thermal performance of building envelope are as follows:

1. *Addition of Thermal Insulation*. For building surfaces without any thermal insulation, this measure can be cost-effective.

2. *Replacement of Windows.* When windows represent a significant portion of the exposed building surfaces, using more energy-efficient windows (high-thermal resistance frame and glazing, low-emissivity glazing, airtight, etc.) can be beneficial in both reducing the energy use and improving the indoor comfort level.
3. *Reduction of Air Leakage.* When the infiltration load is significant, leakage areas of the building envelope can be reduced by simple and inexpensive weather stripping techniques.

The energy audit of the envelope is especially important for residential buildings. Indeed, the energy use from residential buildings is dominated by weather since heat gain and/or loss from direct conduction of heat or from air infiltration/exfiltration through building surfaces accounts for

a major portion (50%–80%) of the energy consumption. For commercial buildings, improvements to the building envelope are often not cost-effective due to the fact that modifications to the building envelope (replacing windows, adding thermal insulation in walls) typically are very expensive. However, it is recommended to systematically audit the envelope components not only to determine the potential for energy savings but also to ensure the integrity of its overall condition. For instance, thermal bridges, if present, can lead to heat transfer increase and to moisture condensation. The moisture condensation is often more damaging and costly than the increase in heat transfer since it can affect the structural integrity of the building envelope.

Electrical Systems

For most commercial buildings and a large number of industrial facilities, electrical energy cost constitutes the dominant part of the utility bill. Lighting, office equipment, and motors are the electrical systems that consume the major part of energy usage in commercial and industrial buildings.

1. *Lighting.* Lighting for a typical office building represents, on average, 40% of the total electrical energy use. There are a variety of simple and inexpensive measures to improve the efficiency of lighting systems. These measures include the use of energy-efficient lighting lamps and ballasts, the addition of reflective devices, delamping (when the luminance levels are above the recommended levels by the standards), and the use of daylighting controls. Most lighting measures are especially cost-effective for office buildings for which payback periods are less than 1 year.
2. *Office Equipment.* Office equipment constitutes the fastest growing part of the electrical loads, especially in commercial buildings. Office equipment includes computers, fax machines, printers, and copiers. Today, there are several manufacturers that provide energy-efficient office equipment (such as those that comply with U.S. EPA Energy Star specifications). For instance, energy-efficient computers automatically switch to a low-power "sleep" mode or off mode when not in use.
3. *Motors.* The energy cost to operate electric motors is a significant part of the operating budget of any commercial and industrial building. Measures to reduce the energy cost of using motors include reducing operating time (turning off unnecessary equipment), optimizing motor systems, using controls to match motor output with demand, using variable speed drives for air and water distribution, and installing energy-efficient motors. Table 4.7.3 provides typical efficiencies for several motor sizes.

In addition to the reduction in the total facility electrical energy use, retrofits of the electrical systems decrease the cooling loads and, therefore, further reduce the electrical energy use in the building. These cooling energy reductions, as well as possible increases in thermal energy use (for space heating), should be accounted for when evaluating the cost-effectiveness of improvements in lighting and office equipment.

The integration of daylighting controls in office buildings is used as an illustrative example of proven energy efficiency measures used to reduce lighting energy consumption. Indeed, several studies have indicated that daylighting can offer a cost-effective alternative to electrical lighting for commercial and institutional buildings. Through sensors and controllers, daylighting can reduce and even eliminate the use of electrical lighting required to provide sufficient illuminance levels inside office spaces. A simplified calculation method has been developed by Krarti et al. (2005) to estimate the reduction in the total lighting energy use due to daylighting with dimming controls for office buildings. The method has been shown to apply for office buildings in the United States as well as in other countries (Al-Mohimen et al., 2005). The simplified calculation method can be used as a predesign tool to assess the potential of daylighting in saving electricity use associated with artificial lighting for office buildings.

TABLE 4.7.3
Typical Efficiencies of Motors

Motor Size (HP)	Standard Efficiency (%)	High Efficiency (%)
1	72	81
2	76	84
3	77	89
5	80	89
7.5	82	89
10	84	89
15	86	90
20	87	90
30	88	91
40	89	92
50	90	93

To determine the percent savings, f_d, in annual use of artificial lighting due to implementing daylighting using daylighting controls in office buildings, Krarti et al. (2005) found that the following equation can be used:

$$f_d = b\left[1 - \exp\left(-a\tau_w A_w / A_p\right)\right]\frac{A_p}{A_f}, \tag{4.7.1}$$

where

- A_w/A_p: window to perimeter floor area. This parameter provides a good indicator of the window size relative to the daylit floor area.
- A_p/A_f: perimeter to total floor area. This parameter indicates the extent of the daylit area relative to the total building floor area. Thus, when $A_p/A_f = 1$, the whole building can benefit from daylighting.
- a and b: coefficients that depend only on the building location and are given by Table 4.7.4 for various sites throughout the world.

HVAC Systems

The energy use due to HVAC systems can represent 40% of the total energy consumed by a typical commercial building. The energy auditor should obtain the characteristics of major HVAC equipment to determine the condition of the equipment, its operating schedule, its quality of maintenance, and its control procedures. A large number of measures can be considered to improve the energy performance of both primary and secondary HVAC systems. Some of these measures are listed as follows:

1. *Setting up/back thermostat temperatures.* When appropriate, setback of heating temperatures can be recommended during unoccupied periods. Similarly, setup of cooling temperatures can be considered.
2. *Retrofit of constant air volume (CAV) systems.* For commercial buildings, variable air volume (VAV) systems should be considered when the existing HVAC systems rely on constant-volume fans to condition part or the entire building.
3. *Installation of heat recovery systems.* Heat can be recovered from some HVAC equipment. For instance, heat exchangers can be installed to recover heat from air handling unit (AHU) exhaust air streams and from boiler stacks.

4. *Retrofit of central heating plants*. The efficiency of a boiler can be drastically improved by adjusting the fuel–air ratio for proper combustion. In addition, installation of new energy-efficient boilers can be economically justified when old boilers are to be replaced.
5. *Retrofit of central cooling plants:* Currently, there are several chillers that are energy efficient and easy to control and operate and are suitable for retrofit projects.

It should be noted that there is a strong interaction between various components of a heating and cooling system. Therefore, a whole-system analysis approach should be followed when retrofitting a building HVAC system. Optimizing the energy use of a central cooling plant (which may include chillers, pumps, and cooling towers) is one example of using a whole-system approach to reduce the energy use for heating and cooling buildings.

Compressed Air Systems

Compressed air has become an indispensable tool for most manufacturing facilities. Its uses range from air-powered hand tools and actuators to sophisticated pneumatic robotics. Unfortunately, staggering amounts of compressed air are wasted in a large number of facilities. It is estimated that only about 20%–25% of input electrical energy is delivered as useful compressed air energy. Leaks are reported to account for 10%–50% of the waste while misapplication accounts for 5%–40% of the loss of compressed air (Howe and Scales, 1998).

To improve the efficiency of compressed air systems, the auditor can consider several issues including whether compressed air is the right tool for the job (for instance, electric motors are more energy efficient than air-driven rotary devices), how the compressed air is applied (for instance, lower pressures can be used to supply pneumatic tools), how it is delivered and controlled (for

instance, the compressed air needs to be turned off when the process is not running), and how the compressed air system is managed (for each machine or process, the cost of compressed air needs to be known to identify energy and cost savings opportunities).

Energy Management Controls

Because of the steady decrease in the cost of computer technology, automated control of a wide range of energy systems within commercial and industrial buildings is becoming increasingly popular and cost effective. An energy management and control system (EMCS) can be designed to control and reduce the building energy consumption within a facility by continuously monitoring the energy use of various equipment and making appropriate adjustments. For instance, an EMCS can automatically monitor and adjust indoor ambient temperatures, set fan speeds, open and close AHU dampers, and control lighting systems.

If an EMCS is already installed in the building, it is important to recommend a system tune-up to ensure that the controls are operating properly. For instance, the sensors should be calibrated regularly in accordance with manufacturers' specifications. Poorly calibrated sensors may cause an increase in heating and cooling loads and may reduce occupant comfort.

As an example of the impact of improved controls on energy use, the performance of demand ventilation control options for car garages are discussed. Automobile parking garages can be partially open or fully enclosed. Partially open garages are typically above grade with open sides and do not need generally mechanical ventilation. However, fully enclosed parking garages are usually underground and require mechanical ventilation. Indeed, in absence of ventilation, enclosed parking facilities present several indoor air quality problems. The most serious is the emission of high levels of carbon monoxide (CO) by cars within the parking garages. Other concerns related to enclosed garages are the presence of oil and gasoline fumes, and other contaminants such as oxides of nitrogen (NO_x) and smoke haze from diesel engines.

To determine the adequate ventilation rate for garages, two factors are typically considered: the number of cars in operation and the emission quantities. The number of cars in operation depends on the type of the facility served by the parking garage and may vary from 3% (in shopping areas) up to 20% (in sports stadium) of the total vehicle capacity (ASHRAE, 2015). The emission of carbon monoxide depends on individual cars including such factors as the age of the car, the engine power, and the level of car maintenance.

For enclosed parking facilities, ASHRAE standard 62-1989 specifies fixed ventilation rate of below 7.62 L/s m^2 (1.5 cfm/ft^2) of gross floor area (ASHRAE, 1989). Therefore, a ventilation flow of about 11.25 air changes per hour is required for garages with 2.5-m ceiling height. However, some of the model code authorities specify an air change rate of 4–6 air changes per hour. Some of the model code authorities allow ventilation rate to vary and be reduced to save fan energy if CO demand-controlled ventilation is implemented, that is, a continuous monitoring of CO concentrations is conducted, with the monitoring system being interlocked with the mechanical exhaust equipment. The acceptable level of contaminant concentrations varies significantly from code to code. A consensus on acceptable contaminant levels for enclosed parking garages is needed. Unfortunately, ASHRAE standard 62-1989 does not address the issue of ventilation control through contaminant monitoring for enclosed garages. Thus, ASHRAE commissioned a research project 945-RP (Krarti et al. 1999) to evaluate current ventilation standards and recommend rates appropriate to current vehicle emissions/usage. Based on this project, a general methodology has been developed to determine the ventilation requirements for parking garages.

Figure 4.7.1 indicates also the fan energy savings achieved by the On–Off and VAV systems (relative to the fan energy use by the CV system). As illustrated in Figure 4.7.1, significant fan energy savings can be obtained when demand CO ventilation control strategy is used to operate the ventilation system while maintaining acceptable CO levels within the enclosed parking facility. These energy savings depend on the pattern of car movement within the parking facility. Figure 4.7.2 indicates three types of car movement profiles considered in the analysis considered by Krarti et al. (1999).

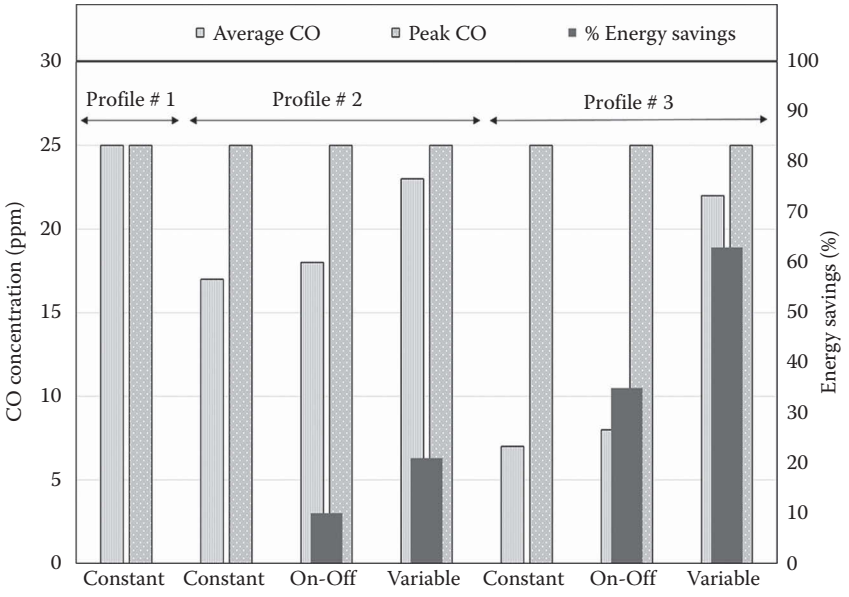

FIGURE 4.7.1 Typical energy savings and maximum CO level obtained for demand CO ventilation controls.

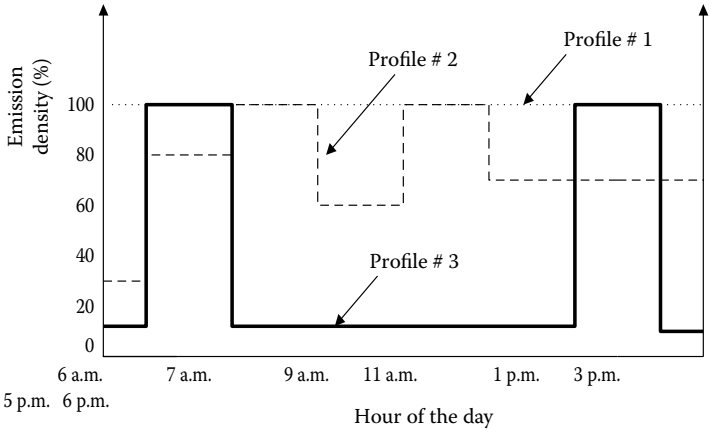

FIGURE 4.7.2 Car movement profiles used in the analysis conducted by Krarti et al. (1999).

Indoor Water Management

Water and energy savings can be achieved in buildings by using water-saving equipment instead of the conventional fixtures for toilets, faucets, showerheads, dishwashers, and clothes washers. Savings can also be achieved by eliminating leaks in pipes and fixtures.

Table 4.7.5 provides the typical water usage of conventional and water-efficient fixtures. In addition, Table 4.7.5 indicates the hot water consumption by each fixture as a fraction of the total water usage. With water-efficient fixtures, a savings of 50% of water use can be achieved.

New Technologies

The energy auditor may consider the potential of implementing and integrating new technologies within the facility. It is, therefore, important that the energy auditor understands these new

TABLE 4.7.5
Characteristics of Water-Using Fixtures

End Use	Conventional Fixtures	Water-Efficient Fixtures	Usage Pattern	Hot Water Usage (%)
Toilets	3.5 gal/flush	1.6 gal/flush	4 flushes/person/day	0

Dishwashers	14.0 gal/load	8.5 gal/load	0.17 loads/person/day	100
Clothes washers	55.0 gal/load	42.0 gal/load	0.3 loads/person/day	25
Leaks	10% total use	2% total use	N/A	50

technologies and knows how to apply them. Among the new technologies that can be considered for commercial and industrial buildings include:

Building Envelope Technologies

Recently, several materials and systems have been proposed to improve the energy efficiency of the building envelope, especially windows, including the following:

- Spectrally selective glasses that can optimize solar gains and shading effects.
- Chromogenic glazing that change their properties automatically depending on temperature and/or light-level conditions (similar to sunglasses that become dark in sunlight).
- Building integrated photovoltaic panels that can generate electricity while absorbing solar radiation and reducing heat gain through the building envelope (typically roofs).

Light Pipe Technologies

While the use of daylighting is straightforward for perimeter zones that are near windows, it is not usually feasible for interior spaces, particularly those without skylights. Recent but still emerging technologies allow one to "pipe" light from roof or wall-mounted collectors to interior spaces that are not close to windows or skylights.

HVAC Systems and Controls

Several strategies can be considered for energy retrofits, including the following:

- Heat recovery technologies such as rotary heat wheels and heat pipes can recover 50%–80% of the energy used to heat or cool ventilation air supplied to the building.
- Desiccant-based cooling systems are now available and can be used in buildings with large dehumidification loads during long periods (such as hospitals, swimming pools, and supermarket fresh produce areas).
- Geothermal heat pumps can provide an opportunity to take advantage of the heat stored underground to condition building spaces.
- Thermal energy storage (TES) systems offer a mean of using less-expensive off-peak power to produce cooling or heating to condition the building during on-peak periods; several optimal control strategies have been developed in recent years to maximize the cost savings of using TES systems.

Cogeneration

This is not really a new technology. However, recent improvements in its combined thermal and electrical efficiency have made cogeneration cost-effective in several applications including institutional buildings such as hospitals and universities.

Case Study

To illustrate the energy audit process described previously, a case study is presented. The activities performed for each step of the energy audit are briefly described. For more details, refer to Kim et al. (1998). The building analyzed in this case study is a medium-size office building located in Seoul, Korea.

STEP 1: BUILDING AND UTILITY DATA ANALYSIS

The first step in the building energy audit process is to collect all available information about the energy systems and the energy use pattern of the building. This information was collected before the field survey, in particular, from the architectural, mechanical, and electrical drawings and utility bills.

Building Characteristics

The building is a 26-story office building with a 2-story penthouse and 4-story basement. It is located in downtown Seoul, Korea. The structure of the building consists of modular concrete and steel frame. The building area is 3920 m^2 and the site area is 6555 m^2. Single-glazed windows are installed throughout the building. Figure 4.7.3 shows a typical floor plan of the building. Table 4.7.6 describes the various construction materials used throughout the building.

Energy Use

Figure 4.7.4 summarizes the monthly electrical energy use of the building for 1993. The monthly average dry-bulb outdoor air temperature recorded for 1993 is also presented in Figure 4.7.4. It is clear that the electrical energy use increases during the summer months (June through October) when the outdoor temperatures are high. During the other months, the electrical energy use is almost constant and can be attributed mostly to lighting and office equipment loads. Preliminary analysis of the metered building energy indicates that natural gas consumption is inconsistent

TABLE 4.7.6
Building Construction Materials

Component	Materials
Exterior wall	5 cm tile
	16 cm concrete
	2.5 cm foam insulation
	0.6 cm finishing material
Roof	5 cm lightweight concrete
	15 cm concrete
	2.5 cm foam insulation
Interior wall	2 cm finishing cement mortar
	19 cm concrete block
Glazing	1.2 cm thick single-pane glazing
Underground wall	25 cm concrete

from month to month. For example, gas consumption during January is six times higher than during December, even though the weather conditions are similar for both months. Therefore, the recorded data for natural gas were considered unreliable and only metered electrical energy data were analyzed.

STEP 2: ON-SITE SURVEY

A one-day field survey was conducted with the assistance of the building operator in the summer of 1996. During the survey, several useful and revealing information and engineering data were collected. For instance:

- It was found that the building had been retrofitted with energy-efficient lighting systems. The measurement of luminance levels throughout the working areas indicated adequate lighting. To determine an estimate of the energy use for lighting, the number and type of lighting fixtures were recorded.
- It was observed that the cooling and heating temperature set points were 25.5°C and 24.5°C, respectively. However, indoor air temperature and relative humidity measurements during the field survey revealed that during the afternoon the thermal conditions

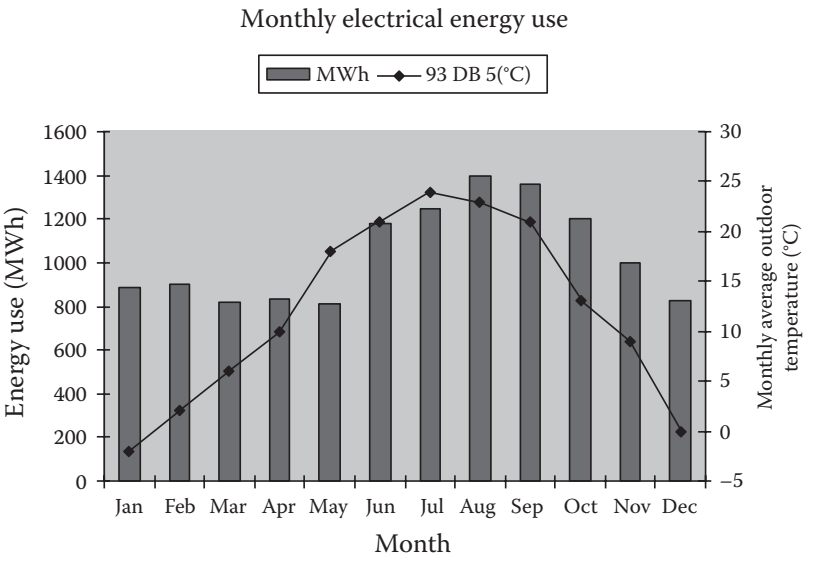

FIGURE 4.7.4 Monthly actual electrical energy consumption.

were uncomfortable in several office spaces, with average air dry-bulb temperature of 28°C and relative humidity of 65%. A discussion with the building operator indicated that the chillers were no longer able to meet the cooling loads following the addition of several computers in the building during the last few years. As a solution, an ice storage tank was then added to reduce the peak cooling load.

- It was discovered during the survey that the building is heated and cooled simultaneously by two systems: CAV and fan coil unit (FCU) systems. The CAV system is complemented by the FCU system as necessary. Two air-handling units serve the entire building, and about 58 FCUs are on each floor.
- The heating and cooling plant consists of three boilers, six chillers, three cooling towers, and one ice storage tank. The capacities of the boilers and the chillers are
  Boilers: 13 MBtu/h (2 units) and 3.5 MBtu/h (1 unit)
  Chillers: 215 tons (5 units) and 240 tons (1 unit)
  The TES system consists of a brine ice-on-coil tank. The hours of charging and discharging are 10 and 13, respectively. The TES system is currently controlled using simple and nonpredictive storage-priority controls.

The internal heat gain sources are shown in Table 4.7.7. Operating schedules were based on the discussion with the building operators and on observations during the field survey.

TABLE 4.7.7
Internal Heat Gain Level for the Office Building

Internal Heat Gain	Design Load
Occupancy	17 m^2/person
	Latent heat gain: 45 W
	Sensible heat gain: 70 W
Lighting	14 W/m^2
Equipment	16 W/m^2
Ventilation	14.7 CFM/person

STEP 3: ENERGY USE BASELINE MODEL

To model the building using DOE-2, each floor was divided into two perimeter and two core zones. Figure 4.7.5 shows the zone configuration used to model the building floors. The main reason for this zoning configuration is the lack of flexibility in the DOE-2 SYSTEMS (Energy Information Agency, 1980) program. Although the actual building is conditioned by the combination of CAV and FCU systems, the SYSTEM module of DOE-2.1E cannot model two different types of HVAC systems serving one zone. Therefore, a simplification has been made to simulate the actual HVAC system of the building. This simplification consists of the following: The perimeter zone is conditioned by the FCUs, while the core zone is conditioned by CAV. Since all the FCUs are located at the perimeter, this simplification is consistent with the actual HVAC system operation.

Figure 4.7.6 shows the monthly electrical energy consumption predicted by the DOE-2 base model and the actual energy use recorded in 1993 for the building. It shows that DOE-2 predicts the actual energy use pattern of the building fairly well, except for the months of September and October. The difference between the annual metered energy use in the building and the annual predicted electricity use by the DOE-2 base-case model is about 762 MWh. DOE-2 predicts that the building consumes 6% more electricity than the actual metered annual energy use. To perform the DOE-2 base-case model, a TRY-type weather file of Seoul was created using the

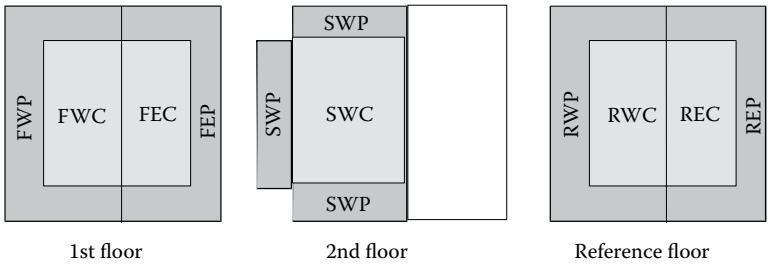

FIGURE 4.7.5 Building zoning configuration for DOE-2 computer simulation.

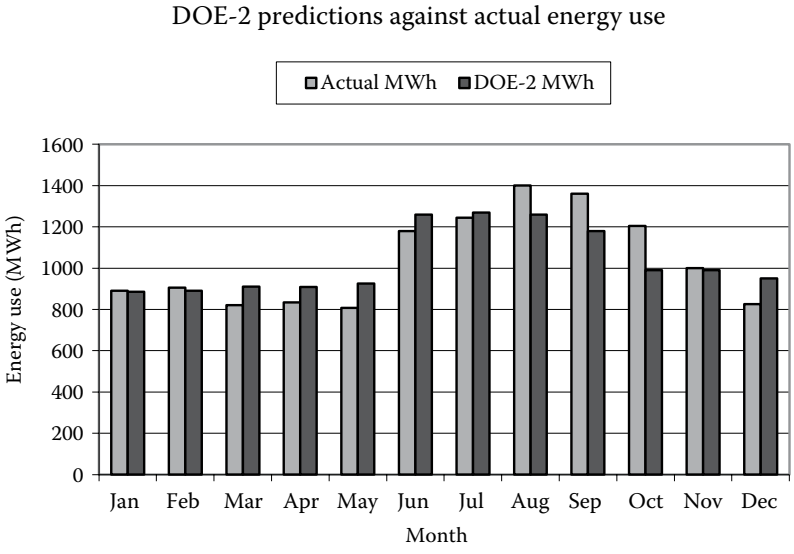

FIGURE 4.7.6 Comparison of the DOE-2 prediction and actual building electrical energy use.

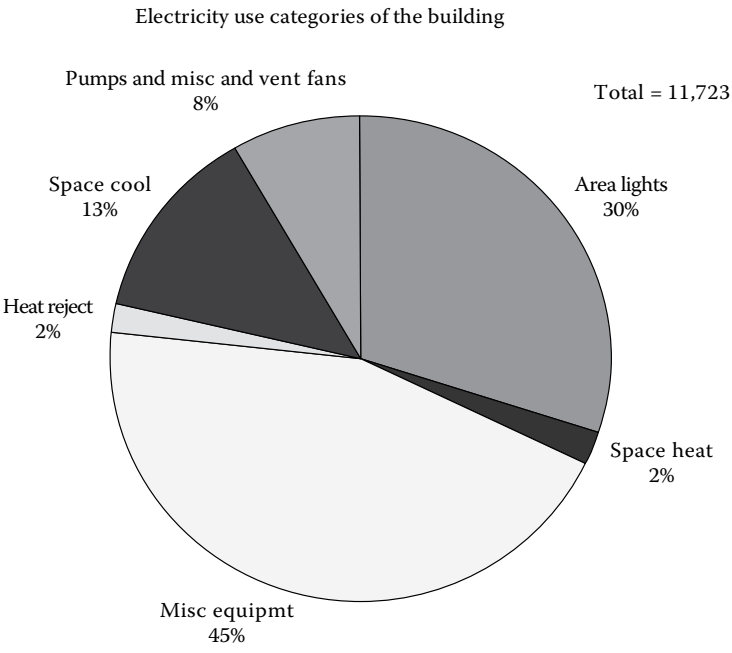

FIGURE 4.7.7 Electricity use distribution.

raw weather data collected for 1993. Using the DOE-2 base-case model, a number of energy conservation opportunities (ECOs) can now be evaluated.

Figure 4.7.7 shows the distribution by end uses of the building energy consumption. The electrical energy consumption of the building is dominated by lighting and equipment. The electricity utilized for lighting and office equipment represents about 75% of the total building electric consumption. As mentioned earlier, a recent lighting retrofit was installed in the building, comprising electronic ballasts and energy-efficient fluorescent fixtures. Therefore, it was decided not to consider a lighting retrofit as an ECO for this study. The electricity consumption for cooling is about 13.1%. The ECOs selected for this building aim mostly at reducing the cooling loads.

STEP 4: EVALUATION OF ENERGY CONSERVATION OPPORTUNITIES

Based on the evaluation of the energy use pattern of the building, several ECOs for the building were analyzed. Among the ECOs considered in the study, six of them successfully reduced energy consumption:

1. *ECO #1: CAV to VAV conversion*. The present AHU fans are all constant-speed fans. They supply conditioned air through a constant-volume air supply system to the selected zones. The system is designed to supply enough air to heat or cool the building under design conditions. Under nondesign conditions, more air than needed is supplied. Changing the system to a VAV system would reduce the amount of air supplied by the AHUs and result in less energy to condition the various zones. For this ECO, a constant-volume reheat fan system assigned to the core zones in the building was changed to a VAV system. In particular, VAV boxes, controlled by the space thermostat, vary the amount of conditioned air supply to the building zones to control the indoor temperature. Both labor and equipment costs were included in the estimation of the payback period for this measure.
2. *ECO #2: Optimal ice storage control*. The current TES system is operated using a nonpredictive storage-priority control. To improve the benefits of the TES system, a

near-optimal controller is suggested. This ECO is analyzed to determine if the cost of electrical energy consumption for the building is reduced when a near-optimal control strategy is used. To determine the savings of this option, the simulation environment developed by Henze et al. (1997) is used. This simulation environment is based on a dynamic programming technique and determines the best operating controls for the TES system given the cooling and noncooling load profiles and electrical rate structure. No DOE-2 simulation is performed for this ECO. The results of the dynamic programming simulation indicate that an energy reduction of 5% can be achieved using a near-optimal control in lieu of the storage-priority control. To implement this near-optimal control, a predictor is required to determine future building cooling/noncooling loads. An example of such a predictor could be based on neural networks (Kreider et al., 1995). The labor cost and the initial cost of adding some sensors and a computer were considered in determining the payback period for this measure.

3. *ECO #3: Glazing retrofit*. For this building, low-e glazing systems were considered to reduce the internal heat gain due to solar radiation. Thus, the cooling load is reduced. In addition, the increased U-value of the glazing reduces the heating load. For this ECO, the existing single-pane windows with the glass conductance of 6.17 W/m^2 K and the shading coefficient of 0.69 were changed to double-pane windows of 1.33 W/m^2 K and 0.15 shading coefficient.
4. *ECO #4: Indoor temperature setback/setup*. In this ECO, the impact of the indoor temperature setting on energy use was analyzed using the DOE-2 simulation program; the heating temperature was changed from 24.5°C to 22.5°C and the cooling temperature was changed from 25.5°C to 27.5°C. There is only a labor cost associated with this measure.
5. *ECO #5: Motor replacement*. Increasing the efficiency of the motors for fans and pumps can reduce the total electric energy consumption in the building. In this ECO, the existing efficiencies for the motors were assumed to range from 0.85 (10 HP) to 0.90 (50 HP). Energy-efficient motors have efficiencies that range from 0.91 (10 HP) to 0.95 (50 HP). Only the differential cost was considered in the economic analysis.
6. *ECO #6: Daylighting control plan*. A continuous dimming control would regulate the light level so that the luminance level inside the zones remains constant. The electricity consumption of the building can be significantly reduced, while the gas consumption can be slightly increased because of the reduced space heat gain from the lighting system. For this ECO, a daylighting system with continuous dimming control was considered for perimeter office zones. The cost of adding the sensors was considered.

TABLE 4.7.8
Economic Analysis of the ECOs

	Electricity Cost (MWon)	LNG Cost (MWon)	Total Cost (MWon)	Capital Cost (MWon)	Saving (%)	Savings (MWon)	Payback Period (Years)
Base Case	984.4	139.1	1123.5	—	—	—	—
ECO #1	940.8	49.8	990.5	465.5	11.8	133.0	3.5
ECO #2	979.1	139.1	1118.2	42.4	0.6	5.3	8.0
ECO #3	977.9	126.9	1104.8	280.5	1.7	18.7	15.0
ECO #4	983.7	106.4	1090.1	16.7	3.0	33.4	0.5
ECO #5	972.6	138.7	1111.4	60.5	1.1	12.1	5.0
ECO #6	911.6	144.8	1056.4	268.4	6.0	67.1	4.0

The impact of the selected ECOs on the electricity use in the building as predicted by DOE-2 simulations is shown in Table 4.7.8. Based on these results, converting CAV to VAV and implementing a daylighting control system with dimming control reduced the total electricity consumption of the building 5.2% and 7.3%, respectively. These savings are significant considering that the electricity consumption for the cooling plant alone is about 13.1% of the total electricity consumption of the building.

The economic analysis was performed using the utility rate of Seoul, Korea. Table 4.7.8 presents the energy cost savings of ECOs in Korean currency (1000 Won = $1). In addition to the electricity cost, the natural gas cost was also included in the economic analysis. The natural gas is used only for heating the building. The economic analysis shows that the VAV conversion reduces the total energy consumption by more than 10%, and the daylighting control saves about 6% of the total energy costs.

Recommendations

The results for economic analysis, the VAV conversion (ECO #1), adjustment of temperature set point (ECO #4), and the daylighting control (ECO #6) are the recommended energy-saving opportunities to be implemented for the audited office building. In particular, the VAV conversion reduces the total energy consumption more than 10%, and the daylighting control saves about 6% of the total energy consumption.

Verification Methods of Energy Savings

Energy conservation retrofits are deemed cost-effective based on predictions of the amount of energy and money a retrofit will save. However, several studies have found that large discrepancies exist between actual and predicted energy savings. Due to the significant increase in the activities of ESCOs, the need became evident for standardized methods for measurement and verification of energy savings. This interest has led to the development of the *North American Energy Measurement and Verification Protocol* published in 1996 and later expanded and revised under the *International Performance Measurement and Verification Protocol*.

In principle, the measurement of the retrofit energy savings can be obtained by simply comparing the energy use during pre- and post-retrofit periods. Unfortunately, the change in energy use between the pre- and post-retrofit periods is not only due to the retrofit itself but also to other factors such as changes in weather conditions, levels of occupancy, and HVAC operating procedures. It is important to account for all these changes to accurately determine the retrofit energy savings.

Several methods have been proposed to measure and verify savings of implemented ECMs in commercial and industrial buildings. Some of these techniques are briefly described as follows.

Regression Models

The early regression models used to measure savings adapted the variable-base degree-day method. Among these early regression models, the PRInceton Scorekeeping Method (PRISM) that uses measured monthly energy consumption data and daily average temperatures to calibrate a linear regression model and determine the best values for nonweather-dependent consumption, the temperature at which the energy consumption began to increase due to heating or cooling (the change point or base temperature), and the rate at which the energy consumption increased. Several studies have indicated that the simple linear regression model is suitable for estimating energy savings for residential buildings. However, subsequent work has shown that the PRISM model does not provide accurate estimates for energy savings for most commercial buildings (Ruch and Claridge, 1992).

Single-variable (temperature) regression models require the use of at least four-parameter segmented linear or change-point regressions to be suitable for commercial buildings.

Katipamula et al. (1994) proposed multiple linear regression models to include as independent variables internal gain, solar radiation, wind, and humidity ratio, in addition to the outdoor temperature. For the buildings considered in their analysis, Katipamula et al. found that wind and solar radiations have small effects on the energy consumption. They also found that internal gains have generally modest impact on energy consumption. Katipamula et al. (1998) discuss in more detail the advantages and the limitations of multivariate regression modeling.

Time Variant Models

Several techniques have been proposed to include the effect of time variation of several independent variables on estimating the energy savings due to retrofits of building energy systems. Among these techniques are the artificial neural networks (Krarti et al., 1998), Fourier series (Dhar et al., 1998), and NILM (Shaw et al., 1998). These techniques are very involved and require a high level of expertise and training.

Summary

An energy audit of commercial and industrial buildings encompasses a wide variety of tasks and requires expertise in a number of areas to determine the best ECMs suitable for an existing facility. This section provided a description of a general but systematic approach to perform energy audits. If followed carefully, the approach helps facilitate the process of analyzing a seemingly endless array of alternatives and complex interrelationships between the building and its energy system components.

4.8 ADVANCED ENERGY-EFFICIENT BUILDING ENVELOPE SYSTEMS

Moncef Krarti and John Zhai

Introduction

Building heating and cooling energy use accounts for up to 40% of the total energy consumption in developed countries (Pérez-Lombard et al., 2008). Heat losses and gains through the building envelope greatly contribute to thermal heating and cooling loads and subsequently to the overall energy performance of buildings (Tuhus-Dubrow and Krarti, 2010; Sadineni et al., 2011). Several advances in building technology have been made that continue to transform building energy performance and promote new and innovative construction techniques and challenges traditional practices. In fact, some of the existing systems that are often required by energy efficiency codes and standards may not provide the optimal energy performance and indoor environmental quality (IEQ). For instance, leaky buildings traditionally perform very poorly in terms of energy consumption, but in general, their IEQ—as a result of the incoming outside air—is fairly good. For the sake of energy efficiency, the trend has been tighter, more effectively sealed buildings, which in turn has led to more IEQ, mold, and sick building syndrome problems. As the push for improved energy performance points designers and builders toward tighter construction, the very principle that reduces the building's energy consumption—reduced infiltration—is a net loser for IEQ.

In this chapter, some advanced technologies of building envelope are presented to challenge the existing paradigms for high-performance buildings. Specifically, four building envelope systems are presented to enhance the energy efficiency and optimize the IEQ of buildings. These advanced building envelope systems include:

- *Dynamic Insulation Materials* (DIMs)*:* These materials are assemblies that can change their thermal resistance through, for instance, a controlled exchange of liquid or gaseous media, and are applied to the exterior walls and roofs of buildings.
- *Variable Reflectivity Coating roofs*: These systems are associated with coatings that can change their reflective properties over time depending on desired controlled strategies. It is well known that static cool roofs can save energy used during cooling periods but may increase energy consumption during swing or heating seasons due to lower heat gains. The variable reflectivity coatings allow the reduction in heating penalty associated with conventional cool roofs.
- *One-Layer Breathing Walls*: These systems provide air ventilation through the walls while recovering thermal energy. Essentially using heat exchanging mechanism, filtrated fresh air is introduced through the walls from outside to inside and is heated or cooled by the thermal energy wasted by conduction and convection with the walls.
- *Multilayer Living Walls:* These walls utilize basic biomimetic principles to adapt to the change in climatic conditions. In particular, these climate-adaptive intelligent walls have embedded systems of air, water, and phase change material (PCM) and can be controlled to maintain acceptable indoor environment under changing outdoor conditions.

In the following sections, an overview of the basic operating concepts of these advanced envelope systems is first provided. Then, their energy performance is summarized based on the reported results and based on either experimental or modeling analyses.

Dynamic Insulation Materials

Background

High thermal resistance materials and assemblies are effective in reducing heat transfer through the building envelope when there is a significant indoor–outdoor temperature difference. However,

building envelopes with high RSI value (*R*-value in SI unit) can be beneficial for one season of the year but are not necessarily beneficial for the other season. For example, in cold climates, high thermal insulation can actually increase building thermal loads—especially during mild periods when it may be beneficial to let heat that is trapped indoors to escape outdoors.

Some studies have theorized on DIMs and systems in which the thermal conductivities of wall assemblies are controllable and tunable, either due to applied electrical voltage to conducting polymers or other electrochromic materials (Jelle et al., 2010, Jelle, 2011; Kalnæs and Jelle, 2014). While some prototypes of electrochromic materials are available, these technologies have only been applied to smart windows rather than opaque building envelope systems. The operating principle of one of the DIM technologies is depicted in Figure 4.8.1. In lieu of traditional, static insulation assemblies (e.g., extruded polysterene (XPS), vacuum insulation panels (VIPs), gas insulation panels (GIPs)), a DIM is a rigid, cellular panel that is placed within the external wall cavities of a building. The DIM panel is designed with either an open cavity or an interconnected system of conduits. Once installed, the bulk thermal diffusivity of the assembly is tailored by the introduction of inert gases with variable conductivities (e.g., carbon dioxide, nitrogen, helium), thereby affecting the rate of heat transfer through the envelope. It is envisioned that the insulation media can be regulated via control strategies based on indoor–outdoor temperature differences and exchanged daily, monthly, or seasonally, depending on the climate and necessary heating and cooling demands. While many have speculated on the potential benefits of DIMs, no studies have yet quantified the potential energy savings of such materials.

Energy Performance

In this section, the potential energy savings of DIMs for buildings is briefly presented based on reported work by Park et al. (2015). Using a dual-control strategy, the DIM thermal resistance is changed from low to high values to accommodate the variations in outdoor conditions and reduce thermal loads for buildings. Total energy savings associated with DIMs is estimated and compared with benchmarks achievable by high-performance static insulation in representative US climates.

A comparative analysis is presented to evaluate the effect of DIMs on the annual energy use for a single-zone residential building located in three US climates: Golden, CO; Madison, WI; Phoenix, AZ. Specifically, four control scenarios of RSI-value of the exterior walls are considered:

- CASE 1: Building envelope with RSI-1.0
- CASE 2: Building envelope with RSI-2.5
- CASE 3: Two-step RSI-value control strategy (switch between RSI-1.0 and RSI-2.5)
- CASE 4: Two-step RSI-value control strategy (switch between RSI-0.5 and RSI-2.5)

The two-step control strategies are achieved by modulating the RSI values of the walls based on heating or cooling requirements and changes in outdoor temperatures. The main goal of the

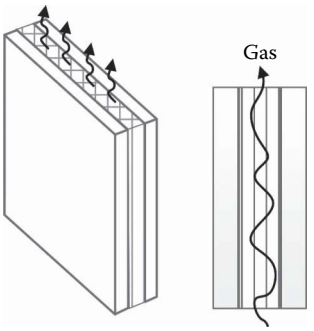

FIGURE 4.8.1 Operating principle of DIMs.

two-step RSI-value control strategy is to maximize the heat gains through the building envelope, and minimize the heat losses through the walls during the heating season. The same control strategy minimizes heat gains and maximizes heat losses during the cooling season.

The heating and cooling set point temperature for a single zone residential building is 19°C and 25°C for 24 h/day during winter and summer season, respectively. Table 4.8.1 and Figure 4.8.2 compare the annual heating and cooling energy end uses obtained for the four DIM control cases outlined above for a residential building located in three US locations. Solar heat gains transmitted through the window assist in heating the zone air, and thus reduce the heating thermal load for the building. However, the addition of heat gains from transmitted solar radiation typically increases building cooling thermal load in most climates. As shown in Figure 4.8.2, low RSI-value walls are more effective to release the heat trapped indoors during cooler nighttime periods than the high RSI-value walls. The two-step control strategies take advantage of the DIM low RSI-value during nighttime, and minimize heat gains through the exterior walls during daytime by increasing their DIM RSI value. Specifically, the two-step-RSI-1/RSI-2.5 control strategy reduces the cooling

TABLE 4.8.1
Heating and Cooling Energy Use Savings Compared to CASE 1 (RSI-1.0 Exterior Walls) When the Building Has Windows and Internal Gains in Three US Locations: Golden, CO; Madison, WI; and Phoenix, AZ

	Heating Energy Use Savings (GJ)			% Savings		
	RSI-2.5	Two-Step RSI-1/RSI-2.5	Two-Step RSI-0.5/RSI-2.5	RSI-2.5	Two-Step RSI-1/RSI-2.5	Two-Step RSI-0.5/RSI-2.5
Golden, CO	–5.55	–5.65	–5.77	–29.0	–29.5	–30.1
Madison, WI	–10.14	–10.14	–10.15	–30.6	–30.6	–30.6
Phoenix, AZ	n/a	n/a	n/a	n/a	n/a	n/a
	Cooling Energy Use Savings (GJ)			**% Savings**		
	RSI-2.5	Two-Step RSI-1/RSI-2.5	Two-Step RSI-0.5/RSI-2.5	RSI-2.5	Two-Step RSI-1/RSI-2.5	Two-Step RSI-0.5/RSI-2.5
Golden, CO	–0.24	–0.67	–1.05	–4.3	–11.8	–18.6
Madison, WI	0.40	–0.18	–0.69	8.5	–3.7	–14.5
Phoenix, AZ	–3.86	–4.70	–5.34	–13.2	–16.0	–18.2

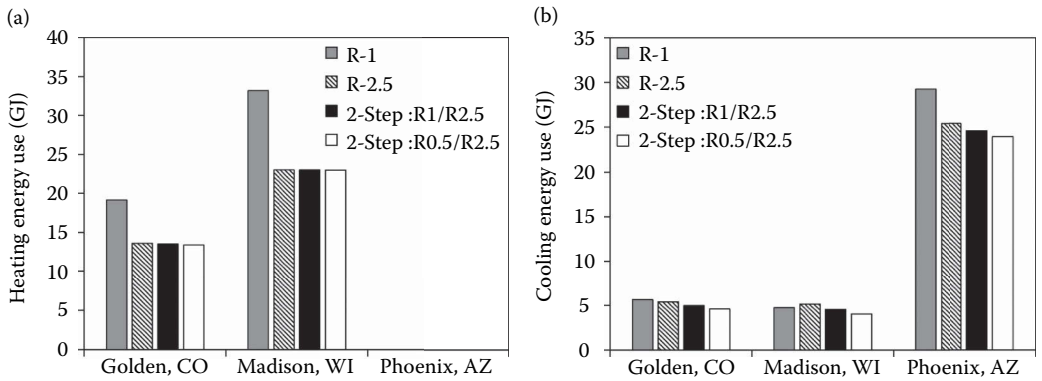

FIGURE 4.8.2 (a) Annual heating energy use and (b) annual cooling energy use for four DIM control strategy when the building has windows and internal gains in three US locations: Golden, CO; Madison, WI; and Phoenix, AZ.

energy use by up to 8% compared to RSI-2.5 wall setting in Golden, CO. While, the two-step-RSI-0.5/ RSI-2.5 control strategy reduces the cooling energy use by up to 15% compared to RSI-2.5 wall setting in Golden, CO as shown in Table 4.8.1. Cooling energy use can be reduced by 11% and 21%, respectively, with two-step-RSI-1/RSI-2.5 and two-step-RSI-0.5/RSI-2.5 control strategy in Madison, WI. Two-step DIM can achieve <6% cooling energy savings in Phoenix, AZ. Two-step DIM has little effect on the heating energy savings. This is because DIM wall maintains the high RSI value during the cold winter.

The number of hours when each DIM exterior wall is set at the low-thermal resistance over a year is shown in Figure 4.8.3 for all orientations and three US climates. DIM walls are mostly activated during cooling season in heating dominated climates (i.e., Golden, CO and Madison, WI) and during the heating season in cooling climate (i.e., Phoenix, AZ). In particular, Figure 4.8.3a and b indicates that the thermal resistance for the northern oriented walls is the most actively controlled during the heating and cooling operation. The solar radiation incident on north-facing walls is smaller than that on other walls, thus the outside surface temperature of the northern wall is generally cooler. Therefore, heat trapped inside the thermal zone can be easily released through the northern oriented walls.

Figure 4.8.4 summarizes the performance of two-step DIM control strategies compared to static RSI-2.5 wall setting during heating and cooling seasons for the residential building with and without windows and internal gains located in the three US locations. The two-step DIM control strategies

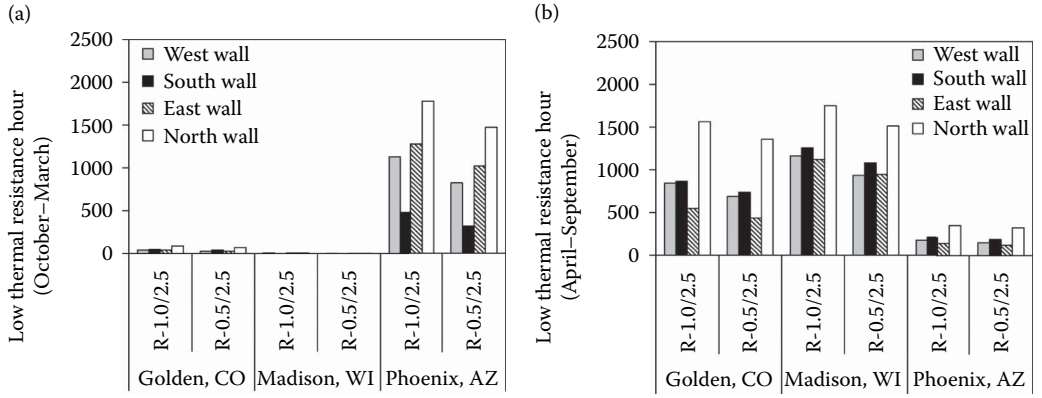

FIGURE 4.8.3 Number of hours for maintaining low RSI value for the exterior walls in the building with windows and internal load in three US locations: Golden, CO; Madison, WI; and Phoenix, AZ.

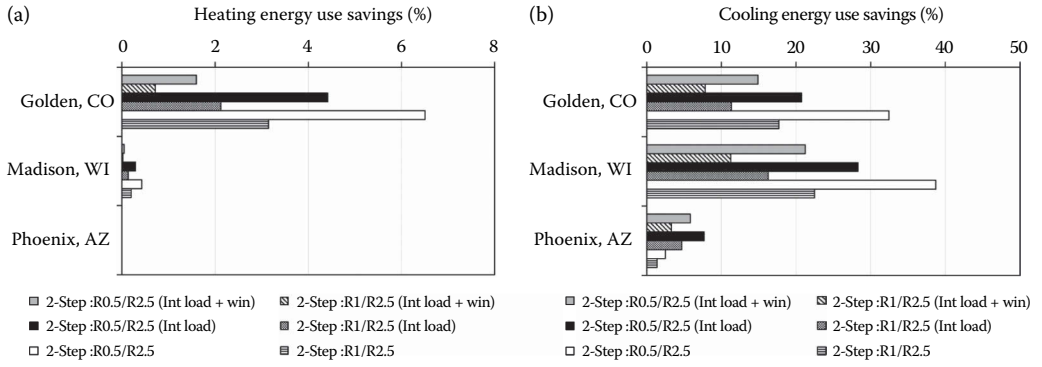

FIGURE 4.8.4 Percent annual energy use savings in (a) heating and (b) cooling for two-step DIM control strategies relative to RSI-2.5 wall setting associated to a residential building in three US climates.

are effective in cooling season regardless of locations. The two-step DIM control wall can achieve more cooling energy savings in heating dominant climates (i.e., Golden, CO and Madison, WI) during the cooling season. As the results of Figure 4.8.4 indicate, the two-step DIM control strategies are effective when the internal loads are minimal.

Variable Reflectivity Coating Roofs

Background

Cool roofs have been utilized as one of passive cooling techniques to reduce cooling energy demand for buildings. Using highly reflective coatings, cool roofs reduce solar heat gains during the summer and can keep exterior roofs cooler compared to roofs with standard reflectivity properties (Akbari and Levinson, 2008).

The benefits of cool roofs to reduce cooling energy use for air conditioning of buildings during the summer and improve thermal comfort for nonair conditioning buildings have been evaluated and tested for several building types and regions around the world (Akbari et al., 2001; Levinson et al., 2005; Akbari and Levinson, 2008; Gao et al., 2014). However, cool roofs have been found to be not necessarily beneficial during winter seasons when buildings are required to be heated. In fact, several studies have noted that cool roofs actually increase building heating loads by reducing the amount of solar heat gains.

In this section, the performance of variable reflectivity roofs, referred to throughout this section as variable reflectivity coating (VRC) roofs, to the static conventional cool roofs in order to assess the potential benefits of developing optically active coatings suitable for opaque building envelope systems. The analysis is based on the work of Park and Krarti (2016).

Thermal Analysis

A series of simulation are conducted to investigate the effectiveness of VRCs applied on the exterior opaque building envelope surfaces. Various combinations of reflectivity settings for building envelope systems (i.e., walls and roof) are considered as shown in Table 4.8.2 based on the potential achievable optical properties for thermochromic materials (Kamalisarvestani et al., 2013). Cases 1 and 2 are considered as the reference cases: Case 1 represents the configuration when the office building has conventional finish coatings for all its walls and roof while Case 2 is associated with configuration when a static (i.e., with constant reflectivity value) cool roof is utilized for the building.

For the VRC material, the solar reflectivity is changed from a high value (i.e., 0.55 in this study) during the cooling period to a low value (i.e., 0.30 in this study) during the heating period.

TABLE 4.8.2
Options for the Reflectivity Settings Applied to the Office Building Exterior Walls and Roof

No. Case	Reflectivity of Exterior Walls	Reflectivity of Exterior Roof
1	0.30	0.30
2	0.30	0.55
3	0.30	VRC
4	VRC	0.30
5	0.55	0.55
6	0.55	VRC
7	VRC	0.55
8	VRC	VRC

TABLE 4.8.3
Insulation Level of Roof and Wall Constructions Used for the Analysis

Insulation Level	Construction Type	*R*-Value (K-m²/W)
High	Roof	5.25
	Wall	2.02
Low	Roof	0.15
	Wall	0.36

Depending on the climate, the heating and cooling periods are adjusted for the office building. It should be noted that the solar reflectivity of the building envelope affects the level of solar radiation absorbed by the building exterior surfaces and thus their temperature. Any variation of outside surface temperature has a great effect on the building thermal load during both heating and cooling operation, especially for poorly insulated envelope systems. In the analysis carried out in this study and to investigate the impact of *R*-value of the building envelope on the effectiveness of the VRC application for both walls and roof, two insulation levels are considered for the analysis as outlined in Table 4.8.3.

First, the analysis is performed when the office building is located in Golden, CO to assess the impact of the application of VRC on both exterior walls and roof. In particular, the analysis considers the variations of building envelope inner and outer surface temperatures as well as of the building heating and cooling thermal loads, and annual energy costs. The results are then utilized to assess the performance and the cost-effectiveness of the application of VRC materials to building envelope surfaces for the office buildings in four US climates.

Impact of Heating Thermal Loads

In this section, the impact of VRC on heating thermal loads for the office building is determined for four US sites representing different climatic conditions including Golden, CO; Chicago, IL; Phoenix, AZ; and Tampa, FL. Figure 4.8.5 summarizes the annual heating loads for four US sites, two thermal insulation levels, and several reflectivity cases listed in Table 4.8.2. In particular, Figure 4.8.5 indicates that the heating load increases for all sites and insulation levels due to the application of a high solar reflectivity coating or VRC on the opaque building envelope. The results outlined in Figure 4.8.5 show, however, that the heating load is more sensitively affected by high reflectivity coatings when the building envelope is poorly insulated. Indeed, a high reflectivity coating roof installed on a well-insulated roof increases the heating load by 1.5 MJ/m^2 in both Chicago, IL and Golden, CO. While on poorly insulated building envelope, the same high reflectivity coating increases the heating load by 26.8 and 31.5 MJ/m^2 in Chicago, IL and Golden, CO, respectively.

Based on the results, the application of high reflectivity coating has more impact in hot climates (i.e., Phoenix, AZ and Tampa, FL) even though the absolute increase in heating load per unit area is not significant. Indeed, the increase in annual heating load in Phoenix, AZ ranges from 0.1 to 6.9 MJ/m^2 depending on the insulation level of the building envelope. This range represents 23%–62% increase in heating load caused by high reflectivity coating compared to maintaining low reflectivity surfaces. Similar results are observed for the heating load in Tampa, FL.

Impact of Cooling Thermal Loads

Figure 4.8.6 shows the variations in the annual cooling loads for four US sites (i.e., Golden, CO; Chicago, IL; Phoenix, AZ; and Tampa, FL), two thermal insulation levels (i.e., *R*-values listed in Table 4.8.3), and eight reflectivity options (i.e., cases listed in Table 4.8.2). The results outlined in Figure 4.8.6 clearly indicate that high reflectivity coating or VRC can greatly reduce the building

cooling load in all four US climates regardless of the thermal insulation level. Similar to the results obtained for the heating loads, the application of high solar reflectivity coatings on the envelope outer surfaces strongly affects the cooling load when the building is poorly insulated. It should be noted, however, that significant cooling load savings can be achieved by employing cool roofs or VRCs for the building envelope surfaces in all locations. The cooling load reduction per unit area is estimated to be 0.4 and 7.4 kWh/m^2 when the office building is located in Golden, CO with, respectively, high and low insulation level. The cooling load per unit area is reduced by 1.6 kWh/m^2 (well-insulated case) and 18.9 kWh/m^2 (poorly insulated case) when the building is in Phoenix, AZ. The percent savings of the cooling load is smaller in Phoenix, AZ and Tampa, FL, even though the reduction per unit area is two times larger than those of Chicago, IL and Golden, CO.

Impact on Annual Energy Costs

Since the seasonal reflectivity control strategies, associated with VRCs considered in this study, affect both heating and cooling thermal loads, annual energy cost analysis combining the costs for both heating and cooling is required to determine the potential benefits and cost-effectiveness of various coating options. For this study, average utility rates of \$7.1/GJ and \$0.1/kWh are considered for, respectively, natural gas (used for heating) and electricity (used for cooling). In this section, a sensitivity analysis is carried out to assess the cost benefits of applying VRCs for the office building located in four US climates. Figure 4.8.7 presents the variations in the annual energy costs per floor area cooling loads for all the insulation and reflectivity cases considered in this study. In particular, the results of Figure 4.8.7 show that the application of VRC to poorly insulated building is effective in reducing the annual heating and cooling energy costs compared to the other coating options

including the static cool roof. Indeed, the dynamic cool roof, through the application of VRC on the roof alone, can save up to 7% in energy costs when compared to the static cool roof option for poorly insulated buildings located in Golden, CO. It should be noted that the simple use of static cool roofs is highly effective in reducing energy costs, especially in hot climates. Indeed, static cool roofs reduce the office building annual energy costs by 25% and 28% for the poorly insulated building located in Phoenix, AZ and Tampa, FL, respectively. Lower but still noticeable energy cost reduction of 14% and 17% can be achieved from static cool roofs in Chicago, IL and Golden, CO, respectively.

When VRCs are considered for both roof and exterior walls, up to 28% of energy cost savings can be achieved when the building is located in Golden, CO, representing 11% additional cost reduction compared to the static cool-roof system. In hot climates, such as that of Tampa, FL, the

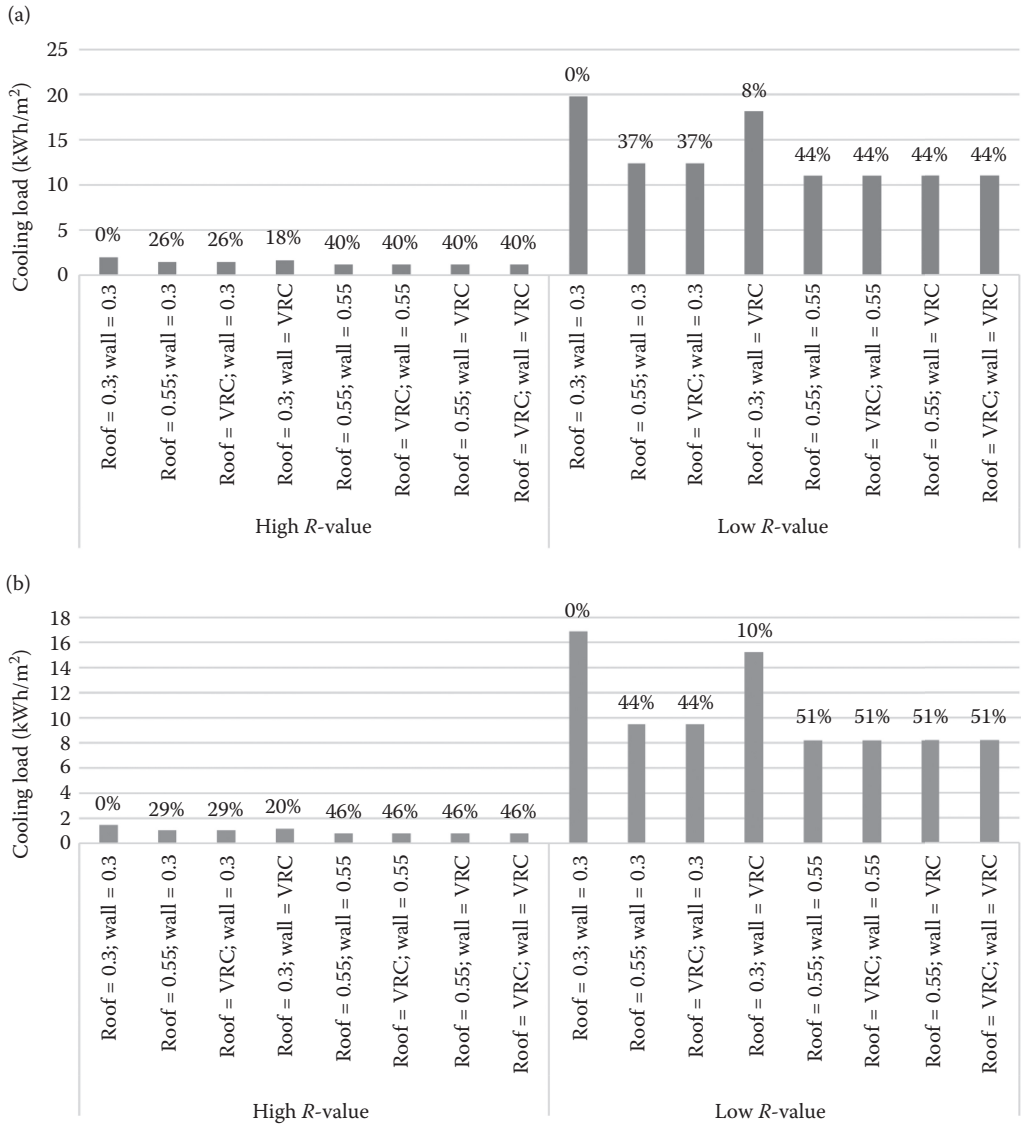

FIGURE 4.8.6 Cooling load per unit area of the building with various reflectivity combinations of exterior walls and roof in (a) Chicago, IL; (b) Golden, CO; (c) Phoenix, AZ; and (d) Tampa, FL.

(*Continued*)

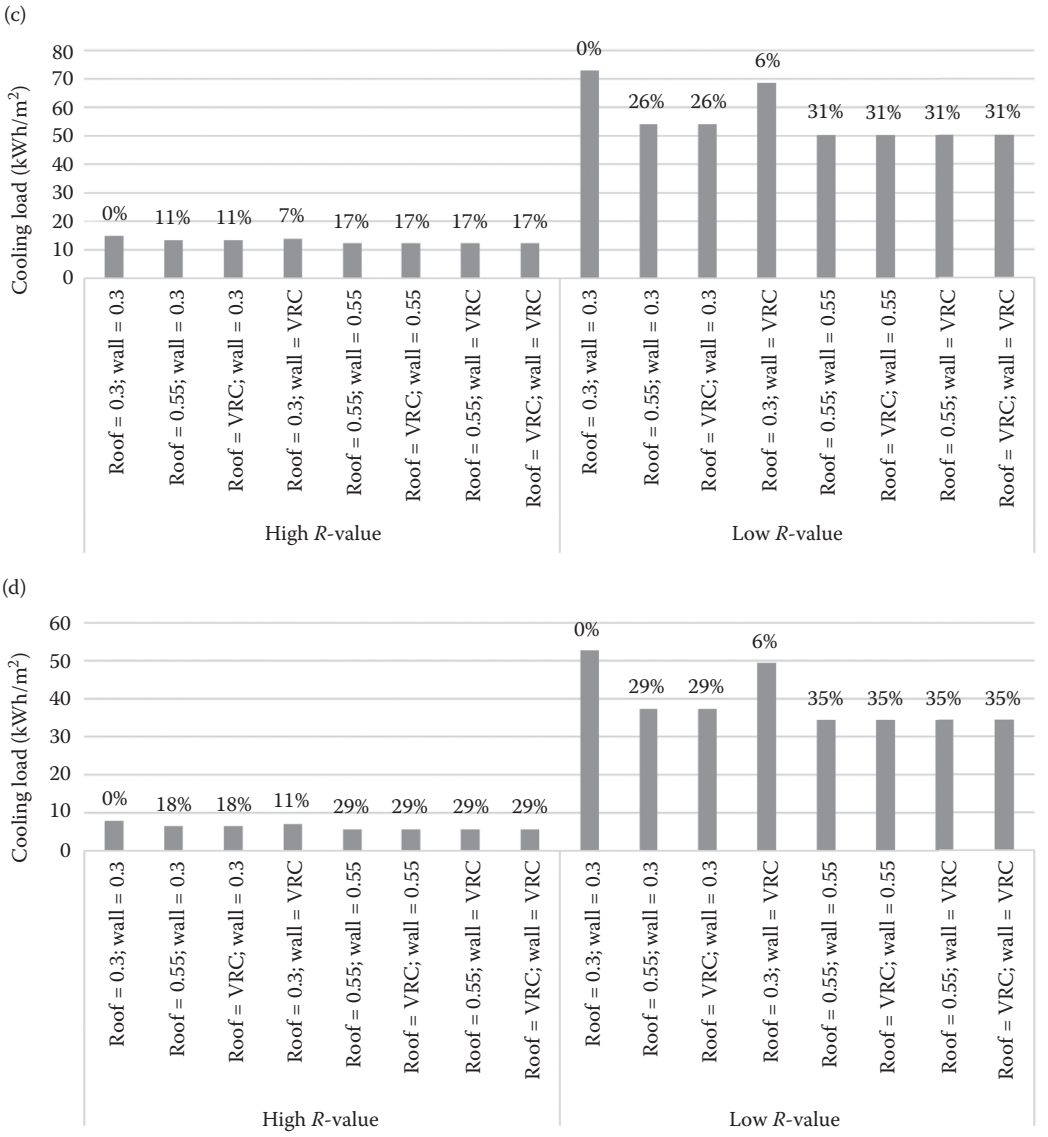

FIGURE 4.8.6 (CONTINUED) Cooling load per unit area of the building with various reflectivity combinations of exterior walls and roof in (a) Chicago, IL; (b) Golden, CO; (c) Phoenix, AZ; and (d) Tampa, FL.

annual energy cost savings can increase to 34% when VRCs are applied to both roof and walls from 29% when VRC is used for only the roof. However, as expected, the effectiveness of dynamic cool roofs compared to the static cool roofs is higher for cold climates and poorly insulated buildings. Indeed, VRCs can reduce the penalties associated with static cool roofs in heating dominated climates. The cost-effectiveness of VRCs depending highly on the climate, the energy prices, and the building thermal loads will be discussed in the following section.

Cost–Benefit Analysis of VRCs

Figures 4.8.8 and 4.8.9 show the variations in annual heating and cooling energy cost per unit floor area as a function of the cool roof and VRCs reflectivity for, respectively, well and poorly insulated office building located in four US sites (i.e., Golden, CO; Chicago, IL; Phoenix, AZ; and Tampa, FL). For VRC applied to opaque building envelope surfaces, the solar reflectivity is changed

from a high value as noted in the *x*-axis during the cooling season to a low value (i.e., 0.30 in this study) during the heating season. While cool roofs have the same reflectivity value shown in *x*-axis throughout the year. The results of Figures 4.8.8 and 4.8.9 clearly indicate that total annual energy cost decreases as the roof reflectivity increases for all four US locations regardless of the thermal insulation level. As noted earlier, dynamic cool roofs (i.e., with VRC applied only on the roofs) reduce the heating energy penalties associated with static cool roofs in heating dominated climates, especially for poorly insulated buildings. However, the application of VRC on both the roof and the exterior walls can considerably reduce the annual energy cost in hot as well as cold climates. In fact, VRC applied to all opaque envelope surfaces results in higher savings relative to either static or dynamic cool roofs in hot climates. For instance and when a well-insulated office building is located in Tampa, VRCs on both roof and walls reduce energy cost by 15% relative to the cool roof options when the coating high reflectivity is 0.55 and by 32% when the coating high reflectivity is 0.9.

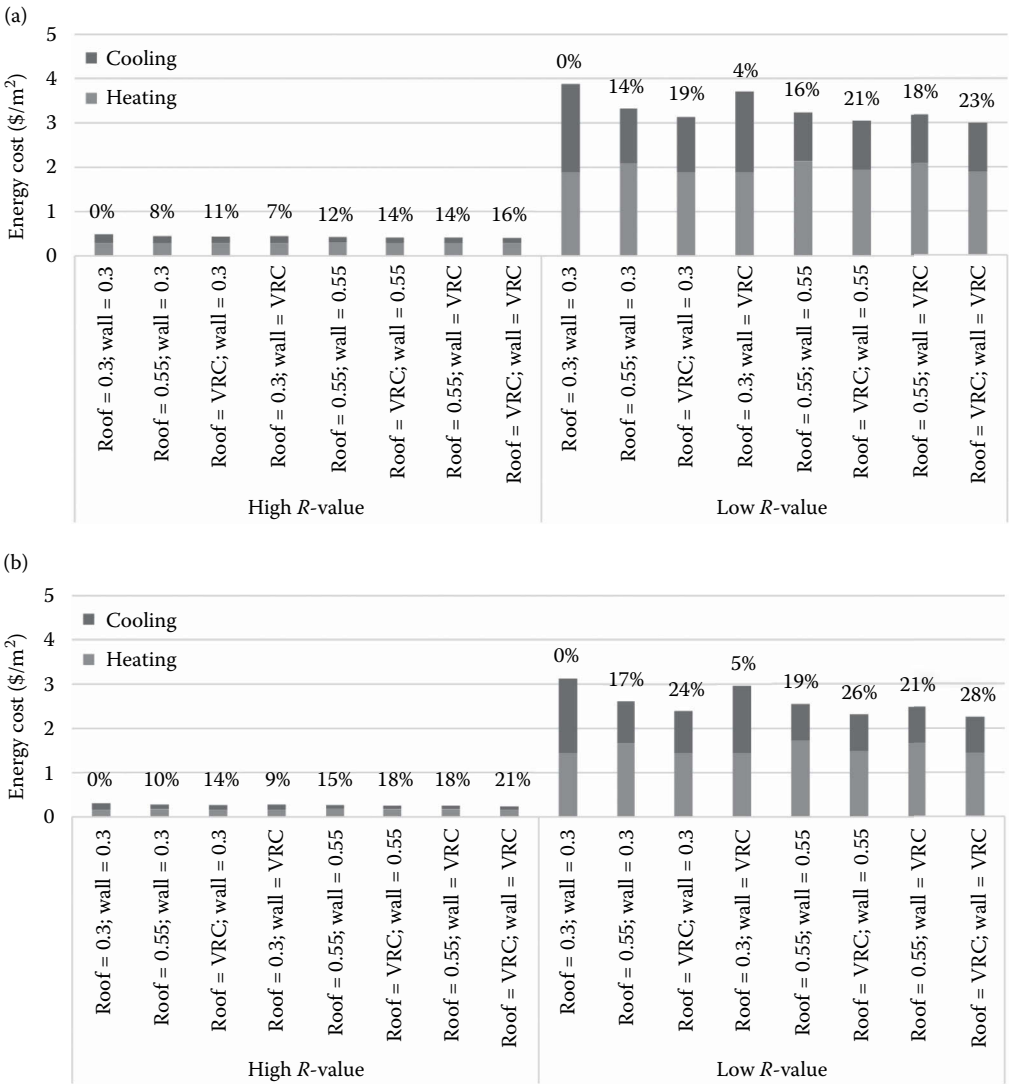

FIGURE 4.8.7 Energy cost of the building with various reflectivity combinations of exterior envelopes in (a) Chicago, IL; (b) Golden, CO; (c) Phoenix, AZ; and (d) Tampa, FL.

(*Continued*)

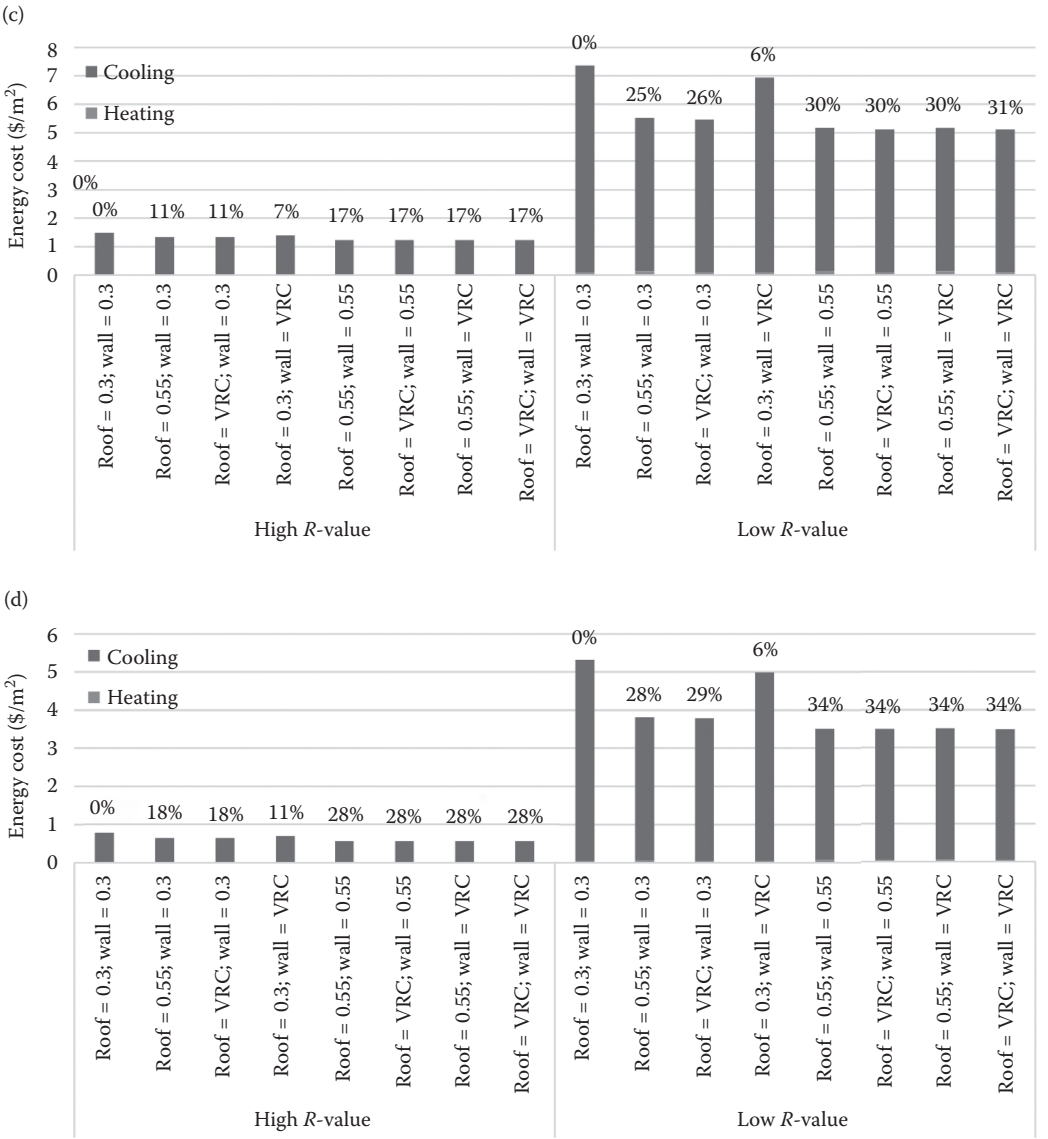

FIGURE 4.8.7 (CONTINUED) Energy cost of the building with various reflectivity combinations of exterior envelopes in (a) Chicago, IL; (b) Golden, CO; (c) Phoenix, AZ; and (d) Tampa, FL.

In fact, the ideal VRC systems with a reflectivity of 0.9 during the summer season and reflectivity of 0.3 during the winter season minimize energy costs for all climates and insulation levels considered in the analysis.

Single-Layer Breathing Wall

Introduction

A promising new technology introduces a method of avoiding the efficiency/air quality compromise, yielding better energy efficiency and improved IEQ. The technology, referred to as a "breathing wall," draws a steady stream of filtered air through the walls and into the building at all times, providing exceptionally clean ventilation air to the occupants. A schematic breathing wall diagram can be seen in Figure 4.8.10. Whereas higher ventilation rates traditionally produce higher energy

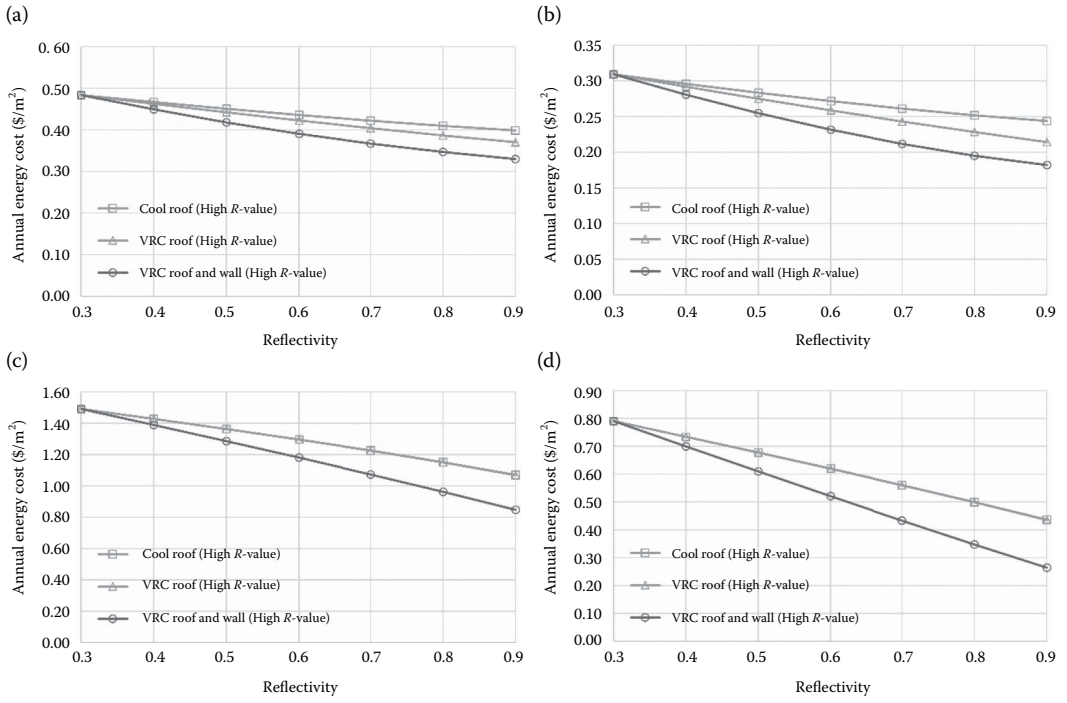

FIGURE 4.8.8 Annual energy cost savings as a function of reflectivity value of cool roof and VRCs for well-insulated building located in (a) Chicago, IL; (b) Golden, CO; (c) Phoenix, AZ; and (d) Tampa, FL.

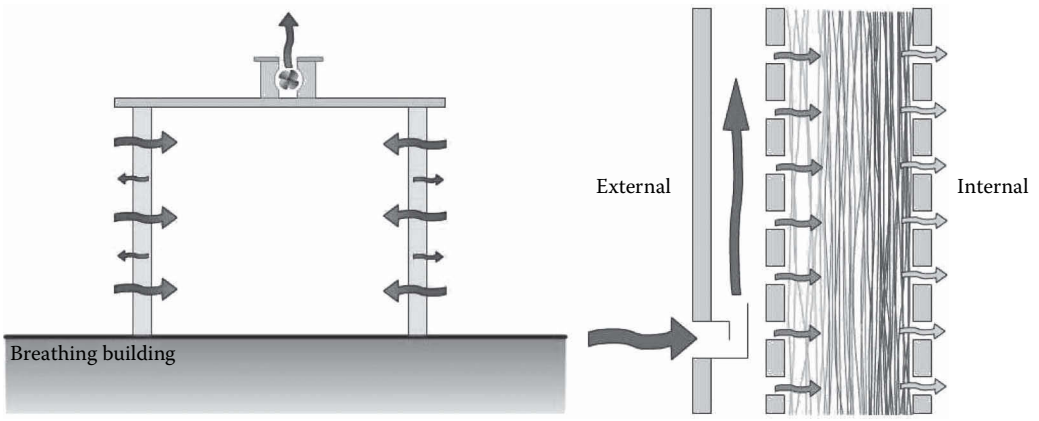

FIGURE 4.8.10 Breathing wall configurations, as proposed by Imbabi and Peacock (2003).

loads in buildings, the "dynamic insulation" used in breathing walls actually works to reduce that load, effectively creating efficient, superinsulated walls.

The projected energy savings and air quality implications associated with breathing wall technology are astounding. Previous studies of the energy and air filtration efficiencies of breathing walls estimated that such technologies can reduce year-round heating and cooling loads between 10% and 40%, while providing a steady stream of fresh ventilation air, filtered to high energy particulate air (HEPA) standards, 365 days per year (Imbabi and Peacock, 2003). Additionally, breathing walls may be able to clean up polluted cities too, as the filtered air exhausted by "breathing wall buildings" will effectively contain lower concentrations of pollutants and particulate matter than the outdoor air. The study also suggests that the filter mechanism of the walls will last throughout the lifetime of the building, providing the energy savings and air filtration for 60+ years, without requiring replacement.

While a few preliminary reports have projected promising energy and IEQ benefits of breathing walls, much research remains to be done. One major issue at hand pertains to understanding the heat transfer mechanism between the breathing wall media and incoming air, particularly under varied ambient conditions. Some of the previous research provides a simple estimation of the wall's insulative properties (U-value), involving only the conventional U-value and the flow rate of incoming air (Taylor et al., 1996). Using this method, the insulation of the wall at certain airflow rates is effectively infinite. While this method will suffice to make broad estimations of the energy savings associated with breathing walls, it may not prove accurate under changing environmental conditions. It is important to understand the behavior of breathing walls under a wide range of conditions, including temperature, humidity, pressure, and airflow rate.

Background

Among the first to conduct experimental studies on the effects of infiltration heat recovery within the building envelope were Bhattacharyya and Claridge (1995). Their one-dimensional model effectively predicted the heat transfer between moving infiltration air and the exterior building envelope. The so-called "heat exchanger" model was then revised and simplified by Barhoun and Guarracino (2004), who studied the particular case of a vertical air cavity within a wall. Separate studies by Buchanan and Sherman (2000), as well as Abadie et al. (2002), added a simulation of the airflow within the interior to a model of the heat recovery within the exterior wall element. Further research related to the movement of air throughout the building envelope has investigated the thermal and heat transfer properties of hollow bricks and double-skin façades. Additionally, Chen and Liu (2004) studied the airflow through porous media for applications within the solar-collector industry.

Several European studies, including Bailly (1985) and Kohonen and Ojanen (1987), have shown the potential energy saving impacts of dynamic insulation in buildings. Full-scale tests were conducted by Baker (2003), Dimoudi et al. (2004), and Morrison and Karagozis (1992) to study the energy performance of a dynamically insulated room. Bailly found that dynamic insulation can potentially save up to 14% of the heating load during the wintertime.

Krarti (1994) developed an analytical model to study the impacts of combined conduction and infiltration/exfiltration upon the thermal performance of dynamic insulation, and demonstrated that the heating load in applications of coupled infiltration and conduction was less than the simple summation of isolated conduction and infiltration. He demonstrates that there is a significant thermal coupling between the leakage and insulation layers that modifies the heat transmission in building thermal envelopes. The correlations developed by Krarti use the Peclet number to indicate the velocity of air moving through the wall. However, the savings is limited due to the fact that the amount of air forced through the dynamic wall must be equal to the air being exhausted. Analysis of the wall temperature profiles shows that the temperature profile within the wall largely depends upon the direction and rate of airflow through the wall. When no air is passing through the wall, the profile is linear, while it takes on a convex shape when air is exfiltrating, and a concave shape when air is infiltrating. The temperature profile throughout the wall is important, as it affects the heat loss due to conduction through the wall. Krarti concludes that the wall as a heat exchanger is capable of reducing the daily heating load due to conduction and infiltration by up to 22%.

Taylor et al. (1996) likewise developed a one-dimensional steady-state model of multilayer breathing wall heat transfer, and proposed to measure the performance through a dynamic *U*-value. One of Taylor's key findings is that very different types of construction will have the same thermodynamic performance with the same airflow, provided the thermal resistance is equal. Another significant finding of the analytical research conducted by Taylor et al. (1996) was that pro-flux flow (heat and airflow in the same direction) and contra-flux flow (heat and airflow in opposite directions) exhibit asymmetrical behavior. Imbabi and Peacock (2003) conducted physical and analytical experiments on dynamically insulated walls. Their research suggests that a layer of wet-blown cellulose with a static *U*-value of 0.168 W/m^2 K, when subjected to an infiltration airflow rate of 1 m/h can achieve a dynamic *U*-value of 0.058 W/m^2 K, which falls further to 1.7E−8 W/m^2 K at an airflow rate of 10 m/h.

Qiu and Haghighat (2007) published research regarding the temperature profile at various depths within a ventilated wall, as well as the concept of treating the wall as a combination of ventilated and nonventilated areas. They developed a numerical simulation in order to study the thermal performance of the diffuse building envelope, and conducted physical testing in order to corroborate the numerical results. Their computer simulations indicate that at low airflow rates, the temperature of the air rises very quickly to approximate the temperature of the solid matrix, allowing for a single medium analytical treatment. This research relies heavily upon the Peclet number (closely related to airflow rate) as a determining factor for breathing wall thermal performance. A key finding of the research is that the breathing wall can be broken up into regions affected by the heat transfer of infiltration, and regions that remain unaffected by infiltration, and are therefore dominated by pure conduction heat transfer. Additionally, it was determined that the ratio of these two areas is one of the key indicators of breathing wall performance.

Existing Products and Technologies

Among the earliest applications of dynamic insulation within buildings were the ceilings of agricultural buildings in Norway in the 1960s (Græe, 1974). Improvements in dynamic insulation technology led to the application of breathing walls within traditional barns, and then in the 1980s, inside a small number of traditional residential dwellings. Among the more contemporary installations of breathing wall technologies is the first major building in the United Kingdom to incorporate such a strategy, the McLaren Community Leisure Centre, in Callander, Scotland.

There are several products currently on the market that incorporate dynamic insulation or some of the properties of breathing walls. A start-up company in the United Kingdom and associated with the research team of Imbabi and Peacock markets "innovative modular breathing wall systems to provide clean, preheated, filtered ventilation air to the building." This project has received substantial funding from the Scottish Executive SMART Program, in order to facilitate development. The specific product sold by EBP is called an Energy*flo* Cell, and it can be easily integrated into a building structure to incorporate the benefits of dynamic insulation. Additionally, Gaia Research Group included dynamically insulated squash courts, bowling hall, sports hall, and swimming pool rooms in the McLaren Community Leisure Centre, which was finished in 1998 in Callander, Scotland. This building was the first major building in the United Kingdom to use dynamic insulation, and is undergoing a detailed monitoring program. Several other companies market "breathing wall" technologies as well, but many of these deal with breathability as it relates to building moisture and mold, rather than the energy-saving performance of dynamic insulation.

Measured and Predicted Thermal Performance

A small-scale breathing wall test facility is developed and used to characterize the performance of a prototype breathing wall (Zhai and Slowinski, 2013). Various experimental parameters, including temperature, pressure, airflow rate, and auxiliary heating load were measured and analyzed.

Test Chambers and Breathing Wall

In order to simulate a wide variety of exterior and interior environmental conditions, separate test chambers of 1.1176 m × 1.1176 m × 1.1176 m each, simulating interior and exterior environmental conditions, are built with R-13 (h-ft^2-°F/Btu) polystyrene panels and can be heated to varying degrees by a system of dimming incandescent lamps. Allowing the temperatures to reach a steady state, this system facilitates breathing wall simulations at winter conditions with a temperature differential of up to 38°C. The test chambers also possess the capability to vary pressure differentials and therefore airflow rates by means of an exhaust fan and a variable outlet damper, in order to develop a pressure drop–flow rate curve for each type of breathing wall construction. Pressures are varied from 2 to 12 Pa and the corresponding air volume flow rates are measured. A small fan is located within the interior space, to encourage even mixing of the interior air. The final configuration can be seen in Figure 4.8.11.

The breathing wall is constructed with outside dimensions of 1.1176 m by 1.1176 m, and features interior and exterior cladding, made of 6.35 mm thick plywood. The exterior façade features an inlet grille located in the center of the wall, 0.767 m up from the bottom. The interior façade features a similar exhaust grille located 0.2 m from the bottom. An air gap is created between the cladding element and the porous breathing wall material, such that air is allowed to freely flow away from the inlet vent and penetrate the porous material in a relatively even fashion. The prototype breathing wall was constructed using commercially available unfaced fiberglass batt insulation, which was spread out across a fiberglass window screen and secured within the wood plane of the wall.

Temperature is measured by thermocouples at 44 different locations, both inside and outside of the test chamber (shown in Figure 4.8.11). The selected locations allow for the determination of average interior and exterior temperatures, average interior wall temperatures, exhaust air temperature, laboratory ambient temperatures, breathing wall vent temperatures, as well as simple wall temperature profiles at four poles throughout the breathing wall media. Thermocouples are embedded at various depths (25%, 50%, and 75%) throughout the breathing wall, to form four different "poles" (see "filter media poles" in Figure 4.8.11) so as to obtain simple temperature profiles throughout the wall in desired locations. Additional thermocouples are located in both the interior and exterior air gaps of the poles. One thermocouple is located within the exterior vent and another within the interior vent, in order to measure both the inlet and exhaust breathing wall air temperatures. Agilent VEE Pro 2.4 is used to monitor and record all of the data from the thermocouples, resistance temperature detector, and digital manometer. Experiments continue as long as necessary

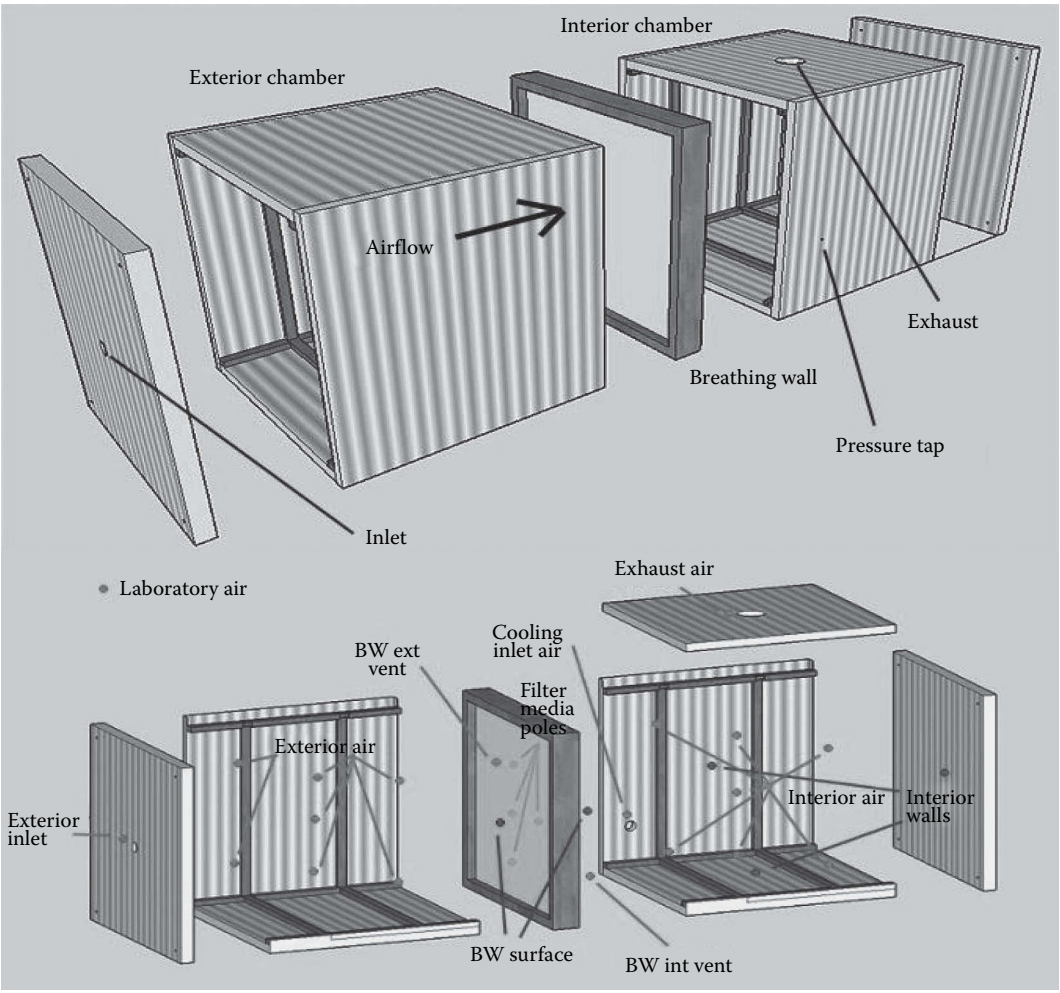

FIGURE 4.8.11 Experimental test chamber setup and thermocouple locations.

to achieve average temperature changes <0.5°C per hour. In some cases, steady-state conditions can be achieved within 2 h, while in others, it may take more than 24 h. The measurement accuracy meets or exceeds all relevant ASHRAE/ASTM standards.

Measurement Results and Analysis

In order to properly document the energy savings of the ventilated breathing wall assembly over a static wall construction, a base case is defined, from which the static wall heat loads can be calculated. The base case consists of a conditioned stream of ventilation air entering through a simple vent in one of the test chamber walls, rather than passing through the breathing wall. Winter conditions are simulated by heating the interior test chamber up to temperatures as high as 60°C, to provide contrast with the "outdoor" environmental conditions found in the exterior chamber, at 22°C. In each of the 13 base case runs, temperature, pressure, and airflow measurements were taken in the same fashion as in the dynamic breathing wall cases. Twenty experiments were performed with varying "outdoor" conditions simulated in the exterior chamber and with ventilation air flowing through the breathing wall. The 20 dynamic runs consist of permutations of four different airflow rates across the breathing wall and five different temperature differentials, with a temperature range similar to that of the base case runs.

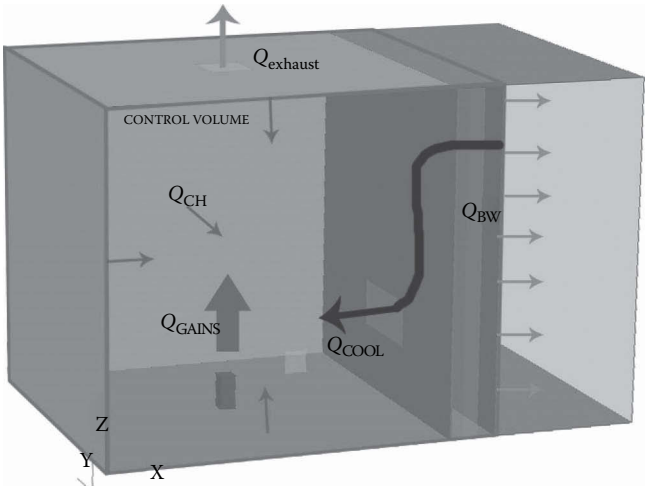

FIGURE 4.8.12 Energy balance model for the test chamber.

It is important to quantify the thermal performance and potential energy saving of breathing walls, such that the benefits of breathing wall technology can easily and effectively be incorporated into whole building energy simulations. Efficiency values that allow for interpretation of the breathing wall's performance can be developed from the energy balance equation. The control volume is defined as the interior surfaces of the interior chamber walls, extending out to the exterior surface of the breathing wall. The energy balance equation accounts for HVAC energy supply within the interior space, as well as the air being exhausted by the exhaust fan and heat loss through chamber walls. A conceptual model of the experimental model energy balance can be seen in Figure 4.8.12.

Equations in the experimental model energy balance include the exhaust energy flow, Q_{exhaust}, as seen in Equation 4.8.1, and the enthalpy being introduced into space as ventilation air through the breathing wall, Q_{cool}, seen in Equation 4.8.2. Note that in the dynamic cases, $T_{\text{cooling-inlet}}$ represents the temperature at the breathing wall exterior vent, while in the base cases, it represents the temperature at the supply inlet on one of the chamber walls:

$$Q_{\text{exhaust}} = \dot{m} \times C_{\text{p}} \times T_{\text{exhaust}} \tag{4.8.1}$$

$$Q_{\text{cool}} = \dot{m} \times C_{\text{p}} \times T_{\text{cooling-inlet}} \tag{4.8.2}$$

Equation 4.8.3 shows the heat flow through the test chamber walls. The UA value of the test chamber is derived from the tests in Section 3.1:

$$Q_{\text{ch}} = UA_{\text{ch}} \times \left(T_{\text{interior-walls}} - T_{\text{lab}}\right) \tag{4.8.3}$$

Q_{gains} is the combination of the heat input from the bulb and from the mixing fan. The final energy balance equation for the test chamber provides an analytical solution for Q_{BW}, shown in Equation 4.8.4:

$$Q_{\text{BW}} = Q_{\text{cool}} + Q_{\text{gains}} - Q_{\text{ch}} - Q_{\text{exhaust}} \tag{4.8.4}$$

Krarti (1994) defined the efficiency of breathing walls (referred to as η_{l}) as a function of the total energy needed by a case with breathing walls, Q_{dynamic}, and that used in a similar scenario with dedicated vents, Q_{static}, as in Equation 4.8.5:

$$\eta_{\text{l}} = 1 - \frac{Q_{\text{dynamic}}}{Q_{\text{static}}} \tag{4.8.5}$$

Taylor et al. (1996) defined efficiency (referred to as η_2) as a function of breathing wall conduction heat exchange (excluding the heat being carried by airflow) and static breathing wall heat exchange, as seen in Equation 4.8.6:

$$\eta_2 = 1 - \frac{Q_{\text{BW, dynamic}}}{Q_{\text{BW, static}}} \tag{4.8.6}$$

In order to account for any increase or decrease in conduction heat transfer through the breathing wall, this study defined the term U_{dynamic} in Equation 4.8.7 simply as the heat flow through the non-vent portion of the breathing wall, divided by the product of wall area and temperature differential across the wall surfaces:

$$U_{\text{dynamic}} = \frac{Q_{\text{BW, dynamic}}}{A_{\text{BW}} \times \left(T_{\text{inside-surface}} - T_{\text{outside-surface}}\right)} \tag{4.8.7}$$

The third definition of efficiency, referred to as η_3, is defined as in Equation 4.8.8 (Zhai and Slowinski, 2013):

$$\eta_3 = 1 - \frac{U_{\text{dynamic}}}{U_{\text{static}}} \tag{4.8.8}$$

Many building energy simulation programs, such as DOE-2 or EnergyPlus, calculate the amount of energy load dedicated to conduction losses through building walls and the amount of heating outside air for ventilation purposes. If U_{dynamic} for a dynamic wall can be determined and used to replace the corresponding U_{static} in the input file of a building energy simulation program, the potential energy savings on an hourly basis using the dynamic wall can then be predicted with these energy simulation programs.

Multiple regression analyses were conducted on the experimental data points, and correlations were developed, respectively, for Q_{static}, Q_{dynamic}, $Q_{\text{BW,static}}$, $Q_{\text{BW,dynamic}}$, U_{static}, and U_{dynamic}. The developed correlation between interior–exterior temperature differential, airflow rate, and dynamic case Q_{dynamic} can be seen in Equation 4.8.9. The calculated R^2 value for this correlation is 93.15%, indicating a fairly close match. In particular, the correlation predicts values with lower values of Q_{dynamic} very accurately, while the data points with higher Q_{dynamic} values appear more scattered:

$$Q_{\text{dynamic,exp}} = \left(6.176 \times \ln\left(1.249 \times \dot{V}\right) - 5.556\right) \times \Delta T_{(\text{avg, inside-avg, outside})} \tag{4.8.9}$$

where $\dot{V}$ is the average "breathing" air velocity over the entire wall surface in CFM/m^2. The applicable mass flow and temperature differential ranges are 5.9–16 CFM and 9°C–38°C, respectively. In contrast to the dynamic case values, the Q_{static} base case values conform much more closely to the determined correlation, shown in Equation 4.8.10. This correlation has an R^2 value of 99.53%, indicating a very close match. Consequently, there is no trend of overprediction or underprediction from the correlation:

$$Q_{\text{static,exp}} = 1.108 \times \dot{V} \times \Delta T_{(\text{avg, inside-avg, outside})} \tag{4.8.10}$$

Similarly, $Q_{\text{BW, static}}$, $Q_{\text{BW, dynamic}}$, U_{static}, and U_{dynamic} are obtained below:

$$Q_{\text{BW, dynamic, exp}} = 1.781 \times \dot{V} + 3.658 \times \Delta T_{(\text{avg, inside-avg, outside})} - 15.483 \tag{4.8.11}$$

$$Q_{\text{BW, static, exp}} = (0.241 \times \dot{V} + 1.866) \times (\Delta T_{(\text{avg, inside-avg, outside})} \times 0.821 + 2.739) \tag{4.8.12}$$

$$U_{\text{dynamic,exp}} = 0.103 \times \dot{V} + 2.165 \tag{4.8.13}$$

$$U_{\text{static,exp}} = 0.211 \times \dot{V} - 0.097 \times \Delta T_{(\text{avg, inside-avg, outside})} + 2.883 \tag{4.8.14}$$

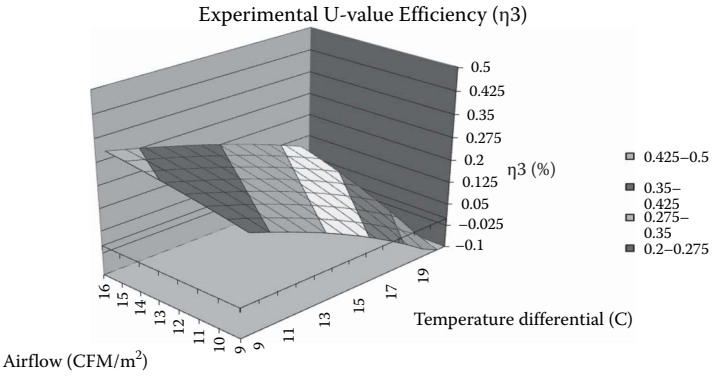

FIGURE 4.8.13 Experimental efficiency (η_3) for varying temperature gradients and airflow rates.

Now that trends in the base and dynamic case indicators have been obtained, they can be compared to examine the measures of efficiency. Previous research has suggested that efficiency measures, at least for one-dimensional cases and for breathing walls with no internal air cavities, depend only upon the airflow rate and not upon the temperature differential. The developed correlations certainly suggest that flow rate plays more of a role, as the coefficients of flow rate in the equations are generally larger. However, the experimental results suggest that temperature differential does have some impact upon efficiency trends. Figure 4.8.13 shows the η_3 contour (defined in terms of U_{dynamic}). The experimental results show a clear positive correlation between airflow rate and efficiency, as well as a clear negative correlation between temperature differential and efficiency. Efficiencies range from –10% to 30%.

Predicted Results with Analytical Formula and Computational Fluid Dynamics Simulation

The study compared the calculated efficiency of the tested wall to the analytical solutions obtained by Krarti (1994) and Taylor et al. (1996). Both analytical solutions were developed for ideal and uniform flow through one-dimensional porous walls. The three-dimensional experiment has small inlet and outlet vents on the walls as well as interior wall cavities, which will introduce different heat transfer behaviors. Figure 4.8.14a demonstrates that the efficiency η_1 does not vary with temperature differential. Taylor's efficiency η_2 appears to vary with temperature differential as noted in Figure 4.8.14b. Experimental efficiencies have similar trends to the analytical solutions, although the efficiencies are much lower, with negative efficiencies below certain airflow rates.

A computational fluid dynamics (CFD) model was created to explore the flow details in and out of the breathing wall that could not be revealed in the physical experiment. A Reynolds Average Navier–Stokes (RANS) CFD simulation tool (with the KE Renormalization Group (KERNG) turbulence model) was used to simulate various tested chamber conditions with a 500 *K* nonuniform grid (identified via a rigorous grid-independence study). Figure 4.8.15 illustrates that free convection circulation loops are formed at both the interior and exterior air gaps within the breathing wall. These circulation loops may play a part in increasing convection heat transfer within the wall and decreasing the efficiency as temperature differential across the wall increases. CFD provides similar efficiency results and trends as the experiments as qualitatively illustrated in Figure 4.8.16b.

Multilayer Living Walls

Background

Using biomimetic principles, multilayer living wall concept can be proposed and developed. Figure 4.8.16 illustrates the vision of such a climate-adaptive intelligent wall structure with embedded systems of air (respiration in body), water (blood in body), and PCM (fat in body). It shows a

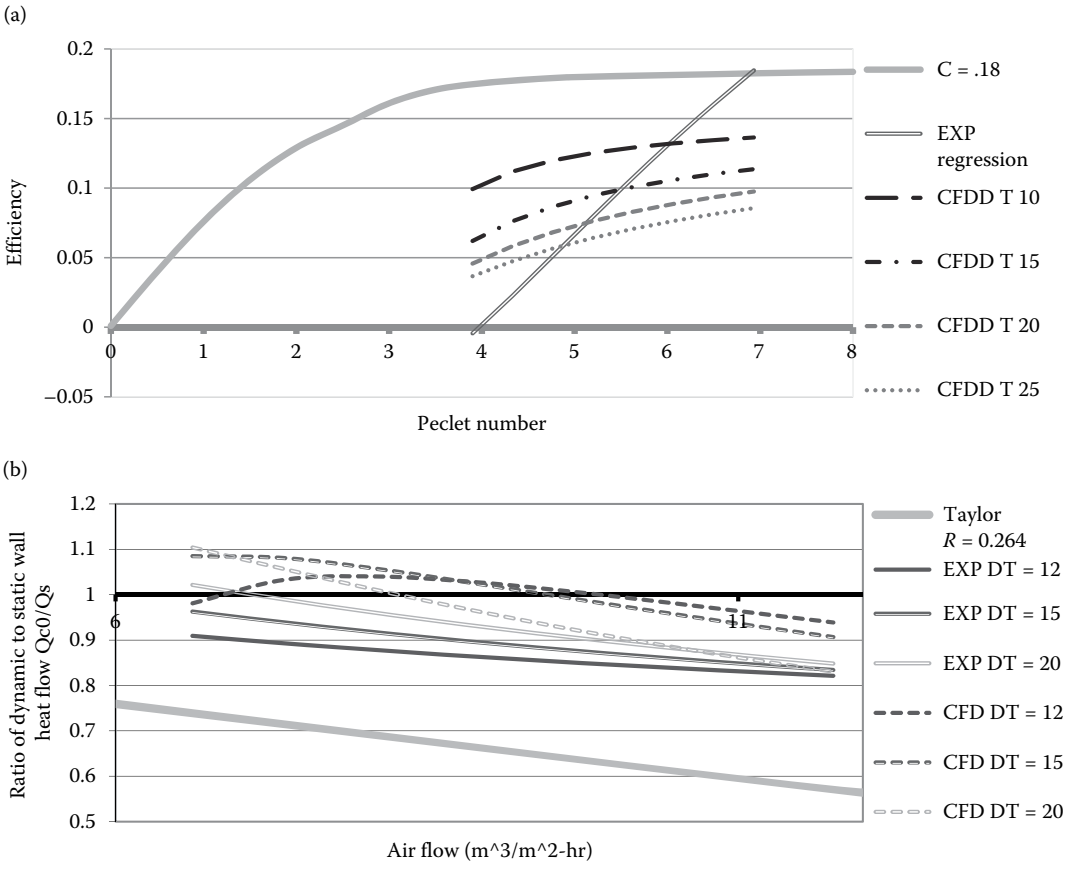

FIGURE 4.8.14 Comparison of analytical efficiency of Krarti and Taylor and CFD results with tested efficiency.

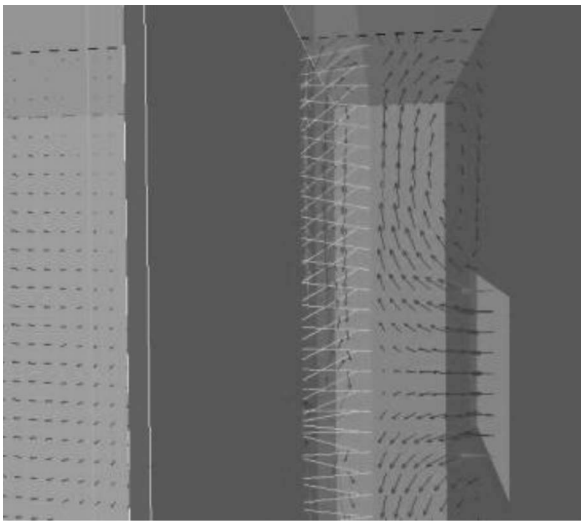

FIGURE 4.8.15 Airflow vectors within the breathing wall, indicating circulation loops. Color profiles are based upon air velocity.

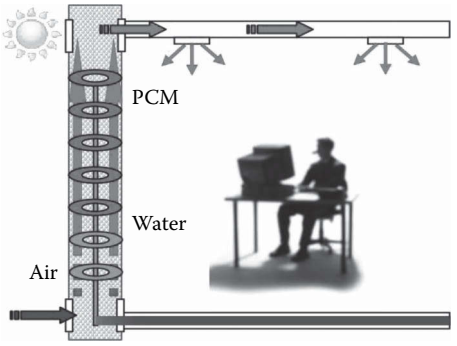

FIGURE 4.8.16 Illustration of a living wall system design; solar energy is harvested via a slab water radiation system and a buoyancy-driven overhead air distribution system.

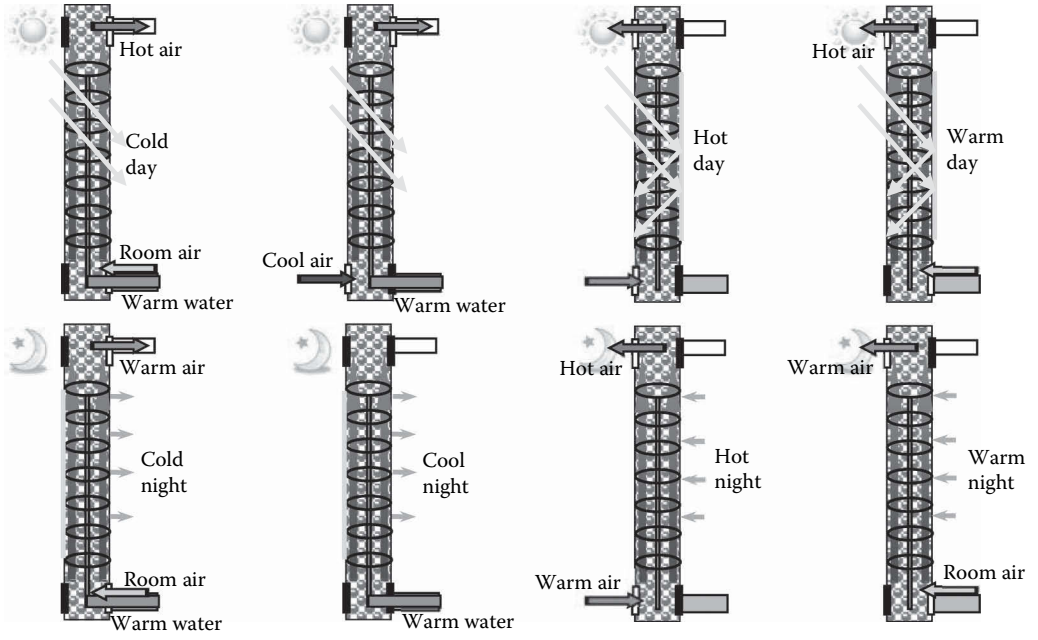

FIGURE 4.8.17 Illustration of different environmental and system operating conditions.

potential design of the living wall system for transferring and use of solar heat via a slab water radiation system and a buoyancy-driven overhead air distribution system. Proper design and control of the heat charge/discharge of PCM and circulation of gas and liquids in microvascular fluid systems can effectively manage the heat gain and loss through the structure, and maintain a pleasant indoor environment with comfortable temperature/relative humidity and adequate fresh air under dynamic climate conditions. This naturally controlled system will not only significantly reduce the total energy cost required to heat, cool, vent, and light the spaces, but also create attractive architectural features. Figure 4.8.17 illustrates different environmental and system operating conditions.

Thermal Models for Advanced Façade Systems

Modeling heat transfer processes of the air, liquid and PCM systems and exploring the thermal coupling fundamentals between various heat sources and sinks are the most important but challenging work. This requires establishing more sophisticated fluid dynamics and heat transfer models that can

account for the coupled multiphysics and multiphase fluid flow and heat transfer processes with connection to both indoor and outdoor environments. A generic program for studying advanced façade systems (named "AdvFacSy") has developed and validated for this purpose using Simulink environment. The program includes (1) weather data reader; (2) solar radiation model; and (3) models for different wall layers (e.g., solid, cavity, glass, PCM, etc.) that can be used to form different wall configurations (AL Saadi and Zhai, 2015).

Using "AdvFacSy," a variety of wall designs can be easily generated and assessed under different climatic conditions. In addition to envelope designs, the program can be used to evaluate different operational strategies such as to charge and discharge energy stored in PCMs using the air in the cavity as a heat transfer medium. The air is driven by thermal buoyancy or mechanical fan. The air can be induced from the outdoor environment or indoor via air vents located at top and bottom of the façade system. The controlling mechanism facilitates the charging and discharging of PCMs in the wall unit. The recovered heat can then be directly used to meet the heat demand, or used to preheat fresh air before treated centrally in air conditioning system, or transported to other heat storage medium for later usage. The program has been well validated against experiments for both conventional multilayer walls and ventilated cavity walls (EL Mankibi et al., 2015).

Simulated Thermal Performance of Stand-Alone Advanced Multilayer Wall

Simulation Parameters The AdvFacSy tool can be used to study the performance of a stand-alone exterior envelope assuming a predefined indoor air temperature representing interior boundary conditions. As a demonstration, the heating season from January to the end of April and again from October to the end of December is modeled. During this period, the indoor air temperature is unchanged at 22°C. The cooling season is from May to the end of September where the cooling set point is constant at 24°C. The exterior boundary conditions are provided using the weather file in EnergyPlus format (EPW) for Golden, CO. The inside and outside convective heat transfer coefficients are important factors that may influence the thermal performance of the PCM-enhanced walls. For this study, the internal convective heat transfer coefficient is assumed to be 4.43 W/m^2 K based on the experimental results from Liu and Awbi for PCM wallboards under natural convection (Liu and Awbi, 2009). The outside convective heat transfer coefficient is based on ASHRAE winter design conditions (ANSI/ASHRAE, 2011).

The main objective of this analysis is to study the general behaviors and identify the overall trends of thermal performance of the PCM-enhanced ventilated walls under typical meteorological weather data. Four performance indicators have been selected to investigate the impact of PCM: peak heating load, annual heating load, peak cooling load, and annual cooling load. The peak heating load is the maximum instantaneous heat flux from indoor environment to the wall surface. The peak heating load is used for sizing heating systems. The annual heating load is the yearly summation of the instantaneous heat flux from the indoor to the wall's surface. The peak cooling load, on the other hand, is the maximum instantaneous heat flux from interior wall's surface to the indoor. The peak cooling load is used for sizing cooling systems. The annual cooling load is the yearly summation of the instantaneous heat flux from the wall's surface to the indoor environment.

For all the cases, the PCMs are assumed to be concentrated as a separate layer with an overall thickness of 12.5 mm. Such systems have been proved to offer higher potential for heating and cooling application when compared to the randomly distributed mixed system (Kim and Darkwa, 2003). A lightweight wall system for residential building is selected. The reference wall has been developed for Golden, Colorado climate based on the Building America House Simulation Protocols (Hendron and Engebrecht, 2010; Engebrecht-Metzger et al., 2012). This analysis can be used for new design or for retrofitting existing buildings.

A ventilated cavity wall design is proposed and tested as schematically shown in Figure 4.8.18, where the PCM is located to the interior side of the wall (the most efficient location as proved previously). The ventilated cavity wall design consists of several components: the main multilayer wall, a cavity, and a glazing, whereas the cavity and glazing characteristics are of top design interest. The

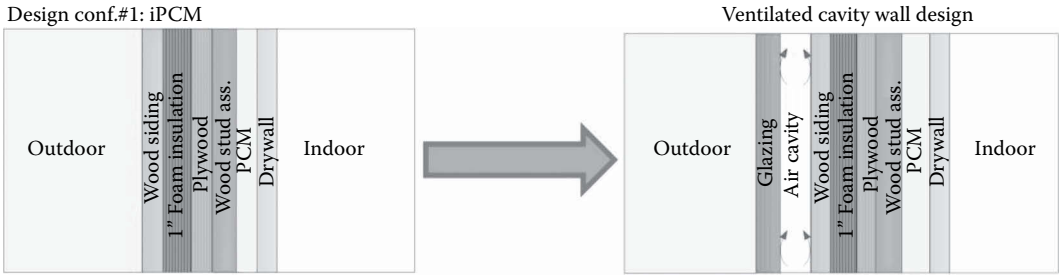

FIGURE 4.8.18 Multilayer wall configuration and the ventilated cavity wall design for harvesting solar for heating purpose.

cavity depth of 0.15 m and vent area of 1.05 m^2 are adopted. A typical double glazing is used and the air is naturally induced from the indoor environment in this design analysis. The rationale behind this design selection has been thoroughly investigated by Al-Saadi (2014). Upon the same design of the ventilated cavity, a base model without the PCM layer is simulated as a comparison. A series of simulations are performed for various PCM characteristics including the latent heat between 50 and 300 kJ/kg at an increment of 50, the melting temperature of 20°C–25°C at an increment of 1°C, and the melting range of 0.1°C, 1°C, 2°C, 4°C, and 6°C.

Simulation Results and Analysis Figure 4.8.19 shows the simulated results of all orientations across all the PCM parameters. The dotted line below all curves represents the contribution of the cavity when no PCM is used. It is apparent that the performance of PCM has been improved by introducing the cavity. There is a clear distinction in PCM's performance as the melting temperature varies. When no cavity is used, the maximum savings in annual heating load was found ~3%. When a cavity is introduced in the south wall, the maximum savings in annual heating loads reaches above 95% as shown in Figure 4.8.19a for the south wall case. Cavity contributes 65% of savings in annual heating loads and the rest (i.e., of more than 30%) is due to PCM layer.

The PCM contributions in west and east are lower than the south wall as shown in Figure 4.8.19c and g. The savings in annual heating loads due to PCM is around 20%, if cavity contribution due to conduction is subtracted. The cavity in North wall is not effective in improving the performance of PCM as shown in Figure 4.8.19e. When PCM is used, the savings in annual heating loads is less than the case when no PCM is used. This is likely due to the storage of PCM which is not utilized internally to reduce heating demand. In all the cases, the optimal melting temperature is close to the heating set point of 22°C with a narrow melting range of 0.1°C. At melting temperature away from the heating set point, the PCMs with wide melting range give more savings.

The savings in peak heating load has improved when the cavity design is compared to the non-cavity design. For all orientations, the savings in peak heating loads are similar as shown in Figure 4.8.19b, d, f and h. For south multilayer PCM wall, a maximum savings in peak load achieved with the noncavity case is 20%. For the cavity design, the maximum savings in peak heating load is around 50%. When cavity contributions are ignored (i.e., 15.40%), 34.5% savings in peak heating load is due to the PCM layer only. This is a 14.5% improvement over the noncavity design. The savings in other orientations are also similar to the south wall. In all cases, the optimal melting temperature is below 20°C with a narrow melting range of 0.1°C.

A clear distinction between PCMs with different melting range is observed. Those with narrow melting range achieve their maximum savings in annual heating loads at melting temperature close to the heating set point, following a triangular shape. This group then tends to give low savings as the melting temperature moves away from the set point. The savings of the wide melting range is flat and therefore are less sensitive to the heating set point. This group can be considered conservative. When the cavity contributions are subtracted, the cavity enhances the performance of interior PCM from 3% with no cavity to 30% for south and 20% for east and west. The cavity on north did

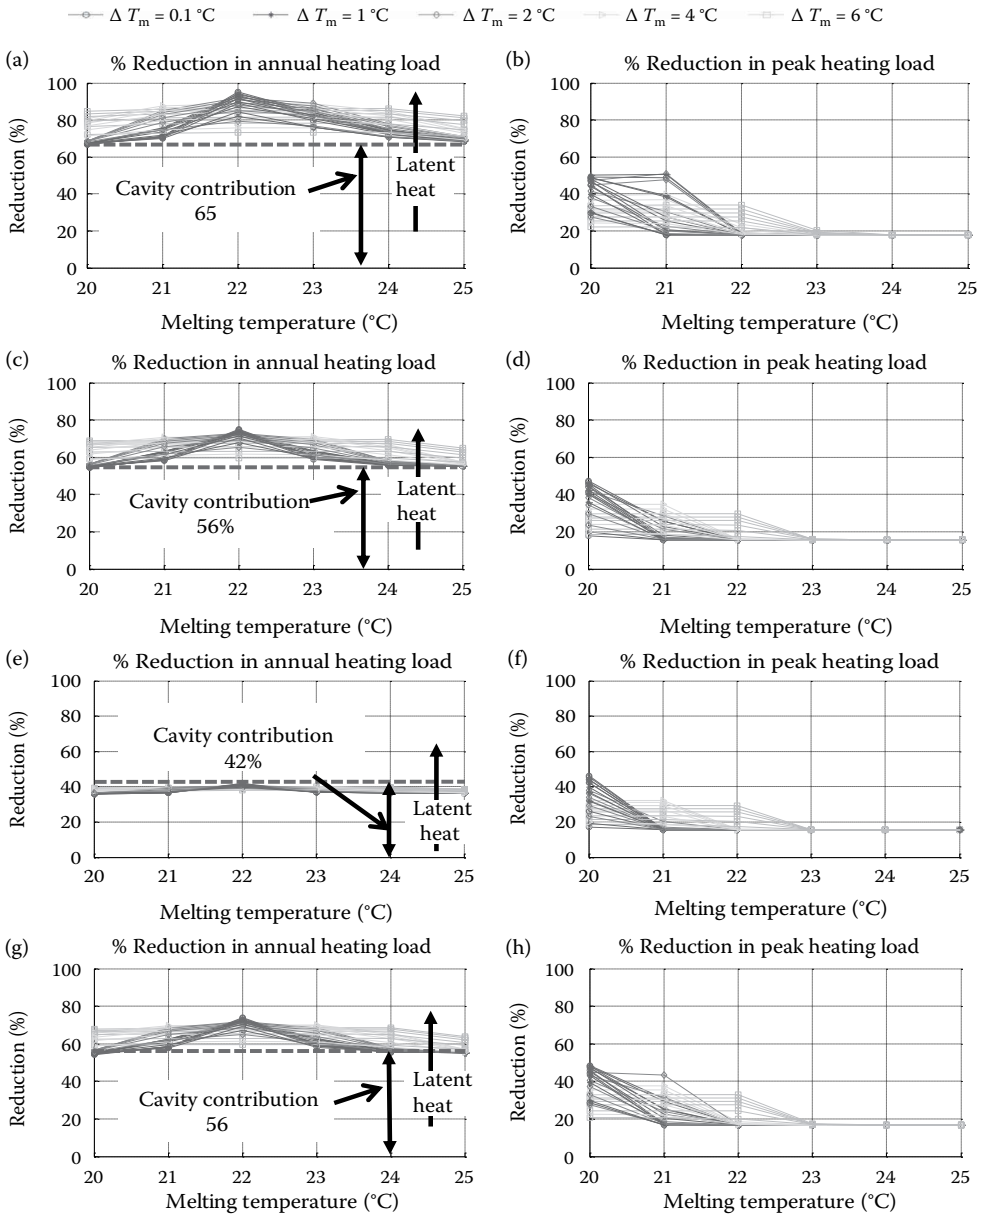

FIGURE 4.8.19 Percentage reduction in heating loads across all PCM's thermal parameters for ventilated cavity PCM-enhanced wall under Golden CO (a) % reduction in annual heating load for south wall, (b) % reduction in peak heating load for south wall, (c) % reduction in annual heating load for west wall, (d) % reduction in peak heating load for west wall, (e) % reduction in annual heating load for north wall, (f) % reduction in peak heating load for north wall, (g) % reduction in annual heating load for east wall, and (h) % reduction in peak heating load for east wall.

not improve the performance of PCM. In all cases, the optimal melting temperature is close to the heating set point of 22°C with a narrow melting range of 0.1°C.

Simulated Thermal Performance of Whole Buildings with Advanced Multilayer Walls

The developed and validated AdvFacSy model was integrated into a full-scale building simulation model, the HYBCELL 1.2 (El Mankibi et al., 2006). HYBCELL 1.2 was developed under

MATLAB/Simulink environment by coupling a thermal model and a pressure airflow model. The building thermal model can be divided into three parts: the envelope model based on the finite volume method, the short-wavelength radiation model based on an accurate description of the sunspot inside the simulated building, and the long-wavelength radiation model using the radiosity method. The airflow model is a pressure model that takes into account the effect of the wind and the thermal buoyancy of air to calculate the airflow through the openings of the building. Indoor air temperature is calculated considering several thermal evolution phenomena, such as heat transfer through the walls, air infiltration and ventilation, internal heat gains, and auxiliary heating or cooling. Schedule and occupation patterns can also be integrated into the model.

The tested building is an 80 m^2 single zone dwelling having a rectangular shape (10 m long, 8 m wide, and 3 m high). The studied multilayer wall represents the south facade. The properties of the walls (refer to Table 4.8.4) and the windows (illustrated by Figure 4.8.20) were defined to represent several configurations (i.e., high and low inertia, large and small glazing area). Table 4.8.4 presents material layer thicknesses adopted in the case of a building envelop with high inertia. In order to simulation building envelop with low inertia, the internal layer (Layer 1) of vertical walls and Layer 2 of roof and floor has been divided by 10 (0.02 m instead of 0.2 m). The building configurations

TABLE 4.8.4
Properties for Building Materials in Multilayer Walls

Wall	Thickness (m)		Density (kg/m^3)	Specific Heat (J/kg K)	Conductivity (W/m K)

	0.1	0.1	1500	800	0.2
Floor and roof	0.01	0.01	1500	700	1
	0.2	0.02	2500	700	1.5
South wall	Studied multilayer wall				

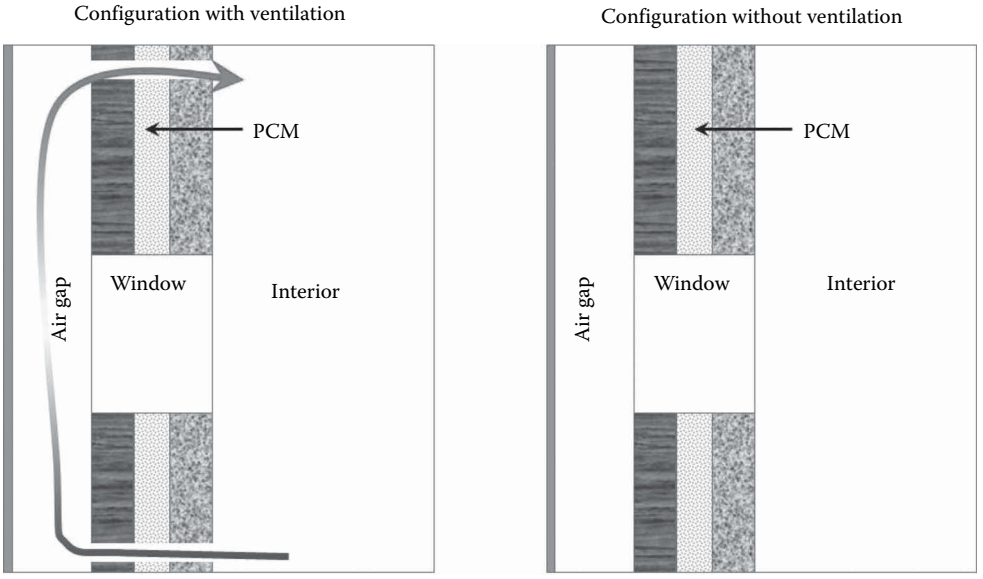

FIGURE 4.8.20 Multilayer wall configurations coupled to a full-scale building.

with large glazing have two windows in each façade except north façade (Figure 4.8.20) with a percentage of 26.39% of glazed area, and the building configuration with less glazed area (13.19%) has only one window per façade except north façade.

The tested multilayer wall is composed of three layers (external sensible storage layer, intermediate latent heat storage layer—PCM, and internal sensible storage layer). The goal is to investigate and optimize the thickness, density, and conductivity of the three layers and the melting temperature range and latent heat of PCM layer. To perform the optimization, NSGA-II (Deb, 2015), a nondominated sorting genetic algorithm (NSGA) tool coupled to Simulink model has been used. The ranking criteria (to minimize) are: heating energy consumption (kWh) and thermal discomfort risk (°C-hours) related to the number of hours when indoor air temperature is above 25°C. The energy consumption is evaluated calculating the injected heat (convective heating) at each step time in order to keep indoor air temperature above the set point. A proportional–integral–derivative (PID) controller maintains the indoor air temperature above 18°C and a shading system is activated to keep indoor air temperature under 26°C. Thermal discomfort risk is calculated using the following equation:

$$\text{Discomfort risk} = \int_{0}^{\text{Simulation time}} \left(\frac{\max\left(0; \left(T_{\text{in}}(t) - 26\right)\right) \cdot \mathrm{d}t}{3600} \right) \tag{4.8.15}$$

where $T_{\text{in}}(t)$ is the indoor air temperature at step time t(°C), dt is the step time (s). Discomfort risk is related to the inertia and greenhouse effect of the multilayer wall cavity. Thus, there is a risk to overheat the building even if the heating system is switched off. If this risk exists in winter conditions it will be higher in summer conditions.

The number of NSGA generations considered is 20 generations with 50 as the size of population. The simulated period is the first week of January. Figures 4.8.21 and 4.8.22 show the examples of

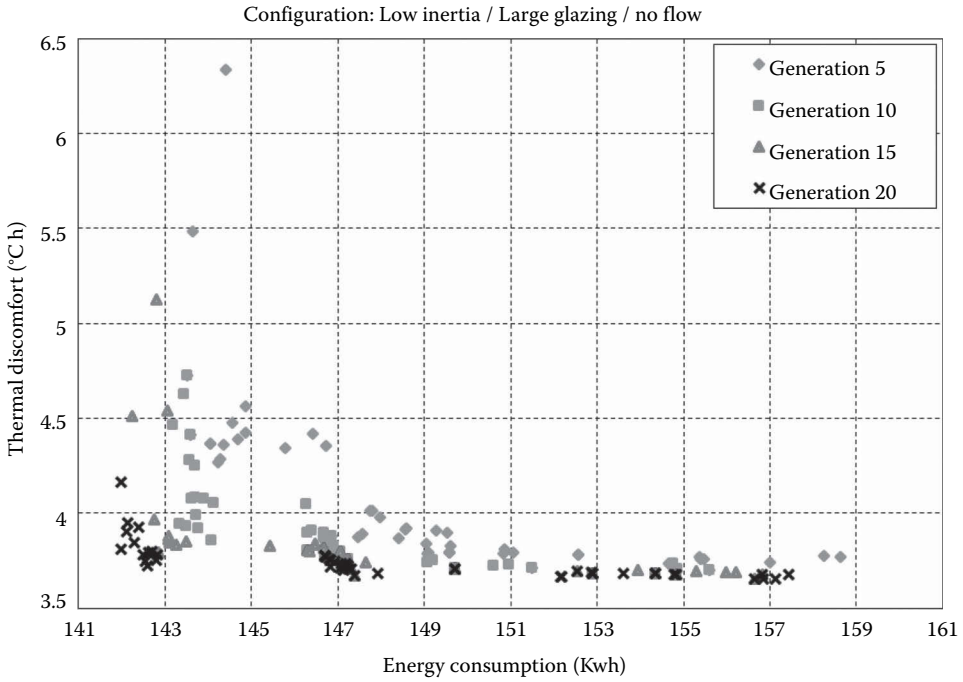

FIGURE 4.8.21 The 5th, 10th, 15th, and 20th generations from GA-based optimization results for low inertia building configuration.

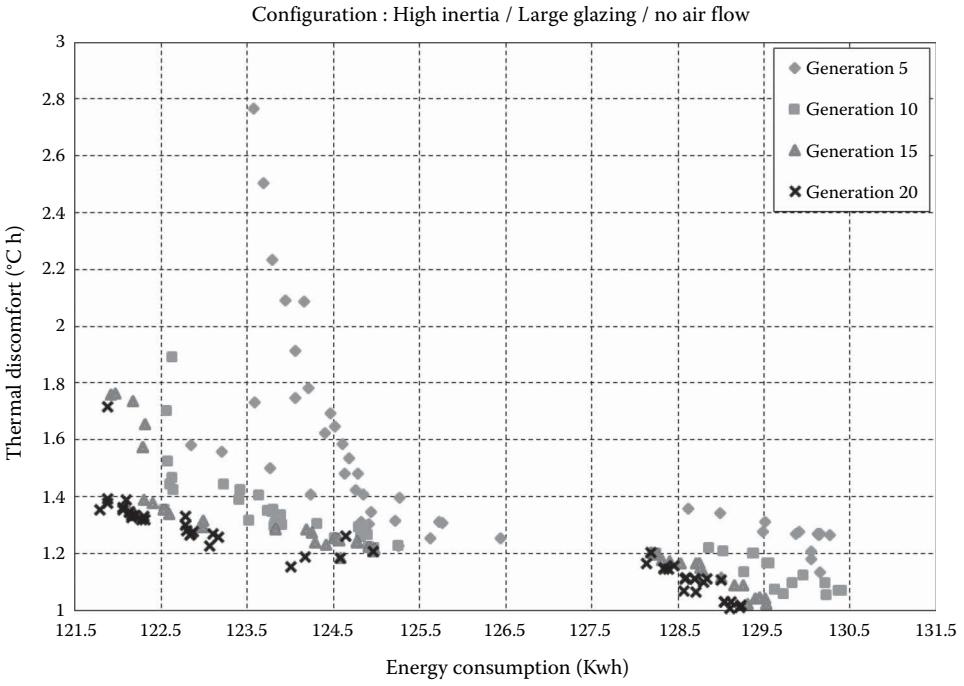

FIGURE 4.8.22 The 5th, 10th, 15th, and 20th generations from GA-based optimization results for high inertia building configuration.

optimization results for the building with high inertia configurations. Each configuration optimization results are shown at the 5th, 10th, 15th, and 20th generations.

Table 4.8.5 summarizes the optimal multilayer wall materials and thicknesses for each tested configuration. Table 4.8.6 shows the energy and thermal discomfort reduction related to the selected optimal multilayer wall configurations shown in Table 4.8.5. The optimal solutions (multilayer wall configurations) are compared to the reference case results. The reference case is a building that has the same characteristics except the fact that the south façade is constituted by a classical wall like all other vertical walls. Thus, there are four reference case studies (with/without inertia and with/without large glazing).

The results show that the performance of multilayer system improves the performance of the reference case study by 28% (building with less inertia configuration) and up to 38% (building with high inertia configuration) in terms of energy consumption. The multilayer configuration without cavity ventilation is thermally more efficient but induces high risk of thermal discomfort. Thus, control strategies of shading and outdoor air circulation should be provided to avoid this risk.

It was found that the PCM layer thickness varies between 1 and 4 cm depending on the whole building inertia. The external and internal layers have to be conductive with high thermal inertia. The thickness depends on the ventilation configuration and the whole building inertia. The internal layer is found to be more sensitive to these two parameters. The same conclusion applies to the glazing ratio and ventilation rate.

Summary and Conclusions

In this chapter, innovative and advanced building envelope systems have been described and their energy performance documented. These advanced wall systems can improve the building energy and thermal performance when designed properly. However and in order to optimize their design and operation, several factors should be considered. Model-based optimal controls may have to be

developed for these systems. A brief summary of the main conclusions and findings outlined for each technology is provided below:

- DIMs have the potential to reduce heating and cooling loads in all three climates compared to statically high insulated walls. In particular, it is found that the two-step DIMs result in higher cooling energy savings in heating dominant locations (i.e., Golden, CO and Madison, WI). Without any internal loads, the maximum cooling energy savings compared to high insulated wall are 32%–39%, respectively, with two-step-RSI-0.5/ RSI-2.5 in heating dominant locations. Moreover, it is found that the effectiveness of DIMs in reducing cooling energy use increase with lower internal heat gains and minimal window size on the wall.
- *Variable Reflectivity Coatings or VRCs* have been shown to offer an effective alternative to static cool roofs to reduce building cooling loads compared without increasing the heating loads. Specifically, it is found that the penalty of increased heating energy consumption associated with static cool roofs is avoided when VRCs are utilized. In particular, the dynamic cool roofs can save up to 15% and 10% in heating energy use compared to static cool roofs for an office building located in, respectively, Chicago, IL, and Golden, CO.
- *Breathing Walls* have a potential to save energy under varying environmental conditions. Both experimental and simulation studies prove that breathing walls can save energy during winter conditions above a certain airflow rate, and their efficiencies, defined by three different metrics, tend to increase with airflow rates. Additionally, in most of the cases, efficiencies tend to show a slight negative correlation with temperature differential, indicating that convection might play a greater role in breathing walls with cavities when the temperature differential is greater. Specifically, the potential energy savings from breathing walls have been shown to range between −10% and +30%, depending upon the airflow rate and temperature differential between indoors and outdoors.
- *Multilayer Living Walls* can offer adaptive envelope systems to changing outdoor conditions. Preliminary analysis results indicate that thermal performance of living walls is enhanced with a PCM as part of the interior layer. For the multilayer PCM-enhanced wall design, a narrow melting range coupled with optimal melting temperature close to the heating and cooling set points achieve maximum savings in annual and peak heating and cooling loads. The full-scale building model results show that when optimized, the living wall system can allow 27%–38% of reduced heating energy consumption while avoiding thermal discomfort.

4.9 USE OF PHASE CHANGE MATERIALS IN BUILDINGS

Jan Kośny and David W. Yarbrough

Introduction and Scope

Thermal storage applications in buildings play an important role in energy conservation. It is greatly assisted by the incorporation of latent heat storage (LHS) in various building components and mechanical systems. It has been observed that building components, which can store excess heat available due to the building's periodic power operation, can also reduce space-conditioning energy consumption. Research has demonstrated that phase change materials (PCMs) improve building energy performance by reducing peak-hour cooling loads and by shifting the peak-demand time. PCMs have been tested as a thermal mass component in buildings for at least 40 years. A key goal in low-energy building research is to find ways to manage differences in time between energy sources and consumption (i.e., building loads). This chapter provides general information about PCM use, discusses the performance of the PCM-enhanced building envelopes, and presents the active space-conditioning systems using PCMs. It reviews the most common PCMs suitable for building applications, and discusses PCM encapsulation and packaging. In addition, this chapter examines the performance of a number of PCM-enhanced building elements and whole-building effects. Laboratory and field experiments used for evaluations of PCM-enhanced building components as well as mechanical systems using PCMs are described. A wide range of commercially available PCM products are identified. Finally, references are given for determining dynamic thermal characteristics of buildings utilizing PCM technologies and numerical tools which can be used to study PCM-enhanced building components.

Properties of Commonly Used PCMs

PCMs are substances with a high heat of fusion which are melting and freezing at a certain temperature or temperature range. They are capable of storing and releasing large amounts of energy. In PCMs, heat is absorbed or released when the material changes from solid to liquid and vice versa; thus, PCMs are classified as LHS materials. The material's ability to store the latent heat is a consequence of different types of phase transitions such as solid–solid, solid–liquid, solid–gas, or liquid–gas phase changes. Of these, however, the solid–liquid transitions are the most commonly used for LHS purposes. A great amount of research data is available today for many different types of PCMs, which are currently available as commercial products for a wide range of phase change temperatures—Farid et al. (2004). For example, Zalba et al. (2003) and Lane (1978, 1980, 1983, 1989) identified over 200 organic substances, inorganic substances, organic eutectics, inorganic eutectics, fatty acids, and noneutectic mixtures with potential for use as a PCM and which are suitable for temperature control applications.

The best-known phase-changing substances, which are commonly used today in technical applications are: paraffins (organic), fatty acids (organic), and salt hydrates (inorganic)—as listed in IEA Task 32, (2005). Different blends of useful eutectic PCMs have also been identified. Figure 4.9.1 depicts phase change enthalpies (Δh, kJ/L) as a function of phase change temperatures (°C) for 12 most common types of PCMs. Phase-changing substances used in commercial applications need to have a possibly high energy of phase transition and, at the same time, they should exhibit melting points that are characteristic for the specific usage. It is expected that PCMs used for building applications should be able to store and release significant amounts of energy on a daily basis for a minimum of 25 years (the common estimate for lifespan of the building components). In addition, this amount of latent heat should be significant compared to the sensible heat gains/losses characteristic for typical building materials.

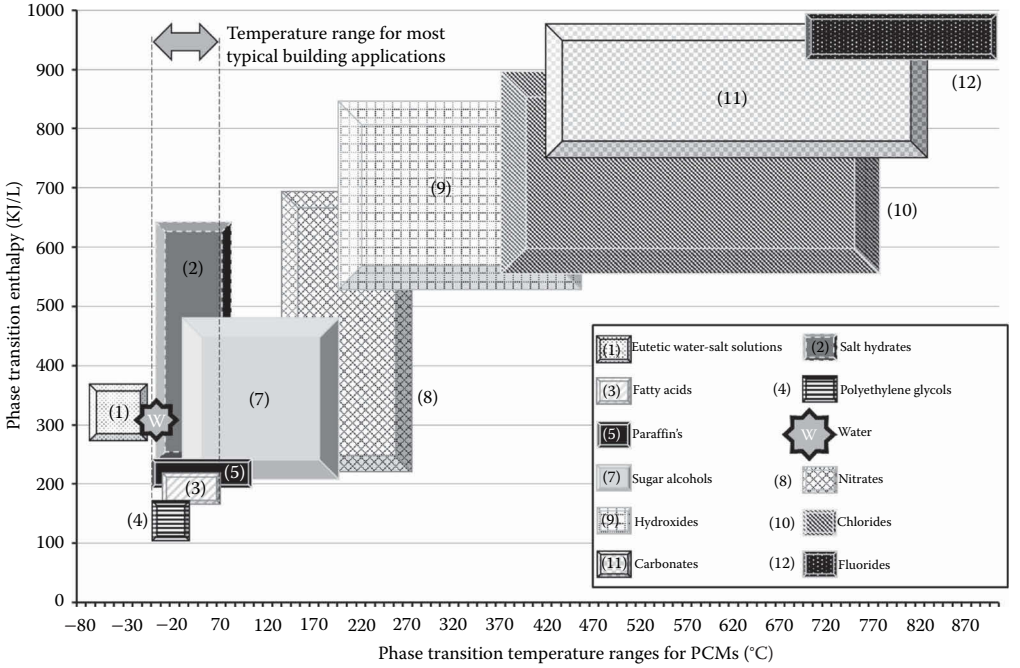

FIGURE 4.9.1 Phase change enthalpy values and transition temperatures for various PCMs.

The majority of PCMs which can be utilized for building applications have Δh values between 100 and 250 kJ/kg. These PCMs are usually 2–10 times lighter than structural materials. They can also store up to 15 times more heat per volume unit, when compared to construction materials such as masonry, concrete, or stone, for a 10 K temperature change. PCM-enhanced building components are often referred to as a lightweight thermal mass. As discussed in Lingayat and Suple (2013), Mehling and Cabeza (2008), and Kośny (2015), numerous differences exist between organic and inorganic PCMs. This includes operating temperature range, phase transition enthalpy, chemical stability, long-term durability, and flammability. These characteristics are especially important for their application in building structures, since the PCM has to be incorporated into the architectural components, finish materials, or thermal insulation.

The category of organic PCMs includes paraffins, fatty acids, fatty acid esters, and alcohols. The key advantages of organic PCMs are their capability to melt and freeze repeatedly without loss of heat storage capability and a fact that they can crystallize with little or no supercooling. Organic PCMs are also noncorrosive. Unfortunately, some organic PCMs exhibit a relatively low fire resistance and readily burn. To enable commercial applications, organic PCMs are often microencapsulated. Sometimes, they are directly blended with carrier materials, or enclosed in plastic containers or foils, arranged in arrays of small pouches. Sometimes, cellular polymers are utilized as carriers for organic PCM. Such process is called shape stabilization—see Inaba and Tu (1997) and Sari (2004). In shape-stabilized PCM products, PCM conforms to the shape of the solid structure during phase transition (Xu et al., 2005). Table 4.9.1 lists the basic physical properties of paraffins having carbon numbers between 14 and 33. They have melting points between 6°C and 71°C, which is within the expected range for building applications.

Salt hydrates, salt mixtures, and metallic materials are frequently utilized for heat storage applications. Of these, hydrated salts are the most commonly used inorganic PCMs because of their low cost. Compared to organic PCMs, they have similar values of Δh (mass basis), but higher values per volume due to their higher density—Kośny (2015). They are also nonflammable and only slightly

toxic (Sharma et al., 2009). Historically, inorganic PCMs were the first LHS materials used in buildings (Telkes, 1952, 1978). These materials were also often installed in solar walls containing massive metal containers. Table 4.9.2 lists the basic phase change properties of selected inorganic PCMs of known phase transition characteristics. In general, for inorganic salt hydrates, densities of solid and liquid phases vary from 1400 to 2000 kg/m^3 (for compounds with melting point suitable for building envelope applications). Hydrated salts are readily available at a low cost. They have a phase change Δh of around 200 kJ/kg and a reasonably high thermal conductivity of about 0.5 W/(m·K). Their thermal conductivity is often at least twice as high as that of organic materials.

The phase transition process for some organic PCMs that occurs at the melting and freezing temperatures involves hydration and dehydration. If water released during the melting process cannot dissolve the crystalline structure of the PCM and there is a significant difference in densities between the solid and liquid phases, then segregation occurs and the heavy component settles on the bottom of the container. Similarly, during the solidification process, poor nucleation of the hydrated salts can result in supercooling and a reduction in the overall performance (Hawes et al., 1993). If an inorganic PCM is not properly formulated, then the situation may become irreversible and the long-term system performance is affected (Farid et al., 2004; IEA, 2005). Building applications are impacted by material compatibility issues that can result in corrosion (IEA, 2005; Mehling and Cabeza, 2008). There are a significant number of other inorganic compounds with desired LHS properties that need to be investigated (IEA, 2005). Since salt hydrates are often not stable at all humidities, they need to be protected from the environment and, for example, loss of water. Plastic pouches or containers are used to protect PCMs from the environment. In many cases, salt hydrates are compatible with plastics.

Utilization of PCMs in the Building Envelope and Interior Fabric

PCMs can be employed in building components for many different purposes, including reduction of space-conditioning energy consumption, thermal peak load shaving and shifting, or improvement of interior thermal comfort. In addition, PCMs can generate a shift of building thermal loads (Kośny and Kossecka, 2013; Kośny et al., 2014). This time-shift can be controlled by the form of PCM application, the PCM location in the case of condensed PCM applications, and the total thermal resistance (*R*-value) of the building component insulation. An approximate temperature range for PCMs used in buildings is from −5°C (building envelope surface temperature during winter) to 70°C (peak roof surface temperature during summer). For more traditional internal building applications, like wall, floor, or ceiling finish, PCM's phase transition temperature should be within the human comfort range of 20°C–30°C. A large variety of research studies demonstrated that an application of thermal mass in well-insulated structures could generate heating and cooling energy savings between 5% and 30% in residential buildings, e.g., see Kośny (2015). Reduction of the space-conditioning energy consumption can be achieved either by improvements in building thermal shell components (i.e., through increasing the thickness of the insulation), or by adding PCM to the walls, roof, attic floor insulation, floors and ceilings, and fenestration components. In early applications, PCMs were often incorporated into conventional construction materials including PCMs mixed with structural concrete, gypsum, or stucco. Manufacturing techniques have been developed for impregnating concrete, gypsum, or ceramic masonry with PCM. It is important to mention that a great variety of PCMs had been tried, including inorganic salt hydrates, organic fatty acids and eutectic mixtures, fatty alcohols, neopentyl glycol, and paraffinic hydrocarbons, e.g., see Feldman et al. (1989), Hawes et al. (1993), Demirbas (2006), and Khudhair and Farid (2007). However, today, after several decades of lab testing and full-scale trials, the most popular PCMs are microencapsulated paraffinic hydrocarbons (Kośny, 2015). Usually, an incorporation of PCMs into the building fabric components involves an application of relatively complex technological processes. It also requires detailed thermal analysis. Please note that a great majority of PCMs used in building envelope applications need to go through a complete phase transition during 24 h time

periods in order to be fully effective. It is crucial that the temperature in the location where PCM is installed cycles above and below the PCM functional temperature range.

In the 1980s, a wide application of organic paraffinic PCMs in gypsum boards took place based on pioneering work of Feldman and Shapiro (1989), Salyer and Sircar (1989), and Tomlinson et al. (1992). In Europe, similar work was initiated by the development of encapsulated paraffinic PCM products. Blends of microencapsulated PCMs with building structural and board materials became at that time a common practice in low energy buildings—see Banu et al. (1998), Hawlader et al. (2003), Zalba et al. (2003), Cabeza et al. (2007), and Kośny (2015). In addition, a variety of manufacturing techniques have been developed for concrete blocks and other ceramic building products containing PCM as discussed by Khudhair and Farid (2004) and Zalba et al. (2003). In the early 2000s, PCM-enhanced building thermal insulations based on incorporating microencapsulated PCM into different types of fiber insulations and plastic foams was introduced (Kośny et al., 2006, 2007a,b). Figure 4.9.2 shows electron microscope images of gypsum and thermal insulation containing microencapsulated paraffinic PCM. PCM-enhanced gypsum boards are still widely considered as the most popular building material using latent heat thermal storage.

Several generations of novel roof designs showing large reductions in peak loads and overall loads have been developed. Results of about 95% reduction of peak-hour cooling loads and over 30% overall cooling load reduction compared with traditional roofs design of the same insulation *R*-value have been reported (Kośny et al., 2010). Figure 4.9.3 shows examples of a standing seam metal roofing system containing arrays of PCM pouches, above sheathing ventilation, reflective insulation, and building integrated PV laminate (Kośny et al., 2012a). Wall applications such as

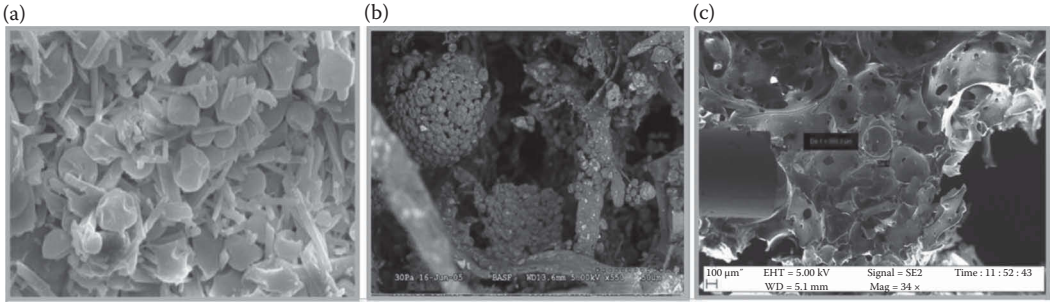

FIGURE 4.9.2 Electron microscope images of PCM-enhanced building materials: (a) PCM-enhanced gypsum composite; (b) cellulose-PCM blend—visible clusters of PCM pellets; and (c) polyurethane foam-PCM blend.

FIGURE 4.9.3 Standing seam metal roof system containing arrays of PCM pouches, above deck ventilation, reflective insulation, and roof-integrated PV laminate.

gypsum or composite boards containing PCM have been tested for the last 40 years, with most of the published research data showing that PCMs can notably enhance energy performance. North American studies (Tomlinson et al., 1992; Feustel, 1997; Kissock et al., 1998; Stovall and Tomlinson, 1995; Zhang et al., 2005; Kośny et al., 2006, 2010; Murugananthama et al., 2010) demonstrated that these applications could generate heating and cooling energy savings of up to 30% in well insulated residential buildings in the southern United States. Similar performance advantages can be found in many reports available worldwide, e.g., see Khudhair and Farid (2004), Zalba et al. (2003), and Kośny (2015).

The major goal of using PCM in fenestration systems is to reduce the building heat gain by absorbing the solar radiation before it reaches the indoor space. An addition of PCMs to the glazing is usually made with transparent plastic containers. PCM-enhanced windows typically consist of a thin layer of translucent PCM combined with a thermally insulating window located on the exterior side. In addition to the exterior thermal envelope applications, PCMs can be incorporated in building components such as internal walls, floors, and ceilings. In these applications, PCMs are usually used to mitigate the interior space temperature fluctuations (Kośny, 2015).

Distributed and Localized PCM Applications in Buildings

Current developments in the area of building technology suggest that both commercial and residential buildings will soon be routinely constructed with low heating and cooling loads. The use of novel building materials containing active thermal components such as PCM will be an important step toward achieving zero-energy buildings. The design of a localized PCM application includes specification of the PCM location in the building enclosure and specification of the thermal resistances bounding the PCM. The location specified must cycle across the phase change temperature for a large part of the year. The amount of PCM used is determined from estimates of the total heat flow across the enclosure during a cycle of operation. The selection of the PCM locations, PCM transition temperature range, and the amount of used PCM are essential for effective and durable use of the PCM-enhanced technologies, considering a relatively long lifespan of building envelopes.

Different configurations of PCM-enhanced gypsum or composite boards, as well as arrays of PCM containers, have been extensively tested as thermal mass components in buildings worldwide. These experiments demonstrated that PCMs can notably enhance energy performance of walls, roofs, and attics. Recent North American studies, performed by Feustel (1995), Athienitis et al. (1997), Kissock et al. (1998), Athienitis et al. (2005), Zhang et al. (2005), Kośny et al. (2006), Murugananthama et al. (2010), and Kośny et al. (2010), have proven that the application of localized PCMs could generate heating and cooling energy savings of up to 30% in well-insulated residential buildings in the southern United States. Childs and Stovall (2012) used numerical analysis to study the thermal performance of different configurations of layered wall cavity insulation using microencapsulated PCM and demonstrated savings.

Paraffinic PCMs are most widely used today as building LHS materials. Though, due to the relatively high cost of paraffin-based PCMs, their flammability, and their origin from petrochemicals, other organic PCMs are being explored today. This includes fatty acids, coming from agricultural and food industry waste. In buildings, interior surfaces such as walls, ceilings, or floors have been traditionally considered as the best locations for the PCM. In case where PCM-enhanced gypsum board or plasters are installed on the interior surfaces, they are expected to stabilize the temperature inside the building. As depicted in Figure 4.9.4, PCM concentrated in the gypsum boards interacts mostly with the building interior space. The combined latent and sensible heat storage capacity of the PCM-enhanced gypsum is used to reduce interior space temperature swings and absorb solar gains coming through the glazing. In this scenario, heat stored in PCM is often discharged by ventilation during the night or by programmed conditioning systems.

Similar to previously described concentrated PCM applications, PCMs can be also mixed with a variety of carrier materials such as concretes, gypsum, foam, or fibrous insulations to

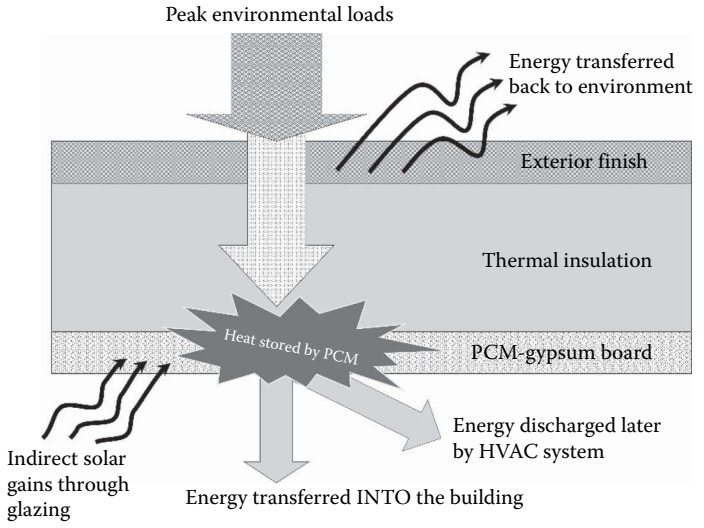

FIGURE 4.9.4 Concentrated PCM application as a part of the interior surface of the building envelope.

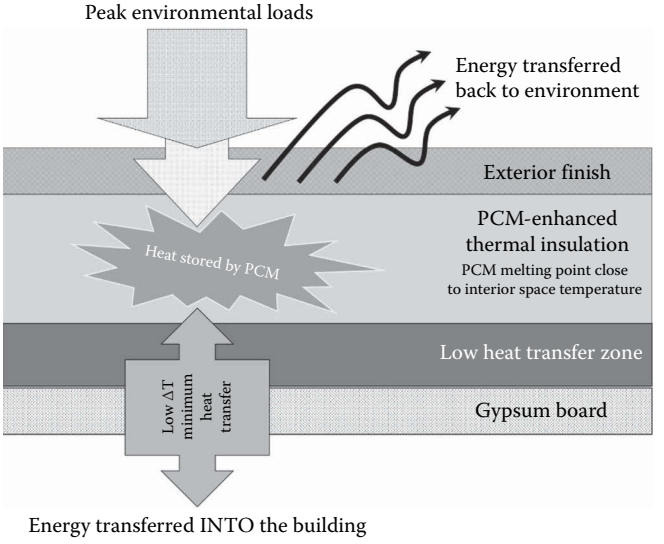

FIGURE 4.9.5 Schematic of a distributed PCM application.

allow distributed applications. As shown in Figure 4.9.5, an application placing PCM inside the wall cavity takes advantage of the large temperature fluctuations that take place on the exterior building envelope surfaces. Many of the North American experimental studies of dispersed PCM applications have been focused either on concrete masonry technologies (earlier works in 1980s), or on lightweight wood framed walls and attics, e.g., see Petrie et al. (1997), Kośny et al. (2006, 2007a,b), Tabares-Velasco (2012), and Kośny et al. (2012b). PCM-enhanced cellulose insulation has been used. Advantages of cellulose originate the fact that natural cellulose fibers can efficiently mix with microencapsulated PCM, while glass or composite fibers have difficulties in structural support of the weight of PCM micropellets. In early North American experiments, paraffinic PCM was utilized—Kośny et al. (2008) and it was later replaced by less flammable bio-based PCM fabricated from waste fatty oils.

Utilization of PCMs in Building Space-Conditioning and Water Heating Systems

A variety of technologies that couple heat pumps to LHS systems have been investigated. Several novel designs of energy storage exchangers utilizing PCMs for storing heat were introduced to ensure the reliable operation of a heat pump under various weather conditions and enhance the system performance at low ambient temperatures. Agyenim et al. (2010) used LHS for residential heating by using a PCM tank (paraffin) that absorbs and releases heat through internal water tubes. Similarly, Stritih (2003) designed two paraffin containers to store latent heat for residential applications. PCM is used in air ducts for LHS. Dolado et al. (2011) and Zukowski (2007) studied the heat transfer between moving air and different forms of PCM containers. These studies led to the conclusion that the air must be blown at high velocity which results in significant fan energy consumption, higher noise levels, and poorer exergy and energy efficiencies.

Domestic hot water tanks generally store heat in the sensible form. PCM heat storage systems have become popular recently due to their capacity of storing energy in high-density PCMs to achieve reduction of temperature stratification within the tank—see Yamaha et al. (2001), Najafiana et al. (2015), and Cabeza et al. (2006). Some advantages were observed, such as the capability of the PCM to reheat the amount of cold water surrounding the PCM after a partial unload. As expected, the PCM-water tank stores up to 8.1% more energy than the water tank, Cabeza et al. (2006).

Laboratory Evaluations of PCM Thermal Performance

It took several decades of intense research and technology development, for PCMs to become one of the most promising technical means of improving the energy efficiency and interior climate stability in residential and commercial buildings. The main benefit of using PCMs is the availability of significant amounts of latent heat during the phase transition processes. In most PCM building applications, the LHS is based on heat absorption or release during a change of phase from solid to liquid and vice versa. The heat storage capacity of materials containing PCMs for a temperature change from T_1 to T_2 that includes the phase change is determined as follows:

$$Q = \int_{T_1}^{T_2} m \cdot c_p \, dT + m \cdot f_m \cdot \Delta h \tag{4.9.1}$$

where f_m is the fraction of the material ongoing phase change, m is the mass, and c_p is the specific heat.

Today, most of commercially used PCM products, when used in small temperature intervals around their phase change temperature, show superior heat storage density (the amount of heat stored in a given material or system per unit volume or mass) compared to sensible heat storage capacity of conventional building materials, such for example, wood, concrete, or brick. Since there are several types of PCMs used in buildings, they also represent a variety of phase change thermal characteristics. That is why during the design process, the enthalpy curve $h(T)$ has to be known to quantify heat storage capacity. Figure 4.9.6 depicts the enthalpy curves for melting and freezing of an organic PCM. Keep in mind that an ideal PCM can be mathematically characterized by four scalar values, namely, the specific heat, c_p, of solid and liquid phases, the phase change enthalpy Δh, and the melting temperature T_m. Still, real phase change processes in real PCMs can be better represented by the function $h(T)$. The precise determination of this function is the goal of variety of available calorimetric measurement techniques. As shown in Figure 4.9.6, enthalpy curves are not always identical for melting and freezing processes. It is often due to the temperature hysteresis phenomenon, which is of course material specific, but it also strongly depends on the test method and equipment—see IEA (2011). In addition, the supercooling effect can be observed in inorganic PCMs. It is associated with impaired PCM nucleation during the freezing process. In many PCM heat storage applications, supercooling can be a source of thermal performance and durability problems.

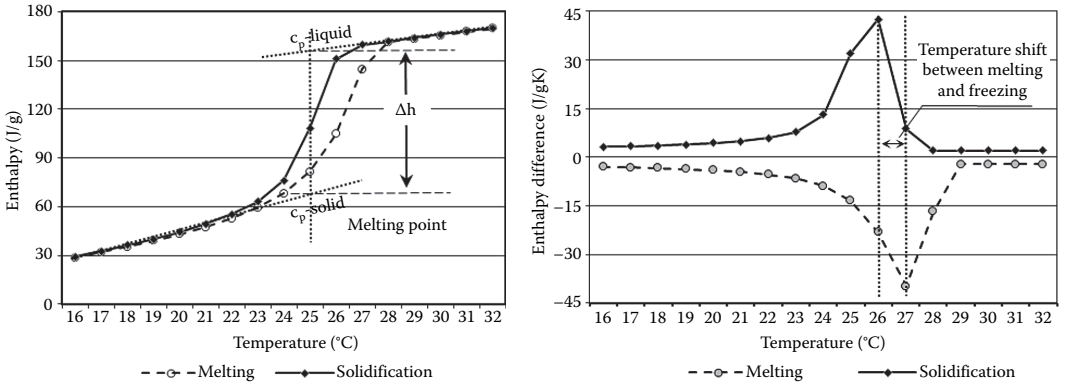

FIGURE 4.9.6 Examples of enthalpy curves for melting and freezing processes showing temperature hysteresis (left) and supercooling effect (right).

In laboratory work, PCM-enhanced building products are usually limited to analysis at the material and systems scale. There are many publications available, which are focused on theoretical and experimental analysis of phase change processes including hysteresis or supercooling phenomena—see Demirel and Paksoy (1993), Martín et al. (2003), Wunderlich (2005), Bony and Citherlet (2007), Mehling and Cabeza (2008), and Günther et al. (2007, 2009). However, the system scale hot-box testing and small building/room experiments can be utilized as well for characterization of building technologies containing PCM—see Kośny (2015).

For a long time, the only readily available material PCM evaluations used differential thermal analysis (DTA) or differential scanning calorimetry (DSC). These techniques were considered as standard tools for the measurement of latent heat of PCMs. These methods, however, require the use of small and relatively uniform material samples (Wunderlich, 2005). Unfortunately, the above requirement is rather unrealistic for most PCM-enhanced building components. Small specimens are not generally representative of PCM-based blends or composites, since these composites are usually heterogeneous. In addition, PCMs used in buildings, due to the cost constrains, are seldom high-quality, pure substances. Typically, PCMs used in buildings contain a wide range of different impurities. That is why a careful sampling is required to obtain the representative test-generated characteristics for building products containing PCMs. This limits the usefulness of DSC and DTA testing procedures to characterize PCMs for use in building applications. Considering the above limitations, Paksoy (1996) introduced the twin water bath method, which determines the thermal storage capacity of PCMs or PCM-based composites. The water bath method is relatively inexpensive, simple and fast, making it widely used today. The method enables evaluation of phase change temperature and the thermal storage capacity of PCM for a wide range of temperatures. In addition, Zhang (1999) and Zhang et al. (2007) proposed the T-history method as an alternative to DSC or DTA testing. It is an inexpensive and easy way to measure the phase change enthalpy of PCM products using test samples significantly larger from what is required for DSC testing. The T-history method can be used for measuring the thermal properties of PCM composites and PCM blends.

Since, most often, PCMs used in building envelopes are difficult to analyze complex heterogeneous composites or structures with multidimensional heat transfer effects, Kośny and Yarbrough introduced a new test method utilizing a ASTM C518 (2013) heat flow meter apparatus—see Kośny et al. (2007b). This method determines the amount of phase change energy available in heterogeneous PCM-enhanced materials to provide thermal storage—Shukla et al. (2013). These developments led to the introduction of a new ASTM standard-ASTM C1784 (2015), "*Standard Test Method for Using a Heat Flow Meter Apparatus for Measuring Thermal Storage Properties of Phase Change Materials and Products.*"

Numerical Tools for PCM Thermal and Energy Performance Analysis

It is expected that the advanced buildings of tomorrow will need to take advantage of the LHS technologies customized for thermal loads mitigation, load shifting from peak to off-peak hours, and for internal thermal comfort improvements. Numerous numerical tools have been developed worldwide to simulate the thermal behavior of PCM-enhanced building components or energy consumption in whole buildings utilizing these technologies. In Crawley et al. (2005), a comprehensive overview was given of various computational capabilities and features which can be found in 20 commonly used building simulation programs. Examples of numerical applications of the programs are listed in Table 4.9.3. It is important to mention here that among a great variety of whole-building computer programs available today, TRNSYS is one of the oldest tools that has been used for decades for analysis of PCM-enhanced building technologies. TRNSYS is the energy simulation software package, developed by the Solar Energy Laboratory at the University of Wisconsin, Madison, USA, that has been extensively used worldwide in the fields of renewable energy engineering, building energy simulations, passive and active solar designs, for over three decades—Pedersen (2007). TRNSYS was adopted by Tomlinson and Heberle (1990) for simulations of the gypsum boards impregnated with paraffin. This work was later continued by Stovall and Tomlinson (1995).

ESP-r is used to simulate PCMs that demonstrate hysteresis. To do this, the program uses different specific heat equations for melting and solidification. ESP-r is a whole-building performance open-source energy tool developed in 1974 by the Energy Systems Research Unit, University of Strathclyde, UK.

The simulation software package "EnergyPlus" was developed by the US Department of Energy. It enables modeling of building energy use with consideration of a variety of HVAC systems. Extensive design options make EnergyPlus a very useful and ideal program for the study of building energy use. EnergyPlus is a collection of modules that are used to calculate heating and cooling requirements. The most recent version of EnergyPlus can be downloaded from the NREL homepage: https://github.com/NREL/EnergyPlusRelease/releases.

CoDyBa is used to analyze transient thermal, and hygrothermal performance of building components subjected to specified climatic conditions (Noel et al., 2001). The program is for the study of heating and cooling strategies including air conditioning, ventilation options, and insulation assemblies. CoDyBa can be used to study the thermal, hygrothermal, and energy performance of building components and buildings of many types and sizes. In addition, it can be used for peak load estimates, building shell optimization, and the design of space-conditioning systems.

The integrated whole-building numerical tool called BSim was developed by the Danish Building Research Institute, of Aalborg University, Denmark. This is a one-dimensional computer model for analysis of heat and moisture transport. BSim is a successor of several earlier-validated numerical components (Rode et al., 2003). Most recent versions of BSim and program technical literature can be downloaded from the Statens Byggeforskningsinstitut, Aalborg University, Copenhagen, Denmark, http://sbi.dk/en/bsim.

WUFI is a set of numerical routines for modeling of heat and moisture transfer within building structures. WUFI, an abbreviation for "Wärme und Feuchte instationär," was developed by Fraunhofer IBP, Holzkirchen, Germany (Kunzel, 1995). Transient heat and moisture transport simulations can be performed in WUFI using user-defined time steps and user-specified time periods. Finite volume methods are employed with building materials containing PCM simulated in WUFI 5.0 and WUFI Plus using temperature-dependent enthalpy.

Examples of PCM Building Applications

The great diversity of building products containing PCM can help in the near future to achieve peak-hour load and HVAC energy consumption reductions. Notable energy savings can be accomplished in residential and commercial buildings, by means of a variety of applications utilizing external envelopes, internal building fabric technologies, and space-conditioning technologies having the capability for passive and active utilization of sensible and latent heat accumulation. Building components with phase transition capability are allowing large amounts of heat to be stored or released due to the latent heat of fusion or solidification. Residential and commercial air conditioning loads during critical peak periods of the day place a burden on the electricity system. Different forms of PCM (boards, containers, and PCM slurry-based systems) could notably reduce the growing peak electrical demand in many climates worldwide. PCM slurry systems have the advantage of low energy consumption and the ability to absorb large amounts of energy cost-effectively. The feasibility of PCM slurry-based mechanical systems used to absorb peak loads in air conditioning units has been analyzed in many projects—see Yamagishi (1999), Schossig et al. (2003), Egolf et al. (2004), Gschwander et al. (2005), IEA Task 32 (2006), Okamoto (2006), Heinz and Streicher (2006), Wang et al. (2007), Thaicham (2008), Maaraoui et al. (2012), and Niu et al. (2013). The major performance issue that usually needs to be validated is the system ability to develop and maintain high volume fraction PCM slurries and the demonstration that pumping the PCM slurry through the heat exchanger can absorb and reject peak air conditioning loads in a cost-effective manner. Further research should be undertaken to find a PCM material that does not exhibit supercooling or to develop a method to induce phase change at the design temperature, e.g., see Goel et al. (1994), Schossig et al. (2003), Bony et al. (2005), Sabbah et al. (2008), and Valan et al. (2013), etc.

The heat capacity of lightweight-construction buildings can be significantly increased by including LHS materials into the building envelope surfaces as well as within the interior building fabric. The use of PCMs in construction materials in a passive way is relatively not new. There were several moderately successful attempts in the 1970s and 1980s to utilize different types of organic and inorganic PCMs to reduce peak loads and heating and cooling energy consumption, as demonstrated by Balcomb et al. (1983), Hawes et al. (1990), and Salyer et al. (1995). These investigations focused on impregnating concrete, gypsum, or ceramic masonry with salt hydrates or paraffinic hydrocarbons. In the 1980s and 1990s, several researchers have investigated methods for impregnating gypsum wallboard and other architectural materials with PCMs including Salyer et al. (1995), Shapiro et al. (1987), Babich et al. (1994), and Banu et al. (1998). One of the simplest methods for addition of PCM to the concrete or gypsum mixtures is a usage of microencapsulated PCM. As an example, Table 4.9.4 shows the physical properties of a commercially available dry plaster mixture containing microencapsulated PCM—Kośny (2015). Different manufacturing techniques, followed with thermal performance of gypsum wallboards and concrete blocks containing PCM, have been discussed by Khudhair and Farid (2004), Zalba et al. (2003), and Hauer et al. (2005). Example material physical characteristics are

presented in Table 4.9.5 for one of the produced Europe gypsum boards containing microencapsulated PCM—Kośny (2015). In addition, an innovative concept of the PCM-enhanced building insulation was introduced by Oak Ridge National Laboratory, USA—Kośny et al. (2006, 2007a).

PCM-enhanced composite boards or panels are usually manufactured with the use of waste wood, cellulose fibers, or fiber-reinforced mineral composites. Composite wood-based products, also called man-made wood, include a range of derivative wood products which are manufactured by binding the wood strands, particles, fibers, or veneers together with most often adhesives to form composite materials. Plywood and oriented strand board are probably the best-known wood-based composites used for construction purposes today. There is also a group of board products utilizing polymer-based shape-stabilized PCM—see Table 4.9.6. Sometimes, these board products are faced with aluminum foil (Kośny, 2015).

TABLE 4.9.4
Physical Properties of Dry Gypsum Plaster Containing PCM

Physical Property	Value
Compressive strength	≥1.5 N/mm²
Thermal conductivity	>0.3 W/m·K
Water vapor diffusion resistance factor μ	10
Shift range of the PCM (23/26)	23°C–26°C
Enthalpy of fusion of the PCM: encapsulated	About 100 J/g
Enthalpy of fusion (*T*s = 23°C–26°C): plaster composite	18 kJ/kg
Thermal conductivity λ (10°C) =	0.19 W/m·K
Density	~0.90 g/cm³

TABLE 4.9.5
Physical Properties of Gypsum Board Containing Microencapsulated PCM

Physical Property	Value
Specific heat	1.2 kJ/kg·K
Thermal conductivity at 20°C	0.20 W/m·K
Thermal conductivity at 35°C	0.19 W/m·K
Shift range of the PCM	23°C or 26°C
Enthalpy of fusion of the PCM	About 110 J/g
Latent heat	330 kJ/m²

TABLE 4.9.6
Dimensions and Characteristics of Composite Board Product with Shape-Stabilized PCM

Board dimensions	1000 mm × 1198 mm × 5.2 mm
Board area weight	24.5 kg/m²
PCM % weight content	60%
PCM melting point	21.7°C
Latent heat (0°C–30°C)	70 kJ/kg
Total heat storage capacity (0°C–30°C)	140 kJ/kg
Solid-phase thermal conductivity	0.18 W/m·K
Liquid-phase thermal conductivity	0.14 W/m·K

4.10 THERMAL BRIDGES IN BUILDING STRUCTURES

Jan Kośny and David W. Yarbrough

Introduction and Scope

Theoretically, the exterior building envelopes should perform a variety of different roles including keeping the exterior climate outside by limiting the transfer of heat, moisture, and air, which helps with maintaining comfortable interior conditions. Additional functions provide a visual and daylight connection to the outdoors, limit noise transmission, support of structural loads, and aesthetically pleasing appearance on both sides. Although building envelopes are usually effective in meeting these requirements, there are situations where they do not perform adequately. Shortcomings in thermal performance are often exhibited by excessive heat transfer (in and out) and unwelcome air or moisture transport across the building envelope that can lead to durability problems and increased energy consumption, as well as to poor thermal comfort within the occupied space. Sometimes, the presence of a thermal bridge results in discoloration on the interior, exterior, or both surfaces of the building envelope. While some cases of poor building envelope performance are associated with inadequate thermal insulation levels, other cases often occur because of construction imperfections; such as discontinuities in the thermal insulation or air barrier systems, compressed insulation, and air-leakage sites.

During the last half-century, numerous wall technologies have been introduced. Some of them are complex three-dimensional networks of structural components and thermal insulation. Moreover, building structural systems are advancing and every year a variety of new materials are introduced. Consequently, buildings are often becoming unforgiving of design errors or assembly imperfections. At the same time, the overall thermal efficiency of a building is a function of the thermal performance of the exterior envelope elements (walls, roofs, and windows), the local heat losses that can occur around the envelope elements where they are penetrated by the heat conducting building components. These areas of intense local heat flow, commonly known as thermal shorts or thermal bridges, can have a significant impact on the overall thermal performance of the building envelope.

With the introduction of advanced materials, a single change in a building envelope configuration may compromise local thermal performance and durability of the exterior envelopes. That is why more and more frequently, only optimized combinations of structural subsystems and insulation materials are specified. In buildings, thermal bridges are responsible for a significant number of thermal performance and durability problems. Thermal bridges, thermal shorts, or cold bridges (different names are used by building professionals in different parts of the world) are understood as unwanted paths for heat flow that bypass the envelope's thermal insulation. Most often this happens when a heat conducting material, for example, a metallic component is placed in the direction of heat flow and parallel to the thermal insulation. In other words, thermal bridging in buildings occurs when a highly conductive (or poorly insulating) material allows an easy pathway for heat flow across the envelope. The most common forms are probably within the eyesight of every reader of this chapter: for example, concrete or metal elements crossing the exterior building skin, structural framing members, perimeters of building openings, and architectural connections. Thermal bridging in buildings contributes to a multitude of problems, including, but not limited to, added energy use during heating and cooling seasons, interior surface condensation problems, mold growth, and material deterioration.

This chapter discusses several types of thermal bridges which can be spotted at various parts of the building skin and architectural interfaces. In order to minimize the resulting energy and durability problems, the proposed engineering solutions need to focus on design that minimizes thermal bridges and the resulting heat losses or gains, and, in many cases, to limit the risk of condensation. Sometimes, these measures occur in parallel with air-sealing efforts. For proper analysis of building thermal bridging, the heat conduction mechanism between adjacent components of the

exterior thermal envelope has to be examined. Materials with high thermal conductivity such as metals or concrete transfer significantly higher quantities of heat than materials with lower thermal conductivity such as wood or thermal insulations. Practical reduction of thermal bridges should be simple, inexpensive, and easy to apply. Several well-known general guidelines for mitigation of thermal bridges include separating highly thermally conductive materials with insulating materials, selecting less thermally conductive materials at the onset of the design, and reducing surface area in contact between highly conductive materials. This chapter will discuss analytical and numerical methods used in the analysis and elimination of thermal bridges. In addition, major building standards regulating this subject are listed.

Definition of Thermal Bridges and Common Consequences of Thermal Bridges

In general, a thermal bridge is defined as a location within the building envelope or architectural component, which exhibits considerably more heat flow than surrounding areas. Thermal bridging refers to the loss of energy by conduction through elements that "bridge" the insulation of a wall or roof enclosure of a conditioned space. While it is a common knowledge that most structural materials contribute to thermal bridging, it is good to remember that, in reality, thermal shorts occur much more often than just when a conductive element passes through or bypasses a thermal insulation barrier. Considering that in building components with temperature gradients, heat flow has multidimensional character and taking into account the complexity of today's building envelopes, these thermal pathways often require three-dimensional numerical analysis.

From the envelope designer's perspective, a thermal bridge is an element or location with missing thermal insulation, insufficient insulation, or reduced insulation performance, relative to adjacent areas of the thermal envelope. The intensity of a thermal bridge depends on differences in the apparent thermal conductivity of neighboring materials. In this light, even thermal insulation materials can generate a thermal bridge effect. As shown in Figure 4.10.1, high-resistance cellular plastic insulation can generate a thermal bridge effect. The infrared image of the building insulated with a use of the vacuum insulation panels (VIPs) packed in the foam casing shows significantly different temperatures in places of VIP connections (Kośny et al., 2014). Bear in mind that foam has about 10%

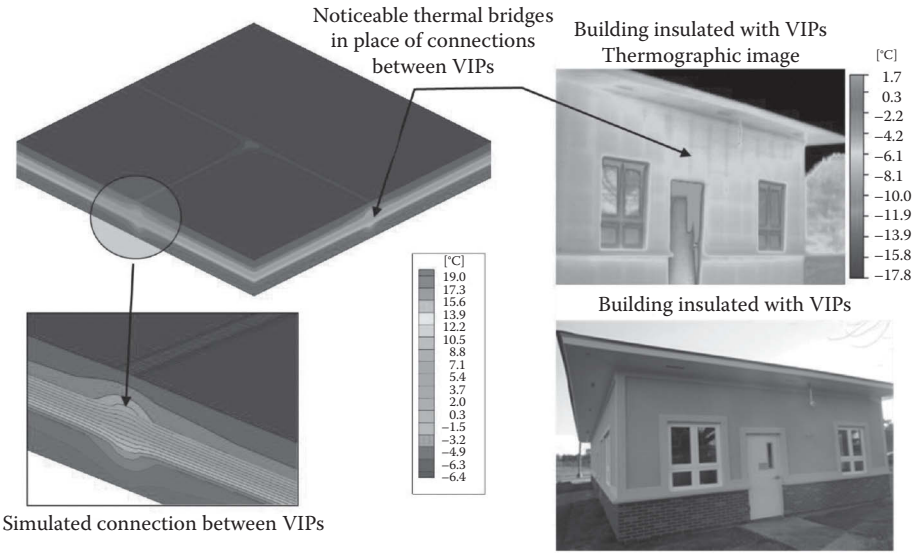

FIGURE 4.10.1 Thermal bridge effect generated by plastic foam surrounding a VIP (left), infrared imaging of a house insulated with VIPs—evidence of thermal bridges in places of VIP connections (right).

of the thermal resistivity than that of the core of a VIP. So, if VIPs are packed with the plastic foam, it is a thermal bridge. The consequences of poorly selected connections between envelope components can produce severe thermal bridging. Taking into account that interface details can have an impact of as much as 50% of the overall wall area for some wall systems, the whole-wall *R*-value (thermal resistance) can be as much as 40% less than what is measured for the clear-wall section (Kośny and Desjarlais, 1994; Christian and Kosny, 1995). Local heat losses through wall interface details may be twice that estimated by design calculations that focus only on the clear wall. Poor interface details also may lead to condensation of water that causes stains and dust markings on the interior finish, thus revealing thermal shorts in an unsightly manner. Moist surface areas can accelerate the propagation of molds and mildews, which can lead to degraded indoor air quality (Hens, 2012). In addition, thermal bridging affects the dynamic thermal performance of a building (Kośny and Kossecka, 2000).

It is good to remember that the exterior skin of a building provides a separation between the interior space and the exterior environment. In a perfect scenario, this separation should be as continuous as possible. This obligation applies to the building thermal insulation as well as to the air and moisture barriers. In the case of discontinuities in the thermal insulation layer, thermal bridges provide unwanted paths of least resistance for heat to move across the building envelope. The following are unwanted effects of thermal bridging:

1. Increased energy consumption: Due to the thermal outflow at the thermally bridged areas, heat is lost from every room (in heating dominated climates) or unwanted heat gains (in cooling dominated climates) resulting in a significant increase in whole-building energy consumption.
2. Mold formation: In cold climates, interior wall temperatures can drop well below the dew point. This leads to condensation, deterioration of plaster and paintwork and conditions for harmful mold formation. Finally, if there is sustained exposure to condensation, the building can experience serious fungi grow that leads to health hazards.
3. Compromised living space thermal comfort: Cold surface temperatures cause uncomfortable living space for occupants.

It is good to remember at this point, that in most of the buildings, even high-performance buildings, the existence of limited thermal bridging is unavoidable, mostly for structural reasons. However, good design and construction can reduce the number of thermal bridges and notably mitigate their effects.

Types of Thermal Bridges and Most Common Locations

The most common flaws in building envelopes are discontinuities in the insulation layer or air/moisture barriers. These problems are caused by improper design, incorrect assembly, or occur over the building's lifetime when the design does not provide adequate consideration of changes due to wind pressures and vibrations. Common imperfections in the thermal insulation barrier include both discontinuities in the insulation layer, installation of insulation in air cavities allowing air circulation around or across the insulation, compression of insulation, and other arrangements which decrease effectiveness. Envelope performance is then compromised by the increased heat-transfer rate. These assemblies usually show increased potential for moisture-related durability issues. Keep in mind that, local condensation and mold formation can be often caused by structural thermal bridges (Trechsel and Bomberg, 2009; Hens, 2012). For example, due to the compromised performance of thermal insulation, during the winter, interior temperatures of the adjacent interior space can drop well below the dew point. This may lead to water condensation on the interior surface and sometimes to deterioration of the interior finish. Considering common electrical penetrations in the exterior walls, it is very likely that water condensation can take place inside the wall cavities

causing a decrease in thermal performance of thermal insulation. Wet insulation, for example, conducts heat by as much as 10 times the design value for dry insulation, e.g., see Langlais et al. (1983), McFadden (1988), and Kumaran (2006). If there is sustained exposure to water condensation inside the building envelopes as well as on the internal surfaces, the building may become a subject to serious material deterioration.

Thermal Bridges Generated by Building Geometry and Architectural Details

Thermal bridges most commonly occur at locations such as corners, overhangs, wall/floor, wall/roof, wall/internal interfaces, and window or door perimeters. Component connections are often high-strength, high-conductivity elements that serve to hold or connect building structural or architectural components. Examples include balconies, wall connections with terraces, perimeters of wall openings, window, and curtain-wall mullions. Geometric thermal bridges do not form literal thermal shorts in the way as, for example, construction thermal bridges do. For instance, more intense heat transfer can occur in the areas where nominal insulation thickness and insulation continuity are maintained. Usually, geometric thermal bridges can be found in the areas where the area of the external building surface is significantly different from the corresponding internal surface area. Identifiable thermal bridge effects occur at corners which accentuate two-dimensional heat-flow paths. As depicted in Figure 4.10.2, some corner constructions may also lead to discontinuities in the envelope insulation and/or the air barrier. Geometric thermal bridges are often unavoidable. However, the energy impact of geometric thermal bridging increases with the complexity of the building form. Therefore, from the thermal and energy standpoint, as well from a long-term durability perspective, it is good to keep the building form as simple as possible.

Thermal Bridges Characteristic of Building Materials and Construction Subsystems

Thermal bridging from heat flow through nonuniform construction elements occurs in two or three dimensions. These thermal bridges are localized and repetitive along the length of the structure. Examples of this type of thermal bridge are provided by metal connectors in concrete sandwich panels as shown in Figure 4.10.3 and small connectors in curtain walls. In high-performance buildings with thick foam insulation installed to provide high *R*-value walls or roofs, the foam sheathing is often connected to the structural substrate using long and relatively thick metal connectors. In addition to being expensive, these connectors often seriously compromise the overall system thermal and hygrothermal performance (Kośny et al., 2013). In longer term, these thermal shorts often

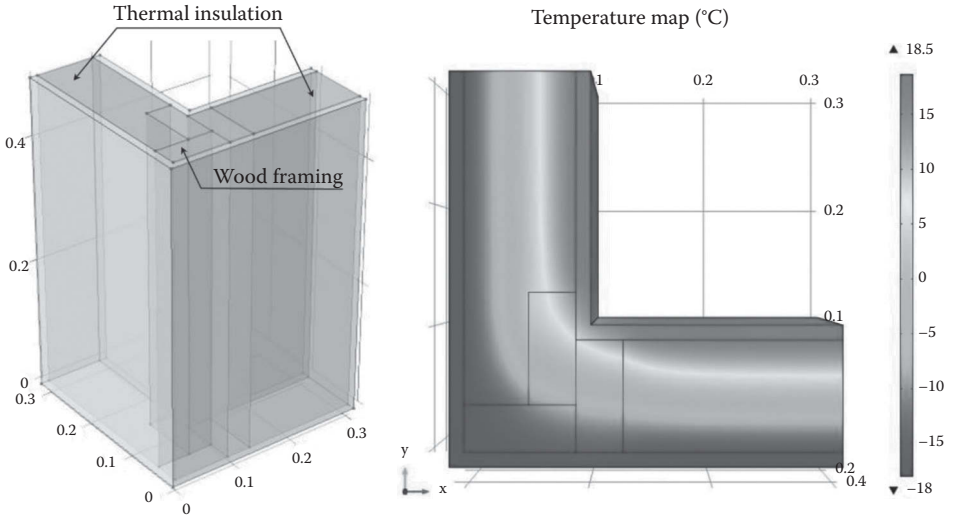

FIGURE 4.10.2 Thermal insulation discontinuity in the corner design using wood studs.

cause durability problems, which are commonly reported for these locations, and which are typically caused by local moisture condensation on thermally bridged cold metal surfaces.

As depicted in Figure 4.10.4, concrete masonry units (CMUs) have different insert designs but high thermal conductivity concrete bridges remain due to two or three concrete webs joining the external and internal concrete skins. Concrete block either empty or filled with thermal insulation will exhibit thermal bridging. The thermal bridge effect can be reduced with interlocking inserts that create a continuous layer of insulation.

Structural Thermal Bridges due to Construction

Structural thermal bridges due to construction are regularly spotted in buildings. This type of thermal bridge is not only the easiest type to recognize, but also easy to comprehend and visualize.

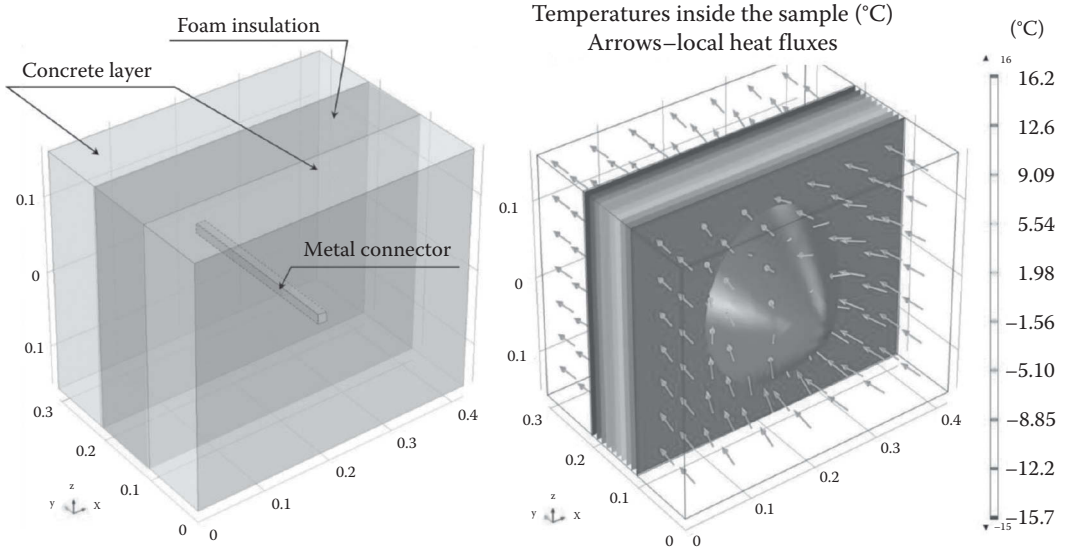

FIGURE 4.10.3 Thermal bridge from metal connector used in concrete-foam-concrete panel.

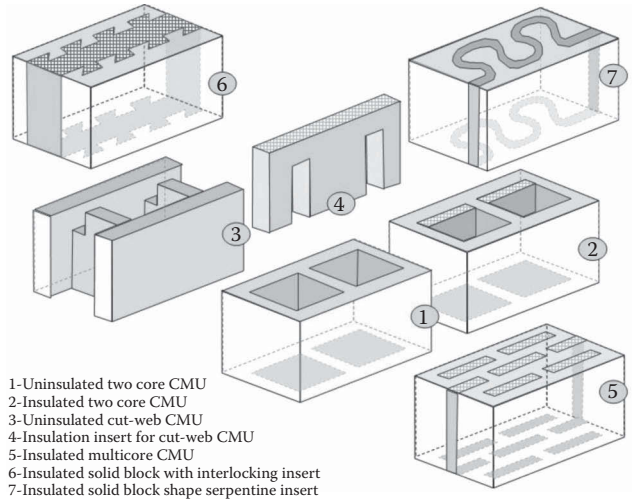

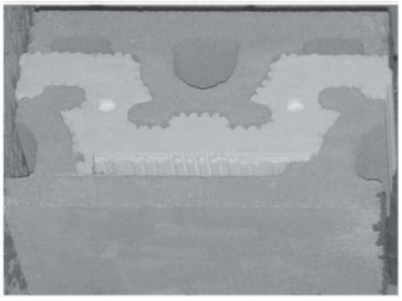

Example of a concrete block with interlocking foam insert

FIGURE 4.10.4 CMUs and common types of thermal insulation inserts.

Construction thermal bridges occur wherever there is a material or component that conducts heat significantly better than thermal insulation and this material passes through the thermal insulation layer. Structural thermal bridging is usually associated with components like steel or concrete combined with discontinuities in the thermal insulation.

Some examples of heat flow paths that result from the design on the building structure are follows:

- Reinforced concrete or steel frame beams and columns
- Roof rafters or floor joists that pass through the thermal envelope
- Wood, concrete, or metal framing members crossing the thermal insulation zone
- Cantilevered structures passing through or anchored in the thermal envelope
- Lintels and headers that interrupt envelope thermal insulation
- Structural connectors between metal-foam-metal sandwich panels.

Figure 4.10.5 shows the wall–floor intersections for the cases of the light-gage steel framed assembly and the structural penetration of the insulation system created by the concrete floor slab. They are both very common thermal bridge configurations, occurring in many commercial and residential buildings. In this case, both the concrete floor slab and the metal I-beam penetrate the vertical-wall insulation, significantly increasing the heat transmission. Significant disturbances in temperature fields can be observed in the case of the light-gage steel wall–floor intersections. The floor–wall connections are often the site of significant thermal bridging when the metal floor joists or concrete floor slabs pass through the wall insulation layer. The easiest fix for this problem is the use of a continuous layer of external thermal insulation. In the case of building retrofits, a pillow of spray foam is often used where the floor joists meet the wall bond beam (floor–wall intersections). It is not a perfect solution, but it helps in cutting thermal shorts, as well as reducing air movement through this detail.

The wall–roof connection is listed in engineering literature as a common location for thermal shorts and air leakage paths due to discontinuities between the wall and roof thermal and air or moisture barriers. The wall air and moisture barriers do not consistently extend to the roof deck

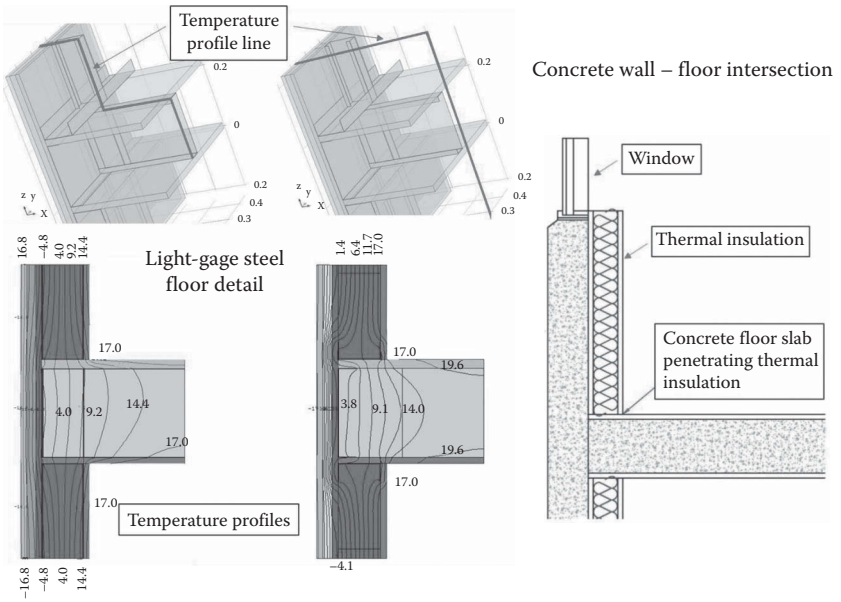

FIGURE 4.10.5 Thermal bridge in wall–floor intersections and the penetration of insulation by concrete construction thermal bridges should be recognized and avoided as much as possibly or minimized by careful design. Keep in mind that any construction thermal bridges will notably compromise local thermal and hygrothermal performance and contribute to the building energy use.

level, and the roof membrane is not always sealed to the impermeable materials in the wall. Instead, the membrane is often turned up at the roof edge, leaving a discontinuity in the envelope air barrier. Depending on the building envelope technology, more or less complex detailing and installation of continues thermal and air/moisture barriers are necessary. As described above, an application of sprayed foam helps in many cases.

Window-wall perimeters are associated with a number of probable thermal defects including highly conducting attachment methods, existing paths for air and moisture leakage, discontinuities in thermal insulation and insulation compression or displacement around the window frames, and placement of the window thermal break in the way that air can easily bypass. Another common mistake is assembly design in which the width of the window frame exposed to the outdoors is greater from the width exposed to the indoors. In cold climates, the greater area for heat loss to the exterior air causes the inner frame to be cold, increasing the potential for local condensation.

The mullions of curtain walls have long been considered as key sources of thermal shorts in commercial glazing systems. This comes from the fact that most curtain wall frames are made of aluminum which is about four times more conductive than steel. Mullions usually connect the exterior surfaces of the building enclosure to the interior, creating a significant thermal bridge. A variety of thermal breaks (added thermal insulation crossing the heat flow paths), which are typically 1–2 cm thick inserts made of less conductive plastic foams or rubbers, have become a characteristic component in modern curtain walls. These thermal breaks are typically located between the face plate and the structural part of the mullion, the rail, in line with the glazing pocket. Sometimes, thermal insulation can be added along the backside of the spandrel panel.* This type of assembly keeps interior and exterior sides of the mullion rail well thermally separated (National Institute of Building Sciences (NIBS), 2012).

Combined Thermal Bridges

In many cases, geometric thermal bridges also include an element of construction thermal bridging. For example, an external wall corner while being a geometric thermal bridge may also have structure creating construction thermal bridging. Similarly, ground floor and external wall junctions often involve a degree of construction thermal bridging. Very good examples of combined thermal bridges are corners with conducting studs or wall intersections with internal partitions. Figure 4.10.6 shows a construction of the corner using light gage steel studs as structural members. In this case, increased heat flow through this architectural detail is caused by the heat transfer through the metal studs, as well as by the corner shape effect (different heat exchange areas on the interior and exterior surfaces).

Durability Consequences of Thermal Bridging

As stated in earlier sections, thermal bridging may lead to condensation in building enclosures. Almost all building materials are susceptible to durability problems associated with increased water content (Sedlbauer, 2001; Kumaran, 2006; Hens, 2012): (i) wet thermal insulation may deteriorate and poorly perform (wet insulation is more conductive), (ii) uncontrolled high moisture content in concretes, mortars, gypsum, or brick will cause material deterioration, (iii) wet bio-based building materials makes great food for fungus and as a result the materials will deteriorate, and (iv) steel components will corrode. In cold climates, one of the most common locations for moisture-related problems is at wall-window perimeters. The positioning of skylights, doors, windows, window walls, curtain walls, and other fenestration within the wall or roof structures may provide a short circuit most often caused by direct connections of the window frame with highly conducting structural components. One of the key recommendations in regard to the window placement is to keep the window frame within the wall thermal insulation plane, e.g., Kośny et al. (2014). Since this recommendation is not always possible due to design or structural reasons, the other option is an application of local thermal insulation inserts, or use of windows with highly insulated frames.

* http://aanb.org/wp-content/uploads/2016/08/Glass-and-Aluminum-Curtain-Wall-Systems.pdf

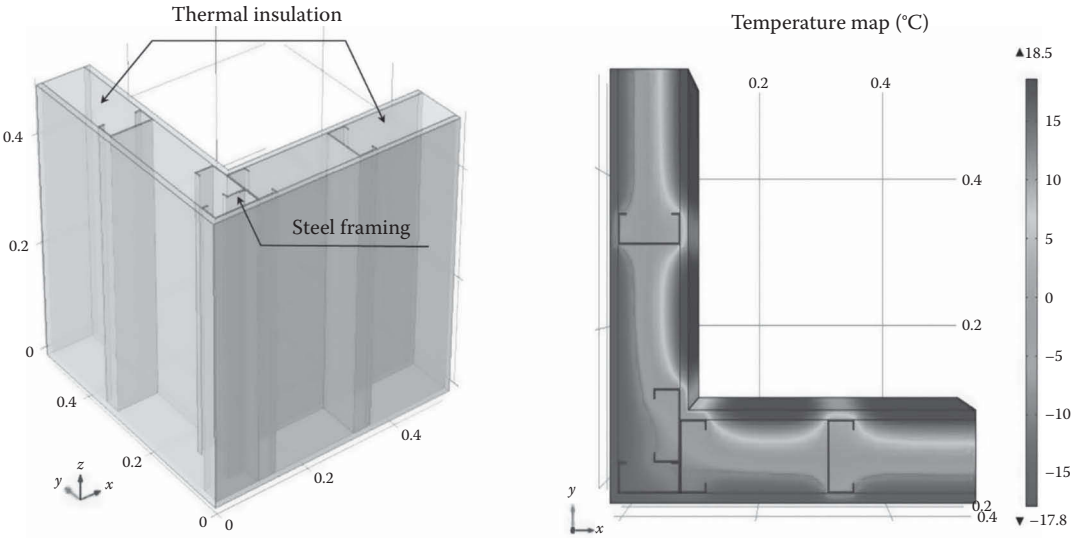

FIGURE 4.10.6 Thermal bridge in corner with light gage steel framing.

Bear in mind that in commercial buildings, a lot of façade shading and decoration details use numerous conductive components; including lintels, anchorage, and hangers that bypass the thermal barrier and produce thermal shorts, which often result in condensation on interior surfaces. Structural-steel framing that extends from the inside to the outside not only makes waterproofing and air barrier details difficult, but also forms a large thermal bridge. Finally, a great number of commercial buildings are constructed today using light gage or heavy gage steel structural profiles. This fact requires special attention during the design of the exterior envelope, because any design mistake coupled with highly conductive metal elements may (most often it will) cause serious thermal shorts and resulting durability problems.

As stated above, thermal bridges may compromise the overall building energy performance, reduce the local thermal and hygrothermal performance of the exterior envelope, and introduce unwanted building durability problems and health risks. Table 4.10.1 summarizes the most typical design problems associated with thermal bridging.

Engineering Methods for Thermal Bridge Analysis

Heat transfer through envelope components is complex and dynamic. The steady-state thermal performance of building envelope technologies and architectural details can be established using engineering calculations, thermal simulations, or through different types of thermal tests. Typically this takes the form of either *R*-value (thermal resistance) or *U*-factor (thermal transmittance) characterizations. Keep in mind that the direction and magnitude of heat flow in building envelope components are affected by solar gains from the sun, outdoor temperature, indoor temperature, and exposed surface area.

R-Value and U-Factor

Thermal resistivity is a material property that is defined as the reciprocal of the apparent thermal conductivity, k_a. Thermal resistance or *R*-value is defined as the thickness of a specimen divided by the apparent thermal conductivity. In either case, these terms are a measure of how effectively the material resists heat flow. Thermal resistance is identified by the term *R*-value with units, $m^2 \cdot K/W$, in SI units or, $ft^{2.\circ}F \cdot h/Btu$, in imperial units. *R*-values are used in the construction industry to describe insulation effectiveness and characterize steady-state heat flow across assemblies. The insulation *R*-value does not describe the overall performance of an assembly. For overall assembly

TABLE 4.10.1
List of Most Typical Design Problems Associated with Thermal Bridging

Typical Consequences	Description of Common Problems Associated with Thermal Bridges
Heat losses	Thermal bridges are the weakest points in the thermal envelope and so, in cold climates, they can contribute considerable heat losses. This reduces the overall building energy efficiency and increases heating costs
Unwanted heat gains	In cooling-dominated and mixed climates, thermal bridges allow unwanted solar heat gains. Roofs and attics are typical building envelope areas which may create intense solar gains if incorrectly designed
Cold internal surfaces	In winter, an intense heat transfer in a thermal bridge area may cause the internal surface temperature to drop, creating a cold spot. The surface relative humidity will thereby increase, yielding a risk of condensation and potential for mold growth. In cold climates, metal window frames in commercial buildings are notorious sources of condensation problems caused by highly conductive materials and insufficient thermal break (Curcija et al., 2013)
Discoloration marks on the interior and exterior surfaces	Depends on climatic conditions, intense thermal bridging (e.g., in case of metal framing) may cause internal or external cold spots, which can yield local condensation. On some surfaces, this may lead to the development of unaesthetic discolorations (e.g., so-called ghosting on the internal gypsum board surfaces in case of steel framed buildings[a])
Risks to thermal comfort and health issues	Cold internal surfaces are uncomfortable to be near and can cause thermal discomfort and perception of draughts. In addition, local cold surfaces within building envelopes usually cause moisture condensation, which in longer term can yield fungus grow, affecting the indoor air quality. It has been well documented in the literature[b, c] that both moisture and mold growth can lead to building occupants health problems (EPA, 2013).[d]

[a] http://www.steelframing.org/PDF/FinalDesignGuideSept82008.pdf.
[b] http://www.cdc.gov/niosh/topics/indoorenv/mold.html.
[c] https://iaqscience.lbl.gov/dampness-risks-house.
[d] http://ec.europa.eu/health/opinions/en/indoor-air-pollution/l-3/8-building-dampness.htm.

performance, the overall thermal resistance of the assembly which is determined from the resistances of the components of the assembly must be determined. The assembly *R*-value of a multilayer structure with one-dimensional heat flow is the sum of the thermal resistances of the layers:

$$R = \sum_{i=1}^{n} \frac{t_i}{k_{ai}} = \sum_{i=1}^{n} R_i \tag{4.10.1}$$

where k_{ai} is the apparent thermal conductivity of the material (layer) i and t_i is the thickness of layer i. R_i is the thermal resistance of the Ith layer.

In a similar way, *U*-factor (thermal transmittance) is used to calculate heat flow across an assembly. It can be calculated as the reciprocal value of the sum of the thermal resistance and the air-film resistance at the exterior and interior surfaces (h_e and h_i). The quantities $1/h_i$ and $1/h_e$ are often referred to as air-film resistances:

$$U = \frac{1}{\frac{1}{h_e} + R + \frac{1}{h_i}} = \frac{1}{R_e + R + R_i} \tag{4.10.2}$$

The *U*-factor in Equation 4.10.3 allows calculation of the rate of steady-state heat flow across an assembly. Most thermal insulations and a great majority of other building materials exhibit heat flow equally in both directions, i.e., these materials are isotropic in this regard. However, some

construction elements, for example, wood, some cellular plastics, reflective insulations or panels using highly conductive materials have different thermal resistances and heat transfer rates in different directions thereby exhibiting anisotropy:

$$Q = U \cdot A \cdot T \tag{4.10.3}$$

Q is the heat flow in Btu/h or W, A is the cross-sectional area (constant in this case), and ΔT is the temperature difference between the exterior air and the interior air.

There are a number of methods for determining the thermal performance of building envelopes, and the appropriate method depends on the types of construction and thermal insulation. The ASHRAE Handbook of Fundamentals (ASHRAE, 2013) provides several methods to determine clear-wall *R*-values and *U*-values. These methods are for assemblies with one- or two-dimensional heat transfer.

Parallel Path Method

A commonly used approach is *the parallel path method*. This method assumes that heat flows independently through regions that are in parallel and there is no heat exchange between regions as shown in Figure 4.10.7.

Considering that some people are more comfortable working with the concept of thermal transmission (U) than thermal resistance (R), the equations are given below for both *R*-values and *U*-factors. The parallel-path calculations yield relatively accurate results for one-dimensional heat transfer, where there is little or no heat exchange between the "parallel" paths in the actual assembly. The parallel-path calculation is useful in cases of simple sandwich constructions or wood-frame assemblies:

$$Q = \left(A_1 / R_{T1} + A_2 / R_{T2} + A_3 / R_{T3} + \ldots\right)\Delta T \tag{4.10.4}$$

$$Q = \left(U_1 \cdot A_1 + U_2 \cdot A_2 + U_3 \cdot A_3 + \ldots\right)\Delta T$$

where

Q is the heat flow through a defined area with multiple adjacent assemblies.

R_{Ti} is the thermal resistance for assembly "*i*", generally obtained by summing the resistance of each layer of material in the assembly including inner and outer air films

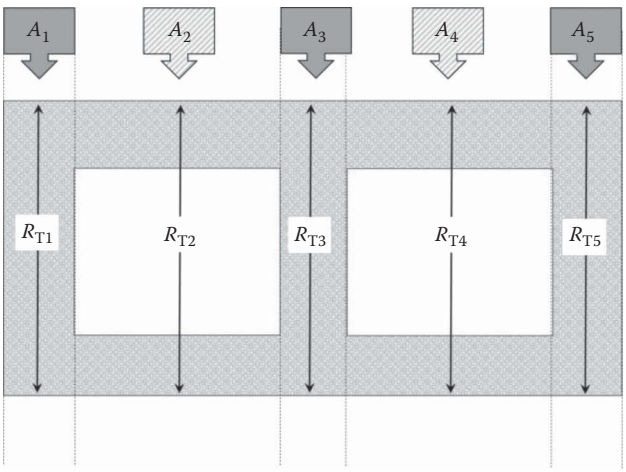

FIGURE 4.10.7 Calculation schematic for the parallel path method.

U_i is the heat transmission coefficient in BTU/(h·ft²·°F) for assembly "*i*" including the effect of the interior and exterior surface films
A_i is the area of assembly "*i*", in ft²
ΔT is the difference between the indoor and outdoor air temperatures.

Effective *R*-value and *U*-factor can be computed using the following equation for a region like that in Figure 4.10.7:

$$R_{\text{eff}} = 1/U = \left(A_1 / R_{T1} + A_2 / R_{T2} + A_3 / R_{T3} + \cdots\right) / A_{\text{total}} \tag{4.10.5}$$

Isothermal Planes (Series–Parallel Path) Method

In buildings with highly conductive structural members or other components made of concrete, steel, aluminum, or glass, the assumption of parallel heat flow is not likely to provide reliable results. In these cases, the *isothermal planes method* provides an alternate procedure for calculating the *U*-value. The name comes from an assumption of uniform temperature (isothermal) for the highly conductive planes separating less conductive layers. This method is used, for example, to analyze heat flow through wood-framed assemblies or masonry walls. The isothermal planes method divides the construction assembly into a series of layers. Hollow masonry units are a very good example of when this calculation method can be applied. The solid webs connecting the face shells are quite conductive compared to the air spaces in the hollow cores, and the face shells conduct heat laterally. As shown in Figure 4.10.8, for a two-core masonry unit, the layer containing the webs and cores is treated with a parallel-path calculation to arrive at an average *R*-Value for the layer. This is then added to the *R*-values of the two face shells in series. In the isothermal planes method, the air-to-air *R*-value is calculated using the following equation:

$$R_{\text{air-to-air}} = \frac{1}{U} = R_e + R_{fe} + \left[\frac{a_w}{R_w} + \frac{a_c}{R_c}\right] + R_{fi} + R_i \tag{4.10.6}$$

where
R_e and R_i are exterior and interior air-film resistances
R_{fe} and R_{fi} are exterior and interior face resistances
a_w and a_c are fractions of the total heat flow area for the webs and air-cores
R_w and R_c are *R*-values (calculated for the space between faces) for all webs and air-filled cores.

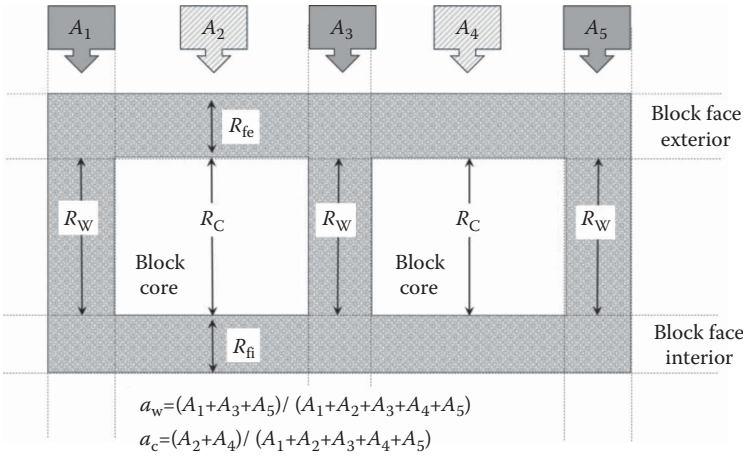

FIGURE 4.10.8 Calculation schematic for the isothermal plane method.

Modified Zone Method

Heat flow through construction assemblies with metal framing or sheathing is more complex and requires special consideration. For walls using light gage steel framing, the ASHRAE Handbook of Fundamentals recommends the use of the ASHRAE Zone Method or modified zone method (ASHRAE, 2013). The modified zone method was designed to improve the accuracy of clear-wall *R*-value calculations for light gage steel-framed walls with insulated cavities containing steel C-shape studs with solid webs (Barbour et al., 1994; Kośny et al., 1995). The modified zone method is similar to the parallel path method and the ASHRAE Zone Method. All three methods are based on parallel-path calculations—the difference being how heat flow through the metal stud (*w* in the figure below) is estimated. In the parallel path method, the "zone of influence *w*" is assumed to be equal to the length of the stud flange—"*L*". In the ASHRAE Zone Method, *w* is assumed to be equal to the length of stud flange plus twice the total thickness of all finish material layers on the thicker side (can be exterior or interior)—as depicted in Figure 4.10.9. In the modified zone method, *w* is determined by the following equation:

$$w = L + z_f \times d_t \tag{4.10.7}$$

where

- w—the zone containing the metal stud
- L—metal stud flange width
- z_f—zone factor determined based on simulations of different steel-stud wall configurations. It depends on the ratio between thermal resistivity of finish material and cavity insulation, depth of stud, and thickness of finish material layers
- d_t—total thickness of all wall finish material layers on the thick side.

The accuracy of the modified zone method was verified by finite-difference modeling of over 200 metal frame walls with insulated cavities (Kośny and Desjarlais, 1994). The modified zone method results are within ±2% of the results of the three-dimensional finite-difference evaluations. Furthermore, for six steel-framed wall assemblies tested at the Oak Ridge National Laboratory and 15 similar wall assemblies tested by Holometrix (Barbour et al., 1994), the results of the modified zone method calculations differed by less than 6.5% from test results—ASHRAE Research Project 785-TRP (1996).

Linear Thermal Transmittance Method

The *linear thermal transmittance method* is a superposition of the local heat flows to calculate the overall heat flow in the building envelope assembly. The heat flows for the full assembly are determined. The methodology for determining the linear thermal bridging coefficient is specified in

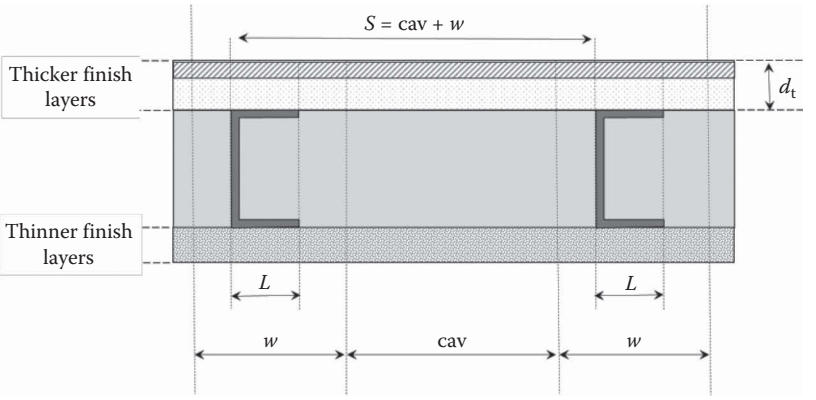

FIGURE 4.10.9 Calculation schematic for the modified zone method.

several ISO standards, including (see ISO 10211, 2007 and ISO 14683, 2007), which deal with methods for determining the heat loss through linear thermal bridges at junctions of building elements. These ISO documents contain specifications for developing thermal models of thermal bridges, which can be utilized for determination of heat losses and surface temperatures—ISO 10211 (2007). The following types of thermal bridges are typically considered:

- Linear thermal bridges: where there is a thermal bridge with a specific length, for example, a lintel.
- Point thermal bridges: where there is a thermal bridge at specific points only, for example, masonry wall ties.
- Repeating thermal bridges: where there is a thermal bridge that repeats at regular intervals within an element of the thermal envelope, for example, timber studs in an insulated wall.
- Nonrepeating thermal bridges: where there is a one-off thermal bridge, for example, a structural column in an insulated wall.

In the linear thermal transmittance method, each construction detail containing a thermal bridge is represented by a heat flow. The thermal effect of the bridge is characterized by its linear thermal transmittance, which is expressed by Ψ [W/m^2·K]. The Ψ-value represents the additional heat flow through the area of the linear thermal bridge, which is in addition to the heat flow for the adjacent, thermally undisturbed area. Two types of thermal bridges are specified in this method: linear and point thermal bridges. A linear thermal bridge is one with a uniform cross section along one of the three orthogonal axes—ISO 14683 (2007), ISO 10211 (2007). It is commonly found in intersections and structural junctions. Examples of point thermal bridges can be visualized by a metal fastener penetrating an envelope assembly, shelf angles, slab edges, balconies, corner framing, parapets, and window interfaces.

A linear thermal bridge is defined mathematically as follows:

$$\psi = L^{2D} - \sum_{j-1}^{N_j} U_j * L_j \tag{4.10.8}$$

where

L^{2D} is the thermal coupling coefficient obtained from 2D simulations—see: ISO 10211 (2007)
U_j is the thermal transmittance of the 1-D component, "*j*," separating the two environments being considered
L_j is the length over which the ψ-value applies.

The linear thermal bridge coefficient can have a negative or positive value. If ψ-value for a specific building component has a negative value, this indicates that the thermal resistance of building envelope has been improved due to the introduction of that component. A positive ψ-value indicates that the presence of the component of interest has reduced the thermal resistance of the building envelope.

The overall thermal resistance $R_{overall}$ [m^2·K/W] of any type of building envelope can be computed with the use of the following equation (assuming that there is only one type of clear field envelope assembly within the area considered for calculations):

$$R_{overall} = \frac{A}{\frac{A}{R} + \sum_{j=1}^{J} L_j \psi_j + \sum_{k=1}^{K} n_k \chi_k} \tag{4.10.9}$$

where

A is the total area of considered assembly [m^2]
R is the thermal resistance of the assembly without thermal bridge effects [m^2·K/W]
L_j is the length of linear thermal bridge [m]
Ψ_j is the linear thermal transmittance of linear thermal bridge [W/(m·K)]

n_k is the number of the point thermal bridge components
χ_k is the point thermal transmittance of the point thermal bridge "k" [W/K].

For building envelope assemblies containing multiple clear-field configurations "i", Equation 4.10.8 has the following form:

$$R_{\text{overall}} = \frac{A}{\sum_{i=1}^{I} \frac{A_i}{R_i} + \sum_{j=1}^{J} L_j \psi_j + \sum_{k=1}^{K} n_k \chi_k} \tag{4.10.10}$$

where
A_i is the area of considered part of the assembly without thermal bridge effects [m^2]
R_i is the thermal resistance of considered part of the assembly without thermal bridge effects [m^2·K/W].

The same calculation methodology is used in ISO standard 6946 (2007) for calculation of the transmission heat transfer coefficients H [W/K], where the contribution due to the thermal bridges is included according to the following equation:

$$H = \sum_{i=1}^{I} \frac{A_i}{R_i} + \sum_{j=1}^{J} L_j \psi_j + \sum_{k=1}^{K} n_k \chi_k = \sum_{i=1}^{I} A_i U_i + \sum_{j=1}^{J} L_j \psi_j + \sum_{k=1}^{K} n_k \chi_k \tag{4.10.11}$$

where
H is the object's total heat transfer coefficient [W/K]
U_i is the thermal transmittance for each considered part of the assembly without thermal bridge effects [W/m^2·K].

Figure 4.10.10 shows basic types of thermal bridges and describes the heat-transfer calculations using the linear transmission method.

Numerical Tools Used in Thermal Performance Analysis

Thermal bridging and construction details in the building envelope impact the thermal performance. These features have both steady-state and dynamic repercussions. Capability for reduction of building loads and successful whole-building integration are dependent, in large scale, on correct predictions

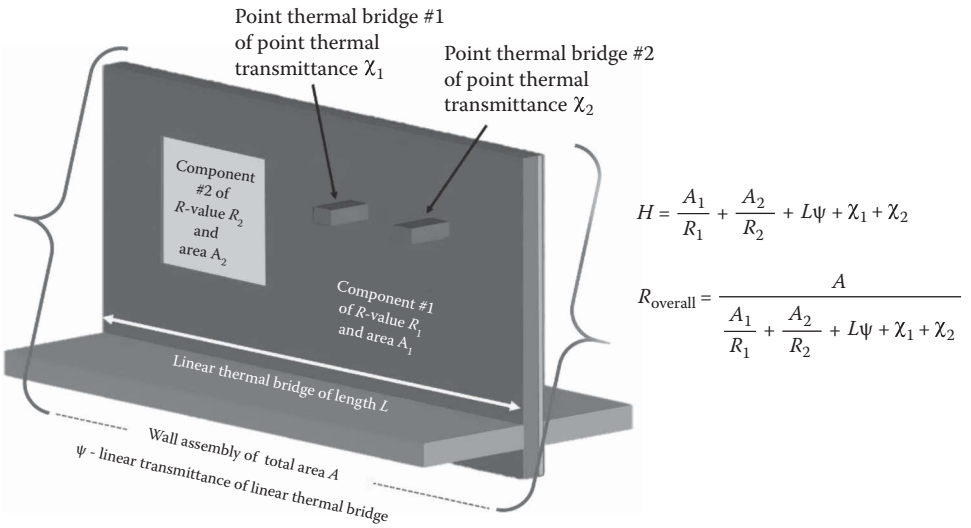

FIGURE 4.10.10 Types of thermal bridges and the linear transmission method.

of building thermal characteristics with building envelopes being one of the most important factors. In other words, building integration and load reductions are only possible when combined with accurate estimations of building envelope-generated thermal loads. Thermal and whole-building energy modeling tools are often useful in determining the local thermal performance as well as the overall energy efficiency of buildings. The energy efficiency for the building enclosure is typically based on individual *R*-values of various building envelope components. The effects of thermal bridges are approximated in these calculations. However, the currently available whole-building energy modeling tools do not always accurately account for the real *R*-values of various interface configurations, such as window-to-wall, wall to partition, wall to foundation, and wall to interfaces (Kośny and Desjarlais, 1994; Kossecka and Kośny, 1998). It is even more difficult to consider thermal bridges formed by steel framing. In these cases, two- and three-dimensional heat transfer programs need to be used to determine local *R*-values; the overall energy analysis can then be modified to consider these effects and arrive at an accurate picture of the overall energy efficiency of the building enclosure.

A great variety of numerical tools for this type of simulations are available and used by practitioners for two-dimensional thermal analysis—Comsol,[*] Heat3[†] AnTherm,[‡] BISCO (for 2D) and TRISCO (for 3D),[§] PSI Therm,[¶] ANSYS Fluent,[**] and PHYSIBEL Voltra.[††] THERM is a free software developed by the Lawrence Berkeley National Laboratory (LBNL), which is commonly used in North America for this purpose.[‡‡] Reports from the European 2010 project funded by the Communities Intelligent Energy Europe Programme[§§]; "Assessment and Improvement of the EPBD Impact (ASIEPI)" lists 29 numerical tools and 26, mostly national, thermal bridge atlases which can be useful in thermal bridge analysis.

Building Performance Standards Dealing with Building Thermal Bridging

In North America, there are three key energy performance standards focused on buildings:

- ASHRAE 90.1 Energy Standard for Buildings Except Low-Rise Residential Buildings-ASHRAE 90.1 (2013)
- ASHRAE 189.1 Standard for the Design of High-Performance Green Buildings Except Low-Rise Residential Buildings—ASHRAE 189.1 (2014)
- National Energy Code of Canada for Buildings 2011 (NECB, 2011)

In Europe, thermal bridge calculations are based on two key ISO standards-ISO 10211 (2007), ISO 6946 (2007) "Thermal bridges in building construction—Heat flows and surface temperatures—Detailed calculations," and "Building Components or Building Elements" which serves for:

- The calculation of minimum (lowest) surface temperatures in order to assess the risk of surface condensation and
- The calculation of heat flows in order to predict overall heat loss from a building (for the constant, steady-state flow case; i.e., time-independent temperature distribution) and
- Determination of linear and point thermal transmittance and surface temperature coefficients (of thermal bridges).

The above specifications include the geometrical boundaries and subdivisions of the model, the thermal boundary conditions, and the thermal values and relationships to be used. The second important standard ISO 6946 (2007) "Building Components or Building Elements-Calculation of Thermal Transmittance" is also available. According to this standard, calculation of heat transfer coefficients of parallel plane surface building components shall be performed based on one-dimensional calculations. For all other more complex heat flow cases with multidimensional heat transfer, the standard ISO 10211 (2007) "Thermal Bridges in Building Construction" requires the implementation of numerical methods.

Following is a list of ISO building standards which can be helpful in the analysis of thermal bridges and building design:

- ISO 7345 "Thermal insulation-Physical quantities and definitions"
- ISO 10456 "Building materials and products-Hygrothermal properties-Tabulated design values and procedures for determining declared and design thermal values"
- ISO 13370 "Thermal performance of buildings-Heat transfer via the ground-Calculation methods"
- ISO 13786 "Thermal performance of building components-Dynamic thermal characteristics-Calculation methods"
- ISO 13788 "Hygrothermal performance of building components and building elements-Internal surface temperature to avoid critical surface humidity interstitial condensation-Calculation methods"
- ISO 13789 "Thermal performance of buildings-Transmission and ventilation heat transfer coefficient-Calculation method"
- ISO 14683 "Thermal bridges in building construction-Linear thermal transmittance-Simplified methods and default values."

Methods of Thermal Bridge Mitigation

As stated earlier, in addition to increased building space-conditioning energy consumption, the heat flow through thermally bridged areas often leads to durability problems and material deterioration, which are frequently associated with the local condensation (which is often a direct product of a thermal bridge). Therefore, thermal bridges need to be correctly characterized and mitigated during the building design stage. The choice of construction method dictates how insulation continuity is approached. Components that form the principal insulation layers should be clearly identified on drawings, and their details developed to ensure continuity of these layers between elements of the construction.

Numerous design strategies are available to help ensure a building design contains as few as possible thermal bridges. In terms of thermal bridging, several general "rules of thumb" have been developed. According to Ziegel (2010), they are as follows:

- The *Avoidance Rule* which states that discontinuities in the insulating layer should be avoided
- The *Breakthrough Rule* which says that any breaks in the insulating layer must have as high an insulating value as possible, and
- The *Geometry Rule* states that building geometry should be as simple as possible and corners in building intersections and architectural details should have a rounded shape, if possible

From the practical standpoint, thermal bridging can be avoided by placing insulation in series with a conductive material, instead of installing it in parallel. For example, you can place thermal insulation outside a framed wall or roof assembly instead of placing the insulation between the structural members. Thermal bridging can also be avoided by examining the elevation area for the lowest local

R-value points and improving them through mitigation of thermal shorts. For instance, replacing metal facade connectors with plastic or composite elements.

From the practical standpoint, consider that simpler building geometry and simpler configurations of architectural details and intersection are more likely to be designed and built correctly. That is why the number of different types of construction technologies within the thermal envelope should be minimized, because thermal imperfections are most likely to occur where one type of construction meets another. Also, some construction details include areas that interrupt the insulation layer. These can be often found in areas of intersections of vertical and horizontal structural components. Although it is difficult to completely eliminate these thermal shorts, their effects can be minimized wrapping the conducting element with thermal insulation (even a thin one) and possibly by overlapping the insulating layers in the vicinity of conducting elements, even though these insulations will not necessarily be in direct contact. Local applications of high-performance insulations, such as aerogel and vacuum panels, are strongly recommended in places with limited spaces for conventional foam or fiber insulations.

In addition, all of the following building details need particular attention during the design process, because they are all essential to limiting heat losses through thermal bridging:

- External wall/roof intersection,
- Connections with partition walls that pass through the insulation plane of the ground floor,
- Perimeters around window and door openings (headers, sills, jambs, and lintels),
- External wall/ground floor junctions,
- Wall/floor intersections,
- Internal and external corners in external walls,
- External wall/balcony intersections,
- Chimneys placed in external walls,
- Service boxes and piping/power line passages located in external walls.

4.11 COMPRESSORS

Christian K. Bach, Ian H. Bell, Craig R. Bradshaw, Eckhard A. Groll, Abhinav Krishna, Orkan Kurtulus, Margaret M. Mathison, Bryce Shaffer, Bin Yang, Xinye Zhang, and Davide Ziviani

Introduction

Compressors for air and other gases are used for many purposes in industrial, commercial, and residential applications. For example, gas compressors in industrial applications are used for refrigeration, air conditioning, heating, pipeline conveying, natural gas gathering, catalytic cracking, polymerization, and other chemical processes. While the gas compressor may be similar in appearance to an air compressor commonly seen at a construction site, they are specially designed to meet a chemical process requirement of pressure, temperature, or flow, and are capable of handling the specific gases or gas mixtures to be used. Rollins (1989) provides a detailed compilation of the available knowledge about air and gas compressors, compressed air systems, pneumatic tools, and the uses of compressed air [1].

This section contains a review, including descriptions of certain design features and characteristics, of the most widely used and commercially available compressors. Two major applications are considered: (1) compressors that are commonly used in vapor compression cycles for refrigeration, air conditioning, and heat pumping applications and (2) compressors that are commonly used to compress air. The most complete set of technical papers about compressors can be found in the Proceedings of the Purdue Compressor Conferences. References [2–15] contain 10,558 pages (1377 papers).

In refrigeration, air conditioning, and heat pumping systems, the compressor is one of the four major components that are used to implement the widely used vapor compression cycle. The other three components are the condenser, evaporator, and expansion device. The compressor compresses the refrigerant and circulates it in a continuous cycle through the closed system. ASHRAE provides a detailed compilation of the available knowledge about refrigerant compressors [16]. The compressors for these applications have been chosen for this section because they are representative of most of the compressors made in large quantities.

Compressed air is essential to almost all manufacturing and construction enterprises. The compressor manufacturing industry is so large that air compressors have been selected for special consideration in this section.

The capacity of gas and air compressors is specified according to their delivered flow rate, whereas the capacity of refrigerating compressors is specified according to their cooling capacity.

There are two basic types of compressors: positive displacement compressors and dynamic compressors. Positive displacement compressors increase the pressure of the refrigerant vapor, air, or other gas by reducing the volume of the compression chamber by means of work usually applied to the compressor's shaft mechanism. Dynamic compressors increase the pressure by a continuous transfer of angular momentum from the rotating parts of the compressor to the fluid, followed by the conversion of this momentum into a pressure rise. Both types are described in this section.

Positive Displacement Compressors and Their Application to Refrigeration, Air Conditioning, and Heat Pumping

Positive displacement compressors depend on a volume change for the compression process, in contrast to dynamic compressors, which depend on acceleration, deceleration, and conversion of kinetic energy into pressure. They are designed for a wide range of flow rates and suction and discharge pressures, and can be used in many applications. Typically, they are used for refrigeration, air conditioning, and heat pumping applications, and for compressing air and other gases for virtually all uses except aircraft propulsion.

When used for cooling and heating, compressors, whether classified as positive displacement compressors or dynamic compressors, are used in vapor compression cycles for applications of air conditioning, refrigeration, and heat pumping. As the key component in vapor compression systems, the compressor raises the pressure of the working fluid so that it can be condensed to liquid at the heat sink temperature, expanded or throttled to reduce the pressure, and evaporated into vapor to absorb heat from the refrigerated source. In these systems, refrigeration compressors are a component in a closed-loop system, which is tightly sealed (often hermetically) to prevent refrigerant loss. These systems are often sealed for life without service or lubricant changes, operating anywhere from 300 to 8000 h per year with a life expectancy of 5 to 15 years, i.e., operating from 10,000 to 120,000 h with no maintenance.

When used in air conditioning, refrigeration, and heat pumps, they must be designed for a variety of refrigerants and compatible lubricants. Commonly used refrigerants include hydrofluorocarbons such as R-410A, R-407C, R-404A, and R-134a, ammonia, carbon dioxide, and various hydrocarbons.

Positive displacement compressors are classified according to their construction, e.g., whether or not they are enclosed in a hermetic housing. They are also classified according to the kinematic arrangement of their parts to accomplish the change in volume.

The particular types of refrigerant compressors to be described in this section are identified according to how they fit into the range on the application chart. This chart is shown in Figure 4.11.1, which shows the application across the top line, from the smallest for household uses to the largest for possible use in freezing plants and for air conditioning tall buildings [17]. Typically, compressors are specified by the horsepower or the kilowatts needed to drive them, or their refrigerating capability measured in tons of refrigeration, Btu/h, or kW.

Modifications to Conventional Vapor Compression Cycles

Vapor compression systems employing pure refrigerants or mixtures of refrigerants have reached a plateau in system optimization, motivating the search for novel approaches for designing systems with higher levels of efficiency and capacity. Two of such approaches that have a direct impact on the design of compressors are described next.

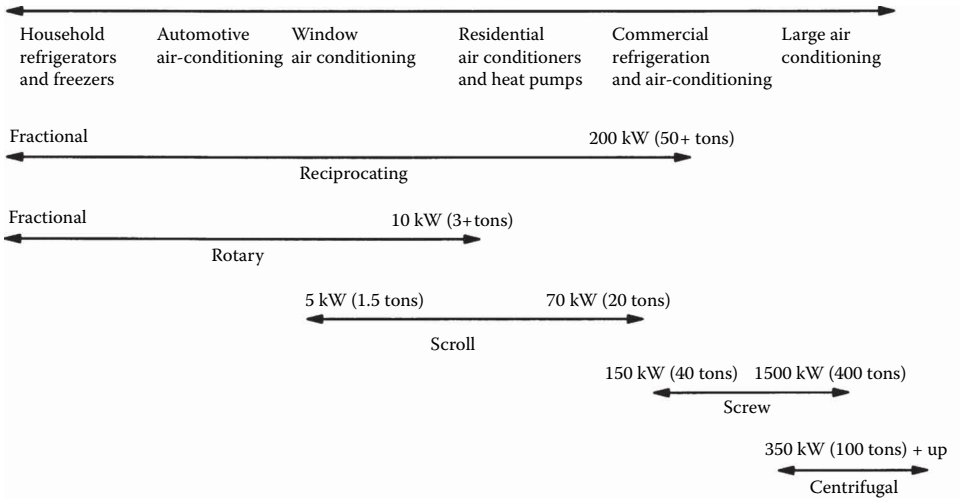

FIGURE 4.11.1 Range of applications of refrigerating compressors. (Data from International Institute of Refrigeration, Paris.)

Liquid Flooded Compression

One means to achieve higher levels of system efficiency is the addition of a significant amount of oil to the refrigerant before compressing it in the compressor, and the addition of an internal heat exchanger after the condenser, as can be seen in Figure 4.11.2 [18]. The ideal flooding liquid has a high density, a high specific heat, extremely low volatility, and good compatibility with the compressor materials. Water meets the first two criteria, but oils are more commonly used as they can better maintain lubrication, while still having reasonable capacity to cool the working fluid as it is being compressed.

This modification to the standard four-component vapor compression system has the following impacts on system design and performance:

- Significant reduction in discharge temperature of the compressor due to cooling by the injected oil. This is particularly relevant for high heat of compression fluids such as the refrigerant blend R404A or refrigerant R32.
- Addition of a large amount of oil allows for improved compressor efficiency, as has been demonstrated experimentally for scroll compressors [19,20]. Experimental results show a monotonic increase in efficiency with increased oil injection rate.
- While the flooding oil takes up a fraction of the suction swept volume of the compressor, it is not usually more than a few percent by volume due to its high density, and this consumption of the suction volume is partially offset by a decrease in internal leakage.
- The addition of the internal heat exchanger increases system efficiency by increasing the latent heat of cooling in the evaporator.

The addition of a large amount of oil flow into the compressor in vapor compression systems offers the dual promise of better compressor performance and an improvement in system efficiency, particularly in large-temperature-lift applications.

Vapor Injected Compression

Another means to achieve higher levels of system efficiency is the use of vapor injected compression with economizing. In a conventional compressor, the compression process takes place in a single process. During this process, the refrigerant heats up which increases the required compression work. A vapor injected compressor uses the injection of saturated vapor to reduce the temperature of the refrigerant during the compression process. Figure 4.11.3 shows conventional and vapor

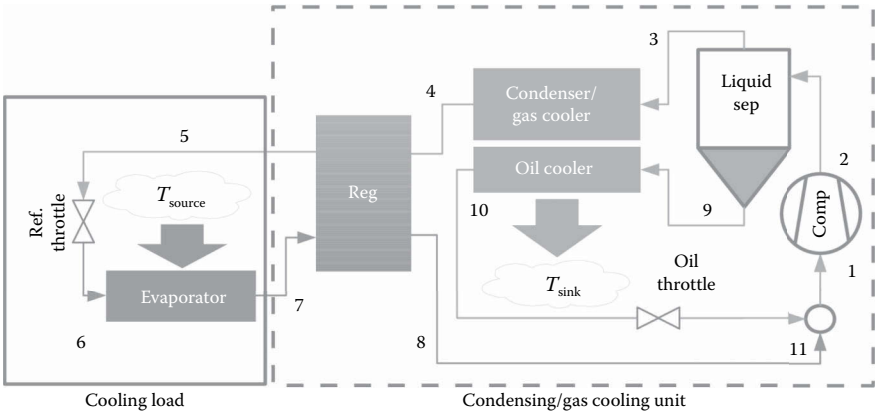

FIGURE 4.11.2 Schematic of the liquid flooded compression (Reg: Internal heat exchanger). (Adapted from Bell, I. H., *Theoretical and experimental analysis of liquid flooded compression in scroll compressors*, Ph.D. Dissertation, Purdue University, 2011. With permission.)

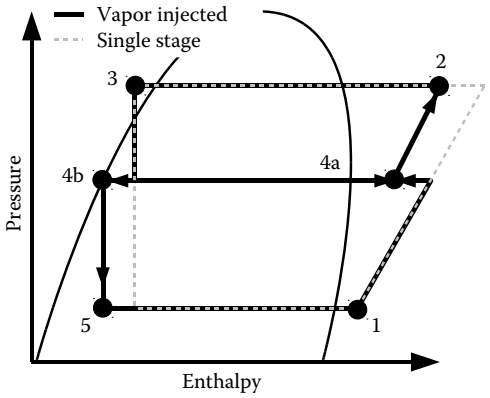

FIGURE 4.11.3 Vapor injected and conventional process in p–h diagram.

injected cycles in a log(p)–h diagram. The refrigerant that is injected into the compression process is taken from the expansion process, either using a vapor separator as shown in Figure 4.11.4 or an economizer. This vapor injection has three effects: (1) it reduces the discharge temperature, which increases the range of the operating envelope; (2) it decreases the inlet quality to the evaporator, reducing the evaporator pressure drop, especially at low evaporation pressures; and (3) it increases the total mass flow rate of the compressor, since vapor injection is typically done after the suction pocket of the compressor closes. This leads to a larger capacity at low suction pressures, which is of advantage for heat pump applications. This increase of capacity can be reduced by bypassing the injected vapor (e.g., point 4a) to the suction side of the compressor. However, this will also reduce the heating COP of the system.

Vapor injection is employed primarily with scroll compressors, which offer the unique opportunity for locating the injection port within a specific angular location of the scroll. Stationary and moving scroll form compression pockets in which volume decreases (and pressure increases) as they move along the compression path. As the compression pockets move past a specific angular position they swipe a certain pressure range, allowing the implementation of vapor injection without the need for implementing actively controlled injection valves. Besides from scroll compressors, vapor injected compression has also been employed in screw compressors and spool compressors, which offer similar characteristics.

Vapor injected compression can be applied to similar applications as cascade cycles, e.g., when large pressure ratios are needed for low-temperature cooling or cold climate heat pump applications. Vapor injected compression can—in principle—be more cost-effective since it does not require two compressors with the associated oil management system. However, vapor injected compressors have the disadvantage of poor performance at low compression ratios due to reexpansion losses and do

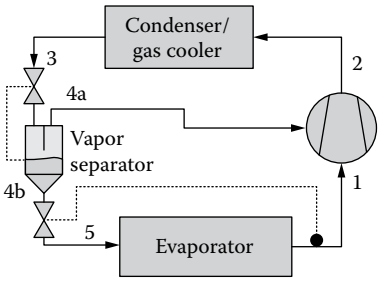

FIGURE 4.11.4 Single-port vapor-injected compression cycle using vapor separator.

not have the option to cost-effectively change the overall compression ratio by bypassing compression stages (as one can do with cascade cycles).

Due to better cycle coefficient of performance for high-pressure ratios than single-stage systems at a larger capacity for low ambient temperatures—at a lower cost than conventional cascade type systems—it is expected that vapor injected compression will eventually become adapted by the industry for low-temperature heat pump applications.

Compressor Type by Construction

Hermetic Compressors

Hermetic compressors, used for many refrigeration applications, have both the electric motor and the compressor inside a welded steel housing, providing a true hermetic seal. The motor shaft is normally connected directly to the compressor shaft. The housing is a steel shell that is welded at the joints to ensure the hermetic seal. If the gas in the housing is suction gas, then the compressor is called a low-side compressor because of the low suction pressure. If the gas in the housing is discharge gas, then the compressor is called a high-side compressor. A high-side design can often be very advantageous by serving as a source of high-pressure oil in the sump to lubricate the compressor components. When oil is injected into or present during the compression process for cooling or sealing, the high-side design provides a cavity where the oil can be separated from the discharge gas before it is delivered from the compressor to the condenser. Advantages of the low-side compressor are improved motor and oil cooling and lighter housing designs because of lower pressure. Hermetic shells are limited to small sizes because of the high cost of producing the larger ones made by a deep-drawing process. Therefore, hermetic compressors are used for smaller capacities. Figure 4.11.5 shows a hermetic reciprocating compressor with part of the shell cut away.

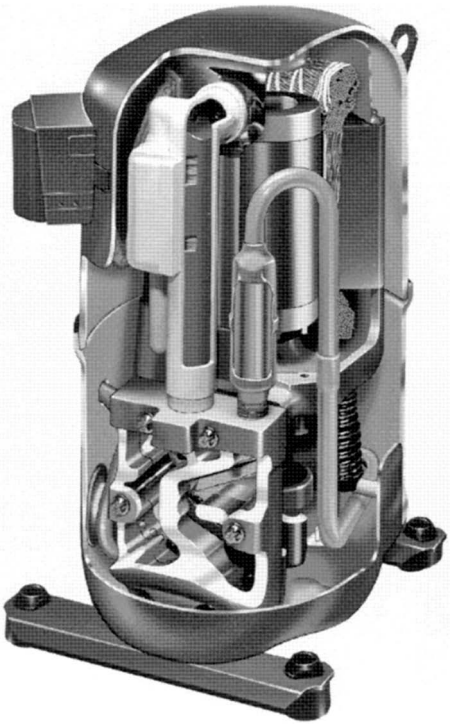

FIGURE 4.11.5 Cutaway drawing of a hermetic reciprocating compressor. (Courtesy of the Copeland Corporation, Sydney, OH.)

Semi-Hermetic Compressors

Semi-hermetic compressors are typically used for medium cooling capacities. They are similar to hermetic compressors except that the outer housing is normally bolted together so that the compressor is accessible for service. An advantage of this design is the ease of construction of multicylinder, large compressors without the need for the expensive deep-drawing manufacturing process. The externally bolted joints are sealed with gaskets that are a source of refrigerant leakage over a long period of time. Figure 4.11.6 shows a cross-sectional drawing of a typical semi-hermetic reciprocating compressor with part of the housing cut away. The electric motor drive is cooled by suction gas as well as by conduction through the motor housing. In many applications, fans are used to force air over the motor housing to aid in cooling. Figure 4.11.7 shows that the semi-hermetic reciprocating compressor provides excellent efficiency as compared to other positive displacement compressors in the medium capacity range. Semi-hermetic reciprocating compressors are normally rugged and durable machines; however, they tend to have relatively high vibration and noise levels.

Open Drive Compressors

Open drive compressors have their motors external to their compressor housings. The shaft connecting the motor and compressor passes through the compressor housing, requiring a shaft seal. The open drive compressor is more sensitive to leakage than the semi-hermetic compressor due to the use of the shaft seal. Open drive compressors are usually used for larger capacities, and often for automotive applications where the power to drive them is taken from the engine.

The semi-hermetic and open drive types make it easier to have multiple cylinders, which is a popular option for larger capacities and higher pressure ratios. The open drive compressors offer more flexibility, especially when repairs are needed. Installing the larger sizes in tandem is a low-cost way to obtain multiple capacities for improved part load efficiencies.

Compressor Type by Kinematic Linkages

Reciprocating Compressors

The reciprocating compressor is the most widely used positive displacement compressor, although the other types described here are being produced in ever-increasing numbers.

Most reciprocating compressors are single-acting machines that use a piston inside a cylinder. The piston is usually driven by a crankshaft through a connecting rod and wrist pin to compress the gas. However, other driving mechanisms are used sometimes, e.g., scotch-yoke mechanisms, electromagnetic drives, or swash-plate, wobble-plate, and Sanderson rocker arm motion mechanisms for axial multipiston arrangements. Figure 4.11.8 shows a cross-sectional drawing of a typical reciprocating compressor. The motor is often cooled by suction gas, although conduction through the shell also plays a part in the cooling. In many larger applications, fans are used to force air over the motor housing to aid cooling. Discharge and suction mufflers are used to reduce gas pulsations and sound. Pulsations are mainly caused by the reciprocating action of the piston and the intermittent opening and closing of the suction valve. Gas pulsations are very important in reciprocating compressors because these have a negative effect on performance and noise characteristics. Sometimes mufflers are an internal component in the compressor. A well-designed muffler can reduce pulsations and improve reciprocating compressor performance. Reciprocating compressors are normally mounted on a spring suspension system external to the housing and/or sometimes inside a hermetic shell to help reduce vibration and noise.

The reciprocating compressor has single or multiple cylinders. Every piston–cylinder setup has suction and discharge valves. The valves operate by differential pressure where gas only runs through them in one direction. Reciprocating compressors operate by drawing refrigerant through a suction valve into the cylinder during the downward stroke of the piston. At bottom dead center when the cylinder has reached its maximum volume and the piston starts its upward travel, the suction valve closes. The gas is then compressed until it reaches the desired discharge pressure at which time a discharge valve opens, allowing the compressed gas to flow into the compressor's discharge plenum and then into the system.

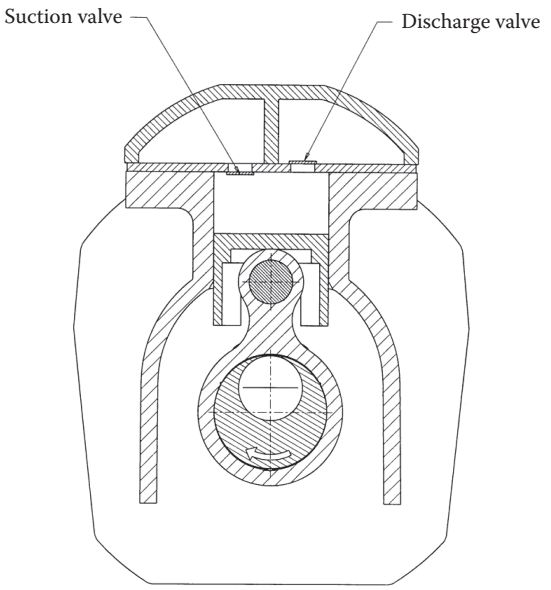

FIGURE 4.11.8 Cross-sectional drawing of a typical reciprocating compressor. (Courtesy of the Copeland Corporation, Sydney, OH.)

The volume inside the cylinder at top dead center is called the clearance volume. The clearance volume can never be reduced to zero, and is typically 1%–5% of the displaced volume due to piston movement. As the piston begins its downward travel, this gas must first be expanded back to suction conditions before the suction valve opens and new suction gas can enter the cylinder; thereby reducing the volumetric efficiency and capacity of the compressor. Single-stage reciprocating compressors are used in applications with pressure ratios ranging from 1.5:1 to 15:1, and two-stage units for applications with pressure ratios of 10:1 and above. At pressure ratios about 15:1, the capacity of high clearance volume compressors is reduced and can approach zero. A certain superheat is usually maintained at the inlet of the reciprocating compressor to avoid liquid entering into the in-cylinder volume which may result in the liquid slugging phenomenon. However, a further superheat in the suction plenum is unwanted as it reduces the compressor volumetric efficiency since the actual density of the gas flowing into the in-cylinder volume is decreased [21]. Figure 4.11.9 shows a typical *P*–*V* diagram of a reciprocating compressor, which indicates the relation between the gas pressure inside the cylinder and piston displacement. Process 1–2 indicates the suction process. Process 2–3 is the compression process during which the gas is compressed to a high pressure when the discharge valve starts to open. Process 3–4 is the process when the in-cylinder gas flows into the discharge plenum. There is some pressure fluctuation during this process due to the vibration of the discharge valve and gas pulsation in the discharge plenum. Process 4–1 is the reexpansion process when the piston starts to move downward and the gas begins expansion until the gas pressure inside the cylinder is low enough for the suction valve to open.

Both the heat transfer inside the suction plenum and the heat transfer between the in-cylinder gas and cylinder wall impact the compressor performance. The cylinder wall temperature changes little compared to its time-averaged value in a single cycle [22]. The heat transfer rate can be determined using developed correlations [23,24]. The heat transfer rate depends on the piston mean velocity and in-cylinder gas instantaneous temperature and pressure. The heat transfer between the gas and its surroundings when it enters into the cylinder and out of the cylinder during the discharge process also needs to be considered [25].

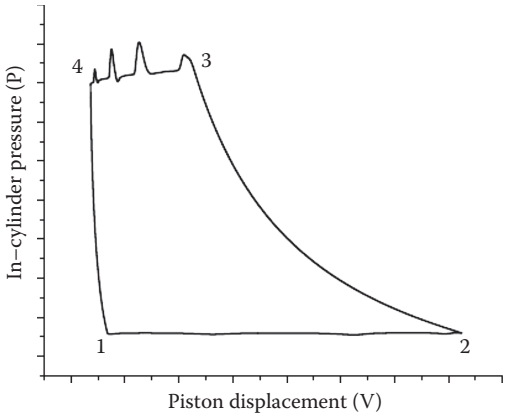

FIGURE 4.11.9 Typical *P–V* diagram of a reciprocating compressor.

Reciprocating compressors with piston ring seals can wear significantly but still provide outstanding performance. Therefore, even as wear increases, they often continue to operate adequately after long service. They are usually considered easy to repair compared to other types, and there is a large cadre of service personnel available. The piston rings in the reciprocating compressors can be lubricated by oil or nonlubricated using self-lubricating piston ring materials instead. The lubricating performance depends on not only the profile and dimensions of the piston ring, but also the properties of the lubricating oil. There is a minimum oil film thickness along the piston ring height between ring profile and cylinder wall which reaches the maximum magnitude when the piston moves in the middle of the downward/upward stroke. The friction between piston ring and cylinder wall gets worse when the piston approaches both the top dead center and bottom dead center due to the slow piston movement and in-cylinder gas pressure [26]. The series of crevice among the piston rings (usually the compressor has several piston rings) creates a path for the gas leaking from or into the in-cylinder volume. The gas pressures in these crevices are different and uniformly distributed. The first piston ring which is closest to the in-cylinder volume usually bears up to 75% of total pressure difference [27].

Capacity modulation can be accomplished in several ways in reciprocating compressors. On multicylinder compressors, some suction valves are often blocked. In some cases the suction process is throttled by passing discharge gas back to the suction side of the system. This type of capacity modulation method has the advantage of being infinitely controllable. However, from the energy utilization point of view, the power used to compress the bypassed gas from suction pressure to discharge pressure brings no beneficial results. In addition, the compressor always works with full load no matter what the required capacity is, i.e., the compressor is always running with high power consumption. There is an alternative method called stepless capacity control and was proposed by Hoerbiger compressor controls [28]. This method uses a pneumatically actuated finger-type unloader to keep the in-cylinder gas from compression in a portion of the stroke so that the discharged flow can be reduced to the partial flow. The actuation of the unloader is controlled by a panel by monitoring the flow requirements. Sometimes the speed of the compressor is varied by mechanical or electrical means, although designers must be careful with valve design to ensure that they work adequately over the range of speeds used. If a variable speed AC motor is used to change the compressor speed, the torsional response of the drive shaft needs to be considered. The capacity modulation of a reciprocating compressor can be related to its volumetric efficiency change which is not only depending on the pressure ratio, but also on the clearance volume. By controlling the auxiliary clearance volume, the volumetric efficiency is changed. This method is a more effective control method at higher pressure ratios. The auxiliary clearance volume can be fixed or variable. Varying the piston stroke by using a movable pin, an adjustable rod, or a linear electric motor can

also have a significant impact on the compressor capacity. According to the report by Danny et al. [29], using a linear electric motor to change the stroke is a very promising approach. In some reciprocating compressors such as swash plate compressors, the piston stroke can be varied by changing the inclined angle of the swash plate. Similarly, in the compressor using the novel Sanderson-Rocker Arm Motion (S-RAM) mechanism, the stroke is also variable by altering the inclined angle between the wobble plate and the machine driving shaft [30].

Hermetic reciprocating compressors for refrigeration and air conditioning applications are produced in sizes ranging from a fraction, up through 25 tons of refrigeration, and are typically used in residential, commercial, and industrial air conditioning, heat pump and refrigeration applications with capacities ranging from ¼ to over 200 tons of refrigeration. Reciprocating compressors may have up to 10 cylinders in radial, in-line, or multiple bank arrangements.

Computer-aided design has greatly improved performance and efficiency of reciprocating compressors, primarily due to new and innovative valve, port and flow passage designs [31]. Computer-aided design studies are also used to improve internal heat transfer, so that further improvements in performance and efficiency can be expected. However, it appears that other designs have potentially inherently superior characteristics for better reliability, volumetric efficiency, pressure oscillations, etc.

Rotary Compressors

Rotary compressors are produced in two general types: the rolling piston compressor and the rotating vane compressor. The most common, shown in Figure 4.11.10, is known as the rolling piston or fixed vane rotary compressor. It is commonly used in small refrigeration and air conditioning applications. The second type, the rotating vane compressor, is shown in Figure 4.11.11. It is most commonly used in automotive applications.

The *rolling piston compressor* is sometimes called a fixed (or stationary) vane rotary compressor because the vane does not rotate with the rotor, but rather slides in a fixed slot in the stationary part of the compressor. The rolling piston name is given to the cylindrical part of the compressor that is mounted on an eccentric shaft since it appears to roll on the surface of the cylinder wall. Further, its position is the controlling element for the compression volume that is formed by the rolling piston, the fixed vane, and the cylinder wall, thereby having a similar function as the piston in a reciprocating compressor. During the suction part of the cycle, suction gas is drawn through a suction port into the increasing volume just described. During the suction process, compression and discharge processes are taking place in the decreasing volume on the opposite side of the piston and vane. These compressors tend to be more reliable than reciprocating compressors primarily because no suction valve is needed and breakage of the suction valve has been a common failure mode.

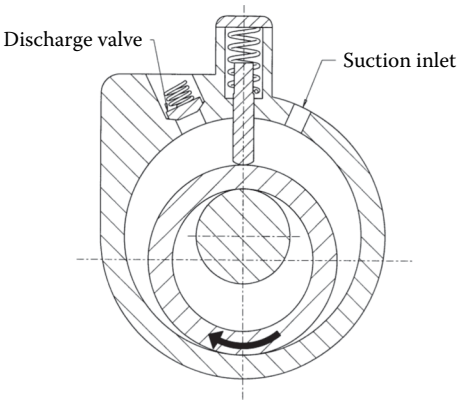

FIGURE 4.11.10 Cross-sectional drawing of a typical rolling piston (fixed vane) rotary compressor. (Courtesy of the Copeland Corporation, Sydney, OH.)

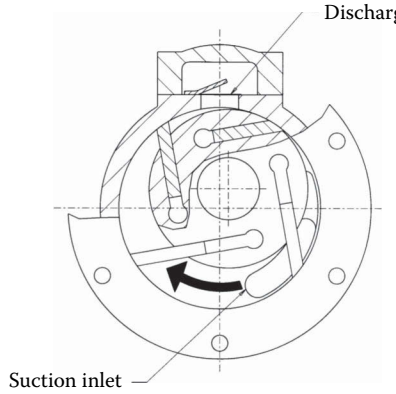

FIGURE 4.11.11 Cross-sectional drawing of a typical rotating vane rotary compressor. (Courtesy of the Copeland Corporation, Sydney, OH.)

Discharge flow is controlled by use of a pressure-operated discharge valve. Another advantage of rolling piston compressors is their small size for a given capacity. However, since rotary compressors are intolerant of contamination, they are usually limited to uses for which the systems are not expected to be opened for servicing. Furthermore, any wear in the compressor, whether it be the bearings, the shaft, the roller, or the vane, increases the clearances, and therefore, has a significant effect on the compressor performance.

To simplify the construction and lubrication system for rolling piston compressors, high side designs are common. However, the high motor and oil temperatures that accompany high side designs limit the pressure ratio (or condensing pressures) that can be achieved without extra cooling.

In air conditioning and refrigeration uses, rolling piston compressors are produced with capacities varying from 600 to 60,000 Btu/h (0.18–17.6 kW). Although there are mechanical means to vary the capacity of rolling piston compressors, variable-speed motors are normally used to achieve capacity modulation.

Pressure ratios range from 2:1 to 10:1. Performance data are shown in Figure 4.11.7. The rolling piston compressor can achieve comparatively high efficiencies, especially when fabricated for units with less than 24,000 Btu/h (7 kW) cooling capacity. The eccentric movement of the piston in the rolling piston is less than that of a piston in a reciprocating compressor of the same displacement. Thus, there is comparatively less vibration and noise compared to reciprocating compressors. However, the rolling piston mechanism is commonly counterweighted to mitigate the imbalance caused by the eccentric movement of the piston. The compressor and motor are normally rigidly mounted in the compressor shell and, therefore, it has relatively high torsional vibration because of the single-cylinder torque pulse.

To reduce the torque pulsations, especially at low speeds, compressors are produced sometimes with two out-of-phase cylinder assemblies. In twin rolling piston compressors, the two cylinder assemblies provide parallel flow paths, which can be useful for increasing the flow rate through the compressor. In two-stage rolling piston compressors, the gas flows through the two cylinder assemblies in series. Breaking the compression process into two stages reduces the pressure ratio acting across each chamber, which can be advantageous for reducing leakage in applications with large temperature lifts. Furthermore, the two-stage configuration allows for the implementation of modifications such as intercooling and economizing. Cooling the working fluid between stages can both increase the compressor efficiency and decrease the discharge temperature, thereby decreasing wear on the compressor.

The *rotating vane rotary compressor*, shown in Figure 4.11.11, has a rotor with slots that contain several vanes. The vanes slide in and out of the rotor and are centrifugally pressed against the

cylinder wall as the assembly rotates. The shaft center is eccentric from the center of the cylinder; therefore, the gas volumes in the pockets between the rotor, vanes, and cylinder vary as the unit rotates. Suction gas enters through a suction port. Discharge gas flow is commonly controlled with a discharge valve. The rotating vane compressor is subject to wear at several sealing surfaces, but is somewhat self-compensating for the wear. It can be more tolerant to contamination than the rolling piston compressor. This type of compressor has cooling capacities ranging from 12,000 to 120,000 Btu/h (3.5–35 kW). It is used primarily in automotive air conditioning applications.

Scroll Compressors

The scroll compressor is the newest of the various types of compressors to be used for the mass market. However, it is rapidly gaining market share. Figure 4.11.12 is a cross section of a typical hermetic scroll compressor. The steel shell is an integral part of the compressor–motor assembly. An internal spring suspension is not required because of the low vibration levels produced by the scroll mechanism. In the dominant conception of the scroll compressor, suction gas is normally used to cool the electric motor. Cooling is also accomplished with direct conduction from the motor to the shell and then to the atmosphere via radiation and natural (or forced) convection.

The compression mechanism consists of two matching spiral scroll members opposite each other as shown in Figure 4.11.13. These scrolls are typically identical, but can be asymmetric. One of the scrolls is typically fixed and the other, driven by a crankshaft, moves in an orbit within the fixed scroll without rotation. Figure 4.11.14 illustrates the process of compression in gas pockets formed by contact of the two scrolls at several radial points. The refrigerant gas enters the lateral openings at the outer diameter between the two scrolls. The lateral openings are then sealed as the orbiting scroll moves, forming two trapped gas pockets indicated by the shaded area at the end of the suction stroke. The gas is then compressed due to the decreasing volume of the pockets as the scroll continues its orbiting motion, moving the compressed gas toward the center of the scroll elements.

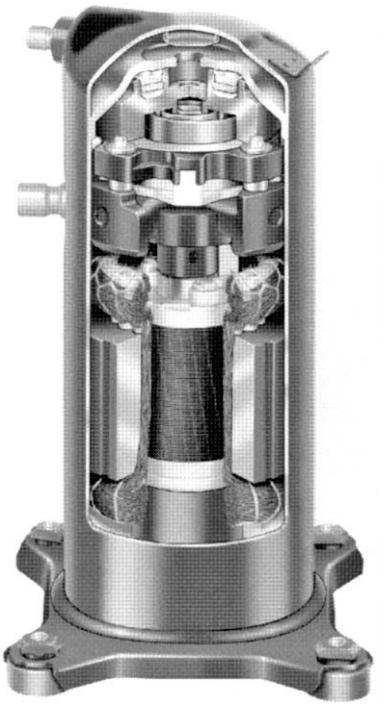

FIGURE 4.11.12 Cutaway drawing of a hermetic scroll compressor. (Courtesy of the Copeland Corporation, Sydney, OH.)

As the gas reaches the center, a discharge port is opened (or uncovered by the motion of the orbiting scroll) which allows the compressed gas to move to the discharge chamber of the compressor and into the system.

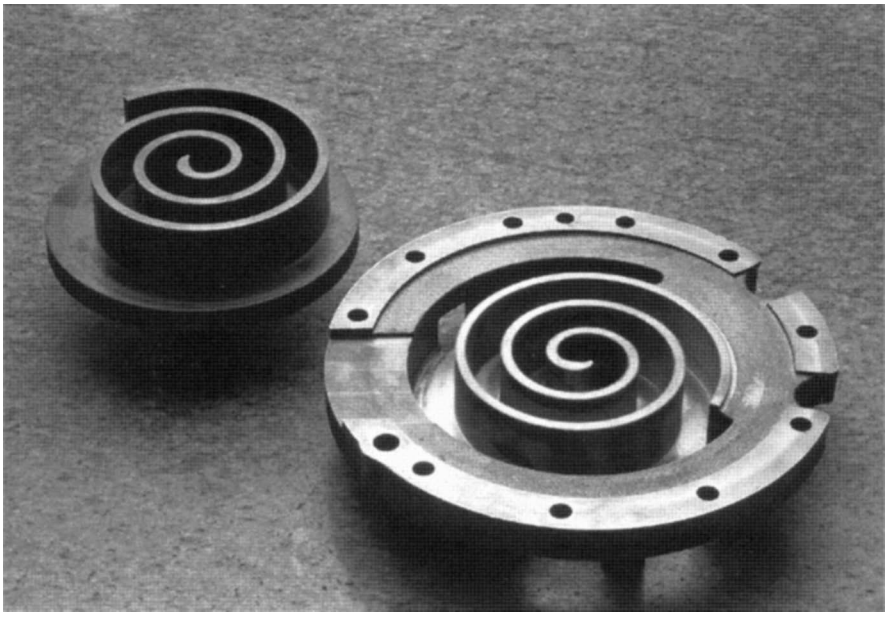

FIGURE 4.11.13 A pair of matching scroll members. (Courtesy of the Copeland Corporation, Sydney, OH.)

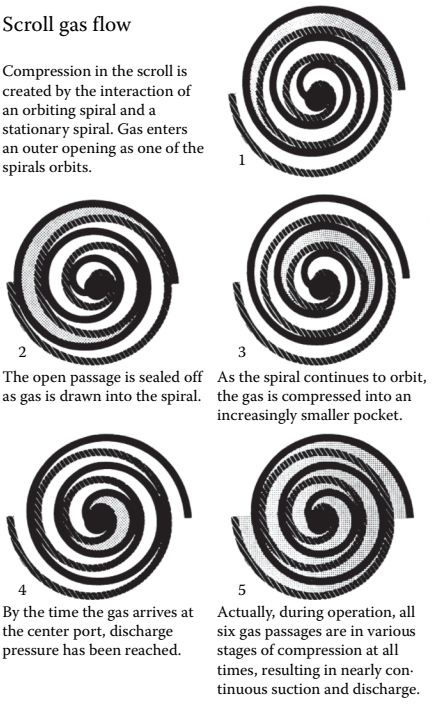

FIGURE 4.11.14 Gas flow in a scroll compressor. (Courtesy of the Copeland Corporation, Sydney, OH.)

The development of advanced machining techniques made high-volume manufacturing of scroll compressors possible. An Oldham coupling (or other analogous methods like the use of idler bearings) is required to keep the orbiting scroll in an orbiting, nonrotating, trajectory. The scroll compressor has a substantial reduction in part count and operational complexity as compared with other positive displacement compressors. The complexity of scroll compressors is typically in the geometry and the addition of compliant mechanisms, not the part count. Operationally, there are many inherent technical advantages with scroll compressors.

The discharge and suction processes in the scroll compressor are completely separated; therefore, there is no clearance volume effect on the volumetric efficiency and capacity of the compressor. As a result, the volumetric efficiencies of scroll compressors are almost independent of the pressure ratio for a given suction condition (i.e., suction density), due to the lack of a clearance volume effect. Thus, virtually all the refrigerant mass that enters the suction cavity of a scroll compressor eventually exits through the discharge port except a small amount lost due to leakage from higher-pressure chambers and heat transfer.

Heat transfer between the suction and discharge processes is also greatly reduced, therefore reducing the heat transferred to the suction gas and improving overall efficiency. The scroll compressor has a constant suction volume flow rate regardless of its operating pressure ratio and the volumetric efficiency remains high, above 90 in most applications. By placing a port in the scroll member, access can be obtained to a point in the compression process. This port can be used to inject vapor or liquid in the middle of compression, making it possible to compound the refrigeration cycle to take advantage of an economizer cycle to achieve high system efficiency and capacity, or to inject oil to cool the working fluid.

There are no valves or valve losses (aside from high-compression ratio applications where discharge valves are commonly employed), and the absence of valves improves reliability and reduces complexity. An almost constant steady flow and relatively low heat transfer gives the scroll compressor the capability of high efficiency. Being dynamically balanced and without valves allows the scroll to operate efficiently at speeds much higher (up to 10,000 rpm) than the rotary or reciprocating compressors, and over a broader range. These features, plus the nearly steady torque and smaller pressure oscillations, result in very low vibration and noise for scroll machines.

Capacity modulation is achieved by varying the speed of the compressor or by delaying the beginning of the compression process. This is done by opening a port that allows gas to flow back to the suction side during the initial compression process. Alternatively, in some scroll compressors, the scroll wraps are allowed to separate for part of the compression process, allowing for smooth capacity control.

By the use of a compliant mechanism, scroll compressors are very tolerant to ingesting liquid and dirt without failure or significant loss in performance. The wear of bearings and other parts does not affect the sealing and has almost no effect on the performance of the compressor. Compliance is accomplished by holding the two scrolls together by means of gas pressure and centrifugal forces, not the mechanical structure.

Scroll compressors are used in a wide range of applications from refrigeration, air conditioning, and heat pumping to air supply for fuel cells. Deployment in vapor compression cycles accounts for a large majority of the applications in air conditioners and commercial refrigeration equipment. Current production sizes range in cooling capacities from 1 to 25 tons of refrigeration (3.5–88 kW). Like the rotary compressors, scroll compressors are smaller in size than reciprocating compressors for the same capacity. They can be designed for the high-pressure ratios needed for large temperature lift heat pump applications.

The increasing market share of the scroll compressors is due to their high reliability, low noise, and several performance advantages with respect to reciprocating compressors.

1. In refrigeration applications, a smaller-displacement compressor can be used to provide adequate refrigerant capacity at very low evaporation temperatures or very high-pressure ratios. This allows the compressor to operate efficiently over a much broader operating range with the same motor.

2. In heat pump applications, the heating capacity at low ambient heating conditions and high-pressure ratios is higher, resulting in a higher heating seasonal performance factor, a measure of the performance of heat pumps.
3. In air conditioning applications, the system is normally sized to ensure adequate cooling at relatively high ambient temperatures. When operating at normal or lower ambient conditions, the capacity of the scroll compressor does not increase rapidly, resulting in less excess capacity. Therefore, there is a reduced load on the coils, which increases overall system efficiency, i.e., which increases the seasonal energy efficiency ratio (SEER). The SEER is a measure of the performance of an air conditioner.
4. Scroll compressors do not usually employ valves, improving their reliability as compared with reciprocating compressors.

Screw Compressors

Screw compressors are generally obtained from the gearing theory of different meshing pairs. They are available in two basic configurations, namely: the Lysholm (or twin screw) type with a pair of meshing rotors, and the single screw type with a central rotor meshing with two gate rotors.

The *twin screw compressor* type is the most common. It utilizes two intermeshing helical rotors, one a male and one a female to achieve the compression process. The male rotor, which is generally the driving rotor, and the female rotor are enclosed in a casing. As their meshing progresses during the rotation, a volume is isolated between the rotors and the casing. Such volume represents the working chamber which is reduced progressively during the compression process. Most of the twin screw compressors present a 4/6 configuration with four lobes in the male rotor and 6 lobes in the female rotor. Both rotors have the same outer diameter. By modifying the number of lobes in the male and female rotors different compression ratios can be achieved as well as the possibility to be used in dry or oil-flooded applications [32].

The suction and discharge processes occur without the use of valves. In particular, when the working chamber at the front ends of the rotors passes across the suction port, the filling process begins until the cut-off point at which the suction volume has a maximum value. At the end of the compression process, the working chamber reaches the rear ends of the rotors and it is exposed to the discharge port. The compression process of a twin screw compressor is shown in Figure 4.11.15 [33]. The port design helps reduce suction and discharge flow losses, and provides a built-in volume ratio that gives peak performance at the corresponding pressure ratio.

The compression process generates axial and bending loads on the rotors as well as contact forces between the rotor lobes which need to be absorbed by the shaft bearings. The bearing loads of twin screw compressors are relatively high due to higher compression ratios achievable especially with oil-flooded twin screw compressors, and the small space between the shafts limits the diameter of the bearing that can be utilized. Normally, antifriction rolling element bearings are used on the twin screws, which result in a finite life under the high loads and often require replacement during the life of the compressor. The overall noise level of the twin screw compressor tends to be high and is at a higher frequency than the other positive displacement compressors. With only two major moving parts, the twin screw has high reliability.

In twin screw compressors, there are two main sources of internal leakages, which are the contact line between the meshing rotors and the clearance between the rotors and the casing. The rotor profile design and the manufacturing of the rotors ensure the existence of a sealing line throughout the compression process, which reduces the amount of pressurize gas that flows backward to low-pressure zones (typically the suction pocket). With respect to the manufacturing process, achievable clearances between the rotors are below 15 μm [32]. The clearances between rotors and casing are more difficult to quantify under running conditions due to the combined effect of thermal expansion and deformation of the rotors. The difficulty encountered in providing a good seal between the rotors and housing is usually met with the use of a large amount of oil (typically called “oil

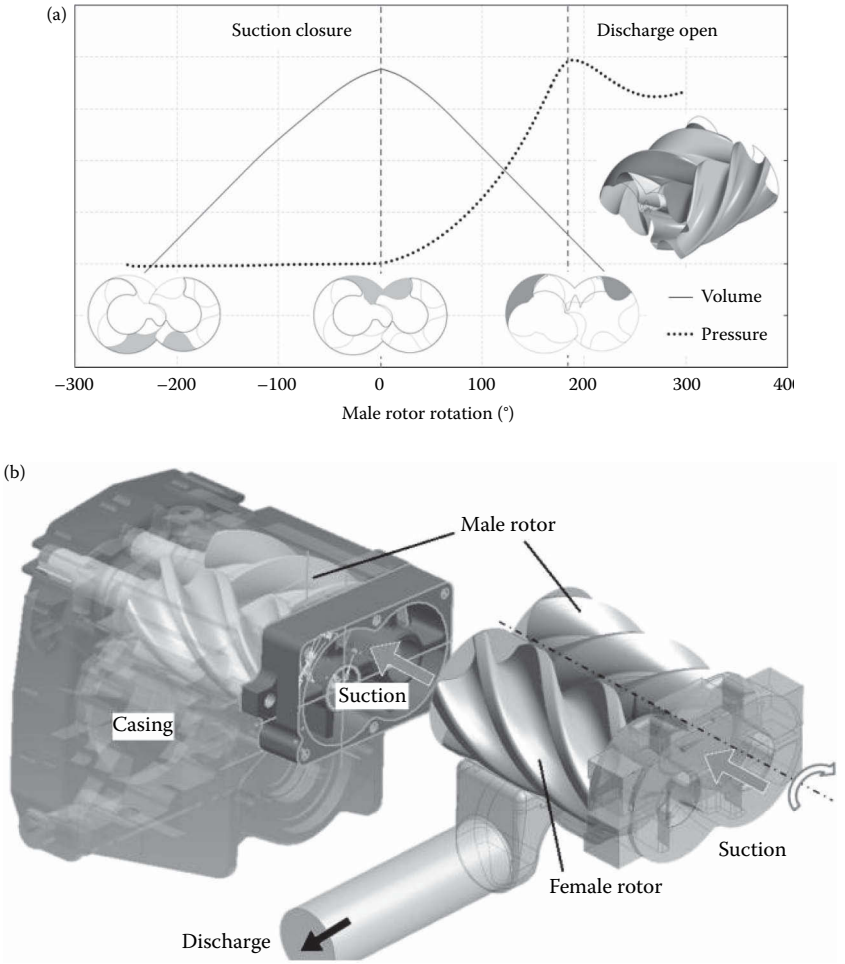

FIGURE 4.11.15 (a) Twin-screw compressor assembly and (b) working process of a twin-screw compressor. (Adapted from Rollins, J. P., Ed., *Compressed Air and Gas Handbook*, 5th ed., Compressed Air and Gas Institute, Cleveland, OH, 1989. With permission.)

flooding") during the compression process. The oil also serves as a coolant during the compression process. Depending on the rotor design and application, the quantity of oil can be substantial and must be separated from the discharge gas flow in most applications, usually by the use of oil separators (semi-hermetic designs). Thus, oil circulation can have a large effect on efficiency and the superheat of the compressor in air conditioning and refrigeration applications. At lower capacities, it is difficult to maintain good sealing. The result is poorer performance at lower capacities and that has traditionally limited applying screw compressors in air conditioning and refrigeration applications below 50 tons of refrigeration (175 kW).

During operation, the capacity of the twin screw compressor is varied to match load requirements by means of different control methods: suction throttling valve, variable speed control, and slide valves. The suction process can be modulated with a gate valve that extends the suction port, delaying the beginning of the compression process, and thus reducing the amount of inlet gas available for compression. Some screw compressors are also equipped with slide valves that shorten the effective length of the rotors by moving parallel to the rotors. Hence, the internal volume ratio is adjusted to the load requirements. The capacity of the screw compressor can be modulated in the range from 100% to 10%.

Besides the traditional twin screw configuration, an oil-flooded *tri-rotor screw compressor* with variable speed control concept has also been commercialized for the HVAC industry in the range of 50–500 tons (175–1750 kW), as shown in Figure 4.11.16 [34]. The tri-rotor configuration reduces the deflection of the rotors allowing a reduction of the amount of oil needed during operation.

The *single screw compressor (SSC)* was originally developed by Zimmern in the 1960s as an oil-injection free compressor. The SSC presents different configurations depending on the type of screw rotor (cylindrical, planar or conical) and the type of gate rotors (cylindrical or planar). The most common configuration is the CP-type (cylindrical-planar) with a central grooved rotor and two gate rotors (or starwheels) that are engaged antisymmetrically with respect to the main rotor rotation axis, as shown in Figure 4.11.17a. The gate rotor teeth sweep the screw grooves to achieve compression which represents a substantial difference with the twin screw compressors. The working process of the SSC is illustrated in Figure 4.11.17b [35]. Similarly to the twin screw compressor, the suction and discharge processes occur without the use of valves. The discharge port presents a triangular shape which follows the trailing edge profile of the groove. The typical grooves to teeth ratio is 6/11, which guarantees smooth engagement (issues arise if a common factor in the engagement ratio is used) and achievable compression ratios. The metallic screw rotor is in contact with high-wear-resistance material gate rotors (typically polyether–ether–ketone or PEEK) in such a manner that the compression process, although requiring cooling, does not necessarily require lubrication. However, the tooth flank is still subjected to wear after several hours of operation. Different meshing pair designs have been proposed to reduce the friction between the tooth flank and the groove. Most of the commercial SSCs adopt a straight-line envelope profile as a contact line between the meshing pair. With the advancements in the machining technology, multistraight line and multicolumn envelope meshing pair have been developed to allow the contact distribution over multiple lines and over a curved surface, respectively [36].

The SSC presents high volumetric efficiency and it does not require significant amounts of oil to seal the high-pressure gas from the low-pressure gas because the land between the trailing edge of a groove and the leading edge of the previous one increases as the pressure increases minimizing the cascade effect. Cooling can be accomplished by the injection of liquid refrigerant.

Due to the fact that the compression process occurs simultaneously in both sides of the main rotor, the swept volume is doubled and the radial loads on the rotor are balanced. The lower bearing loads contribute to lower noise and vibration levels compared to the twin screw compressors, which ultimately leads to an extended bearing life up to 15 years.

Part-load operation is accomplished by means of one or two slide valves on each side of the rotor that control the capacity and the volume ratio.

Screw compressors are made as semi-hermetic compressors, and as open drive compressors. Both twin and SSCs can be utilized to compress a variety of gases. Both designs are amenable to

capacity control by varying shaft speed as well as by use of slide valves to delay the start of compression, thereby reducing the amount of inlet gas available for compression.

When used for air conditioning and refrigeration, screw compressors, similar to scroll compressors, can be designed so that vapor or liquid can be injected in the middle of compression, making it possible to compound the refrigeration cycle with the economizer concept. This is accomplished with a port in the housing that provides access to a point in the compression process.

Screw compressors vary in capacity from 15 to more than 400 tons of refrigeration (53 to more than 1400 kW). Most screw compressors are made in the range of 50–300 tons of refrigeration (175–1050 kW). An advantage of screw compressors with respect to reciprocating compressors above 15 tons of refrigeration (53 kW) is the significantly fewer number of parts and their relatively small size. Screw compressors have also become competitive with centrifugal compressors up to 400 tons of refrigeration (1400 kW) because of their superior part load performance. The part load performance of screw compressors is generally 8%–10% more efficient than for centrifugal technology. Also, screw compressors do not have the surge problems inherent with centrifugal compressors.

Dynamic Compressors

Dynamic compressors belong to the family of turbomachines that include fans, propellers, and turbines. Unlike positive displacement compressors which depend on a volume change for the compression process, centrifugal and axial compressors use the dynamic effect of velocity change,

acceleration followed by deceleration and static pressure recovery, for the compression process. Thus, the technology used is different for centrifugal and axial compressors than for positive displacement compressors.

There are many basic references about the technologies of dynamic compressors. Five references are suggested. The basic theory is covered in Refs. [37,38], and design is covered in Ref. [39]. A reference is suggested for centrifugal compressors [40], and one suggested for axial flow compressors [41].

A key equation used in the analysis of dynamic compressor performance is Euler's pump and turbine equation:

$$W_s = u_2 C_{\theta 2} - u_1 C_{\theta 1} \tag{4.11.1}$$

where W_s is the shaft work input per unit mass of fluid; u, the blade tip velocity; and C_θ, the tangential component of the fluid velocity leaving the blade. This equation, derived from the law of conservation of angular momentum, can be used with the aid of velocity diagrams (see Figure 4.11.20) to show the energy transfer mechanisms in centrifugal and axial flow compressors.

Centrifugal Compressors

Basic Description

In a centrifugal compressor, the suction gas enters the rotating element, or impeller, in the axial direction and is discharged in a radial direction at a higher velocity. The change in diameter through the impeller increases the velocity of the gas flow. This dynamic pressure is then converted to static pressure through a diffusion process, which generally begins within the impeller and ends in a radial diffuser outboard of the impeller. Figure 4.11.18 is a cross-sectional drawing of a typical single-stage centrifugal compressor.

A centrifugal compressor can be a single-stage compressor, having only one impeller, or it can be a multistage compressor, having two or more impellers mounted in the same casing. The suction

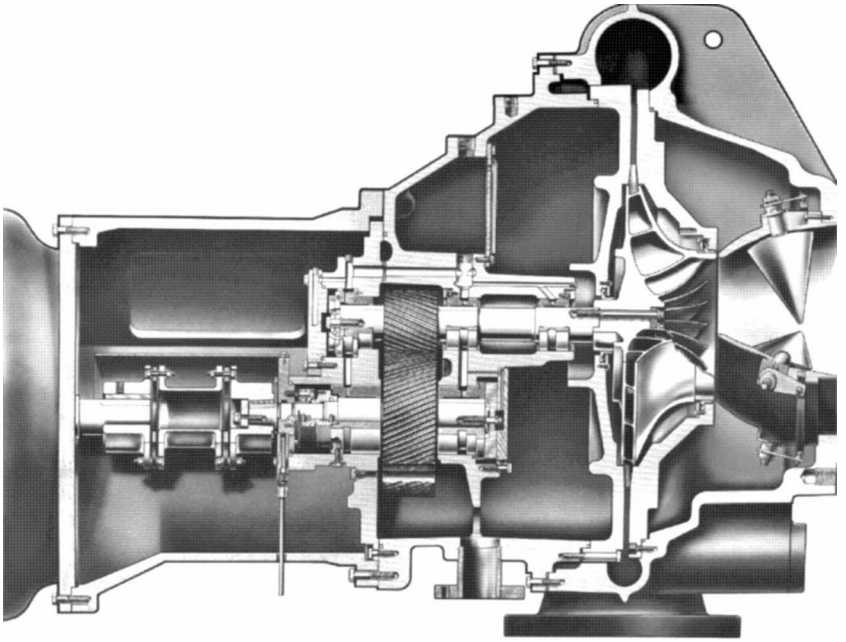

FIGURE 4.11.18 Drawing of a typical single-stage centrifugal compressor. (Courtesy of York International Corporation, York, PA.)

gas generally passes through a set of adjustable inlet guide vanes (prerotation vanes) or an external suction damper before it enters the rotating impeller. The guide vanes (or the suction damper) are used to control the flow rate through the compressor. The high-velocity gas discharging from the impeller enters a radial diffuser, which can have vanes or be without vanes. Diffusers with vanes are typically used in compressors designed to provide high-pressure ratios. These vanes are generally fixed, but they can also be adjustable. Adjustable diffuser vanes can be used for capacity modulation either in lieu of or in conjunction with the inlet guide vanes.

Centrifugal compressors are comparatively simple machines with few moving parts and moderate manufacturing tolerances. Yet they have high efficiency and are very robust. If the compressor's driver allows, the compressor speed can be varied to control the pressure ratio. Centrifugal compressors have a broad flow-handling range. At a given speed, the upper limit on flow is set by stall in the diffuser or impeller passages. The lower limit on flow is marked by surge—an unsteady flow condition marked by increased noise and flow reversal through the machine.

For multistage compressors, the gas discharged from the first stage is cooled and directed to the inlet of the second stage through a return channel. The return channel contains a set of fixed flow-straightening vanes or an additional set of adjustable inlet guide vanes. Once the gas reaches the last stage, it is discharged in a volute or collector chamber. From there, the high-pressure gas flows to the compressor discharge connection.

Design Characteristics

Centrifugal compressors range in flow rate from 150 cfm (0.071 m^3/s) in automobile turbochargers to 25,000 cfm (12 m^3/s) in large industrial process compressors. Pressure ratios per stage range up to 6:1 for air compressors, with higher values attained in research equipment. Figure 4.11.19 shows a typical performance map (head rise vs. flow rate) for such a machine [42]. The horizontal axis is proportional to the suction volume flow rate and the vertical axis is proportional to head (head is the isenthalpic enthalpy increase of the gas flowing through the impeller). The term "head" carries over from pump design nomenclature and is expressed in "feet" or "meters" even for compressors. Head is an index of the pressure ratio across the compressor.

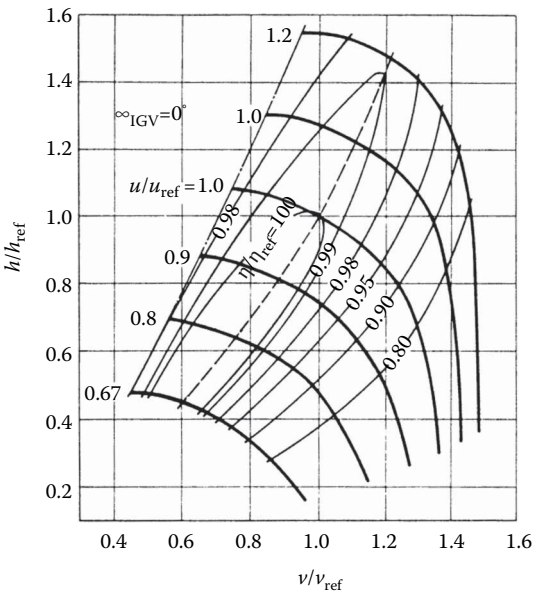

FIGURE 4.11.19 Centrifugal compressor performance map. (From the American Society of Mechanical Engineers, ASME Paper No. 86-GT-127. With permission.)

The plot also shows contours of constant efficiency, η. The head, flow, efficiency, and tip speed, u, all are nondimensionalized in the plot by using reference values. The reference value in each case is the value of the parameter at the design/rating point of the machine.

The right portions of the head-vs.-flow characteristics curves drop because of choking (explained below). The left end of each head-vs.-flow curve is limited by surge, also explained below. The surge limit, shown as a dot-dash line, connects the head/flow curves for different tip speeds. A dashed line in the center of the efficiency contours represents the loci of the "best efficiency points" at all operating speeds.

Performance maps such as the one in Figure 4.11.19 are essential tools for engineers applying compressors in particular applications. An application dictates the flow and head requirements the compressor must satisfy. The map shows the efficiency obtainable from the compressor for this flow and head, and the speed at which it must run.

Most compressors operate over a range of conditions in their applications. The performance map allows the application engineer to determine whether any requirements of the application will cause the compressor to operate too closely to surge or stall limits. If so, speed may have to be changed, prerotation vanes may have to be turned, or a different compressor design may have to be selected.

Operational limits for centrifugal compressors may be set either by structural limits or by flow parameters. For low molecular weight gases such as air, the compressor speed must remain within the stress limits of the impeller materials. Impeller tip speeds commonly fall below 1500 ft/s (460 m/s). For gases with higher molecular weights and lower acoustic velocities, the compressor speed is limited by the compressible flow phenomenon at the impeller and diffuser inlets. Impeller tip speeds commonly fall below a machine's Mach number of 1.5. Mach number here is defined as the impeller tip speed divided by the compressor inlet gas speed of sound. The maximum pressure level for centrifugal compressors is set by the casing design, and can reach several thousand psi (pounds per square inch) for multistage gas compressors used in the process industry.

The bearings in centrifugal compressors can be antifriction bearings in small machines. Plain journal bearings are commonly used in larger machines. Multistage compressors have more complicated bearing systems when operation above the first critical speed is required. The bearings are lubricated by a pressurized oil supply. Suitable seals are provided to minimize or eliminate lubricating oil carryover into the gas being compressed.

Centrifugal compressors are most commonly driven by electric motors with gearboxes to step up the speed to the level required for the compressor's duty. Steam or gas turbines drive some centrifugal compressors. Reciprocating engines are used in a few applications, generally with speed-increasing gears.

The efficiency of centrifugal compressors can be quite high under appropriate application conditions. Isentropic efficiencies of 80%–83% can be attained in single-stage machines. Sources of losses that reduce efficiency are flow friction (due to high gas velocities), separation and mixing losses, windage in clearance spaces, bearing losses, and effects of high Mach number flows (compressibility and local shocks). Losses arising from internal heat transfer generally are negligible in these machines.

Centrifugal compressors continue to be the dominant choice for very large refrigeration sizes, e.g., applications above 1500 kW (427 tons of refrigeration) cooling capacity. This is driven by unchallenged overall system efficiencies in these sizes. Centrifugal compressors are also very simple with few moving parts. They have manufacturing tolerances two orders of magnitude greater than equivalent screw compressors do. Therefore, centrifugal compressors have relatively low manufacturing costs with high reliability. In addition, centrifugal compressors for large-size applications operate within a very narrow band of operating head pressure, thereby minimizing problems associated with surge.

Development Directions

In the future, IPLV (integrated part load value) will become more important, requiring centrifugal compressors to operate efficiently over a broader range of applications. The main challenge for the

next generation of centrifugal compressors will be to maintain the full load efficiency at current levels while meeting the part load challenges of the future.

With the advent of ceramic bearings and hydrostatic bearings coupled with liquid refrigerant used as the lubricant, the elimination of oil management systems and hydrodynamic bearings can be expected. Therefore, oilless compression remains a viable technology for the centrifugal compressor. Indeed, magnetic bearings are offered in some process industry compressors.

Since 1993, centrifugal compressors are being redesigned for CFC refrigerant replacements. Many opportunities exist for increased efficiency and improved thermal aerodynamics. Utilizing the technology of the high-speed, small centrifugal turbines, even smaller sizes of centrifugal compressors are possible. Other opportunities exist for improving reliability and serviceability, for reducing noise and vibration, for increasing the use of electronics for sensing and control, the use of inverters for speed control, and for improving the manufacturing processes to reduce costs.

Flow and Performance Characteristics

Figure 4.11.20 shows the velocity vector diagram for a centrifugal compressor. The velocity diagram indicates that work input to the impeller accelerates the flow to a high velocity at its tip. A static pressure rise may occur across the impeller to an extent dictated by the impeller geometry and gas density change. The diffuser passages downstream of the impeller may be without vanes or may have vanes to decelerate the flow and increase its static pressure. A scroll or volute collects the flow at the radial diffuser exit. A conical diffuser often is located at the collector exit to achieve additional static pressure rise.

Prerotation vanes, fixed or adjustable, may be located upstream of the impeller inlet. These vanes can be used to adjust the impeller work input and inlet flow angles. Also, when turned to large angles, the prerotation vanes act as a throttling device, which may allow the compressor to operate at low mass flow rates where otherwise surging would occur.

The impeller discharge velocity triangle includes the slip factor, *S*. This factor accounts for the mass-averaged deviation of the flow through the impeller. The flow does not leave at the geometric blade angle because of irrotational flow in the absolute reference frame, creating the "slip."

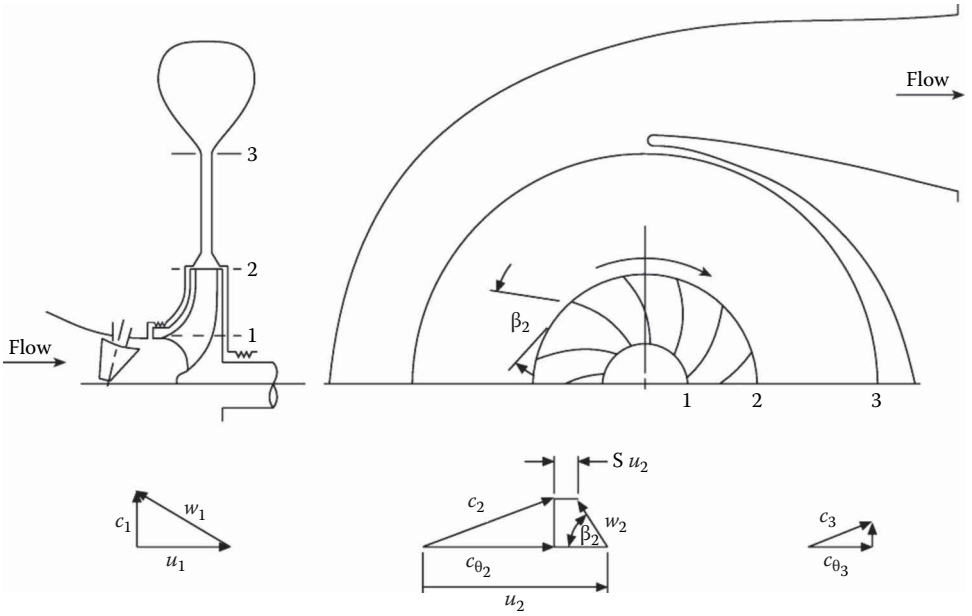

FIGURE 4.11.20 Velocity vectors for a centrifugal compressor.

Equation 4.11.1 shows that the work input to a centrifugal compressor calls for maximizing the product $u_2C_{\theta 2}$. The upper limit on the value of u_2 is set by the strength of the impeller material or by the acoustic velocity of the gas being compressed. Air compressors are limited by impeller strength while refrigerant compressors are limited by flow velocities approaching the sonic limit at the impeller eye (w_1) or at the inlet of vaned diffusers (related to C_2). Note that w is the relative velocity between C and u (see Figure 4.11.20).

The limit for the value of $C_{\theta 2}$ is set by the limit on the value of w_2 and the choice of the impeller discharge blade angle, β_2. Impeller passages act as diffusers, with a maximum limit of 1.4–1.6 set for the value of the diffusion ratio, w_1/w_2, to avoid significant stall losses. The implication of the blade angle is discussed below.

The performance map of a centrifugal compressor for work, head, and losses is illustrated qualitatively in Figure 4.11.21. The compressor losses are at a minimum when flow angles throughout the compressor match the design conditions. At lower flow rates, losses increase as impeller, diffuser, and scroll boundary layer flows stall. Stall with high loss also occurs in the impeller and scroll at high flow rates. Ultimately, surge (low flow) and choke (high flow) limit the compressor's operating range. Surge is a major flow instability in the compressor, accompanied by complete flow reversal, which occurs when stall losses become so great that the compressor no longer can sustain the discharge pressure imposed upon it by the external system. Choking occurs at high flow rates when stall losses within the compressor become larger than the work input can sustain. In high-performance compressors, choking may be affected by added losses from transonic flow disturbances.

Figure 4.11.21 applies to an impeller with "backward leaning" vanes, i.e., $\beta_2 < 90°$. Figure 4.11.20 shows that if $\beta_2 = 90°$, the radial component of C_2 will have no impact on the level of $C_{\theta 2}$. This is because w_2 is radial in direction, if β_2 is equal to 90°. The slip factor, S, essentially remains constant for varying flow rates in a particular impeller. Thus, $C_{\theta 2}$ becomes a maximum that affects the surge limit of a centrifugal compressor and reduces the stable flow range. In Figure 4.11.21, the line representing work input, W, will be horizontal, not sloping downward with increasing flow. With the work input, W, as a horizontal line combined with the loss characteristics shown, the curve representing the head, H, will drop at low flow rates. Thus, surge will occur at higher flow rates for a radial bladed impeller than for a backward leaning one. A radial impeller generates maximum head but exhibits reduced range of flow between surge and choke limits.

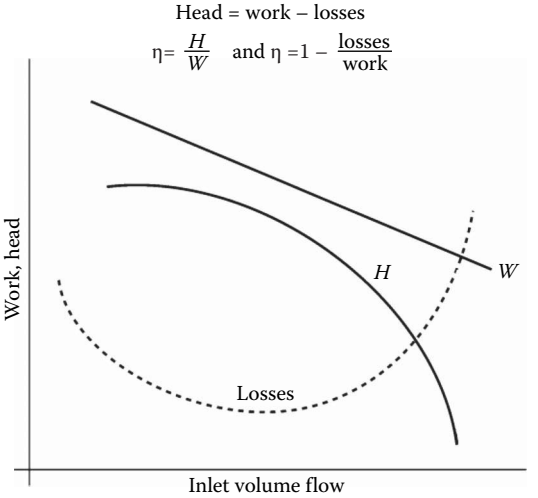

FIGURE 4.11.21 Centrifugal compressor performance at constant speed.

Axial Flow Compressors

Basic Description

In an axial flow compressor, the suction gas enters and the discharge gas leaves the compressor in the axial direction. As shown by the cross section in Figure 4.11.22, axial compressors have a small frontal (inlet) area but are comparatively long in the axial dimension because multiple stages are required for most applications [43].

Axial flow compressors are used primarily as components of gas turbines for power generation or aircraft propulsion. A few are used in process gas compression service where large volume flow rates are required. Typical flow rates for axial flow compressors range from 25,000 cfm (12 m^3/s) in small aircraft engines to 1 million cfm (470 m^3/s) for large stationary plants. The number of stages ranges from 7 to about 17, with the upper limit set by the dynamic considerations of the rotor.

Design Characteristics

Axial compressors are complex machines with high precision required in the manufacturing of the blades. Each blade row is made up of thin, carefully profiled airfoil surfaces, which must have adequate strength to withstand large aerodynamic forces. Consequently, the flow range is narrow for axial compressors as indicated by the typical performance map shown in Figure 4.11.23 [43]. The narrow range of the nearly vertical pressure ratio (or head) vs. flow curves in Figure 4.11.23 contrasts with the broader flow range exhibited by the head vs. flow curves of the centrifugal compressor shown in Figure 4.11.19 [42].

Flow control in axial compressors is achieved by using variable stator vanes and, in engine applications, speed control. The flow range is limited by blade stall on both the high- and low-flow sides of the performance map. Axial compressors can exhibit surge and also rotating stall patterns under low flow conditions—both are unsteady flow conditions. Sometimes, interstage flow bleeds are used to broaden the flow range of these machines.

Compressible flow (Mach number) effects due to the high flow velocities in axial flow compressors commonly limit the pressure ratio that is achieved per stage.

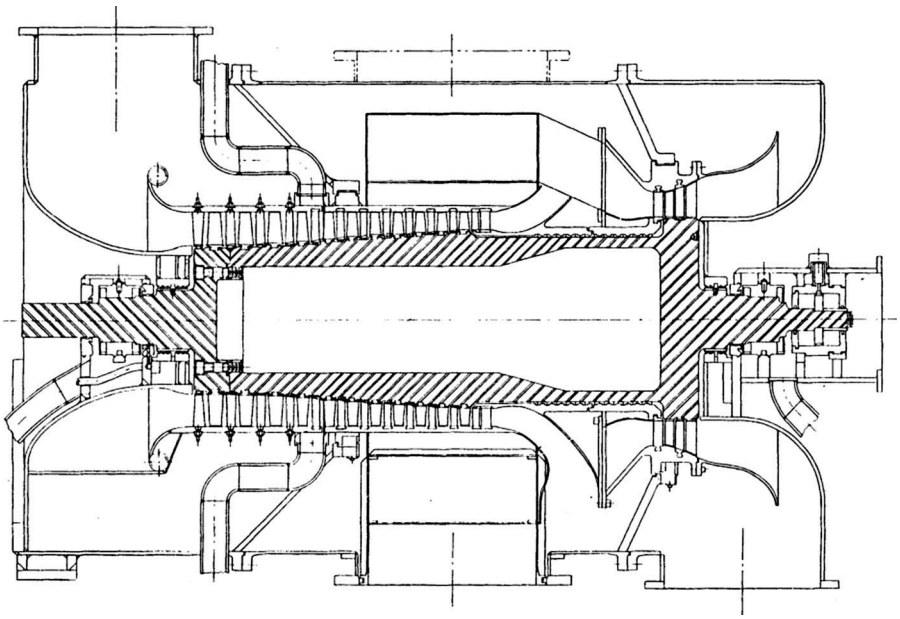

FIGURE 4.11.22 Cross-sectional drawing of an axial-flow compressor. (From the American Society of Mechanical Engineers, ASME Paper No. 58-SA-25. With permission.)

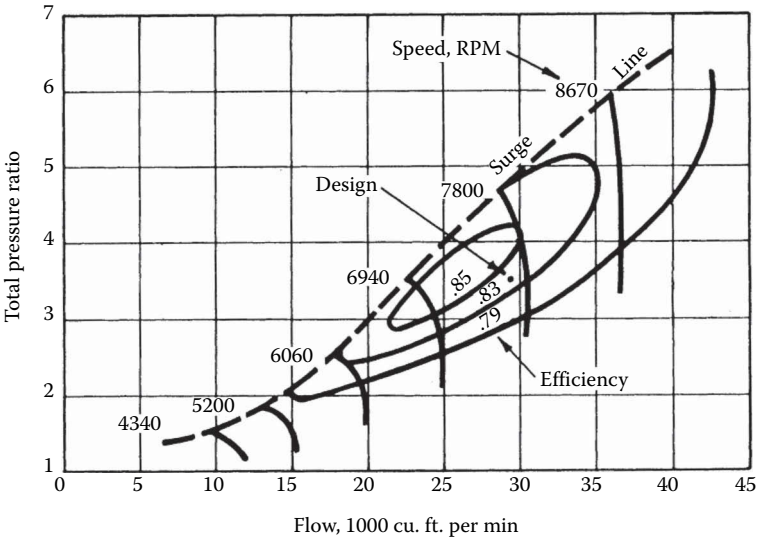

FIGURE 4.11.23 Typical performance map of an axial flow compressor. (From the American Society of Mechanical Engineers, ASME Paper No. 58-SA-25. With permission.)

Tight clearances between rotating blade tips and casing surfaces are required to minimize tip losses. Thus, most axial compressors employ antifriction bearings because of their small clearances. Pressurized lubrication systems are provided, with seals that assure little or no oil carryover into the compressed gas stream.

Gas or steam turbines are the most common drivers for axial compressors. Electric motors with speed-increasing gears sometimes are used in stationary applications.

Axial compressors are employed where high efficiency is essential. Isentropic efficiencies exceed 80% in most applications. Sources of losses which reduce efficiency include flow friction (resulting from high velocities), losses associated with transonic flow, tip clearance losses, flow separation and mixing losses, flow deviation losses in downstream stages, windage losses in disc clearance spaces, and bearing losses. Losses due to internal heat transfer are negligible in axial compressors.

Flow and Performance Characteristics

Figure 4.11.24 shows the velocity vector diagram for an axial flow compressor. The work input in axial compressors occurs as a result of a series of small changes in flow direction taking place at high-velocity levels with no significant change in radius. Small static pressure increases commonly occur across each blade row, downstream of the inlet guide vanes.

Axial compressor blade design practices at first were closely related to aircraft airfoil design practices. In the United States, an NACA airfoil series, and in the United Kingdom, a circular arc airfoil series, were used by compressor designers as jet engines advanced in the 1950s. Wind tunnel tests of cascades of blades provided correlation of lift (angle change) and drag (losses) as a function of blade geometry, pitch/chord ratio, and stagger (blade angle relative to the axis).

Stationary blade rows in axial compressors may be fitted with mechanisms to change their angular position. Inlet guide vanes and the first several stator blade rows may be so equipped to allow the compressor to operate over a wider flow range or range of pressure ratios. Downstream stages sometimes have bleed-off ports to accommodate changes in operating conditions that otherwise might cause subsequent stages to stall.

The basic performance map of a single stage (stator and rotor blade row) of an axial compressor is similar to the performance map of the centrifugal compressor shown in Figure 4.11.21.

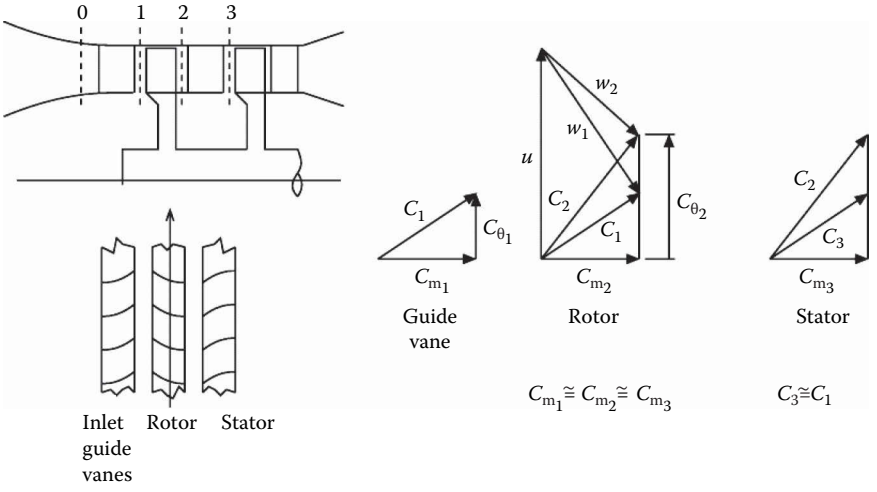

FIGURE 4.11.24 Velocity vectors for an axial flow compressor.

The axial compressor's flow range and work input per stage are much lower than for a centrifugal compressor because of the narrow range of blade inlet flow angles tolerated by the airfoils before stall occurs at positive or negative angles of attack. Axial compressors often run at speeds such that flow velocities approach the velocity of sound in the gas being compressed. Transonic flow can occur at points along the blade rows, increasing the likelihood of stall as flow angles depart from design values.

For axial compressors, Equation 4.11.1 shows that the work input is a result of the product $u(C_{\theta 2} - C_{\theta 1})$ because u, the blade tip velocity, essentially is constant through each blade row. The velocity triangles in Figure 4.11.24 show that both the rotor and stator blade rows act as diffusers. The limits on the value of $(C_{\theta 2} - C_{\theta 1})$ are set by the limits on the amount of diffusion, C_3/C_2 or w_2/w_1 that can be accomplished without high losses caused by diffuser stall.

The velocity, u, has a maximum limit set either by rotor material strength or by the acoustic velocity in the gas being compressed. As values of flow velocities, C_2 and w_1, approach the acoustic velocity, losses increase due to oblique shocks and flow redirection in local regions of transonic flow.

The operating range of a complete multistage axial flow compressor is limited by rotating stall (low flow) and choking (high flow). Rotating stall is a phenomenon that occurs when the stall of one blade (or several blades) on a given blade row causes adjacent blades on the same rotor row to stall. The resulting stall "patch" rotates around the circumference of the blade row. Downstream blade rows are affected by the upstream stall zone and may undergo their own rotating stall, leading to stall for the compressor as a whole. At high flow rates, stall of one or more blade rows creates high losses that prevent the rows from handling increased flow rates against the pressure rise imposed on the compressor by the external system.

Air Compressors

Air compressors can be classified according to whether they are portable or stationary, displacement or dynamic, oilfree or lubricated. An air compressor unit is usually sold including an "airend" (compression module), driver, controls, a cooling system, and a safety system. An enclosure to reduce noise is also available in most cases. A special foundation (or compressor base) is normally not required. "Packaged compressors" are self-contained, unlike refrigeration compressors.

Compressor Types for Various Applications

Factors affecting the selection of an air compressor are initial price, operating cost, reliability, warranty, and the availability of service and parts. Figure 4.11.25 shows the ranges of pressure and capacity typical of different types of compressors used in compressed air systems. The range of different types sometimes overlaps. The reciprocating compressors, such as the one shown in Figure 4.11.26, are used for low cost and low capacity (low flow rate) applications. For industrial applications below about 2500 cfm (1.2 m^3/s) airflow rate, the dominant type is the oil-flooded screw compressor. These are usually purchased as a packaged compressor, such as shown in Figure 4.11.27. For oilfree applications, dry screw or reciprocating compressors are the most popular choices, with

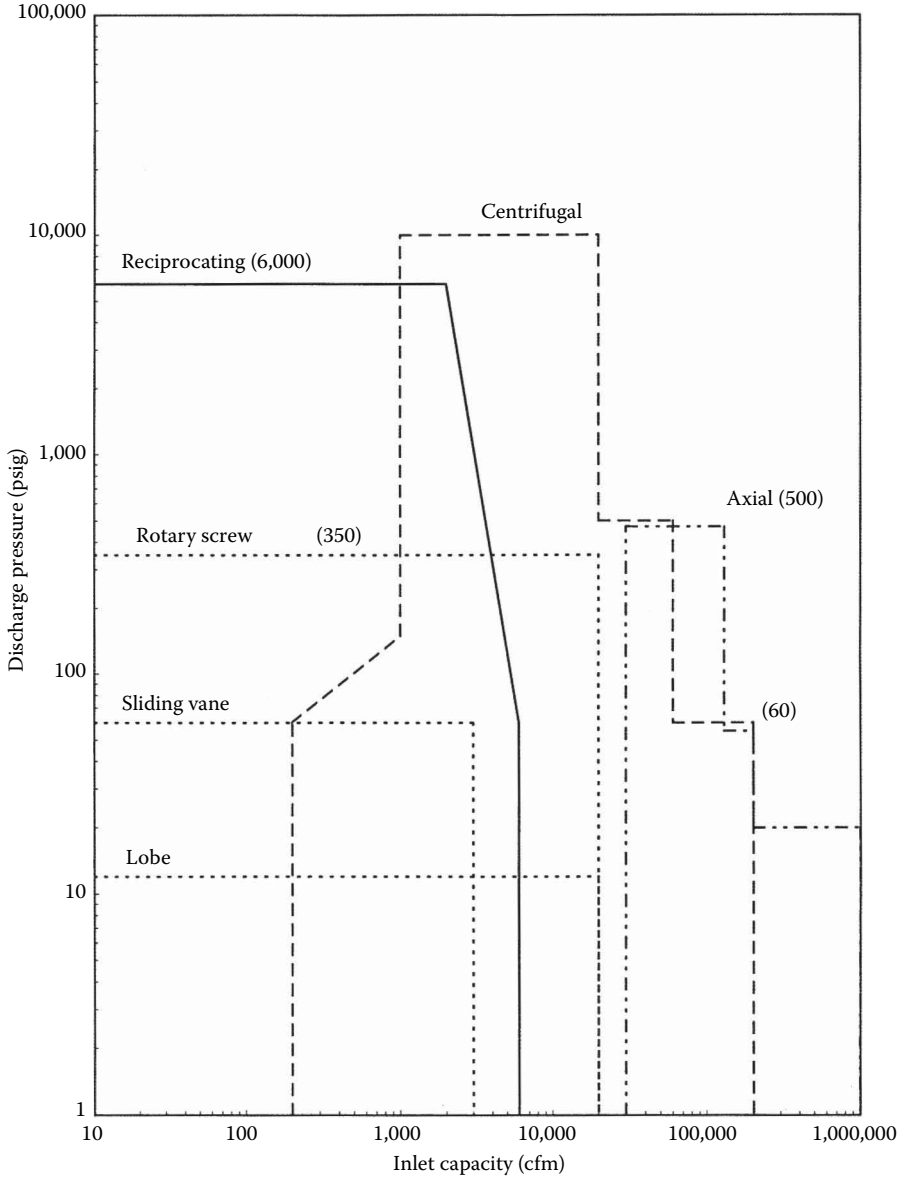

FIGURE 4.11.25 Pressure–capacity chart showing the effective ranges of most air compressors. (Courtesy of Ingersoll-Rand Corp., Woodcliff, NJ.)

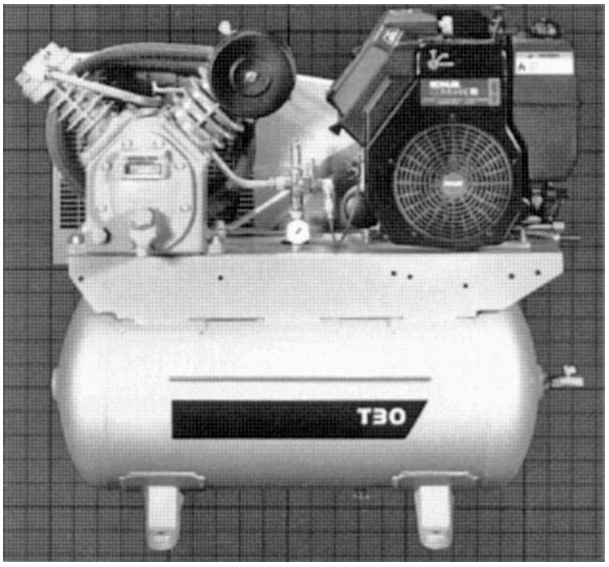

FIGURE 4.11.26 Two-stage reciprocating air compressor package with horizontal receiver tank. (Courtesy of Ingersoll-Rand Corp., Woodcliff, NJ.)

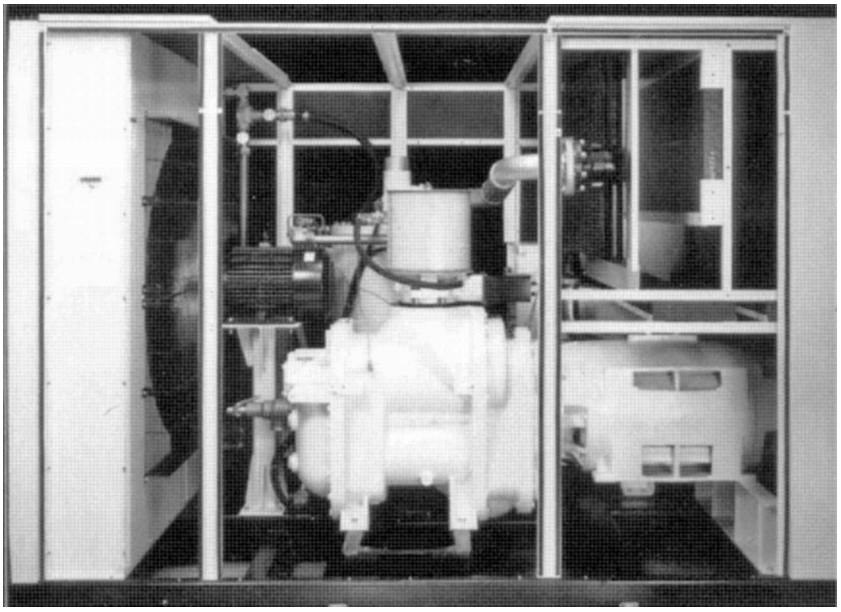

FIGURE 4.11.27 Interior of an air-cooled, two-stage, 200 hp oil-flooded screw compressor package. (Courtesy of Ingersoll-Rand Corp., Woodcliff, NJ.)

dry screw compressors taking an increasingly larger share of the market. Reciprocating compressors are also used where higher pressures are needed. Above 2500 cfm (1.2 m^3/s) airflow rate, centrifugal compressors, such as shown in Figure 4.11.28, dominate, up to the sizes where axial flow compressors become practical.

The smallest portable compressors, i.e., less than 50 cfm (0.0235 m^3/s) airflow rate, are usually built with reciprocating compressors driven by small gasoline engines. Above this range, most

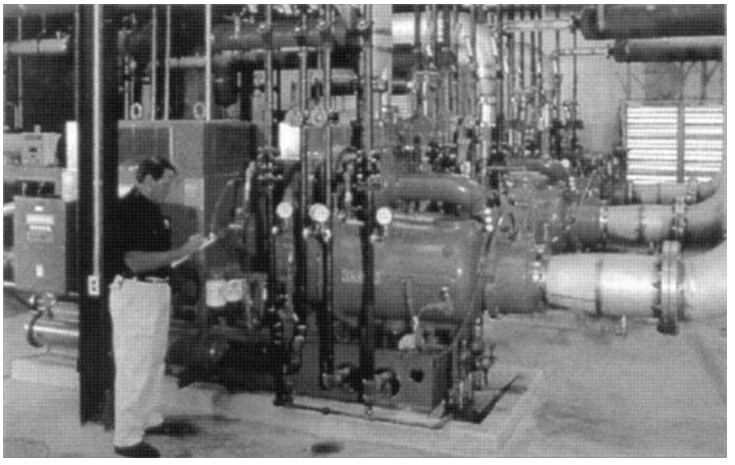

FIGURE 4.11.28 Three 5700 cfm, 1250 hp centrifugal air compressors supplying oilfree air to a textile facility. (Courtesy of Ingersoll-Rand Corp., Woodcliff, NJ.)

portable air compressors utilize an oil-flooded rotary twin screw design driven by a Diesel engine. Low-pressure air compressors with air discharge pressures below 200 psig (1480 kPa) are usually single-stage designs, whereas higher-pressure compressors have multiple stages. Oilfree portable compressors are available with two-stage rotary screw or centrifugal compressors. Most portable compressors have air flow rates from 100 to 1800 cfm (0.047 to 0.85 m^3/s), producing air delivery pressures of 100–150 psig (790–1140 kPa).

Nearly oil-free compressed air can be supplied to the process using an oil-flooded compressor by cooling the air after compression and then passing it through a series of very fine coalescing filters to remove any remnants of the oil aerosols in the compressed air.

Performance Considerations

Ratings

Air compressors are rated on delivered airflow, discharge pressure, and power consumption. The airflow is stated in terms of inlet volumetric flow, sometimes called "free air delivery." It is determined in a test by measuring the mass flow rate at the discharge and dividing by the inlet density. For a bare compressor, the inlet is clearly defined, but for a packaged compressor the inlet can be specified to be at either the package or compression module inlet. The stated flow will usually be lower if the package inlet is used, because the temperature is lower with a higher density. Test codes for measuring compressor performance have been developed by the European Committee of Manufacturers of Compressors, Vacuum Pumps and Pneumatic Tools (PNEUROP), and in the U.S. by the Compressed Air and Gas Institute (CAGI). These test codes have recently been included in ISO 1217, which is gradually becoming the industry standard in Europe and the U.S. This ISO standard specifies a standard package inlet condition of 20°C (68°F), 100 kPa (14.5 psia), and 0% relative humidity. The unit of flow in the ISO system is m^3/s, whereas in the U.S. ft^3/min (cfm) is generally used. Power is normally expressed in kilowatts or horsepower. For portable compressors, fuel consumption is stated instead of power.

Capacity and Pressure Control

Capacity control is an important performance characteristic, since it is a major factor contributing to how efficiently the compressor operates at part load. In addition to on–off control, compressors are usually fitted with an inlet valve. This inlet valve controls the airflow to the compressor by either

opening, throttling, or closing completely in response to pressure-sensing controls. Some compressors are equipped with a check valve that allows the receiver tank to be depressurized during periods of low demand. This reduces unloaded power by reducing the discharge pressure. Speed control is used on engine-driven compressors, and, increasingly, on those driven by electric motors. Dry screw compressors are not throttled at the inlet, since this increases the pressure ratio and thus, the temperature rise across a stage. These compressors are usually equipped with a check valve so the discharge can be depressurized. The inlet valve is either full open (when loaded) or full closed with the discharge at ambient pressure.

Ambient Temperature

Since the heat of compression must be carried away by a cooling system, all compressors have a limiting ambient temperature (LAT) above which the internal temperatures exceed their limits. Higher LAT values are possible with better cooling systems. The engine or motor cooling system also affects the LAT. Portable compressors usually have a temperature switch at the compressor discharge and another for the engine coolant. Exceeding the set point of either switch will cause the compressor to shut down.

Compressors also have low-temperature limits. Typical minimum operating temperatures are 35°F (1.7°C) for stationary compressors, and –10°F (–23.3°C) for portables. A low ambient compressor option is usually available for stationary compressors operating outside in cold climates. The low-temperature limits are due to the potential of the condensate freezing in the pneumatic control system components and in the aftercooler. For portable compressors, engine operation at cold temperatures can be the factor that determines the low-temperature limit. Startup at low temperatures must be carefully controlled to ensure that the compressor receives adequate lubrication. Preheating the oil will sometimes allow the compressor to be started at lower temperatures. In general, dry screw compressors have a more narrow ambient temperature range than oil-flooded screw compressors.

Ambient Pressure and Altitude

Except for dry screw and dynamic compressors, the ambient pressure is usually not a limiting factor from the compression module standpoint. As the altitude increases, the ambient pressure and temperature decrease. As a result, the power requirement of the compressor also decreases. This more than offsets the lower cooling efficiency when operating with less dense ambient air. For portable compressors, the maximum altitude is usually limited by the engine, which loses power capability with altitude. Dry screw and dynamic compressors must operate at lower discharge pressures at higher altitudes, to keep the pressure ratio from exceeding the limit for a particular unit.

Start–Stop Frequency

While on–off operation is an efficient mode of capacity control, it is limited by the maximum start–stop frequency. This is typically six per hour for an electric motor, to prevent overheating the motor starter components. Diesel engines must operate long enough between starts to recharge the battery. In addition, the starter motor and ring gear will wear out prematurely if the start–stop frequency is too high.

Compressor Speeds and Drives

Oil-flooded screw compressors operate most efficiently at a tip speed of about 35 m/s (115 ft/s). At higher tip speeds the efficiency decreases and the noise increases. These “airends” are usually not operated with tip speeds above 50 m/s (164 ft/s). Dry screw compressors must operate at tip speeds near 100 m/s (328 ft/s), to minimize backflow leakage. As a result, they are much noisier than oil-flooded screw compressors and require more acoustical treatment.

In general, a large, slow-running compressor is more efficient and quieter than a small, high-speed compressor. However, the initial cost is higher. As compressor design advances, the trend is to smaller, faster-running compressors, with better silencing techniques and more sophisticated controls to keep operating costs down.

Most portable air compressors are driven by Diesel engines, except those at the lower end of the airflow rates [below 100 cfm (0.047 m^3/s)], where gasoline engines are often used. Electric motor-driven portables are used in some areas. Stationary compressors are driven by electric motors. The majority of them operate at either 1800 rpm with a 60 Hz line frequency or at 1500 rpm where the line frequency is 50 Hz. Very large compressors in process plants are often driven by steam turbines.

Most portable compressors use a drive coupling to transmit the torque from the engine to the compression module, although small compressors are often belt driven. The drive coupling can be a troublesome component and must be carefully selected to minimize operational problems. Ideally, the compressor should be rugged enough to withstand the torque pulses from the engine, so that a torsionally stiff drive coupling can be used. This is often not possible, however, especially with the larger compressors, and a torsionally soft coupling must be used to isolate the "airend" from the engine. In these cases, the engine speed must be maintained well above the torsional critical speed to prevent drive train failures. The torque pulses from an electric motor are mild compared to those from a Diesel engine. As a result, the coupling is often eliminated by directly coupling the compressor and motor. This is accomplished by mounting the compressor drive gear on the motor shaft. If a coupling is used, it can be torsionally stiff.

Maintenance Requirements

One of the primary reasons for the popularity of oil-flooded screw compressors is their ability to operate continuously for many years with only routine maintenance. Filter maintenance is most important, since the incoming air is mixed with the oil and any particles in the incoming air end up in the oil. This same oil is used to lubricate the bearings, and particles in the oil will decrease bearing life. Typically, a 25 μm (0.64 μm) air filter is specified, with cleaning or changing required when the restriction exceeds 25 in. of water (6.2 kPa). The oil system also has a 25 micron (0.64 μm) filter, as well as an oil separation element, which captures particles as small as 1 micron (0.025 μm). Any contamination entering the system ends up in the separator element, thus shortening its life. The use of finer air and oil filters will increase the time between separator element changes. This is usually desirable, since changing the air and oil filters is much easier than changing the separator element.

The coolers must also be kept clean. Dirty or fouled coolers reduce the LAT, sometimes so much that the compressor shuts down because of overheating. Another undesirable consequence of dirty coolers is a shorter bearing life due to higher oil temperatures.

Regular filter maintenance is just as important on dry screw and dynamic compressors. A restricted air inlet reduces the compressor inlet pressure and raises the pressure ratio across it. This can cause overheating of a dry screw compressor and surge in a dynamic compressor.

Thermal Issues

Performance

Assuming adiabatic compression and applying the first law of thermodynamics, the rate of work of compression for a single stage compressor is given by

$$\dot{W} = \dot{m} c_p (T_2 - T_1) \tag{4.11.2}$$

where $\dot{m}$ is the mass flow rate of the compressed air; c_p, the specific heat; T_2, the outlet temperature; and T_1, the inlet temperature. Treating the air as a perfect gas, this becomes

$$\dot{W} = P_1 \dot{V}_1 \frac{k}{k-1} \left[\left(\frac{P_2}{P_1} \right)^{\frac{k-1}{k}} - 1 \right] \frac{1}{\eta} \tag{4.11.3}$$

where k is the specific heat ratio; P_1, the absolute inlet pressure, $\dot{V}_1$, the inlet volumetric flow rate; P_2, the absolute discharge pressure; and η, the adiabatic efficiency. For air, $k = 1.4$ and $c_p = 0.24$ Btu/(lb_m °F) [$c_p = 1.004$ kJ/(kg K)]. In practice, the input power and flow rate for a bare compressor (i.e., without inlet filters or discharge restriction) are measured on a dynamometer, and the adiabatic efficiency is calculated from Equation 4.11.3. This efficiency includes the power lost in the gears and bearings. Positive displacement compressors, including oil-flooded screw compressors, are almost always analyzed using the adiabatic model. Comparing adiabatic efficiencies at different pressure ratios is not a valid procedure. The efficiency should be measured at each pressure ratio of interest.

Examination of Equation 4.11.3 shows that the required power input depends only on the inlet flow rate, the inlet pressure, the pressure ratio, and the k-value. It does not depend on the inlet temperature of the gas or its molecular weight. In two-stage compressors, the power to the second stage can be reduced by intercooling, i.e., cooling the air between the first and second stages. The lower the temperature at the entrance of stage 2, the lower will be V_1 for that stage. By adding even more stages and intercooling before each additional stage, isothermal compression is approached, which requires less power than adiabatic compression. The better the intercooling, the more efficient is the overall compression process. The power increases approximately 1% for every 10°F (5.6°C) rise in inlet temperature to each stage. It is also important to keep the interstage pressure drop as small as possible, as pressure drop increases the pressure ratio for the next stage.

The inlet flow rate depends mainly on the speed, although it decreases slightly as the pressure ratio increases. In oil-flooded screw compressors, the air is heated by hot injection oil, which in turn decreases the inlet density of the air, thus decreasing the mass flow rate. A reasonable approximation for this effect is a 1% decrease in flow per 10°F (5.6°C) rise in the difference between the oil injection and air inlet temperatures. Since the injection oil temperature is held constant by the thermostat in cold weather, this means the flow decreases about 1% for every 10°F (5.6°C) drop in ambient temperature.

Water Condensation

All air contains moisture, the amount being influenced by pressure, temperature, and proximity to oceans, lakes, and rivers. The water content of saturated air (100% relative humidity) is given by

$$W_{sat} = 0.622 \frac{P_{sat}}{P - P_{sat}} \tag{4.11.4}$$

where W_{sat}, is the humidity ratio, in lb_m water vapor/lb_m dry air; P_{sat}, the saturation pressure of water vapor at the temperature of the air; and P, the absolute pressure of the air–water vapor mixture. P_{sat} can be obtained from steam tables. As Equation 4.11.4 indicates, the water-holding capacity of air decreases if the air is compressed, unless P_{sat} is raised by increasing the temperature. The dew point temperature is the temperature at which W_{sat} is equal to the specific humidity of the ambient air. For example, ambient air at 14.7 psia (101 kPa), 80°F (26.7°C), and 60% relative humidity has a saturation pressure of 0.51 psia (3.52 kPa) and a vapor pressure of $0.60 \times 0.51 = 0.31$ psia (2.14 kPa). The humidity ratio is $W = 0.622 \times 0.31/(14.7 - 0.31) = 0.013$ lb_m water/lb_m dry air. If the air is compressed to 200 psig (1480 kPa) and then cooled to 100 °F (37.8°C), $P_{sat} = 0.95$ psia (6.55 kPa) and the water-holding capacity is $W_{sat} = 0.622 \times 0.95/(214.7 - 0.95) = 0.0028$ lb_m water/lb_m dry air. This is much lower than the entering humidity, so the amount of condensation is $0.013 - 0.0028 = 0.010$ lb_m water/lb_m dry air (0.01 kg/kg). At 1000 cfm (472 m^3/s) or 75 $lb_{m,\,air}$/min (34 kg_{air}/min), the condensation rate is $0.010 \times 75 = 0.75$ $lb_{m,\,water}$/min (0.34 kg_{water}/min) or 5 gal_{water}/h (18.9 L_{water}/h). If the compressed air temperature is 180°F (82.2°C), instead of 100°F (37.8°C), the saturation pressure is 7.51 psia (51.8 kPa) and $W_{sat} = 0.022$ lb_m water/lb_m dry air. At this temperature, no condensation takes place. Repeating this calculation for different values of the temperature, one finds that W_{sat} is equal to 0.013 lb_m water/lb_m dry air at 160°F (71.1°C). Thus, the dew point temperature is 160°F (71.1°C).

Condensation in oil-flooded screw compressors is particularly objectionable because the water will mix with the oil and reduce its lubricating qualities. Using a thermostat in the oil system to keep the "airend" discharge temperature above a minimum level prevents condensation. A minimum discharge temperature of 180°F (82°C) is usually adequate for pressures up to 350 psig (2500 kPa). Once the oil has been separated from the air, the air can be cooled in an aftercooler and the condensation removed in a water separator. Since the air is saturated when it leaves the aftercooler, and still above ambient temperature, further condensation will take place in the air line. For this reason, most plants employ an air dryer downstream of the compressor.

Reduction of Energy Use

Compressed air can account for 10%–20% of a manufacturing facility's electricity bill [4]. Energy efficiency for compressed air systems has reached a new height recently with the announcement in 1998 by the U.S. Department of Energy of the Compressed Air Challenge. This initiative is designed to build awareness among users of compressed air about the benefits and approaches for improving and maintaining compressed air system efficiency. Some basic methods for improving efficiency are given by Edwards [44] as follows:

1. Reduce unnecessary demand by eliminating leaks, by using condensate drain valves that open only when a predetermined amount of water has accumulated, by regulating all point-of-use operations at the lowest possible pressure, and by modifying and/or eliminating "blowoffs." Often the output of a low-pressure blower or fan can replace compressed air for "blowoff" operations.
2. Shut off the air supply to "off-line" production equipment. If one point-of-use requires air pressure at a much higher pressure than the rest of the system, consider using a pressure booster or using a separate dedicated system at that point.
3. Use storage tanks to supply air for intermittent events that require large amounts of air for a short time. Storage can eliminate the need for additional compressors to handle peak demands.
4. Reduce pressure drop by having adequate line sizes.
5. Select the compressor sizes and control their operation so that a compressor is either off, or running at rated load. No more than one compressor at a time should operate at part load.
6. Utilize the waste heat.

4.12 PUMPS AND FANS

Robert F. Boehm

Introduction

Pumps are devices that impart a pressure increase to a liquid. Fans are used to increase the velocity of a gas, but this is also accomplished through an increase in pressure. The pressure rise found in pumps can vary tremendously, and this is a very important design parameter along with the liquid flow rate. This pressure rise can range from simply increasing the elevation of the liquid to increasing the pressure hundreds of atmospheres. Fan applications, on the other hand, generally deal with small pressure increases. In spite of this seemingly significant distinction between pumps and fans, there are many similarities in the fundamentals of certain types of these machines as well as with their application and theory of operation. The final section of this chapter discusses vacuum pumps in a very brief fashion. Some of these devices are very similar to conventional pumps discussed earlier, and some are considerably different. This portion of the chapter is very much an overview of the topic.

The appropriate use of pumps and fans depends upon the proper choice of device and the proper design and installation for the application. A check of sources of commercial equipment shows that many varieties of pumps and fans exist. Each of these had special characteristics that must be appreciated for achieving proper function. Preliminary design criteria for choosing between different types are given by Boehm (1987). An abbreviated version of this is given in Table 4.12.1 for pumps.

As is to be expected, the wise applications of pumps and fans require knowledge of fluid flow fundamentals. Unless the fluid mechanics of a particular application are understood, the design could be less effective than is desirable. Some ideas from fluid mechanics that are especially relevant to pump and fan operation are reviewed.

Pumps

Raising of water from wells and cisterns is the earliest form of pumping (a very detailed history of early applications is given by Ewbank, 1842). Current applications are much broader, and these find a wide variety of machines in use. Modern pumps function on one of two principles. By far, the majority of pump installations are of the *velocity head* type. In these devices, the pressure rise is achieved by giving the fluid a movement. At the exit of the machine, this movement is translated into a pressure increase by slowing the fluid velocity. The other major type of pump is called *positive displacement*. These devices are designed to increase the pressure of the liquid while essentially trying to compress the volume. A categorization of pump types has been given by Krutzsch and Cooper (2008), and an adaptation of this is shown below.

I. Velocity head
   A. Centrifugal
      1. Axial flow (single or multistage)
      2. Radial flow (single or double suction)
      3. Mixed flow (single or double suction)
      4. Peripheral (single or multistage)

   B. Special effect
      1. Gas lift
      2. Jet
      3. Hydraulic ram
      4. Electromagnetic

TABLE 4.12.1
Data for the Preliminary Selection of Pumps

	Axial Flow	Centrif. Radial	Turbine (Regen)	External Gear	Screw	Sliding Vane	Piston	Diaphr.	Jet
Max P (bars)	350	350	50	350	350	350	1000	350	350
Min T (°C)	–240	–240	–30	–30	–30	–30	–30	–30	–240
Max T (°C)	500	500	250	400	370	270	370	270	500
ΔP/stage (bar)	2	20	35	200	20	150	1500	70	1
Max flow (m^3/s)	5	10	1	0.1	0.1	0.1	0.03	0.006	1
Max viscosity (Pa·s)		0.2	0.1	400	1000	100	400	100	
Efficiency (%)	50–85	50–85	20–40	40–85	40–70	40–85	60–90	40–70	5–20
Relative purchase cost	Low	Low	Mod	Mod	High	Mod	High	Mod	Low

II. Positive displacement
  A. Reciprocating
    1. Piston, plunger
      a. Direct acting (simplex or duplex)
      b. Power (single or double acting, simplex, duplex, triplex, multiplex)
    2. Diaphragm (mechanically or fluid driven, simplex or multiplex)

  B. Rotary
    1. Single rotor (vane, piston, screw, flexible member, peristaltic)
    2. Multiple rotor (gear, lobe, screw, circumferential piston)

Many factors impact the selection of a pump for a particular application, including the flows anticipated (maximum, minimum, and design, and whether they are continuous or variable), the pressures required at these flows, the type of fluids handled, as well as many other factors. A variety of pump types are available to the system designer. Several of these are compared in Table 4.12.1, and the original reference makes several more comparisons.

In the next two sections, two of the more common categories of pumps are described: centrifugal and positive displacement. There are several subcategories under each of these types, but these will not be delineated in the information given here. References are included that should allow the latter type of information to be found.

Centrifugal and Other Velocity Head Pumps

Centrifugal pumps are used in more industrial applications than any other kind of pump. This is primarily because these pumps offer low initial and upkeep costs. Traditionally, pumps of this type have been limited to low-pressure-head applications, but modern pump designs have overcome this problem unless very high pressures are required. Some of the other good characteristics of these types of devices include smooth (nonpulsating) flow and the ability to tolerate nonflow conditions.

A representative set of typical kind of variations for pumps of this type is shown in Figure 4.12.1. This information can be used for proper pump application.

The most important parts of the centrifugal pump are the *impeller* and *volute*. An impeller can take on many forms, ranging from essentially a spinning disk to designs with elaborate vanes.

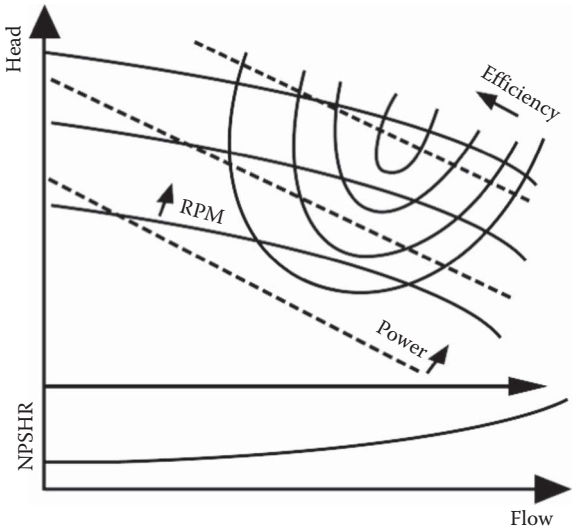

FIGURE 4.12.1 Many pump operating parameters are usually available from the pump manufacturer. An example of typical centrifugal pump parameter variations is shown in this figure.

The latter is usual. Impeller design tends to be somewhat unique to each manufacturer, as well as finding a variety of designs for a variety of applications. This device imparts a radial velocity to the fluid that has entered the pump perpendicular to the impeller. The volute (there may be one or more) performs the function of slowing the fluid and increasing the pressure. A good discussion of centrifugal pumps has been given by Lobanoff and Ross (1992) and in the ASHRAE Handbook (2012).

Very important factors in the specification of a centrifugal pump are the *casing orientation* and *type*. For example, the pump can be oriented vertically or horizontally. Horizontal mounting is most common. Vertical pumps usually offer benefits related to ease of priming and reduction in required net positive suction head (see discussion below). This type also requires less floor space. Submersible and immersible pumps are always of the vertical type. Another factor in the design is the way the casing is split, and this has implications about ease of manufacture and repair. Casings that are split perpendicular to the shaft are called *radially split*, while those split parallel to the shaft axis are denoted as *axially split*. The latter can be *horizontally split* or *vertically split*. The number of *stages* in the pump greatly affects the pump-output characteristics. Several stages can be incorporated into the same casing, with an associated increase in pump output. Multistage pumps are often used for applications with total developed head over 50 atm.

In general, centrifugal pumps become more efficient in larger sizes. This can be seen in the experimental data compiled by Rishel (2000). See Figure 4.12.2.

Whether or not a pump is self-priming can be important. If a centrifugal pump is filled with air when it is turned on, the initiation of pumping action may not be sufficient to bring the fluid into the pump. Pumps can be specified with features that can minimize priming problems.

There are other types of velocity head pumps. *Jet pumps* increase pressure by imparting momentum from a high-velocity liquid stream to a low-velocity or stagnant body of liquid. The resulting flow then goes through a diffuser to achieve an overall pressure increase. *Gas lifts* accomplish a pumping action by a drag on gas bubbles that rise through a liquid.

Positive-Displacement Pumps

Positive-displacement pumps demonstrate high discharge pressures and low flow rates. Usually, this is accomplished by some type of pulsating device. A piston pump is a classic example of

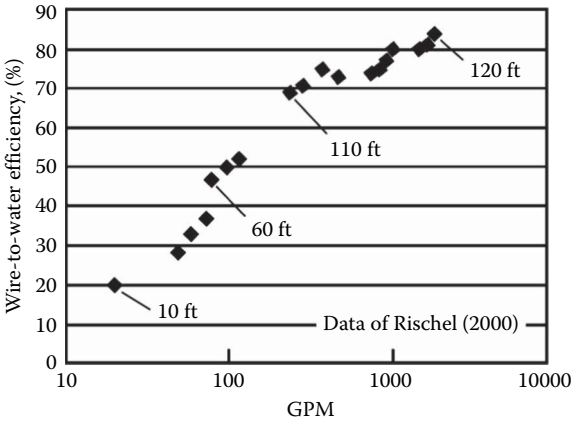

FIGURE 4.12.2 "Wire-to-water" efficiencies for centrifugal pumps shown are based upon the data of Rishel (2000). The head varies throughout the data within the ranges shown.

positive-displacement machines. Rotary pumps are one type of positive-displacement device that do not impart pulsations to the existing flow (a full description of these types of pumps is given by Turton, 1994). Several techniques are available for dealing with pulsating flows, including use of double-acting pumps (usually of the reciprocating type) and installation of pulsation dampeners.

Positive-displacement pumps usually require special seals to contain the fluid. Costs are higher both initially and for maintenance compared with most pumps that operate on the velocity head basis. Positive-displacement pumps demonstrate an efficiency that is nearly independent of flow rate, in contrast to the velocity head type.

Reciprocating pumps offer very high efficiencies, reaching 90% in larger sizes. These types of pumps are more appropriate for pumping abrasive liquids (e.g., slurries) than are centrifugal pumps.

A characteristic of positive displacement pumps that may be valuable is that the output flow is proportional to pump speed. This allows this type of pump to be used for metering applications. Also a positive aspect of these pumps is that they are self-priming, except at initial start-up.

Very high head pressures (often damaging to the pump) can be developed in positive-displacement pumps if the downstream flow is blocked. For this reason, a pressure-relief-valve bypass must always be used on the high-pressure side of positive-displacement pumps.

Pump/Flow Considerations

Performance characteristics of the pump must be considered in system design. Simple diagrams of pumping systems are shown in Figure 4.12.3. First, consider the left-hand figure. This represents a flow circuit, and the pressure drops related to the piping, fittings, valves, and any other flow devices found in the circuit must be estimated using the laws of fluid mechanics. Usually, these resistances (pressure drops) are found to vary approximately with the square of the liquid flow rate. Typical characteristics are shown in Figure 4.12.4. Most velocity head pumps demonstrate a flow vs. pressure rise variation that is a positive value at zero flow and decreases to zero at some larger flow. Positive-displacement pumps, as shown on the right-hand side of Figure 4.12.4, are an exception to this in that these devices usually cannot tolerate a zero flow. An important aspect to note is that a closed system can presumably be pressurized. A contrasting situation and its implications are discussed below.

It is important to maintain the substance inside a pump as a liquid. If conditions exist that convert the flow to a vapor, serious shortcomings in performance can be exhibited that could cause damage to the pump. At the minimum the pump flow will decrease, possibly in a substantial way.

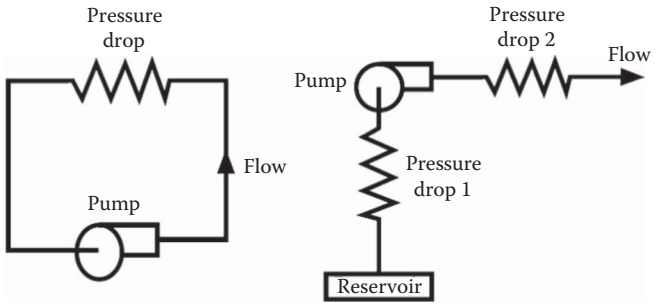

FIGURE 4.12.3 Typical pump applications, either in circuits (see left-hand side above) or once-through systems (right-hand side), can be represented with the frictional drops as shown as resistances. The latter are determined by fluid mechanics analysis.

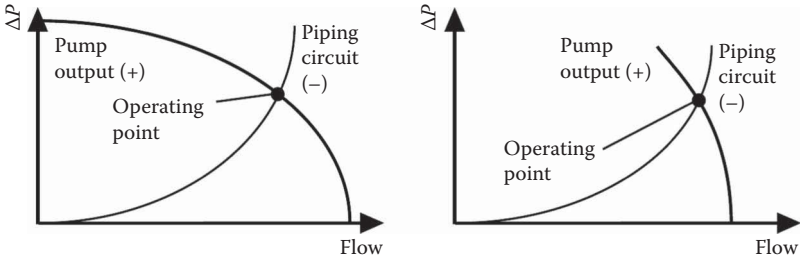

FIGURE 4.12.4 An overlay of the pump flow vs. head curve with the circuit piping characteristics gives the operating state of the circuit. A typical velocity head characteristic is shown on the left, while a positive-displacement pump curve is shown on the right.

The piping diagram shown on the right-hand side of Figure 4.12.3 is a once-through system, another frequently encountered installation. However, the leg of piping through "Pressure Drop 1" shown there can have some very important implications related to *net positive suction head*, often denoted as *NPSH*. In simple terms, NPSH indicates the difference between the local pressure and the thermodynamic saturation pressure at the fluid temperature. If NPSH=0, the liquid can vaporize, and this can result in a variety of outcomes from noisy pump operation to outright failure of components. This condition is called *cavitation*. Cavitation, if it occurs, will first take place at the lowest pressure point within the piping arrangement. Often this point is located at, or inside, the inlet to the pump. Most manufacturers specify how much NPSH is required for satisfactory operation of their pumps. Hence, the actual NPSH (denoted as *NPSHA*) experienced by the pump must be larger than the manufacturer's required NPSH (called *NPSHR*). If a design indicates insufficient NPSH, changes should be made in the system, possibly including alternative piping layout, including elevation and/or size, or use of a pump with smaller NPSH requirements.

The manufacturer should be consulted for a map of operational information for a given pump. A typical form has been shown in Figure 4.12.1. This information will allow the designer to select a pump that satisfied the circuit operational requirements while meeting the necessary NPSH and most-efficient operation criteria.

Several options are available to the designer for combining pumps in systems. Consider a comparison of the net effect between two identical pumps operating in series or operating the same two pumps in parallel. Examples of this are for pumps such as centrifugal units that have characteristics similar to those shown in Figure 4.12.1. It is clear that one way to achieve high pumping pressures with centrifugal pumps is to place a number of units in series. This is a related effect to what is essentially found in *multistage* designs. However, if higher flows are needed at the same pressure rise, similar pumps can be operated in parallel.

Fans

As noted earlier, fans are devices that cause air to move. This definition is broad and can include a flapping palm branch, but the discussion here deals only with devices that impart air movement due to *rotation of an impeller inside a fixed casing*. In spite of this limiting definition, a large variety of commercial designs are included.

Fans find application in many engineering systems. Along with the chillers and boilers, they are the heart of heating, ventilating, and air conditioning (HVAC) systems. When large physical dimensions of a unit are not a design concern (usually the case), centrifugal fans are favored over axial flow units for HVAC applications. Many types of fans are found in *power plants*. Very large fans are used to furnish air to the boiler, as well as to draw or force air through cooling towers and pollution-control equipment. *Electronic cooling* finds applications for small units. Even automobiles have several fans in them. Because of the great engineering importance of fans, several organizations publish rating and testing criteria (see, for example, ASME, 1990).

Generally, fans are classified according to how the air flows through the impeller. These flows may be *axial* (essentially a propeller in a duct), *radial* (conceptually much like the centrifugal pumps discussed earlier), *mixed*, and *cross*. While there are many other fan designations, all industrial units fit one of these classifications. Mixed-flow fans are so named because both axial and radial flows occur on the vanes. Casings for these devices are essentially like those for axial-flow machines, but the inlet has a radial-flow component. On cross-flow impellers, the gas traverses the blading twice.

Characteristics of fans are shown in Figure 4.12.5. Since velocities can be high in fans, often both the total and the static pressure increases are considered. While both are not shown in this figure, the curves have similar variations. Of course the total ΔP will be greater than the static value, the difference being the velocity head. This difference increases as the volume flow increases. At the zero flow (the shutoff point), the static and total pressure difference values are the same. Efficiency variation can show a sharp optimum value at the design point. For this reason, it is critical that fan designs be carefully tuned to the required conditions.

A variety of vane types are found on fans, and the types of these are also used for fan classification. Axial fans usually have vanes of airfoil shape or vanes of uniform thickness. Some vane types that might be found on a centrifugal (radial-flow) fan are shown in Figure 4.12.6.

One of the more important aspects that is an issue in choosing fans for a particular application is fan efficiency. Typical efficiency comparisons of the effect of blade type on a centrifugal fan are shown in Figure 4.12.7. Since velocities can be high, the value of aerodynamic design is clear. Weighing against this is primarily cost but there could be other factors.

An additional aspect that may be important in the choice of fans is noise generation. This may be most critical in HVAC applications. It is difficult to describe noise characteristics in brief terms

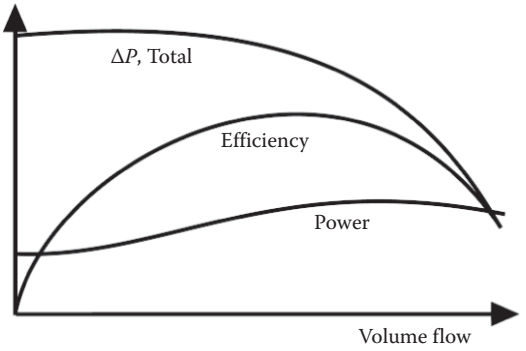

FIGURE 4.12.5 Shown are typical characteristics of a centrifugal fan. The drawbacks of operating away from the optimal conditions are obvious from the efficiency variation.

because of the frequency-dependent nature of these phenomena. However, a comparison of specific sound power level (usually denoted by K_w) shows backward-curved centrifugal fans with aerodynamic blades perform best among the designs. Details of noise characteristics are given elsewhere (ASHRAE, 2011). One point to note is that fan sound is usually at a minimum near the point of maximum fan efficiency.

While each type of fan has some specific qualities for certain applications (some comparisons are given in Table 4.12.2), most installations use centrifugal (radial-flow) fans. A primary exception is for very-high-flow, low-pressure-rise situations, where axial (propeller) fans are used.

Similarities exist between fans and pumps because the fluid density essentially does not vary through either type of machine. Of course, in pumps this is because a liquid can be assumed to be incompressible. In fans, a gas (typically air) is moved with little pressure change. As a result, the gas density can be taken to be constant. Since most fans operate near atmospheric pressure, the ideal gas assumptions can be used in determining gas properties.

Flow control in fan applications, where needed, is a very important design concern. Methods for accomplishing this involve use of dampers (either on the inlet or on the outlet of the fan), variable

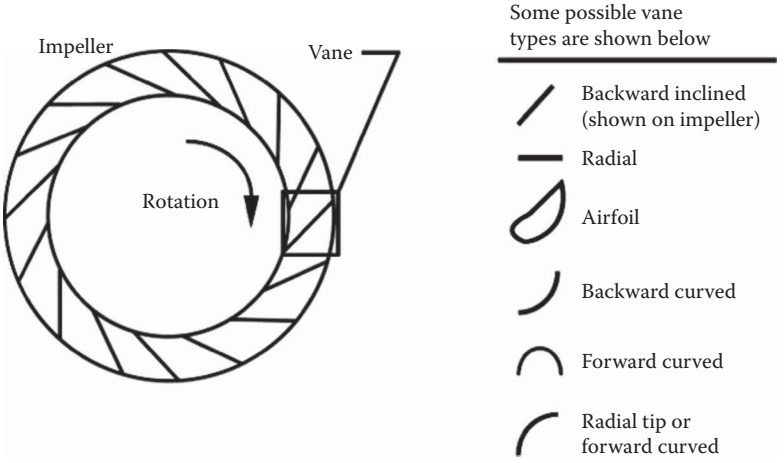

FIGURE 4.12.6 A variety of vane types that might be used on a centrifugal fan are shown.

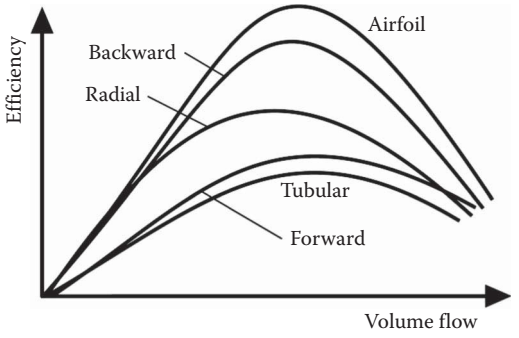

FIGURE 4.12.7 Efficiency variation vs. volume flow rate of centrifugal fans for a variety of vane types is shown.

TABLE 4.12.2
Characteristics of Various Fans

Type of Fan	Specific Speed Range (RPM)	Air Volume (CFM)	Static Pressure	Fan Efficiency	Manufacturing Cost	Size and Weight
Propeller	500,000–100,000	Large	Low	Low	Low	Small
Tubeaxial	300,000–60,000	Large	Low	Medium	Low	Small
VAF, one stage	130,000–50,000	Large	Medium	High	Medium	Small
VAF, two stages	90,000–35,000	Large	Medium	High	Medium	Medium
Mixed flow	80,000–10,000	Medium	Medium	Low	High	Medium
Wide FC	70,000–25,000	Large	High	Medium	Medium	Large
AF, BC, BI	70,000–20,000	Medium	Medium	High	Medium	Medium
Radial tip	65,000–25,000	Medium	Medium	Medium	Medium	Medium
Radial blades	25,000–10,000	Low	Medium	Low	Medium	Medium
Turbo blower	30,000–5,000	Small	High	Medium	Medium	Medium
Multistage turbo blower	8,000–1,000	Small	High	Low	High	Large

pitch vanes, or variable speed control. Dampers are the least expensive to install, and also the most inefficient in terms of energy use. Modern solid state controls for providing a variable frequency power to the drive motor is becoming the preferred control method, when a combination of initial and operating costs is considered.

Types of drive motors can be important to the design of a fan installation. Some guidelines for doing this are given here (Adapted from Bleier (1998) p. 16.2).

1. The most frequently used motors whenever a fan requires 1 hp or more are three-phase squirrel-cage types.
2. Sometimes adjustable-speed drives use three-phase wound rotor motors, but these can be expensive.
3. Single-phase, split-phase induction motors, with an auxiliary winding for starting function, are used for applications up to 1/2 hp. While these tend to be less efficient, they are about as good as can be applied for single-phase power. They require a high starting current.
4. For requirements up to 1/3 hp, single-phase, permanent-split-capacitor motors are used. A capacitor is used instead of the auxiliary winding noted in number 3 (above). A low starting current is realized but is associated with a lower efficiency. Many applications find these used in direct drive arrangements.
5. Up to ¾ hp, single-phase, capacitor-start-and-run, capacitor-run motors are used. Because of an auxiliary winding in series with a capacitor, they are able to furnish high starting torques.
6. For high-speed applications up to 1 hp like vacuum cleaners, single-phase universal motors are used. Although they can be used in direct drives, they have the disadvantage of slightly lower efficiencies and brushes that may need adjustment and replacement.

Drives are also important. A few suggestions Adapted from Bleier (1998, p. 16.2) are shown below.

1. Three-phase motors are used with belt drive for most large fans.
2. Single-phase motors with direct drive are used for most small fans.

3. Belt drive by electric motors or by engines is sometimes used for multistage turbo blowers.
4. Gear drives from electric motors running at very high speeds are used to drive single-stage turbo blowers.

Vacuum Pumps

While this is a topic that involves pumps and systems that are related to conventional pumps and fans, many aspects of the field are quite distinct from what is given earlier in this review. Only a limited amount of information will be listed here comparing the general kinds of pumps used in these systems. The reader who wishes more information can consult the many books on this topic including the one by Hablanian (1997). In these types of applications, various kinds of pumps might be applied for varying degrees of vacuum. Approximate vacuum ranges and relative costs of some of these pumps are shown in Figure 4.12.8.

Pumps for vacuum systems range from conventional pumps discussed earlier for "roughing" applications to very specialized pumps for achieving high vacuum. The general categories shown in Figure 4.12.8 will be discussed briefly in what follows. It should be noted, however, that many more categories of pumps can be defined than are given here.

Mechanical pumps are used to perform "roughing" (roughing is where relatively large flows of evacuated gases are found) processes. That is, they are used to remove the initial amount of gas from the region where a vacuum is desired. Any type of conventional compressor could be used to perform this duty. Compressor devices using pistons, rotational elements, etc., can be candidates to perform this function.

Moving to lower pressure applications, the Roots unit is an example of a *mechanical blower.* It was developed in second half of the 1800 by two Roots brothers. It consists of lobes and is generally for lower pressure roughing applications than conventional compressors.

Diffusion pumps are widely used devices in vacuum applications. This type of unit is a vapor jet pump (a name by which it is also known), and it is the most widely used approach in vacuum systems. It transports gas by momentum transfer as a result of a collision with a vapor stream. Typically, the vapor stream is an organic fluid or mercury. Several stages of compression (usually 3–5) are usually used.

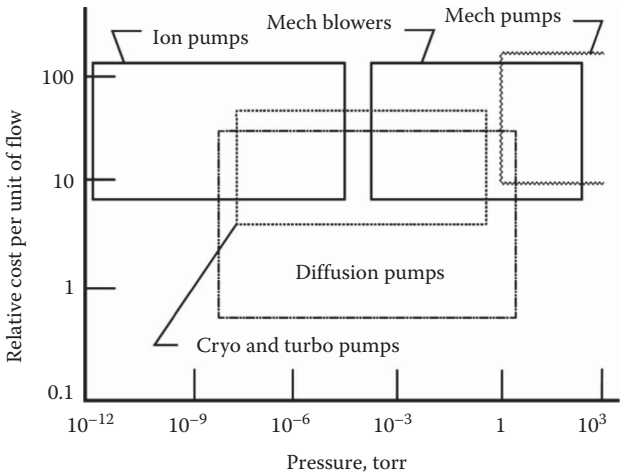

FIGURE 4.12.8 General categories of vacuum pumps are shown with approximate ranges of costs and application pressures. (Adapted from Hablanian, M.H., *High-Vacuum Technology, a Practical Guide*, 2nd ed., Marcel Dekker, New York, 1997.)

A device that acts like a molecular turbine is the basis of the operation of a *turbomolecular pump.* In simple terms, it can be viewed as the special adaptation of an axial flow compressor, as it compresses gas by a momentum transfer from a high-speed rotating element. Several stages of compression are used because the pressure increase per stage is small.

Lowering the temperature below that which will condense a gas is the technical basis of the *cryogenic pump*. These pumps include a very cold porous surface (not the whole pump) that will perform this action. Typically, helium is used as the refrigerant to cool the active surface. This type of pumping is very clean because no foreign fluid comes in contact with the pumped flow.

Several types of devices come under the general name of *ion pumps*. *Gettering pumps* are a form of these configurations where a source of unoxidized titanium (usually in film form) is in contact with the gas that is being pumped. Another approach is to generate ions in the gas being pumped, which will then be energetic and attracted to a surface.

DEFINING TERMS

Cavitation: Local liquid conditions allow vapor voids to form (boiling).

NPSH: Net positive suction head is the difference between the local absolute pressure of a liquid and the thermodynamic saturation pressure of the liquid based upon the temperature of the liquid. Applies to the inlet of a pump.

NPSHA: Actual net positive suction head is the NPSH at the given state of operation of a pump.

NPSHR: Required net positive suction head is the amount of NPSH required by a specific pump for a given application.

4.13 COOLING TOWERS

Anthony F. Mills

Introduction

In a wet cooling tower, water is evaporated into air with the objective of cooling the water stream. Both natural- and mechanical-draft towers are popular, and examples are shown in Figure 4.13.1. Large natural-draft cooling towers are used in power plants for cooling the water supply to the condenser. Smaller mechanical-draft towers are preferred for oil refineries and other process industries, as well as for central air-conditioning systems and refrigeration plant. Figure 4.13.1a shows a natural draft *counterflow* unit in which the water flows as thin films down over a suitable packing, and air flows upward. In a natural-draft tower, the air flows upward due to the buoyancy of the warm, moist air leaving the top of the packing. In a mechanical-draft tower, the flow is forced or induced by a fan. Since the air inlet temperature is usually lower than the water inlet temperature, the water is cooled both by evaporation and by sensible heat loss. For usual operating conditions, the evaporative heat loss is considerably larger than the sensible heat loss. Figure 4.13.1b shows a mechanical draft cross-flow unit. Figure 4.13.2 shows a natural-draft cross-flow tower for a power plant.

Packing Thermal Performance

Counterflow Units

Merkel's method (Merkel, 1925) for calculating the number of transfer units required to cool the water stream, for specified inlet and outlet water temperatures and inlet air condition is (Mills, 1995)

$$N_{\text{tu}} = \frac{g_m S}{\dot{m}_L} = \int_{h_{l,\text{in}}}^{h_{l,\text{out}}} \frac{\mathrm{d}h_L}{h_s - h_G} \tag{4.13.1}$$

$$h_G = h_{G,\text{in}} + (\dot{m}_L / \dot{m}_G)(h_L - h_{L,\text{out}}) \tag{4.13.2}$$

$$h_s(P, T_s) = h_s(P, T_L) \tag{4.13.3}$$

It is imperative that the usual enthalpy datum states be used, namely, zero enthalpy for dry air and liquid water at 0°C. Table 4.13.1 gives enthalpy data for 1 atm pressure. The important assumptions required to obtain this result include

1. A Lewis number of unity;
2. Low mass transfer rate theory is valid;
3. The liquid-side heat transfer resistance is negligible, that is, $T_s \simeq T_L$;
4. The amount of water evaporated is small compared with the water and air flow rates.

The method is accurate up to temperatures of about 60°C; comparisons with more exact results are usually within 3%–5%, and seldom show errors greater than 10%. Notice that the method does not give the outlet state of the air; however, in situations encountered in practice, the outlet air can be assumed to be saturated for the purposes of calculating its density. It is possible to extend Merkel's method to include a finite liquid-side heat transfer resistance, but such refinement is seldom warranted. For typical operating conditions, the bulk liquid temperature is seldom more than 0.3 K above the interface temperature.

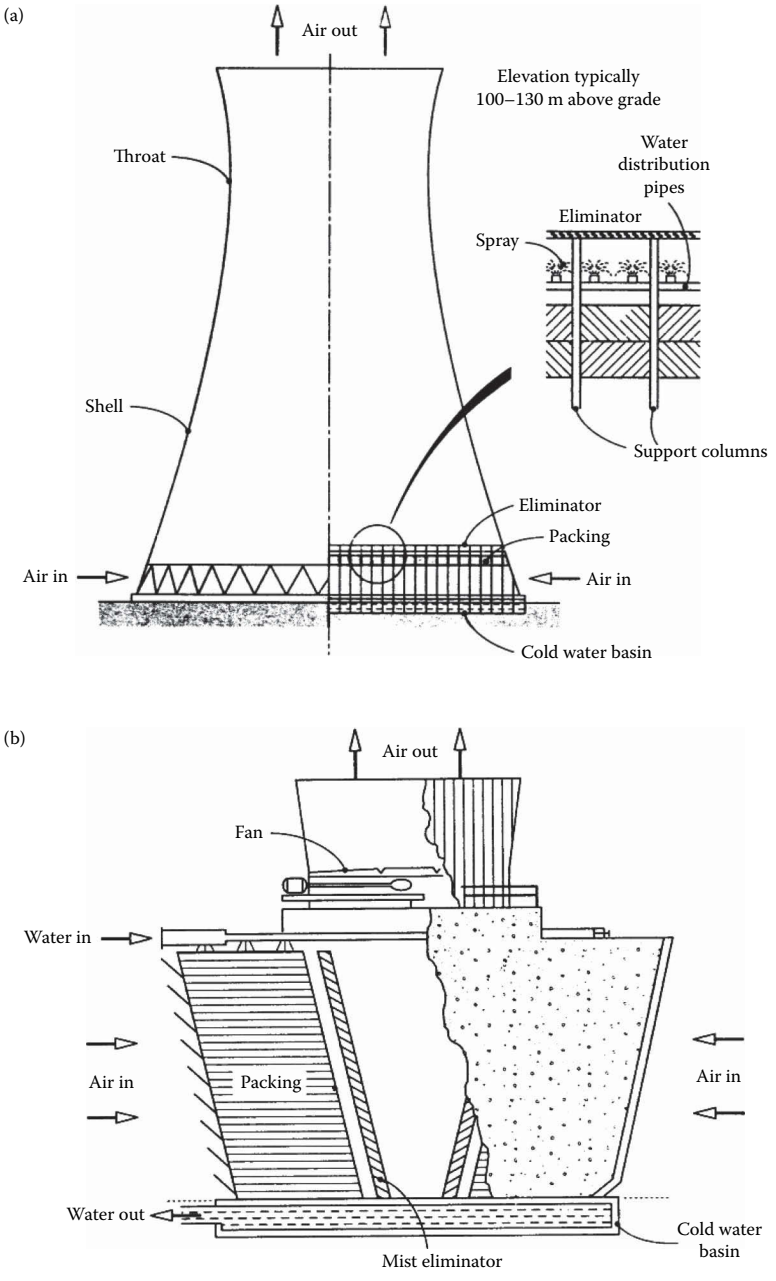

FIGURE 4.13.1 (a) A natural-draft counterflow cooling tower for a power plant. (b) A cross-flow cooling tower for an air-conditioning system.

Cross-Flow Units

Figure 4.13.3 shows a schematic of a cross-flow packing. If we assume that both the liquid and gas streams are unidirectional, and that there is no mixing in either stream, then use of Merkel's assumptions leads to the following pair of differential equations (Mills, 1995):

$$\frac{\partial h_G}{\partial x} = \frac{g_m a}{G}\left(h_s - h_G\right) \tag{4.13.4}$$

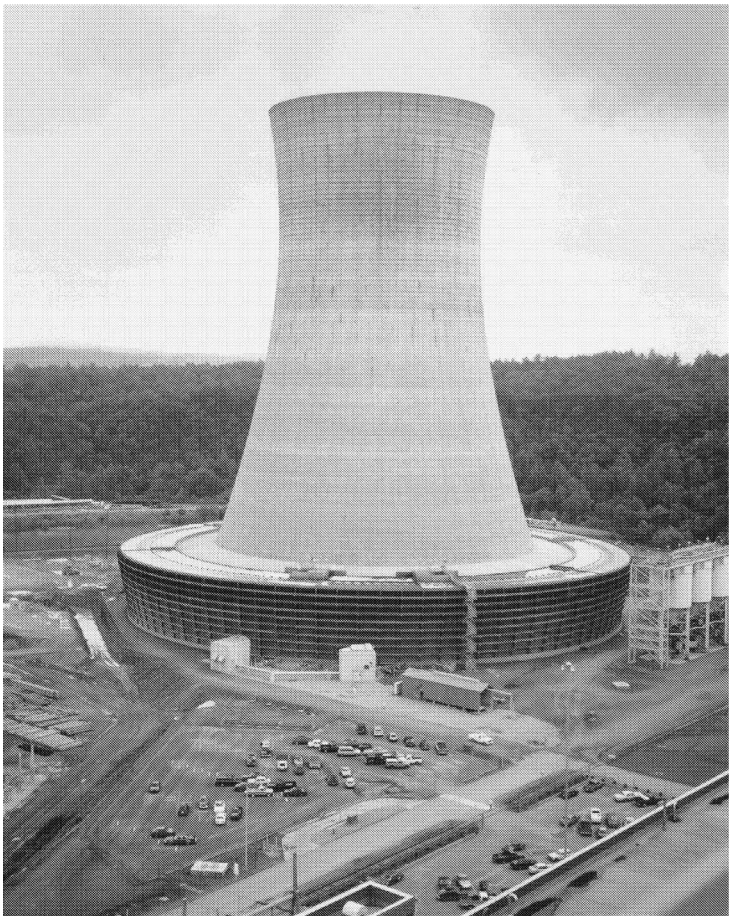

FIGURE 4.13.2 A natural-draft cross-flow cooling tower for a power plant.

$$\frac{\partial h_L}{\partial y} = -\frac{g_m a}{L}\left(h_s - h_G\right) \tag{4.13.5}$$

Also $h_s = h_s(h_L)$ for a negligible liquid-side heat transfer resistance and the required boundary conditions are the inlet enthalpies of both streams. Equations 4.13.4 and 4.13.5 are solved numerically and the solution used to evaluate the average enthalpy of the outlet liquid,

$$\overline{h}_{L,\text{out}} = \frac{1}{X}\int_0^X h_{L,\text{out}}\,\mathrm{d}x \tag{4.13.6}$$

Substituting in an exchanger energy balance on the liquid stream gives the heat transfer as

$$q = \dot{m}_L\left(h_{L,\text{in}} - h_{L,\text{out}}\right) \tag{4.13.7}$$

Sample Calculation

Consider a counterflow unit that is required to cool water from 40°C to 26°C when the inlet air is at 10°C, 1 atm, and saturated. We will calculate the number of transfer units required for balanced flow, that is, $\dot{m}_G/\dot{m}_L = 1$. Equation 4.13.1 is to be integrated numerically, with h_G obtained

[a] The enthalpies of dry air and liquid water are set equal to zero at a datum temperature of 0°C.

[b] The enthalpy of an unsaturated water vapor–air mixture can be calculated as $h = h_{\text{dry air}} + (m_1/m_{1,\text{sat}})(h_{\text{sat}} - h_{\text{dry air}})$.

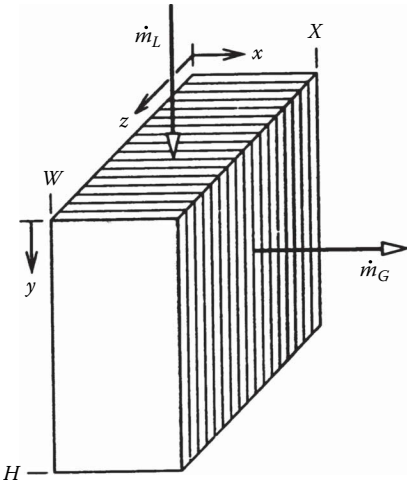

FIGURE 4.13.3 Schematic of a cross-flow cooling tower packing showing the coordinate system.

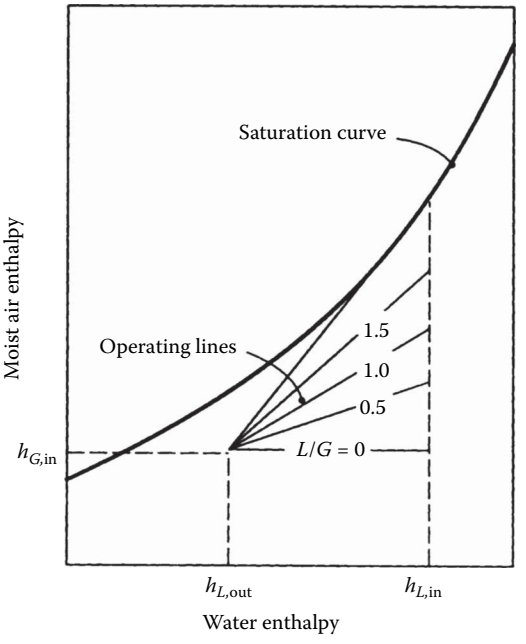

FIGURE 4.13.4 Counterflow cooling tower operating lines for various water-to-air flow-rate ratios shown on an enthalpy chart.

from Equation 4.13.2. The required thermodynamic properties can be obtained from Table 4.13.1. Using Table 4.13.1, $h_{G,\text{in}} = h_{\text{sat}}$ (10°C) = 29.15 kJ/kg, $h_{L,\text{out}} = h_L$(26°C) = 109.07 kJ/kg. Substituting in Equation (4.13.2),

$$h_G = 29.15 + (h_L - 109.07)$$

Choosing 2°C intervals for convenient numerical integration, the table on page 4–865 is constructed, with h_L and $h_s = h_s(T_L)$ also obtained from Table 4.13.1.

Using the trapezoidal rule,

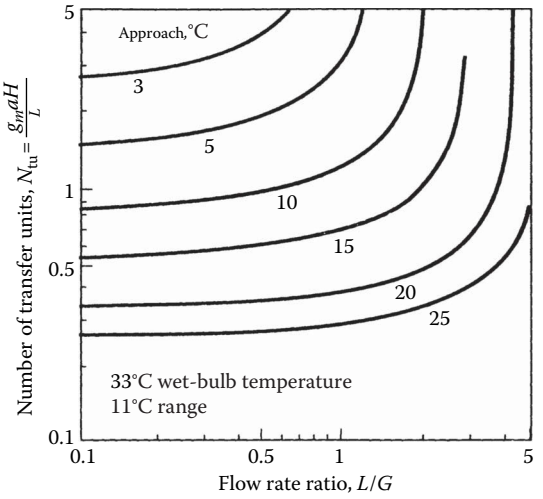

FIGURE 4.13.5 Example of cooling demand curves for a specified wet-bulb temperature and range: N_{tu} vs. flow rate ratio for a fixed approach.

$$\int_{h_{L,\text{out}}}^{h_{L,\text{in}}} \frac{dh_L}{h_s - h_G} = \frac{8.36}{2}[0.02001 + 2(0.01986 + 0.01942 + 0.01871 + 0.01776 + 0.01662 + 0.01536) + 0.01404] = 1.043$$

T_L (°C)	h_L (kJ/kg)	h_G (kJ/kg)	h_s (kJ/kg)	$h_s - h_s$ (kJ/kg)	$\frac{1}{h_s - h_G}$
26	109.07	29.15	79.12	49.97	0.02001
28	117.43	37.51	87.86	50.35	0.01986
30	125.79	45.87	97.36	51.49	0.01942
32	134.15	54.23	107.67	53.44	0.01871
34	142.50	62.58	118.89	56.31	0.01776
36	150.86	70.94	131.10	60.16	0.01662
38	159.22	79.30	144.39	65.09	0.01536
40	167.58	87.66	158.86	71.20	0.01404

From Equation 4.13.1, $N_{tu} = 1.043$. Also, by using Table 4.13.1, $T_{G,\text{out}} = 27.9°$ for saturated outlet air.

Thermal-Hydraulic Design of Cooling Towers

The thermal-hydraulic design of a mechanical-draft cooling tower is relatively straightforward. The flow rate ratio $\dot{m}_L/\dot{m}_G$ can be specified and varied parametrically to obtain an optimal design, for which the size and cost of the packing is balanced against fan power requirements and operating cost. Data are required for mass transfer conductances and friction for candidate packings. Tables 4.13.2a and b give correlations for a selection of packings. In Table 4.13.2b, the mass transfer conductance is correlated as $g_m a/L$, where a is the transfer area per unit volume and $L = \dot{m}_L/A_{fr}$ is the superficial mass velocity of the water flow (also called the *water loading* on the packing). Similarly, we define $G = \dot{m}_G/A_{fr}$. Typical water loadings are 1.8 to 2.7 kg/m^{2}s, and superficial air velocities fall

TABLE 4.13.2A
Packings for Counterflow and Cross-Flow Cooling Towers: Designations and Descriptions

Counterflow Packings

1. Flat asbestos sheets, pitch 4.45 cm
2. Flat asbestos sheets, pitch 3.81 cm
3. Flat asbestos sheets, pitch 3.18 cm
4. Flat asbestos sheets, pitch 2.54 cm
5. 60° angle corrugated plastic, Munters M12060, pitch 1.17 in.
6. 60° angle corrugated plastic, Munters M19060, pitch 1.8 in.
7. Vertical corrugated plastic, American Tower Plastics Coolfilm, pitch 1.63 in.
8. Horizontal plastic screen, American Tower Plastics Cooldrop, pitch 8 in. 2 in. grid
9. Horizontal plastic grid, Ecodyne shape 10, pitch 12 in.
10. Angled corrugated plastic, Marley MC67, pitch 1.88 in.
11. Dimpled sheets, Toschi Asbestos-Free Cement, pitch 0.72 in.
12. Vertical plastic honeycomb, Brentwood Industries Accu-Pack, pitch 1.75 in.

Cross-Flow Packings

1. Doron V-bar, 4×8 in. spacing
2. Doron V-bar, 8×8 in. spacing
3. Ecodyne T-bar, 4×8 in. spacing
4. Ecodyne T-bar, 8×8 in. spacing
5. Wood lath, parallel to air flow, 4×4 in. spacing
6. Wood lath, perpendicular to air flow, 4×4 in. spacing
7. Marley α-bar, parallel to air flow, 16×4 in. spacing
8. Marley ladder, parallel to air flow, 8×2 in. spacing

in the range 1.5 to 4 m/s. No attempt is made to correlate g_m and a separately. The number of transfer units of a packing of height H is then

$$N_{tu} = \frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} \tag{4.13.8}$$

The correlations are in terms of dimensionless mass velocities L^+ and G^+, and a *hot water correction* T^+_{HW}. The hot water correction accounts for a number of factors, such as errors associated with Merkel's method, deviations from low mass transfer rate theory at higher values of T_s, and fluid property dependence on temperature. Frictional resistance to air flow through the packings is correlated as a *loss coefficient* $N = \Delta P/(\rho V^2/2)$ per unit height or depth of packing, as a function of L^+ and G^+. The velocity V is superficial gas velocity. No hot water correction is required.

In a natural-draft tower, the thermal and hydraulic performance of the tower are coupled, and the flow rate ratio $\dot{m}_L/\dot{m}_G$ cannot be specified *a priori*. The buoyancy force producing the air flow depends on the state of the air leaving the packing which in turn depends on $\dot{m}_L/\dot{m}_G$ and the inlet air and water states. An iterative solution is required to find the operating point of the tower. The buoyancy force available to overcome the shell and packing pressure drops is

$$\Delta P^B = g(\rho_a - \rho_{G,out})H \tag{4.13.9}$$

where ρ_a is the ambient air density and H is usually taken as the distance from the bottom of the packing to the top of the shell. The various pressure drops are conveniently expressed as

TABLE 4.13.2B
Mass Transfer and Pressure Drop Correlations for Cooling Towers

Packing Number	C_1 (m^{-1})	n_1	n_2	n_3	C_2 (m^{-1})	n_4	n_5

Ed., Hemisphere, New York, 1990. With permission.

Note: N is the loss coefficient defined by Equation 4.9.10, with velocity based on cross-sectional area for air flow underneath the packing in items 1 through 4.

0.12 times the base diameter to facilitate air flow into the tower. In practice, the air flow distribution in natural-draft towers is not very uniform. However, the assumption of uniform air and water flows in our model of counterflow packing is adequate for most design purposes.

Cost-optimal design of cooling towers requires consideration of the complete power or refrigeration system. For refrigeration, the economics are determined mainly by the operating cost of the chiller (Kintner-Meyer and Emery, 1995).

Cooling Tower Behavior

There are a number of computer programs available that use variations of Merkel's method to calculate the cooling tower performance, for example, TEFRI (Bourillot, 1983), VERA2D-84 (Majumdar et al., 1985), CTOWER (Mills, 1995). These programs can be used to perform parametric studies to obtain the response of cooling towers to environmental, duty, and design changes. However, before using such programs, some thought should be given to the important characteristics of cooling tower behavior. For this purpose, it is useful to consider a graphical representation of Merkel's theory for a counterflow tower. Figure 4.13.4 shows a chart with moist air enthalpy plotted vs. water enthalpy (or, equivalently, water temperature) at 1 atm pressure. The *saturation curve* $h_s(T_s)$ is the enthalpy of saturated air. The *operating lines* $h_G(h_L)$ are given by Equation 4.13.2 and relate the air enthalpy to the water enthalpy at each location in the packing. The slope of an operating line is *L/G*. Since the assumption $T_s=T_L$ is made in Merkel's method, vertical lines on the chart connect h_s and h_G at each location in the packing. The driving force for enthalpy transfer, $(h_s - h_G)$, is the vertical distance between the saturation curve and the operating line. The integral in Equation (4.13.1) averages the reciprocal of this distance. By using this chart, a number of observations about cooling tower behavior can be made.

1. Figure 4.13.4 shows the effect of L/G for fixed water inlet and outlet temperatures, and fixed inlet air temperature and humidity. If we imagine L to be fixed as well, we see that as G decreases, the driving forces decrease, and so a larger N_{tu} is required.
2. The minimum N_{tu} required corresponds to $L/G=0$, that is, an infinite air flow rate, for which the operating line is horizontal.
3. Due to the curvature of the operating line, it is possible for the operating line to be tangent to the saturation curve. The indicated N_{tu} is then infinite, which tells us that the air flow rate must be increased in order to achieve the desired water cooling range.
4. For a mechanical-draft tower, the optimal value of L/G lies between the two limits described in items 2 and 3 above. If L/G is large, the required height of packing is large, and the capital cost will be excessive. If L/G is small, the fan power will be excessive (since fan power is proportional to air volume flow rate times pressure drop).

Range and Approach

Cooling tower designers and utility engineers have traditionally used two temperature differences to characterize cooling tower operation. The *range* is the difference between the water inlet and outlet temperatures (also called simply the hot and cold water temperatures). The *approach* is the difference between the outlet water temperature and the wet-bulb temperature of the entering (ambient) air. The approach characterizes cooling tower performance; for a given inlet condition, a larger packing will produce a smaller approach to the ambient wet-bulb temperature, and hence a lower water outlet temperature. The water cannot be cooled below the ambient wet-bulb temperature. The approach concept is useful because the ambient dry-bulb temperature has little effect on performance at usual operating conditions (for a specified wet-bulb temperature).

Cooling Demand Curves

Electrical utility engineers have found it convenient to use charts of *cooling demand curves* to evaluate packing specifications. Figure 4.13.5 is an example of such a chart, on which the required N_{tu}, for a given inlet air wet-bulb temperature and range, is plotted vs. L/G with the approach as a parameter. Such a plot is possible since the inlet air dry-bulb temperature has only a small effect under usual operating conditions. Now, if it is possible to correlate the mass transfer conductance as

$$\frac{g_m a}{L} = C\left(\frac{L}{G}\right)^{-n} \tag{4.13.11}$$

the N_{tu} of a packing of height H is

$$\frac{g_m S}{\dot{m}_L} = \frac{g_m a H}{L} = C\left(\frac{L}{G}\right)^{-n} H \tag{4.13.12}$$

Equation 4.13.12 can also be plotted on the chart to give the *packing capability line*. For a required approach, the *operating point* of the tower is the intersection of the cooling demand curve and packing capability line. Charts of cooling demand curves are available (Cooling Tower Institute, 1967; Kelly, 1976). Correlations of the form of Equation 4.13.11 do not necessarily fit experimental data well. A dependence $g_m a \propto L^{1-n} G^n$ is implied and, in the past, experimental data were often forced to fit such a relation. If the $g_m a$ correlation does not have the form of Equation 4.13.11, the N_{tu} cannot be plotted as a line on a cooling demand chart.

With the almost universal use of computers and the availability of suitable computer programs, one can expect less use of cooling demand charts in the future. The major sources of error in the predictions made by these programs are related to nonuniform air and water flow, and the

correlations of packing mass transfer and pressure drop experimental data. The experimental data are obtained in small-scale test rigs, in which it is impossible to simulate many features of full-size towers—for example, nonuniform flow due to entrance configuration, nonuniform wetting of the packing, and, in the case of counterflow towers, the effect of spray above the packing and rain below the packing. Furthermore, since testing of packings in small-scale test rigs is itself not easy, considerable scatter is seen in such test data. Correlations of the data typically have root mean square errors of 10%–20%.

Legionnaires' Disease

Legionnaires' disease is a form of pneumonia caused by a strain of legionnella bacteria (sero group I). Smokers and sick people are particularly vulnerable to the disease. Major outbreaks have occurred at conventions and in hospitals, for which the source of the bacteria has been traced to cooling towers of air-conditioning systems. The bacteria require nutrients such as algae or dead bacteria in sludge, and thrive if iron oxides are present. However, properly designed, installed, and maintained cooling towers have never been implicated in an outbreak of the disease. Key requirements to be met include the following:

1. Mist (drift) eliminators should be effective.
2. The tower should be located so as to minimize the possibility of mist entering a ventilation system.
3. Corrosion in the tower and water lines should be minimized by use of glass fiber, stainless steel, and coated steel.
4. The design should facilitate inspection and cleaning, to allow early detection and remedy of sludge buildup.
5. Water treatment and filtration procedures should meet recommended standards.

4.14 PINCH TECHNOLOGY

Santanu Bandyopadhyay and Shankar Narasimhan

Introduction

The human appetite for energy has been growing rapidly, especially since the industrial revolution, and it is now used as one of the indicators of a country's progress and development. According to a UNIDO working paper in 2010 (Upadhyaya, 2010), more than 80% of the world's energy consumption is met by fossil fuels. Out of this, manufacturing accounts for a quarter of the total energy consumption. The increase in energy consumption has concomitantly led to a growing concern about the impact that the burning of fossil fuels has on the environment. While the world continues to seek ways and means of reducing our dependence on fossils fuels, by utilizing renewable energy sources, it is also important to use advanced technological methods to improve the energy efficiency of industrial processes. Pinch technology is a systematic approach that was developed in the mid-1980s to analyze the energy utilization in process industries, and to design integrated energy sub-system of a process which achieves the optimal trade-off between the cost of energy used and the capital investment made (Linnhoff et al., 1982; Klemeš, 2013).

In any design, there exists a trade-off between the capital investment and operating cost. For an energy sub-system, the capital cost is mainly dependent on the number and size of heat transfer equipment (boilers, furnaces, heat exchangers), while the operating cost is primarily a function of the consumption rate of utilities such as fuel, cooling water, refrigerants, steam, etc. Pinch technology effectively captures the trade-off between capital and operating costs, and can be used for the optimal design of the energy sub-system of a process. The method is now widely used to design the heat and power sub-system of processes such as refineries, petrochemical plants, pulp and paper plants, thermal power plants, etc. It is reported that energy savings of up to 30% have been achieved using this technology. Although, pinch technology started by considering heat integration in processes it has now been extended to minimize usage of other resources such as water and to minimize emissions, and has also been rechristened as *pinch analysis* (Linnhoff, 1993). In this chapter, the basic concepts used in pinch technology are introduced and explained. The use of these concepts for the optimum design of a heat exchanger network is also described in detail. The integration of the heat exchanger network with other energy consumers/producers such as distillation columns, pumps, compressors, and turbines is also discussed. There are several books, book chapters, and review articles that the reader can refer to get a more comprehensive understanding of pinch technology. Shenoy (1995) and Kemp (2007) have written books devoted entirely to pinch technology, while the book by Smith (2005) contains several chapters related to pinch technology. A bibliography compiled by Furman and Sahinidis (2002) contains references to more than 400 research papers on HEN synthesis based on pinch technology and mathematical programming methods. Early applications of pinch technology were mainly in refineries and petrochemical plants (Kemp, 2007), but applications to other industries such as pulp and paper (Svensson and Harvey, 2011) and steel (Grip et al., 2013) have been recently reported.

Motivating Example

Before describing the essential concepts of pinch technology and how it can be used to design a heat exchanger network (HEN), a simple example is provided to illustrate the significant role that a HEN structure has on the energy requirements. A simplified example abstracted from a thermal power plant is used to provide the motivation. In a thermal power plant, fuel is burnt in a boiler to generate high-pressure steam, which is subsequently used to generate power. The flue gas from the boiler contains sufficient energy, which can be recovered. The recovered energy can be used to preheat the air used for combustion, or to preheat the water fed to the boiler for generating steam. Figure 4.14.1

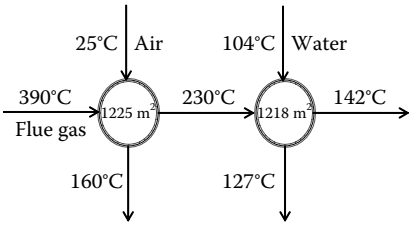

FIGURE 4.14.1 Existing HEN structure.

TABLE 4.14.1
Streams and Their Properties

Stream	Specific Heat Capacity (kJ/kg °C)	Flow Rate (kg/h)
Flue gas	1.1	39,032
Air	1.01	40,072.8
Water (10.5 bar)	4.41	31,824.0

TABLE 4.14.2
Exchangers and Their Properties for Original Configuration

Exchanger	Area (m^2)	Heat Lost by Hot Stream (kW)	Heat Gained by Cold Stream (kW)	Heat Lost to Ambient (kW)	U (W/m^2 K)
HE1	1225.0	1908.23	1517.76	390.47	5.7
HE2	1218.1	1049.53	897.25	152.28	11.3

shows an existing network of two heat exchangers in series used to recover energy from the flue gas. The flue gas is first used to preheat the air in the first exchanger (HE1) and subsequently to preheat pressurized water in the second exchanger (HE2). The flow rate and specific heat capacity of the different streams are given in Table 4.14.1, while the inlet and outlet temperatures of streams from each exchanger are shown in Figure 4.14.1. The heat exchanger areas, heat loads, and heat lost to ambient are given in Table 4.14.2.

From the heat loads of exchangers, it is observed that 2957.76 kW of energy is recovered from the flue gas out of which 542.75 kW is lost (about 20%) to the ambient. From Figure 4.14.1, it is observed that the final exit temperature of the flue gas is 142°C. The question is whether it is possible to extract more energy from the flue gas using the same exchangers. Figure 4.14.2 shows an alternative configuration where the flue gas is first used to preheat water in exchanger HE1 followed by preheating air in exchanger HE2. It is assumed that the overall heat transfer coefficient depends only on the streams exchanging energy. Furthermore, in order to make a fair comparison, it is assumed that heat losses in the exchangers are same as before. Table 4.14.3 shows the heat loads of exchangers for the new configuration. It is observed that the total energy recovered from flue gas is 3375.5 kW out of which the loss to the ambient is almost same as before (542.4 kW). The final exit temperature of the flue gas is 107°C. If this temperature is above the acid dew point, then technically it is possible to extract 10% more energy from the flue gas just by a simple change in the structure of the heat exchanger network (interchange the order in which flue gas exchanges energy with air and water). Although it is not shown here, it is also possible to recover 10% more energy using the same exchangers in a parallel configuration with appropriate apportioning of the flue gas flow rate to the exchangers. This example clearly demonstrates that the heat exchanger network configuration

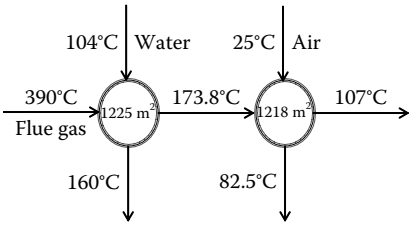

FIGURE 4.14.2 Modified HEN structure.

TABLE 4.14.3
Exchangers and Their Properties for Modified Configuration

Exchanger	Area (m^2)	Heat Lost by Hot Stream (kW)	Heat Gained by Cold Stream (kW)	Heat Lost to Ambient (kW)	U (W/m^2 K)
HE1	1225.0	2578.2	2186.3	391.9	11.3
HE2	1218.1	797.3	645.8	151.5	5.7

plays a significant role in the overall energy consumption of a process. In an actual thermal power plant, several heat exchangers (preheaters, superheaters, economizers, feed heaters, etc.) are used in a series-parallel arrangement. A more complex network of exchangers is used in a refinery to preheat the crude oil using the hot distillate streams of the atmospheric and vacuum columns. The optimal design of the heat exchanger network that can recover the maximum energy by interchanging energy between the process streams, while giving due consideration to the capital investment is a challenging problem. Pinch technology provides an insightful and systematic approach for solving this design problem. Although the description in the rest of the chapter pertains to the design of a HEN for a grassroots design, the concepts of pinch technology can also be used to analyze existing processes and retrofit these designs to recover more energy.

Pinch Technology

One of the important features of pinch technology from a design viewpoint is that it can be used to estimate achievable targets prior to the actual design of a HEN. These estimated targets include the following:

- Minimum external hot and cold utility required for solving a given problem without violating thermodynamic constraints
- Minimum number of heat exchangers required for heat integration
- Minimum overall area of the HEN
- Minimum overall capital cost of the HEN

While the minimum external utility requirements estimate can be shown to be theoretically rigorous, all other target estimates are approximate, but are reasonably good for design purposes. The establishment of such targets prior to design is useful for assessing how closely a proposed design meets these targets. It also indicates the direction in which a proposed design should be modified or evolved for meeting the targets.

Another feature of pinch technology is the extensive use of graphical diagrams such as *composite curves, temperature interval analysis and cascade diagram, source–sink diagram, driving force plots*, etc., which provide significant insights into the energy integration possibilities.

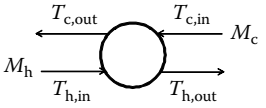

FIGURE 4.14.3 Counter-current heat exchanger.

The computation of the different targets for a given example problem, and the graphical diagrams used in these computations are first explained before the actual design of the HEN.

Interestingly, the mathematical background required for understanding pinch technology is minimal. Essentially, the following three equations that relate the different quantities associated with a heat exchanger are used in the design process. It is assumed that all the heat exchangers are counter-current exchangers, the schematic of one of which is shown in Figure 4.14.3.

$$Q = M_h C_{ph}\left(T_{h,in} - T_{h,out}\right) = M_c C_{pc}\left(T_{c,out} - T_{c,in}\right) \tag{4.14.1}$$

$$Q = UA\Delta T_{ln} \tag{4.14.2}$$

where

$$\Delta T_{ln} = LMTD = \frac{\left(T_{h,in} - T_{c,out}\right) - \left(T_{h,out} - T_{c,in}\right)}{\ln\left(\dfrac{\left(T_{h,in} - T_{c,out}\right)}{\left(T_{h,out} - T_{c,in}\right)}\right)}$$

$$\frac{1}{U} = \frac{1}{h_h} + \frac{1}{h_c} \tag{4.14.3}$$

The first equation relates the heat load of the exchanger (Q) to the heat lost by the hot stream and the heat gained by the cold stream, where for simplicity it is assumed that the specific heat capacities of the streams are constant and do not change with the temperature of the fluid. The second equation is the design equation, which relates the heat load to the overall heat transfer coefficient and area of exchanger, and the third equation relates the overall heat transfer equation to the heat transfer coefficients of the hot and cold streams that are exchanging heat. In general, the stream heat transfer coefficients depend on the geometry of the heat exchanger (such as diameter of the tubes, number of tubes, tube pitch and layout, shell diameter, baffle spacing, etc.). However, for the purpose of designing the HEN, it is assumed that the stream heat transfer coefficients for a given stream are constant and are computed for assumed typical values of the exchanger geometry.

Energy Targeting

Graphical Analysis

Pinch analysis was developed as a systematic physical-insight-based tool for energy conservation in heat exchanger networks (HENs) (Hohmann, 1971; Linnhoff and Flower, 1978; Umeda et al., 1978). The energy targets are obtained via developing temperature-heat duty profiles of heat availability and heat demands of all the process streams. To illustrate the graphical procedure, an illustrative example of two hot streams and two cold streams is considered. Supply and target temperatures of these streams, along with their heat capacity flow rates, are given in Table 4.14.4.

The heat availability profile of all the hot streams (i.e., streams that are to be cooled) is called the hot composite curve. Hot composite curve for this example can be generated by thermodynamically adding two hot streams, H1 and H2. Figure 4.14.4a shows the two hot streams on temperature-heat

TABLE 4.14.4
Stream Data for Illustrative Example

Stream	T_{in} (°C)	T_{out} (°C)	MC_p (MW/°C)	Duty (MW)
H1	210	60	0.10	15
H2	180	30	0.20	30
C3	40	100	0.15	9
C4	60	200	0.30	42

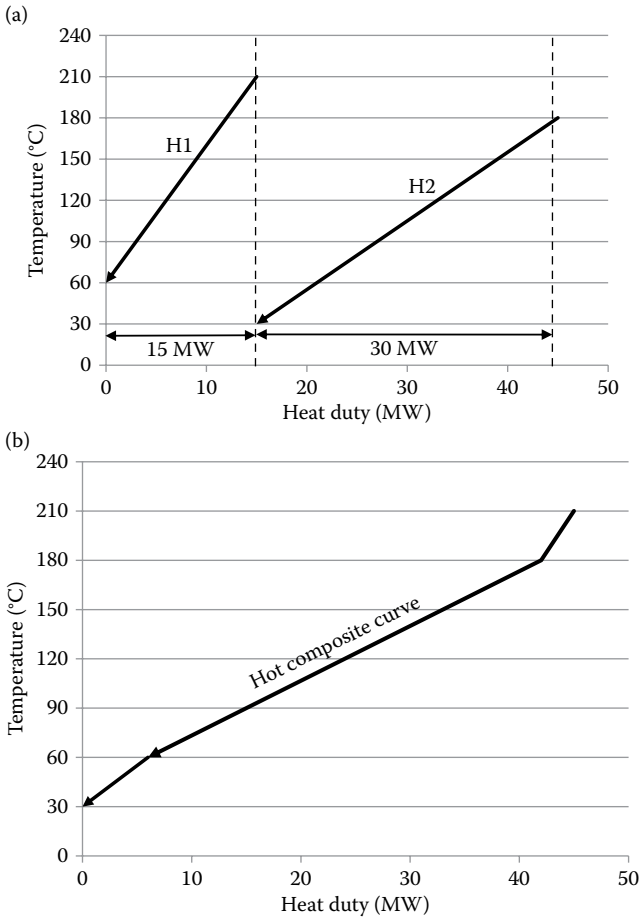

FIGURE 4.14.4 (a) Temperature-heat duty diagrams of hot streams, and (b) Hot composite curve.

duty diagram. The positioning of the streams in the temperature-heat duty diagram is arbitrary on the heat duty scale. However, the horizontal distance for each stream is fixed. This is because the starting value is not important; the overall heat duty of each stream is important. Figure 4.14.4b shows the two hot streams combined together to give a hot composite curve. The addition of heat availability from both the streams can be performed between each temperature interval. This is achieved by combining the duties and heat capacity flow rates of all the streams that have a common temperature range. This can also be done algebraically. Based on the supply and target temperatures of these streams, three temperature intervals can be identified: 30°–60°, 60°–180°, and 180°–210°. Between 30°C and 60°C, heat is available from H2 only. In this temperature interval, the total heat

available is $0.2 \times (60 - 30) = 6$ MW. Between 60°C and 180°C, heat is available from both H1 and H2. In this temperature interval, total heat available is $(0.2 + 0.1) \times (180 - 60) = 36$ MW. Similarly, 3 MW of heat, from the hot stream H1, is available in the temperature interval 180°–210°. For each temperature interval, heat available can be represented as a line segment on a temperature-heat duty diagram. Therefore, the coordinates of the hot composite curve in Figure 4.14.4b are (0, 30), (6, 60), (42, 180), and (45, 210).

Similarly, heat requirement profile of all the cold streams (i.e., streams that are to be heated) is called the cold composite curve. Based on the supply and target temperatures of two cold streams, C3 and C4, three temperature intervals can be identified: 40°–60°, 60°–100°, and 100°–200°. Between 40°C and 60°C, heat is required by C3 only. In this temperature interval, total heat required is $0.15 \times (60 - 40) = 3$ MW. Similarly, 18 and 30 MW of heat are required in the temperature intervals 60°–100° and 100°–200°. By joining these heat requirement line segments, the cold composite curve can be generated. Individual cold streams and the cold composite curve are shown in Figure 4.14.5. The coordinates of the cold composite curve are (0, 40), (3, 60), (21, 100), and (51, 200).

By construction, these composite curves, as a function of temperature, are monotonic in nature. These composite curves are plotted on a single diagram such a way that they are vertically separated

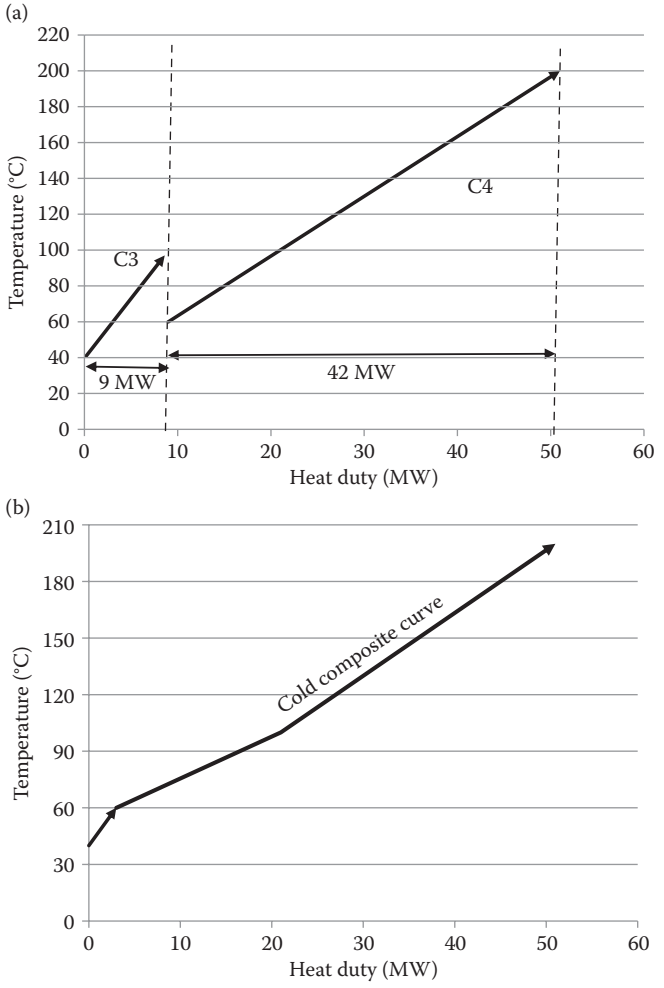

FIGURE 4.14.5 (a) Temperature-heat duty diagrams of cold streams, and (b) Cold composite curve.

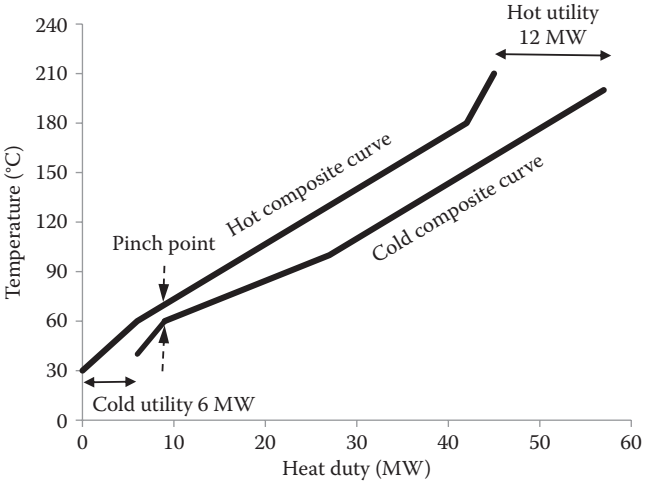

FIGURE 4.14.6 Hot and cold composite curves at ΔT_{min} of 10°C and energy targeting.

by at least a given minimum approach temperature (ΔT_{min}). This vertical temperature difference ensures satisfaction of the second law of thermodynamics and proper heat transfer from the hot streams to the cold streams (see Figure 4.14.6). For this illustrative example, ΔT_{min} is assumed to be 10°C. The overlap of these two composite curves indicates the maximum process heat recovery between hot and cold streams. Overhang of the hot composite curve over the cold composite curve denotes the requirement of the minimum cold utility (to remove excess heat from the system) and similarly, overshoot of the cold composite curve over the hot composite curve indicates the requirement of the minimum hot utility (to supply additional heat to the system). From Figure 4.14.6, the minimum hot and cold requirements are identified to be 12 and 6 MW. The point where ΔT_{min} is observed is known as the pinch point (see Figure 4.14.6). This is the point where the temperature driving force is the least or the composite curves are closest.

Algebraic Analysis

Problem Table Algorithm (PTA), originally proposed by Linnhoff and Flower (1978), is the algebraic tool of pinch analysis for targeting the minimum external utility requirements in a heat recovery network. Over the years, different modifications of the original PTA were proposed. For example, Ozkan and Dincer (2001) combined shifting of stream temperatures and the PTA in one tabular calculation and applied to target utility requirements in a refinery. Salama (2005) introduced numerical calculation procedure based on the reversal procedure of PTA. Based on the geometrical analysis, an algebraic technique was formulated by Salama (2006). An algebraic procedure to target the minimum utilities, known as the modified Problem Table Algorithm (MPTA), was proposed by Bandyopadhyay and Sahu (2010). In this chapter, MPTA is applied for energy targeting. Steps of the proposed algorithm are as follows.

Step 1: Shifting of stream temperatures.

Hot stream temperatures are shifted down by ½ ΔT_{min} and the cold stream temperatures are shifted up by ½ ΔT_{min}. However, it may be noted that any shifting may be permitted as long as the net shifting between the hot and cold stream temperatures are exactly ΔT_{min}. This ensures that there is an adequate driving force (ΔT_{min}) between the hot and cold streams.

Step 2: Determination of sources and demands from shifted stream data.

Inlet of each stream, irrespective of whether it is hot or cold, is considered as a source. Each source produces the heat capacity flow rate (MC_P) at its inlet temperature.

Similarly, the outlet of each stream is considered as a demand that accepts a heat capacity flow rate (MC_P) at respective outlet temperature. Source and demand data for the illustrative example are given in Table 4.14.5.

Step 3: Determination of temperature intervals (column 1)

Temperatures of all sources and demands, as determined in the previous step, are tabulated in decreasing order in the first column. If the value of a particular temperature occurs more than once, the same need not be repeated. The temperature for *k*th row is denoted as T_k. In the first column of Table 4.14.6, temperatures are arranged in descending order for the example.

Step 4: Calculation of heat capacity flows (column 2)

Heat capacity flows (i.e., algebraic sum of heat capacity flows corresponding to any particular temperature) are tabulated in the second column (see Table 4.14.6). Consider flows corresponding to sources as positive and demands as negative. For *k*th row, total heat capacity flow is denoted as F_k.

Step 5: Calculation of net MC_P (column 3)

Cumulative heat capacity flows are tabulated in the third column. Summation of heat capacity flows of all previous rows denotes the cumulative heat capacity flows for any particular row. Due to conservation of mass flow rate and constant specific heat for each

TABLE 4.14.5

Modified Problem Table Algorithm Applied to Illustrative Example

T_{int} (°C)	F_k (kW/°C)	$MC_{p,int}$ (kW/°C)	Q_{int} (kW)	Q_{cas} (kW)	R_{cas} (kW)
205	–0.2	–0.2	0	0	12
175	0.2	0	–6	–6	6
105	–0.15	–0.15	0	–6	6
65	0.3	0.15	–6	–12	0
55	–0.1	0.05	1.5	–10.5	1.5
45	0.15	0.2	0.5	–10	2
25	–0.2	0	4	–6	6

stream, last entry should be zero. Mathematically cumulative heat capacity flow at T_k is given as:

$$\text{CumF}_k = \sum_{l=1}^{k} F_l \tag{4.14.4}$$

Step 6: Calculation of net enthalpy (column 4)

The fourth column represents the enthalpy (Q_k) for each temperature interval. The first entry in the fourth column is kept 0. For all subsequent columns, the difference between the last two temperatures is multiplied by the cumulative heat capacity flows to calculate the enthalpy and tabulated in the fourth column. Mathematically, net enthalpy (Q_k) for each temperature interval can be calculated using the following formula:

$$Q_k = \begin{cases} 0, & \text{for } k = 1 \\ (T_{k-1} - T_k)\left(\sum_{l=1}^{k-1} F_l\right), & \text{for } k > 1 \end{cases} \tag{4.14.5}$$

Net enthalpy, calculated in this column, represents net surplus ($Q_i > 0$) or net deficit ($Q_i < 0$) of enthalpy in each temperature interval.

Step 7: Calculation of cascaded heat duty (column 5)

Cascaded heat duty for each temperature interval can be calculated by summing enthalpies for all previous rows and tabulated in the fifth column. Using Equation 4.14.5, cascaded heat duty for *k*th row may be expressed as:

$$Q_{\text{cas},k} = \left(\sum_{l=1}^{k} Q_l\right) = \begin{cases} 0, & \text{for } k = 1 \\ \sum_{l=1}^{k-1} F_l(T_l - T_k), & \text{for } k > 1 \end{cases} \tag{4.14.6}$$

Step 8: Revised cascade (column 6)

As some of the entries in column 5 may be negative, it suggests an infeasible cascade. The minimum value of Q_{cas} in column 5 is subtracted from each value in the fifth column to obtain the revised feasible cascaded heat duty and tabulated in the sixth column.

$$R_{\text{cas},k} = Q_{\text{cas},k} - \min(Q_{\text{cas}}) \tag{4.14.7}$$

In Table 4.14.6, the minimum value of Q_{cas} in column 5 is 12 MW. Using Equation 4.14.7, revised cascade data are generated and tabulated in column 6.

The first and last values of the sixth column suggest the minimum hot ($Q_{hu,min}$) and the minimum cold ($Q_{cu,min}$) utility requirements, respectively. Based on the data reported in column 6 of Table 4.14.6, the minimum hot and cold requirements are identified to be 12 and 6 MW, identical to the values obtained graphically (see Figure 4.14.6).

The temperature in column 1 that corresponds to zero revised cascaded heat in column 6 is the pinch temperature. For the illustrative example, pinch corresponds to the shifted temperature of 65°C. Therefore, the hot and cold side pinch temperatures are 70° and 60°C.

Golden Rules of Pinch Analysis

The pinch temperature boundary divides the process into two sub-processes, above and below the pinch. The process hot stream segments above pinch temperature should not transfer their energy to cold stream segments below pinch temperature, if a design has to meet minimum utility targets. This is nicely illustrated by the source–sink diagram shown in Figure 4.14.7a. It may be noted that the sub-process above the pinch is a net sink since it requires external hot utility to meet its energy requirements, while the sub-process below the pinch is a net source since it requires external cold utility to transfer the excess energy available. If an amount of energy α is transferred across pinch, then both the hot utility and cold utility requirements increase by the same amount α to satisfy the energy balances above and below pinch. Similarly, if cold utility is used above pinch or hot utility is used below pinch, then both hot and cold utility requirements increase by an identical amount. Figure 4.14.7b–d illustrates this graphically. Therefore, in order to achieve the minimum energy targets for a process, following rules must be obeyed. If these rules are not satisfied, requirement of hot and cold utilities goes up simultaneously, leading to a double energy penalty. These rules are known as golden rules of pinch analysis.

- No heat transfer across the pinch,
- No cold utility above the pinch, and
- No hot utility below the pinch.

Cost Targeting

Once the energy targets are established, the operating cost of the HEN can easily be established. In addition to the operating cost, it is useful to estimate the capital cost of the network. The capital cost of a HEN depends on the number of heat exchangers, number of shells, type of heat exchangers, heat exchange area, material of construction, pressure rating, etc. Capital cost targeting for HEN is briefly discussed.

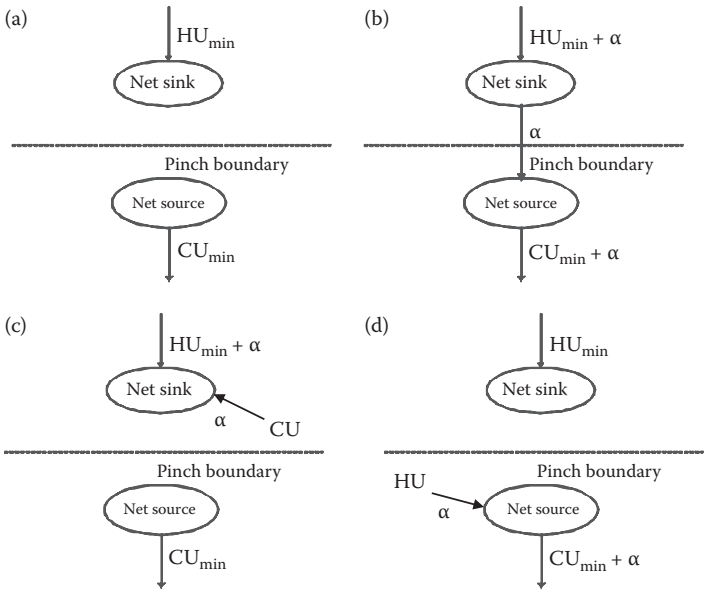

FIGURE 4.14.7 Derivation of golden rules of pinch analysis. (a) No heat transfer across pinch. (b) Heat transfer of α across pinch. (c) Cold utility of α used above pinch. (d) Hot utility of α used below pinch.

Targeting for Number of Heat Exchangers

A minimum number of heat exchangers can be estimated using the mathematical results from graph theory (Linnhoff et al., 1979). The number of heat exchanger in a HEN is related to the number of streams by the following equation:

$$\begin{pmatrix}\text{Number of heat}\\ \text{exchangers}\end{pmatrix}=\begin{pmatrix}\text{Number of streams}\\ \text{including utilities}\end{pmatrix}+\begin{pmatrix}\text{Number of independent}\\ \text{loops in the network}\end{pmatrix}-\begin{pmatrix}\text{Number of independent}\\ \text{components in the network}\end{pmatrix} \tag{4.14.8}$$

Before designing a HEN, a number of independent loops and independent components are not known. For simplicity, it is assumed that there is no loop in the network and there is a single component. These assumptions can simplify Equation 4.14.8 significantly.

$$\begin{pmatrix}\text{Number of heat}\\ \text{exchangers}\end{pmatrix}=\begin{pmatrix}\text{Number of streams}\\ \text{including utilities}\end{pmatrix}-1 \tag{4.14.9}$$

Equation 4.14.9 can be used as a targeting tool to estimate the number of heat exchangers, prior to the design of the HEN. Typically, Equation 4.14.9 is applied for the above pinch and below pinch portion separately to estimate the total number of heat exchangers. For the illustrative example, all four process streams exist above pinch and only hot utility can be used. There are total five streams and hence, four exchangers are expected. Similarly, there are three process streams (H1, H2, and C3), which exist below pinch with cold utility. This leads to a target of three heat exchangers below pinch. The total number of heat exchangers for this example is targeted to be 7.

Targeting for Heat Transfer Area

Heat transfer area may be estimated from the composite curves, after incorporating utility streams. Composite curves may be divided into vertical enthalpy intervals as shown in Figure 4.14.8. Assume a constant overall heat transfer coefficient U for the entire network and countercurrent heat transfer, the heat transfer area for each enthalpy interval may be calculated using the following formula:

$$\begin{pmatrix}\text{Heat transfer area in}\\ \text{an enthalpy interval}\end{pmatrix}=\frac{\text{heat duty of the enthalpy interval}}{U\times\text{LMTD}} \tag{4.14.10}$$

where LMTD stands for the log mean temperature difference of the interval. Different heat transfer coefficient for each stream can easily be incorporated and the following expression may be used for targeting the total heat transfer area for the HEN (Linnhoff and Ahmad, 1990):

$$A=\sum_{k}^{\text{Intervals}}\frac{1}{\text{LMTD}_{\text{k}}}\left[\sum_{i}^{\text{hot streams}}\frac{q_{\text{i,k}}}{h_{\text{i}}}+\sum_{j}^{\text{cold streams}}\frac{q_{\text{j,k}}}{h_{\text{j}}}\right] \tag{4.14.11}$$

It should be noted that Equation 4.14.11 does not predict the true minimum network area for different heat transfer coefficient for each stream. Another difficulty is to estimate heat transfer coefficient for each stream without a detailed design of the heat exchanger.

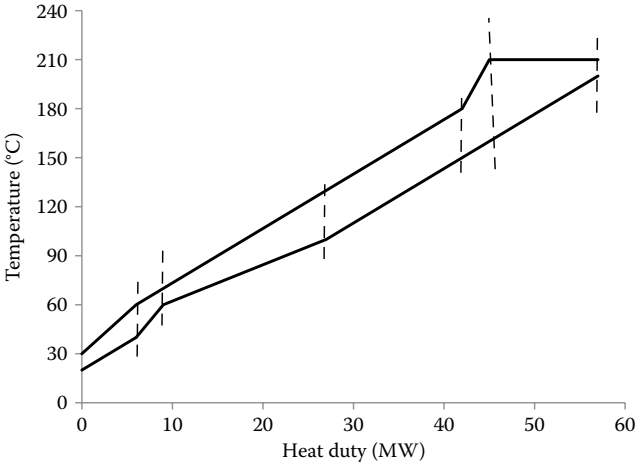

FIGURE 4.14.8 Enthalpy intervals and area targeting.

Cost Optimization

Typically, the cost of a single heat exchanger with surface area A can be estimated using some simplifying relation of the following form:

$$\left(\text{Cost of a Heat Exchanger}\right) = a + bA^c \tag{4.14.12}$$

where a, b, and c are various cost constants that vary according to the materials of construction, pressure rating, and type of exchanger. Using this, a simplified expression may be derived to estimate the capital cost of the entire network (Ahmad et al., 1990).

$$\left(\text{Capital Cost of HEN}\right) = N(a + b(A/N)^c) \tag{4.14.13}$$

where N is the number of heat exchangers.

Once the capital cost is targeted, total annualized cost of the entire network may also be estimated by adding annual operating cost with the annualized capital cost. By varying the total annualized cost of HEN with respect to the $\Delta T_{\min}$, the optimum value of $\Delta T_{\min}$ may be determined (Linnhoff and Ahmad, 1989). A typical capital-energy trade-off, as a function of $\Delta T_{\min}$, is illustrated in Figure 4.14.9. As $\Delta T_{\min}$ increases, the consumption of both hot and cold utilities increases together in order to maintain the energy balances. This leads to increase in operating cost. Typically, energy cost or the operating cost is a piece-wise linear function of $\Delta T_{\min}$. On the other hand, the temperature differences for heat transfer between the hot and cold streams throughout the process become larger as $\Delta T_{\min}$ increases. This means that the heat transfer area decreases, hence decreasing the capital costs. The jumps in the capital cost curve are created due to variation in the expected number of heat exchangers. Combining the energy cost and capital cost allows an optimal value of $\Delta T_{\min}$ to be identified. In practice, the shape of the optimization curve tends to be quite flat and a very precise optimization is often not necessary. As long as the value of $\Delta T_{\min}$ is somewhere in the region of the optimum point, there is little to be lost or gained in terms of the overall cost by small changes in $\Delta T_{\min}$. For chemical processes, a reasonable value of $\Delta T_{\min}$ is usually around 10°C–15°C. A larger value is usually required for refinery processes (typically 15°–30°C). For low-temperature processes, a reasonable value of $\Delta T_{\min}$ is often lower (typically 5°C or less), because of the expense of providing cooling through refrigeration in low-temperature processes.

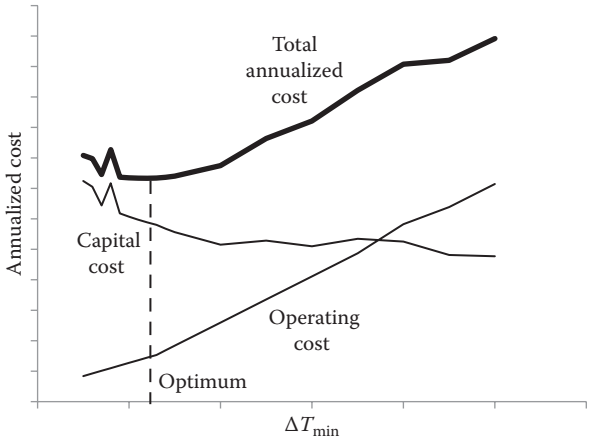

FIGURE 4.14.9 Capital-energy trade-offs and determination of optimum ΔT_{min}.

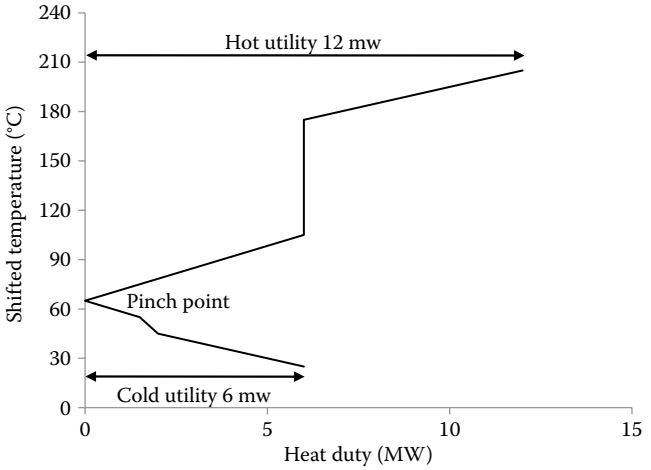

FIGURE 4.14.10 Grand composite curve (GCC).

Targeting for Multiple Utilities

In the previous section, energy targeting is performed with a single hot utility and a single cold utility. However, in many practical situations, multiple utilities are present. To target multiple utilities a piece-wise linear curve, known as the Grand Composite Curve (GCC), may be utilized. GCC may be generated by drawing the shifted temperature (in column 1 of MPTA) against the feasible cascade (in column 6 of MPTA) in a temperature-heat duty diagram. GCC for the example is shown in Figure 4.14.10. The GCC represents the heat demand (segments with positive slope) and supply (segments with negative slope) within each temperature interval. GCC touches the temperature axis at the shifted pinch temperature, signifying no heat transfer across the pinch. The portion of the GCC above the pinch point represents heat demand and requires only hot utilities. Similarly, the portion below the pinch has surplus heat and this surplus heat is rejected through cold utilities.

Figure 4.14.11 illustrates some examples in the use of the grand composite curve. Figure 4.14.11a shows high-pressure steam and cooling water used to satisfy the heating and cooling requirements of a GCC. In Figure 4.14.11b, high-pressure and low-pressure steams are used to satisfy the hot utility requirement of a GCC. Flue gas from a fired heater or from gas turbine exhaust may also be used

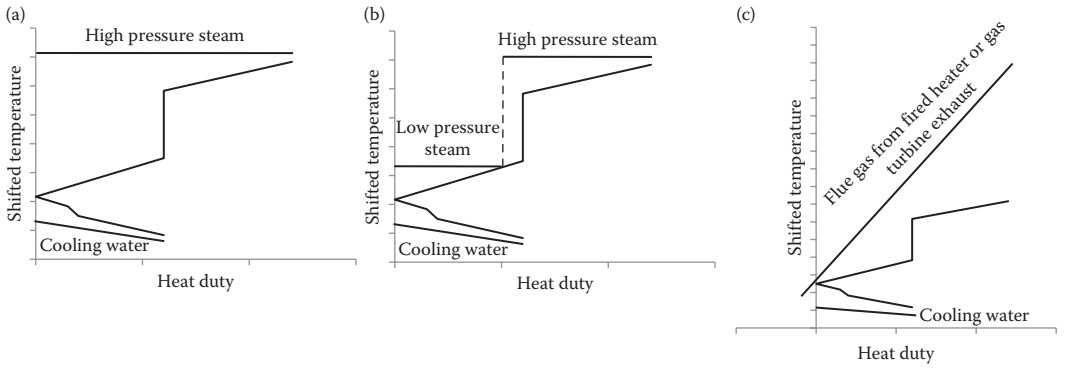

FIGURE 4.14.11 Examples in the use of the GCC: (a) use of high-pressure steam and cooling water, (b) use of multiple steam levels, and (c) use of flue gas as hot utility.

to provide hot utility requirement in a process (see Figure 4.14.11c). Essentially utility profiles are matched against the GCC to target multiple utilities. During profile matching, utility profiles may touch the GCC. This does not imply that ΔT_{min} is zero. It should be noted that the temperature axis in GCC is in shifted scale and the same temperature shift (by $\Delta T_{min}/2$) should also be incorporated in generating the utility profile. Therefore whenever the utility profile touches the GCC, the temperature driving force is exactly equal to ΔT_{min}.

Shenoy et al. (1998) proposed a targeting methodology to determine the optimum distributions of loads for multiple utilities considering the cost tradeoffs. GCC plays an important role in the thermal integration of fired heaters (Varghese and Bandyopadhyay, 2007), integration between various processes (Bandyopadhyay et al., 2010), cogeneration plant (Bade and Bandyopadhyay, 2015), etc.

Network Design and Evolution

In the previous sections, methodologies for setting various targets are discussed. It should be noted that these targets are set prior to the detailed design of the HEN. In this section, a simple methodology, called the pinch design method, to design HEN is discussed (Linnhoff and Hindmarsh, 1983). The starting point is the energy targets and the pinch temperatures. The design procedure starts by setting up a design grid, as shown in Figure 4.14.12. The hot streams are shown at the top of the diagram running in the direction left to right and the cold streams at the bottom of the diagram running right to left. A vertical line at the pinch temperature of 70°C for the hot streams and 60°C for the cold streams divides the grid into two parts (see Figure 4.14.12). To the left of the pinch line is the above pinch portion. To the right of the pinch line is the below pinch portion. It should be noted that

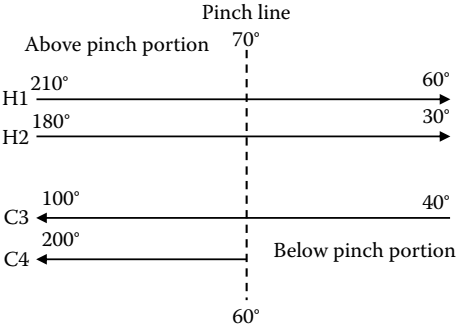

FIGURE 4.14.12 Parallel grid diagram for heat exchanger network design.

all four streams exist above pinch, but only three streams exist in the below pinch portion. Pinch is the most constrained part of the composite curve. Temperature driving force is the minimum at the pinch (see Figure 4.14.6). The design procedure starts at the pinch region and proceeds further.

For the successful design of a HEN, two feasibility criteria have to be met. First feasibility criterion is related to the heat capacity flow rates (MC_p) of the hot and the cold streams. When a hot stream and a cold stream, just above the pinch point, are selected to transfer heat through a heat exchanger, the temperature driving force at the pinch side is exactly ΔT_{min}. The temperature driving force at the other side of the exchanger must be above ΔT_{min}. This is only possible if the MC_p of hot stream is lower than that of the cold stream. The exactly opposite relation has to be obeyed just below the pinch. The MC_p feasibility criterion may be summarized as:

$$\left(MC_P\right)_{\text{hot stream}} \leq \left(MC_P\right)_{\text{cold stream}} \quad \text{just above pinch} \tag{4.14.14}$$

$$\left(MC_P\right)_{\text{hot stream}} \geq \left(MC_P\right)_{\text{cold stream}} \quad \text{just below pinch} \tag{4.14.15}$$

Second feasibility criterion is related to the number of streams present at the pinch. To achieve the energy target, no cold utility to be placed above the pinch. This implies that every hot stream, present just above the pinch, must be brought to the pinch temperature by exchanging heat with a cold stream. Therefore, the number of cold streams, just above the pinch, must be greater than that of the hot streams. The similar argument just below the pinch suggests that the number of hot streams must be greater than that of the cold streams. The number feasibility criterion may be summarized as:

$$\text{Number of hot streams} \leq \text{Number of cold streams} \quad \text{just above pinch} \tag{4.14.16}$$

$$\text{Number of hot streams} \geq \text{Number of cold streams} \quad \text{just below pinch} \tag{4.14.17}$$

Whenever the number criterion is not met, a stream may be split into multiple fractions. It should be remembered that these feasibility criteria are applicable only at the pinch and not away from the pinch. As the temperature driving force is higher, these criteria are not directly applicable.

The next step in the design is to determine the duty of each exchanger. By choosing a large duty, the number of heat exchangers can be minimized. The maximum duty a heat exchanger can have is the lower of the heat duties of the exchanging streams. This is known as tick-off heuristic. These steps can be used to design a HEN. Applications of these steps are demonstrated with the illustrative example.

We start with the below pinch portion (see Figure 4.14.13a). There are three streams below pinch. Both the hot streams start at 70°C, the hot side pinch temperature. The cold stream terminates at 60°C, the cold side pinch temperature. MC_p criterion below pinch (Equation 4.14.15) suggests that C3 with a MC_p of 0.15 can be matched with a hot stream with higher MCp. Only H2 with a MC_p of 0.2 matches that. This also satisfies the number criterion (Equation 4.14.17). Therefore, a match between H2 and C4 is chosen (see Figure 4.14.13b). The heat exchanger in the grid diagram is represented by a vertical line joining two open circles on the streams that are being matched. H2 has 8 MW of heat available and C3 can accept 3 MW of heat. Therefore, the duty of this exchanger is 3 MW. Now, no cold stream is available. The remaining heat of the hot streams must be removed by cold utilities. Two coolers, one on H1 and other on H2, are placed as shown in Figure 4.14.13c. This completes the design of below pinch HEN. It matches with the cold utility target of 6 MW and expected number of heat exchangers of 3.

Now, we start with the above pinch portion (see Figure 4.14.14a). All four streams are present above pinch. Both the hot streams terminate at 70°C, the hot side pinch temperature. Both the cold streams start at 60°C, the cold side pinch temperature. MC_p criterion above pinch (Equation 4.14.14)

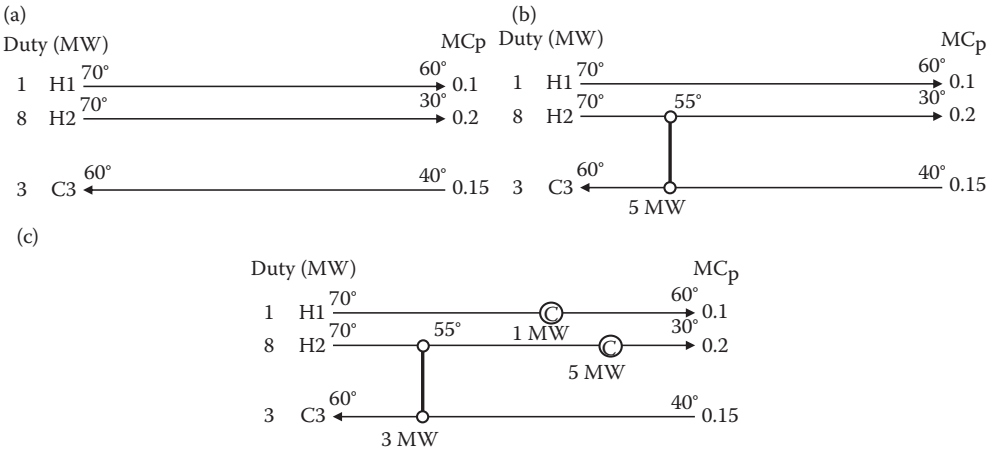

FIGURE 4.14.13 Design of below pinch HEN: (a) below pinch parallel grid diagram, (b) the first match, and (c) placement of coolers.

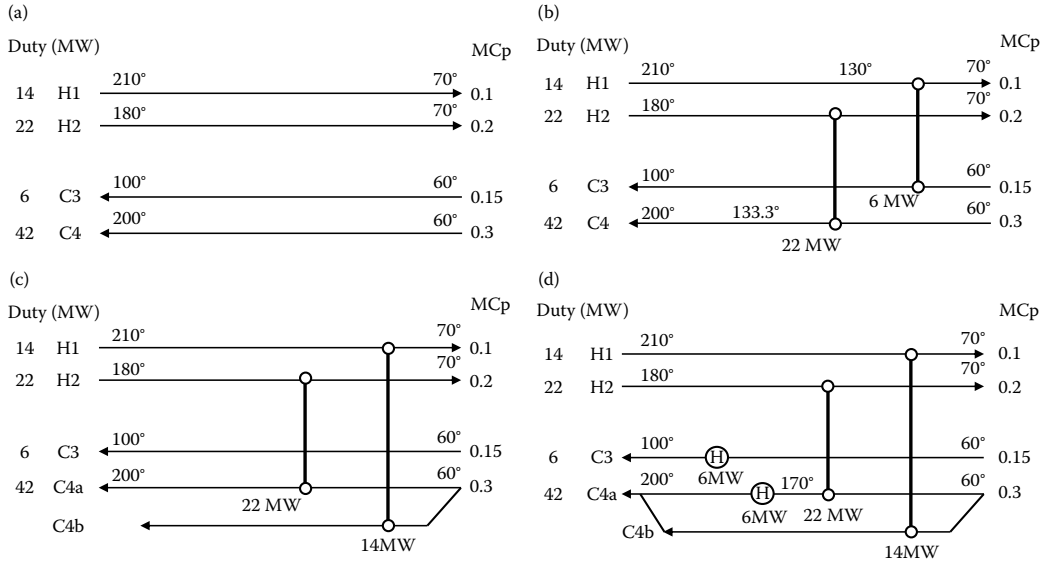

FIGURE 4.14.14 Design of above pinch HEN: (a) above pinch parallel grid diagram, (b) the hidden pinch phenomenon, (c) stream splitting, and (d) placement of heaters.

suggests that C3 with a MC_p of 0.15 can be matched with H1 with a MC_p of 0.1 and C4 with a MC_p of 0.3 can be matched with H2 with a MC_p of 0.2. Number criterion is automatically satisfied as two hot streams are matched with two cold streams. Duties of the H1-C3 and H2-C4 matches are 6 MW (duty of C3) and 22 MW (duty of H2). These matches are shown in Figure 4.14.14b. Now H1 and C4, with a residual duty of 20 MW, are left unsatisfied. However, have a look at the temperatures of the remaining streams. 8 MW of heat is available (remaining H1 stream) from 210° to 130°C and 20 MW of heat is required (remaining C4 stream) from 130.3° to 200°C. This is now impossible to match these two streams without any penalty. This is known as the hidden pinch phenomenon. This is primarily due to the failure of the tick-off heuristic.

One simple way to avoid hidden pinch phenomenon for this example is to avoid using C3 stream. In this case, both H1 and H2 have to match with C4. This leads to two hot streams and a single cold stream, which leads to a violation of the number criterion above pinch (Equation 4.14.16). Therefore,

C4 is split into two (C4a and C4b) and each portion is matched with different hot streams, as shown in Figure 4.14.14c. Duties of the H1-C4b and H2-C4a matches are decided to be 14 MW (duty of H1) and 22 MW (duty of H2). As the MC_p of C4 is exactly sum of the MC_ps of the hot streams, MC_p of C4a and C4b must be 0.2 and 0.1, respectively. This also satisfies the MC_p criterion. Now, no hot stream is available. Remaining heat requirement of the cold streams must be satisfied by hot utilities. Two heaters, one on C3 and other on C4a are placed as shown in Figure 4.14.14d. Two split fractions of C4 are joined and this completes the design of above pinch HEN. It matches with the hot utility target of 12 MW and expected number of heat exchangers of 4. Complete HEN is shown in Figure 4.14.15.

The pinch design method creates a network structure that satisfies the energy and unit targets. The minimum temperature driving force for the network is ΔT_{min}. Based on this initial structure, the network may be evolved and optimized further. Two important concepts are used while evolving a given network: loop and path. A loop is defined by a series of connected matches such that it starts and ends at the same node. One loop is shown in Figure 4.14.16. This loop has the following connections: H(C3), H2-C3, H2-C4, and H(C4). It should be noted that the heaters are connected due to the presence of a single hot utility. It is interesting to note that every loop in a HEN must contain an even number of matches. A path is defined by a series of connected matches such that it starts from a heater and ends at a cooler. One path is shown in Figure 4.14.17. This path has the following connections: H(C3), H2-C3, and C(H2). It is interesting to note that path in a HEN must contain an odd number of matches.

Loops and paths can be used to evolve any network. One classical technique is to identify a loop and distribute the duties of various heat exchanges in the loop. The distribution of the duties may

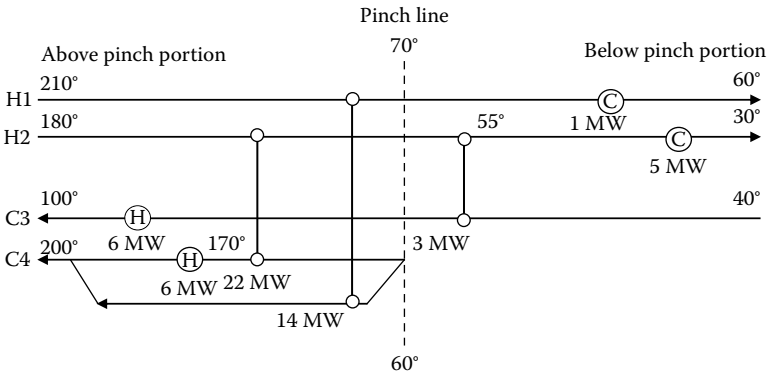

FIGURE 4.14.15 Complete heat exchanger network.

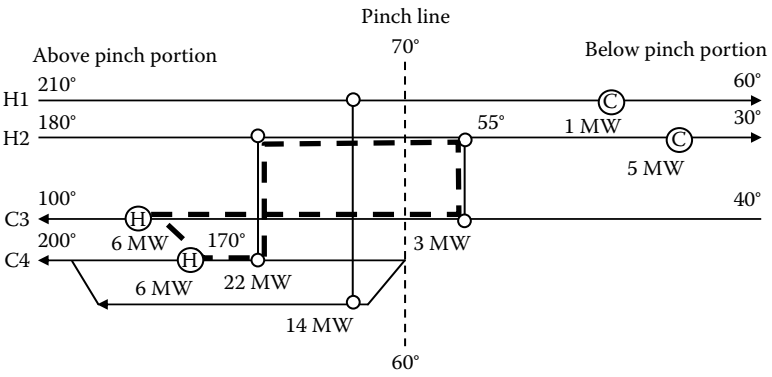

FIGURE 4.14.16 Loop in a heat exchanger network.

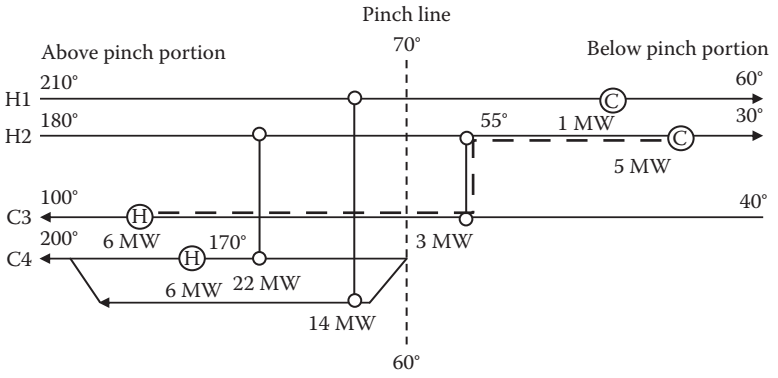

FIGURE 4.14.17 Path in a heat exchanger network.

be performed in such a way that the duty of one exchanger may be reduced to zero while the duties of the other exchangers are positive. This is known as loop breaking. Typically, the heat exchanger with the minimum duty is removed by loop breaking (Linnhoff and Hindmarsh, 1983). By breaking a loop one heat exchanger may be reduced. However, in most cases, this leads to a violation of the minimum approach temperature for some exchangers (certain cases it may become negative). A path is then identified through a heat exchanger where the minimum approach temperature is violated. Heater and cooler duties are increased and duties of other exchangers are adjusted to restore the minimum approach temperature of the network. Distribution of duties of different heat exchangers in a path is known as path relaxation. A combination of loop breaking and path relaxation is performed to evolve a HEN. In general, the breaking of a loop and recovery of temperature violations using a path leads to energy transfer across the pinch and consequent increase in energy requirements. The extra energy penalty incurred can be compared with the decrease in capital cost due to elimination of an exchanger and if the trade-off is favorable, then the evolved network can be accepted. The energy penalty incurred depends on the choice of loop and path used for eliminating an exchanger and there are no guidelines for an appropriate choice of loop and paths for evolutionary synthesis. Alternatively, a rigorous optimization-based formulation proposed by Mehta et al. (2001) using all loops and paths of the process can be formulated which can be used to determine the least energy penalty for eliminating an exchanger. This formulation can also be used to determine whether it is feasible to eliminate an exchanger from a given HEN.

Integrating HEN with Other Energy Devices

In a process, electrical energy is used to drive pumps and compressors. The process may also have a captive power plant for generating electrical power from high-pressure steam. Pinch technology provides clear rules for heat and power integration which can increase the overall reduction in energy utilization.

Figure 4.14.18a shows a process represented as a source–sink diagram with HU_{min} and CU_{min} being the minimum utility requirements. Figure 4.14.18a also shows a heat engine, which is part of the process (such as a turbine) which converts part of the thermal energy it receives (Q_{in}) into useful work W and rejects the remaining energy $Q_{out} = Q_{in} - W$ to the environment. The heat engine operates between the temperatures T_{source} and T_{sink}. The process and heat engine are not heat integrated, and the combined hot utility required by the process and heat engine is $HU_{min} + Q_{in}$, while the combined cold utility required is $HU_{min} + Q_{out}$. The net useful work obtained is W (in the form of electrical energy) which may be used in the process itself or may be exported. Figure 4.14.18b–d conceptually depicts different ways of thermally coupling the heat engine with the process depending on the temperatures, T_{source}, T_{sink} and T_{pinch}. It is observed from these diagrams that if the heat engine is heat integrated across pinch, then there is no net change in the total utility consumption or useful work produced when compared

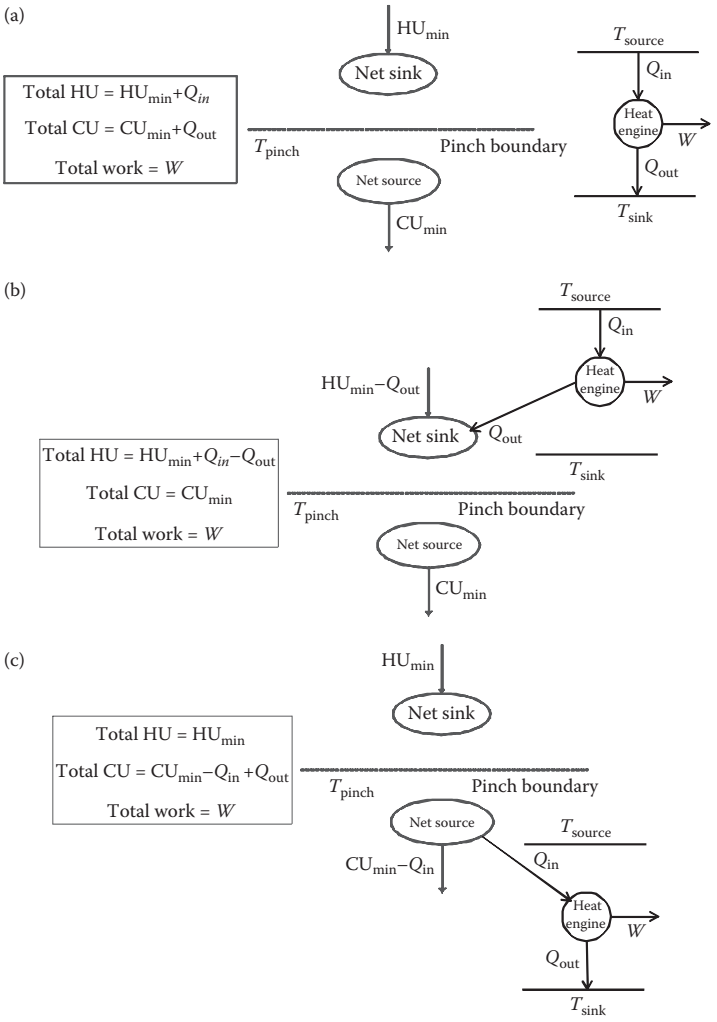

FIGURE 4.14.18 Integration of heat engine with process. (a) Process and heat engine not thermally integrated. (b) Heat engine integrated above pinch. (c) Heat engine integrated below pinch.

to the non-integrated scheme of Figure 4.14.18a. However, if the heat engine is integrated by rejecting heat to the process above pinch or by receiving energy from the process below pinch, then there is net reduction in overall energy consumption of either Q_{out} or Q_{in}, respectively. It may be noted that the diagrams represent the maximum energy reduction that can be obtained by integrating the heat engine with the process. The actual reduction depends on the temperature levels at which the integration is performed, and the available or required process energy at that temperature level.

It may be noted that a distillation column is similar to a heat engine since it takes in heat from a reboiler and rejects heat to the condenser, while performing useful work of separating a multicomponent mixture into products of the desired composition. As an example, consider the process described in Table 4.14.4. A binary distillation column operating at atmospheric pressure is also part of the process. The bottom product has a bubble point temperature of 120°C and the top product has a dew point temperature of 90°C. The reboiler duty is 2.2 MW and condenser duty is 2 MW. One possibility to integrate the column reboiler and condenser with the process HEN is to include the top product stream as a hot stream and bottom product as a cold stream in the stream table. The HEN designed for this extended process will also include the reboiler and condenser of the

distillation column. Alternatively, if the product streams of the column are not included in the process stream table, then we can consider the integration of this column with the background process HEN by treating it like a heat engine. We will assume that a minimum approach temperature of 10°C is required in the reboiler and condenser. Since the condenser temperature is greater than the pinch temperature, the only possibility is to reject heat to the process above pinch by integrating the condenser with the process. In order to satisfy the minimum approach temperature, the cold process stream receiving the condenser duty should be <80°C. From the grand composite curve (Figure 4.14.6), we observe that the net energy deficit from pinch temperature up to 80°C is 1.5 MW. Thus, the maximum amount of energy that can be rejected from the condenser to the background process is 1.5 MW and the remaining energy of 0.5 MW must be met by an external cold utility. The net energy savings by heat integrating the column with the process is 1.5 MW. It is also possible to obtain additional savings by considering the option of increasing the column pressure which will increase both the reboiler and condenser temperatures. The trade-off, in this case, is the increase in capital cost of the column (to withstand the increased pressure) and increased pumping costs as against the reduction in the cost of external utilities.

A similar analysis can be carried out for integrating a heat pump with the HEN. A heat pump takes in energy from a low-temperature source and does useful work on it and rejects it to a high-temperature sink. If the source temperature is below the pinch temperature, then the heat pump can receive energy from the process below pinch. Similarly, if the sink temperature is above pinch, then the heat pump can reject heat to the process above pinch. Thus, it is best if the heat pump is heat integrated across the pinch.

This leads to the following pinch technology rules for heat and power integration:

- Integrate a heat engine above or below pinch, but not across the pinch temperature.
- Integrate a heat pump across pinch (receive heat from below pinch and reject heat above pinch).

Conclusion

Pinch analysis was originally developed as a thermodynamic-based approach for conserving thermal energy through a network of heat exchangers (Linnhoff et al., 1982). It was developed as a holistic tool to analyze overall heat recovery systems for energy conservation in process industries. Problems of pinch analysis can easily be generalized where streams are characterized by both quantity and quality measures. In the case of heat recovery, energy streams are quantified in terms of heat duty (quantity) and temperature (quality). The fundamental problem involves minimization of the externally sourced, high-value resource (e.g., hot utilities in heat recovery pinch analysis) subject to quality constraints (e.g., temperature constraints due to the second law of thermodynamics). It is important to note that a consequence of such an optimization is the simultaneous reduction of unusable waste streams (e.g., rejected heat in heat recovery pinch analysis) (Bandyopadhyay, 2006).

Based on the similarities between heat and mass transfer phenomena, El-Halwagi and Manousiouthakis (1989) proposed the synthesis of mass exchange networks for the efficient use of industrial mass separating agents such as solvents, adsorbents, etc. The primary objective is to recover impurity load from a set of rich streams (process streams containing impurity) to a set of lean streams (process mass separating agent(s) that can remove impurity) and thus reducing the use of external mass separating agent. Advanced problems in a mass exchange network were addressed by Hallale and Fraser (1998).

Further work on mass integration in the 1990s led to the development of pinch analysis techniques for material resource conservation networks including that for industrial water network (Wang and Smith, 1994), refinery hydrogen system (Alves, 1999), and property integration (Kazantzi and El-Halwagi, 2005). In these problems, valuable resources (e.g., water, hydrogen, and other materials) from a set of process sources (stream containing resources) to a set of process sinks (units requiring resources) are recovered and thus, the use of external resources (such as fresh water, fresh hydrogen, etc.) is reduced (El-Halwagi, 2011; Foo, 2012).

Tan and Foo (2007) proposed pinch analysis–based methodology for carbon-constrained energy planning. In carbon-constrained energy planning, energy sources (fossil fuels) are allocated to various energy demands (e.g., regions/areas that require energy), in order to reduce the overall CO_2 emission. Carbon capture and storage planning is one of the important issues for carbon-constrained energy sector planning and applied for country-specific energy sector planning like Ireland (Crilly and Zhelev, 2008), New Zealand (Atkins et al., 2010), China (Chen et al., 2011), India (Krishna Priya and Bandyopadhyay, 2013), etc. Techniques of pinch analysis have been extended to study problems such as to determine the extent of carbon capture to existing power plant that minimizes power loss (Tan et al., 2009; Sahu et al., 2014), to determine the maximum amount of CO_2 to be stored in various storage systems with given capacity and injectivity constraints (Diamante et al., 2014), etc.

There are numerous other extensions of pinch analysis. Other than the examples listed above, pinch analysis has also been applied to aggregate production planning problems (Singhvi and Shenoy, 2002), isolated energy systems (Arun et al., 2007; Bandyopadhyay, 2011), human resource planning, and work scheduling (Foo et al., 2010). Over the years, pinch analysis has established itself as a structural tool for analyzing and conserving resources in numerous diversified applications, such as energy sector planning, financial analysis, supply chain management, isolated energy system design, batch process scheduling, carbon dioxide sequestration, etc. (Linnhoff, 1993; Smith, 2016).

4.15 AIR-CONDITIONING SYSTEMS

Donald L. Fenton

Introduction

The term *air conditioning* refers to all equipment and processes used in maintaining comfortable and healthy indoor air suitable for human occupancy. This includes the adjustment or conditioning of the air, the distribution of air, air motion in the occupied space, and cleanliness of the air. This section of the handbook treats the thermal processes important in maintaining the temperature and humidity of the spaces occupied by humans. The acronym HVAC&R signifies heating, ventilating, air conditioning, and refrigerating where all these activities fall under the umbrella of air conditioning. Consequently, air conditioning is not restricted to only the cooling and dehumidifying of air.

Maintaining comfortable indoor air conditions requires understanding the behavior of the air and water vapor mixture—a subject called psychrometry. A space occupied by humans enclosed by an insulated structure limits the energy gains in the summer and losses in the winter. These energy gains and losses are referred to as cooling loads and heating loads, respectively. They are the energy transfer rates that the heating and refrigerating equipment must meet to ensure indoor comfort. These loads are based on the determination of the severe, but likely, outdoor weather conditions typical for the specific geographical location. The introduction of conditioned air to the occupied space must be sufficient to offset the summer and winter loads. The heating and cooling equipment is generally located a distance away from the space, necessitating an air duct system for the conveyance of the conditioned air.

The inch-pound unit system is used, reflecting its prevalence in the HVAC&R industry in the U.S. Conversion to SI units may be made using suitable factors.

Properties of Moist Air

The thermodynamic properties of moist air and how these properties may change is the subject generally referred to as psychrometrics. Moist air is a binary mixture of dry air and water vapor. NOAA (2016) and Schlatter (2009) report that the composition of dry air is nitrogen, 78.084%(v/v); oxygen, 20.946%(v/v); argon, 0.9340%(v/v); carbon dioxide, 0.0397%(v/v); neon, 0.001818%(v/v); helium, 0.000524%(v/v); methane, 0.000179% (v/v); sulfur dioxide, 0 to 0.0001%(v/v); hydrogen, 0.00005%(v/v); and other negligible gases such as krypton, xenon, and ozone. Carbon dioxide concentration measurements reported from 1995 to 2015 (McGee, 2016) suggest that the annual increase in carbon dioxide concentration is 0.00020% per year. Water vapor concentration varies from 0.001% to 5.0% depending on local conditions and is not included in the dry air composition (Wallace and Hobbs, 2006). The apparent molecular weight of the dry air gas mixture is 28.9645. The dry air gas constant is computed by

$$R_a = \frac{R}{M} = \frac{1545.32}{28.9645} = 53.352 \frac{\text{ft lbf}}{\text{lbm°R}}, \tag{4.15.1}$$

where the molecular weight value is based on carbon having a molecular weight of exactly 12.

Moist air is a mixture of dry air and water vapor. All other contaminants that may be present in the atmospheric air are excluded from moist air. These contaminants may include smoke, pollen, dust, and gaseous pollutants generally present in the ambient or outside air. The quantity of water vapor in moist air varies from none to a maximum amount that depends on the temperature and pressure of the air. This condition of maximum water vapor content is called saturation, which is an

equilibrium condition between the moist air and condensed water. The molecular weight of water is 18.01528 and its gas constant is

$$R_{H_2O} = \frac{1545.32}{18.01528} = 85.778 \frac{\text{ft lbf}}{\text{lbm°R}}. \tag{4.15.2}$$

The barometric pressure and temperature of atmospheric air changes with increasing altitude above sea level. Standard atmospheric conditions are defined at sea level where the pressure is 29.921 in. of mercury (in.Hg) and the temperature is 59°F. The U.S. Standard Atmosphere defines the variation of pressure and temperature with altitude and is generally used to estimate these properties at different altitudes. The troposphere (lower atmosphere) is taken to consist of dry air behaving as an ideal gas. The acceleration due to gravity is also taken to be a constant, 32.1740 ft/s^2. The pressure and temperature are given by

$$T = 59 - 0.00356616Z, \tag{4.15.3}$$

$$p = 14.696(1 - 6.8754 \times 10^{-6})^{5.2559}, \tag{4.15.4}$$

where Z is the altitude (ft), p is the barometric pressure (in.Hg), and T is the temperature (°F). Equations 4.15.3 and 4.15.4 are accurate from sea level to an altitude of 36,000 ft. More extensive information including higher altitudes, other physical data, and SI units may be obtained from NASA (1976).

Thermodynamic Properties of Saturated Water

The thermodynamic saturated state is discussed in Chapter 3 of this handbook. Relationships giving the thermodynamic properties of saturated water have been developed by Herrmann et al. (2009) over the temperature range from −80°F to 200°F. The determination of these properties is based on an ideal temperature scale (International Temperature Scale of 1990 (ITS-90)) almost identical to the generally used practical temperature scale used for measurements. As an example, the standard boiling temperature of water (at 14.696 psia or 29.921 in.Hg) is 211.95°F rather than the usual value of 212°F on the practical scale. The enthalpy and entropy properties of saturated liquid water have values defined as zero at the triple point, 32.018°F. Water at a temperature between its triple point and critical point may coexist in two states, liquid and vapor. When these phases are in equilibrium, all the physical features of the system remain constant with time and the vapor and liquid are saturated.

Over liquid water, the saturation pressure for the temperature range from 32°F to 392°F is

$$\ln(p_{ws}) = \frac{C_1}{T} + C_2 + C_3 T + C_4 T^2 + C_5 T^3 + C_6 \ln T, \tag{4.15.5}$$

where $C_1 = -1.0440397 \times 10^4$, $C_2 = -1.1294650 \times 10^1$, $C_3 = -2.7022355 \times 10^{-2}$, $C_4 = 1.2890360 \times 10^{-5}$, $C_5 = -2.4780681 \times 10^{-9}$, and $C_6 = 6.5459673$, and where T is the absolute temperature (°R) and the subscript "ws" indicates saturated water. The saturation pressure over ice in terms of temperature for a range from −148°F to 32°F is

$$\ln(p_{ws}) = \frac{C_7}{T} + C_8 + C_9 T + C_{10} T^2 + C_{11} T^3 + C_{12} T^4 + C_{13} \ln T, \tag{4.15.6}$$

where $C_7 = -1.0214165 \times 10^4$, $C_8 = -4.8932428$, $C_9 = -5.3765794 \times 10^{-3}$, $C_{10} = 1.9202377 \times 10^{-7}$, $C_{11} = 3.5575832 \times 10^{-10}$, $C_{12} = -9.0344688 \times 10^{-14}$, and $C_{13} = 4.1635019$. The ASHRAE *Handbook of Fundamentals* (2013) gives the thermodynamic properties of water at saturation.

Thermodynamic Properties of Moist Air

Hyland and Wexler (1983a,b) developed formulas for the thermodynamic properties of moist air based on the "thermodynamic temperature scale," an ideal temperature scale almost identical to the generally used practical scale used for physical measurements. The ASHRAE *Handbook of Fundamentals* (2013) gives the thermodynamic properties of moist air based on the Hyland and Wexler equations. These thermodynamic properties are as follows:

Temperature (°F): T, related to the absolute temperature (°R) by T (°R) = T (°F) + 459.67.
Humidity Ratio: W_s, the condition when the water vapor phase is in thermodynamic equilibrium with the condensed water at a certain temperature and pressure. The humidity ratio for a given moist air condition may have a humidity ratio, W, such that it has a value of zero or greater but less than or equal to W_s.
Specific Volume (ft^3/lb): v_a, dry air specific volume.
Saturated Moist Air Specific Volume (ft^3/lb): v_s, volume of saturated moist air per pound of dry air.
Specific Enthalpy of Dry Air (Btu/lb dry air): h_a, reference value is zero at 0°F and 14.696 psia.
Saturated Moist Air Specific Enthalpy Air (Btu/lb dry air): h_s.
Condensed Water Specific Enthalpy (Btu/lb water): h_w, specific enthalpy of water in equilibrium with saturated air at a certain temperature and pressure. The reference value is zero at the triple point of water and saturation pressure.
Water Vapor Pressure (psia): p_w, the actual partial pressure in moist air exerted by the water vapor.
Saturated Water Vapor Pressure (psia): $p_{s,}$ water vapor pressure in saturated air. Very nearly the same as the saturation vapor pressure of pure water, p_{ws}. Therefore, p_s and p_{ws} may be interchanged for one another.
Barometric Pressure (psia): p, atmospheric pressure.
Specific Entropy of Dry Air (Btu/lb°R): s_a, reference value is zero at 0°F and 14.696 psia.
Saturated Moist Air Specific Entropy (Btu/lb°R): s_s.
Condensed Water Specific Entropy (Btu/lb°R): s_w, specific entropy of water in equilibrium with saturated air. The reference value is zero at the triple point of water and saturation pressure.

Numerical values of the properties of moist air are calculated on the basis of several assumptions. These are as follows:

1. The gaseous phase behaves as a mixture of ideal gases.
2. The liquid and solid phases contain no dissolved gases.
3. The equilibrium between the condensed phase and the gas mixture is not affected by the presence of the other component when the mixture and the condensed phase are at the same pressure and temperature.

Several additional properties and related mathematical relationships are useful when considering calculations relating problems regarding moist air. These are as follows:

Dry-Bulb Temperature (°F): T, temperature of air as indicated by a thermometer.
Thermodynamic Wet-Bulb Temperature (°F): T^*, the temperature of water (may be liquid or solid) evaporating into moist air at a certain dry-bulb temperature T and humidity ratio W, brings the air to saturation adiabatically at the same temperature T^* maintaining the pressure at a constant value (Howell et al., 1998).

Wet-Bulb Temperature (°F): T_{wb}, the equilibrium temperature of water in a wet wick surrounding the bulb of a thermometer placed in an air stream. A psychrometer is used to measure simultaneously the dry-bulb and the wet-bulb temperatures using two thermometers. While this process involves the simultaneous transfer of heat and mass from the bulb, it is different than the adiabatic saturation process defining the thermodynamic wet-bulb temperature. However, the correction needed to convert wet-bulb temperatures to thermodynamic wet-bulb temperatures is small.

Humidity Ratio: the humidity ratio is calculated as the mass of water divided by the dry air mass in a sample of moist air.

$$W = \frac{m_w}{m_a} \tag{4.15.7}$$

or that

$$W = \frac{0.621945\, p_w}{(p - p_w)}. \tag{4.15.8}$$

Manipulation of the psychrometric and thermodynamic properties yields

$$W = \frac{(1093 - 0.556T^*)W_s^* - 0.240(T - T^*)}{1093 + 1.805T - 4.186T^*}, \tag{4.15.9}$$

where W_s^* is the saturated humidity ratio if saturated at the wet-bulb temperature and where T and T^* are in °F.

Degree of Saturation: μ, the ratio of the actual humidity ratio divided by the saturated air humidity ratio W_s at the same pressure and temperature.

$$\mu = \frac{W}{W_s}. \tag{4.15.10}$$

Relative Humidity: ϕ, the ratio of the water vapor mole fraction in a given sample of moist air divided by the water vapor mole fraction of a sample saturated at the same pressure and temperature. Using the assumption that the gas mixture may be considered as a mixture of ideal gases gives

$$\phi = \frac{p_w}{p_{ws}}. \tag{4.15.11}$$

Dew-Point Temperature (°F): T_d, the temperature of a sample of moist air after having become saturated at the same pressure and humidity ratio as the original sample of moist air. Also, the dew-point temperature is the saturation temperature corresponding to the saturation pressure as listed in the thermodynamic properties of saturated water. For the temperature range from 32°F to 200°F, the dew-point temperature is given by

$$T_d = 100.45 + 33.193 \ln p_w + 2.319(\ln p_w)^2 + 0.17074(\ln p_w)^3 + 1.2063(p_w)^{0.1984} \tag{4.15.12}$$

and for temperatures less than 32°F,

$$T_d = 90.12 + 26.142 \ln p_w + 0.8927(\ln p_w)^2 \tag{4.15.13}$$

by ASHRAE (2013).

Other properties include specific volume and enthalpy. The specific volume of moist air is given in units of dry air where the atmospheric pressure is the sum of the dry air and water vapor partial pressures. Thus,

$$v = \frac{R_a T}{(p - p_w)}, \tag{4.15.14}$$

where p is the atmospheric pressure, p_w is the water vapor partial pressure, and R_a is the gas constant for air (53.3504 ft-lbf/lbm°R). Combining the expression for W above gives an alternate relationship for v sometimes useful in calculations,

$$v = 0.370486(T + 459.67)\frac{(1 + 1.6058W)}{p}. \tag{4.15.15}$$

The enthalpy is equal to the sum of the enthalpies of the dry air and the water vapor, or

$$h = h_a + Wh_g, \tag{4.15.16}$$

where h_a is the enthalpy of the dry air and h_g is the specific enthalpy for saturated water vapor at the temperature of the moist air mixture. Approximate values for h_a (Btu/lb) and h_g (Btu/lb) are

$$h_a = 0.240T, \tag{4.15.17}$$

$$h_g = 1061 + 0.444T, \tag{4.15.18}$$

where T is the dry-bulb temperature. The resulting expression for the enthalpy h (Btu/lb) is

$$h = 0.240T + W(1061 + 0.444T). \tag{4.15.19}$$

The above relationships for the moist air mixture are generally adequate for air-conditioning design calculations.

Psychrometric Chart

The psychrometric chart displays simultaneously a number of the thermodynamic properties of moist air. An example psychrometric chart is shown in Figure 4.15.1, where several variables are plotted against temperature and the humidity ratio. Processes involving heat transfer and the addition or removal of moisture are readily shown on the psychrometric chart and so the chart is an aid in visualizing the process. Furthermore, the changes that occur in the moist air properties may be observed from the chart (Figure 4.15.1), particularly changes in dry-bulb temperature, humidity ratio, and enthalpy. Observe that the horizontal movement across the chart involves only a change in dry-bulb temperature or a sensible change. On the other hand, a vertical movement on the chart represents a pure latent change where the dry-bulb temperature remains constant but the humidity ratio changes. Figure 4.15.2 shows a schematic view of the psychrometric chart where the process directions common to air conditioning are shown.

We now consider several examples where the use of the psychrometric chart is demonstrated.

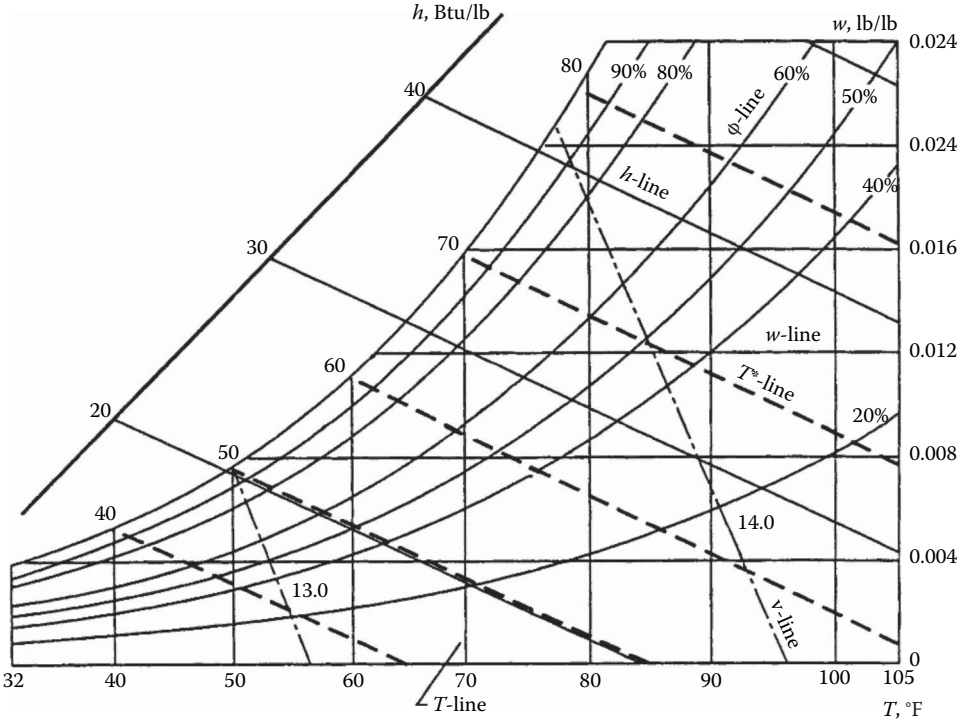

FIGURE 4.15.1 Psychrometric chart. (From Kreith, F., Ed., *The CRC Handbook of Mechanical Engineering*, CRC Press LLC, Boca Raton, FL, 1998. With permission.)

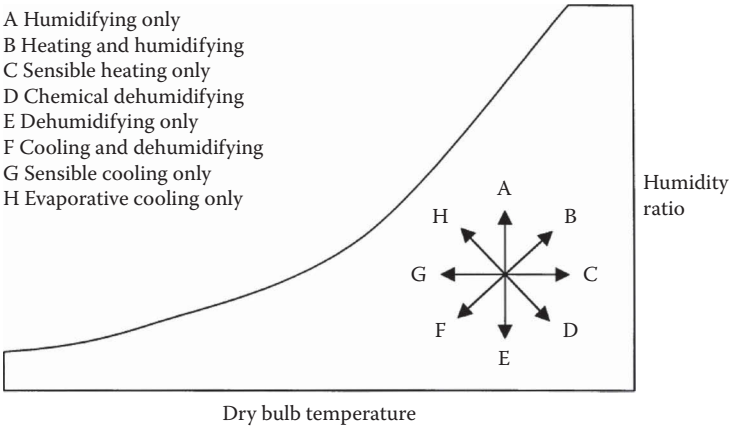

FIGURE 4.15.2 Air conditioning process directions on a psychrometric chart.

Cooling and Dehumidifying Air

Moist air, when cooled to a temperature below its dew point, will condense a portion of the water vapor initially in the mixture. Equipment that could be used to carry out the cooling and dehumidifying process is shown in Figure 4.15.3, where a refrigerant enters and leaves an evaporator coil. The air inlet and exit conditions are defined as well as the condensed water drained from the pan below the coil. If the system operates on a steady-state flow basis (all variables remain constant with time), then the process may be described by the following water mass and energy equations:

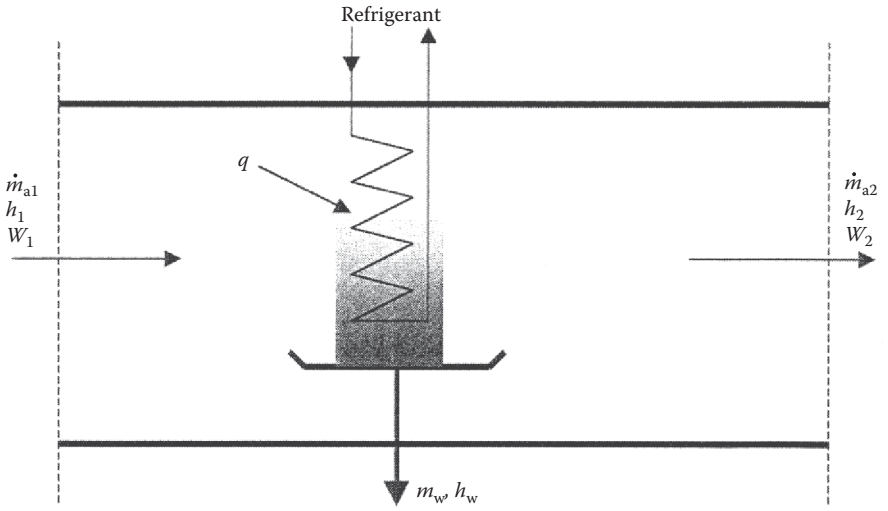

FIGURE 4.15.3 Schematic diagram of cooling and dehumidifying equipment.

$$\dot{m}_a W_1 = \dot{m}_a W_2 + \dot{m}_w, \tag{4.15.20}$$

$$\dot{m}_a h_1 = \dot{m}_a h_2 + \dot{m}_w h_w + q, \tag{4.15.21}$$

where q is the heat transfer from the moist air to the coil. These two equations may be rearranged to give

$$\dot{m}_w = \dot{m}_a (W_1 - W_2), \tag{4.15.22}$$

$$q = \dot{m}_a [(h_1 - h_2) - (W_1 - W_2) h_w], \tag{4.15.23}$$

where the equation for q indicates that the cooling and dehumidifying process includes sensible and latent heat transfer. The sensible and latent heat transfer quantities are

$$q(\text{sensible}) = \dot{m}_a (h_1 - h_2) = \dot{m}_a c_p (T_1 - T_2), \tag{4.15.24}$$

$$q(\text{latent}) = \dot{m}_a (W_1 - W_2) h_{fg}. \tag{4.15.25}$$

Figure 4.15.2 shows the direction of this process on a psychrometric chart where the process is noted to be a line sloping downward to the left. The sensible and latent heat transfers are noted by the horizontal and vertical changes in the condition of the air when passing from the inlet to the outlet, respectively.

Heating and Humidifying Air

The equipment shown in Figure 4.15.4 may be used to heat and humidify moist air during the winter heating season. Water mass and energy balances on the system yield

$$\dot{m}_a W_1 + \dot{m}_w = \dot{m}_a W_2, \tag{4.15.26}$$

$$\dot{m}_a h_1 + q + \dot{m}_w h_w = \dot{m}_a h_2, \tag{4.15.27}$$

which may be solved to give the humidity ratio and enthalpy of the exit air.

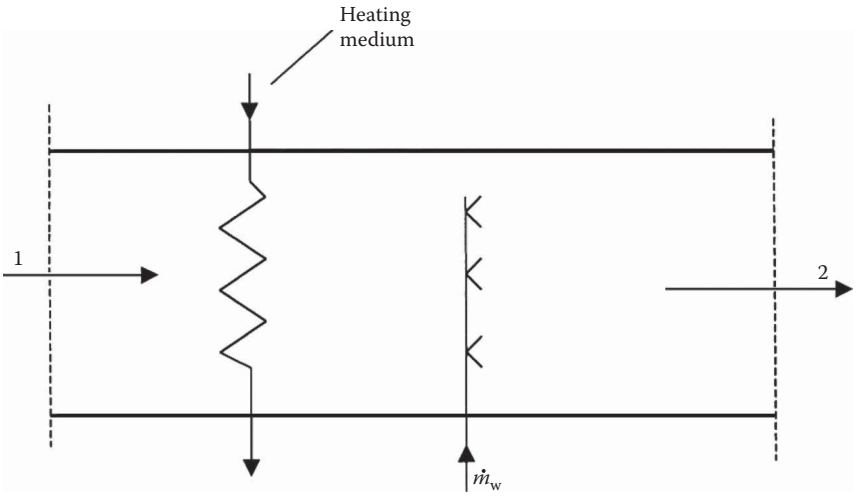

FIGURE 4.15.4 Schematic diagram of typical heating and humidifying equipment.

Adiabatic Mixing of Two Streams

Two streams of moist air converging into one stream are shown in Figure 4.15.5. If there is no heat transfer from the ducts to the surroundings, the mixing process is adiabatic, which is closely approximated by insulated ducts, then the equations describing this process include an air mass balance, a water mass balance, and an energy balance, respectively.

$$\dot{m}_{a1} + \dot{m}_{a2} = \dot{m}_{a3}, \tag{4.15.28}$$

$$\dot{m}_{a1}W_1 + \dot{m}_{a2}W_2 = \dot{m}_{a3}W_3, \tag{4.15.29}$$

$$\dot{m}_{a1}h_1 + \dot{m}_{a2}h_2 = \dot{m}_{a3}h_3. \tag{4.15.30}$$

The above three equations indicate that the leaving humidity ratio and enthalpy are weighted averages of the entering corresponding values. In practice, the approximation is made that the exit temperature is also a weighted average of the entering temperatures where the error, due to the variation

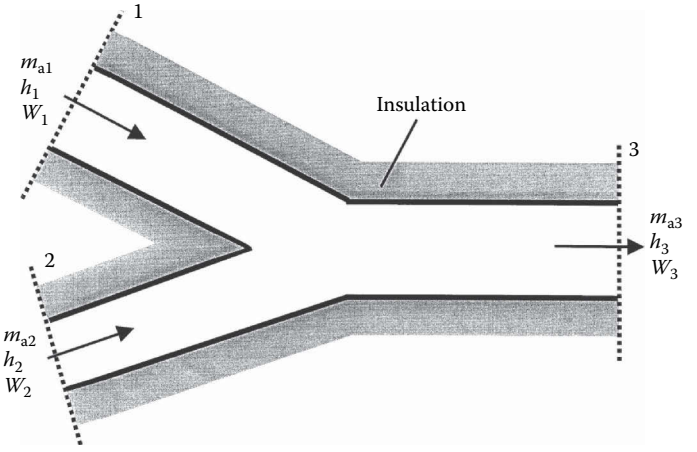

FIGURE 4.15.5 Adiabatic mixing of two streams of moist air.

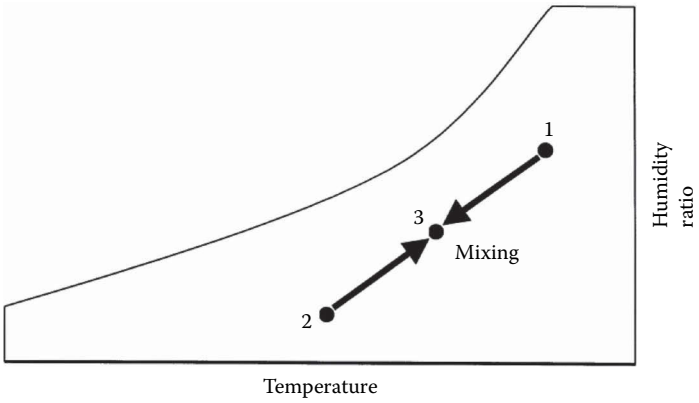

FIGURE 4.15.6 Adiabatic mixing of two streams.

of the specific heats for the moist air, is typically less than 1%. Consequently, the exit condition of the moist air lies on a straight line connecting the two entering conditions, or that

$$\frac{\dot{m}_{a2}}{\dot{m}_{a1}} \cong \frac{\text{distance (1) to (3)}}{\text{distance (2) to (3)}}. \tag{4.15.31}$$

Figure 4.15.6 shows the adiabatic mixing process path on a schematic of the psychrometric chart. The above three equations may also be combined to give

$$\frac{\dot{m}_{a2}}{\dot{m}_{a1}} = \frac{h_3 - h_1}{h_2 - h_3} = \frac{W_3 - W_1}{W_2 - W_3} \cong \frac{T_3 - T_1}{T_2 - T_3}. \tag{4.15.32}$$

Example

Consider the mixing of two streams of moist air where one entering stream has a volumetric flow rate of 5000 cfm with a 40°F dry-bulb temperature and a 35°F wet-bulb temperature. The other inlet stream has a volumetric air flow rate of 15,000 cfm with 75°F dry-bulb temperature and 50% relative humidity. Determine the exit conditions for the leaving air stream.

Solution:
Label the 5000 cfm air stream as "1" and the 15,000 cfm stream as "2." The exit stream is labeled as "3." From the psychrometric chart, Figure 4.15.1, the following information is observed:

$$v_1 \cong 12.65 \text{ ft}^3/\text{lb}, h_1 \cong 14.0 \text{ Btu/lb},$$

$$v_2 \cong 13.68 \text{ ft}^3/\text{lb}, h_2 \cong 28.0 \text{ Btu/lb}.$$

Thus,

$$\frac{\dot{m}_{a1}}{\dot{m}_{a2}} = \frac{\dfrac{\dot{V}_1}{v_1}}{\dfrac{\dot{V}_2}{v_2}} = \frac{\dfrac{5000}{12.65}}{\dfrac{15000}{13.68}} = 0.3605$$

$$0.3605 = \frac{h_3 - h_2}{h_1 - h_3} = \frac{h_3 - 28.0}{14.0 - h_3}$$

$$h_3 = 24.3 \text{ Btu/lb}$$

and from the psychrometric, observe that T_3 is approximately 66°F.

Example

Consider the air-conditioned space shown in Figure 4.15.7, where moist air leaves at 80°F dry-bulb and 65°F thermodynamic wet-bulb temperatures. Due to human occupancy, the moisture gain to the space occurs at the rate of 10.5 lb/h as saturated water vapor at 90°F. The space also has a sensible gain of 20,000 Btu/h. Moist air is introduced into the space at 55°F. Estimate the needed thermodynamic wet-bulb temperature and the volumetric flow rate of the supply air.

Solution:
The sensible heat gain does not involve any heat transfer due to changes in moisture content of the air. The water vapor added to the space adds energy equal to its specific enthalpy. The governing equations involve air, water, and energy balances

$$\dot{m}_{a1} = \dot{m}_{a2} = \dot{m}_a,$$

$$\dot{m}_{a1} W_1 + \dot{m}_w = \dot{m}_{a2} W_2,$$

$$\dot{m}_{a1} h_1 + \dot{m}_w h_w + q_s = \dot{m}_a h_2,$$

where q_s is the added sensible energy, $m_w\, h_w$ is the latent load due to the moisture content change, and $\dot{m}_a$ is the dry air flow rate entering and leaving the space. Rewriting the energy balance gives

$$q_s + \dot{m}_w h_w = \dot{m}_a (h_2 - h_1)$$

and rearranging the water balance yields

$$\dot{m}_w = \dot{m}_a (W_2 - W_1).$$

Compute the ratio:

$$\frac{\text{Total energy added to space}}{\text{Total water added to space}} = \frac{q_s + \dot{m}_w h_w}{m_w}$$

$$= \frac{\dot{m}_a (h_2 - h_1)}{\dot{m}_a (W_2 - W_1)} = \frac{\Delta h}{\Delta W},$$

where the ratio is observed to also equal the enthalpy change divided by the humidity ratio change. A protractor on the psychrometric chart (Figure 4.14.8) shows the slopes associated with

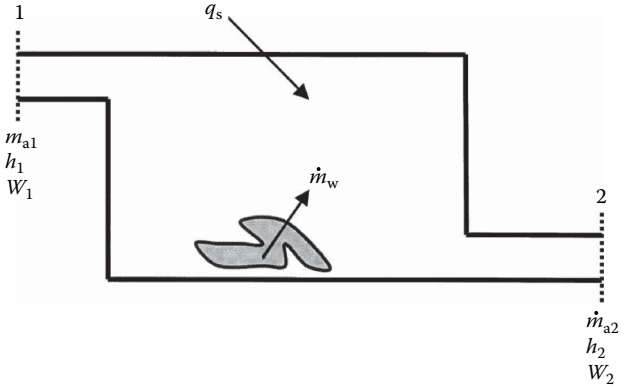

FIGURE 4.15.7 Schematic diagram of an air-conditioned space.

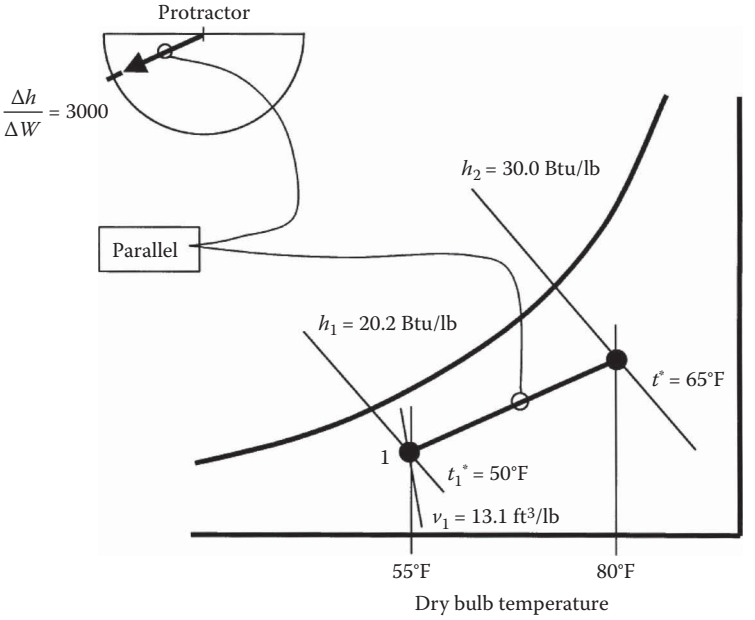

FIGURE 4.15.8 Schematic of the psychrometric chart for an air-conditioned space.

the direction that this process takes on the chart. All the possible supply air conditions lie on this line. From the saturated water thermodynamic property tables, $h_w = 1100.4$ Btu/lb. Thus,

$$\frac{\Delta h}{\Delta W} = \frac{20{,}000 + (10.5)(1100.4)}{10.5} = 3005 \cong 3000.$$

Draw a line through state "2" at a slope equal to $\Delta h/\Delta W = 3000$. Where this line intersects the supply dry-bulb temperature identifies the wet-bulb temperature, which is approximately 50°F. To obtain the volumetric flow rate at state "1," first calculate the mass flow rate:

$$\dot{m}_a = \frac{q_s + \dot{m}_w h_w}{(h_2 - h_1)}.$$

Estimate from the psychrometric chart that $h_1 = 20.2$ Btu/lb (dry air) and $h_2 = 30.0$ Btu/lb (dry air). Thus,

$$\dot{m}_a = \frac{20{,}000 + (10.5)(1100.4)}{(30.0 - 20.2)} = 3220 \frac{\text{lb(dry air)}}{\text{h}} \text{ or } 53.7 \frac{\text{lb(dry air)}}{\text{min}}.$$

The volumetric flow rate is

$$\dot{V}_1 = \dot{m}_a v_1$$

and from the psychrometric chart, $v_1 = 13.1$ ft³/lb (dry air). Thus,

$$\dot{V}_1 = (53.7)(13.1) = 703 \frac{\text{ft}^3}{\text{min}}.$$

Thermal Comfort Conditions

The now widely accepted definition for human comfort is "that condition of mind that expresses satisfaction with the thermal environment" (ANSI/ASHRAE *Standard 55* 2010). Thus, the quantification of human comfort is nebulous in that a person's feelings are important. A number of inside

environmental conditions influence human thermal comfort and include dry-bulb temperature, wet-bulb temperature, dew-point temperature, humidity ratio, air velocity, and the mean radiant temperature. The mean radiant temperature is a representative temperature for all the individual surfaces that exist in the occupied space. The amount and type of clothing affects human comfort. Furthermore, several environmental temperature indices are used to assist with the quantification of thermal comfort. These indices are equivalent temperature, effective temperature, humid operative temperature, the globe temperature, and the resultant temperature, which is applied sometimes in the United Kingdom. As an example of one of these temperature indices, the human operative temperature T_{oh} is the temperature when 100% relative humidity yields the same total heat loss from the skin as would occur for the actual environment (ASHRAE, 2017). Specifically,

$$T_{oh} = T_o + wi_m LR(p_v - p_{oh,s}), \tag{4.15.33}$$

where T_0 is the operative temperature, w is the wet skin fraction, i_m is the moisture permeability index, LR is the Lewis relation, p_v is the partial pressure of water vapor, and $p_{oh,\,s}$ is the saturated vapor pressure at T_{oh}. The operative temperature is given by

$$T_o = \frac{h_r T_{mr} + h_c T_a}{h_r - h_c} \tag{4.15.34}$$

and the Lewis relation is given by

$$LR = \frac{h_e}{h_c}, \tag{4.15.35}$$

where h_c is the convective heat transfer coefficient, h_r is the linearized radiative heat transfer coefficient, h_e is the evaporative heat transfer coefficient, T_{mr} is the mean radiant temperature of surfaces in the space, and T_a is the space air temperature. Note that the operative temperature is the average of the mean radiant and air temperatures weighted by their respective heat transfer coefficients. While these equations and definitions reveal the complexities associated with quantifying human comfort parameters, additional details are needed to make calculations. Refer to the ASHRAE *Handbook of Fundamentals* (2017) for more information.

ANSI/ASHRAE Standard 55 (2010) defines comfort zones, which specify the conditions for reasonable comfort for human occupants either sedentary or slightly active. These comfort zones carefully incorporate the results obtained through research and are different for winter and summer due to the clothing typically worn during these periods. The boundaries of the comfort zones are not sharp, with the upper and lower humidity levels being less precise than the left and right boundaries associated with temperature. Indoor conditions of temperature and humidity for the conditioned space are usually selected to comply with the ANSI/ASHRAE Standard 55 (2010) limits. The specific influence of humidity on human comfort is explored in greater detail by Berglund (1995).

Several models have been reported in the literature that predict the level of thermal comfort that is likely to occur in a given situation and space. Fanger (1982) developed a predictive method based on a steady-state energy balance and Gagge (1971, 1986) devised a two-node model suitable for predicting steady-state human comfort responses. Multisegment models divide the human body into more segments consisting of the head, chest, hands, and feet along with additional tissue layers, so that thermal comfort in spaces with nonuniform conditions may be predicted (Huizenga et al., 2001; Fiala et al. 2003; Zhang et al. 2010 among others). These predictive models are summarized in ASHRAE (2017).

Load Calculations

In the context of HVAC (heating, ventilating, and air conditioning), the term load is applied to a building to designate the thermal energy removal or addition rate needed to maintain the desired

inside air conditions. For summer months, the removal of thermal energy from the space is required, typically performed by a refrigeration system. Spaces during winter months generally require the addition of thermal energy to maintain the desired inside conditions. Both summer cooling and winter heating involve systems accomplishing the conditioning of the inside air. While the phrase "thermal energy" is technically correct for explaining the air warming and cooling processes, it is common in the industry to use the term "heat" to refer to this energy. The discussion here follows the industry practice of using the term heat.

For cooling loads originating from human comfort requirements in buildings, the absorption of solar radiation into the space is significant. Special procedures have been developed by ASHRAE to accurately predict cooling loads. The current procedures (Pederson et al., 1998; Spitler 2009; Spitler 2014) are improvements of earlier methods (ASHRAE, 1975; McQuiston and Spitler, 1992). The cooling load is a transient phenomenon—the heat transfer rate through the space envelope varies with time. An enclosed space where the interior temperature is controlled by a single thermostat is usually referred to as a zone. A large nonresidential building may be composed of many zones sharing walls between them.

The heat balance concept is essentially the application of a control volume around a zone of a building. To be specific, a heat balance zone is an air volume, uniform in temperature, which also includes all the heat transfer and thermal storage surfaces bounding or inside the air volume. While the concept of a zone originates with the thermal behavior of the space, several rooms may comprise a zone. Family residential buildings are usually treated as being one zone. Observe that the wall treatments on the interior surfaces and the furnishings characterize the heat balance zone. The typical zone is a 12-surface volume that is used in determining loads where complex geometry of an actual building is reduced to a simple shape accurately duplicating the zone's thermal features. The important information includes the following:

- Orientation of each surface and configuration area
- Construction features of each surface
- Outside and inside surface environmental conditions

The heat balance approach to load calculations necessitates the use of a digital computer. While it is possible to perform approximate load calculations (more so with the heat load), it is now considered impractical due to the prevalent accessibility of computers.

The migration of moisture through the materials comprising the building's envelope is of concern as well. The accumulation of moisture within the walls of a structure must be avoided to maintain structural integrity, insulating capacity, and indoor air quality. The growth of molds and other biological items are accelerated by the presence of trapped moisture in walls, which in turn degrade the interior air quality. Hosni et al. (1998) have investigated this subject concerning the special concerns that result from high moisture climates such as southern Texas in the U.S. Additionally, Burch and Chi (1997) have developed a moisture migration model, used and partially experimentally verified by Hosni et al. (1998), quantifying the water migration rates in wall structures. The transport of heat, air, and moisture in building material assemblies is further discussed by ASHRAE (2017).

Cooling Load

The cooling load associated with a zone is difficult to accurately predict. For this reason, ASHRAE has continued to improve the available methods (ASHRAE, 2017) for the prediction of cooling load. The use of the heat balance concept, developed by Pederson et al. (1998) and subsequently improved by Spitler (2009, 2014), has simplified the calculation procedures while maintaining adequate accuracy. This is accomplished by performing four heat balances as described below. The cooling load calculations are sufficiently complex that digital computing machines are needed to make the calculations.

Heat Balance on Outside Surface

A heat balance applied to the outer surface of an exterior wall includes three sources of heat: direct and diffuse radiation from the sun (shortwave radiation), radiation from the environment (longwave radiation), and convection heat transfer. The heat balance on the outside surface is

$$q''_{\text{asol}} + q''_{\text{lwr}} + q''_{\text{co}} - q''_{\text{ko}} = 0, \tag{4.15.36}$$

where q''_{asol} is the absorbed direct and diffuse solar radiant heat flux (Btu/h ft^2), $q''_{\text{lwr}}$is the net longwave radiant flux from the air and objects surrounding the outside surface, $q''_{\text{co}}$is the convective heat flux from the air to the surface, and q''_{ko} is the conductive heat flux leaving the surface entering the wall material. All the heat transfer terms are positive with the exception of the conduction term. Inside the wall, the temperature gradient is negative causing the conduction heat flux term to be positive. The solar radiation, longwave radiation, and convection heat fluxes are sometimes combined using a procedure resulting in the sol–air temperature (ASHRAE, 2017). However, ASHRAE's implementation of the heat balance method involves straightforward models for solar, environmental, and outside convection to determine the outside surface heat balance (ASHRAE, 2017).

- q''_{asol} is determined by procedures identified by ASHRAE *(Handbook of Fundamentals,* 2017).
- q''_{lwr} is estimated using the traditional radiant energy exchange models between surfaces. ASHRAE provides guidance giving values for the sky temperature, ground temperature, surface temperature, surface absorptance, and ground view factors.
- q''_{co} is calculated using Newton's law of cooling where the temperature difference between the outside air and outside surface temperature is given by

$$q''_{\text{co}} = h_{\text{co}}(T_{\text{air}} - T_{\text{os}}), \tag{4.15.37}$$

where h_{co} is the outside convection heat transfer coefficient dependent on the velocity of the air next to the surface, and the T_{air} and T_{os} are temperatures of the outside air and outside surface.

The required outdoor conditions are the dry-bulb and the wet-bulb temperatures. The ASHRAE *Handbook of Fundamentals* (2017) shows these temperatures for a number of locations throughout the U.S. and the world. Cooling design day dry- and wet-bulb temperatures for numerous geographical locations are compiled from weather data. Summer climatic data are based on hourly weather observations over at least a 12-year period. The summer month conditions are reported on the basis of 0.04, 1.0, and 2.0 annual percentiles. These annual percentiles represent, respectively, 35, 88, and 175 h from a year of 8760 h. Typically, July 21 in the Northern Hemisphere is taken as the summer design day.

Interior Wall Conduction

Heat conduction through the material comprising the wall may be determined in several ways. Prevalent methods now include numerical finite difference, numerical finite element, transform methods, and time series methods. All of these methods introduce a time-dependent feature into the cooling load calculation where the inside surface and outside surface temperatures and heat transfer rates are time dependent. Direct analysis of the heat transfer has inputs consisting of two temperature functions and outputs consisting of the two heat fluxes. While any of the four mentioned methods yield usable results, Pederson et al. 1998 and Spitler (2014) employ a conduction transfer function (CTF) procedure for reasons of adequate generality and good computation speed. The CTF factors in this formulation may be considered as response factors associated with the wall.

Heat Balance on Inside Surface

A heat balance on the inside surfaces involves four heat transfer terms: conduction through the wall material, convection to the inside air, shortwave radiant absorption and reflection, and longwave radiant exchange. The heat balance on the inside surface is

$$q''_{ki} + q''_{lwx} + q''_{sw} + q''_{lws} + q''_{sol} + q''_{ci} = 0, \tag{4.15.38}$$

where

q''_{ki} = the conduction heat flux to the inside surface from the interior of the wall material
q''_{lwx} = the net longwave radiant flux between the zone surfaces which involves emittance and absorption from all surfaces in the zone space
q''_{sw} = the net shortwave radiant flux to the inside surface from lights
q''_{lws} = the longwave radiant heat flux from the equipment in the zone
q''_{sol} = the transmitted solar radiation flux absorbed at the inside surface
q''_{ci} = the convective heat flux from the surface to the interior air in the zone

A common approximation used in cooling load calculations, also used by Spitler (2014), is to treat the air as completely transparent to longwave radiation.

Furnishings that may be present inside the zone influences the time response characteristics of the space. This influence is complicated to quantify and is under investigation. The furniture in a space adds surface area which participates in the radiant and convective heat exchange processes tending to reduce the time response. On the other hand, the furnishings also add thermal mass to the space, which increases the time response of the space. The inside surface heat balance permits these two features to be accommodated in a reasonable fashion in that both the surface area and the thermal mass are included in the heat transfer processes.

The longwave radiation from internal sources is traditionally estimated by establishing a division between the radiation and the convection heat transfer for the heat that originates from the equipment. The portion assigned to radiation is then distributed among the surfaces in a reasonable manner (ASHRAE, 2017). While this approach is awkward and deviates from the heat balance approach, it is practical in that it avoids the specification of location and temperature of all equipment in the space. The shortwave radiation from the lights and the transmitted solar energy is also distributed to the surfaces in the space in a reasonable manner (ASHRAE, 2017).

The convective heat flux from the inside surface is calculated using Newton's law of cooling:

$$q''_{ci} = h_{ci}(T_a - T_{is}), \tag{4.15.39}$$

where h_{ci} is the inside surface convective heat transfer coefficient, T_a is the zone air temperature, and T_{is} is the inside surface temperature. Numerical values for h_{ci} are available (ASHRAE, 2017), but are based on carefully controlled natural convection experiments. Present-day conditioned spaces are mechanically ventilated, suggesting that the actual inside surface convective heat transfer coefficients may be somewhat different.

Inside Air Heat Balance

The thermal capacitance is generally neglected for the heat balance applied to the air in the space. With this simplification, the air heat balance is performed on a quasi-steady basis for each calculation time increment. The four heat transfers associated with the heat balance are

$$q_{ci} + q_{ce} + q_{iv} + q_{sys} = 0, \tag{4.15.40}$$

where q_{ci} is the heat transfer rate from the surfaces in the zone, q_{ce} is the convection heat transfer rate originating from the internal loads, q_{iv} is sensible load from the infiltration of outside air, and

q_{sys} is the heat transfer to the HVAC system. The convection from the internal surfaces is obtained by summing the contributions from each surface:

$$q_{ci} = \sum_{i=1}^{n} h_{ci} A_i (T_a - T_{is}), \tag{4.15.41}$$

where n is the number of surfaces in the space, h_{cl} is the convection heat transfer for surface "i," A_i is the surface area "i" from which the heat transfer q_{ci} occurs, T_{is} is the temperature of surface "i," and T_a is the inside air temperature. The convection heat transfer from the internal loads q_{ce} is simply added to the heat balance on the air in the space.

This is not strictly correct because the temperatures of these surfaces that produce the internal loads actually add the heat to the air by convection. Unfortunately, this is very difficult to incorporate in the heat balance calculation because the detailed information necessary is usually not obtainable. With the air heat balance, any air that enters the space from the outside is assumed to mix instantaneously with the inside air. The ASHRAE *Handbook of Fundamentals* (2017) presents the latest information on the methods available for estimating the air infiltration rate. Sometimes, the infiltration rate is converted to a parameter equal to the number of air changes per hour (ACH) which would be included in the air heat balance applying the outside air temperature for that time increment (McQuiston et al., 2005).

Heating Load

Air conditioning of a space usually includes the design of a heating system. The heating system provides thermal energy that is then delivered to the space, maintaining the desired space temperature. Additionally, moisture may be added to maintain the relative humidity within acceptable limits.

The actual design of the heating system is dependent on the largest expected heat loss from the space to be heated. If the space is comprised of multiple spaces, each separately controlled by a thermostat, the heat loss is the sum of the largest individual heat losses for each space. Contributions to the heat loss include the following:

- Heat transfer through walls, floor, ceiling, glass, and all other surfaces
- Heat needed to warm the air from the outside entering the heated space
- Heat required to warm or thaw materials brought into the space

The outdoor temperature, wind velocity, and sunlight vary with time which causes the heat loss rate from the space to also vary with time. However, when determining the heat loss rate, or heat load, the outside temperature is selected as a design temperature originating from climatic data for that location. During winter, the coldest days are typically those that involve cloudy and stormy weather where the outdoor temperature has been noted to remain fairly constant. As a consequence, the heat loss rate from the space is also nearly constant. This is especially true when the internal heat gains are small. For this reason, the design heat load is determined on the basis of steady-state heat transfer and one-design outdoor temperature.

The heating system, as regulated by the thermostat, provides only the quantity of heat required to replace the heat that is lost. As the weather conditions change, the amount of heat supplied will vary. The heating system is not designed to withstand the most severe weather conditions ever recorded. To do so would result in a heating system that would rarely operate at full capacity. Rather, it is considered acceptable to not meet the inside temperature requirement for short periods of time. Consequently, the design outdoor temperature and the thermal characteristics of the zone govern the heat load for the space. A related activity is to estimate the energy consumed by the heating system over a year. To do this, simulation studies are made using hourly weather conditions where the heat

loss is then estimated on an hourly basis. The sum of all the hourly heat losses over the heating season is the annual energy consumption needed to heat the space.

Many thermostats incorporate a temperature setback feature to reduce the energy consumption of the heating system. The temperature is lowered several degrees at night and raised during the day when the space is occupied. It turns out that the early morning hours is the time when the heat load is the largest. Additionally, the morning time is typically when the thermostat calls for increasing the temperature. As a consequence, the heating system may need considerable time to meet the indoor temperature demand, during which time the occupants may experience discomfort. The time interval needed to warm the space after thermostat setback may be estimated using the heat balance method (Spitler, 2014).

The determination of the heat load assumes that no solar energy enters the space, internal heat gains are negligible, and the outdoor and indoor temperatures are constant. The calculation of the design heat load from a space is as follows:

1. Choose outdoor design conditions: temperature, humidity, wind direction, and wind speed.
2. Choose indoor design conditions.
3. Determine temperatures in any adjacent unheated spaces, if any.
4. Choose the heat transmission coefficients and calculate the heat loss rates for the walls, floors, ceilings, glass, doors, and all other surfaces where heat is transferred to the outside.
5. Calculate the heat load resulting from the infiltration of air and all other outdoor air entering the space.
6. Sum all the contributions to the heat load from transmission and infiltration.

Outdoor Design Conditions

Heating design day dry- and wet-bulb temperatures along with wind speed for numerous geographical locations are compiled from recent climatic data by ASHRAE's *Handbook of Fundamentals* (2017). Winter climatic data are based on hourly weather observations over at least a 12-year period. Winter month conditions are reported on the basis of 99.6 and 99.0 annual percentiles. These annual percentiles represent, respectively, 35 and 88 h from a year of 8760 h. For example, Wichita, KS has a heating dry-bulb temperature equal to 7.4°F at the 99.6 percentile, which means that for 35 h out of the year the temperature is likely to be below 7.4°F. Other climatic data, if available for a particular condition, suggesting lower dry-bulb temperatures and/or higher wind velocities should be considered in selecting the design conditions.

Indoor Design Conditions

Generally, the design dry-bulb temperature is chosen from the lower portion of the acceptable range, therefore preventing oversizing of the heating system. A heating system operating at conditions less than the design load does so at less efficiency. For this reason, a heating design dry-bulb temperature equal to 70°F is usually chosen. The relative humidity level is typically set at a maximum value of 30% to provide, on the one hand, a healthy environment, while on the other hand assure moisture integrity of the building's envelope.

Heat Transmission Loss

Heat transfer through all the building envelope materials comprising the walls, ceiling, roof, floors, windows, and doors is sensible and is calculated using

$$q = UA(T_i - T_0), \tag{4.15.42}$$

where U is the overall heat transfer coefficient or U-factor (Btu/h ft^2 °F), A is the normal surface area through which the heat transfer passes (ft^2), T_i is the inside design temperature (°F), and T_0 is the outside design temperature (°F). The U and A values are generally different for walls, ceilings,

roofs, and windows and so separate calculations are needed for each. Heat transmission loss through floor slabs and below-grade walls is determined using

$$q = U_s P(T_i - T_0), \tag{4.15.43}$$

where U_s is the overall heat transfer coefficient based on the slab perimeter (Btu/h ft^2 °F) and P is the slab perimeter (ft). Approximate numerical values for U_s are given by ASHRAE (2017).

Infiltration

Every building envelope leaks inside air to the outside due to pressure differences between the inside and outside air. This results in a winter heat loss because the air that is lost is replaced by cold outside air. The load on the heating system is dependent on the amount of heat needed to warm the infiltrated outside air to the inside design temperature and on the moisture added to raise the humidity to the indoor design condition. The sensible heating load is determined by

$$q_s = c_p \dot{V} \rho (T_i - T_0), \tag{4.15.44}$$

where c_p is the specific heat of the air (Btu/lb °F), $\dot{V}$ is the volumetric flow rate of air entering the building (ft^3/h), and ρ is the air density at temperature T_0 (lb/ft^3). The volumetric air flow rate entering the building depends on the wind speed and direction and on the size, among other factors, of the openings through which the infiltration air passes. The ASHRAE *Handbook of Fundamentals* (2017) carefully explains the determination of the volumetric flow due to infiltration. The latent heat loss due to infiltration is given by

$$q_l = \dot{V} \rho (W_i - W_o) h_{fg}, \tag{4.15.45}$$

where ρ is the air density at temperature T_i (lb/ft^3), W_i is the indoor air humidity ratio, W_o is the outdoor air humidity ratio, and h_{fg} is the latent heat of vapor at temperature T_i (Btu/lb).

Infiltration also occurs during summer cooling where warm moist air enters the building providing both sensible and latent loads. Calculation procedures are similar to those applied for winter infiltration.

Air Distribution System Heat Losses

When the ducts conveying warm air pass through spaces outside the conditioned space, heat losses will occur. The heat loss from supply air ducts contributes to the load for the space. While these losses may be reduced by insulating the duct, the heat loss cannot be completely eliminated. The heat loss through a duct may be estimated by

$$q = U A_s \Delta (T_a - T_u)_m, \tag{4.15.46}$$

where U is the overall heat transfer coefficient (Btu/h ft^2°F), A_s is the outside surface area of the duct (ft^2), $\Delta(T_a - T_u)_m$ is the mean temperature difference between the air in the duct, T_a and the temperature of the unconditioned space outside the duct, T_u. For a relatively short duct that is overlaid with 1 or 2 in. of insulation and covered with a reflective material, the mean temperature difference may be approximated by the simple difference between the supply air temperature and the unconditioned space temperature. In the HVAC industry, designers typically assume a duct heat loss equal to 2%–5% of the sensible load of the conditioned space.

Auxiliary Heat Gains

Within a conditioned space, numerous sources of heat may exist. Examples of common heat sources are lights, motors, machinery, and people. Usage patterns of equipment and people occupancy levels

influence the magnitude of the auxiliary heat gain rate. However, as a practical matter, auxiliary heat gains are ignored in those situations where the contribution to the total load is small. An exception is an industrial space where equipment, lighting, and occupancy may result in a significant heat gain. ASHRAE (2017) provides guidance in assessing the contributions from a number of auxiliary sources.

The ASHRAE *Handbook of Fundamentals* (2017) gives specific procedures for space heat load predictions for both residential and nonresidential buildings. The heat losses that occur through residential building slabs, crawl spaces, attics, and the like are well characterized. With nonresidential buildings, ASHRAE provides the latest information on auxiliary heat gains that may be helpful for an accurate prediction of the space heat load.

Refrigeration

The refrigeration system, sometimes called a heat pump, is the equipment in the HVAC system that provides the cooling for the indoor space. Refrigeration is applied to many fields all sharing the need for a source of low temperature. The application of refrigeration to air conditioning involves the removal of heat from the space, thereby maintaining the desired inside temperature. The refrigeration system accomplishes the absorption of heat from the conditioned space by maintaining a surface in the space at a temperature lower than that of the space. Two refrigeration system types are prevalent in air conditioning: the vapor compression system and the absorption system. The vapor compression system is available and popular in sizes applicable for single rooms to those appropriate for large commercial buildings composed of many individual zone spaces.

The capacity of a refrigeration system may be given in terms of kW or Btu/h. However, by tradition dating back to the early 1800s when ice was harvested for use during the summer in the United States, the term "ton of refrigeration" was used. It is still used today. A one-ton refrigeration plant has the capacity to produce one ton of ice per day (24 h). The latent heat of ice is 144 Btu/lb and so the capacity of a one-ton plant is equivalent to 12,000 Btu/h or 200 Btu/min.

A measure of a refrigeration system's performance is called the coefficient of performance or COP, defined by

$$\mathrm{COP} = \frac{\text{useful refrigerating rate}}{\text{net energy input rate}}. \tag{4.15.47}$$

Another measure is the refrigerating efficiency, η_R which is the ratio of the system's actual COP to that system's ideal COP,

$$\eta_R = \frac{\mathrm{COP}}{(\mathrm{COP})_{\mathrm{ideal}}}. \tag{4.15.48}$$

The operating power input of the refrigeration system relative to the refrigerating rate or "effect" is useful when comparing refrigeration equipment of different capacities. A common parameter is the horsepower per ton, given by

$$\mathrm{hp/ton} = \frac{4.715}{\mathrm{COP}}. \tag{4.15.49}$$

Carnot Refrigeration Cycle

The Carnot cycle is a theoretical cycle that is useful because no cycle can be constructed operating under the same temperature conditions with a greater operating efficiency. All the processes in the Carnot cycle are thermodynamically reversible (i.e., all the heat transfers occur at zero temperature difference, no friction occurs in any of the components). This cycle consists of two isothermal processes and two adiabatic processes. The Carnot refrigeration cycle appears as a rectangle

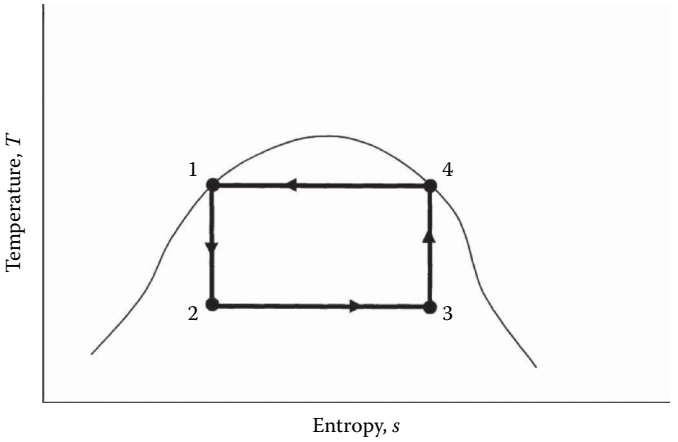

FIGURE 4.15.9 Temperature–entropy diagram for the Carnot refrigeration cycle.

on a temperature-entropy diagram shown in Figure 4.15.9. Observe that the cycle moves through the processes in a counterclockwise direction. Heat absorption occurs during the process occurring between points "2" and "3" and that heat rejection occurs between points "4" and "1." Heat absorption takes place in or adjacent to the space kept cool and heat rejection is made at a location outside the conditioned space. The expansion process identified as process "1" to "2" is adiabatic resulting in a temperature decrease. The compression process, process "3" to "4," is also adiabatic resulting in a temperature increase. Also, note that the expansion process extracts work partially offsetting the compression work. The COP for the Carnot cycle is

$$\text{COP} = \frac{T_c}{T_h - T_c}, \tag{4.15.50}$$

where T_c is the cold temperature and T_h is the hot temperature. The hot temperature is the temperature of the surrounding environment to which the heat is rejected.

Figure 4.15.9 also shows the saturated liquid and vapor lines for the working fluid used in the Carnot refrigeration cycle. The heat absorption and rejection processes represented by horizontal lines in the diagram may be achieved by working fluids undergoing a phase change. This cycle, however, is not practical for two important reasons. The compression process, from "3" to "4," occurs with liquid entering the suction side (inlet) of the compressor. The liquid, if allowed to enter the compressor, will cause very severe damage. The other reason involves the expansion process from "1" to "2." Here, the Carnot cycle requires that work be extracted from the working fluid as it expands, flashing into a mixture of vapor and liquid. One development capable of extracting work from the expansion of the refrigerant is an expander specially developed to operate in the wet expansion region is reported by Brasz (1995). Other approaches to improving the vapor compression cycle efficiency by energy recovery from the expansion process are summarized by Minh et al. (2006). The Carnot cycle remains important as a conceptual cycle in that it serves as a standard by which other cycles may be compared. No refrigeration cycle may have an efficiency greater than that of the Carnot cycle operating between the same cold and hot temperatures.

Vapor Compression Cycle

A practical refrigeration cycle is the vapor compression cycle which consists of the four components shown in Figure 4.15.10. The expander in the Carnot cycle, process "1" to "2," is replaced by an expansion device. Generally, an expansion device is a valve providing a restriction to the flow of

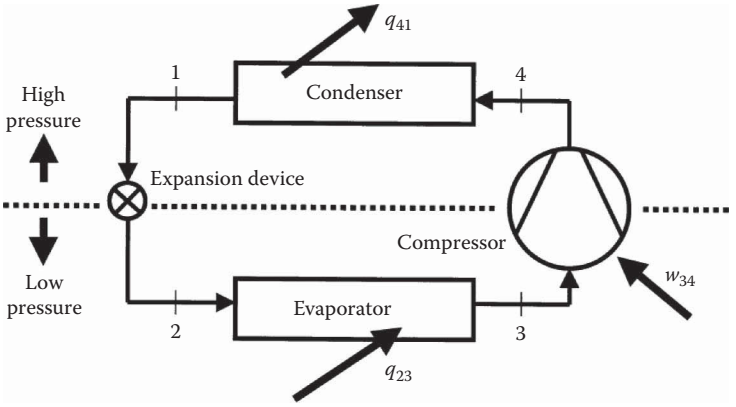

FIGURE 4.15.10 Components for the basic vapor compression refrigeration cycle.

liquid refrigerant. The compressor applied to the process from "3" to "4," operates at a rate sufficient to pump the low-pressure vapor from the evaporator to a high-pressure vapor capable of condensing in the condenser. Thus, the regulation of refrigerant flow to the evaporator by the expansion valve and the pumping action of the compressor involves a cycle with a "low-pressure side" and a "high-pressure side."

An ideal vapor compression cycle operates at the conditions revealed by the pressure-enthalpy diagram shown in Figure 4.15.11. The refrigerant leaving the condenser at state "1" is a saturated liquid. With the sudden pressure drop in the expansion valve, the refrigerant is a saturated mixture of liquid and vapor entering the evaporator. As the liquid refrigerant boils inside the evaporator, it absorbs heat. Only saturated vapor leaves the evaporator and enters the compressor. In this way, no liquid enters the compressor, thereby assuring long life. Ideal or isentropic compression of the refrigerant vapor takes place in the compressor, where the vapor is superheated at the discharge of the compressor. The saturation temperature corresponding to the discharge pressure must be greater than the temperature of the air or water to which the heat from the condenser is rejected. In the condenser, desuperheating occurs first; next, the vapor is condensed to a liquid. In an ideal condenser, no subcooling occurs and so the liquid leaves the condenser as saturated liquid at the condensing pressure. Furthermore, no pressure drop occurs in any of the piping transporting the refrigerant

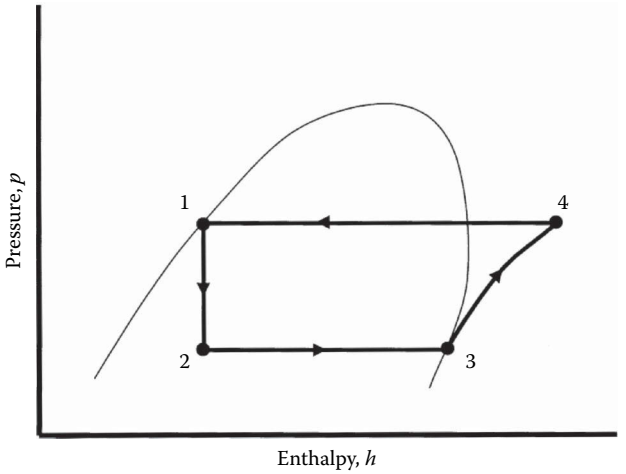

FIGURE 4.15.11 Pressure–enthalpy diagram for the vapor compression refrigeration cycle.

between the components nor in the evaporator and condenser. Only two pressures exist in an ideal vapor compression cycle: low and high pressure. The COP for the vapor compression cycle may be computed using the following relationships:

$$q_{23} = h_3 - h_2, \tag{4.15.51}$$

$$w_{34} = h_4 - h_3, \tag{4.15.52}$$

$$q_{41} = h_1 - h_4, \tag{4.15.53}$$

$$q_{23} + w_{34} + q_{41} = 0, \tag{4.15.54}$$

$$\text{COP} = \frac{h_3 - h_1}{h_4 - h_3}, \tag{4.15.55}$$

where q represents heat transfer, w the input of work to the compressor, and h the thermodynamic property enthalpy.

In reality, there is some pressure drop in the piping connecting the components and in the evaporator and condenser as well. Pressure drop in the piping represents a loss and a departure from the ideal cycle. Pressure drop in the evaporator causes a "glide" or change in the temperature of the boiling liquid as it progresses through the evaporator. Typically, depending on the particular refrigerant in use, the glide may be several degrees Fahrenheit. A similar situation would occur in the condenser. The design of vapor compression refrigeration cycles requires the estimation of the pressure losses in the piping. Information on these pressure drops is given in the ASHRAE *Handbook of Refrigeration* (2014). For the most part, single-component refrigerants (i.e., R-134a) do not exhibit a significant glide in conventional systems. However, refrigerants consisting of blends of chemicals may have larger glides in temperature and may require accommodation of this feature to accurately predict the performance of the cycle.

Estimation of an actual cycle's performance may be based upon consideration of an ideal cycle operating between the same temperatures but having an isentropic efficiency representing actual compressor performance (Stoecker, 1998). Actual compressor isentropic efficiencies typically fall in the range from 70% to 80%. However, the subcooling that may occur in the condenser, the superheat at the exit of the evaporator, and the pressure drops in the piping may be readily accounted for in cycle performance calculations when thermodynamic tables of the refrigerant are available. The ASHRAE *Handbook of Fundamentals* (2017) and NIST (2016) are sources of thermodynamic property data for a number of refrigerants.

Compressors

The compressor is one of the four basic components of the vapor compression cycle. The compressor has two important functions in the cycle: to increase the pressure of the refrigerant vapor from the evaporator so that it will condense, and to maintain the low-side pressure. The evaporator and condenser are heat exchangers facilitating the heat transfer in conjunction with a phase change of the refrigerant. The performance and design of heat exchangers are covered in detail on the heat transfer sections of this handbook.

Compressors fall into two main categories based on their operating principles. These are the positive displacement compressor and the aerodynamic, or more simply, the dynamic compressor. With the positive displacement compressor, the vapor enters the suction port and is subsequently geometrically trapped. The decreasing volume of the trapped vapor due to the expenditure of work causes the compression process to occur. In the dynamic compressor, the vapor enters the suction port whereupon the pressure of the vapor increases as a result of the high rotating velocity which produces a large centrifugal force.

Reciprocating Compressors

The reciprocating compressor is a common positive displacement compressor in the refrigeration industry manufactured in power input capacities from one-tenth of a horsepower to over several hundred horsepower. Compression is achieved by a reciprocating piston inside a cylinder along with the alternate opening and closing of suction and discharge valves. The smaller-capacity compressors are generally single-cylinder units and the large machines use multiple cylinder arrangements where the in-line, *V*, *W*, and radial configurations are available. Figure 4.15.12 is a diagram of a typical single-cylinder reciprocating compressor.

When the compressor is driven by an electric motor, several configurations are available. One is the "open-type compressor" where the crankshaft protrudes out from the compressor's housing. The motor is externally coupled to the compressor shaft. Another configuration is the "hermetically sealed compressor" where the compressor is inside a sealed container. The hermetic compressor is prevalent in small electrically driven units applied to residential air conditioners and smaller commercial units. The hermetic compressor has only the suction line, the discharge line, and the electrical power cable passing through the container's shell or "can." The absence of moving parts provides for a long-term and reliable seal. Another configuration is the "semihermetic compressor," which is identical to the hermetic compressor except that the cylinder heads are accessible for maintenance.

Performance characteristics of the reciprocating compressor include the following:

- *Pressure ratio*: discharge pressure divided by the suction pressure (both absolute pressures)
- *Displacement*: volume swept out by the piston as it moves over the extent of its travel in the cylinder, V_d
- *Displacement rate*: the rate of volume swept by the piston as the compressor operates, $\dot{V}_d$
- *Actual volumetric efficiency*: the actual refrigerant vapor volume flow rate at the suction port divided by the compressor's displacement rate, $\dot{V}_{actual} / \dot{V}_d$
- *Isentropic efficiency*: ratio of the isentropic compression work to the actual compression work

$$\eta_c = \frac{h_{4s} - h_3}{h_4 - h_3}, \tag{4.15.56}$$

where h is the enthalpy and subscripts 3 and 4 correspond to the suction and discharge states shown in Figure 4.15.10.

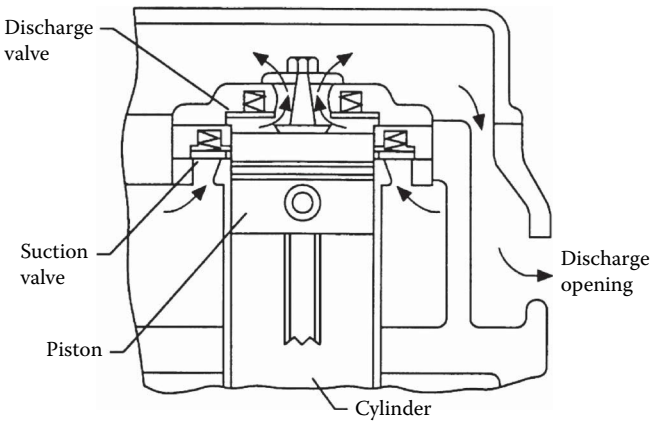

FIGURE 4.15.12 Typical reciprocating compressor cross section. (From Kreith, F., Ed., *The CRC Handbook of Mechanical Engineering,* CRC Press LLC, Boca Raton, FL, 1998. With permission.)

The isentropic efficiency includes the influence of pressure losses across the suction and discharge valves and the heat transfer to the refrigerant vapor from the compressor's internal surfaces. Friction originating from the rubbing of the mechanical parts (e.g., piston rings against the cylinder wall) is also included in the isentropic efficiency. However, leakage is not accounted for in the isentropic efficiency.

Accessories and subcomponents for the reciprocating compressor include a form of capacity control to meet varying refrigerating loads. Several methods are used to achieve capacity control in reciprocating compressors:

- Cycling the compressor on and off to satisfy the required capacity, usually applied to small systems.
- Throttling the suction line, good control but inefficient.
- Returning a portion of the discharge vapor to the suction line, good control, but inefficient and the compressor may operate hot.
- Multicylinder compressors may deactivate cylinders, opening the suction valve and closing the discharge valve, called "cylinder unloading."
- Changing compressor operating speed.

Small compressors are lubricated and cooled with a simple oil splash system. Lubrication oil that is miscible in the refrigerant must be conveyed by the refrigerant throughout the entire cycle. The halocarbon refrigerants use miscible oils and attention must be directed at the sizing of all components and piping to ensure that the velocities are sufficiently high everywhere to prevent the oil from accumulating anywhere in the system.

Scroll Compressor

The newest arrival among positive displacement compressors, it has a widespread application in residential, commercial, and automotive applications. The range of input power that the scroll compressor can accommodate is from about 1 to 60 hp. Refer to Section 4.7 on compressors for details of the scroll compressor.

Capacity control is available using variable-speed motor drives and porting holes in the fixed scroll member to adjust the displacement of the compressor. A control device sequentially opening the ports and venting the refrigerant vapor to the suction port progressively reduces capacity. Capacity control may also be achieved using suction throttling. The isentropic efficiency of the scroll compressor is comparable to the efficiencies of the other compressor types, including the reciprocating compressor. The scroll compressor feature limiting capacity is the size of the scroll. Currently, the largest refrigerating capacity available in a scroll compressor is 180 tons (Emerson, 2013).

Centrifugal Compressor

The centrifugal compressor accomplishes compression by imparting a high velocity to the refrigerant vapor and converting this velocity, actually kinetic energy, to a pressure. The compressor consists of an impeller driven to a high rotating speed. The vapor enters the suction port of the compressor through a set of guide vanes that direct the flow to the center of the impeller. The blades on the impeller are curved in such a way to direct the vapor to flow outward, by centrifugal force, at ever-increasing speeds. Leaving the impeller, the vapor flow enters the diffuser, where a portion of the kinetic energy gained is converted to pressure. Figure 4.15.13 shows a cross-sectional view of a two-stage centrifugal compressor. A two-stage centrifugal compressor utilizes two impellers to perform the compression.

The performance of the centrifugal compressor is obtained by equating the power applied to the impeller to the isentropic work of compression. After rearrangement and simplification (Stoecker, 1982),

$$V_t = \sqrt{g_c J(\Delta h_s)}, \tag{4.15.57}$$

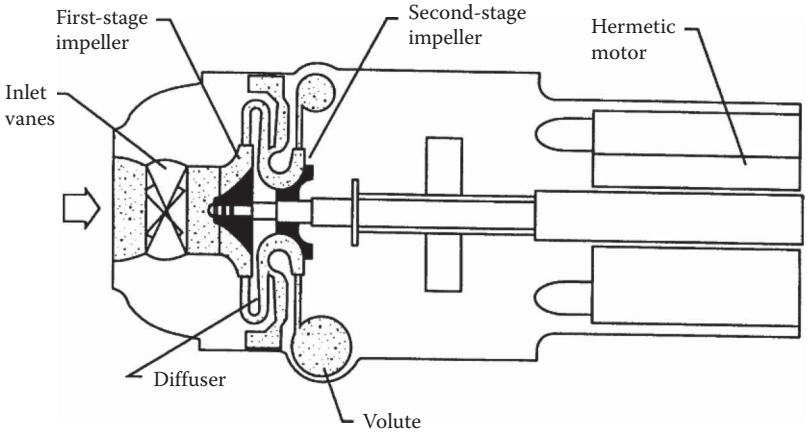

FIGURE 4.15.13 Cross section view of a centrifugal compressor. (From Kreith, F., Ed., *The CRC Handbook of Mechanical Engineering,* CRC Press LLC, Boca Raton, FL, 1998. With permission.)

where V_t is the tangential velocity (ft/s), g_c is a constant equal to 32.17 lb-ft/lbf-s^2, J is a constant equal to 778 ft lbf/Btu, and Δh_s is the enthalpy change for the isentropic work. This expression, while not accurate, does give reasonable approximations. The above expression shows that the refrigerant selected for a centrifugal compressor affects the diameter of the impeller. It turns out that the tip speed of the impeller is limited to approximately 800 ft/s, the actual value depending on the material used for the impeller. Refrigerants with thermodynamic properties similar to those of R-123 are desirable because the diameter of the impeller is smaller. Typically, centrifugal compressors using R-123 require only one compression stage and still have an acceptable tip speed. However, R-123 is not generally used in new equipment due to its toxicity.

A common application of the centrifugal compressor is the chilling of water for a central air-conditioning system. The refrigerating capacity where this compressor is applied ranges from about 50 to 2500 tons. Isentropic efficiencies for centrifugal compressors are usually in the range from 70% to 80%. Capacity control is accomplished by partially closing the inlet guide vanes upstream from the first impeller or varying the rotating speed of the impeller. Other methods of capacity control, such as bypassing the discharge gas, are not used, because they are not efficient.

Rotary Screw Compressor

This compressor is a positive displacement compressor where the compression process occurs in conjunction with the rotation of one or two screws. Details concerning the construction and operation of screw compressors are given in the compressor section of this handbook.

Performance of the screw compressor may be given in terms of the compression volume ratio, V_i, which is defined by

$$V_i = \frac{\text{internal volume when suction port covered}}{\text{internal volume when discharge port uncovered}}, \tag{4.15.58}$$

which gives

$$\text{Pressure ratio} = \frac{p_{dis}}{p_{suc}} = V_i^k, \tag{4.15.59}$$

where k is the ratio of specific heats c_p/c_v. The above equation is only valid when the compression is isentropic. When the compression process is not isentropic, the exponent k is replaced with exponent n which is not equal to k. When the temperature of the vapor remains constant during the compression, the value of n is 1. For actual rotary screw compressors, the value of n lies between k and 1 (Stoecker, 1998).

The discharge pressure for a rotary screw compressor may not match the pressure in the discharge piping. When these pressures are not equal, the adjustment that the vapor undergoes, over- or under-compression, results in losses. Variation of the compressor's volume ratio is possible through the addition of a slide valve that changes the extent of compression that occurs by changing the size of the discharge port. With a variable volume ratio, the over- and under-compression losses are eliminated. Capacity control is achieved by the addition of another slide valve that allows a portion of the suction vapor to bypass back to suction. Oil injection is used to seal the small spaces (approximately 0.0005 in. tolerance) between the lobes and gullies on the screws. Because the oil is heated during compression, it must be cooled to maintain its lubricating properties.

The isentropic efficiency of the screw compressor is about the same as that of the reciprocating compressor. Screw compressors of the same capacity as reciprocating compressors are smaller in size due to their higher rotating speeds. Refrigerating capacities are available from 20 tons to over 1800 tons and are prevalent in the industrial refrigeration field. Recently, screw compressors have been applied to large water-chilling units for air-conditioning applications in commercial buildings.

Absorption Cycle

The absorption refrigeration cycle differs from the vapor compression cycle in that the mechanical work used to compress the vapor is not needed. Rather, the vapor compression process is replaced by a series of processes whereby the refrigerant vapor is first absorbed into a liquid solution, the strong liquid solution is pumped to a higher pressure, and then driven from the generator as a vapor. To accomplish the absorption of the refrigerant and its subsequent release, heat is transferred out of the solution and transferred into the solution. The liquid pump, while requiring the input of work, requires only a small fraction of the work necessary to compress the vapor leaving the evaporator. The diagram in Figure 4.15.14 shows an ideal absorption refrigeration cycle. Observe that three of

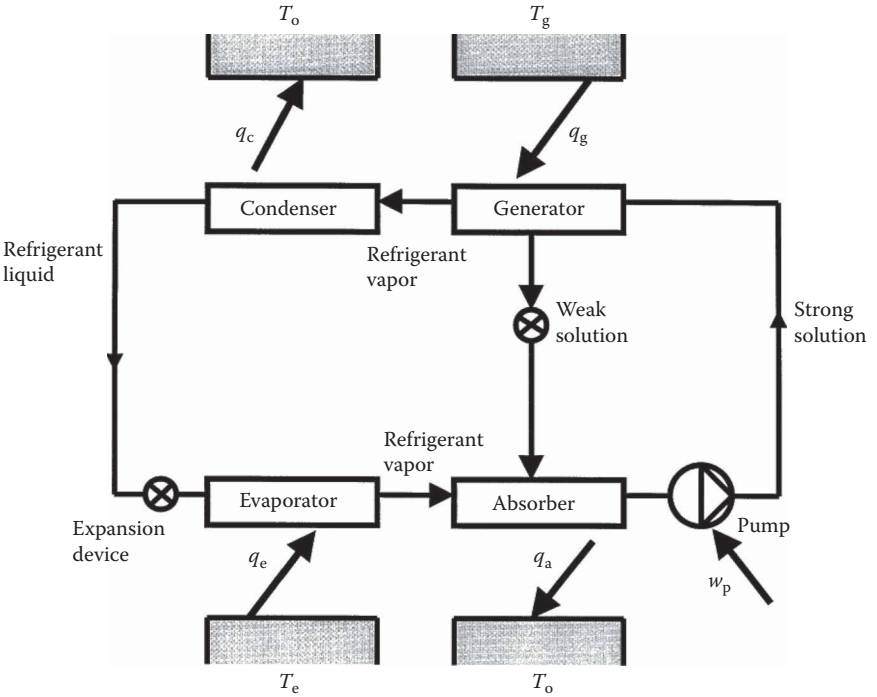

FIGURE 4.15.14 Ideal absorption refrigeration cycle.

the vapor compression cycle's components are also present in the absorption cycle. However, the compressor is replaced by the absorber, liquid pump, and generator which constitutes the path that the liquid solution takes as it circulates through in the cycle.

The working fluid in the absorption cycle is a binary fluid which is a homogeneous mixture of two chemicals. The performance of the absorption cycle depends on the affinity that the two components of the binary mixture have for each other. The pair commonly used for chilling water for air-conditioning applications is lithium bromide and water (Kuehn et al., 1998). In this binary mixture, the refrigerant is water which limits the cycle to temperatures above 32°F. Ammonia–water is another binary pair used in absorption cycles where ammonia is the refrigerant. The ammonia–water pair is typically used in industrial applications where temperatures lower than 32°F must be achieved (Bogart, 1981).

Absorption cycles provide an advantage when waste heat is available. Sources of waste heat may include heat rejected by an electrical power-generating plant, a large internal combustion engine, or an array of solar collectors. Even though the overall performance of the absorption cycle may be significantly less than that of the vapor compression cycle, when waste heat is available it may be competitive on a cost basis. Bosnjakovic (1965) developed the following expression for the maximum COP possible from the ideal absorption cycle shown in Figure 4.15.14:

$$(\mathrm{COP})_{\max} = \frac{T_e(T_g - T_o)}{T_g(T_o - T_c)}. \tag{4.15.60}$$

Refrigerant Selection

Vapor-compression refrigeration cycles used for the air conditioning of commercial buildings, private homes, and automobiles for human comfort have become common in many parts of the world. One factor promoting the widespread application of the vapor-compression cycle was the development of refrigerants composed of halocarbons, all of which are nontoxic and nonflammable. Halocarbons are chemical compounds containing one or more atoms from the halogen family, namely, chlorine, fluorine, and bromine, in conjunction with at least one carbon atom. The technical term for these compounds is chlorofluorocarbons, generally abbreviated to CFCs. This group of refrigerants were called Freon's, soon after their development in the 1930s. Early members of this new group were R-12 and R-11. They have gained prevalent use serving the refrigeration and air-conditioning industry for over 50 years.

During the 1960s, measurements of very small quantities of R-11 were obtained in a number of remote locations on the Earth, including at sea. Questions were raised by many as to whether or not CFC refrigerants present in the atmosphere have an influence on it. The answer became clear as a result of investigations conducted in the 1970s and 1980s. The survival time of a CFC in the atmosphere is very long as a result of its high chemical stability. This permits the CFC molecules to rise to the upper atmosphere and move through the ozone (O_3) layer. In this region of the atmosphere, ultraviolet radiation from the sun is present, which causes the chlorine atom to break free and chemically react with the ozone decreasing its concentration. The chlorine is then free to react again with another ozone molecule, thereby destroying it. This reaction continues for the life of the chlorine atom in the upper atmosphere.

The measurement of significant ozone depletion over Antarctica observed during the spring season of the year and the mounting evidence indicating significant ozone depletion over North America, Europe, and Japan caused a number of countries to make an agreement in Montreal, Canada through the United Nations. This agreement, created in 1987, is called the "Montreal Protocol on Substances that Deplete the Ozone Layer," and has been revised several times since (United Nations, 1994; UNEP, 1995). As a result of this agreement, CFC production has completely ceased. While old systems are still operating with CFC's, new systems are not allowed.

The Montreal Protocol also includes agreements that will result in the future phase-out of another group of refrigerants—the hydrogenated halocarbons referred to as hydrochlorofluorocarbons (HCFCs). A prominent refrigerant in this group is R-22, a refrigerant widely used in air-conditioning systems. R-22 has a modest ozone depletion potential (ODP), but nonetheless, its phase-out has been completed by developed countries. Developing countries are still using R-22 with phase-out having started in 2015 with a 10% reduction per year. R-123, an HCFC, is scheduled to cease its use in new equipment in 2020 and to cease all production in 2030. Another halocarbon class, the hydrofluorocarbons (HFCs), does not contain chlorine and, therefore, is not ozone depleting. HFCs are not regulated by the Montreal Protocol. However, their future is uncertain due to their contribution to global warming.

As a consequence of the Montreal Protocol, R-11 and R-12, which are both CFCs, cannot be used in new refrigeration equipment. In response, the refrigeration industry has developed alternative refrigerants and is conducting research that will lead to additional alternative refrigerants. The selection of suitable refrigerants and the attendant concerns with safety and the environment are decisions that the designer must make.

Selection of Refrigerants

When considering vapor compression refrigeration cycles, two overall system requirements must be considered. These are the temperature of the air-conditioned space and the temperature of the environment to which the heat must be rejected. Generally, the temperature of the boiling refrigerant in the evaporator must be about 20°F below that of the conditioned space. The pressure in the low-side of the system should be greater than atmospheric pressure, preventing air from entering the system due to leaks. Generally, the evaporator pressure is very near the saturation pressure which establishes the temperature of the refrigerant. Refrigerants R-11 and R-123 are exceptions in that evaporator pressures are typically less than 10 psia. The condenser presents an additional system constraint because at the condensing pressure which is very near the saturation pressure, the corresponding saturation temperature of the refrigerant must be about 20°F higher than the environment where the heat is rejected.

Table 4.15.1 lists several physical properties of refrigerants used in air conditioning. The critical pressure is given for the refrigerants. The condensing pressure in a conventional vapor compression refrigeration system must be somewhat less so that the refrigerant vapor may condense at a nearly constant pressure in the condenser. Table 4.15.2 is extracted from ASHRAE (2017) and shows the relative performance of some refrigerants when operating under the same conditions in ideal vapor compression cycles. From the COP values reported in Table 4.15.2, observe that most are about the same. R-410A is the lowest at 10.4 and R-123 is the highest at 11.4. Compressor discharge temperature is highest for ammonia and represents a disadvantage of ammonia particularly when evaporator temperatures are low and the compression ratio is high. However, R-123 should be excluded from the comparison as this refrigerant is uniquely suited to the centrifugal compressor due to their large specific volume resulting in reasonable wheel tip speeds. Otherwise, ammonia has the highest COP at 11.2, which is due to its high latent heat.

The environmental impact of some refrigerants is given in Table 4.15.3 where two characteristics have been selected: ODP and global warming potential (GWP). ODP is the relative capability of the refrigerant to destroy ozone in the atmosphere of the earth. The ODP for R-11 is defined as 1.00. GWP is the capability of the refrigerant to warm the atmosphere of the Earth relative to that caused by carbon dioxide over a period of 100 years. Chemicals in the atmosphere have a unique average residence time which in turn influences the GWP.

Table 4.15.3 indicates that CFCs have high ODP, HCFCs have significantly lower ODP, and HFCs have zero ODP. Halocarbon refrigerants should not be vented to the atmosphere. GWP values indicate that refrigerants, including the HFCs, represent an important segment of the chemicals that contribute to global warming due to the high values. In the future, restrictions on the use of refrigerants high in GWP may occur.

[a] TLV, "threshold limit value" defined as personal exposure limit over a time-weighted average concentration for a normal eight-hour work day and a 40 hour work week.

ASHRAE Classification of Refrigerants

ASHRAE, through Standard 34–2013 "Designation and Safety Classification of Refrigerants," publishes refrigerant classifications as determined by the standard and is periodically updated to include new developments. The ASHRAE classification is based on two refrigerant characteristics: toxicity and flammability. Two levels, "A" (nontoxic) and "B" (toxic), comprise the toxicity classifications. A refrigerant is classified as toxic when exposed to humans at a concentration equal to 400 ppm (v/v) in air causes toxicity (Gopalnarayanan, 1998). Flammability is divided into three classes: highly flammable, moderately flammable, and nonflammable which are designated "3," "2," and "1," respectively. The term flammability refers to the capability of a mixture of the refrigerant vapor and air to propagate a flame. Table 4.15.3 includes the ASHRAE safety classification for several refrigerants.

The prefix "R" is used to designate a refrigerant. As mentioned earlier, letter designations (i.e., CFC) are also applied to halocarbon refrigerants. The numbering of halocarbon refrigerants and some hydrocarbons is dependent on the atoms that make up the molecule. The first digit on the right is the number of fluorine atoms. The second digit from the right is one more than the number of hydrogen atoms, and the third digit from the right is one less than the number of carbon atoms. When the third digit is zero, it is not written. With inorganic compounds serving as refrigerants, the first number on the left is "7." The next digits on the right are equal to the molecular weight of the compound. An example is R-744 (carbon dioxide). When the first digit is "4," the refrigerant is a blend (or zeotrope) of two or more compounds. The two digits to the right provide the constituents that comprise the mixture, and the letter the order in which the designation was made. When a "5" is designated, the refrigerant is a mixture of two compounds which form an azeotrope, which is a special mixture in that neither constituent can be recovered by distillation alone. The digits to the right of "5" indicate the historical order of that azeotrope's commercial introduction.

Table 4.15.3 also lists values for the refrigerant's vapor toxicity via the threshold limit value or "TLV." It is defined as the time-weighted average exposure that a worker can have to a substance for a normal 40-h work week without any adverse health effects.

Exergy Analysis

The ideal vapor compression refrigeration cycle has undergone exergy analyses (Kotas, 1995; Bejan, 1996, 2006; Li, 1996). These analyses are based on the second law of thermodynamics where the property exergy is used to track the losses that occur in the cycle. The second law efficiency for the cycle, defined in the thermodynamics section of this handbook, is relatively small. Calculations applied to idealized cycles show that the greatest exergy loss occurs in the condenser, the next largest loss being in the expansion device. The compressor, considered isentropic, has by far the smallest exergy loss. However, in an actual cycle, the exergy losses in the compressor, condenser, and evaporator are roughly the same at typical air-conditioning temperatures. The least exergy loss occurs in the expansion device in actual cycles (Kotas, 1995). Further considerations regarding the importance of exergy analysis are given in the discussions of Kotas (1995) and Bejan (2006).

Energy Distribution Systems

After the cooling and heating loads are determined for the building or application, the air distribution system must be designed resulting in the selection of equipment. The psychrometric processes discussed earlier play an important role in determining the magnitude of the sensible and latent loads for the space. For example, if winter heating is required, the air temperature and moisture content must be high enough to absorb the entire heating load for the space. The air is heated and humidified before being ducted to the occupied space where it is cooled and dehumidified, which are basic psychrometric processes. For commercial buildings, fresh outdoor air is generally required by national codes and local jurisdictions. To provide the fresh air, the return air is usually mixed with outdoor air before it enters the heating and humidifying equipment. For summer cooling, similar psychrometric processes occur where the air is conditioned by cooling and dehumidification. In both situations, the outdoor air, the return air, and the space load are all important in establishing the needed psychrometric processes.

All-Air Systems

Air-conditioning systems that psychrometrically prepare the air and transport that air through air ducts are called all-air systems. These systems are classified into two types by ASHRAE's *Handbook of HVAC Systems and Equipment* (2012): single-duct systems and dual-duct systems. Single-duct systems have one air flow path in which all the heating and cooling coils are inserted in series. These systems have a common air duct distribution system resulting in one temperature supplied to all the terminal outlets. In contrast, the dual-duct system has the main heating and cooling coils positioned in parallel. Two variations of the dual-duct system are used. One is to maintain the separation of the cool and warm air using two air duct distribution systems—one for the cool air and the other for the warm air. This is a traditional dual-duct system. The other system is to have a dedicated supply air duct for each zone with the mixing of the supply air to the needed conditions occurring at a main mixing damper array. This setup is called a multizone air duct system.

Single-Duct Systems

With single-duct systems, two basic categories characterize most systems: constant air volume and variable air volume (VAV).

Constant Volume

The supply air temperature changes in response to the space load while the air flow rate is maintained constant. The simplest version would be used for a single-zone system where the supply air equipment provides air directly or through air ducts to the space. For more complex systems, multiple-zone reheat is one version that accommodates the requirements of several spaces, each controlled by a separate thermostat. Additionally, multiple-zone systems can simultaneously provide heating and cooling to the zones as needed. Reheat of the air, either preconditioned primary air or recirculated air, occurs with these systems.

Small multiple-zone systems incorporate only low air pressure drops in the ducts and locate the reheat coils in the ducts near each zone. When the system is more complex (i.e., many zones), the primary distribution air ducts have higher pressures to reduce size and cost (McQuiston et al., 2005). Pressure reduction equipment is installed to maintain constant air flow volume for each zone. These systems use conditioned air from centrally located equipment, usually at a constant cold temperature (ASHRAE, 2012). However, to reduce the quantity of reheat required and conserve energy, the cold temperature may be adjusted by the controls.

A modification to the constant volume reheat system incorporates a bypass box replacing the reheat coil. The change becomes a constant volume primary system with a VAV secondary system. To meet the space load, the amount of zone supply air is adjusted by dumping the excess air to the return and simply bypassing the zone altogether. Bypass systems are limited in application to small multiple-zone systems, typically when energy consumption is less important.

Variable Air Volume

The supply air temperature remains constant while the amount of air supplied adjusts to the changing requirements of the space by means of a VAV terminal device. In operation, the air supply temperature is fairly constant, causing the VAV system to be well suited to perimeter and interior zones (ASHRAE, 2012). An opportunity for energy savings exists when using VAV systems for perimeter zones where solar heating results in a reduction of the supply air flow rate to make temperature changes. VAV systems may use individual or common fans, individual or common zone temperature control, and may or may not include auxiliary heating equipment.

Humidity control with VAV systems is more difficult than with constant volume systems. Approaches sometimes taken are to set a lower limit on the air flow rate, provide reheat to prevent overcooling with reasonable relative humidity, and provide ventilation using outdoor air. A typical lower limit on the air flow rate is 50% of the original flow rate.

The VAV system typically uses reheat when the heating occurs at the terminal unit a small distance upstream from the space. This system establishes the following control hierarchy: first, reduce the air flow volume, and second, add heat at the reheat coil. Relative to constant volume reheat, VAV systems consume less energy by reducing the primary air that must be cooled and by reducing the secondary air that needs heating. The terminal unit is adjusted to operate at a predetermined throttling ratio which is arrived at by establishing the lowest air flow rate sufficient to:

- Meet the heating load
- Limit the relative humidity (superseded by independent ventilation system)
- Provide acceptable air movement
- Provide required ventilation air (superseded by independent ventilation system)

Variations in the terminal units include provision for the induction of air from the space and have the advantage of recovering a portion of the heat from the lights (ASHRAE, 2012). The terminal unit may also be fan-powered in either a series or parallel flow arrangement. The advantage with fan-powered units is the larger circulation rate that is possible through the space at lower loads.

Dual-Duct Systems

All the supply air is conditioned in centrally located equipment which in turn is conveyed to the individual spaces by two main parallel ducts. Cold air is conveyed in one duct and warm air in the other. In a dual-duct box near the space, the warm and cold air flows are mixed by a valve in proportion to satisfy the space load. An advantage of the dual-duct system is that no pipes are required to feed the reheat coils, avoiding the possibility of leaks into the conditioned space. However, energy consumption for the dual-duct system is greater than that of the VAV single-duct system. Dual-duct systems may be either constant volume or VAV.

Constant Volume

Single-fan, no reheat resembles a single-duct system except for the face-and-bypass damper at the cooling coil (ASHRAE, 2012). This damper bypasses a mixture of recirculated and outdoor air in response to changes in the heat load. A disadvantage of this configuration is the imprecise control temperature and humidity in the occupied space. An alternative is the single-fan reheat configuration where the single reheat coil is placed in the central unit.

Variable Air Volume

VAV systems utilizing dual-ducts mix the cold and warm air yielding different volume combinations (ASHRAE, 2012). One configuration employs a single fan capable of handling both the cold and hot ducts. Typically, the cold deck is controlled to hold a constant temperature while the temperature of the hot deck is allowed to vary depending on the outside conditions. The hot deck temperature is increased when the outside temperature is low and the humidity high so that the flow over the cold deck increases to improve dehumidification. Another version is the dual fan VAV dual-duct system where each supply fan is independently controlled. The cold deck temperature is maintained constant by a refrigeration unit in conjunction with providing minimum fresh air, or by an economizer when the outside temperature is less than the setpoint temperature for the cold deck. The hot deck may still obtain heat from the recirculated air or from the heating coil when the recirculated air is too cold.

Air-and-Water Systems

Air-and-water systems use both water and air to convey the energy to and from the conditioned space. The supplied air originates from a central room where the heating and cooling equipment is placed and is called "primary air." The supplied water is called "secondary water." This system, as with the systems described earlier, requires a terminal unit for each zone. The terminal unit may be a fan coil device or an induction unit. Sometimes, an ordinary air outlet in combination with a radiant panel may serve as a terminal unit (ASHRAE, 2012).

The purpose of the primary air for heating is to provide fresh air to comply with ventilation requirements. When needed, water may be added to the warm air to improve comfort. For cooling, the primary air is dehumidified in order to achieve comfortable temperature and humidity in the space. The amount of primary air supplied to each space or zone is dependent on the fresh air ventilation requirement and the sensible cooling load at design conditions. Thus, the space humidity is controlled by the primary air. The secondary water is transported to the terminal units to supply a coil with either warm or cold water. When properly operating during the cooling season, the coil is dry, which greatly reduces odors and bacterial growth, while at the same time extending the life of the coil. However, condensate drains are recommended for all air-and-water systems.

Secondary water is supplied using a pump and piping arrangement. At the central plant, the water is typically cooled by heat exchange with the central chilled water plant. Air-and-water systems are classified as two-pipe, three-pipe, or four-pipe systems. All these piping arrangements accomplish the goal of supplying chilled or warmed water to the coil.

- A two-pipe system consists of one supply pipe and one return pipe for either warm or cold water supply temperatures. The seasonal changeover of these systems is relatively difficult.
- A three-pipe system consists of one cold water supply, one warm water supply, and a common return pipe. The mixing of the warm and cold water at the terminal unit generates significant energy losses.
- A four-pipe system consists of a cold water supply and return and a warm water supply and return. This arrangement is relatively efficient and changeover between seasons is convenient.

All-Water Systems

Another system is the all-water system, which may also be employed to heat and cool a space depending on the outdoor conditions. The air in the space is heated and cooled by any combination of the three basic heat transfer mechanisms: conduction, convection, and radiation. Applications include fan-coil units, panels on the floor, walls, or ceiling, and baseboard radiation. For further information on this subject, consult the ASHRAE *Handbook of HVAC Systems and Equipment* (2012).

4.16 HEAT TRANSFER ENHANCEMENT

Raj M. Manglik

Introduction

The imperatives of energy conservation, materials and manufacturing input savings, and in recent years the concerns for environmental conservation, along with associated economic incentives, have led the efforts to produce more efficient heat exchange equipment. The objectives for improving and optimizing the thermal and hydrodynamic performance are generally the following: reduce the size of a heat exchanger required for a specified heat duty, or increase or upgrade the capacity of an existing heat exchanger, or reduce the approach temperature difference (or the inlet temperature difference) for the process streams, and/or reduce the pumping (or blower or fan) power requirements for moving the flow stream.

Heat transfer *enhancement* [or *enhanced* heat transfer, or for that matter enhanced mass transfer (Bergles et al., 1983; Manglik and Bergles, 2004)] refers to the study of techniques for improving the thermal performance of a heat (or mass) exchange device or system. It is sometimes also referred to as heat transfer *augmentation* or *intensification*. In general, this entails an increase in the heat transfer coefficient and encapsulates the broader science and engineering of methods for producing higher convective heat/mass transfer coefficients, reducing frictional losses, and increasing the overall thermal–hydrodynamic efficiencies of exchangers. Attempts to increase "normal" heat transfer coefficients have been recorded for more than 150 years in modern history (Bergles and Manglik, 2013) and indeed date back several thousand years in antiquity (Manglik and Jog, 2009). As a result, there is a very large store of information that has been documented and disseminated in several periodic surveys (Manglik and Bergles, 2004; Bergles and Manglik, 2013; Manglik et al., 2013). The literature comprising of technical publications, excluding patents and manufacturers' literature, has expanded rapidly since 1955 and approximately 350–450 papers and reports on the subject are now published annually.

Methods for enhancement of heat and/or mass transfer can be classified either as *passive techniques*, which require no direct application of external power, or as *active techniques*, which require external power. A listing of the different methods and their classification is given in Table 4.16.1, and a few representations of passive methods in current usage are depicted in Figure 4.16.1. The effectiveness of both types of techniques is strongly dependent on the mode of heat transfer, which may range from single-phase free convection to dispersed-flow film boiling. Brief descriptions of these methods are as follows:

- *Treated surfaces* involve fine-scale alteration of the surface finish or coating (continuous or discontinuous). They are used for boiling and condensing applications; the roughness height is below that, which affects single-phase heat transfer.
- *Rough surfaces* are produced in many configurations ranging from random sand grain-type roughness to discrete protuberances (see Figure 4.16.1a). The configuration is generally chosen to disturb the viscous sublayer rather than to increase the heat transfer surface area. Application of rough surfaces is directed primarily toward single-phase flow.
- *Extended surfaces* are routinely employed in many heat exchangers (see Figure 4.16.1b). Work of special interest to enhancement is directed toward improvement of heat transfer coefficients on extended surfaces by geometrically altering the fin or extended surfaces.
- *Displaced enhancement devices* are inserted into the flow channel so as indirectly to improve energy transport at the heated surface. They are used with forced flow (see Figure 4.16.1c).

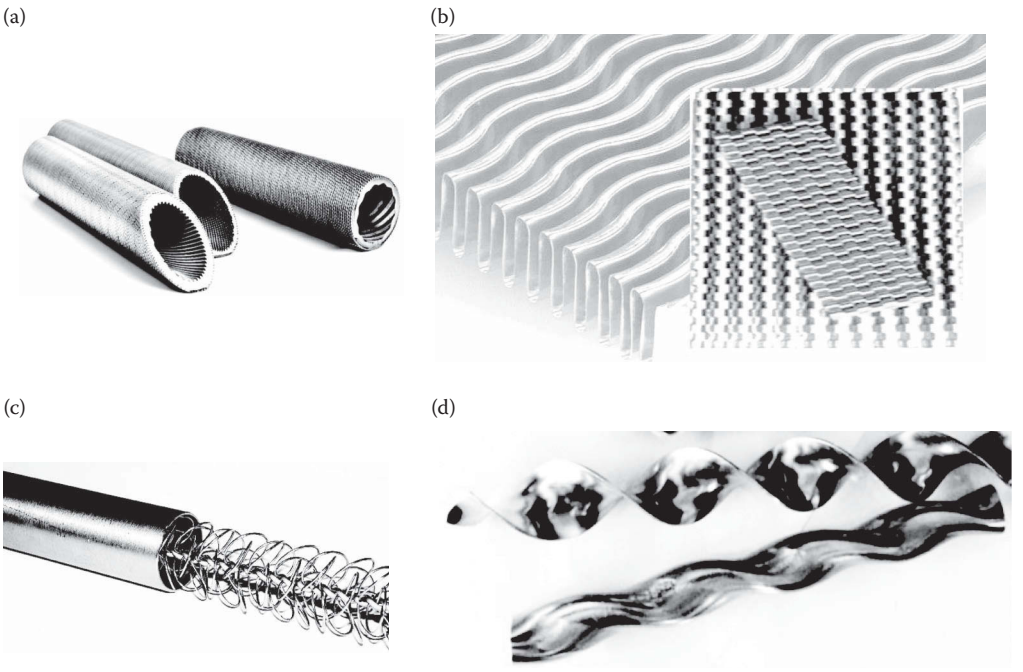

FIGURE 4.16.1 Enhanced surfaces that are typically used in forced convection heat transfer: (a) spirally ribbed and structured surface roughness tubes [photo courtesy Wieland-Werke AG], (b) wavy plate fins and offset-strip fins, (c) displaced enhancement tube insert, and (d) twisted-tape insert and twisted oval tube.

TABLE 4.16.1
Classification of Different Heat Transfer Enhancement Techniques

Passive Techniques	**Active Techniques**
Treated surfaces	Mechanical aids
Rough surfaces	Surface vibration
Extended surfaces	Fluid vibration
Displaced enhancement devices	Electrostatic fields
Swirl flow devices	Injection
Coiled tubes	Suction
Surface tension devices	Jet impingement
Additives for liquids	
Additives for gases	
Compound Enhancement	
Two or more passive and/or active techniques used together	
Examples:	
Rough-surface tube with twisted-tape insert (two passive techniques)	
Rotating internally finned tubes (an active and a passive technique)	

- *Swirl-flow devices* include a number of geometric arrangements or tube inserts for forced flow, which induce rotating and/or secondary flow and promote greater fluid mixing. Examples include axially twisted tubes (see Figure 4.16.1d), coiled tubes, inlet vortex generators, twisted-tape inserts (see Figure 4.16.1d), and axial-core inserts with a screw-type winding.

- *Surface-tension devices* consist of wicking or grooved surfaces to direct the flow of liquid in boiling and condensing.
- *Additives for liquids* include solid particles and gas bubbles in single-phase flows and liquid trace additives for boiling systems.
- *Additives for gases* are liquid droplets or solid particles, either dilute phase (gas–solid suspensions) or dense phase (fluidized beds).
- *Mechanical aids* involve stirring the fluid by mechanical means or by rotating the surface. Surface "scraping," widely used for batch processing of viscous liquids in the chemical process industry, is applied to the flow of such diverse fluids as high-viscosity plastics and air. Equipment with rotating heat exchanger ducts is found in commercial practice.
- *Surface vibration* at either low or high frequency has been used primarily to improve single-phase heat transfer.
- *Fluid vibration* is the practical type of vibration enhancement because of the mass of most heat exchangers. The vibrations range from pulsations of about 1 Hz to ultrasound. Single-phase fluids are of primary concern.
- *Electrostatic fields* (DC or AC) are applied in many different ways to dielectric fluids. Generally speaking, electrostatic fields can be directed to cause greater bulk mixing or fluid or disruption of fluid flow in the vicinity of the heat transfer surface, which enhances heat transfer.
- *Injection* is utilized by supplying gas to a stagnant or flowing liquid through a porous heat transfer surface or by injecting similar fluid upstream of the heat transfer section. Surface degassing of liquids can produce enhancement similar to gas injection. Only single-phase flow is of interest.
- *Suction* involves vapor removal, in nucleate or film boiling, or fluid withdrawal, in single-phase flow, through a porous heated surface.

Two or more of the aforementioned techniques may also be utilized simultaneously to produce an enhancement that is larger than either of the techniques operating separately. Such usage is referred to as *compound enhancement* (see Table 4.16.1 for an example).

Extended descriptions along with many other examples can be found in several surveys and monographs (Bergles, 1998; Manglik, 2003; Webb and Kim, 2005). It should be emphasized here that one motivation, among some others, for studying enhanced heat transfer is to assess the effect of an inherent condition on heat transfer. Some practical examples include roughness that is naturally produced by standard manufacturing, degassing of liquids with high gas content, surface vibration resulting from rotating machinery or flow oscillations, fluid vibration resulting from pumping pulsation, and electrical fields present in electrical equipment (e.g., electric transformers).

The enhanced surfaces and tubular inserts represented in Figure 4.16.1 have been used for both single-phase and two-phase (boiling or evaporation and condensation) heat transfer enhancement. The emphasis here is on effective and cost-competitive (either proven or potential) techniques that have made the transition from the laboratory to commercial heat exchangers; the effectiveness of a method is determined by the relative trade-offs between increased heat transfer coefficient and frictional penalty.

Single-Phase Free Convection

With the exception of the familiar technique of providing extended surfaces (or what are popularly known as finned surfaces), the passive techniques have little to offer in the way of enhanced heat transfer for free convection. This is because the buoyancy-driven flow velocities are usually too low to cause flow separation, or secondary flow, or other such significant flow perturbation that would enhance the convective heat transport.

Serrated, or perforated, or slotted, or similarly segmented or interrupted finned surfaces promote enhanced heat transfer. The periodic restarting of thermal boundary layers over the interrupted extended surfaces is the primary enhancement mechanism that substantially increases the heat transfer coefficient, and this more than compensates for the lost surface area. Pin fins, of either circular or rectangular cross section, and arrayed in staggered or in-line arrangements, are some other extended surface geometries that find wide usage with natural convection, particularly in electrical and electronic cooling (Kraus et al., 2001; Kreith et al., 2011).

Mechanically aided thermal processing, which may entail both heat and mass transfer, is a standard technique in the chemical and food industries when viscous liquids are involved. The predominant geometry for surface vibration has been the horizontal cylinder, vibrated either horizontally or vertically. Heat transfer coefficients can be increased 10-fold for both low-frequency/high-amplitude and high-frequency/low-amplitude situations. It is, of course, equally effective and more practical to provide steady forced flow. Furthermore, the mechanical designer is concerned that such intense vibrations could result in equipment failures.

Since it is usually difficult to apply surface vibrations to practical equipment, an alternative technique is utilized whereby vibrations are applied to the fluid and focused toward the heated surface. With proper transducer design, it is also possible to improve heat transfer to simple heaters immersed in gases or liquids by several hundred percent.

Electric fields are particularly effective in increasing heat transfer coefficients in free convection. Dielectrophoretic or electrophoretic (especially with ionization of gases) forces cause greater bulk mixing in the vicinity of the heat transfer surface. Heat transfer coefficients may be improved by as much as a factor of 40 with electrostatic fields up to 100 kV. Again, the equivalent effect could be produced at lower capital cost and without the voltage hazard by simply providing forced convection with a blower or fan.

Single-Phase Forced Convection

While there are many different geometric manifestations of heat exchangers used in industry (Shah and Sekulic, 2003; Wang et al., 2007), the present discussion emphasizes enhancement of heat transfer *inside* tubes and ducts that are primarily of circular cross section. Representative data for some of the extended surfaces (offset-strip fins and wavy-plate fins) (Kays and London, 1998) and tube with structured roughness (Ravigururajan and Bergles, 1996) are graphed in Figure 4.16.2, along with reference results for plain fins (or unembellished fins) and smooth tube. The smooth tube results are predictions of the following Nusselt number and Fanning friction factor correlations, respectively:

$$\mathrm{Nu}_s = \frac{0.5 f \mathrm{Re}_{D_i} \mathrm{Pr}}{1 + 12.7 \left(0.5 f\right)^{0.5} \left(\mathrm{Pr}^{0.667} - 1\right)} \tag{4.16.1}$$

and

$$f_s = \left(1.58 \ln \mathrm{Re}_{D_i} - 3.28\right)^{-2} . \tag{4.16.2}$$

The subscript *s* in these equations denotes a smooth or unembellished plain tube or surface, and the characteristic length scale for Nu and Re is the inner diameter D_i of the tube. As seen from these plots, while both enhancement devices produce a sizable elevation in the Colburn *j*-factor (or dimensionless heat transfer coefficient) at constant Reynolds number, or velocity, there is also an accompanying large increase in the friction factor. Balancing this penalty to obtain net thermal benefits thus becomes an optimization exercise, and for which several evaluation figures of merit have been devised (Bergles et al., 1974; Bergles, 1998; Manglik, 2003). A representative example is discussed in the subsequent subsection.

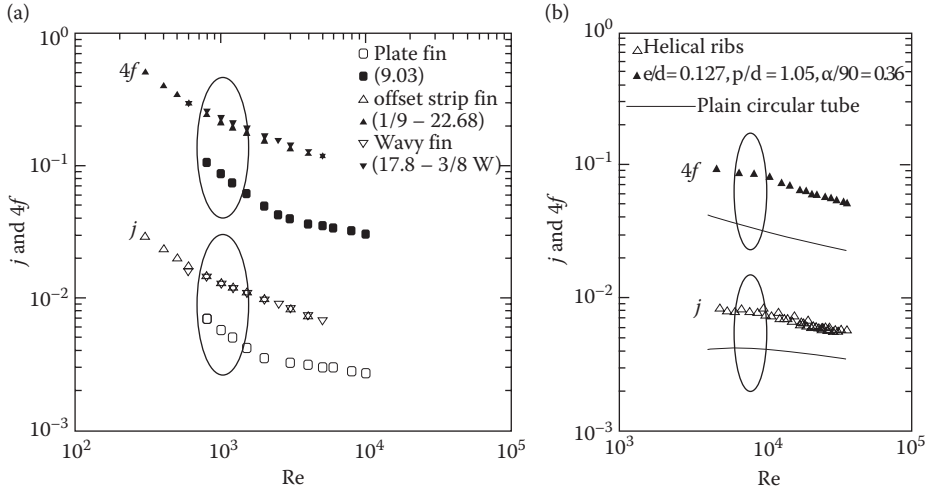

FIGURE 4.16.2 Typical data and results for heat transfer (Colburn *j*-factor) and Fanning friction factor *f* for passive enhancement techniques: (a) plate-fin geometries or extended surfaces (wavy fins and offset-strip fins; data from Kays and London, 1998) and (b) tubes with internal structured roughness (helically ribbed tubes; data from Ravigururajan and Bergles, 1996).

Surface roughness has been used extensively to enhance forced convection heat transfer. Integral or structured roughness may be produced by the traditional manufacturing processes of machining, forming, casting, or welding. Various inserts (spiral wire-coil inserts) can also provide surface protuberances. In view of the infinite number of possible geometric variations, it is not surprising that, even after decades of research and hundreds of reported studies, no completely satisfactory unified treatment of structured rough surfaces is available.

Notwithstanding the increased friction loss that requires balancing in the eventual thermal–hydrodynamic optimization of a heat exchanger (Bergles, 1998; Manglik, 2003), the improvements in heat transfer coefficient with turbulent flow in rough tubes (based on nominal surface area) are as much as 100% and more (Ravigururajan and Bergles, 1994; 1996). In efforts to provide predictive design tools, analogy solutions for sand grain-type roughness and for square-repeated-rib roughness have been proposed. A statistical correlation was also developed subsequently (Ravigururajan and Bergles, 1996), for both the heat transfer coefficient and Fanning friction factor, which was based on new experiments as well as a very large data set available in the literature. These predictive equations are recommended for tubes that have structured roughness made up of transverse- or helical-repeated ribs (the latter are shown Figure 4.16.1a) with turbulent flow and are as follows:

$$\mathrm{Nu}_{\mathrm{D_i},a} = \mathrm{Nu}_s \left[1 + \left\{ 2.64 \mathrm{Re}^{0.036} \left(\frac{e}{D_i} \right)^{0.212} \left(\frac{p}{D_i} \right)^{-0.21} \left(\frac{\alpha}{90} \right)^{0.29} \mathrm{Pr}^{-0.024} \right\}^7 \right]^{1/7}, \tag{4.16.3}$$

$$f_a = f_s \left[\left\{ 29.1 \mathrm{Re}_{\mathrm{D_i}}^{a1} \left(\frac{e}{D_i} \right)^{a2} \left(\frac{p}{D_i} \right)^{a3} \left(\frac{\alpha}{90} \right)^{a4} \left(1 + \frac{2.94 \sin \beta}{n} \right) \right\}^{15/16} \right]^{16/15}, \tag{4.16.4a}$$

where

$$a1 = \left[0.67 - 0.06\left(\frac{p}{D_i}\right) - 0.49\left(\frac{\alpha}{90}\right)\right]; \quad a2 = \left[1.37 - 0.157\left(\frac{p}{D_i}\right)\right],$$
$$a3 = \left[-1.66\times10^{-6}\,\mathrm{Re} - 0.33\left(\frac{\alpha}{90}\right)\right]; \quad a4 = \left[4.59 + 4.11\times10^{-6}\,\mathrm{Re} - 0.15\left(\frac{p}{D_i}\right)\right]. \tag{4.16.4b}$$

In these equations, the characteristic length scale is the smooth or empty inner diameter of the tube, D_i, and the subscript a refers to the enhanced tube, whereas the subscript s refers to the smooth tube. The other special symbols are given as follows: e = protuberance height; p = repeated-rib pitch; α = spiral angle in degrees for helical ribs; n = number of sharp corners facing the flow; and β = contact angle in degrees for the rib profile. Also, the smooth tube Nusselt number and Fanning friction factor are, respectively, given by Equations 4.16.1 and 4.16.2.

Much work has been done to obtain the enhanced heat transfer of parallel angled ribs in short rectangular channels, simulating the interior of gas turbine blades. A variety of shapes and rib patterns have been considered with the focus on improving internal blade cooling (Wright and Han, 2014). In several industrial materials processing applications, jets (gas or liquid) are frequently used for carrying out heating, cooling, and drying operations. For such cases, a number of studies have reported that roughness elements, particularly of the transverse-repeated-rib type, mitigate the deterioration in heat transfer downstream of the jet stagnation region.

In a recent new development (Champagne and Bergles, 2011), a novel technique to render the inside surface of a circular tube with variable-pitch-structured roughness of fixed height, (e/D_i), has been proposed and tested. This is achieved by inserting wire coils of fixed diameter that are made of a shape-memory alloy (SMA); the coil geometry, or spiral tightness, is designed to change in response to fluid flow temperature. Functionally, upon being heated, the wire-coil insert that has fixed (e/D_i) changes from its original compressed shape, which occupies a small fraction of the tube length, to an expanded shape that has the desired or "trained" roughness pitch (p/D_i) and helix pitch $(\alpha/90)$.

Extended surfaces can be considered "old technology" as far as most applications are concerned. The real interest now is in increasing heat transfer coefficients on the extended surface itself, and this is often achieved by a variety of geometrical alterations of the fins so as to produce what would be termed as enhanced extended surfaces. Present-day compact heat exchangers of the plate-fin or tube-and-fin variety use several different such enhanced fins: offset-strip fins (Figure 4.16.1b), louvered fins, perforated fins, wavy or corrugated fins (Figure 4.16.1b), and some newer configurations that are still undergoing laboratory testing and modeling (Huzayyin et al., 2010). Heat transfer coefficients that are several hundred percent above the plain fin values can be achieved without significant loss of surface area; however, the pressure drop is also substantially increased, and, as is the case with all enhancement devices, an appropriate balancing and thermal–hydrodynamic optimization is required for a given application. Common usage includes automobile radiators and oil coolers, aircraft recuperators, evaporators and condensers for refrigeration and air-conditioning units, among many others.

For the case of rectangular offset-strip fins (Figure 4.16.1b), the following correlations are recommended for calculating the Colburn factor j and Fanning friction factor f for varying flow and offset-fin-geometry characteristics (Manglik and Bergles, 1995):

$$j_h = 0.6522\,\mathrm{Re}_h^{-0.5403}\alpha^{-0.1541}\delta^{0.1499}\gamma^{-0.0678}\left[1 + 5.269\times10^{-5}\,\mathrm{Re}_h^{1.340}\alpha^{0.504}\delta^{0.456}\gamma^{-1.055}\right]^{0.1}, \tag{4.16.5}$$

$$f_h = 9.6243\,\mathrm{Re}_h^{-0.7422}\alpha^{-0.1856}\delta^{0.3053}\gamma^{-0.2659}\left[1 + 7.669\times10^{-8}\,\mathrm{Re}_h^{4.429}\alpha^{0.920}\delta^{3.767}\gamma^{0.236}\right]^{0.1}. \tag{4.16.6}$$

Here j_h, or the Colburn j-factor, is defined as $\left(\mathrm{Nu_h}/\mathrm{Re_h}\mathrm{Pr}^{1/3}\right)$, and $\mathrm{Nu_h}$, $\mathrm{Re_h}$, and f_h, are based on the hydraulic diameter of the inter-fin passage given by

$$D_h = \frac{4shl}{\left[2\left(sl + hl + th\right) + ts\right]}. \tag{4.16.7}$$

The special symbols used in these expressions represent the following: α=aspect ratio s/h, δ=ratio t/l, γ=ratio t/s, s=lateral spacing of strip fin, h=strip fin height, l=length of one offset module of strip fins, and t=fin thickness. These equations are based on experimental data for 18 different offset-strip-fin geometries, and they represent the data continuously in the laminar, transition, and turbulent flow regions.

Internally finned circular tubes are typically available in aluminum and copper (or copper alloys), among some other metal alloys, for commercial usage. Correlations (for heat transfer coefficient and friction factor) are available for laminar flow as well as the turbulent regime, for both straight and spiral continuous fins. For internally finned tubes with straight or spiral fins and laminar flows, Watkinson et al. (1975) have proposed the following equations, based on the hydraulic diameter D_h of the tube, which include a common expression for the isothermal Fanning friction factor but two different equations for the respective Nusselt numbers:

$$f_h = \left(\frac{16.4}{\mathrm{Re_h}}\right)\left(\frac{D_h}{D_i}\right)^{1.4}. \tag{4.16.8}$$

Straight-fin tubes:

$$\mathrm{Nu_h} = \frac{1.08 \times \log \mathrm{Re_h}}{n^{0.5}\left(1 + 0.01\mathrm{Gr_h^{1/3}}\right)} \mathrm{Re_h^{0.46}} \mathrm{Pr}^{1/3} \left(\frac{L}{D_h}\right)^{1/3} \left(\frac{\mu_w}{\mu_b}\right)^{0.14}. \tag{4.16.9a}$$

Spiral-fin tubes:

$$\mathrm{Nu_h} = \frac{8.533 \times \log \mathrm{Re_h}}{\left(1 + 0.01\mathrm{Gr_h^{1/3}}\right)} \mathrm{Re_h^{0.26}} \mathrm{Pr}^{1/3} \left(\frac{t}{p}\right)^{0.5} \left(\frac{L}{D_h}\right)^{1/3} \left(\frac{\mu_w}{\mu_b}\right)^{0.14}. \tag{4.16.9b}$$

In these equations, n is the number of fins, L the fin height, t the fin thickness, and p is the spiral pitch; the subscripts w and b, respectively, refer to properties evaluated at the tube-wall temperature and the bulk fluid temperature. Turbulent flow in tubes with straight or helical fins was correlated by Carnavos (1979) as

$$\mathrm{Nu_h} = 0.023\mathrm{Pr}^{0.4}\mathrm{Re_h^{0.8}} \left[\frac{A_c}{A_{ci}}\right]^{0.1} \left[\frac{A_{s,i}}{A_s}\right]^{0.5} \left(\sec\alpha\right)^3, \tag{4.16.10}$$

$$f_h = 0.046\mathrm{Re_h^{-0.2}} \left[\frac{A_c}{A_{c,i}}\right]^{0.5} \left(\sec\alpha\right)^{0.75}, \tag{4.16.11}$$

where $A_{c,i}$ is based on the maximum inside (envelope) flow area, $A_{s,i}$ is based on the maximum inside (envelope) surface area, and α the spiral angle in degrees for helical fins.

A numerical analysis of turbulent flow in tubes with idealized straight fins was reported. The necessary constant for the turbulence model was obtained from experimental data for air. Further improvements in numerical techniques are expected, so that a wider range of geometries and fluids can be handled without resort to extensive experimental programs. Moreover, for use of fins or extended surfaces, whether attached to tubular flow channels or in plate-fin-type ducts, the issue of

fin surface area thermal effectiveness (based on fin efficiency) has to be taken into account in the heat exchanger design. Guidelines for such considerations have been provided in a recent extended analysis (Manglik et al., 2011), and these are generally applicable to all plate-fin geometries as well as other extended surfaces.

Many proprietary surface configurations have been produced by deforming the basic tube. They are often referred to as "convoluted," "corrugated," "spiral," or "spirally fluted" tubes (Bergles, 1998; 1999; Zimparov et al., 2012), and they have multiple-start spiral corrugations along the tube length. The corrugations, or tube surface flutes, are substantially large and deep enough so as to add "extended" area to the otherwise plain tube surface. A systematic survey of the single-tube performance of condenser tubes indicates up to 400% increase in the nominal inside heat transfer coefficient (based on diameter of a smooth tube of the same maximum inside diameter); however, pressure drops on the water side are about 20 times higher.

Displaced enhancement devices are typically in the form of inserts, within elements arranged to promote transverse mixing (e.g., the looped wire insert of Figure 4.16.1c). They are used primarily for viscous liquids, to promote either heat transfer or mass transfer; the wire-loop inserts have been used for enhancement of both laminar and turbulent flow. Displaced-flow promoters, manufactured as bent-strip-type turbulators with a variety of geometric features (Bergles et al., 1991), are also used to enhance the radiant heat transfer in high-temperature applications. In the flue tube of a hot-gas-fired hot water heater, there is a trade-off between radiation and convection (Junkhan et al., 1985).

Another type of displaced insert generates vortices that sweep the heat transfer surface downstream of the element, and thus enhance the downstream flow. Delta wing and rectangular wing promoters, both corotating and counterrotating, have been studied in a variety of geometric attributes (Fiebig, 1995; Bergles and Manglik, 2013). One manifestation of this is to punch a wing-shaped protrusion into the fins of a compact heat exchanger, and this can be achieved in both plate-fin and tube-fin configurations (Bergles and Manglik, 2013). However, no general correlations for f and Nu have been developed to facilitate the implementation in and design of heat exchangers; this is perhaps also a reflection of the challenges of scaling and correlating a large number of parameters that come to play in their usage.

Swirl-flow devices are made up of tube inserts, geometrical surface variations, and tangential fluid entry arrangements that produce swirling and vortex-induced mixing along the flow direction. They typically include twisted-tape inserts, periodic tangential fluid injection, and helically twisted tubes, among a few others (Manglik and Bergles, 2002). Of these, twisted-tape inserts have been widely used to improve heat transfer in both laminar and turbulent flow inside circular tubes. Correlations for predicting Fanning friction factors and Nusselt numbers for laminar flow as well as turbulent flow in tubes have been developed (Manglik and Bergles, 1993a; 1993b).

In the case of laminar flows, the helical swirl generation in the tube fitted with a twisted-tape insert has been found to scale with the following dimensionless swirl parameter (Manglik and Bergles, 1993a):

$$\mathrm{Sw} = \left(\mathrm{Re}_s \big/ \sqrt{y}\right). \tag{4.16.12a}$$

Here y is the tape-twist ratio (180° helical twist pitch divided by tube inside diameter; the geometrical attributes are identified in Figure 4.16.3), and based on the mass flux G (mass flow rate per unit cross-sectional area) the swirl velocity V_s and Re_s are

$$\mathrm{Re}_s = \left(\rho V_s D_i/\mu\right), V_s = \left(G/\rho\right)\left[1+\left(\pi/2y\right)^2\right]^{1/2}. \tag{4.16.12b}$$

Based on this scaling, the isothermal Fanning friction factor is given by

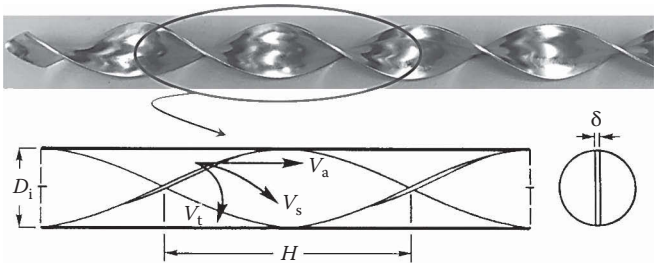

FIGURE 4.16.3 A typical twisted-tape insert and its geometrical descriptors.

$$f_s = \frac{15.767}{\mathrm{Re}_s}\left[\frac{\pi + 2 - 2(\delta/D_i)}{\pi - 4(\delta/D_i)}\right]^2 \left(1 + 10^{-6}\,\mathrm{Sw}^{2.55}\right)^{1/6}, \tag{4.16.13a}$$

where δ is the tape thickness, and f_s is based on the effective swirl velocity and swirl-flow length:

$$f_s = \left(\frac{\Delta p D_i}{2\rho V_s^2 L_s}\right), \text{ and } L_s = L\left[1 + \left(\frac{\pi}{2y}\right)^2\right]^{1/2}. \tag{4.16.13b}$$

For laminar forced convection heat transfer in tubes with twisted-tape inserts and walls maintained at a uniform temperature, the following correlation (Manglik and Bergles, 1993a) is recommended:

$$\mathrm{Nu}_m = \underbrace{4.612\left(\mu_b/\mu_w\right)^{0.14}}_{\text{fully developed flow}}\left[\left\{\underbrace{\left(1 + 0.0951\mathrm{Gz}^{0.894}\right)^{2.5}}_{\text{thermal entrance}} + \underbrace{6.413\times10^{-9}\left(\mathrm{Sw}\cdot\mathrm{Pr}^{0.391}\right)^{3.835}}_{\text{swirl flows}}\right\}^2 + \underbrace{2.132\times10^{-14}\left(\mathrm{Re}_a\cdot\mathrm{Ra}\right)^{2.23}}_{\text{free convection}}\right]^{0.1}. \tag{4.16.14}$$

The interplay of the different groupings (convective effects) on the twisted-tape-induced heat transfer performance is shown in Figure 4.16.4. These correlations have been found to predict very well the data available in the literature (Manglik et al., 2001; Manglik and Bergles, 2013).

In the turbulent flow regime ($\mathrm{Re} \geq 10^4$), the scaling with Sw is inapplicable and instead the Fanning friction factor correlates as

$$f = \left(\frac{0.0791}{\mathrm{Re}^{0.25}}\right)\underbrace{\left[\frac{\pi}{\pi - (4\delta/D_i)}\right]^{1.75}\left[\frac{\pi + 2 - (2\delta/D_i)}{\pi - (4\delta/D_i)}\right]^{1.25}}_{\text{tube partitioning}}\underbrace{\left(1 + \frac{2.752}{y^{1.29}}\right)}_{\text{swirl}}. \tag{4.16.15}$$

For turbulent heat transfer with $\mathrm{Re} \geq 10^4$, the recommended Nusselt number correlation is

$$\mathrm{Nu} = \left(0.023\mathrm{Re}^{0.8}\mathrm{Pr}^{0.4}\right)\underbrace{\left[\frac{\pi}{\pi - (4\delta/D_i)}\right]^{0.8}\left[\frac{\pi + 2 - (2\delta/D_i)}{\pi - (4\delta/D_i)}\right]^{0.2}}_{\text{tube partitioning}}\underbrace{\left[1 + \frac{0.769}{y}\right]}_{\text{swirl}}\phi, \tag{4.16.16}$$

where ϕ is the temperature-dependent property correction factor and

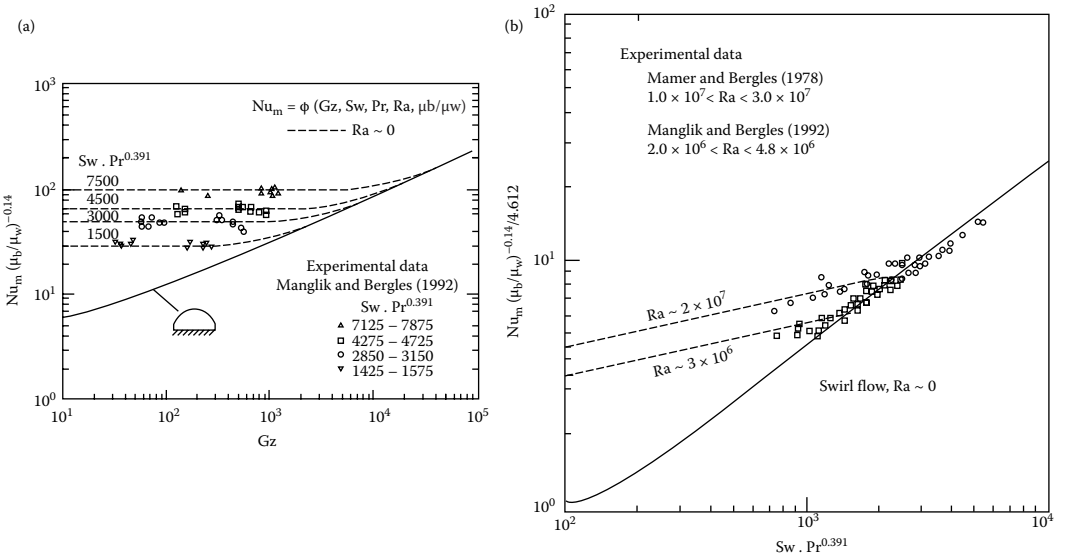

FIGURE 4.16.4 Influence of twisted-tape-generated swirl on the laminar forced convection in circular tubes with uniform wall temperature; comparison of prediction with experimental data. (a) Swirl flow and thermal entrance region and (b) swirl flow with superimposed free convection effects. (Data reported by Marner, W.J., and Bergles, A.E., Augmentation of tubeside laminar flow heat transfer by means of twisted-tape inserts, static-mixer inserts, and internally finned tubes. *Proceedings of Sixth International Heat Transfer Conference*, August 7–11, 1978, Toronto, Hemisphere, Washington DC, pp. 583–588, 1978; Manglik, R.M., and Bergles, A.E., *Wärme-und Stoffübertragung*, 27(4), 249–257, 1992.).

$$\phi = \left(\mu_b/\mu_w\right)^n \text{ or } \left(T_b/T_w\right)^m .$$

$$n = \begin{cases} 0.18 & \text{liquid heating} \\ 0.30 & \text{liquid cooling} \end{cases} \quad \text{and} \quad m = \begin{cases} 0.45 & \text{gas heating} \\ 0.15 & \text{gas cooling} \end{cases}$$

Again, these correlations find generalized vetting with much of the available data, and extended discussions on their development, validity, as well as design and applications issues are given in (Manglik et al., 2001; Manglik and Bergles, 2002).

Another attractive swirl-flow technique is to use noncircular ducts that are helically twisted along their flow axis. Two such examples are twisted oval tubes and twisted rectangular tubes as shown in Figure 4.16.5. With air flows inside constant surface temperature twisted oval tube, up to 2.0–2.5 times higher Nu are obtained, compared to straight oval tubes of same cross-sectional aspect ratio and same pumping power (Bishara et al., 2013). The relative enhancement, however, is less than that with a comparable twisted-tape insert. In the case of laminar viscous liquid ($5 \le Pr \le 100$) flows through twisted rectangular tube, and depending upon the cross-sectional aspect ratio and the helical twist ratio, up to 2.4–13 times higher heat transfer rates can be sustained on a constant-pumping-power basis compared to that in a straight duct (Manglik et al., 2012; Patel et al., 2012). Moreover, when considering the constraint of fixed heat load and pressure drop, as much as 50%–90% reduction in surface area can be obtained in a new heat exchanger.

Performance Evaluation Criteria for Single-Phase Forced Convection in Tubes

Numerous, and sometimes conflicting, factors enter into the ultimate decision to use an enhancement technique: heat duty increase or area reduction that can be obtained, initial cost, pumping

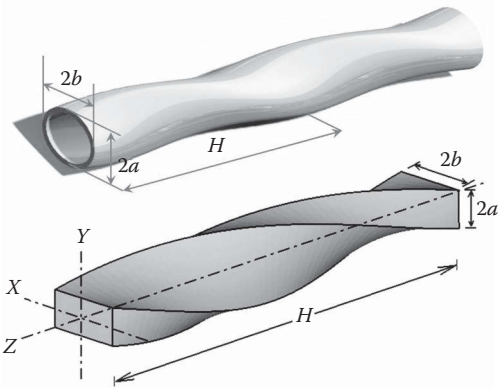

FIGURE 4.16.5 Swirl-producing twisted tubes of oval and rectangular cross sections.

power or operating cost, maintenance cost (especially cleaning), safety, and reliability, among others. These factors are difficult to quantify in a common comparative basis, and a generally acceptable selection criterion may not exist. It is possible, however, to suggest some performance criteria for preliminary design guidance. Several application-objective-based figures of merit have been developed to this end (Bergles, 1998), and a functional listing is given in Table 4.16.2. These seek to provide optimization metrics for the trade-off between improved convection heat transfer and the concomitant frictional penalty.

As an example, consider the criterion FG-2a, in which the basic heat exchanger geometry, approach temperature difference, and the pumping power fixed, and the application objective is to increase the heat transfer or the heat load capacity. This can be expressed as the following ratio of heat transfer rate for the tube with insert q_a and that for the plain or empty tube q_s:

TABLE 4.16.2
Performance Evaluation Criteria or Enhancement Optimization Figures of Merit for Single-Phase Forced Convection in Tubular Heat Exchangers

		Fixed				
Case	**Geometry**	$\dot{m}$	P	q	ΔT_i	**Objective**
FG-1a	N, L	✓			✓	$q \uparrow$
FG-1b	N, L	✓		✓		$\Delta T_i \downarrow$
FG-2a	N, L		✓		✓	$q \uparrow$
FG-2b	N, L		✓	✓		$\Delta T_i \downarrow$
FG-3	N, L			✓	✓	$P \downarrow$
FN-1	N		✓	✓	✓	$L \downarrow$
FN-2	N	✓		✓	✓	$L \downarrow$
FN-3	N	✓		✓	✓	$P \downarrow$
VG-1	–	✓	✓	✓	✓	$(NL) \downarrow$
VG-2a	(NL)	✓	✓		✓	$q \uparrow$
VG-2b	(NL)	✓	✓	✓		$\Delta T_i \downarrow$
VG-3	(NL)	✓		✓	✓	$P \downarrow$

N, number of tubes; L, length of tubes; $\dot{m}$, mass flow rate; P, pumping power; q, rate of heat transfer; and ΔT_i, inlet or approach temperature difference.

$$\text{FG-2a} = \frac{q_a}{q_s} = \left(\frac{\text{Nu}_a}{\text{Nu}_s}\right)_{N,L,D_i,P,\Delta T_i} . \tag{4.16.17}$$

Here, P=pumping power, ΔT_i=inlet or approach bulk temperature difference, N=number of tubes in a shell-and-tube exchanger, and L=length of the tubes.

With the pumping power per tube (neglecting entrance and exit losses) given as

$$P = \frac{\dot{m}\Delta p}{\rho} = \left(\frac{\pi\mu^2 L}{2\rho^2 D_i^2}\right)\left(f\text{Re}^3\right), \tag{4.16.18a}$$

and with a specified $\left(L/D_i\right)$, the fixed pumping power demand thus imposes the following restriction:

$$\left(f\text{Re}^3\right)_a = \left(f\text{Re}^3\right)_s . \tag{4.16.18b}$$

Typical results for tubes with twisted-tape inserts and single-phase convection in the laminar flow regime (Yerra et al., 2006) are presented in Figure 4.16.6. As much as 3.5–5 times higher heat transfer rates are seen to be sustained in heat exchangers, and the enhancement tends to be much higher with larger Re but smaller y and Pr.

Similar evaluations for most passive techniques can be carried out, though it would have different optimization objectives based on the specific heat exchanger application.

Active and Compound Techniques for Single-Phase Forced Convection

Under active techniques, *mechanically aided heat transfer* in the form of either surface rotation or surface scraping can increase forced convection heat transfer. The latter is widely used in the thermal processing of viscous food products. Surface scraping rejuvenates the heat transfer surface with unprocessed media, thereby removing the high-resistance processed media as well as effectively reducing surface fouling; these mechanisms improve convection as well as prevent its deterioration. A novel offshoot of this technique has recently been devised (Solano et al., 2011; Bergles and

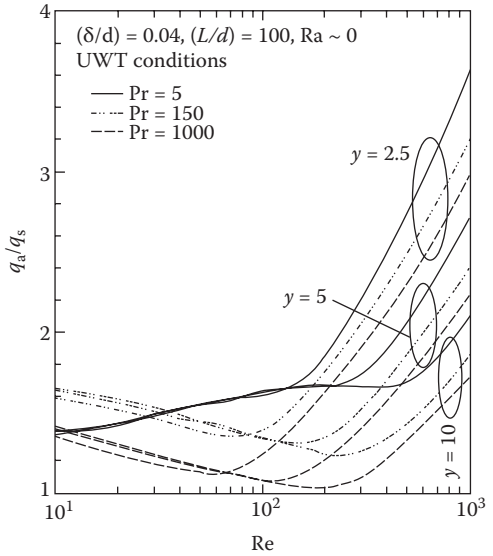

FIGURE 4.16.6 Enhanced heat transfer performance in laminar flows inside circular tubes with twisted-tape inserts for fixed pumping power and heat exchanger size (or criterion FG-2a).

Manglik, 2013); a tube-side self-cleaning scheme for shell-and-tube exchangers, which consists of a reciprocating rod and surface scraper elements.

Surface vibration has been demonstrated to improve heat transfer to both laminar and turbulent duct flow of liquids. In newer approaches to fruitfully employing this technique, as an example, piezoelectric actuators have been used to augment the natural convection heat transfer from air-cooled finned heat sinks. Likewise, *fluid vibration* has been extensively studied for both air (using acoustic fields, e.g., loudspeakers and sirens) and liquids (using flow interrupters, pulsations inducing actuators, and ultrasonic transducers). Pulsations are relatively simple to apply to low-velocity liquid flows, and improvements of several hundred percent can be realized. However, in some recent work, ultrasonic vibrations have also been applied to obtain enhanced subcooled boiling and not single-phase convection; see (Bergles and Manglik, 2013).

Some very impressive enhancements have been recorded with *electrical fields* (DC or AC), particularly in the laminar-flow region and when applied to dielectric liquids. Improvements of at least 100% were obtained when voltages in the 10-kV range were applied to transformer oil. It is found that even with intense electrostatic fields, the heat transfer enhancement disappears as turbulent flow is approached in a circular tube with a concentric inner electrode. In essence, electrostatic fields tend to promote greater bulk fluid mixing or flow disruption and thereby enhance heat transfer.

Compound techniques are a slowly emerging area of enhancement that holds promise for practical applications, since heat transfer coefficients can usually be increased above each of the several techniques acting alone. Some examples that have been studied (Manglik and Bergles, 2004; Bergles and Manglik, 2013) are as follows: circular tubes with structured roughness (ribs and/or corrugations) and twisted-tape inserts, a rough cylinder subject to acoustic vibrations, internally finned tube with twisted-tape inserts, finned tubes submerged in fluidized beds, externally finned tubes subjected to vibrations, rotating channels with internal ribbed roughness, gas–solid suspension with an electrical field, fluidized bed with pulsations of air, and a rib-roughened channel with longitudinal vortex generation.

In an extended recent study (Zimparov et al., 2012), the compound usage of twisted tapes by inserting them inside corrugated tubes (or tubes with structured roughness that in some cases increase area as well), have been considered in turbulent water flows ($3.5 \times 10^3 < \mathrm{Re} < 5.0 \times 10^4$). Several variations of tube corrugation and tape geometries are explored, and the data suggest that, for the specified experimental conditions, the best thermodynamic performance is obtained with a corrugated tube with ($e/d = 0.057$; $p/e = 6.77$) and a tape-twist ratio of $y = 4.7$. In yet another example (Neshumayev and Tiikma, 2007), a twisted-tape insert with a spirally wound strip over its surface has been used for enhanced convective and radiative heat recovery from flue gases inside tubes of fire-tube boilers. The radiation contribution was ascertained to be 20% of the total heat flux.

Pool Boiling

Selected passive and active enhancement techniques have been shown to be effective for pool boiling and flow boiling/evaporation. Most techniques apply to nucleate boiling; however, some techniques are applicable to transition and film boiling.

It should be noted that phase-change heat transfer coefficients are relatively high. The main thermal resistance in a two-fluid heat exchanger often lies on the non-phase-change side. Fouling of either fluid-side surface can represent the dominant thermal resistance and alter this consideration (Bergles and Somerscales, 1995). For this reason, the emphasis is often on enhancement of single-phase flow. On the other hand, the overall thermal resistance may then be reduced to the point where significant improvement in the overall performance can only be achieved by enhancing the two-phase flow stream. Two-phase enhancement would also be important in double-phase-change (boiling/condensing) heat exchangers.

As discussed elsewhere in considering the fundamental aspects of heterogeneous phase change (Bergles, 1988), surface material and finish have a strong effect on nucleate and transition pool boiling.

However, reliable control of nucleation on plain surfaces is not easily accomplished. Accordingly, since the earliest days of boiling research, there have been attempts to relocate the boiling curve through use of relatively gross modification of the surface. For many years, this was accomplished simply by area increase in the form of low helical fins. The subsequent tendency was to structure surfaces to improve the nucleate boiling characteristics by a fundamental change in the boiling process. Many of these advanced surfaces are being used in commercial shell-and-tube boilers.

Several manufacturing processes have been employed: machining, forming, layering, and coating. A few examples of such manufactured surfaces are given in Figure 4.16.7, where the characteristic features of surface modifications produced by different machining methods are highlighted. In Figure 4.16.7a, a tunnel-and-pore arrangement produced by rolling, upsetting, and brushing is depicted. An alternative modification is to roll, split, and reroll very low fins or knurl and roll them into the different T-shaped structures shown in Figure 4.16.7b. In one of the earliest developments in this arena was to sinter or braze metallic particles on the surface to form a porous matric. These surfaces have been found to enhance pool boiling considerably (Bergles, 1997; Manglik, 2006). Wall superheat reductions of up to a factor of ten are common with these surfaces. The advantage is not only a high nucleate boiling heat transfer coefficient, but the fact that boiling can take place at very low-temperature differences.

These structured boiling surfaces, which span the domain of *rough surfaces* and *extended surfaces*, and which were developed for refrigeration and process applications, have also been used as "heat sinks" for immersion-cooled microelectronic chips. For applications in large-scale heat exchangers, shell-and-tube exchangers, for example, the behavior of tube bundles is found to often be different with structured-surface tubes. Enhanced nucleate boiling dominates in such cases, and the convective boiling enhancement, found in plain tube bundles, does not occur.

Some recent noteworthy development has been in the use *additives for liquids* to enhance pool boiling heat transfer. These include solid particles (in recent usage referred to as "nano" particles), liquid traces, soluble substances (e.g., surface-active agents and polymers), and gas bubbles, among some others, to form suspensions or colloidal solutions and liquid mixtures. The addition of surfactants or certain surface-active polymers to water in weak concentrations has been shown to significantly enhance pool boiling from a cylindrical heater (Wasekar and Manglik, 2000; 2002; Zhang and Manglik, 2004; 2005a; 2005b). Up to ~20% enhancement was reported (Athavale et al., 2012) with weak aqueous solutions of the reagent-like polymer HEC QP-300; in stronger solutions with higher polymer concentrations, however, heat transfer degrades at low heat fluxes (incipience and partial boiling) but is enhanced by ~45% at higher heat fluxes (fully developed nucleate boiling). The complex interplay of reagent-induced liquid–solid surface wetting, along with dynamic (time-dependent) changes in the vapor–liquid interfacial tension as well as the shear-dependent shear-thinning (in polymers) has been attributed to the molecular mobility (adsorption-desorption, physisorption, and electrokinetics) of the additive for effecting the enhanced boiling behavior

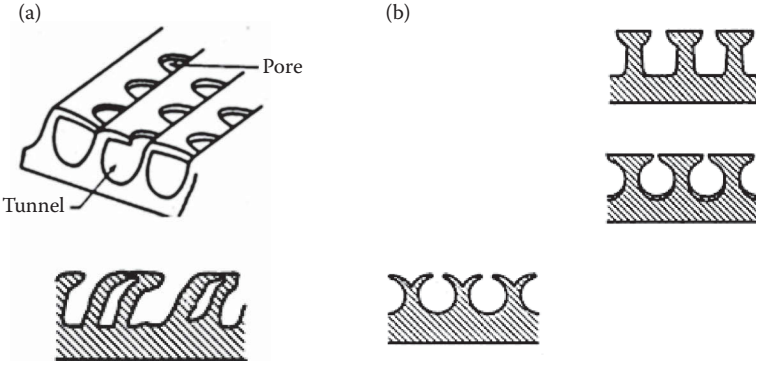

FIGURE 4.16.7 Some examples of structured boiling surfaces produced by machining and forming: (a) deeply knurled surface, or Hitachi Thermoexcel™ surface and (b) low-fin surfaces, or Wieland Gewa™ surfaces.

(Manglik, 2011); Marangoni convection, consisting of both thermocapillary and diffusocapillary convection might also be at play in these situations (Wasekar and Manglik, 2003).

Active enhancement techniques include heated surface rotation, surface wiping, surface vibration, fluid vibration, electrostatic fields, and suction at the heated surface. Although active techniques are effective in reducing the wall superheat and/or increasing the critical heat flux, the practical applications are very limited, largely because of the difficulty of reliably providing the mechanical or electrical effect.

Compound enhancement, which involves two or more techniques applied simultaneously, has also been studied. Electrohydrodynamic enhancement was applied to a finned tube bundle, resulting in nearly a 200% increase in the average boiling heat transfer coefficient of the bundle, with a small power consumption for the field. Another example is the use of a wire mesh to wrap the surface of a micro-finned tube to promote compound pool boiling enhancement with refrigerants (Bergles and Manglik, 2013). The intent is to augment the extended surface with nucleation sites (provided by the wire mesh) so as to aid the nucleate phase-change process.

Convective Boiling/Evaporation

The structured surfaces described in the previous section are generally not used for in-tube vaporization, because of the difficulty in manufacturing. One notable exception is the high-flux surface in a vertical thermosiphon reboiler. The considerable increase in the low-quality, nucleate boiling coefficient is desirable, but it is also important that more vapor is generated to promote circulation.

Structured *rough surfaces*, comprising of helical-repeated ribs and helically coiled wire inserts have been used to increase vaporization coefficients and the dry-out heat flux in once-through boilers.

Numerous tubes with internal fins (*extended surface*), either integral or attached, are available for refrigerant evaporators. Original configurations were tightly packed, copper, offset strip fin inserts soldered to the copper tube or aluminum, star-shaped inserts secured by drawing the tube over the insert. Examples are shown in Figure 4.16.8. Average heat transfer coefficients (based on surface area of smooth tube of the same diameter) for typical evaporator conditions are increased by as much as 200%. A cross-sectional view of a typical "microfin" tube is included in Figure 4.16.8. The average evaporation boiling coefficient is increased 30%–80%. The pressure drop penalties are less; that is, lower percentage increases in pressure drop are frequently observed.

Twisted-tape inserts, or *swirl-flow devices*, are generally used to increase the burnout heat flux for subcooled boiling at high imposed heat fluxes $10–10^2$ MW/m^2, as might be encountered in the cooling of fusion reactor components. Increases in burnout heat flux of up to 200% were obtained at near atmospheric pressure. In the bulk boiling region, the helically flowing liquid tends to be centrifuged to the wall so that a liquid film is maintained during the evaporation process, and thereby delaying dryout until a very high quality. The remaining droplets are then again centrifuged to the wall, which reduces the temperature excursion. To provide additional performance and predictive details, a mechanistic evaluation of subcooled as well as bulk boiling is delineated elsewhere (Manglik and Bergles, 2013). In fact, twisted tapes have been shown to enhance convective vaporization of water

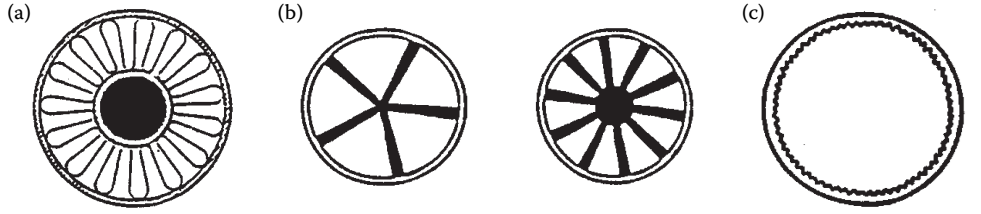

FIGURE 4.16.8 Inner-fin tubes for refrigerant evaporators: (a) strip-fin inserts, (b) star-shaped inserts, and (c) microfin.

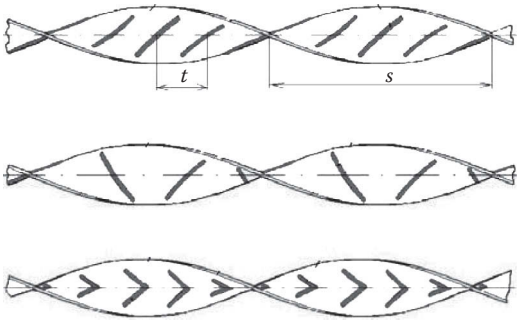

FIGURE 4.16.9 Compound enhancement using twisted-tape inserts that are wire-wound or have wire-laced ribs on their surface in different array configurations. (Adapted from Tarasevich, S.E., Yakovlev, A.B., Giniyatullin, A.A., and Shishkin, A.V., Heat and mass transfer in tubes with various twisted tape inserts. *ASME 2011 IMECE*, Denver, CO. Denver, CO: ASME, New York, Paper No. IMECE2011-62088, 2011).

(low pressure and high pressure), refrigerants (R-11, R-113, R-12, and R-22), a cryogenic fluid (liquid nitrogen), and liquid metals (cesium, mercury, potassium, rubidium, and sodium).

In a recent study on a novel *compound enhancement* usage of twisted tapes that have either wire wraps or laces that form "ribs" on the tape surface (Tarasevich et al., 2011), it has been experimentally shown that two-phase flow behavior is improved. A sampling of some of the modified tapes used in the study is presented in Figure 4.16.9. In the annular flow regime, the liquid accumulation on the tape surface tends to reduce. The small-scale tape-surface wire ribs are perhaps instrumental in disrupting liquid film formation and thereby reducing "dry spots" at the tube surface. While the hydrodynamic behavior has been observed visually, quantification of the heat transfer enhancement has yet to be established (Manglik and Bergles, 2013); though ~2.5 times higher Nusselt number with a 10-fold increase in the frictional resistance has been reported for single-phase flows.

Vapor-Space Condensation

As discussed elsewhere, condensation can be either filmwise or dropwise. In a sense, dropwise condensation is enhancement of the normally occurring film condensation by surface treatment. The only real application is for steam condensers, because nonwetting coatings are not available for most other working fluids. Even after much study, little progress has been made in developing permanently hydrophobic coatings for practical steam condensers. The enhancement of dropwise condensation is pointless, because the heat transfer coefficients are already so high.

Surface extensions are widely employed for enhancement of condensation. The integral low fin tubing (with a tapered narrow-tip to wide-base profile), used for kettle boilers, is also used for horizontal tube condensers. With proper spacing of the fins to provide adequate condensate drainage, the average coefficients can be several times those of a plain tube with the same base diameter. These fins are normally used with refrigerants and other organic fluids that have low condensing coefficients, but which drain effectively, because of low surface tension.

The fin profile can be altered according to mathematical analysis to take full advantage of the Gregorig effect, whereby condensation occurs mainly at the tops of convex ridges. Surface tension forces then pull the condensate into concave grooves, where it runs off. The average heat transfer coefficient is greater than that for an axially uniform film thickness. The initial application was for condensation of steam on vertical tubes used for reboilers and in desalination. According to numerical solutions, the optimum geometry is characterized by a sharp fin tip, gradually changing curvature of the fin surface from tip to root, wide grooves between fins to collect condensate, and periodic condensate strippers. Figure 4.16.10 schematically shows the configuration, as that employed by Mori et al. (1981).

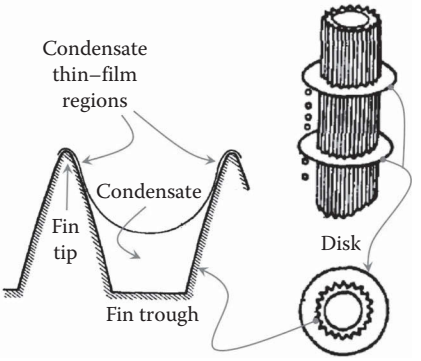

FIGURE 4.16.10 Recommended flute profile and schematic of condensate strippers [adapted from Mori et al. (1981)].

Recent interest has centered on 3-D surfaces for horizontal-tube condensers. The considerable improvement relative to low fins or other 2-D profiles is apparently due to multidimensional drainage at the fin tips. Other 3-D shapes include circular pin fins, square pins, and small metal particles that are bonded randomly to the surface. Another focus area has been to produce hydrophobic surfaces to promote dropwise condensation, which yields order of magnitude higher heat transfer coefficient compared to that in film condensation (Rose, 2015). Plasma ion implantation has been employed in one instance to create high hydrophobicity on surfaces of stainless steel tubes.

Convective Condensation

This final section on enhancement of the various modes of heat transfer focuses on in-tube condensation. The applications include horizontal kettle-type reboilers, moisture separator reheaters for nuclear power plants, and air-conditioner condensers.

Internally grooved or knurled tubes, deep spirally fluted tubes, random roughness, and conventional inner-fin tubes have been shown to be effective for condensation of steam and other fluids.

The microfin tubes mentioned earlier have also been applied successfully to in-tube condensing. As in the case of evaporation, the substantial heat transfer improvement is achieved at the expense of a lesser percentage increase in pressure drop. By testing a wide variety of tubes, it has been possible to suggest some guidelines for the geometry, for example, more fins, longer fins, and sharper tips; however, general correlations are not yet available. Fortunately for heat-pump operation, the tube that performs best for evaporation also performs best for condensation.

Twisted-tape inserts result in rather modest increases in heat transfer coefficient for complete condensation of either steam or refrigerant. The pressure drop increases are large because of the large wetted surface. Coiled tubular condensers provide a modest improvement in average heat transfer coefficient.

Further Information

This section gives some indication as to why heat transfer enhancement is one of the fastest growing areas of heat transfer. Many techniques are available for improvement of the various modes of heat transfer. Fundamental understanding of the transport mechanism is growing, but, more importantly, design correlations are being also established. Many effective and cost-competitive enhancement techniques have made the transition from the laboratory to commercial heat exchangers. Most prominent applications of such technology transfer include airborne recuperators and regenerations, automotive heat exchangers, electronic cooling heat sinks, steam condensers (water cooled and air cooled), steam generators, and petroleum-product processing heat exchangers, among some others.

Moreover, new and emerging applications demand newer variations or manifestations of the enhancement techniques, which perhaps even require advanced manufacturing techniques. This is particularly the case with microscale exchangers, and which might even evolve into much smaller-scale variants. The associated research is also directed more toward characterization of the underlying enhancement mechanisms, so as to develop more phenomenologically scaled or flow-physics-based predictive correlations.

Broad reviews of developments in enhanced heat transfer are available (Thome, 1990; Bergles et al., 1991; Bergles, 1997; 1998; Manglik, 2003; Manglik and Bergles, 2004; Webb and Kim, 2005; Bergles and Manglik, 2013). Also, several journals, especially *Journal of Enhanced Heat Transfer*, which is entirely devoted to the dissemination of new research and developments in enhancement methods, along with *Heat Transfer Engineering*, *Journal of Heat Transfer*, *Journal of Thermal Science and Engineering Applications*, and *International Journal of Refrigeration*, among the numerous other publications, more often feature this technology.

4.17 HEAT PIPES

Sameer Khandekar

Introduction

The term "heat pipe" is a rather interesting way to describe a "synergistic engineering structure" which is equivalent to a material having a thermal conductivity greatly exceeding to that of any known material (Grover, 1966)—for all practical purposes, what it means is that a *heat pipe* is a thermal superconductor. We know that materials around us have different thermal conductivities, that is, the ease with which it transports thermal energy through it when subjected to a temperature gradient. For example, good thermal conductors commonly known are copper (with $k \sim 398$ W/mK) and aluminum (with $k \sim 185$ W/mK), while common insulating materials are wood (with $k \sim 0.1$ W/mK) or Teflon (with $k \sim 0.35$ W/mK). Materials like stainless steel and brass have intermediate values. Exotic materials such as diamond may have very high thermal conductivities, usually exceeding about 2000 W/mK. Coming back to a "heat pipe" and its definition—it sounds like a "pipe" which, of course, carries heat and works like a superconductor; this, necessarily means that its thermal conductivity should be very large. How large?—is a valid question to ask at this point. To be of some worth, it must at least be an order of magnitude greater than, say the common engineering materials used for heat transfer applications, such as copper or aluminum. If such a synergistic engineering structure can indeed be achieved, at a "low" cost, probably also lower weight, and if it can operate "passively," then it certainly sounds a very reasonable proposition to pursue. Indeed, the idea of such a device was conceived in the mid-1960s, which we now know as a "heat pipe."

Before we proceed further, certain terms and concepts associated with heat pipes need some further clarification. First, heat transfer from a hot object (source) to a cold object (sink) can be achieved "actively" or "passively." By "active" method, we mean that some external power, such as an electrically driven fan, is used for flow of a coolant to achieve the required heat transfer. This is usually true for forced convection systems, which may or may not involve any phase-change phenomena. Passive thermal systems, on the other hand, do not need any additional external power source for their operation. The heat that needs to be transferred itself usually acts as the "driver" to help facilitate its own transfer. For example, under natural convection heat transfer, a density gradient is initiated due to the imposed temperature gradient, which leads to a free-convective motion, resulting in passive heat transfer. In a similar fashion, a heat pipe is a passive device. The associated thermal-hydraulic phenomena are driven by the imposed thermal gradient itself. Industrial applications tend to prefer passive systems for obvious advantages, primarily because of reliability and redundancy considerations. Second, it must be noted that a heat pipe is not a "cooling" device, it is a pure "heat transfer" device. A heat pipe is therefore not a "refrigerator," in a thermodynamic sense. It transfers heat in the natural direction only, from high-temperature source to low-temperature sink—but does it so efficiently that it can be termed as a thermal superconductor. There is no external "work transfer" crossing the boundary of a heat pipe.

The reverse of thermal conductivity is thermal resistance—superconductors have exceedingly low resistances. Drawing an analogy of heat conduction with an electrical resistance system, following Ohm's law, wherein the "emf" is the driving potential for the flow of electronic charge through a medium, we can write Fourier's law of heat conduction as

$$\dot{Q} = k \cdot A \left(\frac{\Delta T}{\Delta x} \right) = \left(\frac{\Delta T}{\left(\frac{\Delta x}{kA} \right)} \right) = \frac{\Delta T}{R_{\text{th}}} \tag{4.17.1}$$

where

$$\Delta T = T_{\text{source}} - T_{\text{sink}}\text{, which is analogous to,} \tag{4.17.2}$$

$$I = \Delta V / R_{\text{elec}} \tag{4.17.3}$$

As in the case of electronic transport under an applied voltage, the objective of a heat pipe, or for that matter, any thermal conductor, is to transport maximum amount of heat at a given operating thermal potential difference, thus operating at the lowest possible resistance. The reverse is true for an insulator, wherein the objective function is to minimize the net heat transport when the system is subjected to a thermal gradient.

At this stage, we have understood that a heat pipe is an excellent thermal conductor of heat. Hence, the ensuing net thermal resistance of engineering systems that incorporate heat pipes ought to be rather small. Another important aspect of understanding a heat pipe thermal system is to appreciate the difference between "heat load" and "operating temperature." By heat load, we mean the amount of heat which is handled by the system or which is being dissipated/expected to be dissipated by a given system, say for example, a power electronic component that generates heat due to I^2R_{elec} heating. In principle, the heat load can be removed from this component at any operating temperature which we desire. For a specified heat load and geometry of the system, as the temperature of the sink goes up or down (for whatever reasons, by design or during its operation), the source temperature will keep going up or down, respectively, to satisfy Equation 4.17.1. Hence, under such conditions, the operating temperature of the device (the source temperature) depends on the sink temperature. In this context, it should be appreciated here that heat load and the operating temperature are two distinct entities, linked to each other via the sink temperature and the effective thermal conductivity of the medium connecting the source and the sink. In this background, there are a few pertinent questions to ask ourselves (i) is the component safe and reliable at the operating temperature? (ii) will the heat pipe (or any other thermal conductor) used to transport heat, change its performance with changing operating temperatures? (iii) is there a maximum heat load beyond which the heat pipe will stop working as a superconductor thereby rendering itself to be practically useless—alternately, are there any limitations on the superconducting nature of the device? Naturally, the maximum allowable operating temperature of any system with specified heat dissipation is intrinsically linked to its thermo-physical material properties, functionality, and desirable operating characteristics. For example, typical semiconductor-based microelectronic systems fail, or start underperforming, at the die-level operating temperatures exceeding about 85°C. In the following sections, we will explore the answers to these questions.

What Is a Conventional Heat Pipe?

Let us now explore the physical construction of a basic (conventional) heat pipe and see how thermal superconductivity is realized in a practical device, viz. a "synergistically operating engineering structure." In realizing a standard heat pipe with the goal of creating a superconducting system, the term synergy refers to the collaborative interaction of at least four different concepts of thermophysics: (1) evaporation and/or boiling, (2) condensation, (3) porous media fluid flow, and (4) surface tension driven capillary pumping.

In general, a typical conventional heat pipe utilizes the continuous evaporation/condensation of a suitable working fluid for two-phase heat transport, utilizing latent heat in a closed system, as shown in Figure 4.17.1. A conventional heat pipe consists of three sections: (1) the evaporator section, wherein the heat load to be dissipated is attached; heat comes inside the heat pipe system from here, and hence, the existence of this section is mandatory (otherwise why are we here for anyway!), (2) an adiabatic section, where there is no thermal interaction of the pipe with the environment.

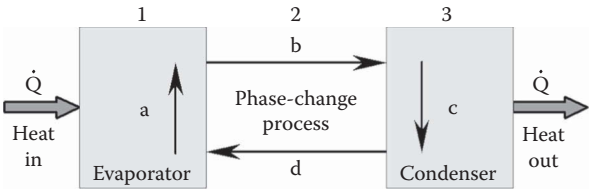

FIGURE 4.17.1 Block diagram showing the components of heat pipe and their respective functions.

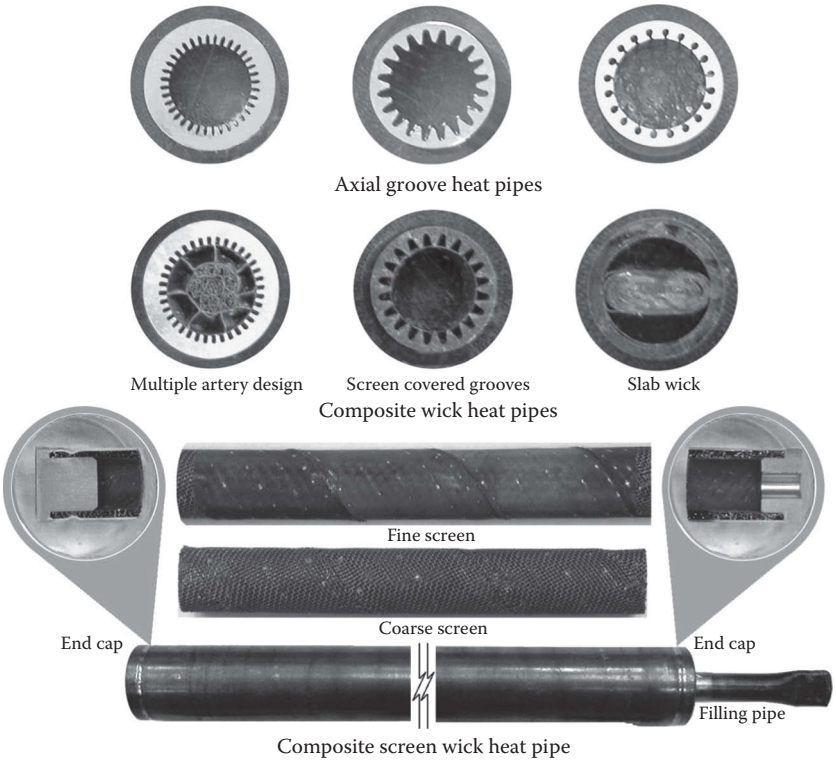

FIGURE 4.17.2 Various types of wick structures (top) and typical construction of a conventional heat pipe using screen wicks (bottom).

Depending on the system, this section may or may not be there. The existence of an adiabatic section, is, in principle, not essential for a heat pipe to operate, and (3) a condenser section, which serves as the heat sink—this is certainly an essential element of the system, as shown in Figure 4.17.1. The physical components of a conventional heat pipe, as shown in Figure 4.17.2, are as follows:

- A container, usually made of metal; glass, ceramics, and polymers can also be employed. For the process of heat transfer to be materialized, the very first resistance that needs to be overcome is the thermal resistance of the container material. Hence, unless there is a special requirement or purpose, good conducting materials are always preferable, at least from a thermal perspective.
- A capillary wick structure, made of sintered metal powders, screens wick or axial grooves cut longitudinally along the length of the heat pipe; woven fiberglass or metals; metal and carbon fibers can also be employed. Various composite wicks have also been used to enhance the performance; for example, axial grooves can be combined with screen wicks. Some designs of the internal wick structures are shown in Figure 4.17.2.

- A small amount of working fluid (which is sufficient to saturate the wick structure), which depends on the heat pipe operating temperature range (can vary from 4 to 2200 K).

For filling the heat pipe, the container is evacuated and then an appropriate amount of working fluid is administered into it. The container is then sealed and the heat pipe is ready for operation. Referring back to Figure 4.17.1, heat (Q) is added to the evaporator section (1) and thereby the working fluid, which is in equilibrium with its own vapor, gets vaporized (a). Driven by the pressure difference between the hot evaporator section and the cold condenser section, the vapor flows (b) to the condenser section (3) and is condensed there (c). During the phase-change processes, the fluid absorbs or releases, respectively, the latent heat of vaporization. The liquid returns (d) through the capillary structure from the condenser to the evaporator driven by capillary forces. By virtue of the capillary pumping action, the heat pipe can be operated in a microgravity field (as in satellites) or against gravity (on the ground with evaporator section located above the condenser section).

Needless to say that there should be good chemical compatibility between all the material components of a heat pipe, that is, container, wick structure, endcaps, etc. lest it will start a chemical reaction between them (say, e.g., the working fluid and the wick or the container), and in the process, unwanted chemical products/noncondensable gases (NCGs) will form inside the system. Additionally, for most heat pipe systems, a thorough sealing is required once the working fluid has been filled inside the evacuated pipe on both ends of the pipe. It is imperative that the soldering/brazing/welding material used for achieving the sealing is also compatible with the working fluid. Purity of the working fluid itself needs to be ensured so that foreign elements do not enter into the system; throughout the active life of the heat pipe, the working fluid inside must remain as a pure single-component two-phase system. (As will be introduced later, there are some specialized heat pipe systems in which a noncondensing gas is intentionally introduced for achieving the desired purpose; here, we are only discussing a standard conventional heat pipe in which NCGs are not tolerated under normal operation.)

It is also worthwhile to mention here that whenever a working fluid is introduced inside an evacuated pipe/container, it "flashes," that is, it undergoes an isenthalpic expansion process from the pressure at which it is stored. During this expansion process (which is a nonequilibrium process), a certain amount of vapor gets automatically generated until the final pressure inside the pipe, once the filling valve is shut, corresponds to the equilibrium pressure corresponding to the temperature at which the heat pipe is stored. If the entire heat pipe, after filling, is relocated to a chamber wherein the temperature is higher or lower, then the fluid pressure inside the pipe will change, and will always be corresponding to the saturation pressure corresponding to the temperature at which the heat pipe is stored. Remember, the phase equilibrium is achieved when the specific Gibbs energy of both the phases equalizes. The phase-change process continues till this condition is achieved. The very idea of the heat pipe operation emanates from the fact that we create a potential imbalance between the evaporator and the condenser, which the fluid cannot tolerate due to thermodynamic constraints and hence, continuously strives to bring the internal system to an equilibrium, thereby achieving our purpose of efficient and passive heat transfer.

The dimensions of conventional heat pipes range from a few centimeters in length and millimeters in hydraulic diameter, up to lengths of more than 10 m and hydraulic diameters of the order of many centimeters. Accordingly, the maximum heat handling capacity (before something drastic occurs because of which the heat pipe stops working and no more behaves as a superconductor) can range from μW to several kW. We will talk about these drastic effects, that is, the maximum heat-carrying capacity of heat pipes, or conversely, the heat transfer limitations in heat pipe operation a bit later.

Brief History of Heat Pipe Development

The discussion on the history of "conventional heat pipes," wherein, as stated earlier, surface tension forces are responsible for internal fluidic transport, must commence from the earlier development

of wickless, gravity driven, closed two-phase thermosyphons, which were patented more than 100 years ago. Such first generation passive devices, as shown in Figure 4.17.3a, are the simplest form of efficient heat transfer devices incorporating a liquid–vapor phase-change system. The system consists of a plain and simple tube (without any wick material inside), filled partially with a working fluid after evacuation, and subsequently sealed. As there is no dedicated and special mechanism for liquid condensate return, such as a capillary porous wick, these thermosyphons work under gravity conditions only. Hence, they are also referred to as "gravity-assisted heat pipes." The first closed two-phase thermosyphon design was patented in 1830 by Jacob Perkins (1766–1849, USA), the first in a row of four generations of ingenious engineers, and widely used in baking ovens to achieve uniform baking—in fact, they were referred to as "Perkins tube." Subsequently, the concept of looped thermosyphons, which are also referred to as "separate type gravity heat pipes" in contemporary times, as shown in Figure 4.17.3b, were patented by Ludlow Patton Perkins, together with W. E. Buck, in 1892, the former being the great-grandson of Jocob Perkins (Groll, 2013).

The story of the invention of conventional wicked heat pipes is a bit more interesting. It was R. S. Gaugler of General Motors Company who first described the use of wick structures, to transport liquid in a closed tube against gravity, in his patent of 1944 (Gaugler, 1944). However, his idea was never implemented by the company and the patent went into oblivion. In another independent study in 1962, Trefethen from Tufts University in Medford, MA, in an internal report for General Electric's Missile and Space Vehicle Department, wrote a rather detailed description on the feasibility of surface tension driven systems for space applications. This report also remained out of public access until 1995 (Groll, 2013). The name "heat pipe" eventually appeared in yet another independent (re-)invention due to George M. Grover at the Los Alamos National Laboratory (LANL, then called as Los Alamos Scientific Laboratory), USA, wherein the idea to employ the pumping action due to surface tension forces, for passive heat transport in an evaporation–condensation heat transfer device which could be of particular interest for application in space reactors, that is, in a microgravity environment, was described. Subsequently, the first scientific paper appeared in 1965, wherein a conventional heat pipe, driven by sodium as the working fluid, was described (Grover

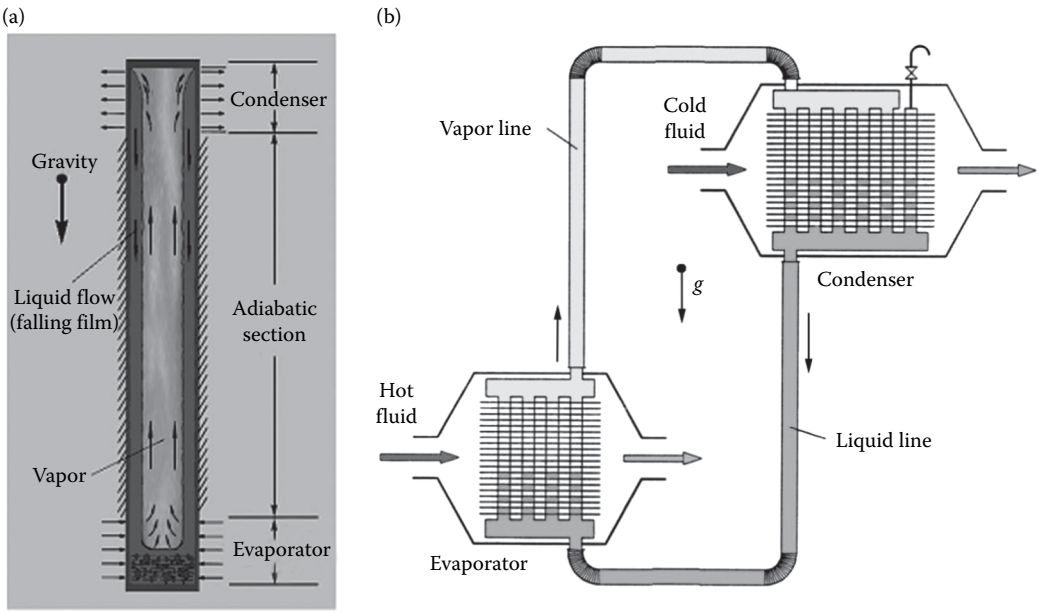

FIGURE 4.17.3 A classical gravity driven two-phase closed thermosyphon (a) and a separate type gravity-assisted heat pipe in which liquid–vapor interface shear is avoided (b).

et al., 1964). In the years which followed, the rapid development of the technology took place, with the primary focus on applications in Space and Nuclear energy sector. Percolation to terrestrial systems, employing two-phase thermosyphons and wicked heat pipes, soon followed with pioneering work carried out by NASA laboratories on the one hand, and several thermal and nuclear systems laboratories in Europe, especially United Kingdom, Italy, Germany, and erstwhile USSR. Today, several different varieties of heat pipes, in various forms, shapes, lengths, wick structures, working fluids, and special features have penetrated in a gamut of applications ranging from space, military, avionics, commercial electronics, medical devices, buildings and structures, power plants, railways and automobiles, deicing and permafrost stabilization, solar heating systems, isothermal furnace liners, blackbody radiators, etc. (Faghri, 1995, 2012, 2014; Groll, 2013; Vasiliev and Kakaç, 2013).

Other Types of Heat Pipes

In the preceding section, we have described a conventional wick-based heat pipe and its predecessor, a gravity-assisted heat pipe or a closed two-phase thermosyphon. In this section, we describe the nuances of the other two major types of heat pipes in wide use and development, that is, (1) loop heat pipes (LHPs) and (2) pulsating heat pipes (PHPs). Finally, we also touch upon two other types of heat pipes, that is, microheat pipes and variable-conductance heat pipes.

Loop Heat Pipes

While the conventional wicked heat pipes are excellent heat transfer devices, their thermal performance gets strongly influenced by the operating orientation. Of course, space application is comparable to horizontal operation on earth-gravity. One of the reasons for inferior performance is the fact that the wick structure is present throughout its length and this presents a substantial pressure drop for liquid return flow. Furthermore, due to the counter-current flow of the liquid and the vapor phase, interfacial interaction also adds to the total pressure penalty. In order to overcome these limitations, LHPs were invented in the early 1980s (Gerasimov et al., 1974, 1975; Maydanik, 2005). Approximately during the same time period, capillary pumped loop (CPL) designs were also evolving in the United States (Faghri, 1995). CPLs and LHPs are qualitatively similar in design; however, their dynamical response is somewhat different (Bazzo and Riehl, 2003; Pouzet et al., 2004; Joung et al., 2010; Boubaker et al., 2015). In this chapter, we will confine our discussion to LHPs, which are comparatively more popular than CPLs. LHPs also use the capillary action to remove heat passively from the evaporator to the condenser. However, in contrast to a conventional heat pipe, the main driving capillary wick structure is present only in the evaporator section. All other components (condenser, liquid return line, and vapor feeder line to the condenser) are made from simple smooth tubing/piping. Hence, net liquid-return pressure drop reduces drastically in comparison to the conventional heat pipes, and the additional viscous interaction between liquid and vapor phases is also absent in LHPs, as both phases move in independent tube sections. With these features and the possibility of using enhanced porous evaporator wicks, LHPs are proving to be substantially better in terms of thermal performance than conventional wicked heat pipes. Even under the adverse gravity conditions, LHPs outperform conventional heat pipes of comparable physical dimensions (Maydanik, 2005; Faghri, 2012, 2014).

A schematic diagram of an LHP is shown in Figure 4.17.4. It shows an evaporator, a condenser, an accumulator volume (compensation chamber), a vapor line, and a liquid line. The evaporator contains the porous wick cartridge. As heat is supplied to the evaporator, liquid vaporizes and menisci form at the liquid–vapor interface in the evaporator wick. Similar to a conventional heat pipe, it develops additional vapor pressure to push the vapor to the condenser through the vapor line. In turn, a capillary driving pressure is created across it which then passively drives the fluid inside the loop. The vapor condenses in the condenser and the capillary forces enable the liquid to return back to the evaporator. The evaporator is used not only as a heat sink to remove the heat, but also as a source to provide the total capillary pumping pressure, thus a highly efficient evaporator is the key to passive action and enhanced thermal performance of LHPs.

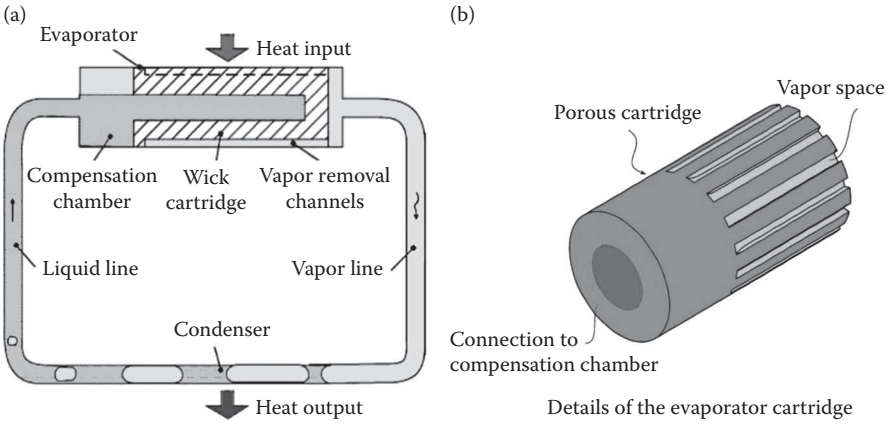

FIGURE 4.17.4 A schematic of an LHP (a) and a typical evaporator cartridge for a cylindrical evaporator (b).

Finely engineered porous wick structures are the key part of the LHP evaporator. This wick structure may be in the form of a cartridge, shown schematically in Figure 4.17.4. The combination of various characteristics like porosity, permeability, pore size, and the effective thermal conductivity of the wick control the thermal performance of LHPs. Typical ranges of porosity, permeability, and pore size of LHPs are 35%–75%, 10^{-12}–$10^{-13}\,m^2$, and 1–20 μm, respectively. Some of the required properties for the porous material of LHPs are: (1) small pore size diameter to ensure a large capillary driving force, (2) large porosity and permeability for low hydraulic resistance, and (3) low effective thermal conductivity to minimize the heat leak from the evaporator to the accumulator. Porous materials used in LHPs include pure metals, alloys, and polymers. Among these, polymers (polyethylene, polypropylene, PTTE) and plastics have the advantage of low-thermal conductivity, but maximum porosity is limited to about 50%. Wicks made of metal or alloys have comparatively higher porosity range but thermal conductivities are also relatively higher. Nickel is the most commonly used metal for evaporator wicks in LHPs because of its lower thermal conductivity and ability to be formed in fine pore sizes with high porosity. LHPs with nickel as the porous wick and ammonia as the working fluid are one of the most suitable combinations for satellite cooling applications. Some of the other metals or alloys used in LHPs include stainless steel, titanium, copper, brass, iron oxide and few composites wicks like nickel–chromium, nickel–copper. The use of copper for LHP capillary wick is also under active consideration in many terrestrial applications, although its thermal conductivity is quite high. Pore size plays an important role in LHP operation. Development of biporous wicks has also gained some ground as these wicks contain pore sizes of two different length scales. Fine pores provide higher capillary force and coarse pores provide higher permeability, which eventually reduces the hydraulic flow resistance. Heat transfer coefficient for biporous wicks is about two to three times more than the monoporous wicks. The most common technique for making LHP wick is via the sintering route; however, other possibilities have been pursued (Launay et al., 2007; D'Entremont and Ochterbeck, 2008; Vasiliev et al., 2009; Samanta et al., 2011; Adoni et al., 2012; Ambirajan et al., 2012; Maydanik et al., 2014).

Suitability for miniaturization, flexibility and modularity of design, possibility of using multiple evaporators, separation of vapor and liquid interfacial interaction, extremely high capillary performance, possibility of providing a flexible coupling between source and sink, and robustness, are some of the positive features of LHPs which qualify them as a clear choice in space missions (Gilmore, 2002; Hoang and Ku, 2002; Kaya and Ku, 2003; Ku et al., 2012). In fact, the aerospace industry is also seriously considering its deployment for thermal management of commercial aircrafts (Bugby et al., 1998; Wang et al., 2008; Sarno et al., 2013). With an improvement in the ability to control the porous wick characteristics through various manufacturing routes, LHPs are expected to cater to a large segment of aerospace thermal management as well as terrestrial and defense

related applications. Adequate literature on modeling is also evolving, although this remains a topic of active research (Siedel et al., 2015). Combined LHP and PHP designs are also under active consideration (Vasiliev et al., 2009; Pastukhov and Maydanik, 2013).

Pulsating Heat Pipes

A PHP, introduced by Akachi (1990, 1996), consists of a plain meandering tube of capillary dimensions with many U-turns as shown in Figure 4.17.5. In this design, in contrast to a conventional heat pipe, there is no additional capillary structure inside the tube. There are two ways to arrange the tube, (1) open loop and (2) closed loop, configuration. As the names suggest, in a closed-loop structure, the tube is joined end to end, as detailed in Figure 4.17.5. The tube is first evacuated and then filled partially with a working fluid, which distributes itself spontaneously in the form of liquid–vapor plugs and slugs inside the capillary tube. One end of this tube bundle receives heat, transferring it to the other end, by the pulsating action of the liquid–vapor/bubble-slug system. There may exist an optional adiabatic zone in between. Also, one or more flow direction control check valves may be introduced at suitable locations to augment the performance (Khandekar, 2004). PHPs can also be developed as flat structures, on to which, electronic circuits can be directly mounted. PHPs have also been embedded on planar metallic/polymer space radiator structures to enhance the effective thermal conductivity of the resulting composite structure; such planar structures have been extensively considered for various applications (Khandekar et al., 2002; Yang et al. 2009; Hemadri et al., 2011; Karthikeyan et al., 2014; Ayel et al., 2015). Figure 4.17.6 shows a range of industrial prototypes of PHPs which have been developed in recent times.

A PHP is a complex heat transfer device with a strong thermo-hydraulic coupling governing its performance. It is essentially a nonequilibrium heat transfer device. The successful performance of the device is primarily due to the continuous maintenance or sustenance of these nonequilibrium conditions within the system. The liquid and vapor slug transport is because of the pressure pulsation caused in the system. Since these pressure pulsations are thermally driven, because of the inherent construction of the device, there is no external mechanical power source required for the fluid transport. In an actual working PHP, there exists a temperature gradient between the evaporator and the condenser section. Further, inherent perturbations are always present in real

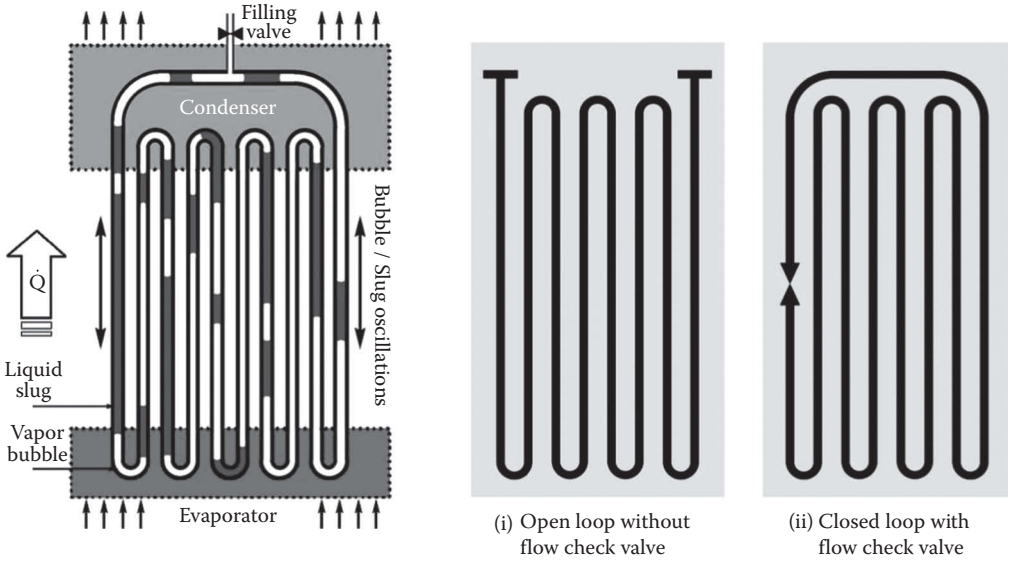

FIGURE 4.17.5 Schematic of a closed-loop PHP without any check valve (left) and two typical operating configurations (right (i) and (ii)).

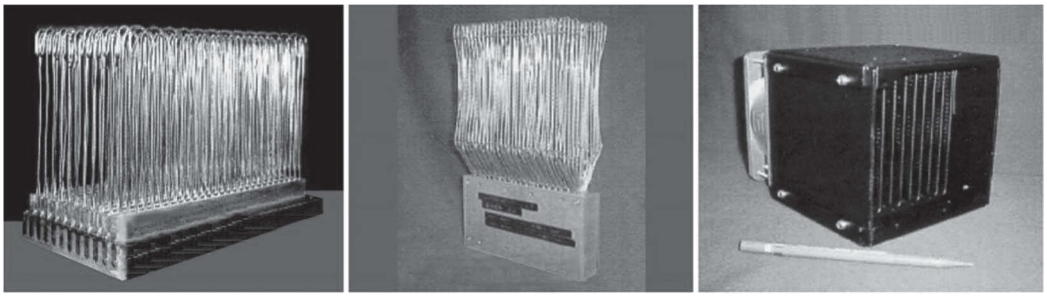

FIGURE 4.17.6 Different engineering prototypes of PHPs which have been designed and tested in recent times.

systems (Khandekar et al., 2003). These perturbations are due to: (1) pressure fluctuations within the evaporator and condenser sections due to local nonuniform heat transfer always occurs in real systems, (2) asymmetrical liquid–vapor distributions causing uneven void fraction in the tubes, and (3) the presence of approximately triangular or sawtooth alternating component of pressure drop superimposed on the average pressure gradient in a capillary slug flow due to the presence of vapor bubbles (Khandekar, 2004).

The net effect of these temperature gradients within the system is to cause nonequilibrium pressure condition which, as stated earlier, is the primary driving force for thermo-fluidic transport in a PHP. A sustained nonequilibrium state exists between the driving thermal potentials and the natural causality which tries to equalize the pressure in the system. Thus, a self-sustained thermally driven oscillating flow is obtained in a PHP. Hence, it is noted that there is no "classical steady state" possible in a PHP operation. Instead, the pressure waves and pulsations are generated in each of the individual tubes which interact with each other possibly leading to secondary and ternary reflections with perturbations. From a force balance of gravity and surface tension leading to the definition of Bond number, the theoretical maximum tolerable inner diameter (D_{crit}) of a PHP capillary tube can be calculated as $\mathrm{Bo}_{crit} \leq 2$, where the Bond number is defined as

$$\mathrm{Bo} = D\sqrt{g\left(\rho_l - \rho_v\right)/\sigma} \tag{4.17.4}$$

where ρ is the density of the involved phases and σ is the liquid–vapor surface tension. At diameters below this value, there is a tendency of surface tension forces to dominate and this assists in the formation of the stable liquid slugs under nonoperating conditions, a prerequisite for PHP operation.

Numerous experimental investigations have been done with the aim of a parametric study of a PHP. These studies indicate the following main variables affecting the PHP performance (Charoensawan et al., 2003; Khandekar et al., 2003; Khandekar, 2004; Khandekar and Groll, 2004a):

- *Geometric variables*: Overall length of the PHP, diameter/size and shape of the tube, length, and number of turns of evaporator/condenser/adiabatic section.
- *Physical variables*: Quantity of the working fluid (filling ratio), physical properties of the working fluid, tube material.
- *Operational variables*: Open-loop or closed-loop operation, heating and cooling methodology, orientation of the PHP during operation, use of check valves, etc.

It is evident that there are multiple variables that simultaneously affect the operation and performance of PHPs. Further, so far as capillary slug flow exists inside the entire device, it has been demonstrated that the latent heat will not play a significant role in the device performance. This is a major difference as compared to a conventional heat pipe that primarily transfers only the latent

heat component of the working fluid. Nevertheless, in PHPs, bubbles are certainly needed for self-sustained thermally driven oscillations. On the other hand, under certain operating conditions, flow may transit to annular flow regime during the PHP operation. The probability of such an event is high with a combination of high Bond number, high heat flux, and a comparatively low liquid filling ratio (~50% or lower). If the flow regime changes from slug to annular, the respective roles of latent and sensible heat transport mechanism may considerably change (Khandekar, 2004; Khandekar and Groll, 2004b; Zhang and Faghri, 2008). Further, the dry-out mechanisms of PHPs are not similar to the conventional heat pipes; this remains a topic of continued research (Yang et al., 2008; Khandekar et al., 2009; Tang et al., 2013; Han et al., 2016).

It is clear that the performance not only depends on a large number of parameters but also on the flow pattern. This makes it all the more difficult to undertake mathematical modeling using conventional techniques. Thus, in order to discern the flow physics, it is logical to split the PHP into different simpler well-posed problems, study their individual behavior and then make a coupling to have a comprehensive understanding of the complex PHP thermo-physics. A few of these simple thermal-hydraulics problems that give insight to the PHP operation are summarized here:

- Isolated studies of vapor–liquid interfaces in confined geometries, including local phase-change mechanisms at the interfaces (Rana et al., 2014; Srinivasan et al., 2015a,b).
- Hydrodynamics of isolated Taylor bubble and continuous Taylor bubble-train flow of two-component two-phase systems can be investigated in minichannels, during upward, downward, and horizontal configurations. No heat transfer and phase change are involved in this analysis; such studies provide the relevant information of frictional pressure drops, local flow patterns inside liquid slugs, interfacial shapes and ensuing enhanced transport properties (Bajpai and Khandekar, 2012; Majumder et al., 2013).
- External pulsations of different frequencies are added to continuous Taylor bubble train, which will make the Taylor bubble system to pulsate and effect of pulsations on hydrodynamics is studied (Mehta and Khandekar, 2014a,b).
- After studying hydrodynamics, the parametric study of heat transfer in these systems is analyzed without the phase-change process being taken into account (Mehta and Khandekar, 2014b).
- Finally, phase change can be incorporated in the Taylor bubble flow, under both unidirectional and oscillating conditions, to map the flow with the functioning of real-time PHPs (Bonnenfant et al., 2012; Rao et al., 2013, 2015; Chauris et al., 2015).

This approach of splitting the problem has enriched the understanding of several new parameters that were not previously accounted for in the modeling of PHP, some of which are:

- *Contact angle hysteresis*—The additional pressure drop associated with the hysteresis phenomenon plays a major role in the hydrodynamics of the system.
- *Vortex circulation inside confined liquid Taylor plugs*—Due to the presence of the two interfaces, local 3-D flow is induced. These internal vortices enhance the ensuing heat transfer.
- *Wettability*—The ability to synthesize different wetting surfaces, give way to different hydrodynamics and heat transfer behavior, enhancing design possibilities of PHPs.
- *Wet flows and dry flows*—Depending on the existence of liquid-film surrounding the vapor phase, the flow can be categorized as wet or dry. In the wet flow, the liquid-thin film accounts for most of the heat transfer, due to its low-thermal resistance. In dry flows, the three-phase contact line motion accounts for much of the dissipation, and the pressure drop is higher in this case than that in the wet flows. The fact that PHPs have both wet and dry flows occurring simultaneously during its working makes its mathematical modeling challenging.

Thus, several insights into some of the fundamental issues of flows in mini/micro channel are revealed and understood, which has not only facilitated the mathematical description of the PHP internal processes, but also other engineering systems which rely on Taylor bubble flows, such as flow boiling heat exchangers for electronics cooling, lab-on-chip devices, micro-reactors, and fuel cells (Khandekar et al., 2010). Mathematical modeling of PHPs through "first" principles is a contemporary problem which remains quite elusive. Simplifications and assumptions made in all the modeling approaches developed so far render them unsuitable for engineering design because the idealizations contained therein are not in sync with the real time transport processes taking place in the device. At present, there are no theoretical models or correlations available that can predict the complex thermo-hydrodynamic transport behavior of PHPs. This prevents their widespread use in industrial applications. Several important conclusions can be made based on the recent literature from the last decade, some of which are elaborated below:

Thin film evaporation and condensation plays a crucial role in the overall dynamics. Unless this is included in the global model, realistic predictions cannot be made. Corollary to this is the fact that unless mass addition/removal from the vapor space is considered, the amplitude of oscillations observed in actual experiments cannot be predicted. Treating the vapor as an ideal gas with only sensible heating/cooling is not sufficient (Mameli 2012; Rao et al., 2013, 2015; Mameli et al. 2014).

The frictional pressure drop required to sustain the flow, especially in the liquid plugs with small *L/D* ratios, may be substantially higher than what is predicted by assuming a simple Poiseuille flow inside them. The fluid flow pattern in the oscillating two-phase "unit-cell" system (i.e., one Taylor bubble with adjoining liquid plug) is rather complex leading to high viscous dissipation. Moreover, three-phase contact lines tend to form inside the system, especially in the evaporator subsection, which lead to very high local dissipation (Janeček and Nikolayev, 2013; Srinivasan et al., 2015a,b). As *L/D* ratio increases, classical Poiseuille friction is sufficient to describe the flow.

Inertia forces play a significant role here. Sudden acceleration and deceleration of the "unit-cell" and its interaction with surface and capillary forces lead to complex flow phenomena, including breakage of liquid plugs into smaller fragments. While most hydrodynamic theories of visco-capillary flows are valid for low capillary number situations (less than ~10^{-3}) and high wettability conditions, engineering scale PHP devices deviate appreciably from such ideal situations. Partial wetting and relatively large capillary numbers are routinely encountered (Khandekar et al., 2010; Rana et al., 2014; Mehta and Khandekar, 2014a).

The radial heat transfer to/from the liquid–vapor system must happen via the capillary tube material. Unlike a conventional heat pipe that attains a quasi-steady state, the transient oscillatory flow patterns inside a PHP manifests itself as a conjugate (conduction–convection) problem. Hence, the interplay of diffusional and convective timescales of the system strongly affects the ensuing thermal-hydraulic response. In effect, thermal properties of the tube material are vital in predicting the overall system dynamical response (Nikolayev, 2013, 2016; Rao et al. 2013, 2015).

It has been conjectured that nonequilibrium states of liquid and vapor coexist during the normal operation of PHPs. Conclusive experimental evidence is yet to come; however, initial results do point toward this fact. It requires very precise and repeatable dynamic measurements of the local vapor and fluid film temperature so as to ascertain nonequilibrium condition and/or metastability. At one extreme is the assumption that vapor and liquid in the Taylor bubbles are always under thermodynamic equilibrium. This essentially means that the relaxation timescales of the phase change by heat addition/subtraction are much faster than the typical characteristics timescales of the internal fluid flow and heat transfer through the walls in the PHP system. However, the essence of the entire PHP thermal phenomena lies in its transient thermo-fluidic characteristics. While one can talk about a "quasi-steady" state in a global sense, nothing is steady on the local level inside an operating PHP. Hence, the assumption of thermodynamic equilibrium between adjacent vapor bubbles and liquid plugs may not be justified. The rapid inertial transient flow, vis-à-vis evaporation/condensation timescales, may lead to situations wherein superheated vapor and/or subcooled liquid coexists for finite timescales (Khandekar 2004; Nikolayev, 2013; Rao et al., 2015).

It is clear from the above discussion that PHPs continue to be a subject of active research, both from experimental as well as theoretical standpoint (Groll and Khandekar, 2002b; Zhang and Faghri, 2008; Khandekar et al., 2010; Tang et al., 2013; Han et al., 2016).

Micro Heat Pipes

Stringent cooling requirements required in the electronics industry concerning miniaturization and higher heat fluxes have led to the introduction of a micro heat pipe by Cotter (1984), as shown in Figure 4.17.7. Micro heat pipes are very small, wickless heat pipes having internal geometries containing sharp angled corner regions responsible for creating the required capillary pressure and also serve as liquid arteries. There are two supplementary definitions of a micro heat pipe. According to the original definition of Cotter (1984), the hydraulic radius R_h of a micro heat pipe is of the order of (greater than or equal to) the capillary radius R_c of the vapor–liquid interface. Subsequent definition of Chen et al. (1992) reflects not only the geometry, but also the physical behavior—it defines a micro heat pipe as a heat pipe for which the Bond number is small typically less than 2. Typical cross-sectional dimensions of micro heat pipes range from some 10 to 100s of μm with heat transport capabilities of some 10s to 100s of mW (Itoh and Polášek, 1990).

A sizable amount of experimental results on individual micro heat pipes as well as micro heat pipe arrays are available. In addition, quite a few papers that refer to "micro" heat pipes really do not correspond to the true "micro" heat pipes as defined here. There exist various hybrid and transitional heat pipe designs/structures in the "meso" or "mini" range too. Some of the variants are without a wick structure, thereby fully relying on the sharp-angled corners for generating capillary pumping, while others can have some form of wicks/microstructured surfaces (Groll and Khandekar, 2002a). Over the years since 1984, periodic reviews on micro heat pipes have appeared covering critical aspects of operations, performance characteristics and limitations, applications and mathematical

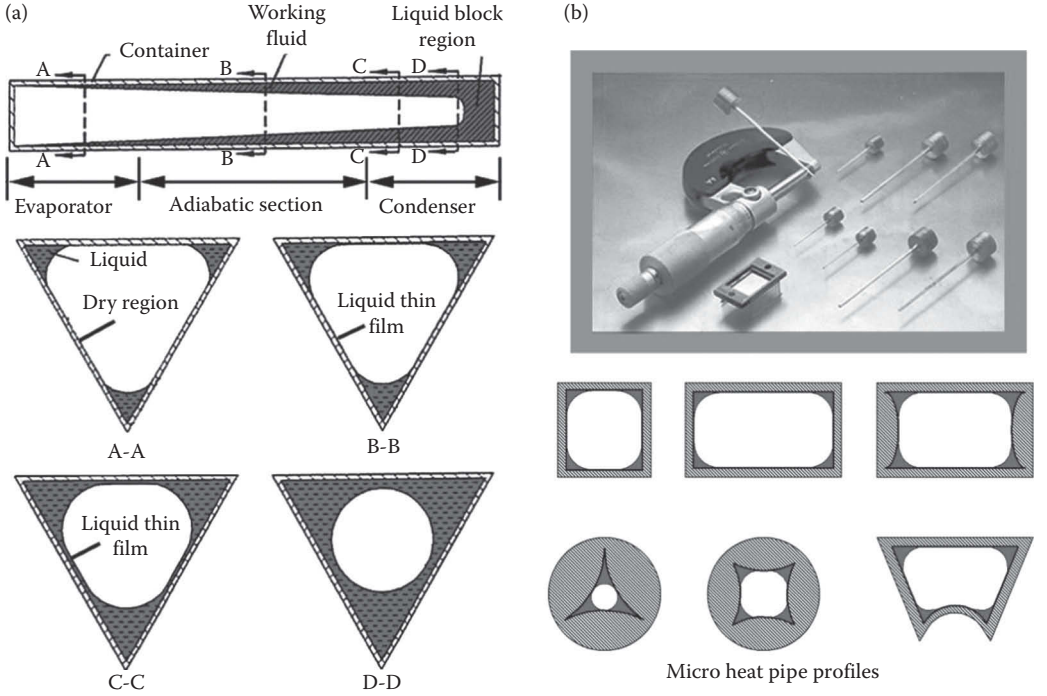

FIGURE 4.17.7 Concept of a micro heat pipe, showing axial and radial cross sections (a) and typical application (b); some possible cross-sectional shapes which provide capillary action due to the presence of sharp angled corners is also depicted below.

modeling (Groll and Rösler, 1992; Cao et al., 1993; Khrustalev and Faghri, 1994; Peterson, 1996, 1997; Groll et al., 1998; Ochterbeck and Peterson, 1999). In the last two decades, there has been a steady decline in the research activity on micro wickless heat pipes, primarily due to the fact that its overall heat handling capacity is rather limited. However, there is indeed sizable amount of fundamental research work which has been carried by various groups (e.g., see Wayner, 1991; Das Gupta et al., 1995; Karthikeyan et al., 1998; Zheng, 2002; Panchamgam et al., 2008; Chatterjee et al. 2011) to understand the microscale evaporation and condensation on a single bubble trapped in a confined tube, which essentially is analogous to a micro heat pipe operation.

The first model of a micro heat pipe was proposed by Cotter (1984) which, although based on simplified assumptions, was quite effective to predict the general qualitative aspects, however, the maximum heat transport capacity was severely over-predicted, as compared to the then experimental results (e.g., Babin et al., 1990; Chen et al., 1992; Swanson and Peterson, 1995; Ha and Peterson, 1998). It was concluded that apart from simple numerical factors and the extreme difference in the typical size, the design considerations for wickless micro heat pipes are essentially the same as those for conventional wicking limited heat pipes. This model led to subsequent refined models, as described by Groll and Khandekar (2002a). Subsequently, Gerner et al. (1992) and Longtin et al. (1994) developed a scaling analysis to investigate the operating limits of a micro heat pipe. Two distinct phenomena were identified, capillary limitation (similar to conventional heat pipes) and dry-outs attributable to interfacial instabilities. Porous media approach with Darcy's equation for two-phase flow imposed by Laplace's capillary equation has been adopted by Chen et al. (1992), Wang et al. (1994), and Tio et al. (2000). This approach has also given satisfactory predictions. On similar lines, Shukla (2009) has also presented a micro heat pipe model.

Variable Conductance Heat Pipes

In many applications, temperature control of the evaporator section (the thermal load) is desirable, irrespective of the variations in the input heat conditions or the thermal conditions existing in the condenser (sink) section. Such applications are frequently encountered in space vehicle applications and satellite thermal management (Karam, 1998; Gilmore, 2002). A conventional heat pipe can be suitably modified to achieve precise temperature control, with or without an active feedback control loop (Bienert and Brennen, 1971; Kirkpatrick and Marcus, 1971; Kirkpatrick, 1973; Groll and Kirkpatrick, 1976). The innovative idea in such devices, generically termed as variable conductance heat pipes (VCHPs) is to change the effective thermal conductivity of the structure, as per the demand. The simplest, nonfeedback controlled, VCHP is as shown in Figure 4.17.8a—such devices were developed as early as 1965 and the space industry gave enormous impetus for their development in the seventies (Gilmore, 2002; Groll, 2013). In such devices, the aim is to maintain the vapor temperature (and thereby essentially also the evaporator temperature) at a constant level, irrespective of heat input and boundary (heat sink) conditions. A standard VCHP consists of inclusion of an NCG buffer inside the system, attached to the condenser section. During normal operation, this NCG tends to collect in the condenser area where the internal fluid pressure is minimum. Depending on the location of the NCG front inside the condenser, the exposed internal area available for vapor condensation is determined. Under normal heat loads, the heat pipe is designed in such a way that the NCG front covers approximately half the condenser area. If thermal load at the evaporator increases, the NCG front is pushed toward the reservoir due to increased vapor pressure. This exposes more area available for vapor condensation, thereby improving the performance of the heat pipe. Hence, the additional thermal load gets accommodated without a corresponding increase in the vapor temperature. Alternately, decrease of heat load pushes the NCG front deeper inside the condenser and blocks vapor condensation. This increases the effective thermal resistance of the heat pipe and hence, for a constant sink temperature, the vapor temperature tends to remain constant. In other words, the reduced condenser area will become just sufficient to maintain the same difference between vapor (condenser) temperature and the sink temperature, and thus keep the vapor temperature constant. In this way, a nonfeedback loop VCHP can be designed and operated

to maintain the vapor temperature within a prescribed limit. While the vapor temperature can, to some degree be kept constant, the more important heat source temperature (i.e., temperature of the component which has to be cooled) will inevitably rise with the increasing heat input due to thermal conductance and resistance between component and heat pipe. To maintain the heat source temperature constant, the increasing temperature difference (for increasing heat load) between heat source and heat pipe must be compensated by a corresponding reduction of the vapor (evaporator surface) temperature. To accomplish this, a feedback control system, active or passive, has to be employed, as shown in Figure 4.17.8b. In the active method, the temperature of the heat sink is sensed, which is linked with an electric heater attached to the wicked reservoir. The heater is activated for decreasing or deactivated for increasing heat input (shut down for maximum heat input). Thereby, the NCG blocks the condenser to such a degree that the required vapor temperature is established to maintain the source temperature constant, viz. large temperature difference between heat source and vapor, ΔT_{HS-v}, for high heat load and small temperature difference for low heat load. Other passive thermal control mechanisms and heat pipe diode designs are also available (Faghri, 1995; Gilmore, 2002).

Other Types of Heat Pipes

Depending on the driving force exploited to run the passive phase-change thermal system, various concepts of "heat pipes" have been proposed and indeed incorporated in real-time thermal systems. As we have seen, while classical heat pipes described earlier make use of capillary forces for liquid

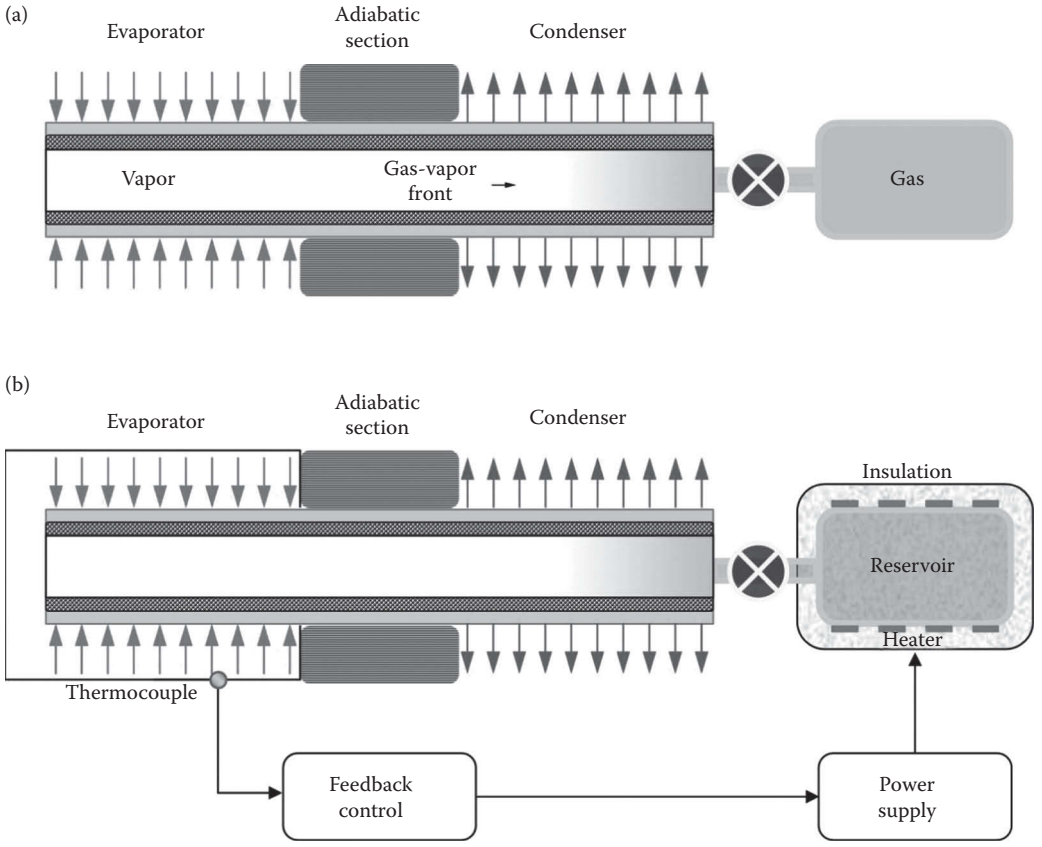

FIGURE 4.17.8 VCHP without feedback system (a) and VCHP with feedback control system (b). Depending on the heat input, the gas–vapor interface position is controlled to vary the exposed available area in the condenser.

return, wickless thermosyphons need gravity force field. When rotating systems needs thermal managements, such as electric motors or power-turbines, centrifugal forces can also be used to make "rotating" heat pipes. Such systems do not require a capillary wick (Bertossi, 2012). If an external electric or magnetic field is used for driving the fluid, this gives rise to electrohydrodynamic flow. Such external fields can also be coupled with capillary forces for enhanced heat transfer. Heat pipe action can also be coupled with sorption systems (Vasiliev and Vasiliev, 2005; Vasiliev and Kakaç, 2013). Concentration gradients can also be effectively harnessed to form electroosmotic heat pipes. In recent years, there is also an effort to incorporate nanofluids (small to moderate concentration of nanometric size metallic/nonmetallic/ceramic powders stably dispersed in conventional working fluids, to get enhanced or tailor-made thermo-physical properties) in heat pipes. At present, however, there are conflicting results regarding the efficacy of such fluids in heat pipe and thermosyphon systems; more focused research in this area needs to be undertaken for clarity (Khandekar et al., 2008; Buschmann, 2013; Sureshkumar et al., 2013).

Conventional Heat Pipe Design and Limitations

We will restrict our attention to the design and limitations of conventional wicked heat pipes in this section. In Section 1, we asked ourselves a question—What are the transport limitations of heat pipes? Obviously, a given heat pipe, with a certain type and geometry of wick structure, a certain length, internal diameter and working fluid, cannot maintain its "superconductivity" at all operating temperatures and/or input heat fluxes. In other words, at given operating temperature of a heat pipe, as we continue to increase the input heat flux to the pipe, there comes a stage wherein its proper operation of a "superconductor" will either degrade or completely cease. Indeed, this stage it is termed as a "dry-out" condition of heat pipe. There are two questions that are relevant for heat pipe dry-out conditions (1) Whether the maximum heat transport possible from a given heat pipe (dry-out heat power or dry-out flux) depends on the operating temperature? and, (2) Which thermo-physical phenomena is responsible for transforming a satisfactorily performing heat pipe, to one that degrades/stops its desired heat transfer operation? Intuitively, one can argue that since the thermo-physical properties of a working fluid depend on the temperature, with nearly all properties substantially varying between the freezing point and the critical point, dry-out conditions must depend on the operating temperature. For example, the viscous stresses scale with dynamic viscosity, the capillary pumping action scales with surface tension and phase velocities will depend on the respective fluid densities. Hence, the maximum heat flux ought to depend on the operating temperature of the heat pipe. As regards the type of phenomena responsible dry-out, there are quite a few different factors responsible for it. Interestingly, which factor predominates the occurrence of a dry-out condition is also a function of the operating temperature. The most common ones are: (1) viscous limitation, (2) sonic limitation, (3) capillary limitation, (4) entrainment limitation, and (5) boiling limitation. We will describe these "phenomena" or limitations briefly hereunder, giving an analytical expression to estimate the dry-out flux:

1. *Viscous limitation*: Imagine a situation when the net pressure drop required to transport the vapor from the evaporator end of the heat pipe to the condenser end becomes comparable to the absolute value of vapor pressure in the evaporator section. Such a situation may occur typically at low operating temperatures, for those working fluids whose saturation pressures at the operating temperature is rather low. In such a situation, it will be impossible for vapor to flow in the heat pipe because the absolute pressure available in the evaporator cannot overcome the dissipation required to send the vapor to the condenser. In other words, the condenser pressure cannot fall below absolute zero pressure! This is called as vapor pressure limitation or viscous limitation of a heat pipe. It can be calculated by using the expression (Dunn and Reay, 1982):

$$\dot{Q}_{\max} = \left(\frac{\pi}{12}\right)\left(\frac{h_{fg}\,\rho_{v,e}\,P_{v,e}}{\mu_{v,e}}\right)\left(\frac{r_v^4}{l_{eff}}\right) \tag{4.17.5}$$

where r_v is the cross-sectional radius of the vapor core (m), h_{fg} is the latent heat of vaporization (J/kg), $\rho_{v,e}$ is the vapor density in the evaporator (kg/m^3), $P_{v,e}$ is the vapor pressure in the evaporator (Pa), and $\mu_{v,e}$ is the vapor viscosity in the evaporator (Pa·s). l_{eff} is the effective length of the heat pipe (m) equal to $l_{eff}=0.5(l_e+2l_a+l_c)$.

2. *Sonic limitation*: The sonic velocity in a gas/vapor scales with the square root of the temperature. At low temperatures, the speed of sound in the fluid medium is correspondingly low. As the input heat flux increases, especially during startups at low operating temperatures, the velocity of vapor flowing in the vapor core of the heat pipe increases. If, under the operating conditions, the vapor velocity reaches sonic speeds, the heat pipe undergoes a "choking" condition. In a sense, the steady-state operation of a normally operating heat pipe can be compared with a gas flow in a nozzle-diffuser arrangement. In the evaporator section, the vapor flow accelerates, attains constant velocity in the adiabatic section and then, as condensation proceeds, there is deceleration of the fluid. Drawing an analogy, the evaporator acts as a nozzle, while the condenser section corresponds to a typical diffuser. When sonic limitation comes due to sufficiently high mass flow rate of the vapor, choking conditions will be experienced in the adiabatic condition, restricting the ability of the pipe to transfer more heat. Sonic limitation is given as (Dunn and Reay, 1982)

$$\dot{Q}_{\max} = 0.474\left(A_v\,h_{fg}\right)\left(\rho_v P_v\right)^{1/2} \tag{4.17.6}$$

where A_v is the cross-sectional area of the vapor core (m^2).

3. *Entrainment limitation*: The vapor and liquid phases flow in opposite directions in a conventional heat pipe, which creates interfacial shear stress. This additional shear is over and above the internal viscous shear in the respective phases. The interfacial shear increases as the input heat flux to the heat pipe increases due to the enhanced relative velocity of the two fluids. A situation may arise while operation when the interfacial shear is so high that small droplets of liquid are "scooped" off or "entrained" by the high vapor flow, depleting the evaporator of the returning liquid. Such a situation may lead to liquid deprived evaporator thereby leading to a total dry-out or a partial dry-out condition. Entrainment limitation is a manifestation of vapor inertia forces exceeding the stabilizing effects of the surface tension on the liquid–vapor interface, the corresponding nondimensional scaling these two effects being the Weber number. The entrainment limitation can be estimated from (Dunn and Reay, 1982)

$$\dot{Q}_{\max} = A_v\,h_{fg}\sqrt{\frac{\rho_v\sigma_l}{2r_{cap,ave}}} \tag{4.17.7}$$

where σ_l is the surface tension (N/m) and $r_{cap,ave}$ is the average capillary radius of the wick. Note that for many applications, $r_{cap,ave}$ is often approximated by $r_{cap,e}$.

4. *Capillary limitation*: This is one of the most important limitation of a heat pipe. As has been discussed, the capillary pumping action provided by the wick structure is at the heart of successful heat pipe operation. This capillary "pump" has to overcome all the dissipative pressure drops which are encountered by the circulating fluid so as to maintain the heat pipe action. The primary dissipative components include the frictional pressure drop required to sustain the flow of liquid in the porous wick and the frictional pressure drop required to be overcome for the vapor flowing in the core. In addition, as has been explained earlier, since liquid and vapor flow in the opposite direction during heat pipe operation, there is interfacial shear stress due to interaction of the phases at the interface.

This additional interfacial shear may be important in the case of axially grooved heat pipes where the interface is exposed, while in the conventional sintered powder or screen wicks, the impact is somewhat less due to interface being protected by the porous wick. The acceleration pressure drop of vapor in the evaporator is usually neglected as there is some partial recovery of this loss in the condenser area due to deceleration effects. Due to the orientation of the heat pipe (in terrestrial conditions), gravitational body forces may also be present, helping the capillary pump when the evaporator is below the condenser and vice versa. The capillary limitation thus occurs, when the capillary pump fails, or in other words, is not able to overcome the net losses due to fluid motion. Since frictional pressure drop in the system scales with flow velocity, at a certain critical heat flux, the corresponding flow velocity of the fluid is such that it makes the capillary pump ineffective. Under these conditions, the heat pipe is said to have "dried out," due to capillary limitation. For most heat pipes, the maximum heat transfer rate due to the capillary limitation, considering simple linear theory, can be expressed as (Dunn and Reay, 1982; Faghri, 1995):

$$\dot{Q}_{\max} = \left[\frac{\sigma \rho_l h_{fg}}{\mu_l}\right]\left[\frac{A_w K}{l_{eff}}\right]\left[\frac{2}{r_{cap,e}} - \left[\frac{\rho_l}{\sigma}\right] g L_t \sin\beta\right] \tag{4.17.8}$$

where K is the wick permeability (m^2), A_w is the wick cross-sectional area (m^2), ρ_l is the liquid density (kg/m^3), μ_l is the liquid viscosity (Pa-s), $r_{c,e}$ is the wick capillary radius in the evaporator (m), g is the acceleration due to gravity ($9.8\,m/s^2$), and L_t is the total length of the pipe (m). The quantity in the first parenthesis on the RHS has the units of heat flux and is called as the "Figure of merit," as explained later in Section 5.1. The estimation of permeability K is not so straightforward for heat pipe wicks. The interdependency of permeability on the porosity ε is highly nonlinear depending on the type and morphology of the porous structure. Although porosity is a geometrical concept, and analytical expressions are indeed available for simple screen wicks or axial grooved wicks. Often, it needs to be experimentally determined. Similarly, use of analytical expressions of permeability K, as a function of porosity $K=f(\varepsilon)$ can be done, if available, with caution. The values strongly depend on the way the wick structure is made, fabricated and eventually integrated and assembled with the heat pipe container. Moreover, cross-flow porosity and axial flow porosity, and hence respective permeability values, tend to be different for most porous structures used in heat pipes. Hence, a certain degree of heuristic knowledge of realistic in situ values of K and ε, is needed for successful modeling and comparison of the estimated values with the experimental data. For more information on analytical expressions of porosity and permeability of wick structures and their complex interdependency, readers are referred to Kaviany (1991) and Faghri (1995).

5. *Boiling limitation*: Liquid to vapor phase change, via the evaporation process occurring at the liquid–vapor interface, is the preferred mode of normal heat pipe operation. The wall superheat levels at the evaporator should be such that nucleation phenomena inside the wicks is avoided. If the superheat increases, it may lead to formation of bubbles inside the porous structure (Carey, 1992). This is detrimental to the heat pipe operation. Nucleation can be avoided if the wettability of the liquid is good, both with the container and the wick, the wick is properly in contact with the container, the container has high thermal conductivity and heat capacity and finally, the working fluid is clean, without any contamination. Boiling limitation usually occurs at higher end of the operating temperature spectrum and can be estimated by) (Chi, 1976):

$$\dot{Q}_{\max} = \frac{4\pi l_{eff} k_{eff} T_v \sigma_v}{h_{fg} \rho_l ln\left(\frac{r_i}{r_v}\right)}\left(\frac{1}{r_n} - \frac{1}{r_c}\right) \tag{4.17.9}$$

If these limitations are plotted, as a function of the operating temperature and for a given conventional heat pipe, then we will get a plot which is schematically shown in Figure 4.17.9. As can be seen, at operating temperatures T_1–T_5, the heat pipe operation gets limited by different limitations, as shown. Plotting such a graph is usually the first step while designing the heat pipe. If the heat handling capacity required from the heat pipe, comes within the design range, then it is acceptable, after incorporating a suitable factor of safety. However, if the requirement falls outside the design space, it means that the design will fail due to some limitation or the other, and hence suitable modifications must be made in the heat pipe geometry, wick structure, etc. to meet the requirements. As mentioned previously, for most conventional heat pipes operating at median values of their permissible range of temperature (between freezing point temperature and critical temperature), the capillary limit is the most dominant and important limit to estimate. This is also highlighted in Figure 4.17.9.

Choice of Working Fluids

The choice of a working fluid is primarily dictated by the desired operating temperature of the heat pipe operation. Several working fluids have been used in heat pipe operation, ranging from cryogenic fluids such as neon, low temperature fluids such as acetone and ammonia, to high-temperature fluids such as lithium or sodium. Needless to say, water is also an excellent fluid for many terrestrial application which are typically above its freezing point. What makes a working fluid appropriate for a given application? From a thermodynamic standpoint, we can argue that it should render a high capillary pumping power on one hand while requiring low dissipative power losses for its own circulation during operation. Therefore, high surface tension is desirable, as this will intrinsically enhance the available pumping power of the heat pipe. Low dynamic viscosity is another requirement as this will lower the frictional flow resistance of the fluid. As heat pipes primarily work on latent heat transfer mode, it is natural to choose a fluid with high latent heat of vaporization. In addition, the liquid density of working fluid must be high. This lowers the net inventory of the fluid per unit heat transferred. In other words, the flow velocity of the two phases per unit heat transferred by the heat pipe will reduce if the density of the fluid is high. This, in turn, lowers the frictional pressure drop. Combining all these attributes, one can get the desired "Figure of Merit," of a working fluid, given as

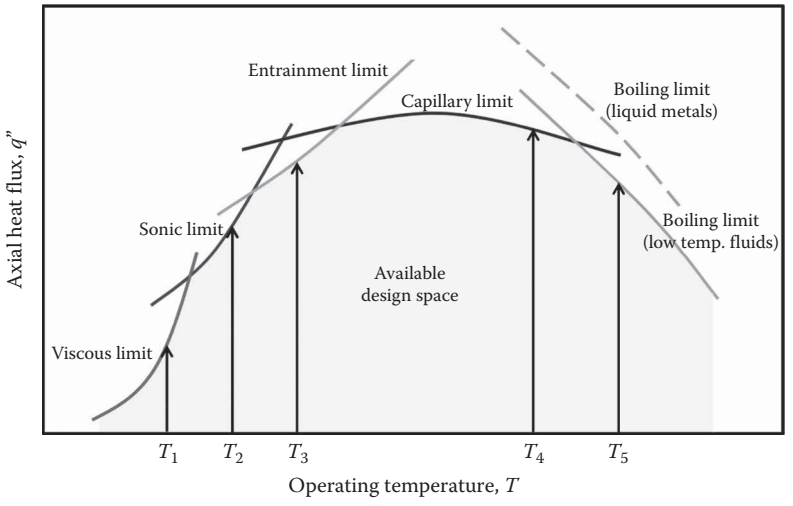

FIGURE 4.17.9 Different limitations of a conventional heat pipe and the available design space in which heat pipe will effectively operate.

$$M = \frac{\sigma \cdot h_{fg} \cdot \rho_l}{\mu_l} \tag{4.17.10}$$

M has the units of heat flux, that is, W/m^2. In addition, M is an implicit function of temperature. Hence, the Figure of merit M scales with the heat flux carrying capacity of a working fluid. Figure 4.17.10 shows the Figure of merit of a few working fluids, as a function of temperature. The typical "inverted U" shape of M is obvious, attributed to the dependence of M on the temperature. A high figure of merit means a corresponding high heat flux handling capacity, subject to heat pipe not getting limited by any thermal-hydraulic phenomena, as detailed earlier.

Genealogy of Heat Pipe Family

Having understood the basic operation, principle and types of heat pipes, we will quickly outline the subtle differences in the operation of these passive thermal systems so that nuances of their design methodology and eventual limitations, are well appreciated. Figure 4.17.11 shows the genealogy of closed passive two-phase heat transfer systems. While the "family tree" is certainly not exhaustive, most relevant systems for the present discussion are included. As will be evident shortly, although all systems shown here have "similar" working principles, there are inherent differences that significantly alter the fundamental heat transfer mechanism and thus the mathematical analyses (Khandekar, 2004).

The presence of a capillary wick for fluid transport is the fundamental characteristics of the first group (Group A) of the family, consisting of conventional and LHPs. While the former has countercurrent flow of the two phases, the latter design avoids it. For analysis of such systems, leading to the determination of maximum heat transport, based on capillary limit, as has been explained earlier (neglecting pressure drops associated with the phase-change process), we use (Faghri, 1995)

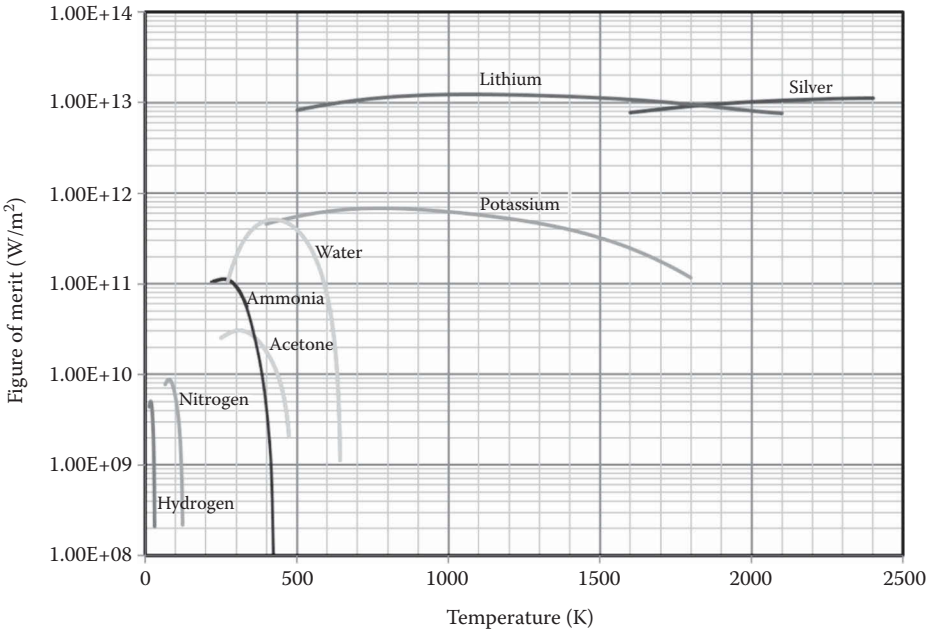

FIGURE 4.17.10 Figure of merit, M, plotted for different fluids, from cryogenic fluids, to medium temperature fluids and liquid metals.

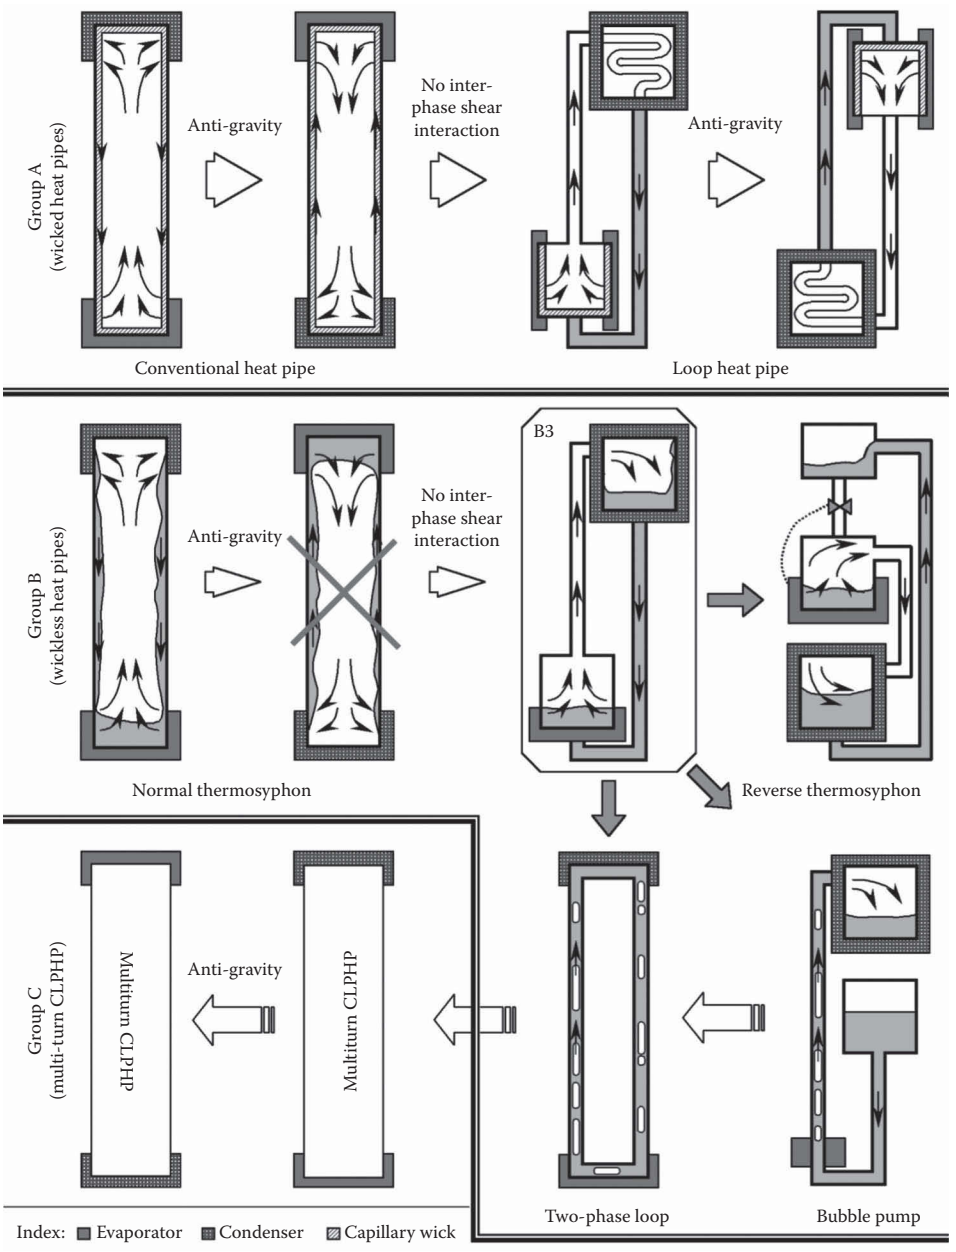

FIGURE 4.17.11 Genealogy of the heat pipe family showing three distinct classes of passive device. Although this classification is not exhaustive, it does include the major types of heat pipes in service.

$$(\Delta P)_{cap} \pm (\Delta P)_{gra} \geq (\Delta P)_{liq} + (\Delta P)_{vap} + (\Delta P)_{liq/vap} \tag{4.17.11}$$

$$(\Delta P)_{gra} = (L_{eff}^{liq} \cdot \rho_{liq} \cdot g \cdot \sin\beta) - (L_{eff}^{vap} \cdot \rho_{vap} \cdot g \cdot \sin\beta) \tag{4.17.12}$$

The R.H.S. of Equation 4.17.11 contains "dissipative" terms that are always positive while the L.H.S. contains the "driving" terms that must be at least equal to the R.H.S. to keep the system running. Thus, all devices in this family can function in antigravity mode if the capillary pumping action

is greater than the gravitational head. The interfacial shear interaction represented by $(\Delta P)_{\text{liq/vap}}$ is avoided in LHPs by the geometrical construction of the device rendering it to be a better alternative to conventional designs.

If the capillary pumping of the first group of devices vanishes, we obtain the second group in the family (Group B). This is represented by the gravity-assisted thermosyphons. Here, the design equation reduces to

$$(\Delta P)_{\text{gra}} \geq (\Delta P)_{\text{liq}} + (\Delta P)_{\text{vap}} + (\Delta P)_{\text{liq/vap}} \tag{4.17.13}$$

Thus, in this group, only the gravity head provides the driving potential. Naturally, since the L.H.S. of Equation 4.17.13 must always be positive for a viable system, antigravity (or zero gravity) operation is not feasible. Usually, $(\Delta P)_{\text{liq/vap}}$ limits the design, leading to counter-current flow limitation (Tien and Chung, 1978; Groll and Rösler, 1992). Such failures can be avoided in design-B3, where the two phases flow in separate channels, as was described in Section 3. This design represents a genealogical crossroad that will lead us to Group C devices including PHPs. All designs discussed so far are primarily based on latent heat transfer. Although sensible heating/cooling does take place, a near isothermal (or isobaric) assumption within the system is justified and hence routinely employed. This assumption is quite realistic for Group A and B devices.

One variation of design-B3 can be obtained by reducing the size of fluid transport channels and the evaporator, to capillary dimensions. One common example of such a case is the standard bubble pump in which, instead of single-phase vapor flow from the evaporator to the condenser, the flow of two-phase mixture results; a direct consequence of slug flow regime being established in the up-header (Benhmidene et al., 2010). In both systems, the construction of the device forces a combination of sensible as well as latent heat transfer. This marks the first significant shift from the previously discussed cases. The second critical aspect is the fact that the gravity head and the dissipative terms are no more based on single-phase calculations but are governed by two-phase pressure drops (effective mixture density and viscosity for given boundary conditions including consideration for the flow regime). This is because, there is no clear stratification of the phases. In addition, depending on the size of the capillary tubes, some additional capillary forces may have to be accounted for depending on their magnitude as compared to the other relevant heads. What complicates the situation further is the inherent presence of two-phase flow instabilities in such systems (Carey, 1992).

Another variation of design B3 comes in the form of an antigravity reverse thermosyphon by incorporating a suitable remote operated valve (e.g., see Sasin et al., 1995; Fantozzi et al., 2002; Filippeschi, 2006). Since there is neither a capillary pumping action nor positive gravity head, the driving potential must come from elsewhere. At the commencement of liquid heating in the evaporator chamber, the remote operated valve is kept closed. Boiling proceeds under nearly constant volume conditions (since there is always some liquid present in the condenser) thereby increasing the local vapor pressure and temperature. After a while, the evaporator pressure becomes high enough to push the liquid out of the condenser, against gravity, toward the accumulator. The evaporator gradually empties while the accumulator starts filling up. A stage is reached when all the evaporator liquid is boiled off. This stage is immediately followed by a rise in heater temperature and a drop in evaporator chamber pressure as the remaining vapor condenses. The remote valve can now be triggered to open by either of these signals creating pressure equalization in the accumulator and evaporator by gravity-assisted liquid return. The cycle then repeats itself. Thus, we observe that a slight design variation necessitates a change in the driving potential; the applicable design criterion now becomes

$$(\Delta P)_{\text{sat}}^{\text{e-acc}} - (\Delta P)_{\text{gra}} \geq (\Delta P)_{\text{liq}} + (\Delta P)_{\text{vap}} \quad \text{where} \tag{4.17.14}$$

$$(\Delta P)_{\text{sat}}^{\text{e-acc}} = (\Delta P)_{\text{sat}}\Big|_{\text{e}} - (\Delta P)_{\text{sat}}\Big|_{\text{acc}} \text{ and} \tag{4.17.15}$$

$$(\Delta P)_{\text{gra}} = (L_{\text{eff}}^{\text{liq}} \cdot \rho_{\text{liq}} \cdot g \cdot \sin\beta) - (L_{\text{eff}}^{\text{vap}} \cdot \rho_{\text{vap}} \cdot g \cdot \sin\beta) \tag{4.17.16}$$

With the preceding discussion, we conclude that the "driving" terms in this family of devices are $(\Delta P)_{gra}$, $(\Delta P)_{cap}$ or $(\Delta P)_{sat}$, acting individually or in a combination as the case may be. The most complicated situation will arise if all the "driving" terms are simultaneously present and two phases are not flowing separately but as a mixture; the design equation then takes the following form (again neglecting the pressure drops associated with phase change in the evaporator and the condenser):

$$\sum_{1}^{2}(\Delta P)_{cap} + \sum_{1}^{2}(\Delta P)_{sat} \pm \sum_{1}^{2}(\Delta P)_{gra}^{\text{two-phase}} \geq \sum_{1}^{2}(\Delta P)_{\text{two-phase}} \tag{4.17.17}$$

where 1 and 2 are specified locations in the system. The RHS includes two-phase friction as well as acceleration terms, if any. Working relationships for Equation 4.17.17 for devices like PHPs are still not available.

Literature on Heat Pipes

Literature on heat pipes is available from multiple sources. Several books and monographs have been written on the subject and some have also been updated in the recent past (Chi, 1976; Dunn and Reay, 1982; Ivanovskii et al., 1982; Peterson, 1994; Faghri, 1995; Reay et al., 2013; Vasiliev and Kakaç, 2013). The material is also available in the form of reports and data compilation. Several well-known journals attract contributions on heat pipes and related technology, both from the stand point of fundamental understanding as well as applications. In recent times, nearly 250 articles appear annually in Web-of-Science recognized journals. For example, over 800 articles have been published in more than 200 journals between 2012 and 2014 (source: Web of Science); major contributions are summarized in Figure 4.17.12 (Lips et al., 2016). In the recent past, research emphasis is on LHPs and PHPs. In parallel, the proceedings of the International Heat Pipe Conference series have been a comprehensive source of information, since the inception of this series of conferences in 1973 at Stuttgart, Germany; the conference has already been held for 17 times, the jubilee edition of which was hosted at the campus of Indian Institute of Technology Kanpur, India, in autumn of 2013. Comprehensive review papers are also available, e.g., see Ochterbeck (2003), Riffat and Ma (2007), Launay et al. (2007), Vasiliev (2008), Khandekar et al. (2010), Maydanik et al. (2014), Siedel et al. (2015), Shabgard et al. (2015), and Chan et al. (2015).

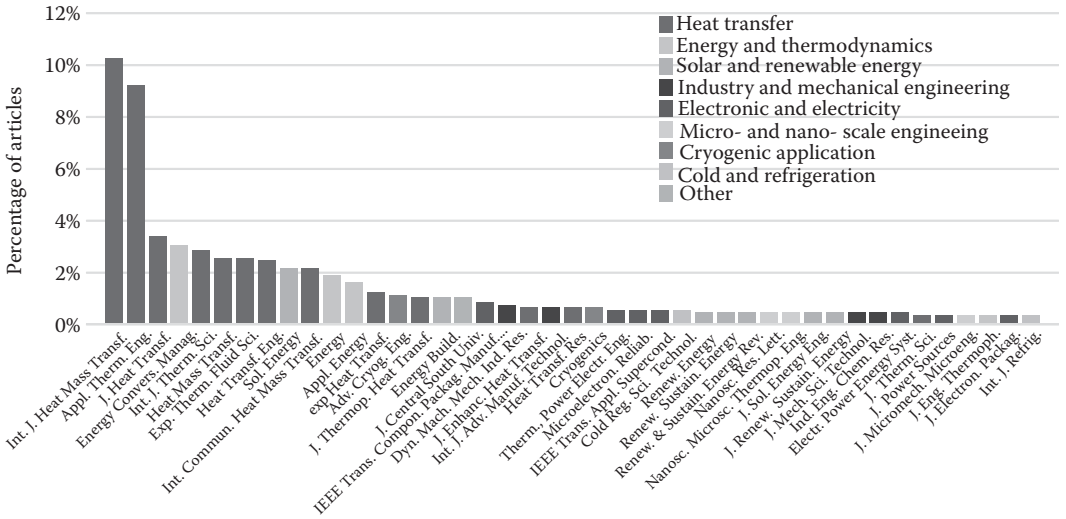

FIGURE 4.17.12 Statistics on journal publications in the field of heat pipe science and technology, taken from Web of Science. (From Lips S., Sartre V., Lefèvre, F., Khandekar S., and Bonjour J., *Interfac. Phenom Heat Transfer*, 4, 33–53, 2016. With permission.)

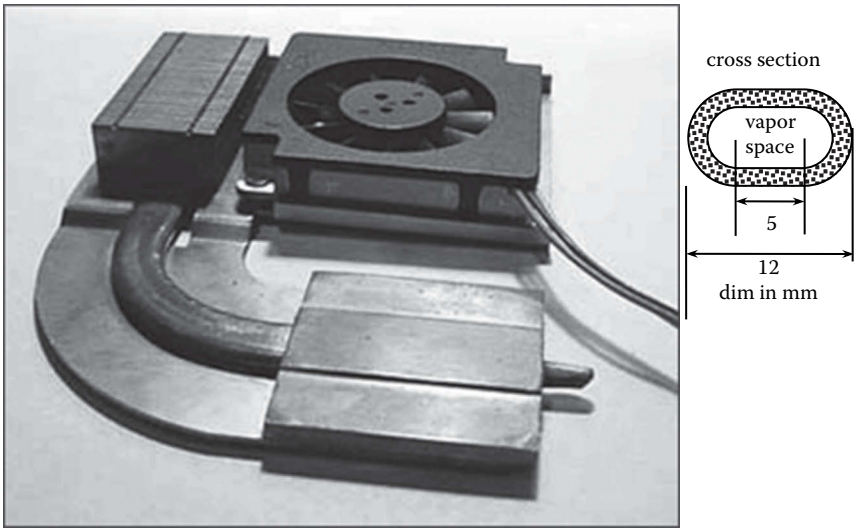

FIGURE 4.17.13 A typical heat pipe system of a laptop computer: example problem.

Example Problem

A copper water heat pipe is used to transfer heat from a microprocessor of a laptop to the ambient. A typical heat pipe-based module, with its cross-sectional shape, is shown in Figure 4.17.13. The evaporator section is 40 mm long while the condenser section is 60 mm long. The total length of the heat pipe is 160 mm. The heat pipe uses a porous capillary structure, 1.0 mm thick, having permeability 1×10^{-10} m^2, and average pore radius of 100 μm. The additional frictional resistance in the liquid due to the bend in the heat pipe is 30% of the total liquid pressure drop. The operating temperature is 70°C. Find the maximum heat transport capability under horizontal operation.

Solution:

Given:

Length of the evaporator section $= l_e = 40$ mm
Length of the condenser section $= l_c = 60$ mm
Length of the adiabatic section $= l_a = 60$ mm
Permeability of wick $= K = 1\times10^{-10}$ m^2
$r_e = r_c = r_{wick}$ = Pore radius = 100 μm
Effective contact angle in the evaporator = 0°
Effective contact angle in the condenser = 90°
The effective length of the heat pipe can be estimated as: $l_{eff} = l_a + 0.5\,(l_c + l_e) = 110$ mm

$$(\Delta P)_{\text{bending}} = 0.3(\Delta P)_{\text{liq}}$$

Thermophysical properties of water can be obtained from the property tables (refer Section 9). At 70°C, the relevant properties are estimated as

$$\rho_l = 977.74 \text{ kg/m}^3;$$

$$\rho_v = 0.197 \text{ kg/m}^3;$$

$$\mu_l = 3.9889\times10^{-4} \text{ Pa-s};$$

$$\mu_v = 1.0860\times10^{-5} \text{ Pa-s};$$

$$\sigma = 0.0644 \text{ N/m};$$

$$h_{fg} = 2.3277 \times 10^{6} \text{ J/kg}$$

Using the given geometric parameters

$$\text{Area of cross section for vapor flow} = A_{vap} = 44.63 \times 10^{-6} \text{ m}^2$$

$$\text{Area of cross section for liquid flow} = A_{liquid} = 28.85 \times 10^{-6} \text{ m}^2$$

$$D_{hyd,vap} = \frac{4A_{vap}}{P_{inner}} = 6.9 \times 10^{-3} \text{ m} = 6.9 \text{ mm}$$

Pressure due to capillary effect of wick (Driving Pressure)

$$(\Delta p)_{cap} = \frac{2 \cdot \sigma \cdot \left[\cos(\theta_{cap,c}) - \cos(\theta_{cap,e})\right]}{r_{wick}}$$

Pressure drop for the in liquid flow in the porous wick

$$(\Delta P)_l = \frac{\mu_l . l_{eff} u_l}{K}$$

$$\dot{Q} = \dot{m} \cdot h_{fg} = (\rho_l u_l A_l) h_{fg} = (\rho_v u_v A_v) h_{fg}$$

$$(\Delta P)_l = \frac{\mu_l l_{eff}}{K} \left(\frac{\dot{Q}}{\rho_l A_l h_{fg}} \right)$$

$(\Delta P)_{vap}$: Pressure drop in vapor which flows in the inner cross section

$$(\Delta P)_{vap} = \frac{f . l_{eff} u_v^2}{2 D_{hyd,vap}}$$

where

- *Case 1*: when the vapor flow is laminar, then

$$f = \frac{64}{\text{Re}_v} \quad \left(\text{Laminar flow fiction factor}\right)$$

- *Case 2*: when the vapor flow is turbulent

$$f = 0.079 \text{Re}^{-1/4} \quad \left(\text{Turbulent flow fiction factor}\right)$$

$$\text{Re}_v = \frac{\rho_v u_v D_{hyd,v}}{\mu_v} = \frac{D_{hyd,v}}{\mu_v} \left(\frac{\dot{Q}}{A_v h_{fg}} \right)$$

To proceed further, let us first assume that the vapor flow is laminar for 70°C operating temperature. We will solve the problem and then verify whether this assumption is true. We get

$$(\Delta P)_{vap} = \frac{64}{\left(\frac{\rho_v u_v D_{hyd,v}}{\mu_v} \right)} \left[\frac{\frac{1}{2} l_{eff} u_v^2}{D_{hyd,v}} \right] = \frac{32 \mu_v l_{eff} . \dot{Q}}{\rho_v^2 h_{fg} A_v D_{hyd,v}^2} = (0.196) \cdot \dot{Q} \text{ Pa}$$

or $(\Delta P)_{vap}$ (by the Hagen–Poiseuille equation)

$$(\Delta P)_l = \frac{\mu_l l_{eff}}{K}\left(\frac{\dot{Q}}{\rho_l A_l h_{fg}}\right) = (6.682)\dot{Q}\ \text{Pa}$$

$$(\Delta p)_{cap} = \frac{2\cdot\sigma\cdot\left[\cos(\theta_{cap,c}) - \cos(\theta_{cap,e})\right]}{r_{cap}} = 1.289\times10^3\ \text{Pa}$$

For finding the capillary limit, we equate the available pumping head, that is, the capillary pressure drop with the net dissipation in the system:

$$(\Delta P)_{cap} = (\Delta P)_l + (\Delta P)_v + (\Delta P)_{bending}$$

$$= 1.3(\Delta P)_l + (\Delta P)_v;\ \text{as}\ (\Delta P)_{bending} = 0.3(\Delta P)_l$$

$$(\Delta P)_{cap} = \left[\left[1.3\times\left\{\left(\frac{\mu_l l_{eff}}{KA_l\rho_l h_{fg}}\right)\right\}\right] + \frac{32\mu_v l_{eff}}{\rho_v^2 h_{fg} A_v D_{hyd,v}^2}\right]\dot{Q}$$

From this, $\dot{Q} = 145.1\,\text{W}$

For this $\dot{Q}$, calculating the vapor Reynolds number we get, $\text{Re}_v = 909.2$.

Hence, the laminar flow assumption for the vapor flow is correct, as $\text{Re}_v < 2300$. Also, for these conditions, the vapor pressure drop is negligible as compared to the liquid pressure drop. In general, using the above set of equations, the maximum heat capacity or capillary limit is calculated by varying wick thickness and results are plotted in Figure 4.17.14.

Thermophysical Property Data

Reliability of the thermophysical data used for the design and development of heat pipes is extremely important. In this context, the design data provided by Brennen and Kroliczek (1979) is very reliable and easy to implement in a computer program. We provide here analytical expressions for various properties in the form of either a power law or exponential fit (as indicated in the table below) for some working fluids. This can be directly used in computer subroutines for calling from the main program.

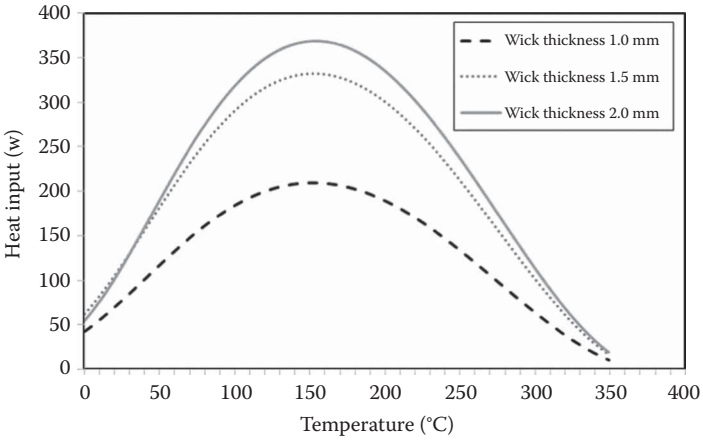

FIGURE 4.17.14 Capillary limit of the heat pipe discussed in the example problem, showing the parametric effect of wick thickness.

** Quantities follow the natural log – law fit, given by : ln(property value)

$$= a_0 + (a_1 * T) + (a_2 * T^2) + (a_3 * T^3) + (a_4 * T^4) + (a_5 * T^5)$$

All other properties follow the simple power-law fit, given by : property value

$$= a_0 + (a_1 * T) + (a_2 * T^2) + (a_3 * T^3) + (a_4 * T^4) + (a_5 * T^5)$$

Summary and Outlook

Heat pipes deserve a special mention in the broad field of thermal management. These simple yet highly efficient class of passive devices have served the industry very well. Their attractiveness lies in the simplicity, excellent performance, possibilities to operate in a wide temperature range, long-term durability, nearly no maintenance and flexibility to cater to a range of applications ranging from space thermal management to terrestrial systems. Heat pipes are also available on several length scales, with submillimeter micro heat pipes to large-scale deployment in, power plants, permafrost stabilization and geothermal energy recovery units. The wave of miniaturization in the commercial electronics industry in the last three decades has provided new impetus and possibilities for the development of frugal heat pipe technology solutions. In this context, copper-water heat pipes have become ubiquitous in PC and laptop industry. Similarly, contemporary satellite operations without heat pipes are unthinkable. In the last two decades, several niche application areas have also emerged, from biomedical to nuclear industry. Starting their journey from simple gravity-assisted thermosyphons applied in bakeries, heat pipes have indeed come a long way, with state-of-the-art high-performance LHPs/CPLs, to deceptively simple, yet one of the most theoretically challenging systems manifested as PHPs.

With a robust history of applications behind them, theoretical understanding of various designs of heat pipes has also progressed. However, several aspects of complex and interlinked thermo-physics of heat pipes still remain to be fully understood. Two glaring examples worth mentioning here are (1) the fundamental understanding of the boiling/evaporation phenomena in LHP evaporator wicks and (2) mathematical description of intricate and coupled thermal-hydraulic mechanisms of heat transfer in a PHP. In addition, even for conventional heat pipe designs, the transient models continue to perform unsatisfactorily as compared to steady-state models. In the last decade, significant developments have been witnessed in material science, composites, polymers, nanotechnology, and indeed on the broader science of interfacial phenomena, wetting, and hierarchical modeling of complex transport physics. The synergistic structure which the heat pipe is, its development cannot remain isolated from these broader developments. There is a need to comprehensively integrate and infuse these developments and progress of several stake-holding topics into the realm of heat pipe technology.

ACKNOWLEDGMENTS

I was introduced to the art and science of heat pipes by Prof. Manfred Groll, my doctoral advisor, in the year 2000. Over the last 40 years, he has trained and inspired a series of students and researchers throughout the world, providing unmatched contribution to this field of engineering science. I dedicate this work to him as he continues his journey of lifelong achievements. I must also mention the special place which Prof. Yuri Maydanik holds in the heat pipe community, not only as an inventor of LHPs, but also as an inspiring entrepreneur. Special thanks to Prof. Jocelyn Bonjour and Prof. Frederic Lefèvre, my collaborators from INSA-Lyon, France. I would like to express my gratitude

to all funding agencies who have supported my research ideas. The contribution of my institute, which has provided excellent atmosphere for professional development, cannot be understated. Last, but not the least, I wish to thank all my graduate students and research associates who have indeed taught me many things!

NOMENCLATURE

Roman symbols

A	cross section (m^2)
D, d	diameter (m)
g	gravitational constant (m/s^2)
h_{fg}	latent heat of vaporization (J/kg)
I	electric current (A)
K	permeability (m^2)
k	thermal conductivity (W/(mK))
L, l	length (m)
M	figure of merit (W/m^2)
P	pressure (Pa)
$\dot{Q}$	heat flow, thermal power (W)
q	heat flux (W/m^2)
R	resistance
r	radius (m)
T	temperature (°C)
t	time (s)
V	electric potential, emf (V)
V, u	velocity (m/s)

Greek symbols

β	inclination with horizontal (°)
ϵ	porosity (–)
μ	dynamic viscosity (Pa s)
ρ	density (kg/m^3)
σ	surface tension (N/m)
θ	wetting angle (°)

Subscripts

acc	acceleration
a, ad	adiabatic
ave	average
ax	axial
c	condenser
cha	characteristic
crit	critical
cap	capillary
e, **E**	evaporator
eff	effective

elec	electrical
gra	gravitational
h, **hyd**	hydraulic
i	inner
l, **liq**	liquid
max	maximum
n	nucleation
rad	radial
s, **sat**	saturation
t	total
th	thermal
v, **vap**	vapor

Nondimensional groups

Bo	Bond number, $\mathrm{Bo}=D\,(g(\rho_l-\rho_v)/\sigma)^{0.5}$
Re	Reynolds number, $\mathrm{Re}=(\rho\cdot v\cdot d_h)/\mu$
We	Weber number, $\mathrm{We}=(\rho_v\cdot v^2\cdot l_{cha})/\sigma$

4.18 LIQUID ATOMIZATION AND SPRAYING

Mario F. Trujillo and Rolf D. Reitz

Sprays are involved in many practical applications, including in the process industries (e.g., spray drying, spray cooling, powdered metals); in treatment applications (e.g., humidification, gas scrubbing); in coating applications (e.g., surface treatment, spray painting, and crop spraying); in spray combustion (e.g., burners, furnaces, rockets, gas turbines, diesel and port fuel injected engines); and in medicinal and printing applications. To be able to describe sprays, it is necessary to obtain a detailed understanding of spray processes.

In the simplest case, the liquid to be sprayed is injected at a high velocity through a small orifice. Atomization is the process whereby the injected liquid is broken up into droplets. Atomization has a strong influence on spray vaporization rates because it increases the total surface area of the injected liquid greatly. Fast vaporization may be desirable in certain applications, but undesirable in others, where the liquid is required to impinge on a target. The trajectories of the spray drops are governed by the injected momentum of the drop, drag forces, and interactions between the drops and the surrounding gas. Control of these and other spray processes can lead to significant improvements in performance and in quality of product, and to reduction of emission of pollutants.

Spray Characterization

Practical atomizers generate sprays with a distribution of drop sizes, with average sizes in the diameter range from a few microns ($1\,\mu m = 10^{-6}\,m$) to as large as 0.5 mm. It is important to quantify the details of the distribution depending on the application. For example, the smaller drops in a spray vaporize fast, and this is helpful to control ignition processes in some combustion systems. On the other hand, the large drops carry most of the mass and momentum of the injected liquid and these drops are able to penetrate into the high-pressure gases in engine combustion chambers. Typical average drop sizes for broad classes of sprays are shown schematically in Figure 4.18.1. It should be noted that the terminology used to describe sprays in Figure 4.18.1 is qualitative and is not universally agreed upon.

Methods for characterizing the size distribution of spray drops are discussed in ASTM (1988) and by Mugele and Evans (1951). A probability distribution function, $F(D)$, is introduced that represents the fraction of drops per unit diameter range about the diameter, D, as shown in Figure 4.18.2. The spray drop sizes span a range from a minimum diameter, D_{min}, to a maximum diameter, D_{max}. It is also convenient to introduce a mean or average drop diameter instead of having to specify the complete drop size distribution. The number median drop diameter represents that drop whose diameter is such that 50% of the drops in the spray have sizes less than this size. Spray drop size distribution data can also be represented as a volume (or mass) distribution function, $F(D^3)$; this gives more weight to the large drops in the distribution. In this case, a volume median diameter or a mass median diameter can also be defined, as indicated in Figure 4.18.2.

Various other mean diameters are also in common use. These are summarized using the standard notation of Mugele and Evans (1951) as

$$(D_{jk})^{j-k} = \frac{\int_{D_{min}}^{D_{max}} D^j f(D)\,\mathrm{d}D}{\int_{D_{min}}^{D_{max}} D^k f(D)\,\mathrm{d}D} \tag{4.18.1}$$

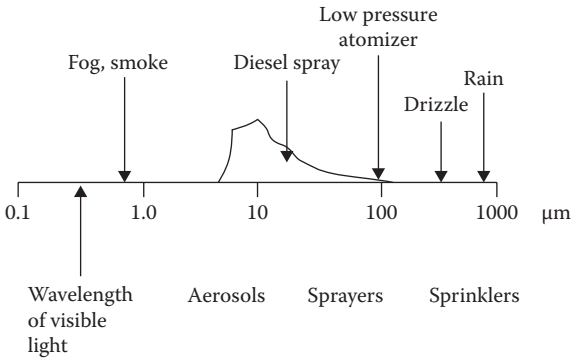

FIGURE 4.18.1 Typical average spray drop sizes for various classes of sprays. A representative size distribution is depicted for the diesel spray.

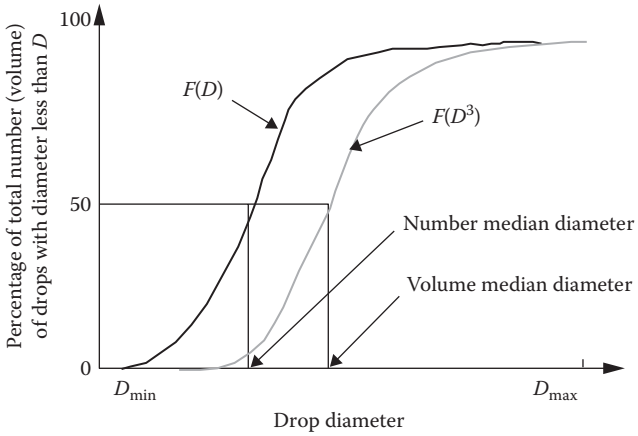

FIGURE 4.18.2 Cumulative spray drop number and volume distributions.

where $f(D) = \mathrm{d}F(D)/\mathrm{d}D$ is the drop size probability density function (usually normalized such that $\int_{D_{\min}}^{D_{\max}} f(D)\,\mathrm{d}D = 1$). Commonly used mean diameters are D_{10} (i.e., $j=1$, $k=0$, sometimes called the length mean diameter (Lefebvre, 1989) and D_{32} (i.e., $j=3$, $k=2$, called the Sauter mean diameter [SMD]). The SMD has a useful physical interpretation in combustion applications since drop vaporization rates are proportional to the surface area of the drop. It represents the size of that drop that has the same volume-to-surface area ratio as that of the entire spray.

Several distribution functions have been found to fit experimental data reasonably well. Among these are the Nukiyama–Tanasawa and the Rosin–Rammler distributions that have the general form (Lefebvre, 1989) $f(D) = aD^p \exp(\{-bD\}^q)$, where the constants a, p, b, and q characterize the size distribution. The higher the parameter, q, the more uniform the distribution, and typically $1.5 < q < 4$. Other distributions have been proposed which consist of logarithmic transformations of the normal distribution, such as $f(D) = a\exp(-y^2/2)$, where $y = \delta \ln(\eta D/(D_{\max} - D))$, and α, δ, and η are constants. In this case, the smaller δ, the more uniform the size distribution. It should be noted that there is no theoretical justification for any of these size distributions. Spray drop size distributions can be measured nonintrusively by using optical laser diffraction and phase/Doppler instruments. A discussion of these techniques and their accuracy is reviewed by Chigier (1983).

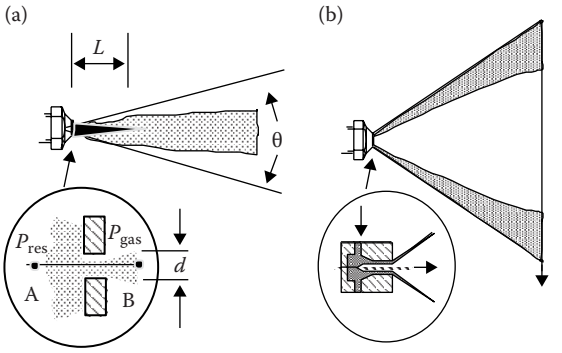

FIGURE 4.18.3 Schematic diagram of (a) solid cone and (b) hollow cone pressure atomizer sprays.

Atomizer Design Considerations

Atomization is generally achieved by forcing a liquid or a liquid–gas mixture through a small hole or slit under pressure to create thin liquid sheets or jets moving at a high relative velocity with respect to the surrounding ambient gas. Desirable characteristics of atomizers include the ability to atomize the liquid over a wide range of flow rates, low power requirements, and low susceptibility to blockage or fouling. In addition, atomizers should produce consistent sprays with uniform flow patterns in operation.

Atomizers can be broadly characterized as those producing hollow cone or solid cone sprays, as depicted in Figure 4.18.3. In solid cone (or full cone) sprays, the spray liquid is concentrated along the spray axis, Figure 4.18.3a. These sprays are useful in applications requiring high spray penetration, such as in diesel engines. In hollow cone sprays, the axis region is relatively free of drops, giving wide spray dispersal, Figure 4.18.3b. These sprays are often used in furnaces, gas turbines, and spray-coating applications.

Many different atomizer designs are found in applications. Common atomizer types include pressure, rotary, twin-fluid (air-assist, air-blast, effervescent), flashing, electrostatic, vibratory, and ultrasonic atomizers, as discussed next.

Atomizer Types

In *pressure* atomizers, atomization is achieved by means of a pressure difference, $\Delta P = P_{res} - P_{gas}$, between the liquid in the supply reservoir pressure, P_{res}, and the ambient medium pressure, P_{gas}, across a nozzle. The simplest design is the plain orifice nozzle with exit hole diameter, d, depicted in Figure 4.18.3a. The liquid emerges at the theoretical velocity $U = \sqrt{2\Delta P/\rho_{liquid}}$, the (Bernoulli) velocity along the streamline A–B in Figure 4.18.3a, where ρ_{liquid} is the density of the liquid. The actual injection velocity is less than the ideal velocity by a factor called the discharge coefficient, C_D, which is between 0.6 and 0.9 for plain hole nozzles. C_D accounts for flow losses in the nozzle.

Four main jet breakup regimes have been identified, corresponding to different combinations of liquid inertia, surface tension, and aerodynamic forces acting on the jet, as shown in Figure 4.18.4. At low injection pressures, the low-velocity liquid jet breaks up due to the unstable growth of long-wavelength waves driven by surface tension forces (Rayleigh regime). As the jet velocity is increased, the growth of disturbances on the liquid surface is enhanced because of the interaction between the liquid and the ambient gas (the first and second wind-induced breakup regimes). At high injection pressures, the high-velocity jet disintegrates into drops immediately after leaving the nozzle exit (atomization regime). Criteria for the boundaries between the regimes are available (Chigier and Reitz, 1996). Aerodynamic effects are found to become very important relative to inertial effects when the jet Weber number, $We_j > 40$, where $We_j = \rho_{gas} U^2 d/\sigma$, σ_{gas} is the gas density, and σ is the liquid surface tension.

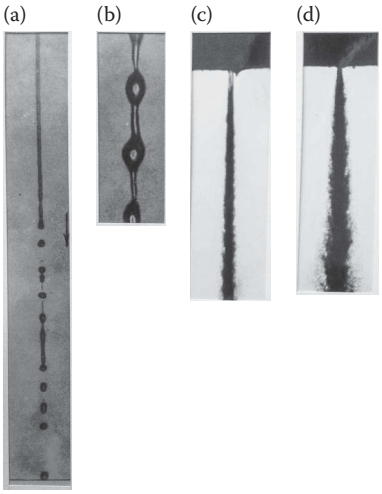

FIGURE 4.18.4 (a) Rayleigh breakup. Drop diameters are larger than the jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (b) First wind-induced regime. Drops with diameters of the order of jet diameter. Breakup occurs many nozzle diameters downstream of nozzle. (c) Second wind-induced regime. Drop sizes smaller than the jet diameter. Breakup starts some distance downstream of nozzle. (d) Atomization regime. Drop sizes much smaller than the jet diameter. Breakup starts at nozzle exit.

Experiments show that the unstable growth of surface waves is aided by high relative velocities between the liquid and the gas, and also by high turbulence and other disturbances in the liquid and gas flows, and by the use of spray liquids with low viscosity and low surface tension.

Liquid breakup characteristics such as the spray drop size, the jet breakup length, and the spray angle have been related to the unstable wave growth mechanism. The wavelengths and growth rates of the waves can be predicted using results from a linear stability analysis with (Reitz, 1988)

$$\frac{\Lambda}{2} = 9.02\frac{(1+0.45Z^{0.5})(1+0.4T^{0.7})}{(1+0.87\mathrm{We}_2^{1.67})^{0.6}} \tag{4.18.2a}$$

$$\Omega\left(\frac{\rho_l a^3}{\sigma}\right)^{0.5} = \frac{0.34+0.38\mathrm{We}_2^{1.5}}{(1+Z)(1+1.4T^{0.6})} \tag{4.18.2b}$$

where Λ is the wavelength, Ω is the growth rate of the most unstable surface wave, and a is the liquid jet radius. The maximum wave growth rate increases, and the corresponding wavelength decreases with increasing Weber number, $\mathrm{We}_2 = \rho_{gas}U^2a/\sigma$, where U is the relative velocity between the liquid and the gas. The liquid viscosity appears in the Ohnesorge number, $Z = \mathrm{We}_l^{1/2}\mathrm{Re}_l$. Here, the Weber number We_l is based on the liquid density, the Reynolds number is $\mathrm{Re}_l = Ua/\nu_l$, ν_l is the liquid viscosity, and the parameter $T = Z\mathrm{We}_2^{1/2}$. The wave growth rate is reduced and the wavelength is increased as the liquid viscosity increases.

The size of the drops formed from the breakup process is often assumed to be proportional to the wavelength of the unstable surface waves in modeling studies (Reitz, 1988). However, the drop sizes in the primary breakup region near the nozzle exist have also been found to be influenced by the length scale of the energy-containing eddies in the turbulent liquid flow (Wu et al., 1995). There is uncertainty about atomization mechanisms since spray measurements are complicated by the high optical density of the spray in the breakup region (e.g., see Figure 4.18.4d). As the drops penetrate into the ambient gas, they interact with each other through collisions and coalescence, and the spray drop size changes dynamically within the spray as a result of secondary breakup and vaporization

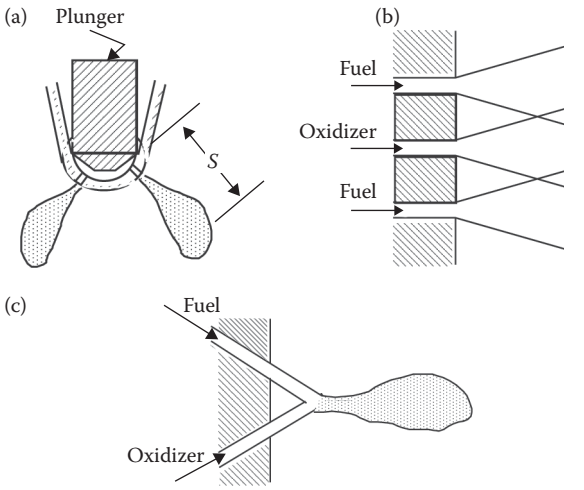

FIGURE 4.18.5 (a) Diesel injector multihole spray nozzle, (b) showerhead, and (c) doublet impingement nozzles.

effects. The drop trajectories are determined by complex drop drag, breakup, and vaporization phenomena, and by interactions with the turbulent gas flow (Reitz, 1988). Recent highly resolved simulations (HRSs) (Deshpande et al., 2015) have reported a drastic difference between the length scales predicted by linear stability analysis, for example, from Equations 4.18.2, and those observed as being responsible for primary atomization.

High-pressure diesel sprays are intermittent and are required to start and stop quickly without dribble between injections. This is accomplished by means of a plunger arrangement that is actuated by a cam and spring system in mechanical "jerk" pump systems (Figure 4.18.5). Modern electronic injectors include electromagnetic solenoids that permit the duration and injection pressure to be varied independently of each other and of engine speed. Experiments on diesel-type injector nozzles show that the penetration distance, S, of the tip of the spray at time, t, after the beginning of the injection is given by (Hiroyasu and Arai, 1978)

$$\begin{aligned} S &= 0.39Ut(\rho_{\text{liquid}}/\rho_{\text{gas}})^{1/2} \quad \text{for} \quad t < t_b \\ S &= 2.46\sqrt{Udt}\,(\rho_{\text{liquid}}/\rho_{\text{gas}})^{1/4} \quad \text{for} \quad t > t_b \end{aligned} \tag{4.18.3}$$

where the "breakup time" is $t_b = 40.5d(\rho_{\text{liquid}}/\rho_{\text{gas}})^{1/2}/U$. The jet breakup length (see Figure 4.18.3a), $L = Ut_b$ is independent of the injection velocity. On the other hand, for low-speed jets, or for jets injected into a low-gas-density environment, $t_b = 1.04C\,(\rho_{\text{liquid}}d^3/\sigma)^{1/2}$, where C is a constant typically between 12 and 16 and σ is the surface tension. In this case, L increases with the injection velocity (Reitz and Bracco, 1986). The functional form of the above jet breakup time and length correlations can be derived for an inviscid liquid in the limits of large and small Weber number, We_2 from the unstable wave growth rate in Equation 4.18.2 with $t_b \sim \Omega^{-1}$.

For high-speed diesel-type jets in the atomization regime, the resulting spray diverges in the form of a cone with cone angle, θ, that is usually in the range from 5° to 20°. θ increases with gas density following $\tan\theta = A(\rho_{\text{gas}}/\rho_{\text{liquid}})^{1/2}$, where A is a constant that depends on the nozzle passage length and (weakly) on the injection velocity (Reitz and Bracco, 1986). Very high injection pressures are required to produce small drops. In diesel engines, ΔP is typically as high as 200 MPa, and drops are produced with mean diameters of the order of 10 μm (see Figure 4.18.1). Drop size correlations have been proposed for plain-orifice sprays, such as that presented in Table 4.18.1 (Lefebvre, 1989). Note, however, that these correlations do not account for the fact that the spray drop size varies with

TABLE 4.18.1
Representative Drop Size Correlations for Various Spray Devices (Dimensional Quantities Are in SI Units, kg, m, s)

Device	Correlation	Notes
Plain orifice	$\text{SMD} = 3.08\nu_l^{0.385}(\rho_{\text{liquid}}\sigma)^{0.737}\rho_{\text{gas}}^{0.06}\Delta P^{-0.54}$	Use SI units
Fan spray	$\text{SMD} = 2.38d_h(\sigma\mu_{\text{liquid}}^2/\rho_{\text{gas}}d_h^3\Delta P^2)^{0.25}$ $+ 0.26d_h(\sigma\rho_{\text{liquid}}/\rho_{\text{gas}}d_h\Delta P^2)^{0.25}$	d_h = nozzle hydraulic diameter
Rotary atomizer	$\text{SMD} = 0.119Q^{0.1}\sigma^{0.5}/Nd^{0.5}\rho_{\text{liquid}}^{0.4}\mu_{\text{liquid}}^{0.1}$	N = rotational speed (rev/s), Q = volumetric flow rate, A_{inj} U
Pressure swirl	$\text{SMD} = 4.52(\sigma\mu_{\text{liquid}}^2/\rho_{\text{gas}}\Delta P^2)^{0.25}(t\cos\theta)^{0.25}$ $+ 0.39(\sigma\rho_{\text{liquid}}/\rho_{\text{gas}}\Delta P)^{0.25}(t\cos\theta)^{0.75}$ $t = 0.0114A_{\text{inj}}\rho_{\text{liquid}}^{1/2}d\cos\theta$	t = film thickness; θ = cone angle, d = discharge orifice diameter
Twin-fluid/air-blast	$\text{SMD} = 0.48d\left(\sigma/\rho_{\text{gas}}U^2d\right)^{0.2}(1+1/\text{ALR})^{0.4}$ $+ 0.15d(\mu_{\text{liquid}}^2/\sigma\rho_{\text{liquid}}d)^{0.5}(1+1/\text{ALR})$	ALR = air-to-liquid mass ratio
Prefilming air-blast	$\text{SMD} = (1+1/\text{ALR})\left[0.33d_h(\sigma/\rho_{\text{gas}}U^2d_p)^{0.6}\right.$ $\left.+ 0.068d_h(\mu_{\text{liquid}}^2/\sigma\rho_{\text{liquid}}d_p)^{0.5}\right]$	d_h = hydraulic diameter, d_p = prefilmer diameter, Figure 4.18.9
Ultrasonic	$\text{SMD} = \left(4\pi^3\sigma/\rho_{\text{liquid}}\omega^2\right)^{1/3}$	ω = vibration frequency

time, and from place to place in the spray. Moreover, experimental correlations often do not include some parameters that are known to influence spray drop sizes, such as the nozzle passage length and its entrance geometry. Therefore, overall drop size correlations should only be used with caution.

The plain-orifice design is also used in twin-fluid-type liquid rocket engines in showerhead and doublet designs (Figures 4.18.5b and c). In the case of doublet nozzles, shown in Figure 4.18.6c, the impinging jets create unstable liquid sheets which break up to produce the sprays. Drop size correlations are available for liquid sheets such as those formed by discharging the liquid through a rectangular slit (see fan spray, Table 4.18.1). Thin liquid sheets or slits lead to the production of small drops. The breakup mechanism of liquid sheets is also thought to involve the unstable growth of surface waves due to surface tension and aerodynamic forces (Chigier and Reitz, 1996).

In rotary atomizers, centrifugal forces are used to further enhance the breakup process. In this case, the liquid is supplied to the center of a spinning disk and liquid sheets or ligaments are thrown off the edges of the disk. The drop size depends on the rotational speed of the disk, as indicated in Table 4.18.1.

A spinning wheel or cup (turbobell) is used in some spray-painting applications. The spray shape is controlled by supplying a coflowing stream of "shaping air."

Centrifugal forces also play a role in the breakup mechanism of pressure swirl atomizers (simplex nozzles). These atomizers give wider spray cone angle than plain orifice nozzles, and are available in hollow cone and solid cone designs. As depicted in Figure 4.18.3b, the spray liquid enters a swirl chamber tangentially to create a swirling liquid sheet. The air-core vortex within the swirl chamber plays an important role in determining the thickness of the liquid sheet or film at the nozzle exit. This type of nozzle produces relatively coarse sprays. A representative SMD correction

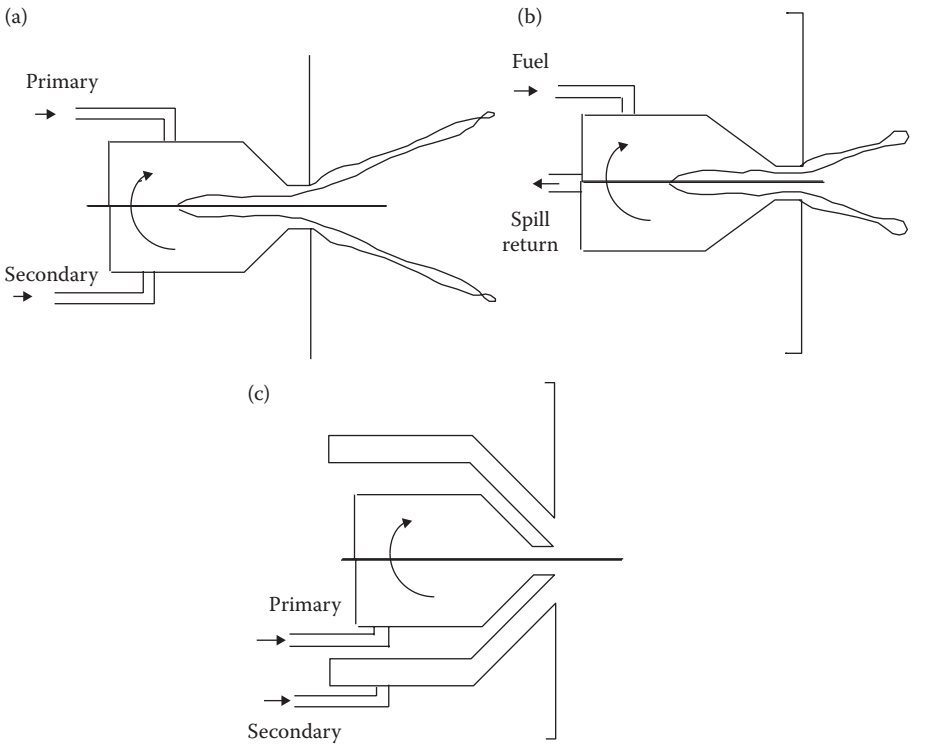

FIGURE 4.18.6 (a) Duplex, (b) dual-orifice, and (c) spill-return-type nozzle designs.

is listed in Table 4.18.1. The spray cone angle depends on the ratio of the axial and tangential liquid velocity components at the exit of the nozzle. This type of atomizer is not well suited for use in transient applications because it tends to dribble at start-up and to shut down when the air-core is not fully formed.

The basic drawback of all pressure atomizers is that the flow rate depends on the square root of ΔP. The volumetric flow rate is $Q=A_{inj}U$, where A_{inj} is the liquid flow area at the nozzle exit, so that a factor of 20 increase in flow rate (a typical turndown ratio from idle to full load operation of a gas turbine engine) requires a factor of 400 increase in injection pressure.

This difficulty has led to the so-called wide-range atomizer designs such as those shown in Figure 4.18.6. The duplex nozzle features two sets of tangential swirl ports; the primary (or pilot) supplies fuel at low flow rates, while the secondary ports become operational at high flow rates. Another variation is the dual-orifice nozzle which is conceptually two simplex nozzles arranged concentrically, one supplying the primary flow and the other supplying the secondary flow. The spill-return nozzle is a simplex nozzle with a rear passage that returns fuel to the injection pump. In this design, the flow rate is controlled by the relative spill amount, and there are no small passages to become plugged. However, the fuel is always supplied at the maximum pressure which increases the demands on the injection pump. But high swirl is always maintained in the swirl chamber and good atomization is achieved even at low flow rates.

In twin-fluid injectors, atomization is aided by a flow of high-velocity gas through the injector passages. The high-velocity gas stream impinges on a relatively low-velocity liquid either internally (in internal mixing nozzles, Figure 4.18.7) or externally (in external mixing designs, Figure 4.18.8). The liquid and gas flows are typically swirled in opposite directions by means of swirl vanes to improve atomization. Air-assist refers to designs that use a relatively small amount of air at high (possibly sonic) velocities. Air-blast refers to designs that use large quantities of relatively

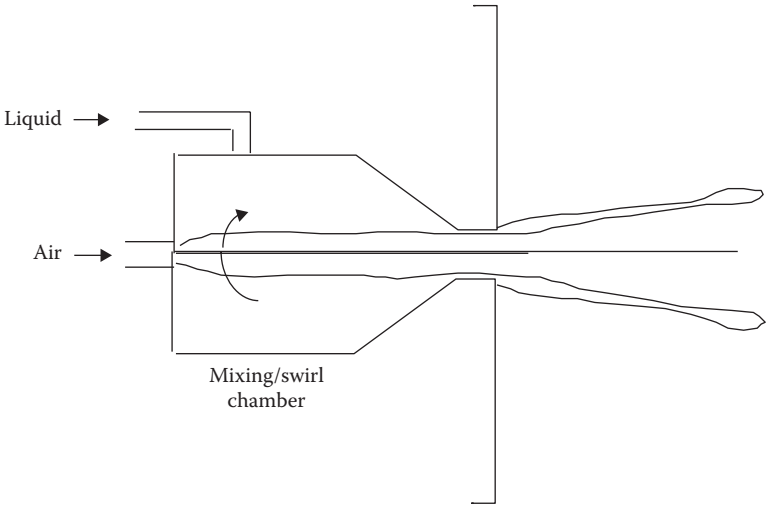

FIGURE 4.18.7 Internal-mixing twin-fluid injector design.

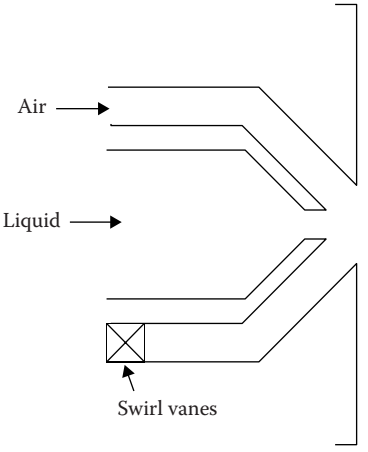

FIGURE 4.18.8 External-mixing twin-fluid injector design.

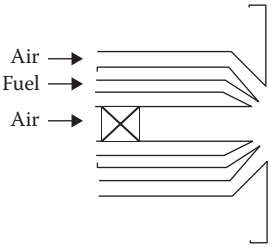

FIGURE 4.18.9 Prefilming air-blast atomizer.

low-velocity air which often supplies some of the air to help decrease soot formation in combustion systems (Lefebvre, 1989) (Figure 4.18.9).

In flashing and effervescent atomizers, a two-phase flow is passed through the injector nozzle exit. In the former, the bubbles are generated by means of a phase change which occurs as the liquid, containing a dissolved propellant gas or vapor, undergoes the pressure drop through the nozzle.

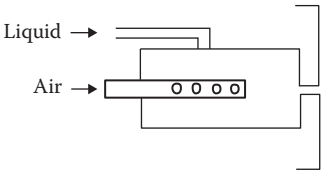

FIGURE 4.18.10 Internal-mixing, effervescent atomizer.

This process is exploited in many household spray cans, but has the disadvantage of releasing the propellant gas required for atomization into the atmosphere. In the so-called effervescent atomizer, air bubbles are introduced into the liquid upstream of the exit orifice, as depicted in Figure 4.18.10. The spray quality is found to depend weakly on the air bubble size and is independent of the nozzle exit diameter. This makes internal mixing, air-assist atomizers very attractive for use with high-viscosity fluids and slurries where nozzle plugging would otherwise be a problem (Lefebvre, 1989).

In electrostatic atomizers, the spray liquid is charged by applying a high-voltage drop across the nozzle. The dispersion of the spray drops is increased by exploiting electrical repulsive forces between the droplets. An electrostatic charge on the drops is also helpful in spray-coating applications, such as in automotive spray painting using electrostatic turbobell sprayers, since the charged drops are attracted to an oppositely charged target surface.

Other atomizer types include vibratory and ultrasonic atomizers (or nebulizers), where the drops are formed by vibrating the injector nozzle at high frequencies and at large amplitudes to produce short-wavelength disturbances to the liquid flow. Ultrasonic atomizers are used in inhalation therapy where very fine sprays (submicron sizes) are required, and an available representative drop size correlation is also listed in Table 4.18.1.

Modeling and Simulating Sprays

The numerical representation of sprays is often accomplished by describing the gas phase in terms of a continuum and the droplets as discrete entities that interact with the gas phase through exchanges of mass, momentum, and energy. This combined liquid/gas phase description is referred to in the literature as the Lagrangian–Eulerian methodology (Balachandar and Eaton, 2010). The most common approach used in practical spray calculations is to employ a Reynolds-averaged–Navier–Stokes to describe the gas phase. For instance, the following equations for mass, chemical species (i), momentum, and energy are solved:

$$\frac{\partial r}{\partial t} + \nabla \cdot (\rho \boldsymbol{u}) = \dot{\rho}_s; \tag{4.18.4a}$$

$$\frac{\partial [\rho Y_i]}{\partial t} + \nabla \cdot (\rho \boldsymbol{u} Y_i) = \nabla \cdot (\mathfrak{D} \nabla Y_i) + \dot{S}_{Y_i} + \dot{C}_{Y_i}; \tag{4.18.4b}$$

$$\frac{\partial \rho \boldsymbol{u}}{\partial t} + \nabla \cdot (\rho \boldsymbol{u}\boldsymbol{u}) = -\nabla \mathrm{P} + \nabla \cdot (\boldsymbol{T}) + \rho \boldsymbol{g} + \dot{S}_{\mathrm{M}}; \tag{4.18.4c}$$

$$\frac{\partial (\rho h)}{\partial t} + \nabla \cdot (\rho \boldsymbol{u} h) = \nabla \cdot (\alpha_{\mathrm{eff}} \nabla \mathrm{h}) + \frac{DP}{Dt} + \dot{S}_h. \tag{4.18.4d}$$

In these expressions, the terms, $\dot{\rho}_s$, $\dot{S}_{Y_i}$, $\dot{C}_{Y_i}$, $\dot{S}_{\mathrm{M}}$, and $\dot{S}_h$ represent, respectively, the source term for droplet evaporation, chemical species production from either spray and/or combustion, momentum source term from the spray, and gas energy deficit associated with spray vaporization. The viscous and turbulent contributions to the stress tensor are included in $\boldsymbol{T}$. The resulting system of unknowns consists of density, chemical species, velocity, pressure, and temperature. To close this

system of equations, an equation of state (EoS) is incorporated into the solution. Under ambient or near-ambient pressure conditions, the ideal EoS provides adequate predictions for the various thermodynamic quantities (Trujillo et al., 2004), but under higher pressures, a more elaborate treatment is necessary consisting of a more general EoS (Qiu and Reitz, 2015). These set of governing equations are generally coupled to equations governing the turbulent kinetic energy and dissipation rate, which also exhibit source terms stemming from the spray.

Theoretically, when the Reynolds-averaging procedure is applied consistently to both liquid and gas phases, the resulting expression for the liquid phase is an evolution equation for the number density ($f(\boldsymbol{x},\boldsymbol{v},r;t)$) of the spray droplets distributed over physical space ($\boldsymbol{x}$), velocity space ($\boldsymbol{v}$), and droplet radius space (r) (for the sake of expedience, we are explicitly skipping the terms associated with departures from sphericity and temperature). This equation was originally introduced by Williams (1958), and more formally derived by Subramaniam (2001). It is given by the following expression:

$$\frac{\partial(f)}{\partial t}+\nabla_x\cdot(f\boldsymbol{v})+\nabla_V\cdot(f\boldsymbol{a})+\frac{\partial}{\partial r}(f\dot{R})=f_{\text{coll}}+f_{\text{break}}\,, \tag{4.18.5}$$

where the gradients over physical and velocity space are, respectively, denoted as ∇_x and ∇_V. The droplet acceleration is given by $\mathbf{a}$, and the rate of change of droplet radius is represented by $\dot{R}$. The right-hand-side terms are sources or sinks due to droplet–droplet collisions (f_{coll}) or hydrodynamic breakup of droplets (f_{break}).

While the expression above does in fact reproduce the evolution of the spray number density, in practical applications it is never solved. The main reason is that this partial differential equation has seven independent variables, discounting temperature and departure from sphericity, and thus represents an almost insurmountable computational challenge. The common alternative, that is frequently adopted, is inspired by direct numerical simulations (DNSs) of dispersed two-phase flow (Elghobashi and Truesdell, 1993), where the solution of droplet position and velocity is performed for every droplet in the computational domain. Rather than tracking each individual droplet in spray modeling efforts, a simplification is often employed, where a given group of droplets, denoted as a parcel, is tracked in exactly the same manner as a droplet. This methodology is referred to as the superparticle method by Ferry and Balachandar (2001).

Under the superparticle methodology, the parcel represents a group of N_{p} identical droplets having the same size, velocity, temperature, position, and other dependent quantities. Thus, for instance, the mass of a given parcel is given by $N_{\text{p}}\rho_{\text{L}}\frac{4}{3}\pi r_{\text{p}}^3$ and a set of relevant evolution equations for parcel position, velocity, and temperature are given as

$$\frac{\mathrm{d}\boldsymbol{x}_{\text{p}}}{\mathrm{d}t}=\boldsymbol{V}_{\text{p}}; \tag{4.18.6a}$$

$$m_{\text{p}}\frac{\mathrm{d}\boldsymbol{V}_{\text{p}}}{\mathrm{d}t}=\frac{\pi D_{\text{p}}^2}{8}\rho_{\text{G}}C_{\text{D}}[\boldsymbol{u}(x_{\text{p}},t)-\boldsymbol{V}_{\text{p}}]\left|\boldsymbol{u}(x_{\text{p}},t)-\boldsymbol{V}_{\text{p}}\right|+\rho_{\text{L}}\boldsymbol{g}\frac{\pi D_{\text{p}}^3}{8}; \quad \text{and} \tag{4.18.6b}$$

$$\frac{\mathrm{d}T_{\text{p}}}{\mathrm{d}t}=\frac{1}{C_{\text{p,p}}m_{\text{p}}}\left[\dot{Q}_{\text{p}}+\dot{m}_{\text{p}}h_{\text{fg}}\right]. \tag{4.18.6c}$$

The sensible heat transfer and heat transfer from phase change are shown, respectively, in the first and second right-hand-side terms of Equation 4.18.6c.

Other more rigorous interpretations for N_{p} based on the droplet distribution function or spray number density are provided in the work of Subramaniam (2001, 2013). The key idea communicated here is that the statistical representation of the spray in terms of parcels must converge to the same statistics as if all of the droplets were individually tracked. In this sense, N_{p} really becomes a

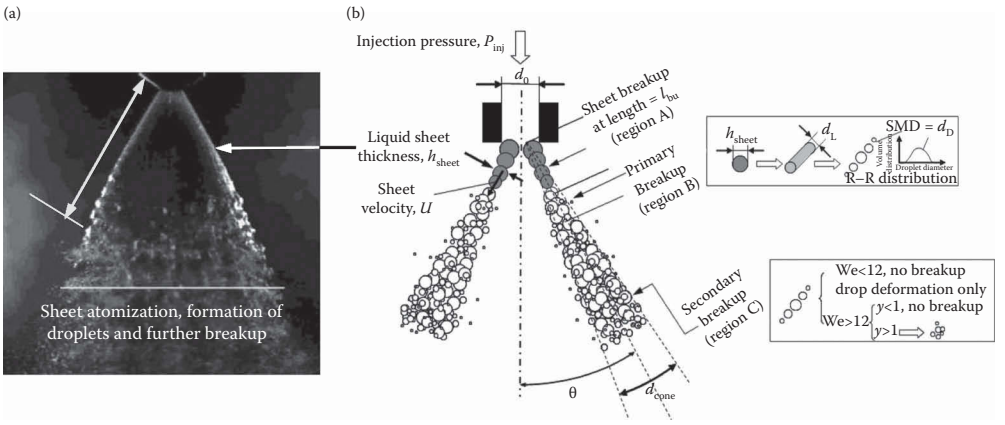

FIGURE 4.18.11 Qualitative comparison between an experimental hollow cone spray (a) and its modeling counterpart (b). Region A in the spray modeling consists of numerical parcels representing the intact liquid sheet. In region B, these initial parcels undergo breakup as dictated by primary atomization models, and in region C, they undergo further breakup governed by secondary atomization models. The authors thank Chris Brown and Vince McDonell for providing the photo image.

statistical weight for the parcel and care must be taken to ensure that as the spray evolves in time, the statistics from the parcel representation remain consistent with the physical spray.

One of the major drawbacks from the Lagrangian–Eulerian treatment is the manner in which primary atomization is treated. To illustrate this, Figure 4.18.11a shows a picture of a hollow-cone spray and its counterpart modeling representation in Figure 4.18.11b. In the modeling procedure, droplets of a specified size are introduced at the nozzle orifice, and an instability model is employed to determine their subsequent breakup. This treatment leads to a size distribution of droplets as shown in one of the encapsulated boxes on the far right of the figure. Additionally, if the resulting droplets are aerodynamically unstable, a second breakup procedure is employed (for secondary atomization), where the corresponding droplet Weber number is used as a discriminating parameter for judging instability.

If we compare this procedure to the actual breakup process as conveyed in Figure 4.18.11a, the most apparent feature is that for a substantial distance from the nozzle orifice, the sheet has remained largely intact; nevertheless, its corresponding modeling representation, at the same locations, is given in terms of droplets. This implies that the predicted momentum interaction with the surrounding gas phase is expected to deviate from experimental findings, since the extent of the gas–liquid interface and its shape is so drastically different between a liquid sheet and a group of droplets. In fact, it is precisely this discrepancy that leads to significant deviations in modeling attempts as presented in Figure 4.18.12, where the experimental image of the spray (Figure 4.18.12a) is compared to the modeling results (Figure 4.18.12b). The red dashed line corresponds to the centerline axis in experiments, and the yellow line is the respective computational axis. The difference between them is substantial and directly affects the downstream spray evolution.

Efforts to address experimental/modeling discrepancies often lead to an optimization of modeling constants for a specific spray configuration. For instance, an optimized set of modeling constants can be used for fuel injection under diesel spray conditions with reasonable good agreement among various diesel spray data sets. However, exercise of these modeling constants for a completely different spray, such as the hollow water spray shown in Figures 4.18.11 and 4.18.12 can potentially, and does in fact, lead to significant discrepancies. While another optimization exercise can be conducted to arrive at better constants for this type of hollow-cone spray, a need exists for generalizing the liquid/gas phase treatment in the near-field and reducing the existing level of empiricism. To

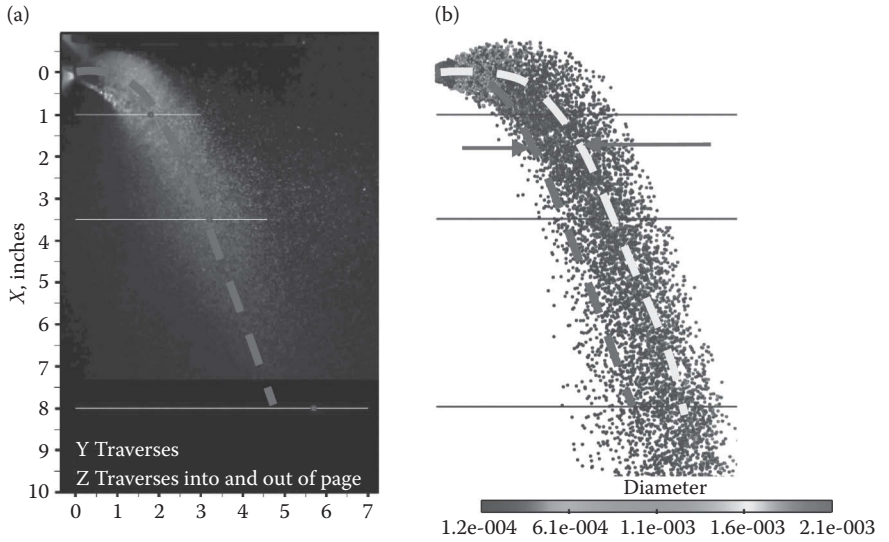

FIGURE 4.18.12 Comparison between the experimental spray axis trajectory, shown in red (a), and the computed axis shown in yellow (b). The liquid injection velocity is 16.6 m/s and the spray is introduced into a cross flow of air at 53 m/s. The initial sheet thickness is 222 μm. Chris Brown and Vince McDonell are gratefully acknowledged for providing the photo image.

address this need, an alternative procedure has been introduced over the last decade, where the goal is to compute from first principles the atomization and spray forming process. This is discussed in the following section.

HRS Strategy

The strategy of performing large-scale numerical simulations of sprays has gained considerable momentum over the last decade (Gorokhovski and Herrmann, 2008; Jiang et al., 2010; Jarrahbashi and Sirignano, 2014; Shinjo et al., 2015). This simulation strategy aims to resolve the injection and the ensuing atomization process directly by solving the underlying equations at the required level of spatial and temporal resolution. Consequently, the Navier–Stokes are solved accounting for changes in density and viscosity between the liquid and gas phases, and incorporating surface tension effects (Chang et al., 1996). This approach is commonly referred in the literature as the DNS methodology; however, it should be kept in mind that due to progressively decreasing length and timescales near the point of hydrodynamic breakup, it is almost impossible to provide adequate level of numerical resolution for all liquid structures present under practical spray conditions. Furthermore, it is not sufficient to adequately resolve the process spatially, but also temporally, and this is particularly difficult since the stable time step size decreases in proportion to $\Delta x^{3/2}$ (Galusinski and Vigneaux, 2008), which again imposes significant computational limitations. Hence, in this document, we employ the term highly resolved simulations, that is, HRS, to more accurately reflect the nature of this type of simulations.

An illustration of HRS approach is contrasted with the traditional modeling methodology in Figure 4.18.13. A key advantage of the HRS is its ability to capture the physics occurring in the near-field of the nozzle. This is where the greatest momentum interaction between the liquid and gas phase takes place, and is the region responsible for initiating much of the turbulence that is responsible for the subsequent mixing of the gas and fuel vapor.

Even though the level of resolution in HRS may be not as high as desirable, a relatively broad spectrum of length scales for liquid structures can still be obtained. To demonstrate this qualitatively, results of the atomization of a liquid jet (diameter = 200 μm) being injected into a gas

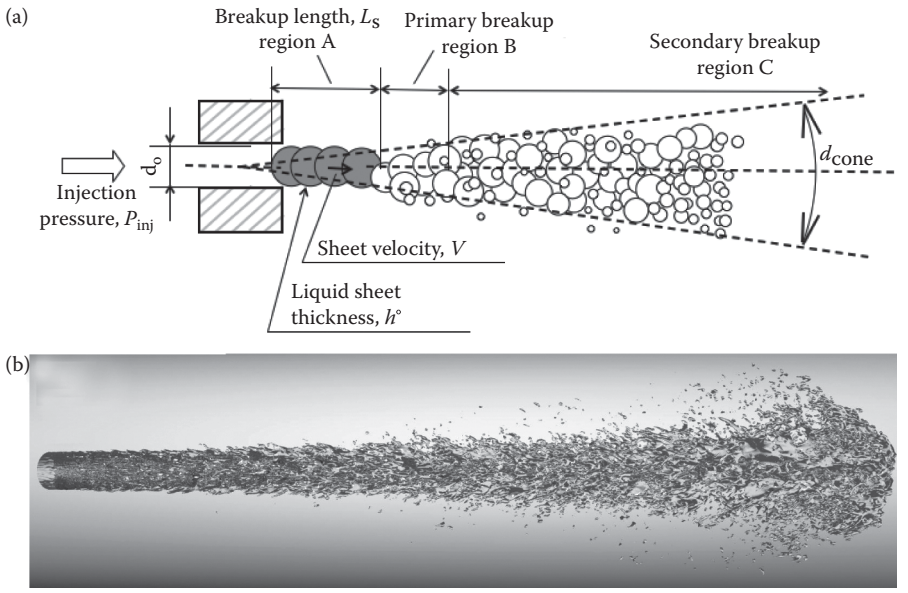

FIGURE 4.18.13 Illustration of the differences between (a) modeling sprays and (b) HRSs of sprays. In modeling, a spectrum of the spray phenomena, for instance, the primary atomization region as depicted in (a), is solved based on a much simpler mathematical representation, whereas in simulations, the actual underlying equations are numerically solved without resorting to approximations.

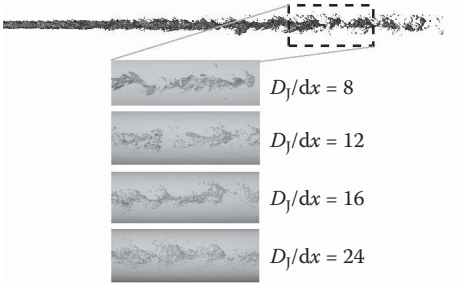

FIGURE 4.18.14 The resolution of the breakup of the intact liquid core is noticeable in these simulations performed under increasing levels of resolution. Whereas the large-scale structures are captured even in coarse-grid simulations, the small-scale droplet population requires an intensive level of refinement.

environment ($\rho_G = 58$ kg/m^3) at 200 m/s are shown in Figure 4.18.14. The upper portion of this figure displays a view of the jet extending 70 diameters downstream of the orifice. The four images below consist of close-up views of the region where the intact liquid core undergoes breakup. The calculations are performed at four different levels of spatial resolution from $D_J \Delta x = 8$ (coarsest) to $D_J / \Delta x = 25$ (finest), where D_J is the jet diameter and Δx is the local grid size. This value for Δx is used uniformly used throughout the primary atomization region with much coarser levels away from the spray. As depicted in Figure 4.18.14, the large-scale characteristics of the breakup are captured relatively well even at $D_J / \Delta x = 12$; however, the population of small droplets requires quite a bit more resolution.

Analogous to the single-phase turbulence problem, where the smallest flow scales put the most demanding requirements on the degree of grid resolution, in sprays, it is the smallest droplets which impose the greatest demands on resolution, and consequently are computationally the most expensive to capture. A popular method for circumventing this problem is the use of adaptive and local

grid refinement strategies adaptive mesh refinement (AMR). Unfortunately, for spray flows at very high injection velocities, for example, diesel, the entire primary atomization region is filled with a dense cloud of droplets, largely counterbalancing any significant benefits from AMR. This does not mean that AMR is not completely ineffective in reducing the computational cost, but only that its benefits are far from those obtained in much cleaner two-phase flow problems.

Due to the complexity involved in capturing the highly dynamic and evolving gas–liquid interface (Γ), the choice of numerical methods that can adequately be employed is confined to implicit interface capturing methodologies. In contrast to explicit surface tracking solvers, where computational nodes are placed directly on Γ, in implicit methods, a characteristic function is described over the entire 3D space from which a reconstruction of Γ can be made. The explicit methodology works very well for various free surface problems, but faces significant difficulties when used under conditions that lead to complex and frequent topological changes. For the spray problem, frequent and complex topological changes are the norm.

The most common implicit numerical strategies are the level set method (Osher and Fedkiw, 2003) and the volume-of-fluid (VoF) method (Tryggvason et al., 2011). Both of these references provide a self-contained and thorough introduction to their corresponding topic. Over the last few years, significant developments have been made in implicit solution strategies, namely, improvements in mass conservation for level set methods (Olsson and Kreiss, 2005; Kees et al., 2011), consistent mass and momentum transport with large density ratios (Raessi and Pitsch, 2012), implementation of particle-based methods for reduction in numerical diffusion in the level set advection (Enright et al., 2005), the introduction of a spectrally refined level set solution (Desjardins and Pitsch, 2009), the use of ghost-fluid cells for improving the treatment of jump conditions at the interface (Desjardins et al., 2008), implementation of an adaptive mesh refinement technique (Fuster et al., 2009), and the introduction of Hermite polynomials combined with semi-Lagrangian schemes resulting in compact numerical stencils (Nave et al., 2010). This continues to be an active area of research, where present efforts are aimed at addressing the broader physics of the spray problem including cavitation and internal nozzle numerical resolution.

One persistent computational issue has been the stringent demands of numerical resolution, particularly at high injection velocities. At present, a common held view in the spray community is the preference of mass or volume conservative methods, for instance, a VoF strategy or a hybrid VoF-level set, over a pure level set implementation. The common complaint is the loss of mass in level set methods. This loss of mass effect is essentially caused by a lower than required resolution of Γ, for instance, liquid bodies characterized by length scales that are well below the local Δx. To illustrate this problem, consider the aftermath of a Rayleigh–Plateau instability where a liquid bridge undergoing breakup results in the formation of two parent droplets and a number of satellite droplets as depicted in Figure 4.18.15.

The VoF representation accurately maintains the mass of the entire liquid system as it evolves in time, even in regions where the details of Γ are well below grid resolution. However, the shape is poorly resolved in comparison to the level set scheme. Specifically, if we consider an interfacial cell, that is, a computational cell that contains a partition of Γ, the gas–liquid interface does not usually conform to a plane or to some other linear reconstruction. Additionally, Γ and its derivatives are continuous in space, not discontinuous at the boundary between computational cells. In VoF methods, some of the most popular reconstruction schemes are those that are explicitly linear, or if they are not, have difficulty maintaining the smoothness of Γ between adjacent interfacial computational cells. Other popular VoF methods, such as the algebraic VoF procedure of interFoam (Deshpande et al., 2012), which is distributed within the open-source toolbox OpenFOAM does not perform a subgrid reconstruction of the interface. It relies on clever procedures for limiting the degree of numerical diffusion, and thus is able to contain Γ to within a band having a thickness of approximately two to three computational cells.

In spite of the high numerical accuracy of advanced level set methods and their reinitialization strategies for transporting Γ (Desjardins and Pitsch, 2009; Nave et al., 2010; Anumolu and Trujillo,

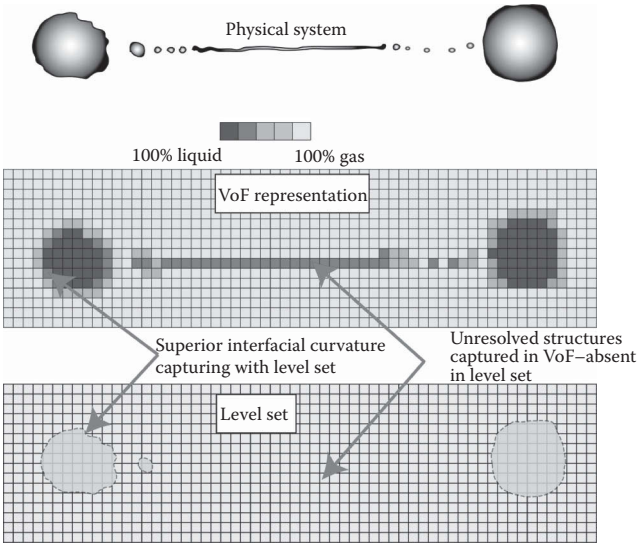

FIGURE 4.18.15 The underlying representation afforded by the VoF and level set methods are contrasted corresponding to the formation of ligaments and satellite droplets following a Rayleigh–Plateau instability. The level set scheme provides much more accurate Γ representation, but suffers in regions where the liquid structures are below grid resolution. The VoF method remains mass conservative, but does not do well in representing the shape of Γ.

2013), realistic spray problems often result in the formation of such small droplets and associated liquid structures, that the required resolution is simply too high to enforce. Consequently, the choice for VoF or other mass conserving methods is often made, particularly in cases of inadequate resolution. Under these demanding conditions, the symptoms of numerical errors for VoF are generally erroneous predicted shapes for Γ, whereas for level set methods, a common symptom is the complete elimination of underresolved liquid structures. Since this is a much more impactful consequence, it is much easier to accept the VoF errors. Future work in dealing with the resolution issue is currently being invested in the design of massively parallel computations leveraging the largest computational resources on the globe.

Further Information

Information about recent work in the field of atomization and sprays can be obtained through participation in the Institutes for Liquid Atomization and Spraying Systems (ILASS-Americas, -Europe, -Japan, -Korea). These regional ILASS sections hold annual meetings. An international congress (ICLASS) is also held biennially. More information is available on the ILASS-Americas homepage at http://ucicl.eng.uci.edu/ilass. Affiliated with the ILASS organizations is the Institute's Journal publication *Atomization and Sprays* published by Begell House, Inc., New York.

4.19 HEAT TRANSFER IN PLASMA SPRAYS

Milind A. Jog

Introduction

Thermal plasmas are increasingly used for manufacturing and materials processing applications which include plasma spraying, thermal plasma chemical vapor deposition, plasma sintering, plasma synthesis, plasma spheroidization, decomposition (waste-destruction), microelectronic manufacturing, and net shape manufacturing (Ayyaswamy and Cohen, 2002; Boulos et al., 1994; Graves, 1989; Rojas et al., 2009; Smith et al., 1989; Verdelle et al., 2015). The high temperature sustained by plasmas facilitates energy transport and the free electrons and ions provide an environment for chemical reactions (Mostaghimi and Boulos, 2015). In many of these applications, the heat transport from plasma to particles is critical in determining the quality of the products. For example, in plasma spheroidization, irregular fine powder particles are injected in a thermal plasma. Heat transfer from the plasma results in melting the particles. Under ideal conditions, the molten droplet thus formed becomes near spherical under the action of surface tension. Upon quenching, the droplets solidify as spheres. The spherical particles can be compacted to form near net-shape products. This method has been used to form carbide–metal composites. The heat transfer from the plasma determines the temperature, the degree of melting, and therefore the shape, eventual porosity, and quality of the product. In plasma spraying, powder of the coating material is introduced in plasma flow. Heat transfer from the plasma results in melting the powder. The molten droplets thus formed then impinge on a surface to be coated. Subsequent spreading and solidification forms a thin coat. Such techniques are used for example in aerospace industries for thermal barrier coating of turbine blades and in biomaterials industries to coat artificial bones. The quality and uniformity of the coating depends upon the velocity, temperature, and shape of the drop as it impacts the surface (Fukai et al., 1993; Liu et al., 1994a,b; Trapaga and Szekely, 1991; Trapaga et al., 1992; Vardelle et al., 1982, 2015). More recently, nano-scale coatings have been achieved by plasma spraying of suspensions and solutions (Fauchais et al., 2015). It is evident from these examples that the plasma-particle heat transport is of immense importance in achieving the desired product quality in materials processing applications. The prediction and control of the plasma-particle heat transfer is therefore critical to the improvements of these manufacturing methods and in the design of the required plasma systems (Chen et al., 1997). This chapter summarizes the state-of-the-art in heat transfer analysis and provides design correlations useful in applications. The drag force acting on the particle and the rate of heat transfer from plasma are the two important quantities of interest. These are usually expressed in dimensionless form in terms of drag coefficient C_D and Nusselt number Nu. These are defined as:

$$C_D = \frac{F_D}{\frac{1}{2}\rho U_\infty^2 A_F}, \tag{4.19.1}$$

where F_D is the drag force, ρ is the gas density, U_∞ is the free stream velocity, and A_F is the frontal area. For a spherical particle, the frontal area is $\frac{\pi d^2}{4}$, where d is the sphere diameter.

$$\mathrm{Nu} = \frac{hd}{k}, \tag{4.19.2}$$

where h is the heat transfer coefficient, d is the particle diameter, and k is the gas thermal conductivity.

Defining Features of Plasma Heat Transfer

Computational modeling as well as experimental measurements of particle–plasma heat transfer are challenging due to a number of unique features of thermal plasma flows. The plasma velocities, temperatures and consequently plasma electrical–thermophysical properties can change by orders of magnitude over a short distance. Furthermore, the charged species production and recombination processes have a strong nonlinear dependence on electron temperature and number densities. The transport in plasma, the charged particle processes, and the electron–ion recombination at the particle surface must all be considered to determine the heat transfer from plasma. To study the heat transfer from plasma, the hydrodynamic, the thermal, the electrical effects, and the surface phenomena must all be considered. Effects of large property variations, electric field effects, coupled with nonspherical particles and multiparticle interactions are elaborated below.

Effect of Electron–Ion Transport on Particle Heat Transfer

The analysis and modeling of heat transfer from plasma to a solid/liquid surface is significantly more complicated than that for a nonionized gas by the fact that it involves, over and above the hydrodynamic and the thermal boundary layers, an electrical sheath (sometimes referred to as the electrical boundary layer) close to the surface. This is caused by the low electron and ion number densities in the vicinity of a solid surface due to their recombination at surfaces (Kuryshev and Sakhin, 2001; Pfender, 1989; Zhang, 2005). As a result, the electric field near a surface can be significant even if the far away plasma is field free. The processes that take place in the electric sheath region govern the motion of electrons and ions, their recombination, and contribute to the heat transfer from the plasma to the surface. The relative sizes of the hydrodynamic and thermal boundary layers with respect to the electric sheath, and their interaction determines the flow field close to the boundary and therefore determines the heat/mass transport to the boundary.

Large Variations in Thermophysical Properties

Thermal conductivity, mass diffusivity, density, and viscosity are strongly dependent on temperature for gases and plasmas. The thermal conductivity, diffusivity, and viscosity increase with temperature with a roughly square root dependence on temperature for an ideal gas at low pressures. Once ionization and dissociation are taken into consideration, the plasma properties have a more complex dependence on temperature. Furthermore, the particle surface temperature is close to its melting temperature (~1000–3000 K) (Streibl et al., 2006; Xiong et al., 2006), and away from the particle surface, within a relatively short distance, temperature may reach the free stream temperature (>10,000 K) (Schein et al., 2015). Consequently, the thermophysical properties may change by an order of magnitude in the flow field around a particle. As a result, the flow and temperature variation around a particle injected in thermal plasma flow can be quite different from that of a particle injected in a gas flow where thermophysical property variation is relatively small. Detailed thermophysical and electrical properties of plasmas are available in Wen (2004), Brown (1967), and Devoto (1963).

Noncontinuum Effects

Powder particle injected in plasma sprays can range from a micrometer to hundreds of micrometers. In many applications, low-pressure plasmas may be used. Additionally, the high temperatures present in plasma spraying systems lead to low density of gases. A combination of these effects can give rise to Knudsen numbers ($\mathrm{Kn} = \frac{\lambda_m}{d}$, λ_m = mean free path) in the noncontinuum range. These effects have to be considered in plasma systems as well.

Nonspherical Particle Shapes

Powder particles typically injected in plasma spray system may not be spherical. Based on the size of the particle, the flow Reynolds number may be in the intermediate regime. Once the particles get heated and begin to melt, their shape deforms. The molten drops thus formed may attain an

TABLE 4.19.1
Correlations for Drag Coefficient for Plasma Flow over an Isolated Sphere in Plasma

Correlations (Hossain et al., 2007; Proulx et al., 1985)	Applicable Range of Reynolds Number	Equation Number
$C_{Df} = \frac{24}{Re}$	$Re \le 0.2$	4.19.3
$C_{Df} = \frac{24}{Re}\left(1+\frac{3}{16}Re\right)$	$0.2 < Re \le 2.0$	4.19.4
$C_{Df} = \frac{24}{Re}(1+0.11Re^{0.81})$	$2.0 < Re \le 21.0$	4.19.5
$C_{Df} = \frac{24}{Re}(1+0.189Re^{0.62})$	$21.0 < Re \le 200$	4.19.6

oblate-like or a prolate-like shape. Clift et al. (1978) provide regime map of droplet shapes in gas flow based on the Weber number and Bond number. Hence the effect on heat transfer due to nonspherical particle shape with large thermophysical property variation in the flow field needs to be taken into consideration for plasma flows.

Multiparticle Interactions

In plasma spraying process, due to the injection of a large number of particles into the plasma flow, the flow field and heat transfer around a given particle gets significantly affected by the proximity of neighboring particles. Therefore, the appropriate Nusselt number and drag coefficients for closely spaced particles are likely to be considerably different from that for an isolated sphere, and are needed to incorporate the effects due to interparticle interactions in plasma spray simulations. Simulations of particle/plasma flow and heat transfer in plasma torch have typically employed the particle-source-in-cell method (Proulx et al., 1985, 1991; Rojas et al., 2009; Sato et al., 2004). In this method, for each time step, the continuity, momentum conservation, and the energy conservation equations for the continuous phase are solved first. The drag force and heat transfer to the particles are considered as momentum/energy source terms in the corresponding equations for the continuous phase. The source terms for a computational cell are determined by summing the contribution of individual particles in that cell by using drag force and Nusselt number correlations for an isolated particle. The particle trajectories are then determined based on the calculated flow field. In addition to plasma sprays, fuel sprays in combustion systems have dense sprays where interparticle effects have been addressed. These studies are discussed in detail in a monograph by Sadhal et al. (2012) and a review by Ayyaswamy (1995).

Modeling, Data, and Design Correlations

Heat Transfer to a Single Particle

Spherical Particle

Before addressing heat transfer to a spherical particle from a plasma flow, it is worthwhile considering flow over a particle from a nonionized gas. Monographs by Clift et al. (1978) and Sadhal et al. (2012) provide extensive reviews of experimental, numerical, and analytical work in Newtonian flows while Chhabra (2007) covers non-Newtonian flows. In typical spray applications, the gas flow may be turbulent. However, the particle sizes are small and Reynolds number

based on the particle diameter is in the laminar regime. At low Re (0 < Re < ~20), the flow tends to conform to the particle surface and the local heat transfer decreases monotonically from the front stagnation point to the rear. For intermediate Re (20 < Re < ~140), there is flow separation near the rear stagnation point. The recirculatory toroidal vortex thus formed brings fluid from the free stream closer to the particle surface and the local Nusselt number increases near the rear stagnation point. From Reynolds number of about 140 onward, the flow begins to exhibit unsteady character eventually leading to vortex shedding above Re of 400. Well-established correlations are available for drag coefficient and Nusselt number for flow of nonionized gas over a spherical particle. These are often modified with appropriate correction factors to account for property variation and noncontinuum effects.

A number of models have been recommended in the literature to account for large property variations. Joshi et al. (1986) have outlined a method for calculating mass transfer in plasma flow by using integral conductivity as $I(T) = \int_{T_r}^{T} \chi(T)\,\mathrm{d}T$ and an effective conductivity as $\chi_{\text{average}} = \dfrac{I(T_\infty) - I(T_s)}{T_\infty - T_s}$. They showed that when average properties are evaluated using this integral approach, the constant property correlations for heat and mass transfer can be used in terms of effective properties. Other researchers have proposed corrections factors based on ratios of properties evaluated at the particle surface temperature and the far-field temperature. This approach of introducing correction factors to constant property drag and heat transfer correlations (Table 4.19.1) has been extensively employed in the literature for its simplicity and accuracy. This is outlined below.

Correction factor for large property variations:

$$f_1 = \left(\frac{\rho_\infty \mu_\infty}{\rho_s \mu_s}\right)^{-0.45}. \tag{4.19.7}$$

Correction factor for noncontinuum effects:

$$f_2 = \left[1 + \left(\frac{2 - a_c}{a_c}\right)\left(\frac{\gamma}{1+\gamma}\right)\frac{4}{\mathrm{Pr}_s}\mathrm{Kn}\right]^{-0.45} \quad \text{for} \quad 0.01 < \mathrm{Kn} < 1, \tag{4.19.8}$$

where a_c is the accommodation coefficient, Pr is the Prandtl number, γ is the heat capacity ratio, the subscript s indicates particles surface conditions while the subscript ∞ indicates far-field conditions.

The overall drag coefficient is calculated using the correction factors as:

$$C_D = C_{Df} f_1 f_2 \tag{4.19.9}$$

For heat transfer to an isolated spherical particle (Chyou and Pfender, 1989; Hossain et al., 2007; Young and Pfender, 1987):

$$\mathrm{Nu}_f = 2.0 + 0.6\mathrm{Re}_f^{1/2}\mathrm{Pr}_f^{1/3}, \tag{4.19.10}$$

where the subscript f denotes that the quantities are evaluated at the film temperature.

Clift et al. (1978) recommend the below correlation that covers a large range of Prandtl numbers:

$$\mathrm{Nu}_f = 1 + \left(1 + \frac{1}{\mathrm{Re}_f \mathrm{Pr}_f}\right)\mathrm{Re}_f^{0.41}\mathrm{Pr}_f^{1/3} \quad \text{for} \quad 1 \le \mathrm{Re} \le 400, \quad 0.25 \le \mathrm{Pr} \le 100. \tag{4.19.11}$$

Correction factor for property variations:

$$f_3 = \left(\frac{\rho_\infty \mu_\infty}{\rho_s \mu_s}\right)^{0.6} \left(\frac{c_{p,\infty}}{c_{p,s}}\right)^{0.38}. \tag{4.19.12}$$

Correction factor for noncontinuum effects:

$$f_4 = \left[1 + \left(\frac{2 - a_c}{a_c}\right)\left(\frac{\gamma}{1+\gamma}\right)\frac{4}{\mathrm{Pr}_s}\mathrm{Kn}\right]^{-1} \quad \text{for} \quad 0.001 < \mathrm{Kn} < 1, \tag{4.19.13}$$

$$\mathrm{Nu} = \mathrm{Nu}_f f_3 f_4, \tag{4.19.14}$$

where a_c is the accommodation coefficient, Pr is the Prandtl number, γ is the heat capacity ratio, the subscript s indicates particles surface conditions while the subscript ∞ indicates far-field conditions. Recommended value of the accommodation coefficient $a_c = 0.8$.

Nonspherical Particles

Heat transfer to nonspherical particles in plasma flow was addressed by Wen and Jog (2005). Reynolds number of 20, 50, and 100 were considered for prolate and oblate particles from disk-like (axis ratio = 1.6) to cylinder-like (axis ratio = 0.4). Particle surface temperatures between 2000–3000 K and far-field temperatures of 5,000–12,000 K were considered. Their predictions show that there is flow separation at the rear of the particle with the streamlines showing a toroidal vortex flow pattern. For a spherical particle, the flow separation begins at Re of around 20 near the rear stagnation point, while it is delayed for a prolate shape and is present at a lower Re for an oblate particle. Moreover, the size of the recirculation zone is larger for an oblate particle as it provides the largest obstruction to the flow. For a prolate particle, the gradients of velocity and temperature are the highest near the front stagnation point. However, for an oblate particle, the gradients are the highest near the lateral midpoint along the surface. Figure 4.19.1 compares the local Nusselt number for three different aspect ratios. For a prolate particle, the heat transfer coefficient is the highest near the front stagnation point and decreases monotonically along the particle surface. The heat transfer between plasma and the surface decrease plasma temperature as it moves along the particle surface. This in turn reduces the temperature gradient close to the surface and the corresponding heat transfer coefficient. A similar trend in heat transfer coefficient is evident for a sphere in the front half. However, a recirculatory vortex in the rear of the particle brings hot plasma gas close to the particle surface and increases the heat transfer coefficient. For an oblate particle, the local heat transfer coefficient is not the highest at the front stagnation point but occurs around a location about halfway (Hader and Jog, 1998b).

For plasmas, viscosity and thermal conductivity are strong functions of temperature with both properties increasing with temperature. If we compare flow field and temperature field results obtained with constant property assumptions, it is found that the variable property computations predict a smaller recirculating zone as well as higher velocity and temperature gradients compared to the constant property flow. When the Nusselt number is based on thermal conductivity evaluated at the far-field temperature, the Nusselt number values are low with higher plasma temperatures.

The effect of particle aspect ratio on the overall Nusselt number is nonlinear but monotonic. Moreover it is not a function of Reynolds number for $20 < \mathrm{Re} < 100$. The best fit for the overall Nusselt number for aspect ratios from 0.4 to 1.6 with variable property flow is given in Wen and Jog (2005) as

$$\frac{\mathrm{Nu}}{\mathrm{Nu}_{\mathrm{sphere}}} = \exp\left[-0.255\left(\frac{b}{a} - 1\right)\right], \tag{4.19.15}$$

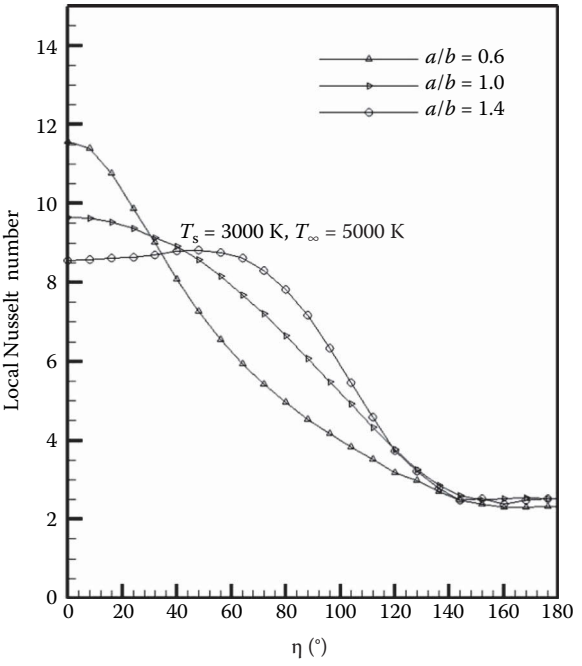

FIGURE 4.19.1 Variation of local Nusslet number for nonspherical particles. Length of the axis along the flow is 2*b* and that perpendicular to the flow is 2*a*. (Based on data from Wen, Y., and M. A. Jog, *Int. J. Heat and Fluid Flow,* 26(5), 780–791, 2005.)

where 2*b* and 2*a* are the lengths of the axis along the flow and perpendicular to the flow, respectively. This correlation deviates less than ±3% from the numerical solutions.

Heat Transfer to an Array of Particles

To determine the rate of heat transfer to particles introduced in plasma spraying, computer simulations have typically relied on source-in-cell methods (Crowe et al., 1977; Sripada et al., 1996). The continuity, momentum conservation, and the energy conservation equations as well as ionized species conservation equations are first solved in the continuous phase. The drag force and heat transfer to the particles are accounted for via source terms in the momentum and energy conservation equations. These source terms for each cell must be recalculated at each time step by summing the contribution of individual particles in that cell by using drag force and Nusselt number correlations for an isolated particle. The particle trajectories are then determined based on the calculated flow field. Similar methods have also been employed in the analysis of fuel sprays in combustion systems. To determine multiparticle interactions, a cylindrical cell model (Sripada et al., 1996; Tal et al., 1983) has been employed to describe the hydrodynamics of particle assemblages. An array of uniformly spaced spheres is analyzed (see Figure 4.19.2). By using symmetry and periodic structure of the particles in an array, the problem is reduced to one of spheres in tandem. The domain around the particles in tandem is considered axisymmetric.

Plasma flow over an array of spheres was considered by Verma and Jog (2000). They showed that the drag force and Nusselt number for the downstream spheres are lower compared to those for the first sphere. The values of C_D and Nu for the second and the third sphere are nearly equal and remain essentially the same thereafter. Because the drag coefficient and the Nusselt number for the second and the successive spheres are nearly the same, the results for the second sphere can be used for any interior sphere of the array. Verma and Jog have presented the results for drag coefficient and Nusselt number for such an interior particle normalized by those for an isolated

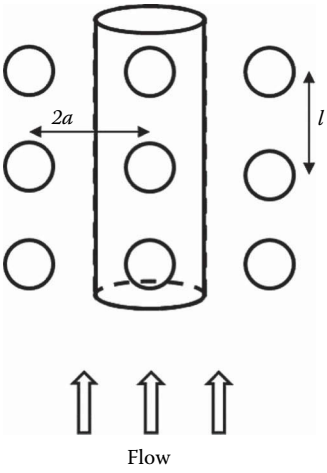

FIGURE 4.19.2 Schematic of the cylindrical cell model.

sphere. The results for normalized drag coefficient are shown in Figure 4.19.3, whereas those for the normalized Nusselt number are shown in Figure 4.19.4. When the longitudinal distance between successive particles is low, the wake region of the forward particle creates a low-pressure region in front of the next particle and the pressure drag decreases. Furthermore, the recirculating flow in the wake region can cause reduction or reversal in the direction of local shear stress in the front surface of the following sphere and reduces friction drag. Therefore, the total drag coefficient decreases with the decrease in longitudinal spacing. When longitudinal spacing is held constant and lateral spacing is decreased, it results in an increased drag coefficient. The flow

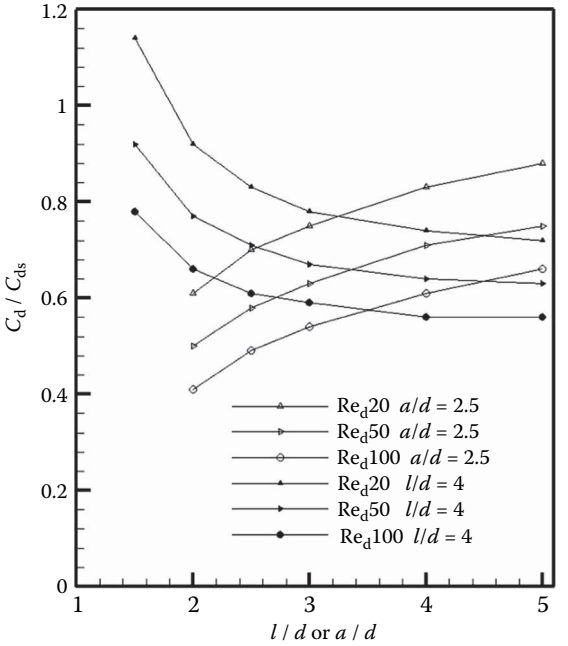

FIGURE 4.19.3 Normalized drag coefficient for particle arrays. (Based on data from Verma, A. and M. A. Jog, *Int. J. Heat and Mass Transfer,* 43, 101–112, 2000.)

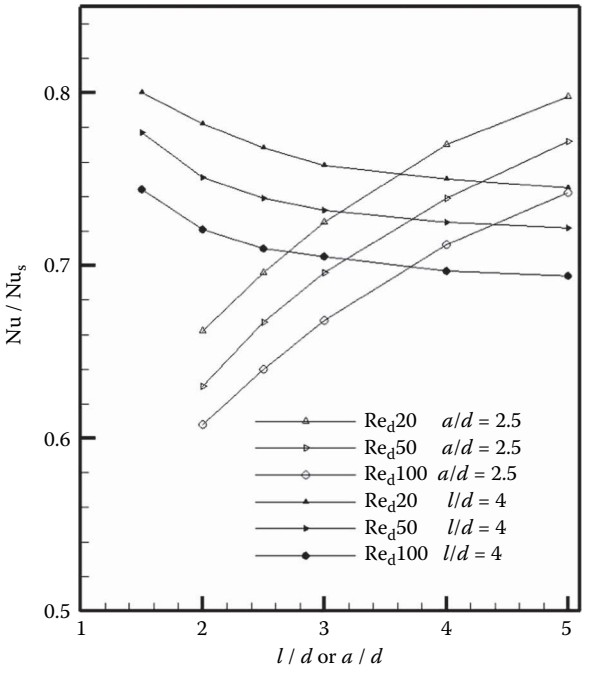

FIGURE 4.19.4 Normalized Nusselt number for particle arrays. (Based on data from Verma, A. and M. A. Jog, *Int. J. Heat and Mass Transfer,* 43, 101–112, 2000.)

velocity between adjacent spheres increases as the particles are brought close to each other. This gives rise to higher velocity gradients and increases the drag force. Verma and Jog have correlated their numerical results for the normalized drag coefficient for an interior particle for the range of Reynolds number from 20 to 100 with $2 \le (a/d, l/d) \le 5$ as

$$\frac{C_D}{C_{D,\text{sphere}}} = 1-(0.86+0.006\text{Re}^{0.5})(l/d)^{(-1.3+0.173\ln\text{Re})}+5.41\text{Re}^{-0.4}\exp(-a/d), \qquad (4.19.16)$$

where $2a$ is the lateral spacing and l is the longitudinal spacing between adjacent particles as shown in Figure 4.19.2. The above correlation fits the numerical results within ±3%.

The results for the variation of normalized overall Nusselt number of an interior sphere with lateral and longitudinal spacing are shown in Figure 4.19.4. Reduction in lateral spacing between adjacent spheres gives rise to higher flow velocity in the region between the adjacent spheres. This increases the convective heat transport and the corresponding Nusselt number. However, the normalized overall Nusselt numbers for an interior sphere is always lower than that for an isolated sphere at the same Reynolds number. For instance, at $l/d = a/d = 2.5$, the overall Nusselt number for the interior sphere is about 31%–36% less than an isolated sphere for Reynolds number range of 20–100. Verma and Jog (2000) provide a correlation for the overall Nusselt number for an interior sphere for $20 < \text{Re} < 100$, $\text{Pr} = 0.7$ and $2 \le l/d, a/d \le 5$, as

$$\frac{\text{Nu}}{\text{Nu}_{\text{sphere}}} = 1-\left[0.571-\frac{1.08}{\text{Re}}\right]\left(\frac{l}{d}\right)^{(-0.544+0.0011\text{Re})}+0.25\exp\left(-\frac{a}{d}\right), \qquad (4.19.17)$$

where $2a$ is the lateral spacing and l is the longitudinal spacing between adjacent particles as shown in Figure 4.19.2.This correlation fits their numerical results within ±3%.

Electric Field Effects

When a particle is injected in a plasma flow, more electrons impact on its surface and the particle gets negatively charged. This is because of the large difference in mobilities of ions and electrons. The negatively charged particle repels electrons and attracts ions. Eventually, the flow of the ions and electrons becomes equal at the surface and the surface is then at the floating potential (Khrapak et al., 2007; Seshadri, 1973). An electric sheath of the order of Debye length, with steep gradients in electron/ion densities and temperatures as well as large gradients in electric potential, is formed around the particle. The regimes of plasma heat transfer can be addressed in terms of the relative magnitude of the appropriate length scales. The length scales of importance are d (length scale of the particle), λ_D (the Debye length), λ_m (the smallest mean free path), δ (hydrodynamic boundary layer thickness), and δ_T (thermal boundary layer thickness). Note that the boundary layer thicknesses are introduced only to give a physical picture of the regions of importance near the surface.

In thermal plasma spraying applications, the overall plasma flow is collision-dominated (Boulos et al., 1994). However, even for a collision-dominated plasma, the mean free path need not be the smallest length scale in the problem. At higher temperatures and higher charged particle densities, the Debye length can be smaller than the mean free path. A comparison of the length scales shows the following regimes:

1. Continuum thinsheath $d \gg \delta, \delta_T > \lambda_D \gg \lambda_m$ (4.19.18)

2. Continuum moderate sheath $d \gg \lambda_D \geq \delta, \delta_T \gg \lambda_m$ (4.19.19)

3. Continuum thick sheath $\lambda_D \geq d \gg \delta, \delta_T \gg \lambda_m$ (4.19.20)

4. Noncontinuum sheath $d \gg \delta, \delta_T > \lambda_m \gg \lambda_D$ (4.19.21)

Note that the Prandtl number for the neutral gas varies with temperature. In general, the value is O(1), therefore δ and δ_T are of the same order. In the first three regimes, the electric sheath is collisional, whereas in the last regime it is collisionless. These regimes would correspond to different operating conditions. For example, the last regime is relevant for DC plasma spraying and the first regime would be appropriate for RF plasma spraying. The heat transfer characteristics are different in each regime as the dominant governing mechanisms are different in each regime. For example, in the last regime the sheath is very small and therefore the charged particle number densities are likely to be high close to the surface. As a result, the recombination rate of the charged particles and the corresponding heat transfer effect may be high. In the third regime, the transport from the neutral gas may be dominant and the electrical effects may be small.

Early studies of the interaction of a solid body with plasma were carried out in the context of electrostatic probes (Chung et al., 1975). The asymptotic analyses of Cohen (1963) and Su and Lam (1963) provide the current–voltage characteristics for a spherical probe in a weakly ionized plasma. The theory was extended by Barad and Cohen (1974) to include moderate ionization by including charge–charge and charge–neutral collisions. These analyses were limited to isothermal and stationary plasma. A review of the probe theories and experiments is available in Chung et al. (1975). Lam (1964) has discussed the probe characteristics for electrostatic probes in flowing plasmas. He suggested that the flow field can be divided into three regions, an electric sheath, a viscous boundary layer, and a quasi-neutral region. However, his analysis was restricted to stagnation point probe characteristics. These studies predict the variations of electron and ion number densities and their rate of recombination close to a solid surface but do not provide plasma-surface heat transfer due to electron ion recombination.

The electrical charge effects on heat transfer were analyzed for an isolated stationary sphere in plasma by Jog (1995) and Jog and Huang (1996). It was found that the charged particle recombination

and conduction contribute significantly to heat transport (Jog, 1995; Jog and Huang, 1996; Yeh, 2007; Yeh and Wei, 2004). The contribution of ions and electrons was a function of plasma temperature and the particle surface temperature. Increase in heat transport due to electron–ion recombination at the surface for a particle in rarefied plasma has also been reported (Gnedovets and Uglov, 1992). Meyer and Pfender (1973) have carried out detailed heat flux measurements for plasma flow over cylindrical wires. A significant part of the total heat transport was attributed to recombination of ions and electrons. These studies show the importance of surface phenomena on heat transfer.

To determine the heat transfer to particles from electrons, ions, and neutral gas, conservation equations for mass, momentum, and energy are solved along with the conservation equations for the electrons and ions densities, and an equation for the electric field. The neutral velocity field can be determined first at low degree of ionization. The electron ion diffusion, drift, and convection are then calculated. At low degree of ionization, the neutral velocity can be considered as the overall velocity of plasma. The electron and ion velocities will be different from neutral velocities due to diffusion and drift effects. At the higher degree of ionization, the charge–charge collisions may become comparable to charge–neutral collisions. The electron and ion flow is obtained by solution of the continuum conservation equations for electron and ion densities and temperatures (Mitchner and Kruger, 1973). A model for production and recombination of electrons and ions in the main body of the plasma (Jog et al., 1991, 1992) as well as recombination at the particle surface must be included in the formulation. In the electric sheath region, the complete governing equations need to be solved. However, away from the particle surface, as the ion and electron densities are expected to be large, the governing equations may be simplified (Jog, 1995). The solutions of electron, ion densities, temperatures, and the electric field in the sheath region must be matched with the solutions in the main body of the plasma. A computational method to achieve such matching has been outlined in Zhang (2005).

The heat transport at the interface is determined by accounting for all the forms of energy transport at the surface (Ecker, 1981). The conduction by electrons, ions, and neutrals, as well as energy deposited by recombination of electrons and ions at the particle surface needs to be accounted for. The drag force on the particle can be calculated by evaluating the pressure and the viscous forces. Instantaneous velocity of the particle can be determined by the balance of drag, inertia, gravity, and buoyancy forces. The governing equations are as follows:

$$\nabla \cdot (\rho \vec{u}) = 0 \tag{4.19.22}$$

$$\rho \vec{u} \cdot \nabla \vec{u} = -\nabla p + \nabla \vec{\tau} \tag{4.19.23}$$

$$\rho c_p \vec{u} \cdot \nabla T_n = \nabla \cdot (\chi_n T_n) \tag{4.19.24}$$

$$\nabla \cdot [\vec{u} N_e + \Gamma_e] = P - R \tag{4.19.25}$$

$$\nabla \cdot [\vec{u} N_i + \Gamma_i] = P - R \tag{4.19.26}$$

$$\nabla \cdot \vec{E} = -\frac{e}{\varepsilon_0}(N_i - N_e) \tag{4.19.27}$$

$$\Gamma_e = -\frac{\mu_e}{e}\nabla(N_e k T_e) + \mu_e N_e \nabla V \tag{4.19.28}$$

$$\Gamma_i = -\frac{\mu_i}{e}\nabla(N_i k T_i) - \mu_i N_i \nabla V \tag{4.19.29}$$

$$\vec{q}_e = \frac{5}{2} k T_e \Gamma_e - \chi_e \nabla T_e \tag{4.19.30}$$

$$P - R = \gamma N_e \left[\frac{2 g_i N_n}{g_n} \left(\frac{2\pi m_e k T_e}{h_P^2} \right)^{3/2} \exp\left(-\frac{e V_i}{k T_e} \right) - N_e N_i \right], \tag{4.19.31}$$

where $\gamma = 1.09 \times 10^{-20} T_e^{-9/2} \text{m}^6/\text{s}$. In the above, u is velocity, p is pressure, χ is thermal conductivity, subscripts e, i, and n are for electrons, ions, and neutral gas, respectively. E is electric field, V is electric potential, N is used for number densities, q is heat flux, Γ denotes charge species flux, μ_e and μ_i are electron and ion mobilities, k_B is Boltzmann constant, e is the amount of charge on a single electron, and ε_0 is the permittivity of the free space, P and R are rates of production and recombination of electrons and ions, g_i is the statistical weight of ions, g_n is the statistical weight of the ground state of neutrals, m_e is the mass of an electron, h_P is Planck's constant, and V_i is ionization voltage.

In plasma sprays, the particle sizes are typically less than 100 μm and the corresponding Reynolds number less than 100 (Vardelle et al., 2015). Hader and Jog (1998a) have considered heat transfer to a spherical particle from a plasma flow with Re < 100 and have analyzed the heat transfer from electron–ion recombination on the particle surface relative to the convective heat transfer. Figure 4.19.5 shows the variation of Nusselt number for electron–ion recombination, neutral gas, and the total heat transfer as a function of Reynolds number based on particle diameter. It is evident that all contributions increase with increasing Reynolds number. This is to be expected as a stronger flow at higher Reynolds number results in thinner hydrodynamic, thermal, as well as electric boundary layer over majority of the sphere surface. Furthermore, the charged species contribution is temperature dependent and increases significantly with increasing far-field temperature.

Figure 4.19.5 compares their predictions of Nu for two values of far-field temperature and a value of surface temperature close to reported data (Fincke et al., 1990). While correlations are not available to account for these effects, the results shown in Figure 4.19.5 provide a useful measure of the extent of contributions from the charged species recombination.

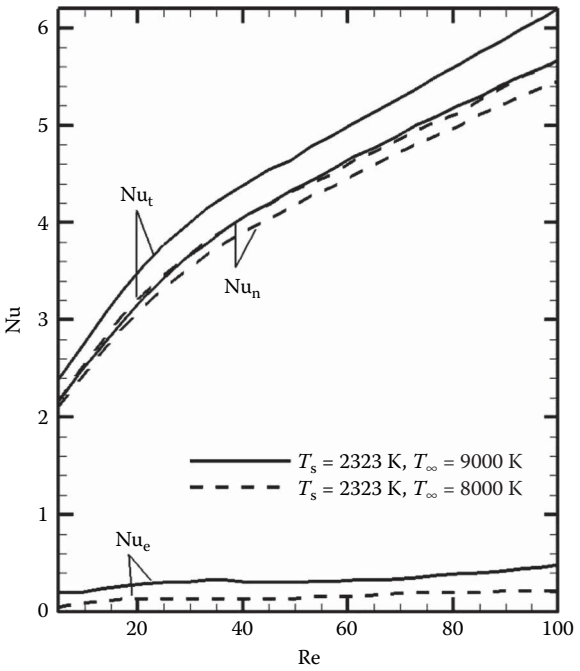

FIGURE 4.19.5 Variation of Nusselt numbers for electron–ion recombination and neutral gas. (Based on data from Hader, M. A., and M. A. Jog, *Phys. Plasmas,* 5(4), 902–909, 1998a.)

Summary

Plasma spraying is employed in a variety of applications from depositing nano-scale to macro-scale coating to net-shape manufacturing. Particles are injected in plasma jet in plasma spraying process and heat transfer from plasma to particles determines the efficacy of the process. The analysis of heat transfer is complicated by unique features of plasma particle interactions that include large electrical–thermophysical properties variations over a short distance, electrical boundary layer and electron–ion recombination on the particle surface, nonspherical particle shape, noncontinuum conditions, and multiparticle interactions. These features are discussed here and data and design correlations are provided to determine drag and heat transfer interactions between particles and plasma flow in plasma spraying process.

4.20 THERMAL PROCESSING AND PRESERVATION OF FOODS

Prabhat Kumar and K.P. Sandeep

Introduction

Thermal processing is one of the most common methods used to preserve foods for consumption at a later time (days, weeks, months, or years). The degree of thermal processing required depends on various product factors and the storage conditions (ambient, refrigerated, or frozen). Some of the product factors include pH, water activity, physical property (density), rheological properties (such as viscosity for a Newtonian fluid, and consistency coefficient and flow behavior index for power-law fluids), thermal properties (such as thermal conductivity and specific heat), dielectric properties (such as dielectric constant and loss factor) for electromagnetic (microwave and radio frequency) heating, and electrical property (electrical conductivity) for ohmic heating. Some of the above product characteristics dictate the types of microorganisms (both pathogenic and spoilage) that could potentially grow in the product depending on the amount of air in the product (aerobes, anaerobes, microaerophiles), the storage conditions (psychrotrophs/psychrophiles, mesophiles, and thermophiles), and special factors such as low water activity (xerophiles), high salt content (halophiles), and high sugar content (osmophiles). The steps involved in thermally processing the product are to determine the target organism (the most thermally resistant organism that could potentially be of concern in the product), identify a surrogate organism (a nonpathogenic organism that has similar kinetics of inactivation in the product under consideration), establish an optimized thermal processing protocol (time–temperature combination or *F*-value required to ensure product safety and quality), and identify the thermal processing equipment (retort with or without agitation, tubular/shell-and-tube/scraped-surface/electromagnetic/ohmic) and associated system and process parameters that can be used to deliver the required thermal treatment. Depending on the product characteristics and desired storage conditions, the product may be subjected to blanching, pasteurization, hot filling, retorting, or aseptic processing.

Product Considerations

The choice of a thermal processing system is based on several product considerations including the characteristics of the product (pH, water activity, etc.) and properties of the product (physical properties, rheological properties, thermal properties, dielectric properties for electromagnetic heating, and electrical properties for ohmic heating).

pH

The extent of thermal treatment given to a food product depends on whether the food product is an acid product, an acidified product, or a low-acid product. An acid food product is defined as the one with a natural pH of less than 4.6. pH is a measure of acidity and is defined as the negative logarithm of H^+ ion concentration. pH normally ranges from 0 to 14 with 7 being regarded as neutral pH (pH of pure water). Acid food products include apple juice, orange juice, ketchup, etc. An acidified food product is the one with a finished equilibrium pH of less than 4.6 and a water activity (a_w) greater than 0.85. Example of acidified foods include peppers treated in an acid brine, pickled foods, etc. Acidified food products are typically treated at 90°C–95°C for a period of 30–90 s to inactivate microorganisms. A low-acid food product is any food other than alcoholic beverages with a natural equilibrium pH greater than 4.6 and a water activity greater than 0.85. These food products include butter, cheese, fresh eggs, pears, papaya, and raisins (Skudder, 1993). Low-acid food products are capable of sustaining the growth of *Clostridium botulinum* spores which is capable of producing a potent neurotoxin. Foodborne botulism is a severe type of food poisoning caused by the ingestion of

foods containing the potent neurotoxin formed during the growth of *C. botulinum*. The spores of *C. botulinum* must be destroyed or effectively inhibited to avoid germination and subsequent production of the deadly toxin which causes botulism.

Water Activity

Water present in a food product may be broadly classified as free water (if it is available to participate in various biochemical reactions) and bound water (if it is not available to participate in various biochemical reactions). Water activity is a measure of the amount of free water in a product. It is determined as the ratio of the vapor pressure of water in that product to the vapor pressure of pure water at that same temperature. It is also sometimes defined as equilibrium relative humidity divided by 100. Water activity is determined using a hygrometer. Most microorganisms require water for their growth and hence grow faster in high water activity foods. Accordingly, lowering water activity is one of the common techniques used to preserve many types of foods. Since most bacteria do not grow rapidly at water activity levels below 0.85, that is used as a cutoff value for foods likely to be shelf-stable with minimal or no thermal processing. Between a water activity of 0.80 and 0.85, molds are generally the organisms of concern. Between water activity values of 0.5 and 0.8, osmophilic yeasts, xerophilic molds, and halophilic bacteria are the organisms of concern.

The magnitude of water activity may be adjusted to control various reactions such as microbial growth, enzyme activity, Maillard browning, lipid oxidation, and vitamin degradation. It may also be used to control caking/clumping, rehydration, and texture. Its magnitude also enables quantification of moisture migration within a product. At low water activity, lipid oxidation is the main reaction that takes place. As water activity increases, Maillard browning begins to take place. Beyond a certain level of water activity, caking/clumping, crystallization, and enzymatic activity start to take place. As water activity approaches 0.80, mold growth starts to take place. After that, yeasts and bacteria begin to grow.

As far as food products are concerned, fresh fruits and vegetables, milk, juices, and raw meats have a water activity value generally higher than 0.95. At the intermediate range, products such as cooked bacon, chocolate syrup, and sweetened condensed milk have water activity values between 0.7 and 0.9. Products such as dried fruits and honey fall under the lower end of the spectrum of water activity, with values between 0.5 and 0.7.

Physical Properties

The physical property of interest in thermal processing is density. Density (ρ) is defined as mass per unit volume with the units of kg/m^3. Materials with more compact molecular arrangement have higher densities. Specific gravity is defined as the ratio of the density of a material to the density of water at the same temperature. There are three types of densities for food materials—solid density, particle density, and bulk density. Solid density does not take into account the internal pores in the food materials. Particle density is defined as the ratio of the actual mass of a particle to its actual volume. Particle density accounts for the internal pores in the food materials. Bulk density is defined as the mass of the food material per unit volume. Bulk density accounts for the void spaces between the particles. The void space in food materials is described by porosity which is the ratio of the void volume to the total volume of the material.

Rheological Properties

Rheology is defined as the science of flow and deformation of materials. The main rheological property is viscosity. Viscosity (μ) is defined as the fluid property which denotes the resistance between the internal layers of a fluid to movement. It is also called absolute or dynamic viscosity. Its unit is Pa s (N s/m^2) or poise (dyne s/cm^2) and is given by:

$$\mu = \frac{\sigma}{\dot{\gamma}},$$

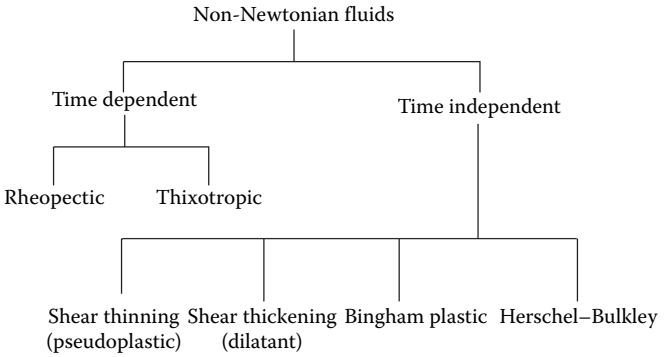

FIGURE 4.20.1 Classification of non-Newtonian fluids.

where σ is the shear stress and $\dot{\gamma}$ is the shear rate. Force per unit area is defined as stress and when the force is applied parallel to the surface, the stress is called shear stress. Shear rate is the relative change in velocity divided by the distance. Liquids that follow the above equation exhibit a direct proportionality between shear rate and shear stress and are called Newtonian fluids. Examples of Newtonian fluids include water, fluid milk, honey, and fruit juices. Fluids that do not have a direct proportionality between shear rate and shear stress are known as non-Newtonian fluids. Non-Newtonian fluids can be classified as time-independent and time-dependent (Figure 4.20.1). For time-dependent fluids, the shear stress vs. shear rate graph is not the same as a function of time. For example, for a constant shear rate, the shear stress may increase or decrease as a function of time.

The relationship between shear stress and shear rate for Newtonian and non-Newtonian fluids is shown in Figure 4.20.2.

Two important types of time-independent non-Newtonian fluids are shear thinning (pseudoplastic) and shear thickening (dilatant). The difference between these two can be understood on the basis of apparent viscosity. An apparent viscosity is calculated by assuming that the non-Newtonian fluid obeys Newton's law of viscosity at a selected shear rate. The slope of the straight line from the origin to a point on the curve at a given shear rate gives the value of apparent viscosity. For a shear thinning fluid, the apparent viscosity decreases as the shear rate increases. Some examples of shear thinning fluids are condensed milk, fruit purees, mayonnaise, mustard, and vegetable soups. For a shear thickening fluid, the apparent viscosity increases as the shear rate increases. Some examples of shear thickening fluids are 40% raw corn starch and some types of honey.

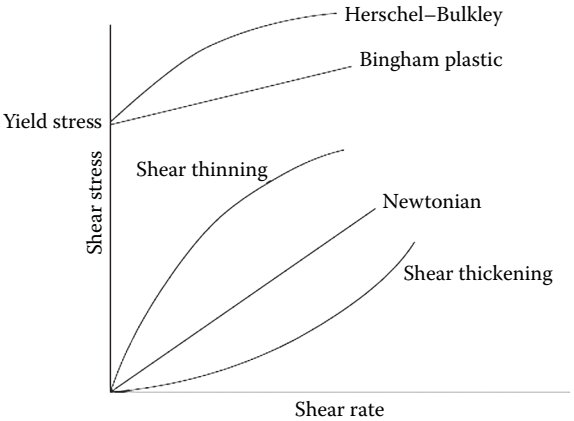

FIGURE 4.20.2 Relationship between shear stress and shear rate for Newtonian and non-Newtonian fluids.

Another class of non-Newtonian fluids requires an application of a stress prior to any flow. This stress is known as the yield stress (σ_0). After the application of yield stress, those fluids which behave like a Newtonian fluid are known as Bingham plastic. If the fluids behave as shear thinning fluids, then they are known as Herschel–Bulkley fluids.

Time-dependent non-Newtonian fluids attain a constant value of apparent viscosity only after some time has elapsed after the application of shear stress. The fluid is known as thixotropic if its viscosity decreases over time and rheopectic if the viscosity increases over time.

Thermal Properties

Thermal properties include specific heat, thermal conductivity, and thermal diffusivity. They have a significant effect on the rate of heat transfer into the food product. Study of thermal properties of the food product plays an important role in the design of thermal processing systems.

Specific heat (c_p) is the amount of heat that is gained or lost by a unit mass of product for a unit change in temperature without changing state and is given by the following equation:

$$c_p = \frac{Q}{m(\Delta T)},$$

where Q is the heat gained or lost (kJ), m is the mass (kg), and ΔT is the temperature change (°C). For processes where a change of state takes place (freezing or thawing), an apparent specific heat is used. Specific heat plays an important role in the thermal analysis of food processing equipment used in heating or cooling of foods. Comprehensive databases (Singh, 1994), predictive equations, or experimental methods are generally used to obtain the values of specific heat.

Thermal conductivity (k) is the quantity of heat (Q) conducted per unit area (A) through a unit length (L) of material due to a unit temperature difference (ΔT) and is given by the equation:

$$k = \frac{QL}{A\ (\Delta T)}.$$

The units of thermal conductivity are W/m K. Thermal conductivity of a food plays an important role in calculations involving the rate of heat transfer by conduction. Thermal conductivities of water and air at 20°C are 0.597 and 0.0251 W/m-K, respectively (Singh and Heldman, 2001). The thermal conductivity of food materials is bounded by water and air on the upper and lower end, respectively. Comprehensive databases (Singh, 1994; Krokida et al., 2001), predictive equations, or experimental methods are generally used to obtain the values of thermal conductivity.

Thermal diffusivity (α) is the rate at which temperature at one point in a material is transmitted to another point. It is the ratio of thermal conductivity to volumetric heat capacity and is given as:

$$\alpha = \frac{k}{\rho c_p}.$$

The units of thermal diffusivity are m^2/s. Thermal diffusivity can be calculated by determining the values of thermal conductivity, density, and specific heat. However, this approach requires considerable time and elaborate instrumentation. Another approach is the direct measurement of thermal diffusivity by experimental methods.

Dielectric Properties

Interaction of electromagnetic (microwave and radio frequency) energy with materials depends on their dielectric properties. Metals are not heated significantly by electromagnetic waves as they are excellent reflectors. Dielectric materials are better absorbers and transmitters of electromagnetic waves. Dielectric materials are heated mainly through the absorption of electromagnetic energy and the absorption depends on composition and temperature of the materials along with the frequency

of the electromagnetic wave. Dielectric properties determine the heating behavior of a material when subjected to an electromagnetic field. Therefore, knowledge of dielectric properties is important for the design of a heating system based on electromagnetic energy.

Dielectric properties consist of dielectric constant (ε') and dielectric loss factor (ε''). Dielectric constant is a measure of the ability of a material to store electromagnetic energy, whereas dielectric loss factor is a measure of the ability of a material to convert electromagnetic energy to heat (Metaxas and Meredith, 1983). Dielectric constant and dielectric loss factor can be defined in terms of complex permittivity (ε). The complex permittivity (ε) is composed of a real part (ε', relative dielectric constant) and an imaginary part (ε'', effective relative dielectric loss factor) and is given by the following equation (Saltiel and Datta, 1999):

$$\varepsilon = \varepsilon_0(\varepsilon' - j\varepsilon''),$$

where $j=(-1)$ and, ε_0 is permittivity of free space (8.86×10^{-12}F/m).

Electrical Properties

Understanding of electrical properties (electrical conductivity) is an important parameter for the design of Ohmic heating system. Electrical conductivity is the ability of a material to transport an electric charge. Electrical conductivity (σ) is the reciprocal of electrical resistance (R) through a unit cross-sectional area (A) over a distance (L), given by the following equation:

$$\sigma = \frac{L}{AR}.$$

The electrical resistance of a sample is determined as the ratio of voltage (V) across the sample divided by current (I).

Microorganisms

The microorganisms important in thermal processing are bacteria and fungi because they can multiply in foods and cause spoilage or public health issues. There are various types of bacteria and fungi and each has a specific range of conditions (temperature, oxygen, pH, water activity, type of nutrients, etc.) under which they can grow rapidly.

Bacteria are a large group of unicellular prokaryotic microorganisms. They are found in a wide range of shapes such as spheres (cocci), rods, and spiral. Bacteria reproduce asexually through the process of binary fission. Under favorable growth conditions, bacteria can grow and divide rapidly. The growth cycle of bacteria can be divided into four phases: lag, log, stationary, and death. During the lag phase, bacteria adapt to the new surrounding and multiple slowly. During the log phase, bacteria multiply at a very rapid exponential rate. During the stationary phase, growth rate slows down again and eventually they stop multiplying resulting in their death in the death phase. Some species of rod-shaped bacteria can form highly resistant structures known as spores. Spores can survive extreme stress conditions such as high heat and pressure. Bacteria in this dormant state may remain viable for thousands of years (Tucker and Featherstone, 2011).

Fungi are a group of eukaryotes that include yeasts and molds. Fungi are neither plants nor animals as they possess properties similar to plants (cell wall) as well as animals (absence of chlorophyll). Yeasts are unicellular fungi which derive their energy from organic compounds and do not require sunlight to grow. Yeasts are larger than bacteria, but smaller than molds. Yeasts reproduce asexually by budding in which a small bud forms on the parent cell and gradually enlarges into another yeast cell. Yeasts are either obligate aerobes or facultative anaerobes. They grow best in a neutral or a slightly acidic medium and are generally destroyed above a temperature of 50°C. Yeasts are used in the food industry for leavening of bread and production of alcohol. However, their ability

to grow at low pH and water activity (a_w) make them organisms of concern for spoilage in fruit products such as juices and jams (Tucker and Featherstone, 2011).

Molds are multicellular fungi that grow in the form of hyphae (multicellular tubular filaments). Molds reproduce both sexually and asexually by means of spores produced on specialized structures or in fruiting bodies. All molds are aerobic and some can grow in low oxygen conditions. They can also grow at extreme conditions (high acid, high salt, low temperature). Molds are used in the food industry for production of cheese and soy sauce. Molds are also capable of consuming acids, which can remove the acidic condition that inhibit the growth of *C. botulinum*. Spoilage of food products by mold is primarily due to mycotoxins (aflatoxin, ocratoxin, patulin, etc.), which are secondary metabolites produced by molds (Tucker and Featherstone, 2011).

Classification Based on Gram Staining

Bacteria can be classified as gram-positive or gram-negative based on gram staining. Gram staining is a method based on the chemical and physical properties of bacterial cell wall. The four basic steps of gram staining include applying a primary stain (crystal violet), addition of iodine, decolorization with alcohol (ethanol), and counterstaining with safranin. After gram staining, gram-positive organisms appear purple, whereas gram-negative organisms appear pink. Gram-positive is more resistant to changes in environment because of its thick peptidoglycan layer (Tucker and Featherstone, 2011).

Classification Based on Oxygen

Based on oxygen requirement, microorganisms can be classified into aerobes, anaerobes, facultative anaerobes, and microaerophiles. Aerobes grow in the presence of atmospheric oxygen, whereas anaerobes grow in the absence of atmospheric oxygen. Facultative anaerobes are in between these two extremes and can grow in either the presence or absence of atmospheric oxygen. Microaerophiles require a small amount of oxygen to grow.

Classification Based on Temperature

Based on the response to temperature, microorganisms can be classified into psychrophilic, psychrotrophic, mesophilic, and thermophilic. Psychrophilic microorganisms have an optimum growth temperature between 12°C and 15°C, but can grow up to 20°C. Psychrotrophic microorganisms have an optimum growth temperature between 20°C and 30°C, but can grow up to 0°C. Mesophilic microorganisms have an optimum growth temperature between 30°C and 42°C, but can grow between 15°C and 47°C. Thermophilic microorganisms have an optimum growth temperature between 55°C and 65°C, but can grow between 40°C and 90°C.

Classification Based on pH, Water Activity, Salt, and Osmotic Pressure

Most microorganisms grow best at neutral pH and only a few are able to grow at a pH value of less than 4.0. Bacteria are more selective about pH requirements than yeasts and molds which can grow over a wide range of pH. Microorganisms which can withstand low pH are known as aciduric. Bacteria require higher a_w for growth as compared to that required by yeasts and molds. Gram-negative bacteria cannot grow at a_w less than 0.95 whereas most gram-positive bacteria cannot grow at a_w less than 0.90. However, *Staphylococcus aureus* can grow at a_w value as low as 0.85 and halophilic bacteria can grow at a minimum a_w value of 0.75. Halophilic microorganisms require a high salt concentration for growth. Most yeasts and molds can grow at a minimum a_w value of 0.88 and 0.80, respectively. Xerophilic (microorganisms which can grow in low a_w conditions) molds and osmophilic (microorganisms which can grow in high solute concentration) yeasts can grow at a_w values as low as 0.61.

Target Organism

The goal of "processing" a formulated product is to use one or more mechanisms to either inactivate microorganisms (such as by the use of heat) or prevent their growth (by use of appropriate chemicals) to render the product safe for consumption. This includes all microorganisms that may be of public

health significance or may spoil the product. The target organism is the most resistant organism to the method of control of the organisms. If heat is used as the means of inactivating microorganisms, the most thermally resistant organism under the prevailing conditions would be the target organism. For example, for producing a shelf-stable product which has a pH greater than or equal to 4.6 and a water activity greater than 0.85 by thermal processing, the target organism is spores of type A *C. botulinum*.

Surrogate Organism

Thermal process validation involves assurance that the established thermal processing protocol (time–temperature combination based on theoretical considerations) would result in a safe product. This could potentially be achieved by incorporating the target organism at the appropriately high level into the product, thermally processing the product, and conducting microbial analysis to ensure that an adequate level of destruction of the target organism was achieved. However, this is a very risky proposition as it would potentially expose operators to the pathogenic target organism and also contaminate the system and facilities. Thus, a safer proposition would be to identify a nonpathogenic organism that has a similar inactivation kinetics as the target organism and use it as a substitute for the target pathogen. This nonpathogenic organism is called the surrogate organism and is used in process validation in place of the target organism.

Kinetics of Reactions

Kinetics of reactions refers to the rates of various reactions that take place within a food product under various processing and storage conditions. These may be reactions associated with microbial destruction, enzymatic inactivation, and changes in quality/nutritional attributes such as texture/color/flavor/vitamin change. Most of these reactions can be described by the following equation:

$$-\frac{\mathrm{d}c}{\mathrm{d}t} = k_n c^n,$$

where "c" is the concentration of the reacting species (it may be the number of microorganisms, enzyme activity level, vitamin content, etc.), "k_n" is the rate of the reaction, and "n" is the order of the reaction. In order to determine the rate and order of a reaction, a graph of ln ($-\mathrm{d}c/\mathrm{d}t$) is plotted on the y-axis vs. ln (c) on the x-axis. The slope of this graph is the order of the reaction and the intercept is "ln (k_n)". Orders of reactions may take whole number values ($n=0$ for zero-order reaction, $n=1$ for first-order reaction, $n=2$ for second-order reaction) or fractional values ($n=1.3$ for color change in a certain vegetable or $n=0.7$ for a certain flavor change).

D Value

When a homogeneous microbial population is subjected to a constant temperature, T, the rate of microbial destruction follows a first-order reaction kinetics and is given by (David et al., 1996):

$$\frac{-\mathrm{d}N}{\mathrm{d}t} = K_T N,$$

where N is the number of microbes surviving after time t (s) and K_T is the reaction rate (s^{-1}). Integration of the above equation from time 0 to time t yields:

$$\frac{N}{N_0} = e^{-K_T t},$$

where N_0 is the number of viable microorganisms at time $t=0$.

The above equation can be rewritten as:

$$\log_{10}\left(\frac{N}{N_0}\right) = \frac{-t}{D},$$

where $D=2.303/K_T$. D (decimal reduction time) is the time required to reduce the number of surviving microbial population by 90%. D value is a measure of heat resistance of microorganisms. Microorganisms with a higher D value have a higher heat resistance. D value determined at a reference temperature (T_{ref}) is denoted by D_{ref}.

z Value

The effect of temperature on D value is generally described by the following expression (David et al., 1996):

$$\log_{10}\left(\frac{D_T}{D_{ref}}\right)=\frac{T_{ref}-T}{z},$$

where D_T is the D value at temperature T and z is the change in temperature (°C) required to change the D value by 90%. D and z values are the basis of thermal process calculations and are commonly used to design a thermal process.

F Value

The ratio of D_{ref} to D is the lethal rate (L_r). Thermal death time or F value of a process is defined as the process time at a given temperature required for total destruction of a microbial population or the time required for destruction of microorganisms to an acceptable level. F value can be expressed as a multiple of D value for first order microbial kinetics. The F value required for a process depends on the nature of food (pH and water activity), storage conditions after processing (refrigerated vs. room temperature), target organism, and initial population of microorganisms. F value is usually expressed with a superscript denoting z value and a subscript denoting temperature. F value can be computed in terms of lethal rate as:

$$F_{T_{ref}}^{z}=\int_0^t L_r\,dt=\int_0^t\left(10^{\frac{T-T_{ref}}{z}}\right)dt=-D_{ref}\log\frac{N}{N_0}.$$

For a constant temperature process, the above equation for F value reduces to:

$$F_{T_{ref}}^{z}=10^{\frac{T-T_{ref}}{z}}t.$$

The F value at a reference temperature of 121.1°C (250°F) and a z value of 10°C (18°F) is referred to as the F_0 value. The main microorganism of concern for low acid foods is *C. botulinum*, which has a $D_{121.1}$ value of 0.21 min. For processes where *C. botulinum* is the target organism, F_0 value represents the process time necessary to achieve a 12 log reduction (12D) in microbial population of *C. botulinum* at 121.1°C. A thermal process designed to reduce the probability of survival of spores of *C. botulinum* to an acceptable level (12D process) is referred to as the botulinum cook. The F_0 value for a botulinum cook is 2.52 (12×0.21) min. An F_0 value of 2.52 min indicates that the process is equivalent to a heat treatment of 2.52 min at 121.1°C (250°F). Thus, many combinations of time and temperature can yield an F_0 value of 2.52 min. F value can be written in terms of F_0 value as:

$$F_{T_{ref}}^{z}=F_0\times L_r=F_0\times 10^{\frac{T-T_{ref}}{z}},$$

The ratio of F_0 value of the process to the F_0 required for commercial sterility is known as lethality. Thus, lethality must be at least 1 for commercial sterility of the product (David et al., 1996).

C Value

The destruction of nutrients and inactivation of enzymes follow similar first order kinetics to that of microbial destruction. Destruction of nutrients in food products is quantified by the term cook value (*C*), which has been defined as:

$$C = \int_0^t 10^{\frac{T-T_{\text{ref}}}{z_c}} \, dt$$

The *C* value at a reference temperature of 100°C (212°F) and a z_c value of 33.1°C (59.6°F) is referred to as the C_0 value.

Process Optimization

The objective of a food processor is to produce a safe product which retains nutritional and quality attributes at an acceptable level. Therefore, the appropriate combination of time and temperature used for processing is based on factors such as nutrient retention and enzyme inactivation in addition to safety. D_c and z_c values for destruction of nutritional and quality attributes are generally larger than those of microorganisms. This implies that the rate of destruction of microorganisms at a higher temperature will be much higher than the rate of destruction of nutritional and quality attributes. Thus, thermal processing of food products at higher temperature can achieve commercial sterility with better retention of nutritional and quality attributes (David et al., 1996).

Heating Equipment

Retorts

A retort (usually a large cylindrical vessel) works on the principle of cooking under pressure. Pressurized hot water (water immersion, cascading water, or water spray) or steam in the retort is used to raise the temperature of a product already in a package (metal can, glass, metallized pouch, or plastic) to approximately 120°C–125°C. This high of a temperature is needed to inactivate spores of *C. botulinum*, which is the target organism for producing shelf-stable foods that have a pH of 4.6 or higher. In most types of retorts, several (hundreds) containers of food are placed in crates/baskets with or without perforations and one or more of these crates are loaded into the retort for processing. Generally, the older style retorts are oriented vertically, whereas newer retorts are oriented horizontally to facilitate movement of product in and out of the retort easily.

1. Classification based on continuity of process
   Based on continuity of the process, retorts are classified as batch or continuous. Batch retorts may be used by small or large processors. However, continuous retorts are used only by large processors.
   a. Batch
      In a batch retort, containers are loaded into the retort, thermally processed, cooled, and then taken out of the retort. Batch retorts may be oriented horizontally or vertically. Horizontal retorts involve easy loading of crates by means of a rail or track on which multiple crates can be pushed into the retort. In vertical retorts, a crane mechanism has to be used to hoist crates and load them into the retort. The heating medium for batch retorts may be hot water (in the form of containers being immersed in hot water, flowing/cascading over the containers or being sprayed by water).

      Large water immersion retorts generally consist of two horizontal cylinders, one on top of another. The bottom cylinder contains the packaged food product in crates, whereas the top cylinder contains hot water under pressure. When the containers are ready for thermal processing, the preheated water from the upper cylinder is

quickly flooded into the bottom cylinder via large ports connecting the two cylinders. Preheating the water in the upper cylinder shortens the come-up time of the retort (time taken to get all points within the retort to the required processing temperature). If there were only one cylinder and steam was used to heat a large volume of water in that cylinder, it would take a long time for the water to attain the required temperature.

In a cascading water retort, rows of containers in a crate are separated from containers in the row above by means of perforated divider plates. Pressurized hot water then cascades over containers through the perforations, thereby ensuring that all containers receive relatively uniform flow of water over it.

In a water spray retort, pressurized hot water is sprayed over containers of food via multiple nozzles placed at specific locations within the retort. The orientation of the nozzles and the spacing between them are critical in ensuring uniform thermal treatment of all containers of food.

b. Continuous

In a continuous retort, containers are continuously loaded into the retort at a certain rate at one end and continuously taken out of the retort at the same rate at the other end. Continuous retorts increase the throughput and lower the manpower cost. Continuous retorts can be classified as static (hydrostatic) and rotary (hydrolock, sterilmatic, reel and spiral, etc.) retort.

Hydrostatic retorts are vertical systems which uses a water leg as a steam valve. A tall leg of water results in an increase in pressure at the bottom of the leg. At this point, steam can be used to increase the temperature of the water to values as high as 130°C (or higher, if needed), depending on the height of the water. The hydrostatic retort is well suited for products that require long cook and cool times along with higher throughput. The containers of food are transported through this leg of water by means of chains containing slots for the containers to be placed. As the containers travel through the retort, they are subjected to increasing temperatures as they move from top to bottom. Once they receive adequate heat treatment, they pass through legs of water wherein cold water is used to cool off the products.

A continuous rotary retort is a fully automated system designed for high throughput, lower energy consumption, and uniform product quality. These systems require a cylindrical container with limited variation in can diameter and height (Weng, 2005). Containers of food are placed in slots on the outer part of a helical reel mounted around a horizontal cylindrical vessel that is jacketed. Steam is used to heat the products in cans as they are transported in a spiral manner on the reel from one end of the retort to the other.

2. Classification based on mixing

Retorts are also classified based on the nature of mixing induced within the product as static, rotary, and reciprocating. The container size, type of product, and quality considerations generally dictate the type of mixing imparted to the containers of food.

a. Static

As the name suggests, in a static retort, there is no movement of the containers. When there is no movement, the only mechanism for equalization of temperatures within the food in containers is natural (free) convection. Thus, for products that are not viscous or do not contain large particles, this type of retort may be applicable. Additionally, it may be suited in situations where the container size is small enough so that the temperature gradient within the product is not large.

Generally, we associate static retorts with small-scale operations. However, static retorts may be small or large and may or may not contain crates/baskets. A crateless static retort is one type of static retort used by large processors. In this, containers of food are transported on a conveyor belt and loaded from the top into a large vessel

containing water to cushion the fall of containers into the retort. Once the containers are loaded, steam is introduced into the retort to begin the cooking process. Once thermal processing is completed, cold water is introduced into the retort to cool the product. Once cooling is completed, the bottom of the retort opens up and containers fall into a flume of water (cushion) and are transported via a conveyor belt for labeling and palletization.

b. Rotary
When dealing with viscous and particulate food products or large containers, the temperature gradient within a food product may be too large, thereby compromising the quality of the product towards the center of the container. In these cases, a rotary motion is imparted to the containers to mix the product, and equalize the temperature distribution within the product. The rotation may be imparted in an axial or end-over-end manner.

In axial rotation, containers are rotated about their central axis. This causes the air bubble within the container to continuously move along the periphery of the container. In a batch retort, this type of rotation is usually imparted to containers when they are placed in L-shaped slots attached to a reel that rotates within the retort. In a continuous retort, this type of rotation is imparted when the containers are placed on ledges/slots on the periphery of a reel that rotates.

In end-over-end rotation, containers are subjected to flipping action across their ends. This causes the air bubble within the container to continuously move from the top to the curved surface to the bottom. Unlike in axial rotation wherein individual containers rotate about their axis, in end-over-end rotation, generally, a group of containers (usually, one or more crates/baskets) are rotated as one entity. For this to be accomplished, the containers are packed tightly within the crate/basket and held in place by some mechanism to ensure that they do not move around during rotation. This type of agitation is conducive to only batch retorts.

c. Reciprocating
In a reciprocating retort, one or more crates/baskets are placed within the retort and the entire system of crates (with containers) is moved back and forth at a preset speed. This reciprocating action imparts a random mixing action within the product. Studies have shown that the time of processing decreased and product quality increased when using this type of retort. However, one of the concerns with this type of retort is the relatively rapid wear and tear of moving parts within the retort.

Tubular Heat Exchanger

A tubular heat exchanger consists of two or more concentric tubes. The product and heating/cooling media flow in alternate tubes in the same or opposite directions. The double tube heat exchanger (two concentric tubes) is the most common type of tubular heat exchanger. Triple tube heat exchangers (three concentric tubes) are used occasionally, whereas quadruple tube heat exchangers (four concentric tubes) are not commonly used.

1. Double tube
The most common noncontact type of heat exchanger is the double tube heat exchanger. It consists of a tube located concentrically inside another tube of larger diameter. The two fluids flow in the inner and outer tube respectively (Figure 4.20.3).

Double tube heat exchangers can be classified according to the path of fluid flow through the heat exchanger. The three basic flow configurations are cocurrent, countercurrent, and cross-flow. In cocurrent heat exchangers, both the fluid streams enter simultaneously at one end and leave simultaneously at the other end as shown in Figure 4.20.3. In countercurrent heat exchangers, both of the fluid streams flow in opposite directions. In cross-flow heat

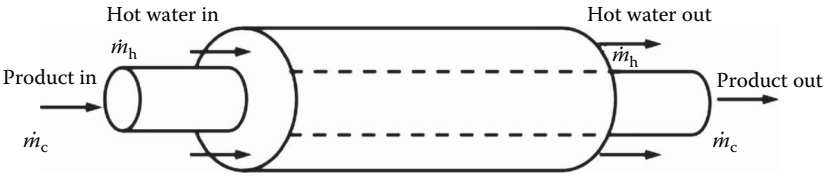

FIGURE 4.20.3 Schematic of a double tube heat exchanger.

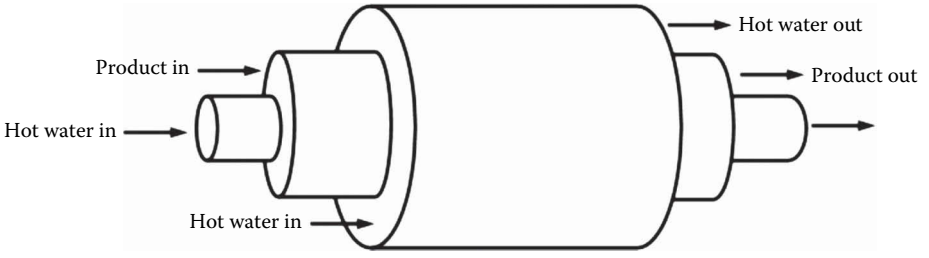

FIGURE 4.20.4 Schematic of a triple tube heat exchanger.

exchangers, one fluid flows through the heat transfer surface at right angles to the flow path of the other fluid (Kakac and Liu, 2000). When both fluid streams are simultaneously in cocurrent, countercurrent, and multipass cross-flow, then the arrangement is called mixed flow. Generally, a countercurrent configuration is preferred since it results in a higher amount of heat transfer. However, when rapid initial cooling of a heat-sensitive product is desired (to minimize quality losses occurring at a greater extent at high temperatures), a cocurrent configuration may be used. In this case, a cocurrent configuration may be used for the initial cooling and a countercurrent configuration may be used for the latter stage of cooling.

2. Triple tube
   A slightly modified version of the double tube heat exchanger is the triple tube heat exchanger. It consists of three concentric tubes. Product flows in the inner annular space and the heating/cooling medium flows in the inner tube and outer annular space (Figure 4.20.4).

   Advantages of a triple tube heat exchanger over a double tube heat exchanger include larger heat transfer area per unit length and higher overall heat transfer coefficients due to higher fluid velocities in the annular regions. Batmaz and Sandeep (2004) developed an expression for effective overall heat transfer coefficient for a triple tube heat exchanger to facilitate comparison of a triple tube heat exchanger to an equivalent double tube heat exchanger.

Shell and Tube

Shell and tube heat exchanger is another common noncontact type of heat exchanger used in the food industry. In this type, there is a small or large shell that houses multiple tubes within it. When the shell is small, it is often called a multitube heat exchanger and when the shell is large, it is the conventional shell-and-tube heat exchanger.

1. Conventional shell and tube
   This consists of a bundle of tubes connected in parallel and enclosed in a large cylindrical shell. A schematic of a shell-and-tube heat exchanger is shown in Figure 4.20.5.

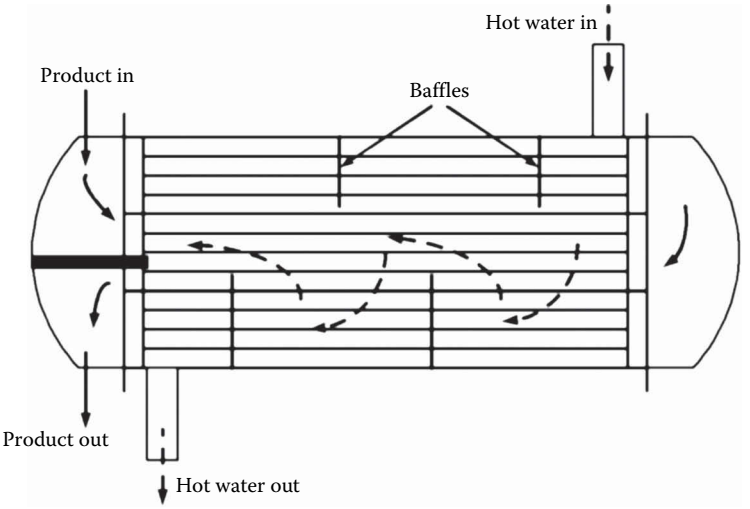

FIGURE 4.20.5 Schematic of a shell-and-tube heat exchanger.

One of the fluids flows inside the tubes while the other fluid flows over the tubes through the shell. To ensure the flow of shell-side fluid over all of the tubes, baffles are used in these heat exchangers. The segmented baffle is the most commonly used baffle and it causes the shell-side fluid to flow in a zigzag manner across the tube bundle. This enhances turbulence on the shell side of the heat exchanger and thus improves the rate of heat transfer. However, improperly designed segmented baffles cause low local heat transfer coefficients in flow stagnation regions where the baffles are attached to the shell wall. Baffles also result in excessive pressure drop by separating the flow at the edges of the baffles. Helical baffles are an alternative to segmented baffles as they offer the following advantages: improved shell-side heat transfer, lower pressure drop for a given shell-side flow rate, reduced shell-side fouling, and prevention of flow-induced vibrations. However, helical baffles are associated with fabrication and manufacturing difficulties (Stehlik et al., 1994). The tubes may be arranged to permit one or more passes of the product through the tubes.

2. Helical shell and tube
   In this type of heat exchanger, tubes are coiled and placed in a large cylindrical shell. The ratio of the diameter of the tube to the diameter of the coil and the vertical spacing between successive coils are important design parameters. The main difference in the flow in straight tubes and helical tubes relates to secondary flow. For flow of a Newtonian fluid under laminar flow conditions in a straight tube of circular cross section, a parabolic velocity profile exists under fully developed flow conditions. In this case, flow takes place only in the axial direction. However, in a coiled tube, flow takes place predominantly in the axial direction (primary flow), but also partly in the radial direction (secondary flow). This is called the Dean effect. The strength of primary flow is generally much greater than that of secondary flow. Nevertheless, the secondary flow creates radial movement of fluid elements and hence causes mixing of fluid elements. This increases the rate and uniformity of temperature distribution within the product.

Scraped Surface Heat Exchanger

Scraped surface heat exchangers are used for viscous products (diced fruit preserves and soups) containing particles of sizes up to approximately 15 mm. Particle concentrations of up to 40% can be accommodated by these heat exchangers. These heat exchangers consist of a jacketed cylinder enclosing scraping blades on a rotating shaft. The rotating action of the blades prevents fouling on

the heat exchanger surface and improves the rate of heat transfer and mixing. A summary of studies on heat transfer in scraped surface heat exchangers has been presented by Rao and Hartel (2006).

Electromagnetic Heating

Electromagnetic heating refers to the use of electromagnetic waves (generated when an electric field couples with a magnetic field) to heat a food product. While infrared, radio frequency, and microwaves can cause heating of a food product, infrared heating is not often used as it results predominantly in heating only the surface of a food product. However, radio frequency waves and microwave can cause heating within a food product, and hence they have been successfully used for various food processing applications.

1. Radio frequency
   Radio frequency (RF) waves are a part of the electromagnetic spectrum and have a frequency between 3 kHz and 300 MHz. Their low frequency, in comparison to that of microwaves, results in a greater depth of penetration of the waves into a product. RF systems are typically equipped with electrodes, the polarity of which is reversed at a preset frequency. The commonly used frequencies with RF are 13.56, 27.12, and 40.68 MHz, with the latter being the most common. They may be used in a conveyor belt configuration for treating discrete solid materials or as a flow-through tube configuration for pumpable materials.

   RF has been used in the timber industry for drying glued joints and in the textile industry for drying heat-sensitive fabrics. In the food industry, it has been used predominantly for the post-bake stage drying (final drying) of cookies and crackers. The main benefit of using RF over hot air for this is that hot air heats up all parts of the cookies and crackers, thereby having a tendency to crack them, while RF targets only the polar component within the product (mainly water), thereby preventing the tendency to cause cracking.
2. Microwave
   Microwaves are a part of the electromagnetic spectrum and have a frequency between 300 MHz and 300 GHz. They lie between the radio (3 kHz–300 MHz) and infrared (300 GHz–400 THz) frequencies of the electromagnetic spectrum. Microwave radiation has the ability to heat materials by penetrating and dissipating heat in them. The important advantages of microwave heating as compared with conventional heating include instant start-up, faster heating, and energy efficiency. The main disadvantage associated with microwave heating is nonuniform heating of the food products. In the U.S., only four microwave frequencies (915 ± 13; $2{,}450 \pm 50$; $5{,}800 \pm 75$; and $24{,}150 \pm 125$ MHz) are permitted by the Federal Communications Commission (FCC) for industrial, scientific, and medical applications.

   The power absorption for volumetric heating using microwave is given as (Coronel et al., 2008):

$$P = 2\pi f \varepsilon_0 \varepsilon'' E^2,$$

   where P is power absorbed (W/m^3) per unit volume, f is the microwave frequency (Hz), and E is the electric field strength (V/m). Power penetration depth (δ_p), often used in microwave heating applications, is the distance within the product at which power drops to e^{-1} of its value at the surface of the material and is given by the following equation (Nelson and Datta, 2001):

$$\delta_p = \frac{\lambda}{2\pi\sqrt{2\varepsilon'\left[\sqrt{1+\left(\frac{\varepsilon''}{\varepsilon'}\right)^2}-1\right]}},$$

where λ is the wavelength of the microwave in free space. Power penetration depth is used to calculate the tube diameter for a continuous flow microwave heating system.

Continuous flow microwave heating systems have been developed to rapidly and uniformly heat various viscous and particulate foods. The resulting product has much better quality and nutritional attributes than the equivalent product processed using conventional thermal processing technologies.

Ohmic Heating

Ohmic heating, also known as Joule heating, electric resistance heating, and electroconductive heating is a process in which an alternating current is passed directly through a conductive food product. The heat is generated internally due to the resistance of the food product to the applied electric current. The heating is rapid due to volumetric generation of heat. The heat generated is given as:

$$P = E^2\sigma,$$

where E is the electric field strength and σ is the electrical conductivity. Electric field strength (V/m) can be varied by adjusting the electrode gap or the applied voltage. Electrical conductivity is the measure of how well a substance conducts electricity and is expressed in the units of Siemens per meter (S/m). The efficiency of Ohmic heating is dependent on the electrical conductivity (σ) of the product (Coronel et al., 2008).

Ohmic heating has been used successfully to thermally process various food products, including various types of soups, especially in Europe. For some products, soaking the product in salt solution, to increase its electrical conductivity, may be needed.

Process Considerations

The most common methods of thermal processing include blanching, pasteurization, hot filling, and sterilization. These methods have been described below.

Blanching

Blanching is a mild heat treatment commonly applied to fruits and vegetables prior to freezing, drying, or canning. Blanching is performed to inactivate enzymes, enhance drying and rehydration, remove tissue gases, enhances color of green vegetables, and reduce the microbial population. The effectiveness of blanching is usually evaluated by enzyme activity (peroxidase and catalase). Blanching is usually accomplished by bringing the product in contact with hot water, hot air, or steam for certain period of time. Water blanching can be conducted as a batch operation by dipping a batch of product in hot water for the required amount of time. Continuous hot water blanching can be accomplished using a screw-type, drum-type, or pipe-type blancher. The screw-type blancher consists of a trough fitted with a helical screw. The drum-type blancher consists of a perforated drum fitted internally with a helical screw. The pipe-type blancher can be used for solid products which can be pumped with water. Similar to water blanching, steam blanching can also be accomplished as a batch or continuous process. The heating time necessary to accomplish blanching depends on the type and size of fruit/vegetable, the method of heating, and the temperature of the heating medium. Typical blanching times at 100°C for commercial blanching range from 1 to 5 min (Lund, 1975).

Pasteurization

Pasteurization refers to heat treatment of a product to kill all vegetative pathogenic microorganisms in it. The time–temperature combination for the pasteurization of milk is 63°C for 30 min, which is referred to as a low-temperature long time process and 72°C for 15 s which is referred to as a high-temperature short time process. The heat treatment in pasteurization is not sufficient to inactivate

all spoilage-causing vegetative cells or heat-resistant spores. Therefore, the shelf life of pasteurized low-acid products such as milk and dairy products is approximately 2–3 weeks under refrigerated conditions. Ultrapasteurization refers to pasteurization at temperatures of 138°C or above for at least 2 s either before or after packaging. This process further extends the shelf life of the product. Ultrapasteurization results in the destruction of a greater proportion of spoilage microorganisms, leading to an extended shelf life of about 6–8 weeks. This process has been used for flavored milks and nondairy creamers in portion pack cups (David et al., 1996).

The choice of heating system for pasteurization depends on the characteristics (rheological and thermal properties) of the product, potential for fouling, ease of cleaning, and cost.

Direct-type heating system (steam injection and steam infusion) is used for homogeneous and high-viscosity products and is particularly suited for shear-sensitive products such as creams, dessert, and sauces. In a steam injection heating system, liquid product is heated by injection of culinary steam into the product. Rapid heating by steam combined with rapid methods of cooling can yield a high-quality product. A steam infusion heating system, similar to steam injection, involves infusing a thin film of liquid product into an atmosphere of steam which provides rapid heating. Direct heating system (steam injection or steam infusion) adds water to the product (10% water addition per 56°C increase in product temperature) due to the condensing steam. The amount of added water should be either accounted for in the product formulation or removed by flash cooling in a vacuum chamber.

There are four main types of indirect-type heating systems: tubular, shell and tube, plate, and scraped surface heat exchangers. Tubular heat exchangers are used for homogeneous and high-viscosity products (soups and fruit purees) containing particles of sizes up to approximately 10 mm. The simplest tubular heat exchanger is a double-pipe heat exchanger consisting of two concentric pipes. Shell and tube heat exchangers consist of a shell (typically cylindrical in shape) with one or more sets of tubes inside it. The tubes may be coiled in a helical manner or arranged in a trombone fashion. This type of heat exchanger is used when a greater degree of mixing than that achieved in a tubular heat exchanger is desired. Plate heat exchangers are used for homogeneous and low-viscosity (<5 Pa s) products (milk, juices, and thin sauces) containing particle sizes up to approximately 3 mm. These heat exchangers consist of closely spaced parallel plates pressed together in a frame. These heat exchangers provide a rapid rate of heat transfer due to the large surface area for heat transfer and turbulent flow characteristics. Scraped surface heat exchangers are used for viscous products (diced fruit preserves and soups) containing particles of sizes up to approximately 15 mm. These heat exchangers consist of a jacketed cylinder housing with scraping blades on a rotating shaft. The rotating action of the scraping blades prevents fouling on the heat exchanger surface and improves the rate of heat transfer. This type of heat exchanger is the best choice for viscous products containing particulates (Skudder, 1993). Apart from tubular, shell and tube, plate, and scraped surface heat exchangers, pasteurization can also be accomplished in a vat- or tank-type heat exchanger. In a tank-type heat exchanger, product is pumped into a jacketed vat or tank, heated to pasteurization temperature, held for required time, and pumped from the vat to the cooling section (Mitten, 1963).

Volumetric heating systems such as microwave and ohmic heating can provide very rapid heating which is desirable for aseptic processing. However, it is challenging to maintain a uniform temperature distribution within the product. Microwave heating systems apply rapidly changing electromagnetic field to the product. Movement or vibration of the molecules of the product due to the changing electromagnetic field generates heat. An ohmic heating system operates by directly passing the electric current through a product. The electrical resistance of the product to the passing electric current generates heat (Coronel et al., 2008).

Hot Fill

Acid/acidified products such as juices and beverages packed in hermetically sealed containers using an appropriate hot filling process yields a commercially sterile shelf-stable product. Hot filling, also

known as "hot fill and hold," refers to filling unsterilized containers with a sterilized acid/acidified food product that is hot enough to render the container commercially sterile. A hermetically sealed container is a container that is designed and intended to be secure against the entry of microorganisms and thereby maintain the commercial sterility of its contents after processing. Commercial sterility means the condition achieved either by (1) the application of heat which renders the food free of microorganisms capable of reproducing in the food under normal nonrefrigerated conditions of storage and distribution and viable microorganisms (including spores) of public health significance, or by (2) the control of water activity and the application of heat, which renders the food free of microorganisms capable of reproducing in the food under normal nonrefrigerated conditions of storage and distribution. Commercially sterile food products are shelf-stable with a longer shelf life (1–2 years) (David et al., 1996; Anderson et al., 2011).

Sterilization

Sterilization refers to killing of all living microorganisms including spores in the food product. Food products are never completely sterilized, instead they are rendered commercially sterile. Sterile product means that there is a complete absence of viable microorganisms in it. A viable microorganism is one that is able to grow when exposed to optimum conditions. Low-acid food products are commercially sterilized since they are capable of sustaining the growth of *C. botulinum* spores (Lund, 1975; David et al., 1996). Commercial sterility can be achieved by in-container sterilization and in-flow sterilization. In-container sterilization generally refers to the retorting process, whereas the in-flow sterilization refers to aseptic processing.

1. Retorting
   Traditionally, retorting has been used to process low-acid food products to ensure destruction of *C. botulinum* spores. Conventional retorting involves filling of the product in metal cans, glass jars, retortable semirigid plastic containers or retortable pouches; double-seaming or heat sealing; followed by heating, holding, and cooling in a pressurized batch or continuous retort. Retorting of foods in cans, invented by Nicholas Appert in the early 1800s, still remains the preferred choice for preservation of foods. Retorts can be operated in either a batch or continuous mode of operation. Batch retort is the most versatile sterilization system with the ability to handle different products (conduction heating and convection heating) and package types. Batch retort can further be classified into still/static (horizontal, vertical, or crateless) retort and agitating/rotary (end over end or axial rotation) retort. When steam is used as the heating medium, it should be introduced into the retort with care such that all the air in the retort is displaced. Removal of air by steam is also known as venting. Cooling is accomplished by shutting off steam and introducing cold water into the retort. Overpressure is often used to prevent internal pressure inside the container from destroying its integrity. The rotary retort agitates the product inside the container by the movement of the air bubble created by the headspace, resulting in enhanced heat transfer in the container. A larger headspace results in faster heating of a product due to efficient mixing. Different heating media and heating methods used in various batch retorts include steam, water, steam–air, water cascading, water spray, or water immersion (Lund, 1975; Weng, 2005).
2. Aseptic processing
   Aseptic processing offers an alternative to conventional retorting to meet the demand for convenient and high-quality foods. Aseptic processing of foods is a process in which the product and the package are sterilized separately and brought together in a sterile environment. It involves sterilization of a food product, followed by holding it for a specified period of time in a holding tube, cooling it, and packaging it in a sterile container. Aseptic processing uses high temperature for a short period of time, yielding a high-quality (nutrients, flavor, color, or texture) product as compared to that by conventional canning.

Some of the other advantages associated with aseptic processing include longer shelf life (1–2 years at ambient temperature), flexible package size and shape, less energy consumption, less space requirement, eliminating the need for refrigeration, easy adaptability to automation, and need for fewer operators. However, some of the disadvantages of aseptic processing include slower filler speeds, higher overall initial cost, need for better quality control of raw ingredients, better trained personnel, better control of process variables and equipment, and stringent validation procedure. Some of the products which are aseptically processed include fruit juices, milk, coffee creamers, purees, puddings, soups, baby foods, and cheese sauces (David et al., 1996). Sterilization of products in aseptic processing can be accomplished using tubular, shell and tube, scraped surface, or volumetric heating (microwave and ohmic) systems.

Outlook for the Future

Thermal processing has been the most common technique used for inactivating microorganisms. Though nonthermal techniques such as high-pressure processing have been successfully used for certain special categories of foods, thermal processing will likely continue to be the predominant technique used for inactivating microorganisms in food. Some of the advancements expected in the area of thermal processing of foods include improved design of conventional heat exchangers for heating foods, improvements in volumetric heating technologies for rapidly and uniformly heating foods, development of rapid cooling techniques, and development of miniature sensors that can be implanted within food particles to determine the time–temperature history at the cold spot within a food so as to facilitate process validation. Additional work on synergistic effects of heat and other hurdles (such as antimicrobials, redox potential, and nonthermal technologies) is also expected to be an area of research and development of interest to food processors.

4.21 THERMAL CONDUCTION IN ELECTRONIC MICROSTRUCTURES AND NANOSTRUCTURES

Sanjiv Sinha, Krishna Valavala and Jun Ma

Structures with physical dimensions ranging from a few nanometers to hundreds of micrometers are the essential building blocks of electronic integrated circuits. Current flow in circuits causes Joule heat dissipation in transistors as well as in interconnects (Waldrop, 2016; Li et al., 2009; Pop et al., 2006). Heat transfer engineering across multiple length scales (Sinha and Goodson, 2005) is necessary to limit the resulting temperature rise. Typically, the highest temperatures in a circuit occur inside the transistors (Su et al., 1994). For design purposes, the distribution of transistor temperatures is ignored in favor of a single temperature for the circuit that represents the maximum value. This is commonly referred to as the junction temperature. Increased junction temperatures affect nearly all key figures of merit of a very large-scale integrated (VLSI) circuit. In particular, temperature affects circuit speed, lifetime, power dissipation, and power plane integrity (Haensch et al., 2006; Hanson et al., 2006). Effective thermal management is necessary across the gamut of modern electronic circuits, from established applications such as microprocessors, power semiconductors, semiconductor lasers, sensors, actuators, and light-emitting diodes to emerging and related areas such as phase change memory (PCM), flexible electronics, and spintronics. Figure 4.21.1 shows a few examples of semiconductor devices that form the key elements of diverse electronic circuits in which heat transfer issues arise.

Across decades, advancements in electronics largely relied on the continued miniaturization of the transistor, in keeping with the famous Moore's law (Moore, 1965). The road map followed thus far by the industry has targeted shrinking the physical dimensions of the transistor to achieve faster circuits and more devices per area, which in turn have enabled even larger-scale integration. Underlying this road map is the principle of "device scaling" (Dennard et al., 1974). The essential idea is to shrink the distance that current must travel in the transistor (approximately equal to the length of the gate terminal) while maintaining the same electric field. In practice, this requires ticking off a complex engineering checklist that spans expertise in semiconductor fabrication, materials physics and chemistry, device physics, circuit design, and computer architecture to name a few. While heat transfer did not feature near the top of the design checklist for many decades of the evolution of Moore's law, power dissipation has always been a major consideration (Mahajan et al., 2000). In the early years of microelectronics, a shift from bipolar transistors to complementary metal-oxide-semiconductor (CMOS) field-effect transistors (FETs) was necessary to limit power dissipation. With the introduction of CMOS, power ideally would be dissipated only during the process of switching the state of a device. Individual transistors became more energy efficient with shrinkage, but the chip power density crept up with increased transistor count per unit area (Mahajan et al., 2002; Samson et al., 2005). In the last decade, transistors have approached a size regime where quantum mechanical tunneling introduces leakage currents even during the off state where ideally no power should be dissipated (Haensch et al., 2006). Figure 4.21.2 shows the power density for both active and the passive states versus gate length. As dimensions reach below 100 nm, both active and passive power contribute equally to the total power density. The industry has responded with many innovations to limit leakage power, including three-dimensional transistors (Topol et al., 2006). However, increased power density with successive generations of integrated circuits has ultimately put a cap on the switching speed (or frequency). And further miniaturization of the most cutting-edge semiconductor devices would make them atomistic scales where altered transport physics stem gains from miniaturization. Even with the expected demise (Waldrop, 2016) of the conventional form of Moore's law, there remain significant opportunities for innovation such as three-dimensional circuits, where heat transfer engineering continues to play an important role.

Figure 4.21.3 shows the schematic of a packaged microprocessor and illustrates the heat flow path for silicon microprocessors (Prasher, 2006). Heat generation occurs in the transistors and

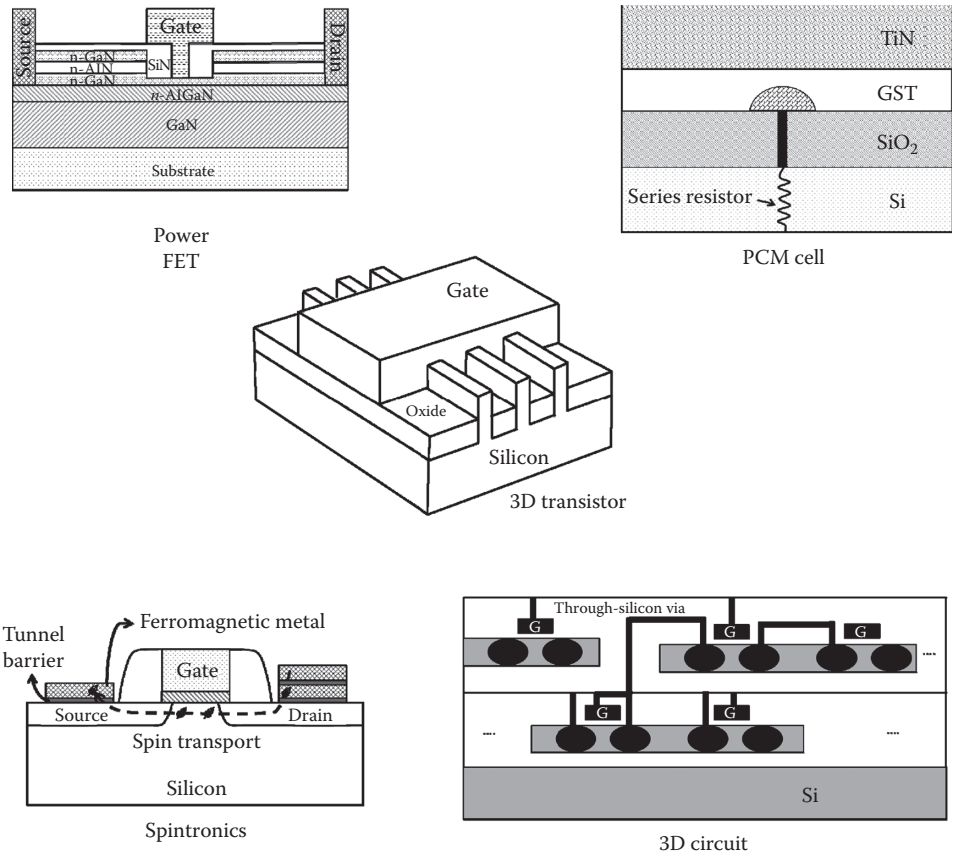

FIGURE 4.21.1 Examples of the diversity of semiconductor devices. In power conversion, GaN FET handle high voltages and power densities. A PCM cell uses heat to change the electrical resistance of phase change material. Advanced three-dimensional silicon transistors are nanoscale with sub-20 nm gate lengths (approximately equal to the distance between the source and drain terminals). The electron spin state is employed as the fundamental signal in a spintronic transistor. Three-dimensional circuits integrate multiple device layers and require innovative heat flow paths.

interconnects. The major heat flow path is toward the heat sink from where heat is transferred to the ambient through convection. At steady state, the thermal circuit shown in Figure 4.21.3 applies. The key temperature nodes are those at the junction (T_J), the case (T_C), the sink (T_S), and the ambient (T_O). The key thermal resistances are due to the die (R_{DIE}), the first-level thermal interface material (R_{TIM1}), the heat spreader ($R_{SPREADER}$), the second-level thermal interface material (R_{TIM2}), and the heat sink (R_{SINK}). Heat produced in the chip flows across the first-level thermal interface material (TIM1) to a heat spreader that is typically integrated with the chip. The heat spreader aims to address nonuniformity in heat production across the surface of the chip. Computational cores, for example, produce more heat than memory caches. The second-level TIM (TIM2) and the heat sink help to reject heat to the ambient.

Thermal management of an integrated circuit spans several distinct engineering disciplines. Figure 4.21.4 shows the multiple scales involved in thermal engineering of integrated circuits. Device level thermal considerations form the first level of thermal management where the effect of elevated temperatures on the performance and reliability of transistors must be understood. The level of detail goes down to the microscopic physics of electron scattering. Circuit level thermal considerations form the second level. It is now common for VLSI circuit designers to incorporate thermal modeling in circuit models to more accurately predict power dissipation, reliability, circuit

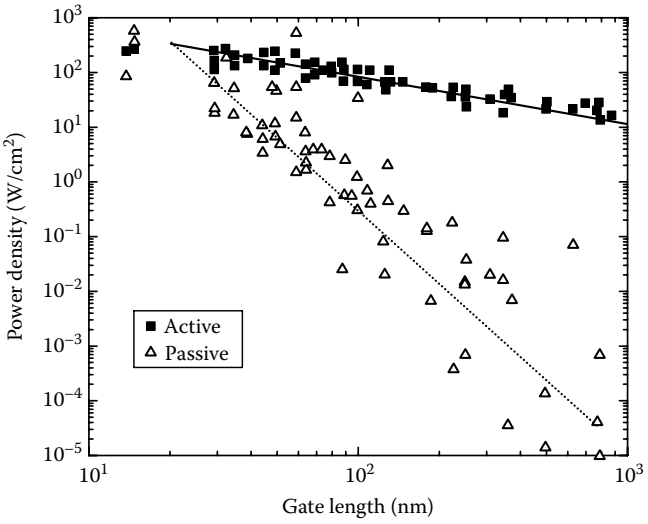

FIGURE 4.21.2 With shrinking gate length, the power density expended in useful functions is equaled by the passive power density, placing greater requirements on thermal engineering down to the circuit level. (Data from Haensch, W. et al., *IBM J. Res. Dev.,* 50 (4/5), 339–61, 2006).

timing characteristics, and supply voltage variations among others. At a higher level, software techniques such as dynamic thread migration and temperature aware task scheduling also find use in limiting temperature rise. On the hardware side, the focus is on cooling technologies (Garimella et al., 2006; Shakouri, 2006), TIMs (Prasher, 2006), and thermal characterization.

Based on the physical length scales involved, the heat transfer problem is typically separated into three hierarchies: chip level that ranges from the transistor to the circuit to the die; package level that includes TIMs and heat spreaders integrated with the die; and finally, system or platform level that includes external heat pipes, heat sinks, fans as well as other electronic components on the printed circuit board. This chapter is mainly concerned with the first two levels of hierarchy. The only mode of heat transfer available is conduction. However, the orders of magnitude in the length scales involved bring significant complexity to the conduction physics. Further, interconnection between charge and heat transport at the smallest length scales in the problem plays an important role in heat transfer engineering. The following material delves first into fundamental physics and then discusses relevant modeling and experimental techniques. Data for a wide range of materials relevant to electronics follow. Application of the techniques to semiconductor devices is discussed at the end of the chapter.

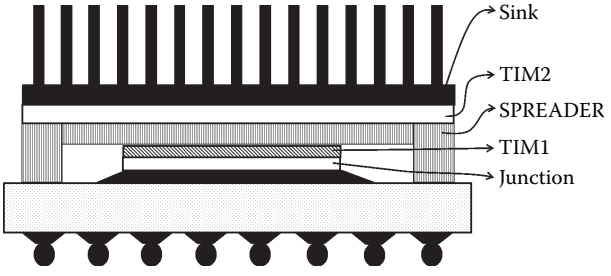

FIGURE 4.21.3 Schematic of desktop microprocessor packaging. The junction temperature is the highest temperature in the silicon die. Heat flows to the ambient toward the top. The path includes the TIM1, an integrated spreader, TIM2, and a heat sink. Nonuniformity of heat generation in the die complicates thermal solutions.

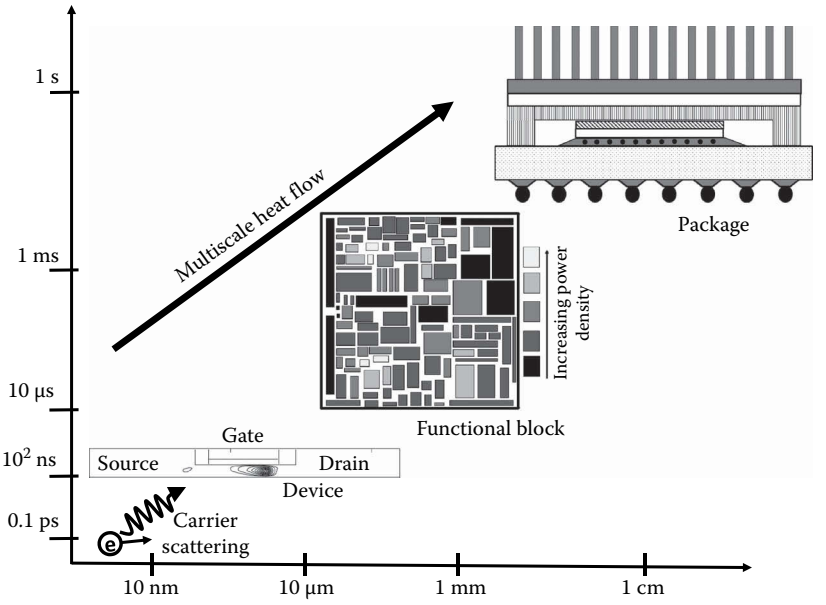

FIGURE 4.21.4 Heat flow in semiconductor electronics involves several orders of magnitude in length and timescales. Carrier scattering that dissipates Joule heat occurs at ~10 nm length scales over 0.1 ps timescales. Heat diffusion out of the transistor occurs over ~100 ns. Interconnects also experience severe heating. At the scale of functional blocks of the integrated circuit, heat production is highly nonuniform. Ultimate removal occurs through the package.

Fundamental Heat Conduction Physics

The Fourier law for heat conduction (Incropera, 2006) in a material medium is a phenomenological equation that relates heat flux to the temperature gradient in the material,

$$q = -\ddot{\kappa}\nabla T, \tag{4.21.1}$$

where $\boldsymbol{q}$ is the heat flux, ∇T is the temperature gradient, and $\ddot{\kappa}$ is the thermal conductivity tensor of the medium. For an isotropic medium, a scalar thermal conductivity κ appears in the equation above. The value of κ can be further interpreted by considering the microscopic mechanisms responsible for energy transport that depend on the medium. In gases, for instance, molecular motion transports heat. The kinetic theory provides a simple relation between thermal conductivity and molecular motion as

$$\kappa = \frac{1}{3} C\bar{v}\Lambda, \tag{4.21.2}$$

where C is the volumetric heat capacity, $\bar{v}$ is the mean molecular speed, and Λ is the mean free path of gas molecules between collisions. Even in solids where the microscopic mechanism for heat conduction arises in the transport of energy by electrons and quantized lattice vibrations (or phonons), the above expression can be reinterpreted as the conductivity of a gas of electrons or phonons.

Further considering conservation of energy in an infinitesimal volume of the material leads to the heat diffusion equation. In an isotropic medium without any heat source,

$$\frac{\partial T}{\partial t} = \alpha_T \nabla^2 T, \tag{4.21.3}$$

where α_T is the thermal diffusivity of the medium and is defined as the ratio of the thermal conductivity to the heat capacity per unit volume. The heat diffusion equation above assumes the presence of continuum. Continuum refers to a description of matter in which it is infinitely divisible. Provided material properties are known, the above equation can be readily solved in complicated geometries to obtain spatial and temporal temperature distributions.

In electronic circuits, however, the relevant length scales are often in micrometers and nanometers where the continuum description of matter may break down. It then becomes necessary to consider the physical process of heat conduction in more detail. Internal energy is transported in solids via energy carriers, typically electrons and phonons (Ziman, 1960; Ashcroft and Mermin, 1976). Both electrons and phonons are quantum particles. The term phonon refers to the energy quantum of the displacement field of a crystal lattice. Electrons dominate heat transport in metals and phonons in dielectrics. The kinetic theory of matter provides a framework for considering energy transport by carriers such as electrons and phonons.

The theory aims to describe the motion of carriers through a statistical distribution function in three-dimensional physical space, three-dimensional velocity (or momentum) space and time. Consider a system of gas particles that may represent either electrons or phonons in a solid. A six-dimensional infinitesimal volume is formed by the volume in physical space between position vectors $\boldsymbol{r}$ and $\boldsymbol{r}+\mathrm{d}\boldsymbol{r}$ as well as the volume in velocity space between $\boldsymbol{v}$ and $\boldsymbol{v}+\mathrm{d}\boldsymbol{v}$. The distribution function f provides the number of particles in the volume through

$$\mathrm{d}N = f\left(\boldsymbol{r},\boldsymbol{v},t\right)\mathrm{d}r\mathrm{d}v. \tag{4.21.4}$$

The distribution function is not stationary but changes due to drift of the particles in physical space as well change in their velocities due to external forces and collisions (or scattering). Detailed consideration of different mechanisms for collisions is often necessary to obtain a reliable answer. Balancing particle numbers leads to an equation for the distribution function called the Boltzmann transport equation (BTE) that is the cornerstone of modeling transport. The BTE written for a particle under an external force is

$$\frac{\partial f}{\partial t} + v\cdot\nabla f + a\cdot\nabla_v f = \left.\frac{\partial f}{\partial t}\right]_{\mathrm{SCATTER}}, \tag{4.21.5}$$

where $\boldsymbol{a}$ is the acceleration of the particle under any external force, and the term on the right-hand side is the net rate of change in f due to scattering. In principle, the solution of the distribution function can provide the heat flux in the medium. At any location, this requires integrating over particles of all velocities as

$$q\left(\boldsymbol{r},t\right) = \int \boldsymbol{v} f\left(\boldsymbol{r},\boldsymbol{v},t\right) E\left(\boldsymbol{v}\right)\mathrm{d}\boldsymbol{v}, \tag{4.21.6}$$

where $E(\boldsymbol{v})$ is the energy of the particle as a function of its velocity. At thermodynamic equilibrium, the net transport of all quantities such as particle flux, mass, momentum, and energy must be zero at all locations and times. The corresponding distribution function, f_0, depends on the type of particle. For electrons, the equilibrium distribution is the Fermi–Dirac (FD) distribution, whereas for phonons, the equilibrium distribution is the Bose–Einstein (BE) distribution. The equilibrium distribution depends on the temperature of the medium, the chemical potential, and the energy of the particle. Figure 4.21.5 plots the distribution functions for FD electrons and BE phonons. Both distributions converge to the classical Maxwell–Boltzmann distribution at high energies.

The scattering term in Equation 4.21.5 is complicated in general. The full solution to the BTE is both computationally expensive and fairly complex and has only been attempted in limited cases.

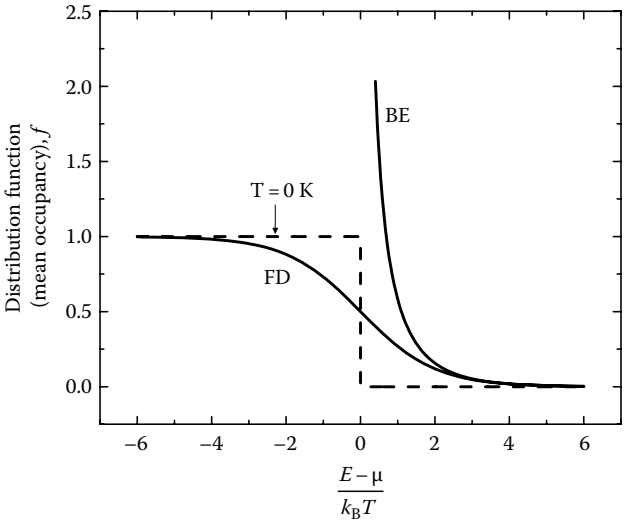

FIGURE 4.21.5 The distribution functions for FD and BE gases. The dashed line shows the FD distribution at 0 K. The occupation is a function of the energy of the particle in relation to the thermal energy, $k_B T$. (Figure prepared by Dhruv Gelda.)

It is difficult to proceed with the BTE without further simplification of the scattering term. The simplest approach is termed the relaxation time approximation. The scattering term on the right-hand side of Equation 4.21.5 is simplified to

$$\left.\frac{\partial f}{\partial t}\right]_{\text{SCATTER}} = -\frac{f - f_o}{\tau}, \tag{4.21.7}$$

where f_0 is the distribution function at thermal equilibrium and τ is a relaxation time. Here the intention is to capture the basic relaxation of the system toward a thermal equilibrium and is especially useful in calculating transport coefficients.

As an example, consider the problem of calculating the thermal conductivity of a medium where external forces are absent and a temperature gradient is present. Since the timescale of interest is much larger than the relaxation time of carriers (typically of the order of picoseconds to nanoseconds at room temperature), steady state is assumed. Using Equations 4.21.7 and 4.21.5 simplifies to

$$v \cdot \nabla f = -\frac{f - f_0}{\tau}. \tag{4.21.8}$$

Typically, the gradient of temperature is small enough that temperature varies very little over the length scale $v\tau$. Therefore, we expect f to be only slightly different from the local f_0 and the difference to be linear in the perturbing gradient. Discarding terms nonlinear in the perturbing gradient renders the equation explicit. This simplification is called "linearizing the BTE." Assuming a temperature gradient in the x-direction, the linearized BTE under the relaxation time approximation reduces to

$$v_x \frac{\partial f_0}{\partial x} = -\frac{f - f_0}{\tau}, \tag{4.21.9}$$

and yields $f = f_o - \tau v_x \frac{\partial f_o}{\partial x}$. Since f_0 is a function of temperature and particle energy, its spatial gradient arises only from any gradient in temperature and thus, $\frac{\partial f_o}{\partial x} = \frac{\partial f_o}{\partial T}\frac{\partial T}{\partial x}$. Using Equation 4.21.6 to describe the heat flux along x,

$$q_x(x) = \int v_x f_o(T(x), v) E(v)\, d\boldsymbol{v} - \int v_x^2 \tau \frac{\partial f_o}{\partial T}\frac{\partial T}{\partial x} f_o E(v)\, d\boldsymbol{v}, \tag{4.21.10}$$

where the first integral vanishes since f_0 is isotropic with respect to velocity. The temperature gradient inside the second integral can be taken out since it is independent of velocity. Comparing the expression with the Fourier law of Equation 4.21.1 yields the thermal conductivity of the medium as

$$\kappa = \int v_x^2 \tau \frac{\partial f_o}{\partial T} f_o E(v)\, d\boldsymbol{v}. \tag{4.21.11}$$

Evaluation of the integral above requires knowledge of two quantities: the variation of the energy E with v and the scattering time τ. These depend on the type of carrier, whether electron or phonon, and are also specific to the material, rendering κ a material property.

Since both electrons and phonons are quantum particles, they can also be described as waves. The wave dispersion relation provides the variation of energy with particle velocity or equivalently, particle momentum. In the case of electrons, the relation is commonly stated between E and the wave number k instead of the velocity or momentum. The momentum of a free electron is $\hbar k$ from the de Broglie relation, where $\hbar$ is the reduced Planck constant. In the case of phonons, the relation is stated between the frequency ω and k. The energy of a phonon is related to its frequency through $E = \hbar\omega$. Obtaining accurate dispersion relation for electrons or phonons requires detailed considerations of these particles. The scattering time is even more involved with multiple scattering mechanisms at play. A common approach is to consider individual scattering mechanisms in as much detail as possible, while considering each to be completely independent of others. The overall scattering time is then given by Matthiessen's rule, which is $\tau^{-1} = \sum \tau_{\text{individual}}^{-1}$. Prominent mechanisms for scattering depend on the type of particle. Electrons prominently scatter with impurity atoms, crystal imperfections, ionic impurities, phonons, plasmons, and surfaces. Similarly, phonons prominently scatter with other phonons, electrons, surfaces, impurities, and crystal imperfections.

Properties of Electrons in Metals

Most properties of electrons in metals require consideration of quantum mechanics. The simplest Sommerfeld theory mainly includes the Pauli exclusion principle leading to the use of the FD distribution instead of the classical Maxwell–Boltzmann distribution. Postulating electrons in the metal to be quantum particles in a box without any forces and to be independent of each other, the Schrödinger wave equation describes such one electron states as plane waves with momentum $\hbar k$ and energy $\frac{\hbar^2 k^2}{2m_e}$, where m_e is the electron rest mass and k is the wave number. The wave numbers are discrete in each direction of wave vector space, for example, $k_x = n_x 2\pi/L_x$, where n_x is an integer and L_x is the size of the crystal along the x-direction. Therefore, each allowed state or discrete k-point in wave vector space has a volume $(2\pi)^3/(L_x L_y L_z)$ or $(2\pi)^3/V$, where V is the physical volume of the crystal.

The properties of the free electron gas in the metal are an average of the value across all states weighed by the probability of occupation of each state. Since states are closely spaced and many, it is more convenient to convert the summation over states to an integral. Further since most properties of interest are independent of the direction in wave vector space and instead depend only on the energy associated with the state, it is useful to average over energy instead. Converting the integral

over k to an integral over E requires knowledge of the density of states, $D(E)$, which is a function of energy describing the number of states between energy E and $E+dE$ per unit physical volume of the crystal and per unit energy interval dE. The density of states for free electrons in three dimensions is given by

$$D(E) = \frac{m_e}{\hbar^2 \pi^2} \sqrt{\frac{2m_e E}{\hbar^2}}. \tag{4.21.12}$$

The density of states function changes with confinement of the electron to fewer dimensions.

The probability of occupation of a state depends on its energy and is given by the FD distribution function as

$$f(E) = \frac{1}{1 + e^{\frac{E - E_F}{k_B T}}}, \tag{4.21.13}$$

where E_F is the Fermi energy and k_B is the Boltzmann constant. At 0 K, electrons occupy all states up to the Fermi energy and leave all states above E_F unoccupied. The Fermi energy is a material property providing a measure of the average energy of the electron (0.6 E_F) and ranges between 5 and 10 eV for most metals.

The thermal properties of the electron gas can be readily calculated using the above framework. The internal energy per unit volume, u_E, for instance, is given by

$$u_E = \int_0^\infty E f(E) D(E) \mathrm{d}E \cong u_E(T=0) + \frac{\pi^2}{6} (k_B T)^2 D(E_F), \tag{4.21.14}$$

where the integral is evaluated using the Sommerfeld expansion. The heat capacity of electrons per unit volume is then

$$C_e = \left. \frac{\partial u}{\partial T} \right|_V = \frac{\pi^2}{3} (k_B)^2 D(E_F) T = \gamma T, \tag{4.21.15}$$

where the constant γ is a material property. Except at low temperatures ($\lesssim$10 K), the heat capacity of electrons contributes little to the overall heat capacity of solids. However, the heat capacity is important in evaluating the thermal conductivity of electrons using the expression in Equation 4.21.2. For electrons in metals, the mean speed is the Fermi speed, v_F that is of the order of 10^6 m/s in most metals. Table 4.21.1 lists the electronic properties of some common metals. A convenient way to estimate the thermal conductivity of metals is to take advantage of the Wiedemann–Franz Law that relates their thermal conductivity to their electrical conductivity as

$$\kappa = L_o \sigma T, \tag{4.21.16}$$

where L_o is a proportionality constant called the Lorenz number and is theoretically evaluated to be 2.44×10^{-8} WΩK^{-2}, and σ is the electrical conductivity.

Properties of Electrons in Semiconductors

Semiconductors are distinct from metals in possessing a gap in the allowed energy bands of electrons. Carriers can be thermally excited across the bandgap such that the electrical conductivity changes with temperature. Semiconductors can be categorized into intrinsic and extrinsic.

TABLE 4.21.1
Properties of Electrons in Metals

Metal	Electron Concentration (10^{28}/m^3)	Fermi Energy (10^{-19} J)	Fermi Velocity (10^6 m/s)	Electrical Conductivity (10^5 /Ωm)	Thermal Conductivity at 300 K (W/mK)	Electron Mean Free Path at 300 K (nm)

An intrinsic semiconductor is chemically pure and only possesses thermally excited charge carriers. The electrical conductivity at room temperature can be similar to that of an insulator. In an extrinsic semiconductor, a small amount of impurity atoms are added in a process known as doping to drastically improve the electrical conductivity. Based on carrier polarity, extrinsic semiconductors can be *p*-type or *n*-type, where holes and electrons are, respectively, the majority charge carriers. The activation energy for electrons to be donated by or accepted to impurity states is usually low enough that most remain activated at room temperature. The concentration of majority charge carriers is almost identical to the concentration of impurities. Electrical conductivity can be made to vary several orders of magnitude depending on the doping concentration.

The Sondheimer model does not extend well to semiconductors. A more detailed band structure must be taken into consideration to properly account for the bandgap. Further, charge carriers contributed by foreign dopants shift the Fermi level. The effect of the periodic potential imposed by the lattice ions on conduction electrons is important. The quantum mechanical behavior of electrons in a periodic potential can be addressed through an effective mass, m^* that is different from the rest mass. The effective mass is a property of the crystal and can be anisotropic and energy dependent (and even negative). Charge transport usually involves carriers at the bottom of the conduction band and at the top of the valence band. The effective mass of the carrier depends on the curvature of the E–k relationship as $m^* = \dfrac{\hbar^2}{d^2E/dk^2}$.

Charge transport can be analyzed using the linearized BTE under the relaxation time approximation as

$$\mathbf{v} \bullet \left[\nabla f_0 + q\varepsilon \frac{\partial f_0}{\partial E} \right] = \frac{f_0 - f}{\tau}, \tag{4.21.17}$$

where $\boldsymbol{v}$ is electron velocity, f_0 and f are the equilibrium and the nonequilibrium distribution, respectively, ε is the electrical field, and τ is relaxation time. If a temperature gradient is also present, the new distribution function becomes

$$f = f_0 - \tau \mathbf{v} \bullet \left[q\varepsilon - \frac{E - E_F}{T} \nabla T \right] \frac{\partial f_0}{\partial E}. \tag{4.21.18}$$

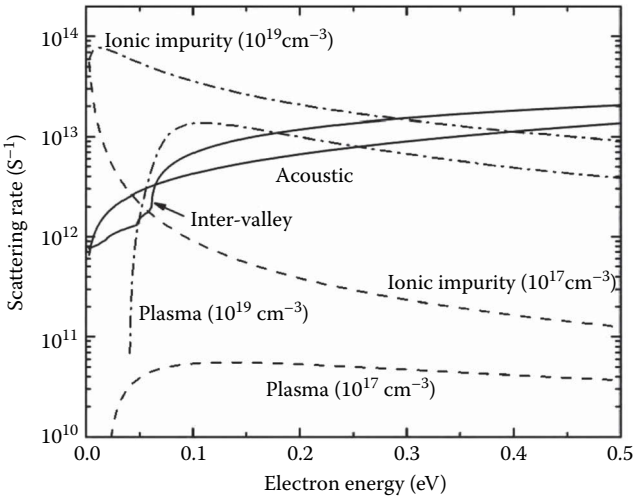

FIGURE 4.21.6 Scattering rates of electrons in silicon at 300 K as a function of electron energy. The solid lines represent scattering mechanisms insensitive to doping. Dashed and dot–dashed lines represent doping levels of 10^{17} cm^{-3} and 10^{19} cm^{-3}, respectively. (Adapted from Ma, J. and Sinha, S., *J. Appl. Phys.*, 112, 073719, 2012. With permission. The current density along the direction of the electric field is

$$J_Z = \int_{\varphi=0}^{2\pi} \frac{1}{4\pi}\, \mathrm{d}\varphi \int_{\theta=0}^{\pi} \sin\theta\cos\theta\, \mathrm{d}\theta \int_{E=0}^{\infty} fD(E)qv\, \mathrm{d}E, \tag{4.21.19}$$

where θ and φ are the polar and the azimuthal angles in spherical coordinates. The electrical conductivity is

$$\sigma \equiv \frac{J_Z}{\varepsilon_z} = -\frac{2q^2}{3m_C^*} \int_{E=0}^{\infty} \frac{\partial f_0}{\partial E} D(E)E\tau\, \mathrm{d}E, \tag{4.21.20}$$

where m_C^* is the conductivity effective mass and $D(E)$ is electron density of states. The relaxation time τ can be calculated assuming Matthiessen's rule. Key scattering mechanisms include electron–phonon (acoustic and intervalley), ionic impurity, and plasmon scattering (Fischetti, 1991). Figure 4.21.6 plots key scattering rates for silicon to illustrate their relative contribution at 300 K. Two different doping concentrations are considered for impurity scattering.

Properties of Phonons in Crystals

Atoms located at the lattice sites of a crystal undergo small oscillations about their equilibrium positions at all temperatures. The resulting atomic displacement field in the crystal stores and transports energy. Except in metals, they are the dominant contributors to thermal transport in solids. Quantum mechanically, the atomic displacement field may be described either as an infinite number of distinguishable, quantized oscillators, or as a gas of indistinguishable particles called phonons. Consider an atom with position vector $\boldsymbol{R}$, displaced from its equilibrium position $\boldsymbol{R}_0$ in the lattice by $\boldsymbol{u}$, where $\boldsymbol{R}=\boldsymbol{R}_0+\boldsymbol{u}$. The amplitude of motion is small, on the order of 10^{-3} nm compared to the interatomic spacing that is a few angstroms. The potential energy of the crystal can be expanded in a Taylor series in terms of the small displacements as

$$\Phi(\boldsymbol{R}) = \Phi(\boldsymbol{R}_o) + \sum_{\beta}\left[\left.\frac{\partial\Phi}{\partial u_\beta}\right|_{\boldsymbol{R}_o} u_\beta\right] + \frac{1}{2}\sum_{\beta,\beta'}\left[\left.\frac{\partial^2\Phi}{\partial u_\beta\,\partial u_{\beta'}}\right|_{\boldsymbol{R}_o} u_\beta u_{\beta'}\right] + \cdots, \tag{4.21.21}$$

where the subscript β is an index over the directions (x, y, or z). The first term in the expansion is constant. The derivative appearing in the second term represents net forces and must vanish when evaluated at the equilibrium position, $\boldsymbol{R}_o$. The derivative in the third term is a harmonic force constant assuming restoring forces are linear to the displacement. The series is typically truncated at this term assuming harmonic springs and the force constants can be used to obtain vibrational modes of the crystal. The equation of motion of an atom in the lattice along the direction β is

$$m\frac{d^2u_\beta}{dt^2} = -\frac{\partial\Phi}{\partial u_\beta} = -\frac{\partial}{\partial u_\beta}\left[\Phi(\boldsymbol{R}_o) + \frac{1}{2}\sum_{\beta,\beta'}\left[\left.\frac{\partial^2\Phi}{\partial u_\beta\,\partial u_{\beta'}}\right|_{\boldsymbol{R}_o} u_\beta u_{\beta'}\right]\right] = -\sum_{\beta'}\left.\frac{\partial^2\Phi}{\partial u_\beta\,\partial u_{\beta'}}\right|_{\boldsymbol{R}_o} u_{\beta'}, \tag{4.21.22}$$

where m is the mass of the atom.

To illustrate the idea, consider the simple case of motion along one direction (longitudinal) in a linear chain of atoms. The equation of motion for the pth atom in the chain can be written as

$$m\frac{\mathrm{d}^2u_p}{\mathrm{d}t^2} = \sum_j K_j\left(u_{p+j} - u_p\right), \tag{4.21.23}$$

where K_j is the force constant between the pth and the $(p+j)$th atom in the chain. The above equation takes plane waves as solutions of the form $u_p = Ae^{i(pka-\omega t)}$, where A, k, and ω are the amplitude, the wave number, and the frequency of the vibrational wave, respectively, and a is the interatomic spacing (or lattice constant). Inserting the solution into Equation 4.21.23 and solving yields the wave dispersion relation between frequency and wave number. Interatomic forces typically weaken beyond the first few neighbors. Assuming only the first neighboring atoms to have a nonzero force constant, the dispersion relation simplifies to

$$\omega = \sqrt{\frac{\sum_{j>0}\left[2K_j\left(1-\cos(jka)\right)\right]}{m}} = \sqrt{\frac{\left[2K_l\left(1-\cos(ka)\right)\right]}{m}} = \sqrt{\frac{4K_l}{m}}\left|\sin\left(\frac{ka}{2}\right)\right|, \tag{4.21.24}$$

where K_l is the longitudinal force constant between nearest neighbors. The above relation points out some of the prominent features of the phonon dispersion relation: Stiffer springs and lighter masses lead to higher frequency modes. The dispersion is nonlinear at large k's but linear in the limit of small k's. The speed at which a phonon of frequency ω transports energy is its group speed, given by the derivative of ω with respect to k,

$$v_{\mathrm{ph}}(k) = \left.\frac{\partial\omega}{\partial k}\right|_k. \tag{4.21.25}$$

In a three-dimensional crystal, there are several possible dispersion relations, corresponding to different types of motion. The lowest frequencies are associated with acoustic phonons that in the limit of long wavelength, travel at the speed of sound in the crystal. Acoustic phonons may be longitudinally or transversely polarized. A crystal lattice may have more than one atom at each lattice point. In crystals with such polyatomic bases, optical phonons exist in addition to acoustic phonons. In the limit of long wavelength, an optical phonon mode has atoms in the basis moving in opposing directions. This gives them a polar character and facilitates interaction with light. However,

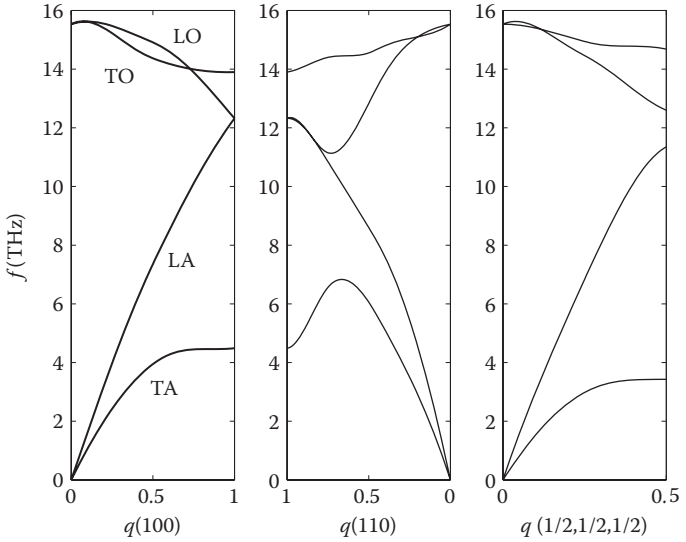

FIGURE 4.21.7 Realistic phonon dispersion relation for silicon along different crystallographic directions of high symmetry. The branches are longitudinal optical (LO), transverse optical (TO), longitudinal acoustic (LA), and transverse acoustic (TA).

optical phonons are higher in frequency and are not sufficiently excited at room temperature to dominate thermal transport. Their contribution, though small at room temperature, may still need to be considered for accurate predictions of thermal conductivity in certain crystals. Figure 4.21.7 plots the dispersion curves for phonons in silicon. The relation is different along different directions in the crystal.

The above description of the modes of vibration of a crystalline lattice is completely classical. To take into consideration quantum behavior, it is further necessary to treat the modes as independent quantum harmonic oscillators. For a three-dimensional lattice with N atoms, there are $3N$ possible modes corresponding to the degrees of freedom. The contribution of a particular mode (k, $\omega_s(\boldsymbol{k})$) to the total energy can only be discrete values of $\left(\overline{n}_{\boldsymbol{k},s}+1/2\right)\hbar\omega_s\left(\boldsymbol{k}\right)$, where s is an index for the phonon branch (whether acoustic or optical and whether longitudinal or transverse), $\overline{n}_{\boldsymbol{k},s}$ is the occupation of the mode at thermodynamic equilibrium given by the BE distribution. The BE distribution function for phonons is the same as the Planck distribution,

$$\overline{n}_{\boldsymbol{k},s}=\frac{1}{1-e^{\frac{\hbar\omega_s(\boldsymbol{k})}{k_BT}}}. \tag{4.21.26}$$

The internal energy density is then

$$u_{\text{ph}}=\frac{1}{V}\sum_{\boldsymbol{k},s}\hbar\omega\left(\overline{n}_{\boldsymbol{k},s}+\frac{1}{2}\right)+u_{\text{EQUILIBRIUM}}, \tag{4.21.27}$$

with the heat capacity of phonons per unit volume of the crystal being

$$C_{\text{ph}}=\left.\frac{\partial u_{\text{ph}}}{\partial T}\right|_{\text{V}}=\frac{1}{V}\frac{\partial}{\partial T}\sum_{\boldsymbol{k},s}\left[\frac{\hbar\omega_s\left(\boldsymbol{k}\right)}{1-e^{\frac{\hbar\omega_s(\boldsymbol{k})}{k_BT}}}\right]=\frac{\partial}{\partial T}\sum_{s}\int\frac{\mathrm{d}\boldsymbol{k}}{\left(2\pi\right)^3}\frac{\hbar\omega_s\left(\boldsymbol{k}\right)}{1-e^{\frac{\hbar\omega_s(\boldsymbol{k})}{k_BT}}}, \tag{4.21.28}$$

where the conversion from the sum to the integral relies on the fact that k points are closely spaced in wave vector space and that the volume per k-point is $V/(2\pi)^3$. Evaluation of the integral in Equation 4.21.28 correctly reproduces the heat capacity of solids as a function of temperature, with the classical Dulong–Petit law emerging in the limit of high temperatures. Figure 4.21.8 plots the heat capacity of phonons in platinum as a function of temperature. The heat capacity of electrons in the same metal is also plotted for the sake of comparison. At low temperatures, the phonon heat capacity varies as $\sim T^3$, a fact that is often used to interpret the thermal conductivity of novel materials.

Since the integrand in Equation 4.21.24 is a function of frequency, it is useful to integrate over frequency rather than $\boldsymbol{k}$. Similar to electrons, the conversion requires the use of the density of states. For phonons this is defined as the function $D(\omega)$ and counts the states between frequencies ω and $\omega+d\omega$ per unit volume and per unit frequency interval. For historical reasons, a simplified dispersion model is often used to evaluate the heat capacity. The Debye model of phonon dispersion assumes a linear, isotropic dispersion for acoustic phonons similar to photons in vacuum. All three phonon branches, corresponding to one longitudinal and two transverse polarizations, have the same dispersion relation, $\omega = c_D k$, where c_D is the Debye speed. However, unlike photons, the total number of phonon modes in the crystal is limited to $3N$ as discussed previously. To reflect this, a cutoff wave number, k_D is chosen such that the total number of states within a sphere of radius k_D is the total number of modes, $3N$. Despite the simplifications, the Debye model is surprisingly accurate in predicting the heat capacity of many crystals. The cutoff frequency corresponding to the cutoff wave number is called the Debye frequency, ω_D. The Debye temperature, θ_D is proportional to the Debye frequency and is related as $\theta_D = \hbar\omega_D / k_B$. At temperatures comparable to or below the Debye temperature, the quantum behavior of phonons is important. At higher temperatures, phonons behave classically as the normal modes of vibrations of a crystal lattice. The phonon density of states in three-dimensions, assuming Debye dispersion is useful in evaluating the integral in Equation 4.21.28 and is given by

$$D(\omega) = \frac{3}{2\pi^2}\frac{\omega^2}{c_D^3}, \omega \le \omega_D . \tag{4.21.29}$$

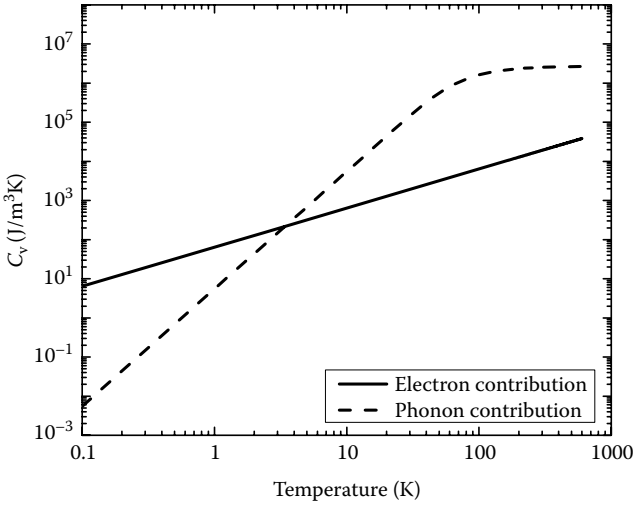

FIGURE 4.21.8 Comparison of the contribution of electrons (solid line) and phonons (dashed line) to the volumetric heat capacity of a solid (metal) as a function of temperature. The electronic contribution is significant only at low temperatures ($\lesssim$10 K). (Figure prepared by Dhruv Gelda.)

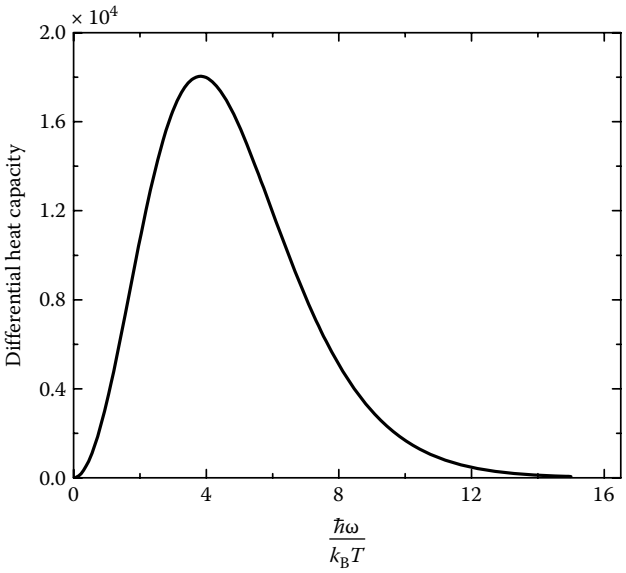

FIGURE 4.21.9 Contribution of different frequencies to the heat capacity of silicon as per the Debye model. The peak occurs close to 4 $k_B T$. The heat capacity is the area under the curve up to the Debye frequency.

Figure 4.21.9 plots the spectral contribution to the heat capacity using the Debye model. Table 4.21.2 lists properties related to phonons for some common solids.

Theory of Interfacial Thermal Transport

Thermal transport across interfaces holds special significance in thermal transport involving electronic micro- and nanostructures. With ever-increasing materials integration, modern integrated circuits are brimming with material interfaces that have significant impact on heat flow. The theory of interfacial thermal transport offers qualitative insight but is usually not quantitatively accurate. Quantitative theories invariably involve atomistic models that remain unwieldy for practical purposes. Generally, good experimental data on thermal transport across interfaces are an important part of device and circuit thermal design. Thermal interfaces fall in two broad categories: Atomically jointed interfaces where a chemical bond exists at the interface and mechanically jointed interfaces

TABLE 4.21.2
Properties of Phonons in Solids

Solid	Atomic Density (10^{28} m^{-3})	Mass Density (10^3kg/m3)	Longitudinal Phonon Velocity (km/s)	Transverse Phonon Velocity (km/s)	Debye Temperature Θ_D (K)
Si	5.00	2.33	8.97	5.33	645
C (diamond)	17.6	3.51	17.5	12.8	2230

where the materials are forced together by mechanical forces. Microscopic theory is necessary to understand the first, whereas continuum heat conduction and contact mechanics provide insight into the second. The focus of this chapter is on the microscopic theory of interfacial thermal transport.

When heat flows across an atomically perfect interface between two solids, a temperature jump ΔT arises at the interface corresponding to a thermal resistance at the interface. Initially discovered by Kapitza (Swartz and Pohl, 1989) while investigating the superfluidity of helium at low temperatures, the interfacial resistance between liquid helium and a solid (and often between two dielectric/semiconducting solids) is also called the Kapitza resistance. The theoretical picture of interfacial thermal transport involves the net radiation of energy across the interface via the crossing of energetic particles. For a more detailed picture, it is necessary to consider the dominant energy carriers on the two sides of the interface. Figure 4.21.10 illustrates the two broad classes of interfaces. In an interface between two metals, thermal transport involves the transmission of electrons across the interface. In an interface between a metal and a dielectric, energy must be transferred from the electron gas in the metal to the phonon gases in the metal and the dielectric. For an interface between dielectrics/semiconductors, only phonon transport across the interface needs to be considered.

Consider a dielectric–dielectric interface with a differential temperature drop δT across it. Ignoring any electron–phonon and inelastic scattering processes, the problem reduces to the net radiation of phonons across the interface. The net heat current from side 1 to 2 is the difference between the currents crossing the interface from either side and can be written as

$$q_{\text{net}} = \frac{1}{2}\left[\begin{array}{c} \sum_s \int \frac{d\boldsymbol{k}_1}{(2\pi)^3} \left|\boldsymbol{v}(\omega,\boldsymbol{k}_1)\cdot\hat{\boldsymbol{n}}_1\right| \hbar\omega(\boldsymbol{k}_1)\alpha_{12}(\omega,\boldsymbol{k}_1)\left[\bar{n}(\omega, T+\delta T)\right]- \\ \sum_s \int \frac{d\boldsymbol{k}_2}{(2\pi)^3} \left|\boldsymbol{v}(\omega,\boldsymbol{k}_2)\cdot\hat{\boldsymbol{n}}_2\right| \hbar\omega(\boldsymbol{k}_2)\alpha_{21}(\omega,\boldsymbol{k}_2)\left[\bar{n}(\omega, T)\right] \end{array}\right], \tag{4.21.30}$$

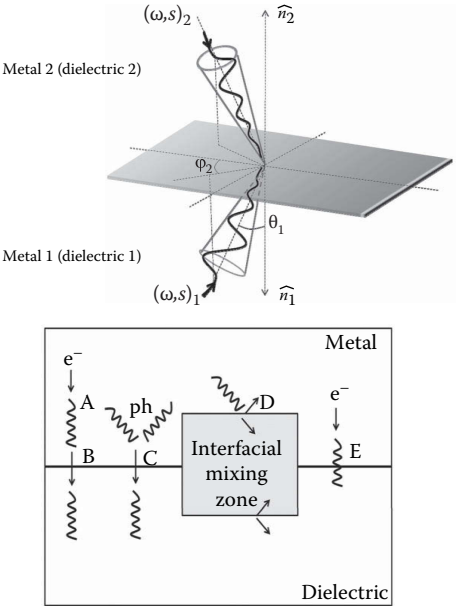

FIGURE 4.21.10 The geometry for considering thermal interface conductance between two metals or dielectrics (or semiconductor) is shown on top. The consideration for metal–dielectric (or semiconductor) is more complex involving several possible channels for energy transfer across the interface. (Adapted from Singh, P. et al., *Appl. Phys. Lett.*, 102, 181906, 2013. With permission.)

where $\hat{\boldsymbol{n}}_i$ is the unit normal at the interface into side i, α_{ij} is the probability that a carrier incident from side i crosses into j, and the factor 1/2 is included to reflect the fact that only half the phonons near the interface on either side are incident toward the interface. The integration is over all possible $\boldsymbol{k}$ on each side of the material. Note that the two integrals do not have the same k space for integration.

Each of the integrands can be written out in spherical coordinates and the integration can be performed over all frequencies and solids angles. The geometry is shown in Figure 4.21.10. For example, the current at the interface from side 1 can be written as

$$q_1 = \sum_s \int_{\omega=0}^{\omega_{\max,1}} \int_{\varphi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \alpha_{12} \frac{1}{4\pi} \hbar\omega v_1 \cos\theta D_1(\omega) \bar{n}(\omega, T+\delta T) \sin\theta \, d\theta \, d\varphi \, d\omega, \tag{4.21.31}$$

where α and v are, in general, functions of $(\omega, \theta, \varphi)$. The two transmission coefficients α_{12} and α_{21} are related as follows. At thermal equilibrium, the net current must be zero. The two integrals in Equation 4.21.30 can be merged into one by performing the integration to the higher of the two cutoff frequencies and explicitly noting that the density of states function in the material with the smaller cutoff frequency will be zero past the cutoff frequency. For the new integral to vanish, the condition is

$$\alpha_{12}(\omega,\theta,\varphi) v_1(\omega,\theta,\varphi) D_1(\omega) = \alpha_{21}(\omega,\theta,\varphi) v_2(\omega,\theta,\varphi) D_2(\omega), \tag{4.21.32}$$

where the subscripts for v and D indicate that they are different functions for the two sides. Thus, knowing the function α from either side is sufficient to calculate the integral in Equation 4.21.30.

To obtain an expression for the interfacial conductance, consider the limit of small δT to Taylor expand the function $\bar{n}(\omega, T+\delta T)$. From Equations 4.21.30 through 4.21.32, the interfacial thermal conductance is

$$G = \sum_s \int_{\omega=0}^{\omega_{\max,1}} \int_{\varphi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \alpha_{12} \frac{1}{4\pi} \hbar\omega v_1 \cos\theta D_1(\omega) \frac{\partial \bar{n}(\omega, T)}{\partial T} \sin\theta \, d\theta \, d\varphi \, d\omega, \tag{4.21.33}$$

where we have assumed that side 1 has the higher cutoff frequency. If side 2 has the higher cutoff frequency, the integration limit for frequency in Equation 4.21.33 would be $\omega_{\max,2}$, with the functions v_1 and D_1 set to zero for frequencies between the two cutoff frequencies. Equivalently, the calculation can proceed from side 2 if α_{21} is known instead of α_{12}, again with the integration limit for frequency set to the higher of the two cutoff frequencies.

The transmission function can be fairly complicated in reality since it not only depends on the bulk phonon properties of the two materials but also on the chemical (for example, bonding) and physical (for example, roughness or dislocations) state of the interface. Extant models only consider ideal interfaces and make further simplifying assumptions. The two popular models are the acoustic mismatch model (AMM) and the diffuse mismatch model (DMM). Neither is quantitatively reliable when compared against experimental data. Their utility lies more in providing physical insight into temperature dependence, for instance. Due to their simplicity, they continue to be popular in the literature.

The AMM (Khalatnikov, 1952) theorizes that the resistance arises due to the difference in acoustic properties of two media. At low temperatures, only long wavelength phonons (corresponding to sound waves in the crystal) are excited. Due to differences in acoustic speeds, phonon momentum is different in the two media. (In the limit $k \to 0$, the phonon momentum is $\hbar k$). In general, it is

difficult to satisfy both momentum and energy conservation for a phonon traversing the interface, leading to a resistance. In terms of acoustics, this can be thought of as an acoustic impedance mismatch at the interface. Khalatnikov's original formulation considers the interface between liquid He and copper but the formulation can be revised to consider the more complicated interface of two elastic solids. In either case, it is possible to show that the thermal conductance at the interface is finite and proportional to T^3. The transmission coefficient for longitudinal phonons at the interface between elastic solids is

$$\alpha_{12} = \frac{4\dfrac{\rho_2 c_{l2}}{\rho_1 c_{l1}}\dfrac{\cos\theta_2}{\cos\theta_1}}{\left(\dfrac{\rho_2 c_{l2}}{\rho_1 c_{l1}} + \dfrac{\cos\theta_2}{\cos\theta_1}\right)^2}, \tag{4.21.34}$$

where ρ is the mass density and c_l is the longitudinal speed of sound in the medium. The function depends on the angle θ. The angle on the other side of the interface may be eliminated from the expression during calculations by using the acoustic Snell's law for refraction, $c_{l2}\sin\Theta_1 = c_{l1}\sin\Theta_2$. While the theory explains the qualitative behavior of the interfacial resistance versus temperature, it is not quantitatively reliable. Several modifications have been suggested over the decades since Khalatnikov's work but a quantitatively accurate general-purpose theory at low temperatures is still lacking.

The DMM (Swartz and Pohl, 1989) theorizes that the resistance arises due to the mismatch in the phonon density of states. The key idea is that, at room temperature, phonon wavelengths contributing to heat conduction are comparable to the mean surface roughness height. Therefore, scattering should be diffusely at the interface and randomize the wave vector and polarization of the phonon. The principle of detailed balance and the fundamental definition of diffuse scattering are cleverly employed to obtain the transmission coefficient of phonons. The Debye approximation is used in the original formulation but more accurate dispersion can be inserted instead to evaluate the transmission coefficient. The model predicts a ~T^3 behavior for the thermal conductance but provides a different quantitative value than the AMM. The transmission coefficient for DMM assuming the Debye dispersion model for the two materials is

$$\alpha_{12} = \frac{\sum_s c_{2,s}^{-2}}{\sum_s c_{1,s}^{-2} + \sum_s c_{2,s}^{-2}}, \tag{4.21.35}$$

where the summations are over the phonon polarizations. The coefficient is independent of phonon frequency and incidence angle.

Within the Debye model, the interfacial thermal conductance for AMM (DMM) simplifies to

$$G_{\text{AMM (DMM)}} = \left(\frac{k_B T}{\hbar}\right)^3 \frac{k_B}{2}\frac{3}{\pi c_D^2}\Gamma_{\text{AMM (DMM)}} \int_0^{\Theta_D/T} \frac{z^4 e^z \mathrm{d}z}{\left(e^z - 1\right)^2}, \tag{4.21.36}$$

where the function Γ depends on the choice of the model and is given by

$$\Gamma_{\text{AMM}} = \int_0^{\min\left(\frac{\pi}{2},\Theta_{\text{MAX}}\right)} \alpha(\theta)\sin\theta\cos\theta\ \mathrm{d}\theta;\ \Gamma_{\text{DMM}} = \frac{\alpha_{\text{DMM}}}{2}. \tag{4.21.37}$$

The upper limit of the integral for AMM must be carefully considered for total internal reflection when the transmission is into the material with the higher speed of sound. The upper limit in this case will be less than $\pi/2$.

Another important benchmark for interfacial thermal conductance is the radiation limit (Stoner and Maris, 1993). In this limit, all phonons incident from the side with the lower density of states have a transmission coefficient of unity. At temperatures large compared to the Debye temperature, this simplifies to

$$G_{\mathrm{RAD}} = \frac{k_{\mathrm{B}}\omega_{\mathrm{D,1}}^3}{24\pi^2}\sum_s\left(\frac{1}{c_{s,2}^2}\right), \tag{4.21.38}$$

where 1 is the side with the lower Debye frequency.

Heat flow across metal–dielectric interfaces are complicated by the involvement of the energy transfer between electrons and phonons. While data suggest that the coupling between electrons and phonons plays an important role, it is still unclear which electron–phonon couplings are relevant: with phonons in the metal, with phonons in the dielectric, or with interfacial phonon modes. One approach is to consider the electron–phonon conductance $G_{\mathrm{e-ph}}$ and the phonon–phonon $G_{\mathrm{ph-ph}}$ conductance in series (Majumdar and Reddy, 2004). The DMM provides the phonon–phonon conductance $G_{\mathrm{ph-ph}}$. The net conductance is

$$G_{\mathrm{net}} = \frac{G_{\mathrm{e-ph}}G_{\mathrm{ph-ph}}}{G_{\mathrm{e-ph}} + G_{\mathrm{ph-ph}}}. \tag{4.21.39}$$

Obtaining $G_{\mathrm{e-ph}}$ presents some difficulty. An empirical approach is to assume a small departure from equilibrium. An energy balance based on the Fourier law yields an electron–phonon thermal conductance, $G_{\mathrm{e-ph}} = \sqrt{Bk_{\mathrm{p}}}$ (Majumdar and Reddy, 2004), where B is the electron cooling rate and k_{p} is the phonon thermal conductivity of the metal. Another approach is to obtain $G_{\mathrm{e-ph}}$ directly from the Bloch–Boltzmann–Peierls formula for electron–phonon interaction (Singh et al., 2013). With this, the expression is

$$G_{\mathrm{e-ph}} = \frac{D_{\mathrm{ac}}^2 m^{*2} k_{\mathrm{B}} T_{\mathrm{e}} L}{4\pi^3\hbar^3\rho(T_{\mathrm{e}} - T)}\int_0^{q_{\mathrm{D}}} q^3\left(\left(e^{\frac{\hbar v_{\mathrm{s}} q}{k_{\mathrm{B}}T}} - 1\right)^{-1} - \left(e^{\frac{\hbar v_{\mathrm{s}} q}{k_{\mathrm{B}}T_{\mathrm{e}}}} - 1\right)^{-1}\right)\left(\ln\left(\frac{1 + e^{\frac{E_{\mathrm{F}}}{k_{\mathrm{B}}T_{\mathrm{e}}}} e^{-\left(\frac{\hbar^2 q^2}{8m^*} + \hbar v_{\mathrm{s}} q\right)/k_{\mathrm{B}}T_{\mathrm{e}}}}{1 + e^{\frac{E_{\mathrm{F}}}{k_{\mathrm{B}}T_{\mathrm{e}}}} e^{-\frac{\hbar^2 q^2}{8m^* k_{\mathrm{B}}T_{\mathrm{e}}}}}\right)\right)\mathrm{d}q, \tag{4.21.40}$$

where D_{ac} is the deformation potential for electron scattering by acoustic phonons, v_{s} is the speed of longitudinal waves, q is the phonon wave vector, ρ is the density of the metal, and L is the characteristic length scale for energy transfer. A suitable choice is $L = 3\Lambda_{\mathrm{e}}$, where Λ_{e} is the electron mean free path in the metal. This corresponds to ~95% energy loss. The electron gas is assumed to be in equilibrium at temperature T_{e} and the phonons to be in equilibrium at temperature T.

Heat flow across metal–metal interfaces is important in technologies such as heat-assisted magnetic recording, spintronics, and magnetic sensors. Recent measurements (Wilson and Cahill, 2012) on metal multilayers (Al/Cu and Pd/Ir) have experimentally validated the Wiedemann–Franz law for metal–metal interfaces,

$$\frac{G_{\mathrm{e-e}}AR}{T} = L_{\mathrm{o}}, \tag{4.21.41}$$

where $G_{\mathrm{e-e}}$ is the interfacial thermal conductance per unit area due to electron transport, AR is the specific electrical resistance of the interface, and L_{o} is the Lorenz number estimated from the

Sommerfeld theory discussed above. Further, the value of G can also be obtained from a DMM for electrons, similar to the consideration above. The expression for G in this case is

$$G_{e-e} = \frac{Z_{e1} Z_{e2}}{4\left(Z_{e1} + Z_{e2}\right)}, \tag{4.21.42}$$

where $Z_e = \gamma T v_F$ is the product of the electron heat capacity per unit volume and the Fermi velocity for each side, respectively.

Modeling Techniques for Materials, Devices, and Circuits

The basic theory described above provides the framework for simulating the thermal behavior of electronic materials, devices, circuits, and packaging. The most detailed models in terms of physics are at the materials level. At the device and circuit levels, the interplay with electrical behavior is important and hence, the emphasis is on electrothermal simulations. In contrast, at the package level, mechanical integrity becomes important and hence, thermomechanical modeling forms the focus. The implementation of thermal models in circuit simulations and packaging is discussed later. The basic thermal equation in these cases is the heat diffusion equation. Here, we discuss detailed physical models of heat conduction at the materials and device levels.

Since phonon wavelengths that dominate heat conduction are approximately 0.1–2 nm at room temperature, a full quantum treatment of heat conduction is rarely warranted at room temperature unless the characteristic dimension approaches nanometers rather than several tens of nanometers. Generally, semiclassical and classical methods for modeling phonon transport are adequate. Semiclassical modeling involves either the use of the phonon BTE (Sinha and Goodson, 2005) with varying details of phonon dispersion or the Monte Carlo (MC) (Liu, 2001; Péraud et al., 2014) technique to statistically simulate phonon transport. Another choice is molecular dynamics (MD), which though classical in origin can be extended to a semiclassical treatment, and involves the use of the linear response theory to compute transport coefficients. MD can also be used to compute physical parameters needed by the BTE (Allen and Tildesley, 1987). Figure 4.21.11 summarizes the hierarchy of semiclassical thermal modeling and highlights the main features of each approach.

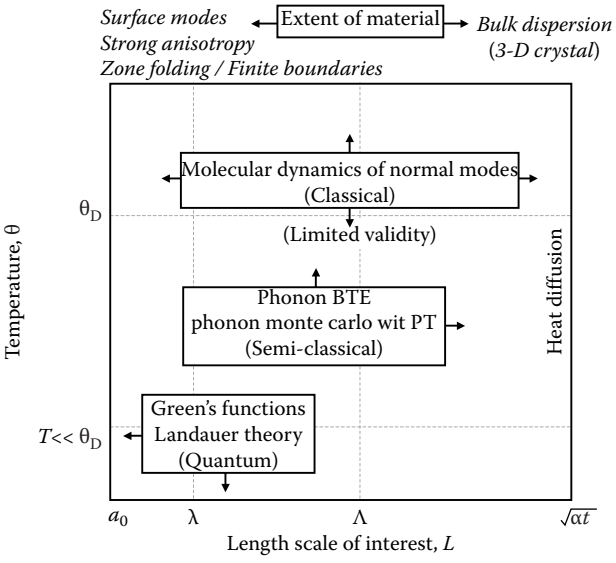

FIGURE 4.21.11 Regimes for subcontinuum thermal modeling relevant to electronics. (Adapted from Sinha, S. and K.E. Goodson, *Int. J. Multiscale Comput. Eng.*, 3, 107–33, 2005. With permission.)

The phonon BTE (also called the Peierls BTE) (Peierls, 1955) is the fundamental semiclassical equation to describe phonon heat conduction in solids. The fundamental assumption in deriving the phonon BTE is that there exists a distribution function, $n_{q,s}(\boldsymbol{r},t)$, which provides the average occupation of the phonon mode ($\boldsymbol{q}$, s), in the neighborhood of a location $\boldsymbol{r}$ at time t. The equation assumes the simultaneous prescription of phonon position and momentum with arbitrary precision. However, in quantum mechanics, these quantities correspond to noncommuting operators and hence, obey the uncertainty principle. The semiclassical BTE for phonons resolves this contradiction by treating phonons as wave formed from a superposition of the normal modes of the crystal such that each wave packet has a small spread δq in the wave vector and is localized in space in a region of size δr such that $\delta q \delta r \sim 1$. Figure 4.21.12 illustrates a spatially Gaussian phonon wave packet (Sinha et al., 2005).

In the semiclassical model, the number of phonons becomes a function not only of the wave vector $\boldsymbol{q}$ and polarization s but also of the spatial coordinate $\boldsymbol{r}$. This evolves in time in a six-dimensional phase space due to motion in real space, due to anharmonic scattering with other phonons, and due to scattering with impurities and boundaries. The solution to the phonon BTE requires the evaluation of the collision term. Though Peierls obtained the formal expression as an integral in wave-vector space over all allowed scattering processes, it is too complicated to be directly evaluated in practice. Instead, the relaxation time approximation has been widely used, with explicit solutions available in the literature for deriving the thermal conductivity. The derivations of the relaxation times involve time-dependent perturbation theory from quantum mechanics (see Kroemer (1994), for example).

Klemens (Han and Klemens, 1993) and others (Callaway, 1959; Holland, 1963) have developed semiempirical expressions for the relaxation rates that model thermal conductivity data over a wide range of temperatures. It is important to note that the original expressions are evaluated using simplified phonon dispersion relationship. Mass difference (isotope) and Umklapp scattering are of the form $\tau_m^{-1} = A\omega^4$ and $\tau_U^{-1} = BT\omega^2 e^{-C/T}$. The value of A depends on the isotope concentration. A commonly used value is (Holland, 1963) $A = 1.32 \times 10^{-45}$ s^3. Using values from Holland (1963) as a starting point, the values of B, C, and the cutoff frequency ω_C can be iteratively determined to simultaneously fit the high-temperature thermal conductivities of bulk silicon and silicon nanostructures, respectively (Li, 2002). Following this procedure, the values are $B = 1.6 \times 10^{19}$ s/K, $C = 152$ K, and $\omega_C = 4.3 \times 1013$ rad/s. The relaxation rate for boundary scattering is available from several models. Figure 4.21.13 plots the scattering rates for phonons in silicon as a function of frequency.

In the simplest Casimir limit, phonons are assumed to scatter diffusely at the boundaries without any other scattering mechanisms present in the bulk of the crystal. The rate is given by $\tau_B^{-1} = v / L_C$, where L_C is the limiting (smallest) size of the crystal and v is the phonon speed. If other scattering

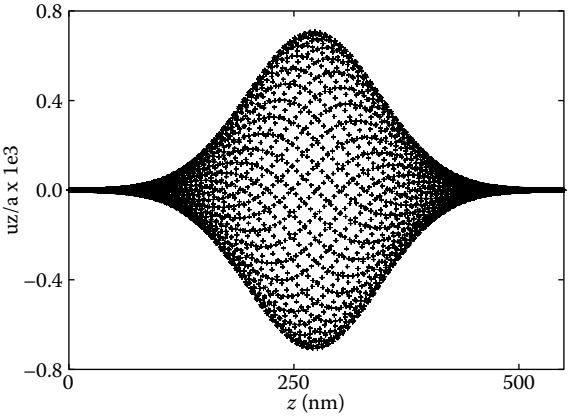

FIGURE 4.21.12 The spatial distribution of energy in an LO phonon wave packet. (Adapted from Sinha, S. and K. E. Goodson, *Int. J. Multiscale Comput. Eng.*, 3, 107–33, 2005. With permission.)

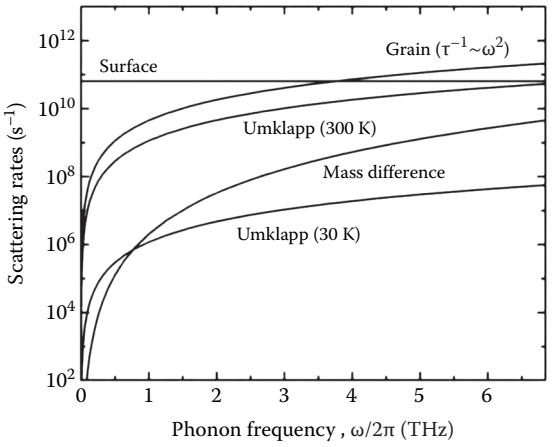

FIGURE 4.21.13 Frequency-dependent phonon scattering rates calculated for silicon. Rates for Umklapp scattering are shown at 30 and 300 K. The characteristic dimension for the surface as well as grain boundary scattering is assumed to be 100 nm in each case. (Adapted from Ma, J. et al., *Nano Lett.*, 13 (2), 618–24, 2013. With permission.)

mechanisms may be assumed to have an overall scattering time τ, an analytical solution to the BTE proposed by Fuchs and Sondheimer (Fuchs, 1938; Sondheimer, 1952) applies. Figure 4.21.14 plots the reduction in thermal conductivity from the value in the bulk as a function of the ratio of the crystal size to the mean free path. Scattering at the boundary may be fully diffuse or may have a partially specular character. This is modeled using a single parameter termed the specularity, p. The specularity parameter reflects the physics that a part of the phonon spectrum with long wavelength should be specular and the part with wavelengths comparable to the surface roughness height should be diffuse. Boundary scattering at room temperature is typically assumed to be diffuse since phonon wavelengths contributing to thermal conduction are a few nanometers and comparable to the surface roughness heights. This corresponds to $p=0$ with $p=1$ being fully specular.

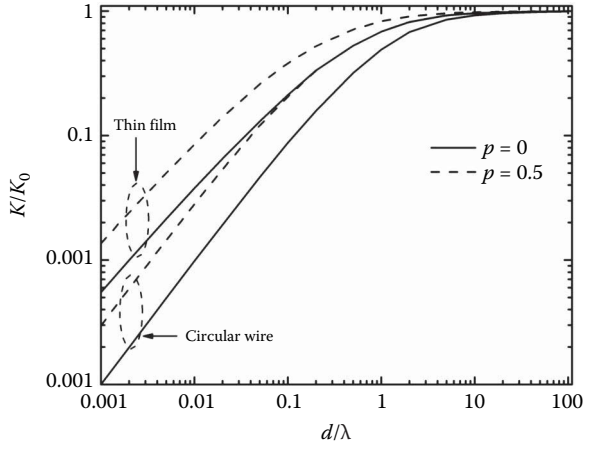

FIGURE 4.21.14 The ratio of thermal conductivity in a finite-size crystal to that in the bulk based on the Fuchs–Sondheimer model (Sondheimer, 1952). The ratio is shown for circular wires and thin films. The x-axis is the ratio of the characteristic length (wire diameter or film thickness) normalized by the MFP. Solid and dashed curves represent specularity, p of 0 and 0.5, respectively.

A key conceptual problem in using the relaxation time approximation is the requirement for a thermodynamic temperature that governs the scattering rate. Since phonons are not in an equilibrium distribution during transport, the temperature cannot be defined in a rigorous sense. The usual practice in such nonequilibrium problems is to define an *ad hoc* "equivalent" temperature based on the local energy (Majumdar, 1993; Chen, 1996, 2001; Sverdrup et al., 2000). We note that this equivalent temperature does not represent the local phonon population but rather the local energy density.

Recent state-of-the-art simulations of thermal conductivity (Ward and Broido, 2011; Esfarjani et al., 2011) have used *ab initio* calculations of the quantum mechanical Schrödinger wave equation to compute interatomic force constants including anharmonic terms. This allows a direct computation of phonon–phonon scattering rates and hence, the thermal conductivity of a bulk material. Figure 4.21.15 shows the computed contributions of different phonon wavelengths and mean free paths to the thermal conductivity of silicon at 277 K. Phonon mean free paths span a range from 10 nm to 10 μm, with substantial contributions from phonons with mean free paths in the micrometers. The range of wavelengths is from 0.1 to ~1 nm.

Solution techniques for the BTE span a range, from MC simulations with detailed scattering rates but relatively small and simple spatial domains to discrete ordinates methods that are suitable for radiative transfer-type formulations of the BTE. The MC method is a statistical sampling technique that can be applied to a wide variety of problems, from simulating a complex physical system such as neutrons in a reactor to solving a mathematical problem such as an integration in multidimensional space. In the MC method, a physical process may be simulated directly without requiring knowledge of the underlying governing equations. The sole requirement is that the process be describable in terms of probability density functions (pdfs). The simulation proceeds by sampling from the pdfs using a computer-generated sequence of random numbers. The MC technique can be applied to simulating a distribution of phonons by tracking the trajectories of individual phonons in phase space, provided the pdfs associated with all scattering events are known. The probabilities for phonon–phonon scattering are particularly difficult to evaluate rigorously in a phonon MC scheme. Instead, the relaxation time approximation is typically employed to make calculations feasible.

The linearized solution to the phonon BTE is of limited usability in modeling transport where the departure from equilibrium is significant. The equation for phonon radiative transfer (EPRT) (Majumdar, 1993) mimics the radiative transfer equation for photons for which solution techniques

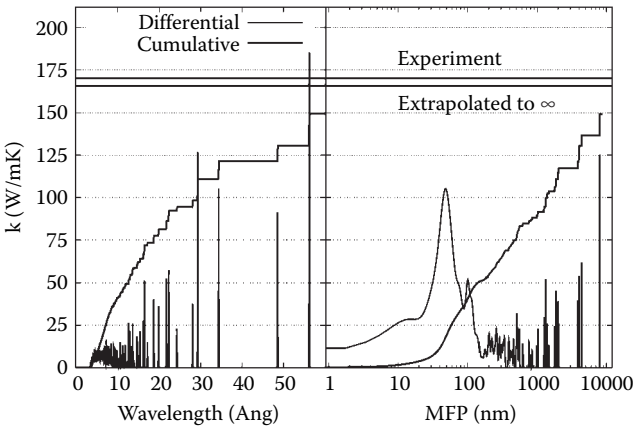

FIGURE 4.21.15 Cumulative contributions of phonons to the thermal conductivity at 277 K, showing contribution based on wavelength (left) and mean free paths (right). Both differential and cumulative thermal conductivities are shown. For comparison, the extrapolated (to infinite k-point mesh) and experimental κ are also shown with horizontal lines at 166 and 174 W/mK, respectively. (Adapted from Esfarjani, K. et al., *Phys. Rev. B*, 84, 085204, 2011. With permission. Copyright 2011 American Physical Society.)

are well developed. The EPRT is written in terms of the phonon intensity, I_ω, with the one-dimensional form being

$$\frac{1}{v}\frac{\partial I_\omega}{\partial t}+\mu\frac{\partial I_\omega}{\partial x}=-\frac{I_\omega-I_\omega^o\left(T\left(x\right)\right)}{v\tau}, \tag{4.21.43}$$

where μ is the direction cosine and v is the (Debye) velocity. The phonon intensity is given as

$$I_\omega=\sum_s vn\left(\omega\left(q,s\right),x,t\right)\hbar\omega D\left(\omega\right). \tag{4.21.44}$$

The EPRT reproduces the expected radiative behavior in the acoustically thin limit and conforms to the Fourier heat flux law in the continuum limit. The EPRT has been used to investigate transport in thin films (Majumdar, 1993; Joshi and Majumdar, 1993; Zeng and Chen, 2000), interfacial transport (Majumdar, 1991), subcontinuum heat sources (Narumanchi et al., 2003), and ballistic conduction from nanoparticles (Chen, 1996).

Another modification of the phonon BTE is the ballistic-diffusive transport equations (BDEs) (Chen, 2001), in which the form of the distribution function is assumed *a priori*. The BDE divides the distribution function, n, at any point into a ballistic, n_b and a diffusive part, n_m. The ballistic part originates from the boundary and experiences out-scattering only, while the diffusive part originates inside the domain and evolves through in-scattering or through a source term. The equations are formally written as

$$\begin{aligned}\frac{1}{|\boldsymbol{v}|}\frac{\partial n_b}{\partial t}+\hat{\boldsymbol{\Omega}}\cdot\nabla n_b&=-\frac{n_b}{|\boldsymbol{v}|\tau}\\ \frac{\partial n_m}{\partial t}+v\cdot\nabla n_m&=-\frac{n_m-\overline{n}}{\tau},\end{aligned} \tag{4.21.45}$$

where $\hat{\boldsymbol{\Omega}}$ is the unit vector along the direction of propagation. Under the gray body approximation, the solution to the BDE matches the solution to the phonon BTE reasonably well. A formulation that is conceptually similar to the BDE but has been developed specifically for semiconductor devices is the split-flux model (Sinha and Goodson, 2005).

The application of the BTE to device problems has focused on the "phonon hotspot" effect. The solution to the BTE for phonon transport in the vicinity of a nanoscale heat source (Chen, 1996) with dimensions smaller than the mean free path reveals a region of nonequilibrium next to the heat source. Phonons emitted from the source do not scatter immediately outside, as is implicitly assumed under the Fourier law. Rather, they travel ballistically over long distances compared to the dimensions of the source. From the perspective of the Fourier law, however, transport is diffusive. The difference between the two temperature profiles is shown for a one-dimensional heat source in Figure 4.21.16. The BTE predicts the effective temperature rise to be larger than the Fourier law. Effectively, this can be thought of as an added thermal resistance to the thermal resistance predicted by the Fourier law.

Fundamental thermal transport in different materials can also be simulated using MD. In new materials where relaxation times are difficult to calculate or obtain, molecular simulations present a better path to understanding heat conduction physics. MD refers to the solution of classical equations of motion (Newton's laws) for a set of molecules. In the context of phonon transport in solids, this amounts to solving the dynamics of atoms in a crystal lattice. For a system of p atoms interacting through a potential, Φ, the equation of motion for the ith atom is

$$m_i\ddot{\boldsymbol{r}}_i=-\nabla_{r_i}-\Phi, \tag{4.21.46}$$

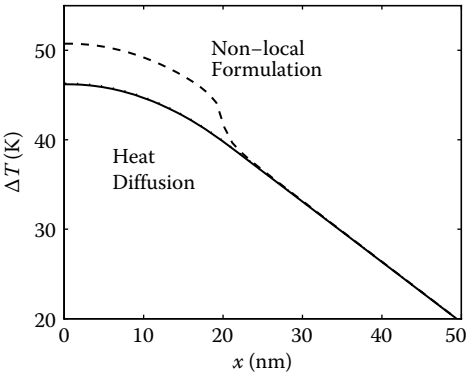

FIGURE 4.21.16 When the characteristic dimension becomes comparable to the energy carrier mean free path, subcontinuum phenomena outside the Fourier law can be observed. Temperatures near a subcontinuum heat source can be elevated compared to predictions from heat diffusion. (Adapted from Sinha, S., and K. E. Goodson, *Int. J. Multiscale Comput. Eng.*, 3, 107–33, 2005. With permission.)

where $\boldsymbol{r}$ is the position of the atom. The interatomic potential has the general form

$$\Phi = \sum_i \Phi_1(\boldsymbol{r}_i) + \sum_i \sum_{j>i} \Phi_2(\boldsymbol{r}_i, \boldsymbol{r}_j) + \sum_i \sum_{j>i} \sum_{k>j>i} \Phi_3(\boldsymbol{r}_i, \boldsymbol{r}_j, \boldsymbol{r}_k) + \cdots, \tag{4.21.47}$$

where Φ_1 is the self-potential, Φ_2 is the contribution from pairs of atoms, and Φ_3 is the contribution from triplets of atoms. A potential that includes terms only till Φ_2 is called a pair potential. A three-body potential includes terms up to Φ_3. Finite difference algorithms (Allen and Tildesley, 1987) such as the Verlet or the Gear predictor–corrector are used to solve the system at each time step, which is usually less than a femtosecond. Computational constraints dictate that a trade-off be made between the size of the system and the time for the simulation. Since the maximum phonon wavelength is given by the size of the system, long wavelength phonons are cut off in an MD simulation. Use of periodic boundary conditions and a careful choice of the system size offset this limitation. Parallelization permits simulations of systems comprising tens of thousands of atoms. MD has generally been used in thermal modeling to compute phonon relaxation times, the thermal conductivity of materials, and the thermal conductance of interfaces. *Ab initio* simulations can be further combined with MD (Ward and Broido, 2011; Esfarjani et al., 2011) to compute the interatomic forces and consequently phonon relaxation times and mean free paths. These simulations represent the state of the art in the thermal modeling of materials.

In simulations of semiconductor devices, charge transport is the primary focus. When a thermal part is included, the simulations are referred to as electrothermal simulations. Electrothermal transport in a semiconductor device involves charge transport by electrons and holes and energy transport by phonons, with the two systems interacting strongly. The charge carriers gain energy from the applied electric field and subsequently lose it to the lattice while restoring thermodynamic equilibrium through scattering. The process may proceed in the reverse direction as well since electrons and holes may absorb lattice phonons and gain energy. The latter occurs near the device source where phonon absorption enables the less energetic carriers to overcome the potential barrier. At the drain terminal, electrons shed energy gained from the field by emitting phonons. In addition, charge carriers also interact with photons during generation and recombination.

Semiclassical electron transport in a device is governed primarily by three sets of equations (Muller and Kamins, 1977; Blotekjaer, 1970). The first is a set of equations for conservation of particles. The second set relates the particle currents to the field and the particle gradients, and finally, the Poisson equation provides the electrostatic potential inside the device due to charged immobile

dopant atoms and mobile carriers. This basic set comprises what is known as the drift-diffusion model (Blotekjaer, 1970). The drift-diffusion model does not include an energy conservation equation but instead assumes isothermal conditions. This can lead to inaccuracies in the diffusion term since temperature dependence is ignored. The next model in the hierarchy is the hydrodynamic model (Wachutka, 1990), which includes an energy equation. The constitutive equations for continuity and momentum are derived by taking moments of the Boltzmann equation for electrons. Heat generation is derived rigorously from irreversible thermodynamics using Onsager's relations. Higher in the hierarchy are MC device simulations (Fischetti and Laux, 1993) that track the trajectory of electrons inside the device. The MC method implements a quantum mechanical description of electron–phonon scattering.

Thermometry Techniques

Measurements are a key component in the thermal engineering of electronic micro- and nanostructures, offering insight and data where the guidance of theory is often qualitative. Thermometry at micro- and nanoscale dimensions requires sophisticated miniaturized probes that often need to be custom designed and fabricated in semiconductor cleanrooms. In almost all cases, the experimental structure requires cleanroom fabrication. Like macroscopic measurements, measurements at microscopic scales may also employ thermocouples. However, there exist several options beside thermocouples: Electrical resistance thermometry relies on the change in electrical resistance of metals or semiconductor diodes with temperature. Thermoreflectance relies on the change in reflectance (originating in the change in the complex dielectric constant) with temperature. Raman thermometry relies on the shift in the frequency of the Raman line with temperature. Infrared thermometry relies on measuring emission characteristics in the infrared. Thermal expansion of a polymer is used as the transducer in Joule expansion thermometry. Length scales approaching a few nanometers and timescales approaching a few picoseconds can be measured, though not simultaneously. Temperature changes as small as 100 mK are routinely measured.

Among experimental thermometry techniques intended for measuring material properties, the more important ones are the 3-omega (3-ω) method and frequency domain thermoreflectance for micrometer scale thin films, time-domain thermoreflectance (TDTR) for nanometer scale thin films, suspended bridge platform for one-dimensional and two-dimensional nanostructures. Other techniques such as infrared thermometry, Raman thermometry, and scanning probe methods are described in the literature (Cahill et al., 2014).

The 3-omega measurement (Cahill, 1990) is widely used in measuring the thermal conductivity of thin films and has been extensively discussed in the literature (Dames and Chen, 2005). A schematic of measurement device configuration is illustrated in Figure 4.21.17. A thin metal line, acting as a heater and a thermometer, is deposited on the film. During the measurement, a sinusoidal current at a frequency ω through the metallic heater sets up an oscillatory temperature rise,

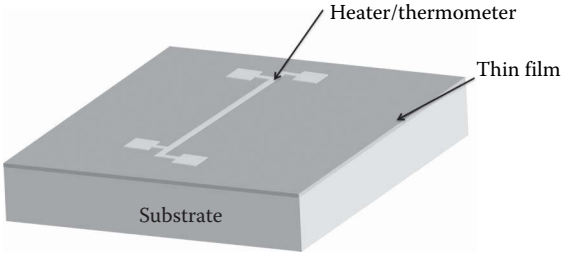

FIGURE 4.21.17 Schematic of a device for 3-ω measurement of thin film thermal conductivity. The metal line serves as the heater/thermometer. It is usually deposited through a shadow mask or patterned lithographically.

ΔT at the harmonic frequency 2ω. This results in a voltage across the metal line that oscillates at 3ω. Measurement of the 3ω voltage via a lock-in amplifier provides ΔT as

$$\Delta T = 2\frac{V_{3\omega}}{I_0}\left(\frac{\mathrm{d}R}{\mathrm{d}T}\right)^{-1}, \tag{4.21.48}$$

where I_0 is the 1ω current and $\mathrm{d}R/\mathrm{d}T$ is the temperature coefficient for heater resistance.

In the simple case when the thermal penetration depth $\sqrt{\alpha_T / 2\omega}$ >> film thickness d, ΔT has a constant contribution from the film and a frequency-dependent component from the semiinfinite substrate:

$$\Delta T = \frac{p}{\pi l k_s}\left(\frac{1}{2}\ln\frac{\alpha_T}{b^2} - \frac{1}{2}\ln(2\omega) + 0.923 - i\frac{\pi}{4}\right) + \frac{pd}{2blk_f}, \tag{4.21.49}$$

where p is the heating power, l and $2b$ are length and width of the heater, k_s and k_f are the thermal conductivities of the substrate and the thin film, respectively. By measuring the 3ω voltage at different frequencies, it is possible to decouple the two components and extract the thermal conductivity of both the thin film and the substrate.

In a more general case when a multilayer system is involved, an N-layer heat diffusion model (Borca-Tasciuc et al., 2001) can be used. The temperature rise is

$$\Delta T = \frac{-p}{\pi l k_1}\int_0^\infty \frac{1}{A_1 B_1}\frac{\sin^2(\lambda b)}{\lambda^2 b^2}\mathrm{d}\lambda, \tag{4.21.50}$$

where

$$A_{i-1} = \frac{A_i\dfrac{k_i B_i}{k_{i-1}B_{i-1}} - \tanh(\phi_{i-1})}{1 - Ai\dfrac{k_i B_i}{k_{i-1}B_{i-1}}\tanh(\phi_{i-1})}, i = 2..N$$
$$\mathrm{Bi} = \left(\lambda^2 + \frac{i2\omega}{\alpha_{Ti}}\right)^{1/2}, \phi_i = B_i d_i \tag{4.21.51}$$

In the above expression, the layer number count starts at the topmost film and properties are assumed to be isotropic. The thermal diffusivity α_T and the individual thicknesses d_i appear in the above equations. Figure 4.21.18 shows a typical plot for a frequency sweep for ΔT. The sample is a silicon nanostructure on a bulk silicon substrate. The fit to the data yields the thermal conductivity. The fitting process works best when the only unknown is the thermal conductivity of the thin film or when the thin film contributes most of ΔT.

TDTR (Cahill et al., 2014) is an optical, noncontact technique that can be used to measure the thermal conductivity of materials. TDTR can be applied to bulk materials, thin films, and individual interfaces. A schematic of the typical experimental setup used is shown in Figure 4.21.19. A Ti:sapphire laser oscillator produces a series of sub-picosecond optical pulses (λ=785 nm) at a high repetition rate, typically 80 MHz. The output of the laser is split into a "pump" beam and a "probe" beam with their relative optical paths being adjusted using a mechanical delay stage. The intensity of the pump beam is modulated using an electro-optic modulator at a frequency, f=9.8 MHz. A part of the reflected beam from the surface is deflected into the CCD camera using a beam splitter. This creates a dark field image in the camera that helps to focus the beams accurately on the sample surface.

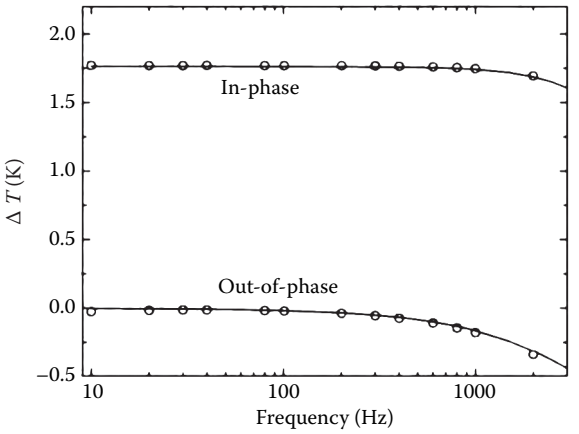

FIGURE 4.21.18 The in-phase and out-of-phase components of the temperature rise measured at different frequencies in a 3-ω measurement.

The pump beam produces ultrafast heating and the probe beam measures the change in the temperature of the surface through the dependence of the optical reflectivity R on temperature. A thin film of aluminum is deposited on the sample and acts as transducer due to its large coefficient of thermoreflectance, $dR/dT \approx 10^{-4}\ K^{-1}$ near room temperature and at the wavelength used. The changes in the reflected probe intensity caused by the pump beam occur at the modulation frequency f and are extracted using lock-in amplifier. The lock-in signal has an in-phase and an out-of-phase component, $V(t) = V_{in}(t) + iV_{out}(t)$. Typically, the in-phase signal is used in the analysis but the out-of-phase signal can be used to correct for the nonidealities in the experiment. Factors such as defocusing of the pump beam and change in the overlap between the

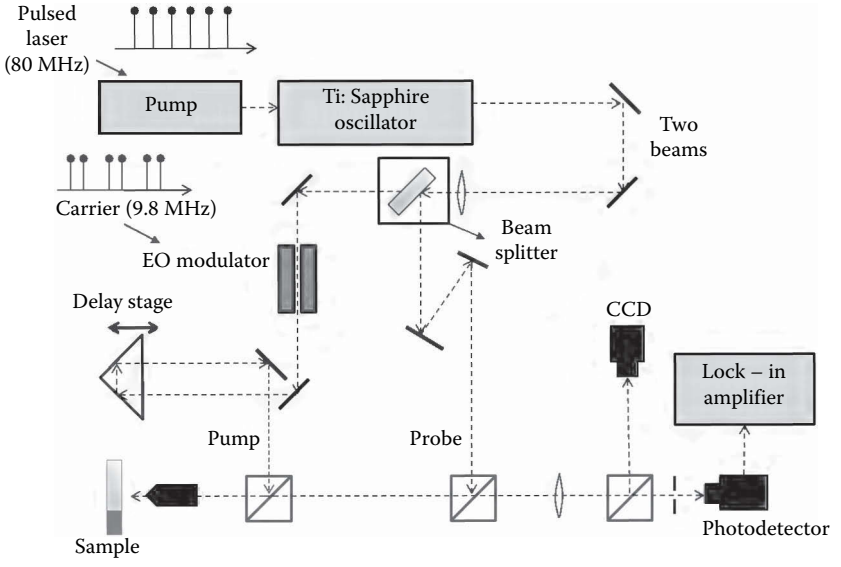

FIGURE 4.21.19 Schematic of the TDTR experimental setup. A Ti:sapphire laser oscillator produces a series of sub-picosecond optical pulses. The output of the laser is split into a "pump" and a "probe" path using a beam splitter. The pump beam is modulated using an electro-optic modulator. The relative path difference between the pump and the probe beam is adjusted using a variable delay stage. (Figure prepared by Dhruv Gelda.)

pump and the probe beams affect both the $V_{in}(t)$ and $V_{out}(t)$ similarly. Therefore, the ratio of the two components $(V_{in}(t)/V_{out}(t))$ is a more robust measurement (Cahill et al., 2014). This ratio is compared with a numerical calculation of heat transport in multilayer structures. The numerical model solves the heat diffusion equation in frequency domain assuming periodic heating from the pulsed laser. The unknown thermal properties, e.g., the thermal conductivity of a thin film, are treated as fitting parameters and adjusted to minimize the difference between the model and the experimental data.

One of the major limitations of TDTR is that the technique is sensitive to the cross-plane thermal conductivity of the material. Except in special cases such as highly anisotropic material, it is difficult to estimate the in-plane thermal conductivity. The penetration depth, δ of thermal waves at a modulation frequency f is given by $\sqrt{\alpha_T / \pi f}$, where α_T is the thermal diffusivity. If the sample consists of a thin film of thickness, $d(< \delta)$, TDTR typically cannot separate the thermal conductance of the film from the thermal conductance of the film–substrate interface.

A microelectromechanical-fabricated device is widely used to measure the thermal conductivity of one-dimensional structures (Shi et al., 2003). Figure 4.21.20 shows the device that includes two suspended membranes supported by long, thermally resistive silicon nitride (SiN_x) beams. These membranes are designated as heating and sensing membranes. Each membrane has a platinum (Pt) coil sandwiched between two SiN_x films (Ghossoub et al., 2013) that serve as resistive heaters/thermometers. The platinum coils (with electrical resistances R_H and R_S) are connected to the contact pads via Pt leads (resistance R_L each) that pass through the supporting beams. Figure 4.21.21 shows a silicon nanowire suspended across the membranes that was transferred from its fabrication wafer. The entire device is kept at bath temperature T_O in a high-vacuum cryostat.

Once the entire device equilibrates to its bath temperature T_O, a DC current, I is passed through the Pt coil in the heating membrane. Joule heat is generated in the coil ($Q_H = I^2 R_H$) and two of the leads ($2 \times Q_L = 2 \times I^2 R_L$) connecting the coil to the contact pads. Half of the heat generated in the

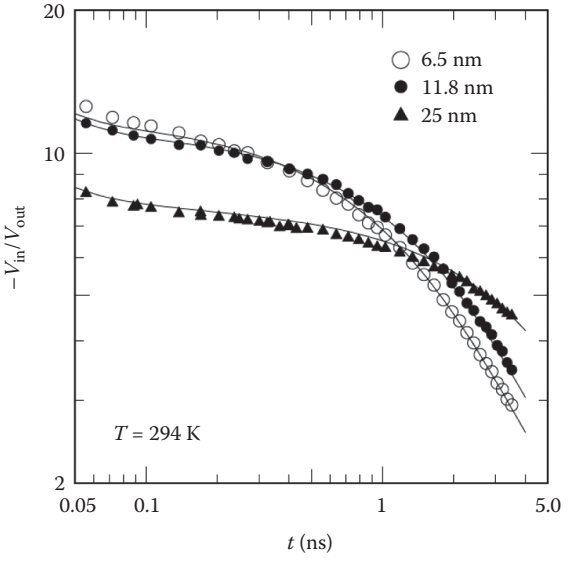

FIGURE 4.21.20 TDTR data acquired at room temperature for $TiN/SiO_2/Si$ samples. Data points are labeled by the SiO_2 thickness. The ratio of the in-phase to out-of-phase signals at the 9.8 MHz modulation frequency is plotted as a function of the delay time t between pump and probe. The solid lines are fits with the thermal conductivity of SiO_2 as the one free parameter. (Adapted from Costescu, R. M. et al., *Phys. Rev. B* 67, 054302, 2003. With permission. FIGURE 4.21.21 Scanning electron micrographs of a device used to measure the thermal conductivity of one-dimensional structures. The device has two suspended membranes with platinum heater/thermometer lines sandwiched between silicon nitride films. Each membrane is supported by six long thermally resistive silicon nitride beams. The sample to be measured is placed across the membranes and temperature of one of the membranes is raised by Joule heating.

leads reaches the membrane and the other half flows to the substrate at temperature T_O. The total heat in the heating membrane $Q_H + Q_L$ now flows to the substrate at T_O through two pathways. One pathway is directly through the beams supporting the heating membrane at temperature T_H. This pathway is represented by the lower branch of the thermal circuit in Figure 4.21.22. The upper branch in the thermal circuit represents the second heat conduction pathway through the sample, the sensing membrane at temperature T_S and its beams.

By conservation of energy, the heat flowing through the first pathway $Q_1 = G_B(T_H - T_O)$ and the second pathway $Q_2 = G_B(T_S - T_O)$ adds up to the total heat in the heating membrane $Q_H + Q_L$. Assuming the thermal conductance of the beams supporting the heating and the sensing membranes to be equal (G_B), the thermal conductance of the beams is

$$G_B = \frac{Q_H + Q_L}{(T_H - T_O) + (T_S - T_O)}. \tag{4.21.52}$$

Finally, the heat flowing through the sample $G_S(T_H - T_S)$ is the same as the heat flowing between the sensing membrane and the substrate $G_B(T_S - T_O)$. This yields the sample conductance G_S as

$$G_S = G_B \frac{(T_S - T_O)}{(T_H - T_S)}. \tag{4.21.53}$$

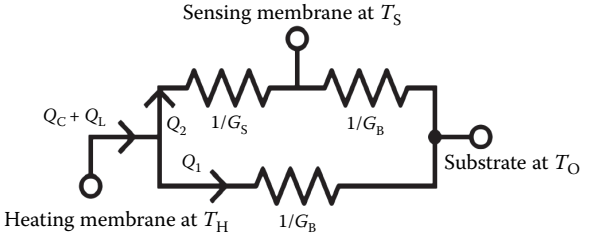

FIGURE 4.21.22 Thermal circuit showing the flow of the generated heat $Q_H + Q_L$ from the heating membrane at T_H to the substrate at T_O. Thermal conductance of the sample is obtained by measuring steady-state temperatures of the membranes and the heat flowing through the sample.

The steady-state temperatures, T_H and T_S, of the two membranes are obtained by measuring the coil resistances, R_H and R_S. The heat flowing through the heating membrane $Q_H + Q_L$ is obtained as $(R_H + R_L) I^2$ by measuring $R_H + R_L$. To measure these resistances, small AC currents at different frequencies are passed through the coils on the heating and sensing sides, and the corresponding voltage drops measured using lock-in amplifiers (Shi et al., 2003). The resistance data can then be converted to a temperature rise using the calibration curve for R_H and R_S. Figure 4.21.23 shows a typical temperature rise measurement at various DC heating currents.

The sample conductance obtained using this device includes the contact conductance between the membranes and the sample. Care should be taken to minimize this contact resistance. Furthermore, for samples with conductance lower than 100 pW/K, the temperature rise on the sensing side may be comparable to the noise equivalent temperature rise, resulting in high error margins.

The above techniques lend themselves well to the measurements of thermal conductivity and conductance in micro- and nanostructures. In addition, measurements on individual transistors, circuit blocks, and complete integrated circuits are of critical importance in applications. Device scale thermometry may employ electrical resistance measurements in contacts to the device or noncontact electroluminescence. Temperatures of circuit blocks can be measured by measuring the frequency shifts of ring oscillators or using electrical resistance thermometers. Finally, infrared cameras and point-by-point thermoreflectance can produce thermal images of circuits and entire chips with spatial resolution on the order of ~10 μm. These are discussed later in the chapter.

Thermal Conductivity/Conductance of Materials/Interfaces

The main effect of the small dimensions of structures used in electronics is to alter the thermal conductivity of the medium due to scattering of carriers at the surfaces and interfaces. In most cases, the heat diffusion equation still applies provided the altered size-dependent thermal conductivity and accurate interfacial thermal conductance are taken properly into account. While theory provides physical insight into altered properties, experimental data are necessary in most cases.

The thermal conductivity of silicon (Toberer et al., 2012) is the most studied and best understood. Figure 4.21.24 shows the data for thermal conductivity of silicon at 300 K as a function of limiting crystal size. Boundary scattering of phonons serves to reduce thermal conductivity as discussed previously. The Casimir limit is shown for comparison. While the data for thin

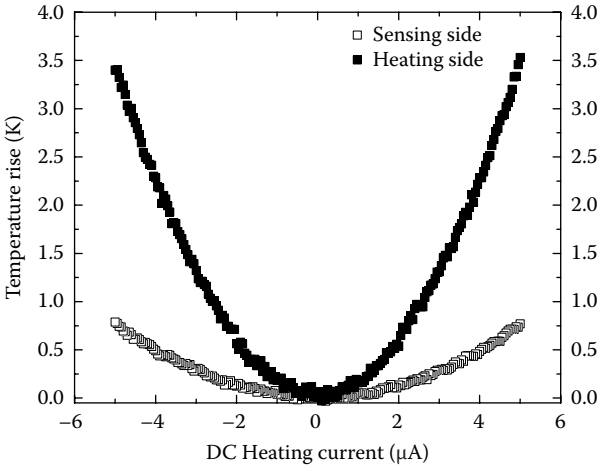

FIGURE 4.21.23 Temperature rise in the membranes at different DC heating currents during a measurement.

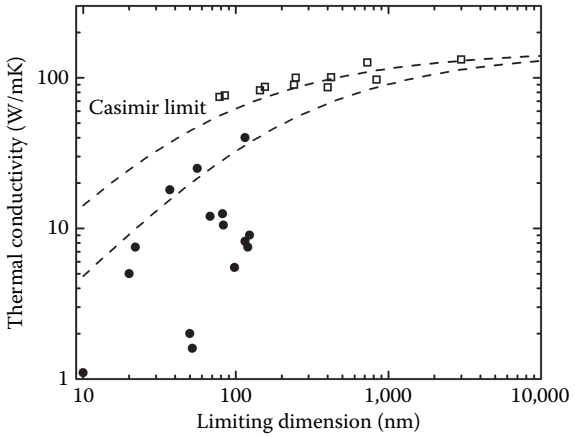

FIGURE 4.21.24 Summary of room temperature thermal conductivity data of silicon nanostructures plotted against the limiting dimension for surface scattering. The closed and open symbols represent nanowires (Boukai et al., 2008; Hochbaum et al., 2008; Li et al., 2003; Ghossoub et al., 2013) and thin films (Asheghi et al., 1998; Ju and Goodson, 1999), respectively. A prediction of thermal conductivity assuming boundary scattering at the Casimir limit of completely diffuse scattering is also plotted following Mingo's modified Callaway model (Mingo, 2003). The geometric factor F for boundary scattering is used with values: $F=1$ for cylindrical wire and $F=4$ for thin films (Wang and Mingo, 2011).

films and smooth surface nanowires appear close to the Casimir limit, the data for rough surface nanowires fall significantly below the Casimir limit. The measurement technique for nanowires differs significantly from that for thin films. There has been speculation whether some of the data for nanowires are unduly influenced by contact resistance (Shi, 2012) in some measurements. Figure 4.21.25 further plots data for doped silicon films at 300 K. At large doping concentrations in excess of ~10^{19} cm^{-3}, thermal conductivity is reduced possibly due to strong electron–phonon scattering.

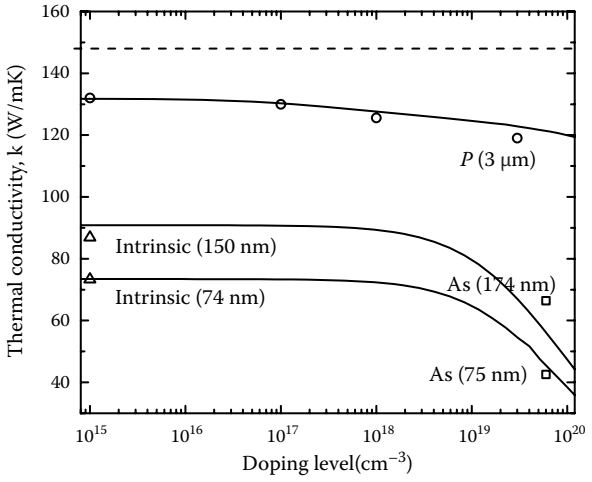

FIGURE 4.21.25 Thermal conductivity as a function of doping concentration at 300 K. The open circles, triangles, and squares are different measurements (Ju and Goodson, 1999; Asheghi et al., 2002; Liu et al., 2006). The curves are calculations for P-doped (3 μm thick), As-doped (174 nm thick), and As-doped (74 nm thick) single crystal silicon films, respectively. (Adapted from Ma, J. and Sinha, S. *Appl. Phys.*, 112, 073719, 2012. Copyright 2012 American Institute of Physics. With permission.)

A multitude of dielectric films are critical in electronics. Figure 4.21.26 presents thermal conductivity data for silicon dioxide and nitride films with various thicknesses. Since these films are, in many cases, in close proximity to heat-producing regions of semiconductor devices, any changes in their thermal conductivity with thickness must carefully be taken into account in simulations. Figure 4.21.27 presents thermal conductivity data for thin films of other dielectrics that find current use in electronics. The theory of minimum thermal conductivity (Cahill and Pohl, 1987) provides a convenient comparison point for the thermal conductivity of amorphous materials. The model assumes the Einstein model for phonons where neighboring atoms are completely uncorrelated. Thus, the mean free path equals the lattice spacing. The minimum value is given by

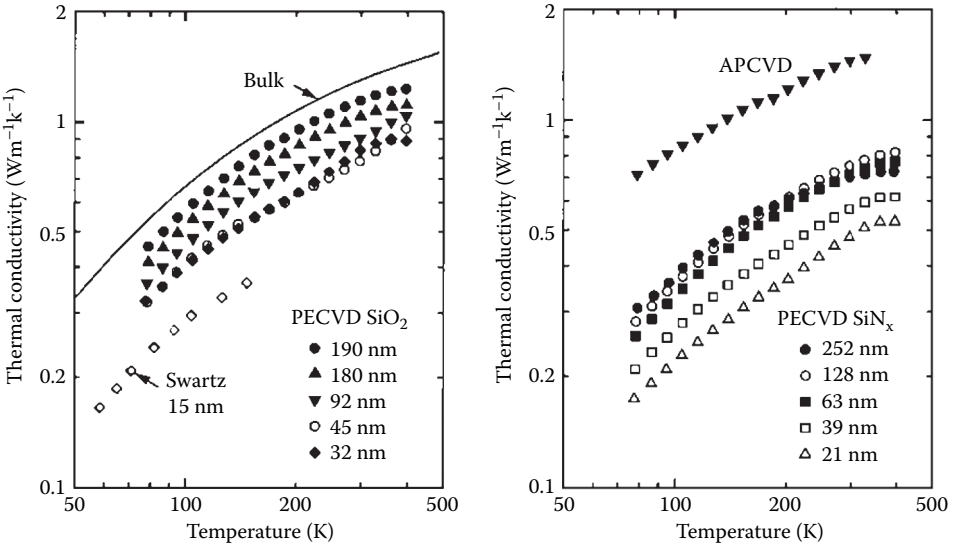

FIGURE 4.21.26 Thermal conductivity of SiO_2 and SiN_x at different film thicknesses. (From Lee, S.-M. and D. G. Cahill, *J. Appl. Phys.*, 81, 2590–5, 1997. Copyright 1997 American Institute of Physics.)

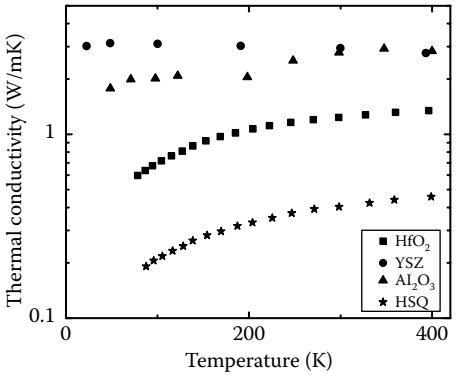

FIGURE 4.21.27 Thermal conductivity vs temperature data for HfO_2 (Lee et al., 1995), α-Al_2O_3 deposited by low-temperature ALD (Cappella et al., 2013), 3 mol% polycrystalline yttria-stabilized zirconia (YSZ) of density 6 Mg/cm^3 (Schlichting et al., 2001), and Dow Corning's flowable oxide FOx HSQ (Costescu et al., 2002). The room temperature thermal conductivity of HfO_2 grown by ALD is reported as 0.48, 0.81, and 0.95 W/mK for 5.6, 11.8, and 20 nm film thicknesses, respectively (Panzer et al., 2009). DC sputtered α-Al_2O_3 show room temperature thermal conductivity of 1.6 W/mK (Lee et al., 1995).

$$k_{\mathrm{MIN}} = \left(\frac{\pi}{6}\right)^{\frac{1}{3}} k_{\mathrm{B}} n_{\mathrm{a}}^{\frac{2}{3}} \sum_{i=1}^{3} v_i \left(\frac{T}{\theta_{\mathrm{D},i}}\right)^2 \int_0^{\theta_{D,i}} \frac{x^3 e^x \mathrm{d}x}{\left(e^x - 1\right)^2}, \tag{4.21.54}$$

where i is an index specifying all three acoustic phonon polarizations, $\theta_{\mathrm{D},i}$ is the Debye temperature associated with polarization i, v_i is the speed of sound, and n_{a} is the number density of atoms. In the high-temperature limit, $k_{\mathrm{MIN}} = \frac{1}{2}\left(\frac{\pi}{6}\right)^{\frac{1}{3}} k_{\mathrm{B}} n_{\mathrm{a}}^{\frac{2}{3}} \sum_{i=1}^{3} v_i$.

Besides silicon, III–V materials are of critical importance in optoelectronics and power electronics. Figure 4.21.28 plots the temperature-dependent thermal conductivities of leading III–V bulk materials. The values should be used with caution since thermal properties in III–V devices can be significantly altered due to the presence of multilayer structures that introduce interfaces, dislocations, and impurities.

The search for electronic materials beyond silicon has driven interest in the thermal properties of almost every potential candidate. Among these, one- and two-dimensional materials/structures attract great interest. Figure 4.21.29 shows the temperature-dependent thermal conductivity of several one-dimensional material structures: single-wall carbon nanotubes (CNTs), multiwall CNTs, smooth and rough silicon nanowires, Si/SiGe superlattice nanowires, InAs nanowires, and SiGe nanowires. Figure 4.21.30 further plots the temperature-dependent thermal conductivity of exfoliated single-layer graphene supported on silicon dioxide as well as suspended five-layer hexagonal boron nitride. For low-dimensional materials/structures, the low-temperature slope of thermal conductivity provides insight into the scattering processes. At low temperatures (~5–30 K), boundary scattering of phonons is the dominant scattering process governing heat conduction in dielectrics. From Equation 4.21.2, the thermal conductivity is $\kappa \sim Cv\Lambda$. In the Casimir limit, the mean free path at low temperatures is proportional to the size of the crystal and is temperature independent. The temperature dependence in thermal conductivity arises only from that in the heat capacity. The temperature dependence of the heat capacity of phonons is $\sim T^d$, where d is the dimension of phonon modes. Thus, at low temperatures, the thermal conductivity too should follow $\sim T^d$. Low-temperature data are thus invaluable in checking the dimensionality involved in phonon heat conduction as well as the applicability of the Casimir limit.

Two-dimensional materials such as graphene are considered attractive for future applications and fall under the category of emerging materials. Figure 4.21.30 plots the thermal conductivity of single-layer graphene supported on oxide as well as suspended five-layer hexagonal boron

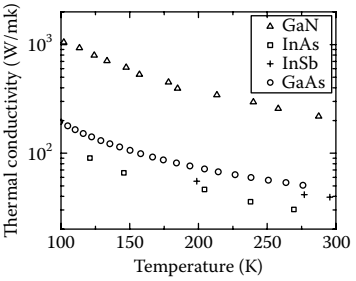

FIGURE 4.21.28 Temperature dependence of the bulk thermal conductivity for III-V semiconductors. Data are shown for GaAs (Inyushkin et al., 2003) crystal with natural composition of gallium isotopes (open circles), *n*-type GaN (Jeżowski et al., 2003) crystals grown under high pressure (open triangles), InSb (plus marks) (Busch and Schneider, 1954), and undoped single crystals of InAs (open squares) (Le Guillou and Albany, 1972).

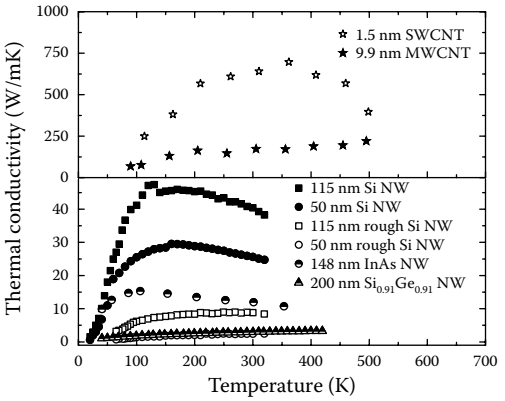

FIGURE 4.21.29 Thermal conductivity as a function of temperature for various one-dimensional materials. The data shown in the top panels are for 1.5 nm diameter single-walled CNT (open stars) and 9.9 nm diameter CNTs with five shells (solid stars) (Pettes and Shi, 2009). Bottom panel shows the data for smooth (Li et al., 2003) and rough (Hochbaum et al., 2008) silicon nanowires, Si/SiGe superlattice nanowires (Li et al., 2003), InAs nanowires (Zhou et al., 2011), and SiGe nanowires (Kim et al., 2010).

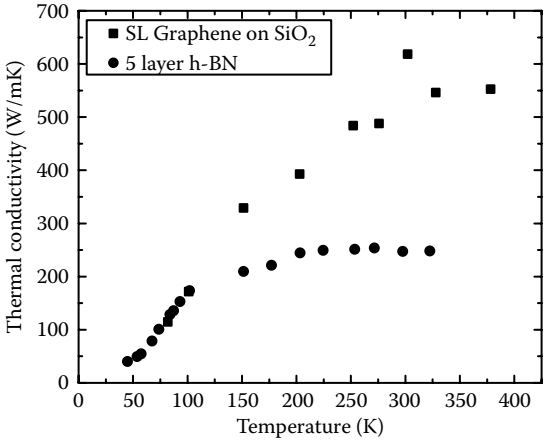

FIGURE 4.21.30 Thermal conductivity of exfoliated single-layer graphene supported on silicon dioxide film (solid squares) (Seol et al., 2010) and suspended five-layer h-BN (solid circles) (Jo et al., 2013) as a function of temperature.

nitride. While thermal conductivity data have also been reported for suspended single-layer graphene, consensus values do not exist. The earlier measurements appear to have larger experimental uncertainties than reported (Shi, 2012). Data for suspended graphene should therefore be used with caution.

Data for interfacial thermal conductance are equally important in the thermal engineering of electronics. While there is a wealth of data on the thermal conductance of material interfaces, the objective is often to measure ideal interfaces and compare against theory. Thus, in many cases, the material combinations chosen are motivated by the availability of high-quality surfaces. Figure 4.21.31 compiles thermal conductance measured across several different solid–solid interfaces (Lyeo and Cahill, 2006). At room temperature, the thermal conductance of good quality interfaces ranges between the lowest and the highest values by a factor of ~60 with high values approaching 500 W/m^{2}K. Besides interfaces formed from bulk materials, interfaces formed by

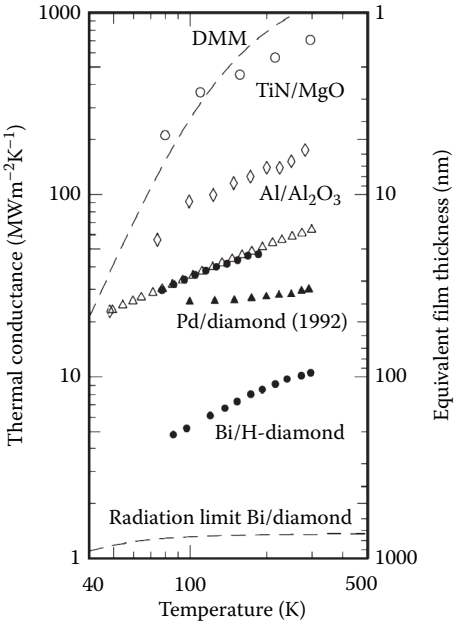

FIGURE 4.21.31 Compilation of the thermal conductance of solid–solid interfaces. The right-hand axis gives the equivalent thickness of a thin film with thermal conductivity 1 W/mK that has the same thermal resistance as these single interfaces. The dashed line labeled "DMM" is a theoretical calculation of the TiN/MgO interface using a modification of the diffuse mismatch model. (Adapted from Lyeo, Ho-Ki and David G. Cahill, *Phys. Rev. B* 73, 144301, 2006. With permission. Copyright 1997 American Institute of Physics.)

low-dimensional materials such as CNT and graphene are important for device applications. Figure 4.21.32 plots the temperature dependence of the interfacial thermal conductance for carbon materials, including single-layer graphene, multilayer graphene, and CNT.

While significant advances have been made in understanding interfacial thermal conductance, a more important question from an engineering perspective is whether the conductance can be altered through engineering. Experiments involving thermal transport across a self-assembled monolayer

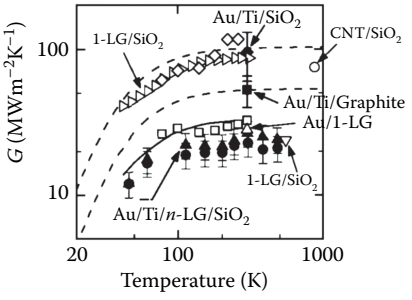

FIGURE 4.21.32 Temperature dependence of the interface thermal conductance (G) for interfaces involving carbon materials: single-layer graphene (1-LG), multilayer graphene (n-LG), graphite, CNT. Data are shown for Au/Ti/1-LG/SiO_2 (solid triangles), Au/Ti/3-LG/SiO_2 (solid circles), Au/Ti/SiO_2 (solid diamond), Au/Ti/graphite (solid square), 1-LG/SiO_2 (open right triangles and open triangle down), Au/1-LG (open triangle up), SWCNT/SiO_2 (open circle), Au/graphite (open squares), and Ti/graphite (open diamonds) interfaces. The dashed lines are DMM calculations for G of Au/Ti/SiO_2 (top) and Au/Ti/graphite (bottom) interfaces. The solid line is the prediction using DMM calculations of $G_{Au/Ti/graphite}$ and measurements of $G_{1\text{-}LG/SiO2}$. (Reprinted from Koh et al., *Nano Lett.*, 10, 4363–8, 2010. of molecules sandwiched between quartz and Au showed that the interfacial thermal conductance increases significantly as the density of covalent bonds (contributed by thiol end groups) is increased between samples. Figure 4.21.33 shows the data where the conductance nearly doubles from 36 to 65 MW/m^{2}K.

Power Dissipation and Heat Flow in Devices and Circuits

The experimental and theoretical techniques discussed above provide insight into thermal transport in semiconductor devices, circuits, and chips. We now discuss important aspects of thermal management in semiconductor applications. As described in Figure 4.21.4, the heat flow spans multiple length and timescales. Challenges in thermal engineering are unique to the level of consideration, whether device, circuit, chip, or package level.

At the device level, power dissipation is dictated by the microscopic physics of electron–phonon scattering. Electrons accelerated by the electric field in the channel of the transistor relax to equilibrium by emitting phonons. In the device physics literature, such electrons are termed hot electrons. Scattering is typically stronger with high-energy optical phonons and occurs over timescales of ~0.1 ps (Pop et al., 2006). The relaxation of nonequilibrium phonons occurs over ~ps (optical to acoustic) to ~ns (acoustic to acoustic) timescales. Figure 4.21.34 shows the region of heat generation in an 18 nm gate length silicon-on-insulator device (Sinha and Goodson, 2005). The peak volumetric heat generation is 6×10 W/m and the region of intense heat production is on the order of a few nanometers, much smaller than the mean free path of phonons in the lattice bath. A phonon "hotspot" effect can arise if phonons from the heat source travel without scattering over distances much larger than the size of the source. However, the presence of interfaces in close proximity can serve to relax nonequilibrium phonons.

Heat conduction from the transistor occurs through the electrical contacts that act as extended surfaces for conducting heat away from the device. The body of the device serves to spread heat further. The presence of numerous thin film materials and material interfaces complicates the analysis of heat conduction. The thermal conductivity of materials and the conductances of the interfaces must be accurately known to predict temperature distributions reliably. The temperature rise in individual transistors has been measured using numerous techniques. In particular, the electrical

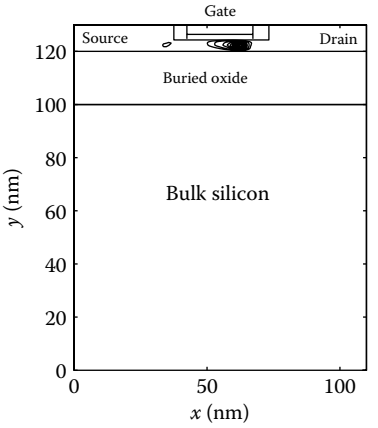

FIGURE 4.21.34 The region of Joule heat dissipation in a thin-body SOI transistor with a gate length of 18 nm. The contours correspond to the spatial distribution of Joule heat and are equi-spaced at 0.5 W/μm^3 with a peak of 60 W/μm^3. (Adapted from Sinha, S. and E. Kenneth, *Int. J. Multiscale Comput. Eng.*, 3, 107–33, 2005. With permission.)

resistance of the gate terminal (Su et al., 1994) has been used as a thermometer to obtain an average temperature for the current-carrying channel. For example, in silicon-on-insulator transistors with 360 nm buried oxide, the measured temperature at ~6 mW power was in the range 60°C–100°C depending on the thickness of the channel. In comparison, the temperature was 40°C in a bulk device at similar power. Besides steady-state measurements, time-resolved electroluminescence (Polonsky and Jenkins, 2004) measurements have yielded temporal temperatures. From the data, the thermal time constant of a 110 nm *n*-type silicon-on-insulator FET is ~107 ns, consistent with a lumped capacitance model.

Circuit level thermal modeling and measurements (Pedram and Nazarian, 2006) are the next level in the hierarchy. The total power dissipation in a CMOS VLSI circuit is the sum $P_{\text{dynamic}}+P_{\text{short circuit}}+P_{\text{static}}$, where the first term represents the dynamic power consumption that occurs when the output signal of a CMOS logic cell changes; the second term represents the power dissipated when both *n*- and *p*-transistors conduct simultaneously to create a short between the supply and the ground; and the third term is mainly due to leakage currents through the gate or subthreshold conduction. While in ~μm size silicon transistors, the dynamic power density is six orders of magnitude larger than the leakage power density, the two power densities become comparable in ~10 nm size transistors (Haensch et al., 2006). Both the short-circuit power and the static power are temperature dependent. Therefore, heat conduction in the chip must be accounted for in circuit models to accurately predict power dissipation. Thermal models in circuit simulations take advantage of the analogy between electrical and thermal circuits. Figure 4.21.35 shows a representative thermal circuit (Pedram and Nazarian, 2006) where the heat flow from a heat source is the current source. The use of resistances, capacitances, and a voltage source for the ambient temperature follows the usual practice. It is critical to consider heat flow along the metal interconnects in detail (Lin et al., 2007a,b). Electrothermal solutions can take two approaches. Thermal and electrical circuits can be solved simultaneously or alternately, they can be solved one at a time and fed to the other. The latter is less computationally intensive and sometimes favored for full-chip simulations. Measurement techniques at the circuit level involve thermometry through embedded temperature sensors or through imaging using infrared imaging as well as thermoreflectance (Altet et al., 2006).

The third problem in the hierarchy is the more practical one. Eventually, heat produced in the circuit needs to be rejected to the ambient. Packaging technologies have introduced numerous innovations to enable advancements through Moore's law (Mahajan et al., 2000). The heat conduction path

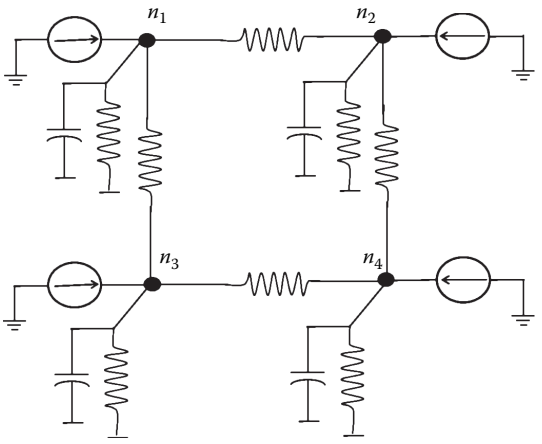

FIGURE 4.21.35 Example of a thermal circuit used in electrothermal modeling of circuits. Temperature is computed at the nodes, *n*. The heat flow is a current source with the thermal resistances and capacitances as indicated. The ground is at the ambient temperature.

from the chip to the ambient goes through the TIM1, the heat spreader, the TIM2, and the heat sink. The heat flow pathway is not one-dimensional since the initial heat distribution on the chip is highly nonuniform. The nonuniformity (Prasher, 2006) is taken into account through a density factor (*DF*). The total thermal resistance, R_{ja}, can be written as the sum $R_{ja}=DF\times\Psi_{jc}+R_{cs}+R_{sa}$, where the subscripts *j*, *a*, *c*, and *s* denote the junction, the ambient, the case (package), and the sink. The symbol Ψ denotes a thermal resistance per unit area. The *DF* has units of cm^{-2} and is numerically 1 for a 1 cm^2 chip heated uniformly. Typically, $DF > 1$ due to nonuniform heating. Within the package, the resistance due to TIM1 is a critical component. Table 4.21.3 lists the thermal conductivities of some important TIMs (Prasher, 2006) employed in electronics along with their thermal properties. The microscopic level theory and measurements discussed above have direct utility in improving thermal interface materials through improved understanding of heat conduction across interfaces.

Summary

Thermal engineering plays a vital role in the advancement of nanoelectronics, with impact at all levels from nanoscale devices to entire packages. Multiple physical length and timescales in transport, the close interplay with charge transport, and the multitudes of materials involved combine to

TABLE 4.21.3
Thermal Conductivity of TIMs

TIM Type	Examples	Range of Thermal Conductivity (W/mK)
Greases	AIN1, Ag, ZnO, Silicon oil	3–5
Gels	Al, Ag, silicone oil, olefin	3–4
Phase change materials	Polyolefins, epoxies, polyesters, acrylics, BN, alumina, Al, CNTs	0.5–5
Phase change metallic alloys	Pure In, In/AG, Sn/Ag/Cu, In/Sn/Bi	30–50
Solders	Pure In, In/AG, Sn/Ag/Cu, In/Sn/Bi	30–50

create a challenging but interesting problem. With a wide variety of experimental tools and more under development, and powerful theory to provide detailed insight, innovative solutions will continue to emerge. Engineering in this complex environment requires knowledge spanning multiple disciplines. This chapter provides a glimpse into some of the most important aspects.

4.22 ROLE OF COOLING IN ELECTRONICS RELIABILITY

Pradeep Lall

Introduction

The focus of this chapter is on cooling in electronic applications. The need and applicability of cooling to electronics has been discussed in detail with discussions on material limits, device performance parameters, and failure mechanisms. The fallacies with the current methodology for characterization of the functional relationship between temperature and electronic reliability have been discussed. It has been shown that material limits alone seldom justify the need for cooling. Temperature is more closely linked to degradation in performance. In many cases, just lowering temperature alone may or may not improve reliability—since a majority of the failure mechanisms are based on temperature cycling, spatial temperature gradient, and time-dependent temperature change. A methodology for evaluating the effects of temperature on reliability, determining the maximum operating temperature, and characterizing the functional relationship between temperature and electronic reliability has been discussed.

The cooling needs and constraints vary with the specific product–application requirement. The application areas have been broadly categorized into device level including PCB and IC packages and system level including space- and size-constrained and environment-constrained devices. The space- and size-constrained devices have been categorized into handheld communication devices such as smartphones and portable computing applications such as tablets and laptops. The environment-constrained devices include outdoor telecommunication enclosures and high-altitude electronics. For each electronic application, the temperature constraints and their basis have been discussed in detail. Typical material sets and heat transfer schemes and their relative effectiveness have also been discussed.

Application aspects of cooling in electronics have been discussed in detail. It is not the intent of this chapter to teach the reader basics of heat transfer—the reader is referred to previous chapters in the book or other basic texts on heat transfer for an in-depth treatment of the basics.

Understanding the Role of Temperature in Design

There has been a common belief that reliable electronics can be achieved by lowering temperature. Typically, statements such as “lower the temperature by 10°C and double reliability” are used to characterize the effect of temperature on reliability. The belief in the harmful effects of temperature has woven itself into today’s screening and thermal management processes. It is important to emphasize that cooling should be resorted to only when necessary. In this section, we will discuss some of the motivations for incorporating cooling in design and their validity.

The motivation for cooling electronics is based on three major premises: (1) material degrades or causes a fire hazard; (2) higher temperature activates failure mechanisms and decreases reliability; and (3) higher temperature degrades performance. Determination of requirements for cooling and design operation temperature is based on the reliability benefits, performance benefits, material limits, and auditability.

Material Limits

Materials typically used in electronics will withstand sustained operation at 125°C with the electronics operating in automotive underhood applications mounted on-engine or on-transmission expected to sustain exposure to high temperatures up to 175°C–200°C in the presence of vibration. The majority of the present-generation electronics products use lead-free solders. SnAgCu-based formulations including SAC105 and SAC305 and their variants are widely used, and have melting points in the neighborhood of 217°C–220°C. Typical peak reflow temperatures are in the

neighborhood of 230°C–240°C depending on the lead-free solder alloy formulation and the assembly. Based on historical precedence of products built using this profile over a number of product generations, it is fairly well known that the typical materials including molded-packages electronics, silicon circuits, discrete components, and printed-circuit boards (PCBs) do not undergo any permanent degradation when exposed to temperatures of up to 260°C. Table 4.22.1 shows the material limits for most of the common materials used in electronics. A brief review of the temperature limits indicates that material limits alone would seldom justify the need for cooling.

Impact on Performance

The parameters, which are sensitive to temperature, depend on device technology and are referred to as the temperature-sensitive electrical parameters (TSEPs). Table 4.22.2 shows the TSEP versus device technology.

The allowable junction temperature, T_J, is determined based on allowable values of the TSEP. The allowable variation in the values of the TSEP allows the device to function without significant degradation in performance. The reference temperature, T_R, is ordinarily measured with a thermocouple at the point of interest. The junction and reference temperature measured values are used to calculate the thermal resistance and the allowable power dissipation. The interested reader is referred to Lall et al. (1997) for a more detailed treatment of the Electrical Parameter Variations versus Temperature.

Impact on Reliability

The impact of temperature on reliability is typically the most misunderstood. Accelerated tests including burn-in are often run at high temperatures in hope that the high temperature will target the dominant failure mechanisms and reveal the suitability of a technology or design for a stress environment. It is often the case that the failure mechanisms precipitated in accelerated testing do not correspond to field life. Because of the nonlinearity of stress domain of the failure mechanisms—mechanisms accelerated by high-temperature accelerated stress may not exist in the equipment operating range of −55°C to 125°C. A stress domain is the set of values of stress magnitude over which the failure mechanism can be extrapolated in accordance with a single functional relationship. Linear stress domain signifies that the tendency of occurrence of any one failure mechanisms varies at a uniform rate with change in stress. Conversely, in the presence of a nonlinear domain, the accelerated test may not accurately predict how the device will fail during normal use. While high magnitudes of a stress may cause the device to fail instantly, low values of the same stress may not result in failure in any reasonably observable duration of time.

The naïve practitioner may often ignore the nonlinearity of the stress domain extrapolate the test results to the equipment operating temperature range. Further, the overall device, component, or assembly reliability is often incorrectly characterized by functional relationships such as the Arrhenius or Eyring models, and assigned an activation energy, and then used to extrapolate the test results to operating conditions. While individual failure mechanisms may be described using the Arrhenius or Eyring models, the device, component, and system's reliability dependence on temperature is more complex, often being determined by the dominant failure mechanisms and their dependence on temperature. One of the fairly obvious reasons for the continuous dependence on the use of a single activation energy to characterize the temperature dependence of a component is the imposing simplicity of extrapolation.

There are other circumstances in which the use of an activation energy to describe the temperature dependence of a device, component, or an assembly falls short of describing the true temperature dependence of electronic reliability. Several of the failure mechanisms may not be dependent on a steady-state temperature stress—but are instead driven by temperature cycling, spatial temperature gradient, and time-dependent temperature change. Such mechanisms have a minor or no dependence on the absolute value of temperature. Lowering temperature does not reduce the probability of failure by such mechanisms.

TABLE 4.22.1
Material Degradation Limits of Electronic Materials Based on Temperature Stress Alone

	Typical Material Sets	Material Degradation Limit due to Temperature Stress Only (°C)
	Integrated Circuits	
Mold compound	Epoxy	T_g = 155°C –175°C; T_{max} = 215°C –245°C
	Silicone Room-Temperature-Vulcanization (RTV), lead encapsulation	T_{max} = 260°C; T_{min} = –54°C
Wire bond	Gold	T_m = 1064.2°C
	Copper	T_m = 1084.7°C
	Aluminum	T_m = 660.31°C
Flip-chip	95Pb/5Sn	T_m = 308–312°C
	Electro-deposited Nickel	T_m = 1455°C
TAB	Polymide	T_g = 332°C –344°C; T_{max} = 344°C –360°C
	Copper metallization	T_m = 1084.7°C
Interposer substrate	BT-epoxy	T_g = 220–230°C; T_{max} = 150–170°C
	Elastomers	T_{max} = 300°C; T_{min} = –120°C
	Polymide	T_g = 332–344°C; T_{max} = 344–360°C
Package I/O	Alloy 42 (lead frame)	T_m = 1427°C
	Copper (lead frame)	T_m = 1084.7°C
	Sn1Ag0.5Cu solder	T_m = 216.84 ± 0.5°C
	Sn3Ag0.5Cu solder	T_m = 217–218°C
	63Sn/37Pb solder	T_m = 183°C
Metallization	Copper	T_m = 1084.7°C
	Aluminum	T_m = 660.31°C
Chip	Silicon	T_{max} = 300°C –350°C; T_m = 1414°C
	Gallium arsenide	T_m = 1283°C
	Discretes	
Spring contacts	Beryllium copper	T_m = 1587°C –1750°C
	Phosphor bronze	T_m = 900°C –1050°C
Capacitors, resistors, inductors	Ceramic (BeO)	T_m = 2527°C
	Ceramic (Al_2O_3)	T_{max} = 1000°C
	Copper	T_m = 1084.7°C
	Polymide	T_g = 332°C–344°C; T_{max} = 344°C–360°C
	Assembly Level	
Interconnections	Sn1Ag0.5Cu solder	T_m = 216.84 ± 0.5°C
	Sn3Ag0.5Cu solder	T_m = 217°C–218°C
	Solder joints (63Sn/37Pb)	T_m = 183°C
	Copper metallization	T_m = 1084.7°C
PCB	FR-4	T_g = 130°C–140°C
	High T_g laminate materials	T_g = 175°C–180°C
Plastic casings	ABS	T_{max} = 85°C
	PC/ABS	T_{max} = 90°C

T_g, glass transition temperature; T_{max}, maximum continuous service temperature; T_m, melting temperature.

TABLE 4.22.2
TSEP versus Device Technology

Device Technology	TSEP
MOSFET	V_{th}, $V_{DS(on)}$, $R_{DS(on)}$
IGBT	V_{th}, $V_{CE(s)}$
Bipolar	V_{BE}, $V_{CE(s)}$
Diode	V_F

Table 4.22.3 shows a summary of the variation in the temperature dependence of typical failure mechanisms in the temperature range of –55°C to 400°C (Lall et al. 1997). The interested reader is referred to Lall et al. (1997) for an in-depth treatment on the subject.

Thermal Characteristics of PCBs

Conventional PCB is typically a layered composite consisting of copper foil and a glass-reinforced polymer (FR-4). Figures 4.22.1 and 4.22.2 show the cross-section of four-layer PCB with metal layers and plated-through holes and blind vias.

Figure 4.22.3 shows the mathematical equivalent of the PCB cross section. Azar and Graebner (1996) and Graebner (1995) have shown that for many thermal calculations, it is convenient to treat the PCB as a homogeneous material, with two different effective thermal conductivities—one describing heat flow within the plane (in-plane) and another for heat flow through the thickness of the plane (through). The equations for calculating each of these conductivities, given the values for the thickness and thermal conductivity of each layer, are presented:

$$K_{\text{in-plane}} = \frac{\sum_{i=1}^{N} K_i t_i}{\sum_{i=1}^{N} t_i}, \tag{4.22.1}$$

$$K_{\text{through}} = \frac{\sum_{i=1}^{N} t_i}{\sum_{i=1}^{N} \frac{t_i}{K_i}}, \tag{4.22.2}$$

where K is the conductivity in (W/mK) and t is the thickness in (m). The subscripts in-plane, through, and I indicate the in-plane, through, and the individual-layer components, respectively. Equations 4.22.1 and 4.22.2 assume complete copper planes, which is typically not the case in most designs

(except for layers with ground planes). The nonground plane layers are accounted for calculating the fractional coverage of copper by

$$K_i = f_i K_{\mathrm{Cu}}, \tag{4.22.3}$$

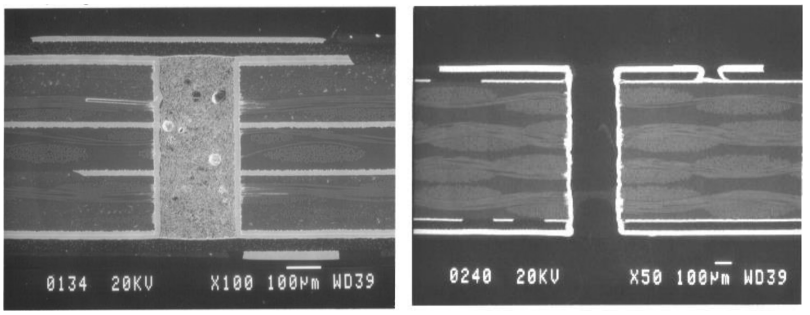

FIGURE 4.22.2 Cross-section of high-density interconnect PCBs with and without filled vias. (Courtesy of Motorola).

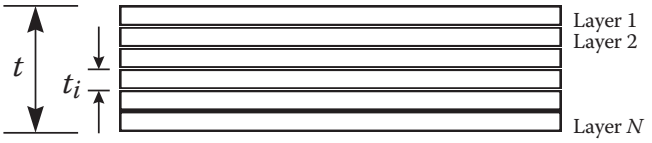

FIGURE 4.22.3 Mathematical equivalent of the PCB cross-section.

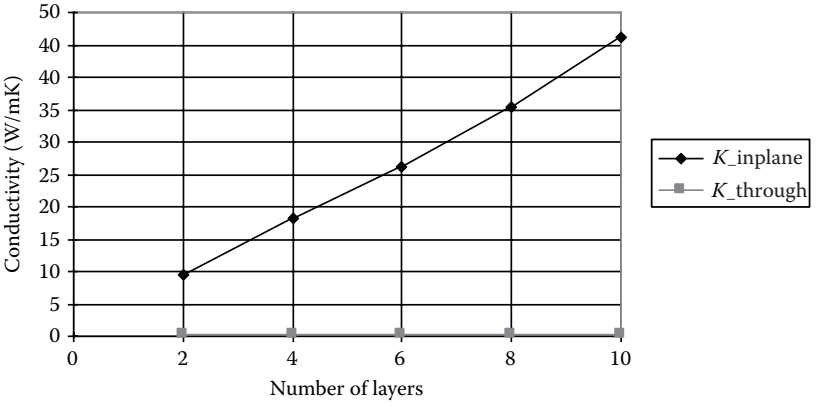

FIGURE 4.22.4 Conductivity versus number of layers for a 55 miles thick FR-4 PCB with 1/2 oz/ft^2 copper on the internal layers.

where f_i is the fractional coverage of copper for layer i. Figure 4.22.4 shows the in-plane and through conductivity for a 55 mils thick 2-layer, 4-layer, 6-layer, 8-layer, and 10-layer PCB with 1/2 oz/ft^2. Copper on the internal layers (assuming that the layers consist only of copper and FR-4, i.e., no vias) where the thermal conductivity for copper is 390 W/mK and thermal conductivity for FR4 is 0.25 W/mK. Figure 4.22.4 indicates that the $K_{\text{in-plane}}$ is two orders of magnitude higher than K_{through}. Heat flow through the copper layers dominates the heat transfer because of the large differential in the thermal conductivities of the copper and FR-4 layers. For the same reason, a typical PCB is not an efficient conductor of heat, leading to significant local variations in the PCB temperature in the vicinity of heat-generating components. Thermal conduction is not very efficient for heat flow in a direction lacking a continuous copper path.

Thermal Characteristics of Electronic Packages

Package Architecture

Most electronic packages consist of a silicon chip bonded to an interposer or a lead frame through wire bonds or controlled collapse solder joints. The package I/O is either solder balls on the substrate or leads on the lead frame. Table 4.22.4 shows schematic of package cross section and package characteristics for common chip-scale package families including (1) Flex-Substrate BGA, (2) Elastomer-on-Flex Package, (3) Partial-Array Chip-Scale Package, and (4) Rigid or Flex Interposer Chip-Scale Package. Other conventional design includes Thin Small Outline Package (TSOP), Quad Flat Pack (QFP), Small Outline Integrated Circuit (SOIC), etc. The interested reader is referred to the IPC-SM-782 for a more detailed description of the standard package types.

Materials and Properties

Table 4.22.5 shows the typical material sets used in integrated circuit packages and their thermal conductivities. Die attach bonding is used to mechanically attach the die to the lead frame and also to provide a heat flow path to the lead frame. A typical adhesive is a thermally conductive epoxy composite with a thermal conductivity of 0.8 W/mK. The epoxy adhesive layer is typically 25 μm thick. Wire bonding and flip-chip are the commonly used techniques for the first-level interconnection in the plastic package interconnection technology. Traditionally, the gold wire has been the preferred material on account of its high oxidation resistance and low work hardening characteristics. Recent advances have resulted in the use of copper interconnects for wire bonding. The migration to copper interconnects has been triggered by the higher cost of gold wire in comparison with copper.

TABLE 4.22.4
Schematic of Package Cross-Section and Characteristics for the Common Chip-Sale Packages

Package Schematic	Characteristics
Package Schematic  Flex-Substrate BGA	*Flex-Substrate BGA* is a ball-grid array format chip-scale package. The chip is wire bonded to the single-sided flex-polymide substrate. Package I/Os are solder balls, which go-through holes in the substrate and connect to the solder pads on the chip side of the polymide substrate
 Elastomer-on-flex BGA	*Elastomer-on-Flex Package* involves a chip flipped on to an elastomeric substrate. All the chip I/Os are routed to a single-sided flexible circuit, which is bonded to the other side of the elastomeric substrate by beam leads (gold or copper 18 μm thick). The beam leads are extensions of the printed circuit on the flexible circuit, which are connected to solder balls
 Partial array BGA	*Partial-Array Chip-Scale Package* is a ball-grid array format chip-scale package. The chip is connected through wire bond interconnects to a multilayer organic substrate. Package I/Os are solder balls, which go-through holes in the substrate and connect to the solder pads on the chip side of the polymide substrate
 Rigid or flex interposer package	*Rigid or Flex-Interposer Chip-Scale Package* The rigid or flex interposer packages consists of a solder-bumped integrated circuit (IC), which is flip-chip bonded to an (rigid or flex) interposer substrate—approximately 8 mils thick—and then underfilled with an encapsulant. Chip I/Os are routed to package I/Os through the interposer substrate to solder bumps attached to the bottom side of the interposer substrate

The thermal conductivity of the gold wire is 319 W/mK while that of copper is in the neighborhood of 368–400 W/mK. The majority of electronic mold compounds (EMCs) in plastic packages use epoxies with fillers made of silica, alumina, aluminum–nitride particles. The fillers in the molding compound are intended to improve its mechanical strength, thermal conductivity, adhesion to package components, chemical resistance, electrical resistance, coefficient of expansion match, and thermal and moisture resistance in the operational temperature range. The thermal conductivity of a typical EMC is 0.67 W/mK with a glass transition temperature of 150°C. EMCs, in addition to providing protection for the silicon chip, are required to meet U-94, plastic flammability standards. In order to meet these conditions, flame retardants are added into molding compounds, which at high temperatures can work as catalyst and accelerate process of failure of bond wires. Commercially available PEMs are able to operate in the neighborhood of 175°C. Thermal degradation causes major changes in physical and chemical properties of the molding compound, which can severely affect the reliability of electronic devices. Prolonged exposure to very high-temperature results in degradation of the binding material in molding compound accompanied with oxidation producing a gradual loss of weight. Figures 4.22.5 and 4.22.6 show plots of percentage weight loss and aging duration, for mold compounds A, B, C, D for thermal aging at 200°C and 250°C.

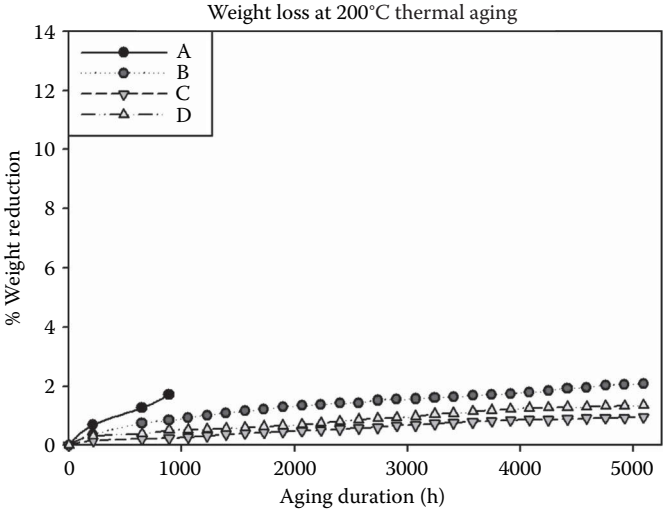

FIGURE 4.22.5 Weight loss of epoxy mold compounds A, B, C, and D at 200°C. (From Lall, P. et al., Degradation mechanisms in electronic mold compounds subjected to high temperature in neighborhood of 200°C, *Electronic Components and Technology Conference, 64th ECTC*, pp. 242–254, Orlando, FL, May 27–30, 2014.)

Mold compound-A is a high-temperature epoxy molding compound capable of low warpage and excellent reflow crack resistance. Mold compound-B is a higher temperature version of the mold compound-A. Mold compound-C is a multiaromatic epoxy with multiaromatic hardener and low-alpha filler with a filler content of 85%. Mold compound-D is a silicone encapsulation material capable of high electrical resistivity, high thermal and mechanical stability. Silicone-based encapsulants (EMC-D) exhibit the best high-temperature performance in the neighborhood of 200°C–250°C in comparison with high-temperature epoxies and multiaromatic epoxy with multiaromatic hardeners.

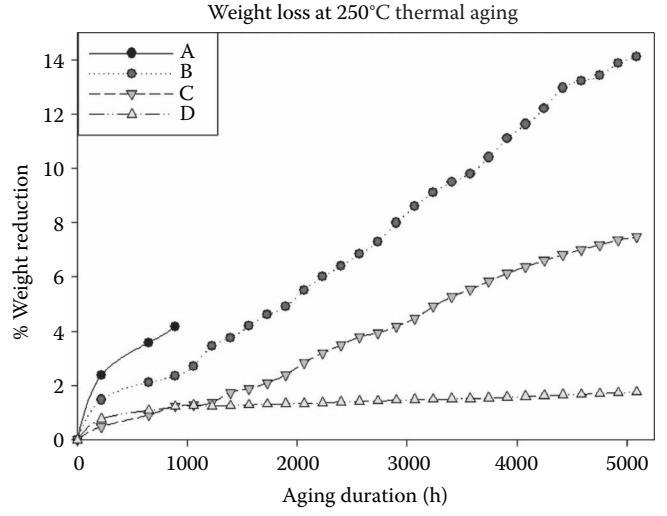

FIGURE 4.22.6 Weight loss of epoxy mold compounds A, B, C, and D at 250°C. (From Lall, P. et al., Degradation mechanisms in electronic mold compounds subjected to high temperature in neighborhood of 200°C, *Electronic Components and Technology Conference, 64th ECTC*, pp. 242–254, Orlando, FL, May 27–30, 2014.)

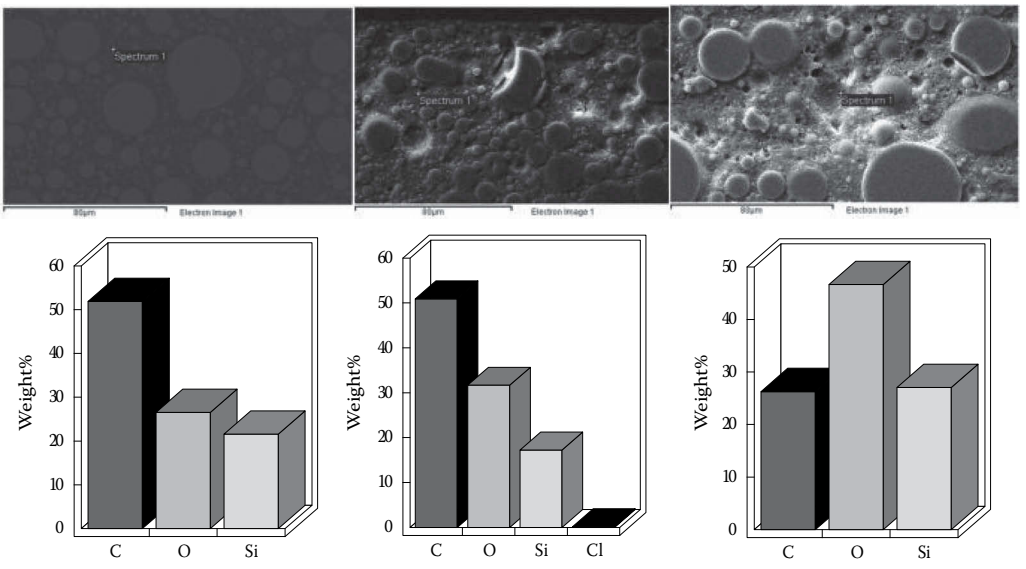

FIGURE 4.22.7 Molding compound "A", 200°C. (From Lall, P. et al., Degradation mechanisms in electronic mold compounds subjected to high temperature in neighborhood of 200°C, *Electronic Components and Technology Conference, 64th ECTC*, pp. 242–254, Orlando, FL, May 27–30, 2014.)

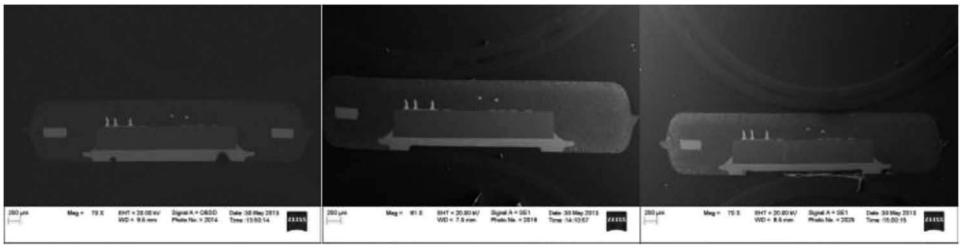

FIGURE 4.22.8 Molding compound "A", 250°C. (From Lall, P. et al., Degradation mechanisms in electronic mold compounds subjected to high temperature in neighborhood of 200°C, *Electronic Components and Technology Conference, 64th ECTC*, pp. 242–254, Orlando, FL, May 27–30, 2014.)

The high-temperature epoxy mold compounds (EMC-A) exhibit the poorest performance in comparison with multiaromatic epoxy with multiaromatic hardner and silicone-based encapsulants.

Lall et al. (2014) have studied the high-temperature survivability of a number of mold compound families at 200°C and 250°C of sustained operation. High-temperature epoxy molding compound-A exhibits rapid growth of oxidation layer was shown in Figures 4.22.7 and 4.22.8. Exposure to 200°C aging oxides is majority of the EMC-A volume (indicated by the light gray region), and exposure to 250°C results in complete oxidation of the EMC-A after 2000 h of aging. Mold compound-A exhibited the highest rate of weight loss and mold compound oxidation. EMC-A became very brittle after 2000 h, which its handling was a major issue. Mold compound cracked easily and broke during normal handling. EDX analysis was performed on white oxidation layer in the mold compound revealed higher oxygen content and lower carbon content in degraded layer as compared to time 0 samples. Loss of carbon is because of evaporation of products of decomposition of long polymer chains. Higher oxygen content shows that some of the products are oxidized. Results are shown in Figure 4.22.9.

Multiaromatic epoxy with multiaromatic hardener EMC-C exhibited an oxidation layer after 2000 h of aging at 200°C and 1000 h of aging at 250°C, shown in Figures 4.22.10 and 4.22.11. Oxidation layer is at along edges of the package, and from there it propagates toward the center of

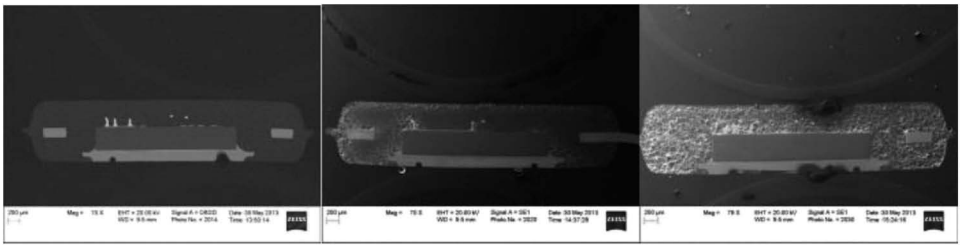

FIGURE 4.22.9 EDX analysis of EMC candidate-A—(a) time 0, (b) intermediate oxidation, and (c) complete oxidation. (From Lall, P. et al., Degradation mechanisms in electronic mold compounds subjected to high temperature in neighborhood of 200°C, *Electronic Components and Technology Conference, 64th ECTC*, pp. 242–254, Orlando, FL, May 27–30, 2014.)

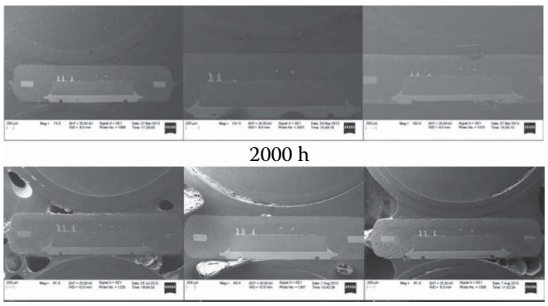

FIGURE 4.22.10 Molding compound "C", 200°C. (From Lall, P. et al., Degradation mechanisms in electronic mold compounds subjected to high temperature in neighborhood of 200°C, *Electronic Components and Technology Conference, 64th ECTC*, pp. 242–254, Orlando, FL, May 27–30, 2014.)

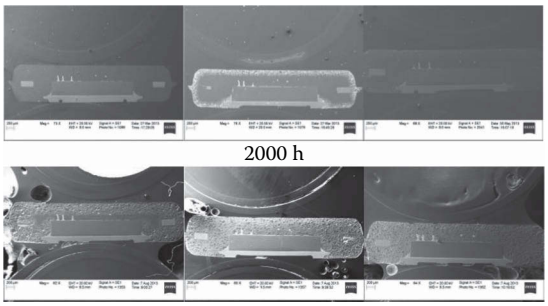

FIGURE 4.22.11 Molding compound "C", 250°C. (From Lall, P. et al., Degradation mechanisms in electronic mold compounds subjected to high temperature in neighborhood of 200°C, *Electronic Components and Technology Conference, 64th ECTC*, pp. 242–254, Orlando, FL, May 27–30, 2014.)

the package. For 200°C case, a large cross section of the mold compound was oxidized after 5000 h, and at 250°C, complete cross section area was oxidized. Silicone encapsulation material, EMC-D, results were very different and are shown in Figures 4.22.12 and 4.22.13. There was no oxidation area observed at edges of the package in this case; but there were oxidation spots spread throughout the cross-section in all cases. The density of the oxidation spots increased for the aged samples, but even after aging for 5000 h, however most of the area did not exhibit oxidation.

The predominant semiconductor material in the electronics industry today is silicon. The thermal conductivity of silicon is temperature dependent. Figure 4.22.14 shows the thermal conductivity of silicon versus temperature in the range of 75°C–150°C.

Effect of Aging on the Material Properties of Lead-Free Solders

Material properties for both SAC105 and SAC305 lead-free solder alloys are sensitive to the aging temperatures for a given period of time. Properties degrade nonlinearly under exposure to temperatures between 25°C and 125°C for times of 1 day to 61 days (Figures 4.22.15 through 4.22.30; Tables 4.22.6 through 4.22.21). The 1-day aged samples exhibit a higher elastic modulus and higher ultimate tensile strength compared to solder samples aged at the elevated temperature in each case.

Samples exposed to 60 days of isothermal aging exhibited the lowest elastic modulus and ultimate tensile strength of all the cases tested. Also, a special case where the rate of cooling effects (reflowed vs water quench) on material properties of SAC Alloys were determined for 1 day aging at 25°C (Lall et al. 2013).

Understanding Basic Semiconductor Thermal Parameters

Key parameters used to describe the thermal capability of a semiconductor device include (1) T_J, junction temperature; (2) T_C, case temperature; (3) T_A, ambient temperature; (4) TSP, temperature-sensitive

consists of a resistor–capacitor network as shown in Figure 4.22.31. Resistors R_1, R_2, and R_3 are all analogous to individual thermal resistances.

Resistor R_1 is the thermal resistance from the device's junction to its die bond. Resistor R_2 is the thermal resistance from the die bond to the device's case. Resistor R_3 is the thermal resistance from the device's case to ambient. The thermal resistance from the junction to some reference point is equal to the sum of the individual resistors between the two points. For instance, the thermal resistance $R\theta_{JC}$ from junction-to-case is equal to the sum of resistors R_1 and R_2. The thermal resistance

$R\theta_{JA}$ from junction-to-ambient, therefore, is equal to the sum of resistors R_1, R_2, and R_3. The capacitors model the transient thermal response of the circuit. When heat is instantaneously applied and or generated, there is a charging effect that takes place. This response follows an RC time constant determined by the resistor–capacitor thermal network. Thermal resistance, at a given time, is called transient thermal resistance, $R\theta_{JR(t)}$.

$$R_{\theta JR} = \frac{T_J - T_R}{P_D}, \tag{4.22.4}$$

$$P_D = \frac{T_{max} - T_R}{R_{\theta JR}}, \tag{4.22.5}$$

$$T_J = P_D R_{\theta JR} + T_R. \tag{4.22.6}$$

Generally, T_J is measured utilizing an electrical characteristic of the device that is repeatable and an accurate function of temperature. A key factor in understanding thermal resistance measurements is that if the application configuration is different from that of the measured device, the thermal results will be different. Thermal data on manufacturers' data sheets are designed for comparison with other manufacturers' devices and to give the user a place to begin their thermal management solution.

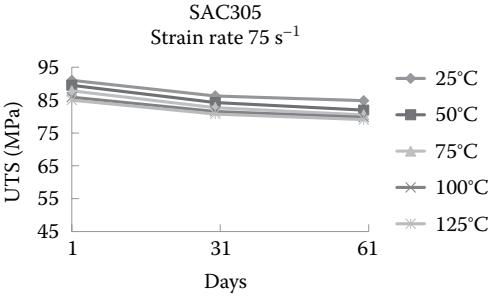

FIGURE 4.22.30 Effect of temperature on ultimate tensile strength of SAC305 at strain rate of 75 s^{-1}. (From Lall, P. et al., High strain rate properties of SAC105 and SAC305 leadfree alloys after extended high-temperature storage, *Proceedings of the SMTA*, Ft. Worth, TX, pp. 363–377, October 13–17, 2013.)

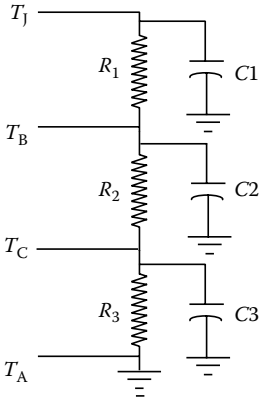

FIGURE 4.22.31 Thermal electrical equivalent circuit heat generated in a device's junction flows from a higher temperature region through each resistor–capacitor pair to a lower temperature region (From Mulgaonker, S. et al., *IEEE Transactions on Components, Packaging, and Manufacturing Technology: Part A,* 17(4), 573–582, 1994; Mulgaonker, S. et al., *IEEE Transactions on Components, Packaging, and Manufacturing Technology: Part A,* 18(4), 739–748, 1995. With permissions.) (Courtesy of Motorola).

The thermal performance of power-plastic ball grid array (PBGA) packages cannot be adequately quantified by the traditional $R\theta_{JA}$ measurements. Power-PBGA packages are typically designed thermal vias and "thermal balls," which couples the thermal performance of the package to that of the board. Mulgaonkar et al. (1994, 1995) have shown that the thermal performance of the package is dominated by the thermal performance of the PCB.

Figure 4.22.32 shows the comparison of thermal performance between a 100 lead 14 mm × 14 mm plastic QFP package and a 119 lead 14 mm × 22 mm PBGA package mounted on a single-layer and a four-layer board. There are 32 vias from the die paddle of PBGA to the array of 21 thermal balls. The thermal balls are soldered to an array of board pads. The board pads are connected to the ground plane in the PCB with 32 vias. The planes in the circuit board are solid 1 oz. copper. While the two packages have very similar thermal performance as measured on the standard single-layer PCB, there is a substantial difference in the performance on the four layer boards. PBGA packages are more closely coupled to the PCB than QFPs—in terms of their sensitivity to temperature and power dissipation of neighboring components. The higher thermal conductivity of the four-layer board with two solid 1 oz. planes causes more of the board to act as a heat sink. The effect is enhanced for the PBGA packages because there is metal conduction path from the die pad to the ground plane of the PCB. This path has much lower thermal resistance than the equivalent path for the QFP.

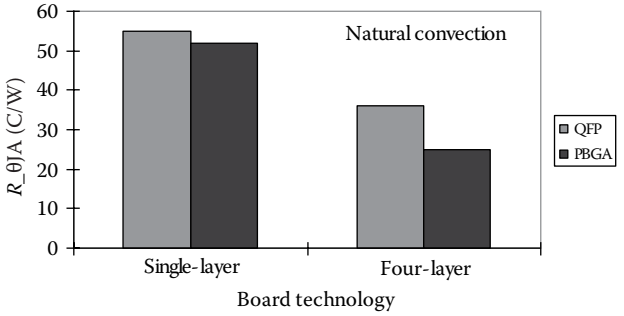

FIGURE 4.22.32 Comparison of thermal performance between a 100 lead 14 mm×14 mm plastic QFP package and a 119 lead 14 mm×22 mm PBGA package mounted on a single-layer and a four-layer board (From Mulgaonker, S. et al., *IEEE Transactions on Components, Packaging, and Manufacturing Technology: Part A,* 17(4), 573–582, 1994; Mulgaonker, S. et al., *IEEE Transactions on Components, Packaging, and Manufacturing Technology: Part A,* 18(4), 739–748, 1995. With permissions.) (Courtesy of Motorola).

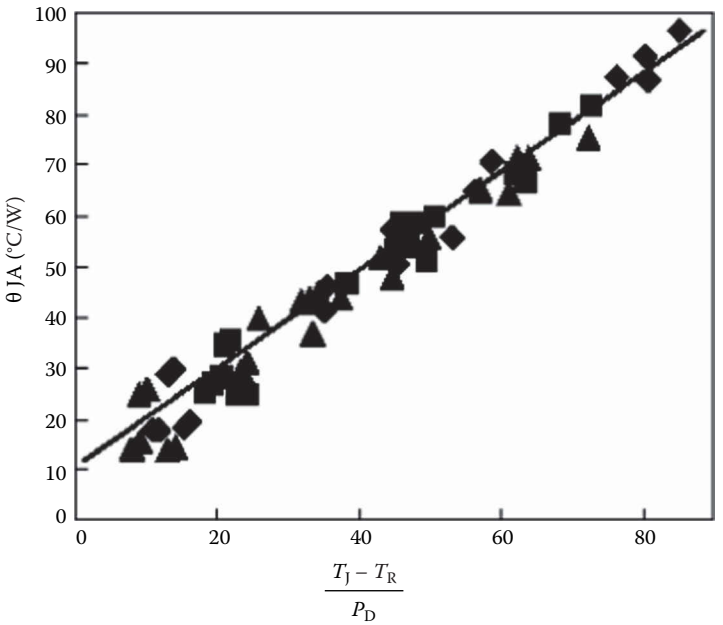

FIGURE 4.22.33 $R_{\theta JA}$ versus $(T_J - T_R)/P_D$ for a PBGA subjected to natural convection and various conditions of forced convection, 1 and 2 m/s (From Mulgaonker, S. et al., *IEEE Transactions on Components, Packaging, and Manufacturing Technology: Part A,* 17(4), 573–582, 1994; Mulgaonker, S. et al., *IEEE Transactions on Components, Packaging, and Manufacturing Technology: Part A,* 18(4), 739–748, 1995. With permissions.) (Courtesy of Motorola).

Figure 4.22.33 shows the $R\theta_{JA}$ versus $(T_J - T_R)/P_D$ for a PBGA on a populated board subjected to natural convection and various conditions of forced convection, 1 and 2 m/s. The thermal performance of PBGAs is linearly dependent on the board temperature rise above ambient (divided by package power dissipation). Mulgaonkar et al. (1994, 1995) have represented the thermal performance of electronic packages with equations of straight lines of the form "$y=mx+c$," where "m" is the slope and "c" is the intercept (Table 4.22.22).

A more traditional way to examine the data is to use a table of θ_{JA} determined by a variety of techniques (Table 4.22.23). The junction temperature depends on the environment including the

TABLE 4.22.22
Parameters for Thermal Performance of Electronic Packages (Mulgaonkar et al. 1994, 1995)

Sixteen components at 1 W	104	84

Source: Courtesy of Motorola.

conductivity of the board and the power dissipation of surrounding components. The single component on a multilayer board represents the lower extreme with the higher extreme represented by packages mounted closely together on both sides of the board. The values obtained from the single component on a multilayer board would predict a lower value of the junction temperatures for most applications than would be observed in the typical case with substantial power dissipation in other devices on the board. The effect of the board's power density on the junction temperature is shown by the doubling of the observed θ_{JA} when the packages are mounted on both sides of the board compared to the single sided board (Table 4.22.23). Mounting the packages on both sides of the board effectively halves the area available for power dissipation for each package (Mulgaonkar et al. 1994, 1995).

The traditional θ_{JA} is useful for comparing package performance and as a preliminary estimate to determine whether further analysis is needed. It gives no information to account for the range of thermal performance given as examples in Table 4.22.23. The board temperature is determined by a full board level thermal simulation. There are a number of commercial software codes 6–8 that perform a board level thermal solution with varying degrees of sophistication. These range in sophistication from the 2 1/2 dimensional finite difference or finite element codes to the computational fluid dynamics codes that simultaneously solve the conduction and the fluid flow convection. For all these simulation codes, a simplified thermal model for the package is required.

Thermal Interface Materials

Integrated circuits are kept within their operating temperature limits by transferring the generated heat to the ambient environment. This is often done by attaching a heat sink to the semiconductor package surface. When the electronic component and heat sink surfaces are brought together, typically <1% of the surfaces make physical contact. Much of the surfaces are separated by a layer of interstitial air. The reason is that all surfaces have a certain roughness due to microscopic hills and valleys. Superimposed on this surface roughness is a macroscopic nonplanarity in the form of a

concave, convex, or twisted shape. When the two such surfaces are brought together, only the hills of the surfaces come into physical contact. Some heat is conducted through the physical contact points, but much more has to transfer through the air gaps. Air is a poor conductor of heat and is replaced by a conductive thermal interface. Interface materials fill the voids and grooves created by imperfect surface finish of two mating surfaces, thus forcing air out and improving surface contact and the conduction of heat across the interface.

Typical thermal interface materials include greases, reactive compounds, elastomers, and pressure-sensitive adhesive films. All are designed to conform to surface irregularities. Some have secondary properties and functions, as well. Thermal greases and epoxies provide the lowest interface resistance, but they are pastes and require care in handling. Elastomers eliminate handling problems but they sometimes require high compressive loads even with well-prepared surfaces. Thermal tapes offer great convenience but their gap filling properties are limited.

Interpretation of Material Data

The thermal properties of interface materials are be measured by either ASTM test standard D5470-93 or military specification MIL149456A. Both methods are recognized throughout the industry as standards. High contact pressures (300 psi for ASTM and 500 psi for MIL SPEC) are used to reduce the effects of interface resistance generated by trapped air in the interface. The data gathered at high pressures are then used as the published thermal performance characteristics.

In typical microelectronics packaging applications, the contact pressure varies between 10 and 50 psi and data provided at 300 psi will be an underestimation of material thermal resistance. Any pressure exceeding 50 psi might damage the packaging itself. Typically, the manufacturers do not publish low-contact pressure data because of the case dependency of interface resistance. The thermal resistance of the interface material is a function of the contact pressure.

Types of Thermal Interface Materials

Thermal Greases

Thermal greases are made by dispersing thermally conductive ceramic fillers in silicone or hydrocarbon oils to form a paste. Table 4.22.24 shows some typical grease materials and their thermal conductivity. Sufficient grease is applied to one of the mating surfaces such that when pressed against the other surface, the grease flows into all voids to eliminate the interstitial air. Excess grease flows out past the edges and the thinnest possible thermal joint is formed as the two surfaces come into contact at their high points. Joint integrity has to be maintained with spring clips or mounting hardware. Thermal greases are notoriously "user unfriendly," but provide very low thermal resistance between reasonably flat surfaces. Grease does not provide electrical insulation between the two surfaces, and excess grease that flows from the joint should be cleaned up to prevent contamination problems. Greased joints can also dry out with time, resulting in increased thermal resistance.

Thermal Epoxies

Epoxies are useful in cases where a permanent thermal bond is needed, but soldering is not an option. There are three general types: (1) Silver-filled epoxy can be used from –55 to +125°C,

TABLE 4.22.24
Typical Thermal Greases and Their Thermal Conductivities

Thermal Grease	Thermal Conductivity (W/mK) @ 300 psi
Zinc oxide/silicone based	0.56
Al_2O_3/nonsilicone	2.78
AlN/nonsilicone	3.47

(2) Al_2O_3, and (3) Aluminum Nitride (AlN) (Table 4.22.25). Both Al_2O_3 and AlN types can operate up to 130°C for a limited amount of time. Thermally conductive compounds are an improvement on thermal grease as these compounds are converted to a cured rubber film after application at the thermal interface. Initially, these compounds flow as freely as grease to eliminate the air voids and reduce the thermal resistance of the interface. After the interface is formed, the compounds cure with heat to a rubbery state and also develop secondary properties such as adhesion. Formulations with adhesive properties do not require mechanical fasteners to maintain the integrity of the joint. Since the binder cures to a rubber, these compounds do not have the migration or the dry joint problems associated with thermal greases. Compounds can be used to fill large gaps where greases would bleed from the joint on account of their migratory nature. Clean-up is also simple as excess material is easily removed after it has been cured to a rubber. Cure times range from 24 h at 22°C or 2 h at 65°C for silver-filled epoxies to 1 h at 85°C for Al_2O_3- and AlN-filled epoxies.

Elastomer Pads

Thermally conductive elastomers are silicone elastomer pads filled with thermally conductive ceramic particles, often reinforced with woven glass fiber or dielectric film for added strength. These elastomers are available in thickness from about 0.1 to 5 mm and hardness from 5 to 85 Shore A. Unlike compounds and greases, elastomer pads provide electrical insulation and can be used between surfaces that are at different electrical potential. They are typically used under discrete power devices where electrical isolation is required.

Elastomers do not flow freely like the greases or compounds, but will deform if sufficient compressive load is applied to conform to surface irregularities. At low pressures, the elastomer cannot fill the voids between the surfaces and the thermal interface resistance is high. As pressure is increased, more of the microscopic voids are filled by the elastomer and the thermal resistance decreases. For most high durometer materials, mounting pressures around 300–500 psi eliminate the interstitial voids and reduce interface resistance to a minimum. Mounting pressure must be permanently maintained by using fasteners or springs to hold the two surfaces together.

Table 4.22.26 shows the thermal performance of some common conductive elastomers. Despite the 3–6 W/mK thermal conductivity, the thermal resistance at low pressures is in the neighborhood of 1.8°C/W, twice that of grease. Typical contact area at low pressures is in the neighborhood of 30%.

TABLE 4.22.25
Typical Thermal Epoxies and Their Thermal Conductivities

Thermal Epoxy	Cure Time	Thermal Conductivity (W/mK)
Silver filled	24 h @ 22°C or 2 h @ 65°C	1.39
Al_2O_3 filled	1 h @ 85°C	0.93
AlN filled	1 h @ 85°C	2.78

TABLE 4.22.26
Typical Elastomer Pad Materials and Their Thermal Conductivities

Elastomer Pads	Thermal Conductivity (W/mK)
Paraffin/Al	3.46–6.54
97% Graphite	3.38–5.62
Al_2O_3	1.63–4.33

Adhesive Tapes

Thermally conductive adhesive tapes are double-sided pressure-sensitive adhesive films filled with sufficient ceramic powder to balance their thermal and adhesive properties. The adhesive tape is usually supported either with an aluminum foil or a polyimide film for strength and ease of handling. Polyimide support also provides electrical insulation. Adhesive tapes perform much like the elastomeric films, in that they also require some initial mating pressure to conform to irregularities in the mating surfaces. They are also unable to fill large gaps between nonflat surfaces. However, once the joint is formed, the adhesive tapes require no mechanical support to maintain the mechanical or thermal integrity of the interface.

Adhesive tapes provide convenience in attaching a heat sink to a semiconductor package because, unlike liquid adhesives, no cure time is required. The film is applied to one of the surfaces, usually to the heat sink, and it is then forced into contact with the semiconductor package to complete the thermal joint. The application pressure is typically 10–50 psi for a few seconds duration. The bond thus formed can be considered permanent and the heat sink is reliably attached to the semiconductor.

However, this convenience comes at a price. The thermal resistance for adhesive tapes is only slightly better than a joint without any thermal interface material. This is because the thermal tapes do not fill gaps as well as liquids, and thermal joints made with tapes will normally include considerable interstitial air gaps. For the most part, the quality of the two joining surfaces will determine the amount of contact that can be achieved and the thermal performance that can be expected. The high shear strength of these thermal tapes means that reliable joints between heat sinks and semiconductors can be achieved, even with poor surfaces and no mechanical fasteners.

Computers

Portable computing applications bring with them the challenges of size, weight, and power consumption. Microprocessor (CPU) is the major source of heat dissipation in a portable computer. Cooling systems, in general, increase the size and weight of the portable computer.

Understanding Temperature Limits

Heat from a portable computer is passively dissipated by warming the outside surface (skin) of the plastic or the housing material over the ambient air and actively dissipated by using a fan and heat exchanger. Most fan designs can remove about 4–8 W of heat and the rest is passively dissipated by natural convection and radiation from the outside surface. The passive dissipation of the heat requires elevation of the notebook skin temperature over the air temperature. Typically, as a guideline the portable computer-skin temperature is kept lower than 50°C. Typical ambient operation temperatures are in the neighborhood of 25°C–35°C, an environment that applies to most air-conditioned places. Most personal computer chassis result in an internal 10°C temperature increase over ambient temperature. In such an environment, the portable computer-skin temperature will be 40°C–50°C (assuming 15°C above ambient). Since the human body temperature is 37.1°C, temperatures in the neighborhood of 40°C are perceived as normal and temperatures above 50°C are perceived as hot to touch. The temperature specifications for many keyboards are generally in the range 55°C–60°C and thus the keyboard operation will be at the specification limit. Similar logic can apply to other temperature-sensitive components (e.g., HDD, CD-ROM) inside the notebook (AMD 1998; Intel 1998b).

Figure 4.22.34 shows the maximum temperature versus component for a portable computer. Notebook computers are generally put together with standard components of varying maximum ambient temperatures. The failure mechanisms are device dependent. Floppy disk drive and compact disk drives start to degrade in the neighborhood of 50°C–55°C. The media in floppy disk drives warps and sticks to the casing at high temperatures. CD-ROM drives have laser diode aligned to the compact disc—large dimensional changes produce misalignment and malfunction.

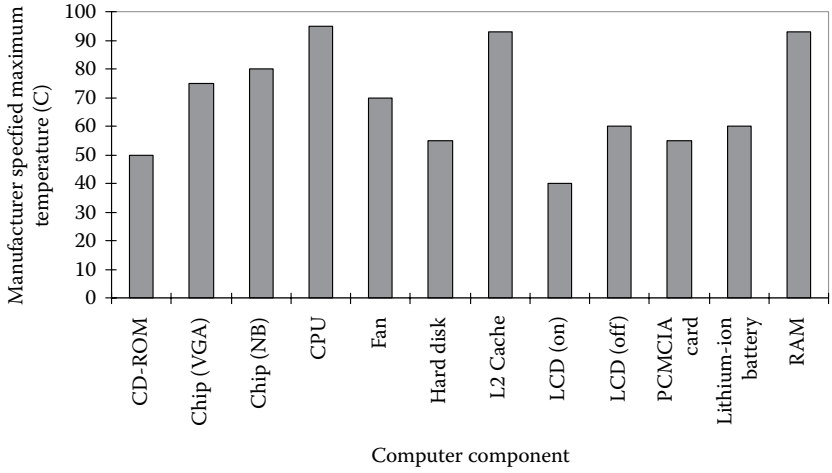

FIGURE 4.22.34 Manufacturer specified maximum temperature for personal computer components. (Based on data from Sterner, J., Thermal design challenges in a Pentium notebook computer, *Proceedings of the IMAPS International Systems Packaging Symposium*, pp. 107–112, December 1997. With permission.)

Temperature dependence of hard drive performance is often claimed by manufacturers of HDD cooling products. However, temperature (below a certain temperature limit, T_{limit}) does not directly affect the performance of the drive in any significant way. Seek times and data transfer rates generally stay the same with variation in temperature below T_{limit}. The rise in temperature, however, does require thermal recalibration, producing a very small performance degradation. Many SCSI drives, operating at 10,000 rpm, have a thermal recalibration loop. The rise in ambient temperature causes the drive to warm up—the platters expand, and their geometry changes, thus making recalibration necessary. During recalibration, the hard drive makes a short pause to recalibrate itself. Generally, hard drives operating in cooler environments recalibrate less frequently. However, new generation drives with embedded servo do not have a thermal recalibration loop, and thus their performance is totally unaffected by the operating temperature (up to a certain temperature limit). Hard disks are high precision machines with very tight tolerances. Large temperature variations ($T_{ambient} > T_{limit}$) cause dimensional changes, which cannot be compensated—causing malfunctions. Typical upper limit (T_{limit}) on hard drive temperature is in the neighborhood of 60°C. Cooling is generally recommended for all hard drives with rotation speeds higher than 7200 rpm (Steinbrecher 1998).

Figure 4.22.35 shows the power dissipation in typical ACTIVE and PASSIVE cooled portable computers. The ACTIVE and PASSIVE computers compared in Figure 4.22.35 have different equipment. Figure 4.22.36 shows the computer surface temperature versus power dissipation for a typical ACTIVE and typical PASSIVE cooled portable computer for an ambient temperature of 25°C. The bottom surface of the computer is insulated. The top (keyboard) and side walls are used as a radiator. The notebook casing is made of ABS/PC plastic or painted metal chassis (emissivity = 0.95) and has an isothermal casing temperature. The data presented in Figures 4.22.35 and 4.22.36 are for an ACTIVE cooled portable computer 10 in. × 12.3 in. × 1.0 in. base unit (excluding lid thickness) and a PASSIVE cooled portable computer with base size of 8.2 in. × 10.2 in. × 0.65 in.

In general, ACTIVE cooled portable computers can dissipate more power than PASSIVE cooled portable computers and still meet the temperature specification for the computer-casing temperature (Figure 4.22.35). While CPU is not the only component dissipating heat, it is certainly one of the major contributors to increase in computer surface temperature. Other major contributors are the graphics card, memory, hard drives, and power supplies. For operation at 15°C above ambient temperature (25°C), about 15–17 W of total platform power (entire notebook power minus the display power) can be managed passively in a typical notebook. The allowable power dissipation for

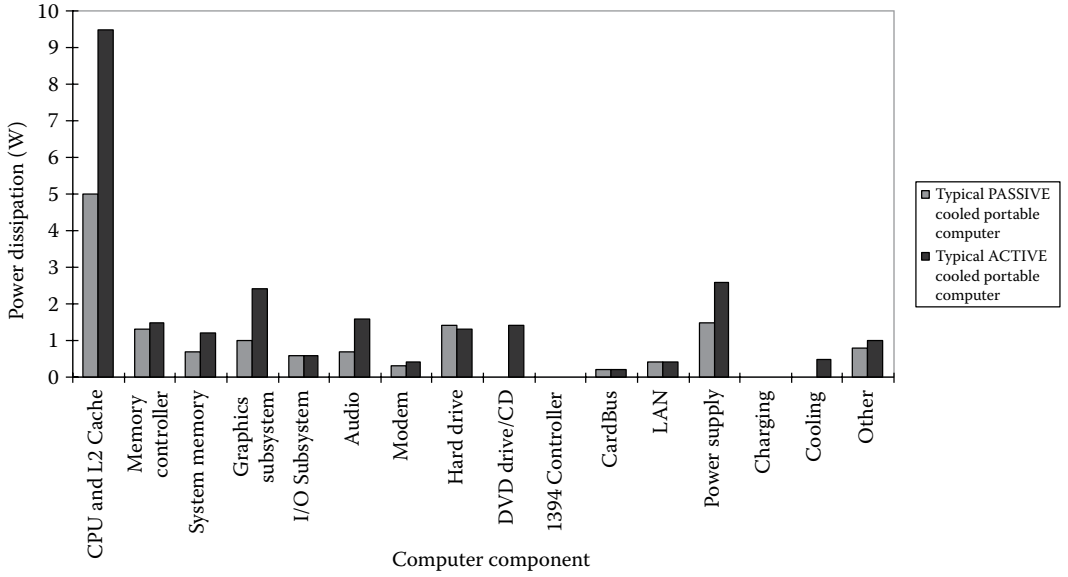

FIGURE 4.22.35 Power dissipation in typical ACTIVE and PASSIVE cooled portable computers. The ACTIVE and PASSIVE computers compared in the figure have different equipment. ACTIVE cooled portable computers can dissipate more power for any temperature specification of the computer-casing temperature. (Based on data from Intel Corporation, *Mobile Power Guidelines 2000*, Available from http://developer.intel.com/design/ mobile/intelpower/, Revision 0.8, September 16, 1998b.)

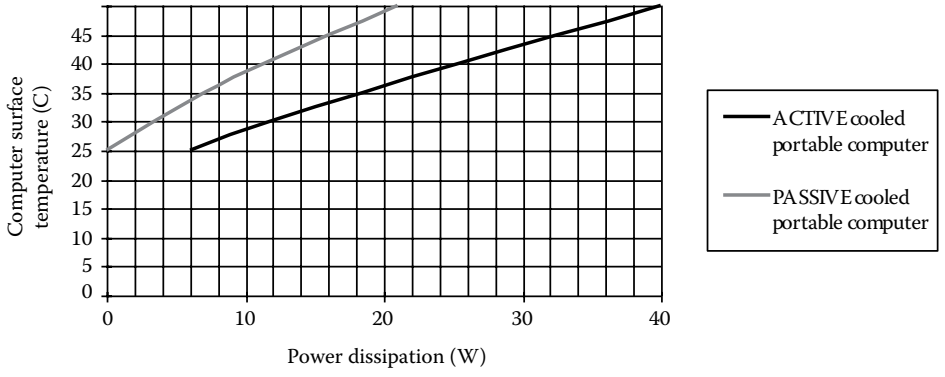

FIGURE 4.22.36 Computer surface temperature versus power dissipation for a typical ACTIVE and a typical PASSIVE cooled portable computers for an ambient temperature of 25°C. The ACTIVE and PASSIVE computers compared in the figure have different equipment. (Based on data fromIntel Corporation, *Mobile Power Guidelines 2000*, Available from http://developer.intel.com/design/ mobile/intelpower/, Revision 0.8, September 16, 1998b.)

an actively cooled portable computer is in the neighborhood of 24–25 W (Figure 4.22.36). [Based on data from Intel (1998b).]

Casing Materials

External skin temperature of the portable computer is designed to be safe to human touch. For most purposes, temperatures above 50°C are deemed unsafe to human touch. Computer casings are generally made of ABS (acrylnitrite–butadiene–styrene) resin, PC/ABS blend (polycarbonate/ABS), or

magnesium alloy. The maximum temperature for continuous operation for both ABS and PC/ABS casings is in the range of 85°C–90°C. Table 4.22.27 shows the properties for some typical ABS and PC/ABS blends used for computer housings.

The ABS resin has low-thermal conductivity and the molding process constraints limit the wall thickness of ABS enclosure to a minimum of 1.2–1.4 mm. Acrylonitrile–butadiene–styrene (ABS) thermoplastic resin is widely recognized as an engineering material offering a good balance of properties centering around toughness, hardness, and rigidity. Resin grades in this product family consist of a blend of an elastomeric component and an amorphous thermoplastic component. The elastomeric component is usually polybutadiene or a butadiene copolymer. The amorphous thermoplastic component is SAN, a copolymer of styrene and acrylonitrile. The flexibility offered by the use of the three monomer system (A, B, and S) allows the tailoring of the property profile.

Variation of the ABS material include blends of amorphous PC and ABS terpolymer, which combine the most desirable properties of both materials resulting in an optimum balance of performance, processability, and cost. By varying the ratio of PC and ABS, resins can be tailored to meet the specific property requirements of a wide range of high-performance applications from automotive body panels and computer housings, to instrument panels and cellular phones. CYCOLOY resins offer the processability of ABS together with the mechanical properties, impact and heat resistance of PC. These thermoplastic alloys are formulated for exceptional flow for filling thin-wall sections and complex parts.

In contrast, magnesium alloy can be injection molded to a wall thickness of 0.7 mm. Magnesium's best attributes are its high strength-to-weight ratio and light weight. As a structural material, it can be alloyed with several other elements including aluminum, manganese, rare-earth elements, silver, zinc, and zirconium. The various alloys have unusually high strength and are light weight. Magnesium is most commonly found alloyed with aluminum where its addition to aluminum increases hardness and improves corrosion resistance. Magnesium also possesses superior heat radiation properties, heat stability, electromagnetic interference shielding properties, and damping capabilities. Recent developments in thin-wall casting combined with magnesium's other characteristics are leading to increased applications in the electronics field for cellular telephones, video cameras, and personal computers (casings, battery shields, etc.). Table 4.22.28 shows the properties for typical magnesium alloys used for computer housings.

Typical Heat Transfer Schemes

Figure 4.22.37 shows some of the typical active and passive heat transfer schemes used for portable computing applications. Figure 4.22.37a shows a passive heat transfer scheme with the use of a heat pipe along with a heat spreader to conduct the heat from the microprocessor. Figure 4.22.37b shows an active heat transfer scheme using a finned heat sink and fan. Figure 4.22.38 shows the representative Dual In-line Memory Module (DIMM) layout in a high-performance server. The buffered DIMM module shows a number of Dynamic Random Access Memory (DRAM) devices and a buffer chip. The basic layouts of other memory modules are similar. Figure 4.22.39 shows the temperature variation across a registered DIMM with a peak temperature of 120°C.

In desktop computers, fans are used to evacuate the hot air from the case. Figure 4.22.40 shows some of the common fan configurations in AT and ATX form-factor cases. Case fans come in many flavors, but usual sizes include 80 mm × 80 mm and 92 mm × 92 mm. The size and location of the fan depends on the computer case. Most desktop computers come in AT or ATX form-factor cases. In general, most designs use some combination of fans blowing air into and out of the computer case. The idea being that the CPU located directly in the airflow will get cooled. However, as the power supply gets hot, the fan blows warm air toward the CPU. There are two possibilities for installing the fan: Either above the power supply on the back (especially common with ATX cases) or on the lower part of the front side (common with AT cases). Care is exercised in determining the direction of air flow for each of the fans to make sure that (1) the fans do not create an air short circuit, which prevents circulation of air through the computer case and (2) the fans do not try to work against each other and try to create a vacuum inside the case.

Figure 4.22.41 shows the temperature variation across DRAM chips in a DIMM on a desktop machine. The increase in system performance with each new processor generation increases the

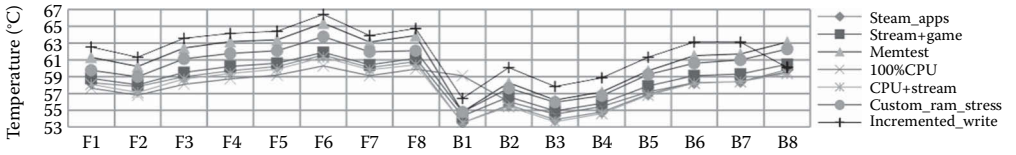

FIGURE 4.22.41 Temperature variation across DRAM chips in a DIMM on a desktop machine. (From Liu, S. et al., Hardware/software techniques for DRAM thermal management, *Proceedings of the 17th IEEE International Symposium on High Performance Computer Architecture (HPCA)*, pp. 1–11, 2011.)

system level thermal demands. In order to meet these thermal needs, the current systems require either multiple fans or heat sinks to maintain the necessary junction temperatures for the baseboard components. Need for multiple fans can be avoided by using FAN DUCTS. The fan duct distributes the air from a single fan to all parts of the system that require cooling—thus avoiding the need for multiple fans. A recommended path for a low-cost solution in these systems is to provide a fan duct that blows external air onto the processor core components (processor, chipset, graphics, graphics controller, and memory) (Intel 1998a).

Handheld Communication Devices

Mobile communication products such as cellular phones, pagers, two-way radios, personal digital assistants are being driven to increased functionality and smaller form factors by technological enhancements at device, package, and system levels.

Understanding Application Requirements

Typically, handheld products involve plastic cases, which have been snap-fitted or screwed together—space is at premium. The electronic packages are assembled in small, confined enclosures, and the stand-alone thermal performance of the packages does not guarantee similar levels of performance on the phone. The problem is further complicated by the fact that the plastic housings for handheld products have to remain cool enough to be safe to human touch.

Pagers typically are receivers and their active components dissipate low power (a few milliwatts) over a short operational time (several milliseconds). Cooling is generally not a concern. However, newer pagers including two-way paging involve transmitting signals with a power dissipation of approximately 1 W over an extended period of operation. Phones generate most of their heat in the power amplifier (PA) module (PA). The PA can dissipate power in the range of 1–3 W. Typically, cellular phones are two board designs including the main RF board and a keypad board. Typically, the keypad board has the front keypad popples for the phone and very few if any components. The PA module and other ICs are mounted on the main RF board. Two-way radios are similar to cellular phones except the power dissipation requirements are in general significantly larger. Handheld two-way radio PA may generate 1–10 W of power depending on the mode of operation. Two-way radios, like the cellular phones, are two-board designs including a main RF board and a keypad board. The PA in general is located on the main RF board.

Thermal Management: Some Test Cases

The choice of thermal management schemes is severely limited because of the space, size, weight, and cooling system power requirement constraints. The added weight of carrying a heavy cooling system in a handheld communication device is typically not an attractive option—let alone put up with the fan noise while talking on the phone or two-way radio. Cooling system power requirements further increase battery size and reduce standby and talk time. Passive cooling schemes in general are preferred—most of the heat generated in handheld portable products by the integrated circuits is

transmitted to the externals predominantly by conduction and to a lesser extent by natural convection and radiation.

Table 4.22.29 shows some of the common passive heat transfer schemes implemented by providing a solid conduction path between the PA module and the product casing. The solid conduction path between the PA and the system housing can be either a metal block or a thermally conductive pad (epoxy or silicone with a thermal conductivity of ~2 W/mK), a metal spring (~0.8 mm thick), or a thin metal foil (~0.04 mm thick). The material for metal block, spring, or foil could be either copper or aluminum. The metal block, conductive pad, or spring is simply inserted into the gap and the contact is maintained by the press fit. An adhesive tape may be required to attach the foil to the PA and housing. The metal foil can also be used as a heat spreader on the inside surface of the system case. If the power dissipated by the PA can be effectively transferred to the case wall (such as by a solid conduction path), then the heat spreader can quickly distribute the local heat flux over the larger area, reducing component temperatures.

Figure 4.22.42 shows the PA temperature versus power dissipation at the PA for various thermal enhancement techniques. Lee et al. (1998) showed that the least effective enhancement was made by positioning the thermal pad between the board (on the back side of the PA) and the case. The configuration with the thermal pad directly contacting the PA reduced PA temperature by 34%. The copper spring, due to its higher thermal conductivity and larger heat transfer cross-sectional area, provided the best solid conduction path. The copper foil provided an intermediate enhancement. In addition to the solid conduction path, adding the heat spreader to the case further reduced the PA temperature by an average of 26%. A combination of a thin metallic spring and a heat spreader on the enclosure provided the highest enhancement with a 68% reduction in PA temperature.

Casing Materials

Typically handheld portable product casings are made from ABS or PC/ABS blends. Materials are chosen based on various attributes including thin-wall molding, mold release, elastic modulus, and thermal conductivity. Table 4.22.30 shows the mechanical and thermal properties for typical handheld product casing materials.

Impact of Temperature on Handheld Product Reliability

In general, high temperature does not drive the reliability of handheld portable products. High-temperature bake is often used to cure moisture-related problems in PCBs and packages. A 24 h

Density (lb/in.^{3})	0.043

bake at 150°C prevents popcorn or blistering of the packages or the PCB during reflow. However, high temperature during operation does impact the handheld product casing temperature.

Product reliability has a dominant dependence on the thermal cycling instead of high steady-state temperature. Thermal fatigue is a wear-out mechanism as a result of product usage (e.g., making phone calls, operating in home, office, car, leaving phone in the car, etc.) in different environments and product power cycling (turning ON and OFF). Figures 4.22.43 through 4.22.45 show the dominant chip-scale package failures caused by thermal fatigue in package form factors typically used in handheld communication products.

Figure 4.22.43 shows an cross-section of a Flex-Substrate BGA after thermal fatigue failure. The 48 I/O, 0.8 mm pitch Flex-Substrate BGA packages (SRAM) were soldered onto a 0.8 mm thick,

Immersion Ni/Au finish PC Board. The board assemblies were subjected to Liquid-Liquid Thermal Shock (LLTS), −55 to 125°C, 5.8 c/h. The primary crack propagation site is at the package-to-solder joint interface.

Partial-Array BGAs fail primarily by solder joint failure. Figure 4.22.44 shows a cross-section of a Partial-Array BGA Package (48 I/O, 0.5 mm pitch) after thermal fatigue failure. The 48 I/O, 0.5 mm pitch Partial-Array BGA was soldered to a 1.2 mm thick, OPC finish, PC Board and subjected to LLTS, −55 to 125°C, 5.8 c/h. The primary crack propagation site is at the package substrate-to-solder joint interface.

Elastomer-on-Flex Packages fail in thermal fatigue, primarily due to the fracture of the beam leads internal to the package. Figure 4.22.45 shows cross-section for Elastomer-on-Flex Packages (48 I/O, 0.65 mm and 0.75 mm pitch, FLASH) soldered onto 0.8 mm thick, Ni/Au finish PC boards. Beam lead failure typically occurs in the neighborhood of 400 (Vendor A) to 650 cycles (Vendor B) depending on the package Vendor. The board assemblies were subjected to LLTS −55 to 125°C, 5.8 c/h. The interested reader is referred to Lall et al. (1998) for a more detailed discussion of non-linear reliability modeling and failure mechanisms for the Elastomer-on-Flex Packages.

Figure 4.22.46 shows the thermal fatigue reliability for the Partial-Array BGA (0.5 mm pitch 48 I/O), Elastomer-on-Flex Package (0.65 mm pitch, 48 I/O), Flex-Substrate BGA (0.8 mm pitch, 48 I/O). Weibull distribution distinguishes between failure mechanisms by difference in the slopes of the distributions. The similarity in the slopes of the Flex-Substrate BGA and the Partial-Array

With permissions.)

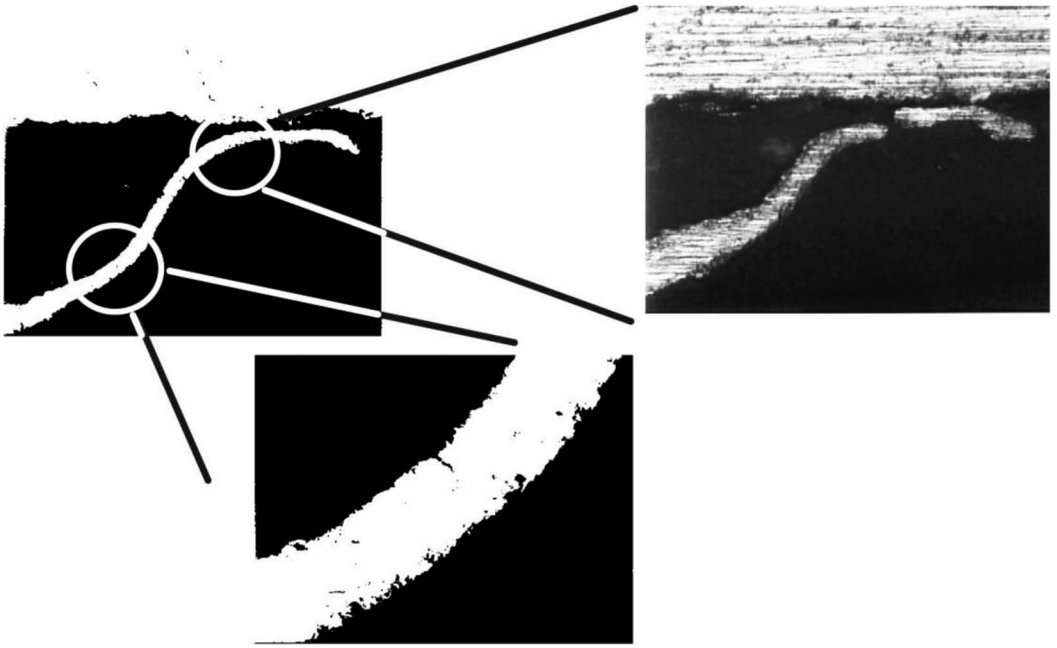

FIGURE 4.22.45 Cross-section of the Elastomer-on-Flex Package after thermal fatigue failure. The solder joints do not fail—the dominant failure mechanism is the thermal fatigue failure of the beam leads internal to the package. (Lall, P. et al., Reliability characterization of the SLICC package, *Electronic Components and Technology Conference (ECTC)*, Orlando, FL, May 28–31, pp. 1202–1210, 1996; Lall, P. et al., *Influence of Temperature on Microelectronic and System Reliability*, Boca Raton, FL: CRC Press, 1997; Lall, P. and Banerji, K., Assembly-level reliability characterization of chip-scale packages, *Electronic Components and Technology Conference (ECTC)*, Seattle, Washington, DC, May 25–28, Session 13, Paper 2, 1998a; Lall, P. and Banerji, K., Assembly-level reliability of flex-substrate BGA, elastomer-on-flex packages, and 0.5 mm pitch partial array packages, *Surface Mount International Conference (SMI)*, San Jose, CA, August 23–27, 1998b. With permissions.)

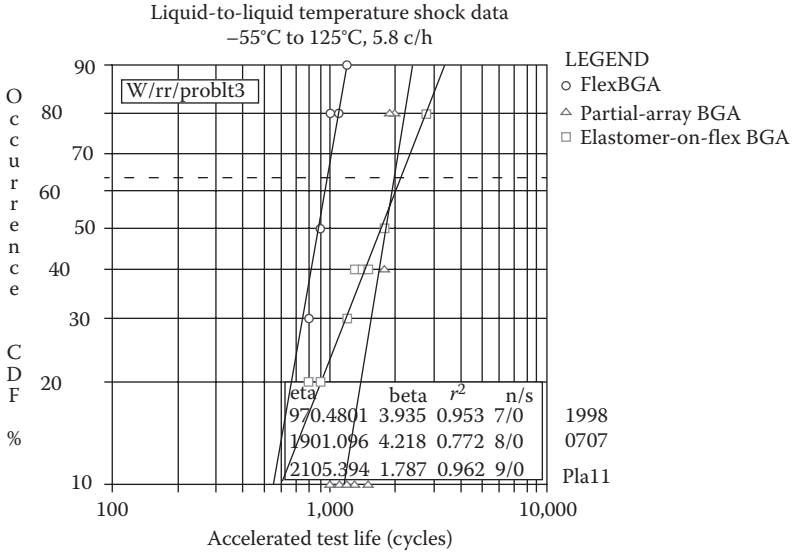

FIGURE 4.22.46 Weibull distributions for the Flex-Substrate BGA Package, Elastomer-on-Flex Package, and the Partial-Array BGA Package subjected to LLTS, –55 to 125°C, 5.8 c/h.

BGA Packages is because of similarity in the mechanisms of failure—solder joint fatigue. The difference in the slope of the Elastomer-on-Flex Package is because of a different failure mechanism—beam lead failure. Figure 4.22.47 shows the normalized accelerated test time-to-first failure of the packages (LLTS –55°C to 125°C, 5.8 c/h) versus package type.

Acceleration Transforms

Environmental usage profile has been developed based on phone usage profile, typical environmental extremes, and the measured thermal behavior of the radio. The profiles (Figure 4.22.48) have been developed for two distinct environmental conditions—extreme (hot, cold). Nonlinear finite element simulations have been run to evaluate the field life and correlate the LLTS cycles to years of field life.

Acceleration transforms have been derived based on nonlinear finite element model predictions. An acceleration transform quantifies the acceleration factor for an accelerated test environment compared to actual field use environments. The acceleration transform is in turn determined by several variables including the component and board—geometry, materials, architecture, and most

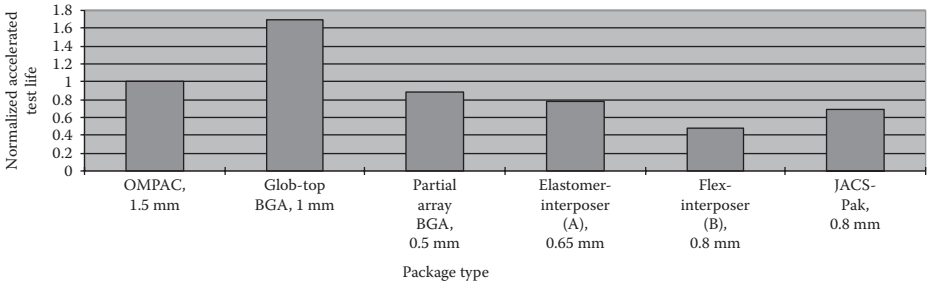

FIGURE 4.22.47 Comparison of the thermal fatigue reliability for the Partial-Array BGA (0.5 mm pitch 48 I/O), Elastomer-on-Flex Package (0.65 mm pitch, 48 I/O), Flex-Substrate BGA (0.8 mm pitch, 48 I/O), and Glob-top BGA (1 mm pitch, 196 I/O) versus OMPAC (1.5 mm pitch, 68 I/O).

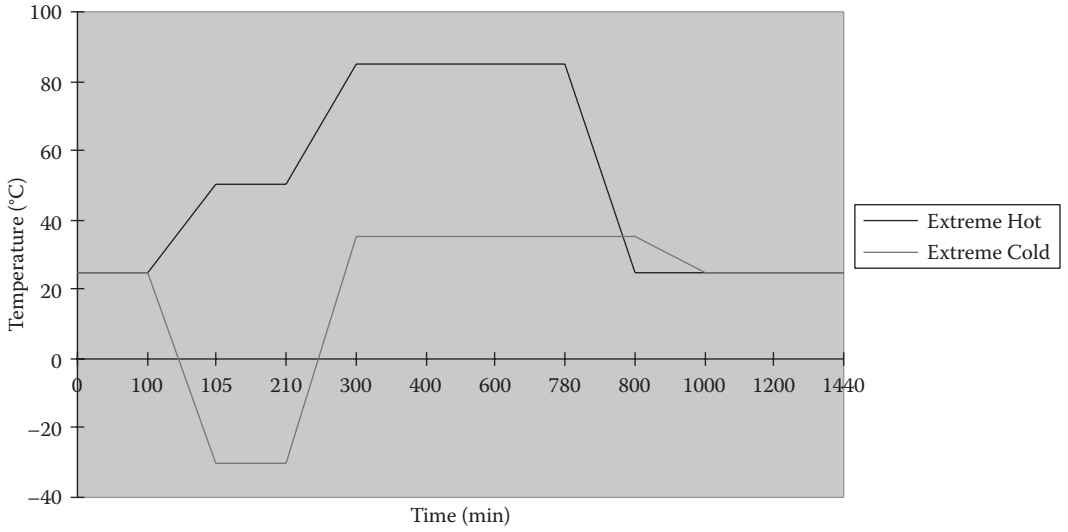

FIGURE 4.22.48 Schematic of temperature profile for extreme hot and extreme cold environments. (From Lall, P. and Banerji, K., Assembly-level reliability characterization of chip-scale packages, *Electronic Components and Technology Conference (ECTC)*, Seattle, Washington, DC, May 25–28, Session 13, Paper 2, 1998a; Lall, P. and Banerji, K., Assembly-level reliability of flex-substrate BGA, elastomer-on-flex packages, and 0.5 mm pitch partial array packages, *Surface Mount International Conference (SMI)*, San Jose, CA, August 23–27, 1998b. With permissions.)

importantly the field profile. Ideally, one would like to have one acceleration transform, which can be used to evaluate the field life once the life in accelerated test has been evaluated.

Unfortunately there is no universal acceleration transform—further, there can be no such universal relationship. The reason being that the variables that influence this acceleration transform vary from component to component and thus can be derived only for a class of components, e.g., plastic BGAs, ceramic BGAs, TSOPs, pendulum, etc., in specific product architectures. Care has to be exercised in using such a simplification of the damage mechanics as the "acceleration transform."

The acceleration transform lumps into itself several geometry and architecture variables integral to the component, solder joint geometry, and the assumed field profile. If any of the variables change, the acceleration transform has no option but to change. For this reason, acceleration transforms make sense for a particular set of conditions and for particular components. The field profile is the temperature–time plot of the field environment for the radio. The acceleration transform represents the relationship between the accelerated test life and field life for a particular accelerated test and particular field profile. Solder is viscoplastic in nature—which means that it is sensitive to absolute value of temperature, temperature ramp rate, and time spent at temperature. Changes in either the field profile or accelerated test conditions change the damage sustained in solder and thus the joint reliability. *For this reason, the acceleration transforms presented in this paper are valid for the accelerated test conditions and environmental profiles for which they have been derived.*

Figure 4.22.49 shows the acceleration transforms for the 0.5 mm pitch, 48 I/O Partial-Array Package and the Flex-Substrate BGA 0.8 mm pitch, 48 I/O package. The vertical bars indicate the time-to-first failure for the package in each environment. The acceleration transforms can be used to calculate the accelerated test requirement for each package or inversely predict field life in any field use environment or any combination thereof. It is known from Miner's superposition rule that

$$\sum_{i=1}^{m} \frac{n_i}{N_i} = 1, \tag{4.22.7}$$

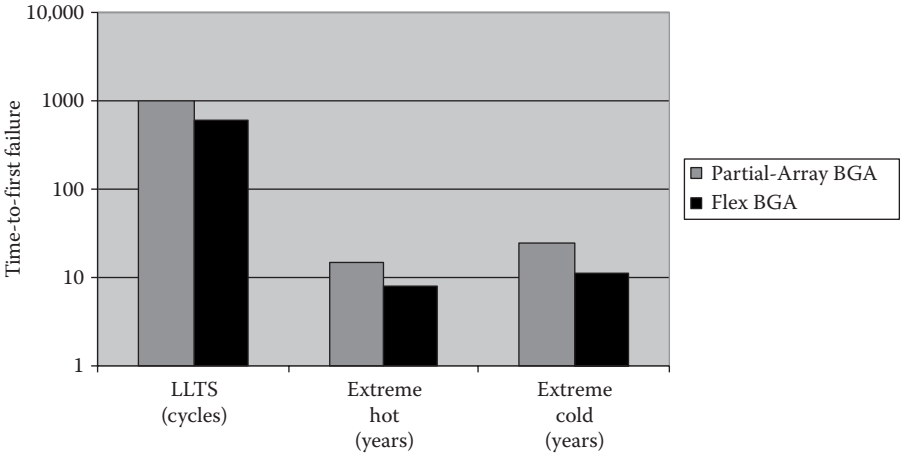

FIGURE 4.22.49 Acceleration transforms for Partial-Array BGA (0.5 mm pitch, 48 I/O Package) and Flex-Substrate BGA (0.8 mm pitch, 48 I/O Package) subjected to thermal fatigue. (From Lall, P. and Banerji, K., Assembly-level reliability characterization of chip-scale packages, *Electronic Components and Technology Conference (ECTC)*, Seattle, Washington, DC, May 25–28, Session 13, Paper 2, 1998a; Lall, P. and Banerji, K., Assembly-level reliability of flex-substrate BGA, elastomer-on-flex packages, and 0.5 mm pitch partial array packages, *Surface Mount International Conference (SMI)*, San Jose, CA, August 23–27, 1998b. With permissions.)

where n_i is the number of cycles in a particular environment, and N_i is the number of cycles to failure in the same environment, Miner's superposition rule states that the cumulative damage at end of life will be equal to 1. For example, the accelerated test requirement for a 10-year field life can be calculated, based on Figure 4.22.49 and Miner's superposition, as follows: $-n_i = 10$ years; $N_i = 15$ years for Extreme Hot Environment ($m = 1$); and $N_i = 1025$ for accelerated test environment, we want to find out $n_i = ?$

$$n_i = \frac{10}{15} \times (1025) = 684 \text{ cycles}. \tag{4.22.8}$$

Thus, 684 cycles of LLTS are required for the 0.5 mm pitch, 48 I/O Package to guarantee a 5-year life in Extreme Hot. The above method can also be used to calculate the accelerated test requirement for any combination of the above environments. For example, we want to calculate the accelerated test requirement for a product which will be in Extreme Hot for 6 years and in Extreme Cold for 4 years—$n_1 = 6$ years; $N_1 = 15$ years for Extreme Hot Environment; $n_2 = 4$ years; $N_2 = 25$ years for Extreme Cold Environment; and $N_i = 1025$ for accelerated test environment, we want to find out $n_i = ?$

$$n_i = \left(\frac{6}{15} + \frac{4}{25}\right) \times (1025) = 574 \text{ cycles}. \tag{4.22.9}$$

Thus, 574 cycles of LLTS are required for the 0.5 mm pitch, 48 I/O Package to guarantee a 10-year life (6 years in Extreme Hot and 4 years in Extreme Cold) (Lall et al. 1998).

Outdoor Telecommunication Electronics

Telecommunication electronics is extremely decentralized—located away from the controlled and protected environment of the central office—outside the plant (OSP).

Understanding the Environment

The OSP environment contains rain and humidity, dust and pollutants, significant daily and annual temperature swings, wide solar heat-load variations, and physical abuse. To protect electronics from this hostile environment, they are housed in a variety of OSP enclosures, which can range from small buildings (30 m^3) to small boxes (3×10^{-3} m3) that are mounted on the homes of customers. Heat densities within OSP enclosures can be large, often rivaling those of electronics designed for controlled indoor environments. Insolation is the amount of solar energy that is absorbed and transmitted into the enclosure.

The second source of heat in an outdoor enclosure is the solar energy that is absorbed and transmitted into the enclosure. The total insolation includes direct shortwave radiation from the sun, diffuse shortwave radiation that has been scattered by the atmosphere, and any shortwave radiation that is reflected from the ground or nearby surfaces. It is a complicated function of the orientation of the enclosure with respect to the earth–sun line; the amount of moisture, dust, and contaminants in the air; and the solar reflectivity and location of nearby surfaces (e.g., landscaping, fences, and buildings). Procedures for calculating the total shortwave radiation for an enclosure with a known location and orientation are well documented. [See References ASHRAE (1977) and HVAC (1987).]

Typically, outdoor enclosures are designed for the maximum solar load at the maximum ambient air temperature and the maximum internal heat load (Bellcore 1993). The maximum solar load is a function of the enclosure location and orientation. Figure 4.22.50 shows the total insolation incident on a 2 ft×4 ft×6 ft enclosure located in a low-reflecting open field environment (i.e., no surrounding reflecting surfaces). The shortwave absorptance of the enclosure surface affects the solar load absorbed into the enclosure. Table 4.22.31 shows typical values of the shortwave absorptance and longwave emittance for common enclosure surface treatments including polished aluminum and oil-based paints (white, light green, and light gray). Shortwave absorptance controls the fraction of

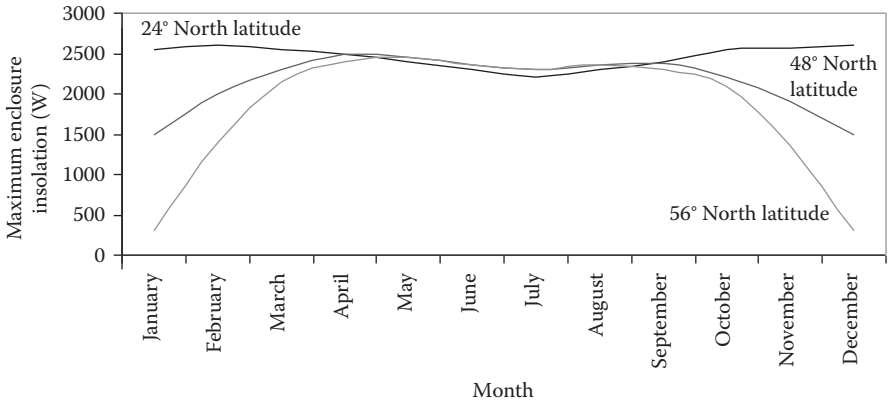

FIGURE 4.22.50 Maximum enclosure insolation versus calendar month and latitude.

TABLE 4.22.31
Typical Values of Shortwave Absorbtance for Common Enclosure Surface Treatments

Surfaces	Shortwave Absorptance	Longwave Emittance
Polished aluminum	0.03	0.05
White (oil-based paint)	0.2	0.9
Light green (oil-based paint)	0.5	0.9
Light gray (oil-based paint)	0.75	0.9

incident solar heat absorbed into the enclosure, and the longwave emittance controls the heat that is dissipated by radiation to the surroundings.

Hot surfaces radiate heat continuously in proportion to the fourth power of their absolute temperature (Stefan–Boltzmann law); the net heat radiated depends on the longwave emissivity of the surface and on the emissivities and temperatures of the surroundings.

The major heat sink for the heat dissipated from the enclosure is the local ambient air. The temperature of this sink varies widely with location, time of year, and time of day. Typical specification on the ambient air temperature range is −40°C to +46°C (−40°F to +115°F) (Bellcore 1993). Sky temperature is always lower than ambient air temperature, especially when the air contains little water vapor: This is the reason that frost occurs on terrestrial surfaces even when the air temperature is well above freezing. The atmosphere/remote sky is most effective as a radiant heat sink during the spring and fall, when dew point and dry-bulb temperatures are relatively low, and in dry dessert climates. It is not effective under overcast conditions or summer conditions of high dew point/dry-bulb temperatures.

Typical Heat Transfer Methods

Passive cooling methods are predominantly used in outdoor enclosures on account of their simplicity and lack of maintenance. The most common cooling method used today in the OSP is relatively simple. The enclosure is unventilated to protect the internal equipment from the rain, dust, and contaminants in the outside air. The internal heat is transferred primarily by convection to the inside surfaces of the enclosure, by conduction through the walls of the enclosure, and then by convection and radiation to the external heat sinks. Other passive methods include natural (free) convection in conjunction with phase change materials (PCMs) and solar reflectors. PCMs are substances that change phase, most often from solid to liquid, as they absorb heat. PCMs are selected for the temperature at which they change phase and for the latent heat associated with phase change. PCMs are sometimes used in conjunction with thermosiphons. Typical PCMs for high-temperature applications include waxes, salts, and paraffins. Water (ice) is used for low-temperature applications. The PCM is kept inside or attached to the enclosure in appropriately designed and sealed reservoirs (Figure 4.22.51). PCMs take advantage of thermal inertia and phase change effects. For example, an enclosure with PCMs during daylight hours will absorb heat through the cabinet walls and protect the electronics within the enclosure from overheating. The heat absorbed during the day will then be released to the outside world at night when it is cooler.

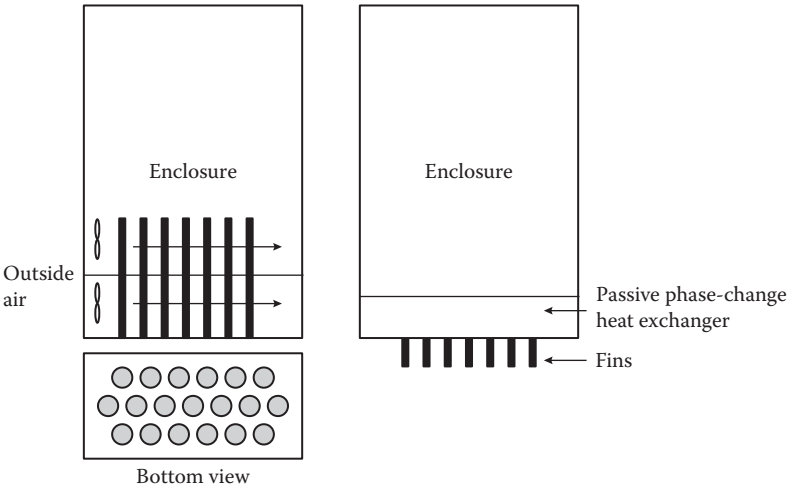

FIGURE 4.22.51 Heat transfer scheme for an outdoor enclosure using phase change materials. (From Marongiu, M.J. and Clarksean, R., Thermal management of outdoor enclosures using phase change materials, *Electronics Cooling*, Vol. 4, No. 1, January 1998.)

PCMs can also be incorporated into assisted systems for the cooling of enclosures. In order to enhance cooling, PCMs can be incorporated into a heat exchanger structure in which two fluids that are at different temperatures are separated by a PCM (possibly in encapsulated form). Hotter, internal air is first circulated through the heat exchanger and cooled by transferring its energy to the PCM, which slowly changes phase. This will occur during the hottest part of the day when external air temperatures prevent the use of outside air to cool the enclosure. Later in the day, when outside air temperatures drop, outside air is brought in to remove the heat stored in the PCM. Figure 4.22.51 shows a sketch for this simplified heat exchanger (Marongiu and Clarksean 1998).

High-Altitude Airborne Electronics

The heat transfer scheme is chosen based on the electronic module power dissipation surface density. Free convection is favored for power dissipation densities less than 500 W/m^2 (0.05 W/cm^2) on the surface of a fully populated PCB. Forced convection is used for power dissipation densities up to 4000 W/m^2. Heat pipes, liquid cooling, and boiling heat transfer is favored for power dissipation densities greater than 4000 W/m^2 (0.4 W/cm^2). This upper limit for forced air cooling is dictated by the fact that heat sinks cannot be used on the circuits due to the lack of space in avionics racks. The boards are designed for a minimum pitch.

Understanding the Environment

Figure 4.22.52 shows the decrease in density (kg/m^3) with increase in altitude (km). Air pressure at high altitudes greater than 21 km (70,000 ft) is so low that very little air is available for cooling. The volumetric flow (m^3/s) needed to cool the unit increases with increase in altitude. The static air temperature decreases with increase in altitude. In most hot day cases, the air temperature decreases with altitude. Typically, the reduction in temperature only occurs up to approximately 12 km (40,000 ft). On most cold days, the temperature actually increases with altitude in the first 3 km then the temperature begins to decrease. Cold days are not of great concern because the hot day defines the design point for worst case cooling conditions.

Impact of Equipment Location

Location of the equipment on aircraft affects electronic cooling designs based on the different qualities of air. Equipment located in the pressurized bay may be cooled by forced air cooling using

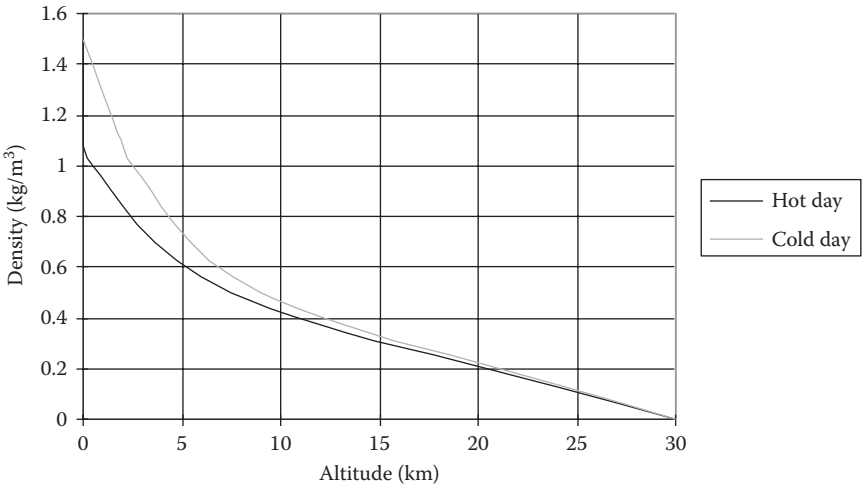

FIGURE 4.22.52 Variation in air density with altitude. (From Marthinuss Jr., J.E. and George, T.H., Cooling electronics at high altitudes made easy, *Electronics Cooling*, Vol. 4, No. 3, September 1998.)

a fan. The flow rate (Q) can be calculated from the overall power dissipation (P_d) and air temperature increase through the equipment by

$$Q = \frac{P_d}{(T_{out} - T_{in})\, m_p c_p}, \tag{4.22.10}$$

where T is the air temperature increase through the equipment, the subscripts out and in indicate the air temperature at the outlet and the inlet, m_p is the air specific mass, and c_p is the specific heat. The pressure drop can be calculated at the flow rate Q ($\nabla P = f(Q)$). A fan can be selected for the application based from a manufacturer's catalog using these two characteristics (Q, ∇P). Air velocity distribution obtained on each circuit should provide (1) a convective heat transfer coefficient sufficient to limit the temperature gradient between the components and the air and (2) provide uniformity of air flow distribution on each board. Local heat sinks can also be used on high power components, if space is available. Alternatively, a more powerful fan can be selected.

Electronics located in depressurized bays experiences a decrease in air density with increase in altitude. The air density decreases with decrease in atmospheric pressure. The air mass flow rate decreases with decrease in air density. This means that a fan with a higher volumetric flow is needed. Lower mass flow rate increases the outlet air temperature going through the equipment. This may or may not be compensated by the lower static air temperature at the inlet for higher altitudes.

Fighter aircraft typically have an environment control system—which can provide cool air to the electronic equipment. Flow rates and pressure drops obtained in such an environment is sufficient to cool the electronics efficiently. The main problem of forced convection cooling in such situation is due to air pollution. This air contains particles such as dust, sand, metals, and fluid droplets, such as oil, kerosene, and liquid water. Unfiltered air used for electronics cooling increases the risk of micro short circuits, abrasion, or chemical degradation of the components. Cooling with unfiltered air is obtained by avoiding contact between the components and the pollutants—air is passed through cold plates installed at the board level or at the rack level.

Figure 4.22.53 shows a compact-finned cold plate embedded in a double-sided circuit. This is an air flow-through module. The heat generated by the electronic components is transferred first by conduction through the board and then by forced air convection. The forced convection heat transfer coefficient is enhanced by the compact fins of the cold plate. Air is usually directed along the width of the circuit boards in order to limit the pressure drop.

Figure 4.22.54 shows a rack that has two cold plates cooled by the environmental control system air. The rack includes circuit boards, which are cooled by conduction enhanced by a metal (generally aluminum or copper) plate in contact with the wall cold plates through thermal clamps located on each side of the circuit.

Direct air forced convection on components may authorize power dissipation densities on a fully populated board, up to 3000 W/m^2, with an air velocity in the range of 5 m/s. This type of design requires nonpolluted air and a powerful fan on account of the high velocity of 5 m/s, which will generate high-pressure drops. An Air Flow-Through Module (AFT) may allow power densities up

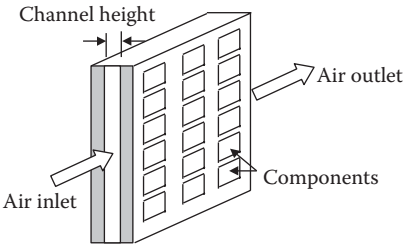

FIGURE 4.22.53 Schematic of a typical air flow-through module. (From Assouad, Y., Forced convection cooling of airborne electronics, *Electronics Cooling*, Vol. 3, No. 2, May 1997.)

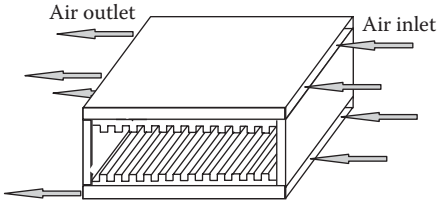

FIGURE 4.22.54 Schematic of a typical air-cooled rack for conduction-cooled electronic modules. (From Assouad, Y., Forced convection cooling of airborne electronics, *Electronics Cooling*, Vol. 3, No. 2, May 1997.)

to 3000 W/m^2 or more, but with a very large pressure drop penalty. For 3000 W/m^2, the pressure drop will be in the order of 5 mbar for a 100 mm wide module, which yields, for a 200 mm wide classical module, a total pressure drop of 10 mbar, not accounting for the distribution and collecting air chambers (Assouad 1997). Conduction-cooled modules in an air-cooled rack are limited to power densities up to 1500 W/m^2, due to the parabolic temperature gradient from conduction in the metal plate embedded in the PCB.

Fan Selection

Fan selection is based on attainable flow rate and pressure drop at the higher operating altitudes. The attainable flow rate is determined by the fan supply curve and the pressure drop is determined by the system pressure drop curve. The intersection of the two curves determines the operating point.

Conventional fans run at a constant speed. The operating point of a conventional fan varies with density since the pressure drop and flow rate curves vary with air density. The volumetric flow rate for a conventional fan is constant, while the pressure output is drastically different at different altitudes. The decrease in density produces a decrease in pressure drop and the volume flow rate.

$$\frac{Q_{h1}}{Q_{h2}} = \left(\frac{D_{h1}}{D_{h2}}\right)^3 \left(\frac{\omega_{h1}}{\omega_{h2}}\right), \tag{4.22.11}$$

where Q is the volume flow rate, D is the fan diameter, ω is the fan's rotational velocity (RPM), and the subscripts $h1$ and $h2$ indicate fan operation at heights $h1$ and $h2$.

$$\frac{\Delta P_{h1}}{\Delta P_{h2}} = \left(\frac{D_{h1}}{D_{h2}}\right)^3 \left(\frac{\omega_{h1}}{\omega_{h2}}\right)^3 \left(\frac{\rho_{h1}}{\rho_{h2}}\right), \tag{4.22.12}$$

where ΔP is the pressure drop, D is the fan diameter, ω is the fan's rotational velocity (RPM), ρ is the air density, and the subscripts $h1$ and $h2$ indicate fan operation at heights $h1$ and $h2$. Since the fan diameter and fan rotational velocity is constant, the equations can be reduced to

$$Q_{h1} = Q_{h2}, \tag{4.22.13}$$

$$\Delta P_{h1} = \Delta P_{h2} \left(\frac{\rho_{h1}}{\rho_{h2}}\right). \tag{4.22.14}$$

Equation 4.22.13 shows that the volumetric flow rate is constant with height for a conventional fan. Equation 4.22.14 shows that the pressure output of the fan is directly proportional to the density of the air. Thus, the mass flow rate will drop even though the volumetric flow rate is constant since the two are related as follows:

$$Q_h = \frac{\dot{m}_h}{\rho_h}, \tag{4.22.15}$$

where Q is the volume flow rate, $\dot{m}$ is the mass flow rate, ρ is the air density, and the subscript h denotes the altitude.

A slip fan is very different from a conventional fan. A slip fan allows the blades to slip or run at different speeds from the motor driving the fan, which allows the fan to work under many different altitudes and changing density conditions. The pressure flow rate curves for a slip fan at different altitudes are more consistent than a conventional or nonslip fan.

Summary

The need and applicability of cooling techniques in electronics has been discussed in terms of material limits, performance, and reliability. The use of acceleration transforms for determining the required operational temperature for temperature-dependent mechanisms has been discussed. The thermal management of electronic systems has been discussed based on application temperature constraints. Typical heat transfer schemes for each application environment have been discussed.

4.23 DIRECT CONTACT HEAT TRANSFER

Harold R. Jacobs

Introduction

Direct contact heat transfer refers to the transport of thermal energy between two or more mass streams without separation by intervening walls. Generally, the interaction is between only two streams and there is generally a degree of mass transfer as well. In the above definition, the words mass streams are used; however, the term direct contact can also refer to batch processing such as in a stirred reactor. Nonetheless, the study of continuous processing is more likely. In process heat transfer, direct contactors are used in absorption refrigeration, distillation, electric power generation (as open feedwater heaters and in conjunction with dry cooling towers in the so-called Heller cycle), food processing, drying, emergency cooling of nuclear reactors, quenching of hot gases, and in wet cooling towers. Other process equipment includes condensers such as barometric condensers, and spray condensers. The process of liquid spray combustion (Law, 1984) in a variety of applications also is a direct contact heat transfer process through the fact that the fuel is injected as a spray of drops which must be preheated to the point of evaporation. In general, the vaporization process, normally required as the combustion takes place, fits the definition of direct contact heat transfer. Many environmental processes such as the formation of ice, snow, or rain utilize the same physics as in other direct contact processes. Thus, direct contact heat transfer is ubiquitous.

In process-type direct contact heat and mass transfer, we normally deal with only two mass streams, although three or more can occur. For example, in some pipeline problems and in the extraction of heavy oils in the petroleum industry, water, oil, and air are sometimes encountered. This is often the case in off-shore production.

In process heat transfer equipment, the mass streams can be cocurrent, countercurrent, or even cross flow. The streams may be composed of, for example, systems that are liquid–liquid, liquid–vapor, liquid–gas, liquid–solid, gas–solid, or even solid–solid. The streams can be composed of the same chemicals, as in the case of steam-water, or can be partially miscible or completely so. One or both streams can be dispersed (made up of defined masses, particles, drops, bubbles) or continuous.

As noted previously, heat transfer may be accompanied by mass transfer such as in the case of dryers, distillation columns, wet cooling towers, condensers, and in combustion systems. The possibilities are legion. Thus, in this section we must limit ourselves to a few fundamental processes. The reader is referred to the literature or specific review articles such as Sideman (1966), Sideman and Moalem-Maron (1982), Jacobs (1988a), articles by Jacobs (1988a,b), Taitel and Tamir (1969).

The fundamental processes to be included here are sensible heat transfer between parallel fluid streams in co-or counterflow; sensible heat transfer to a disperse flow of particles, drops, or bubbles; flow with condensation, and flow with evaporation with similar geometries to that for sensible heat transfer.

Heat Transfer between Continuous Parallel Streams

Falling Films

In cooling towers, wetted wall towers, packed beds, etc., a liquid is injected into the device in a number of ways, resulting in a thin film of liquid running over solid vertical or inclined surfaces in the form of a coherent thin film or in rivulets under the influence of gravity. Such flows are generally classified under the name of falling films. The solid substructure can take any variety of forms including a bed of spheres, raschig rings, berl saddles, or a structured array of metal chevrons, for

example. The packing can be in an organized array or random and can include particles of different sizes and be of a variety of materials, generally wettable by one of the streams.

The initial work on falling films can be traced to Nusselt (1916). Since that time, many studies have been performed. Hasson et al. (1964a,b) investigated a vertically falling film while neglecting the effects of surface tension, interfacial shear, and pressure gradients. He obtained a universal nondimensional curve for the developing film thickness. Murty and Sastri (1974) studied the problem of a film exiting a slot flowing down an inclined plane of defined height. The surrounding gas was assumed to be quiescent, and pressure variation and surface tension were assumed to be negligible. Assuming a smooth interface and continuity of velocity and shear at the interface, they determined the thickness of the film as a function of the length along the plate. Murty and Sarma (1976) presented an expression for film thickness for either laminar or turbulent flow down an inclined wall with a cocurrent gas stream and incorporated interfacial shear and gravity effects in the nondimensional film thickness. Experimental nondimensional velocity profiles were used to present a universal, nondimensional film thickness. Tekic et al. (1984) repeated the model of Murty and Sastri (1974) but incorporated normal and tangential stresses on the film interface and neglected the interfacial shear of the still air. Their results presented a family of curves for liquids with different physical properties, but underpredicted the film entrance length.

While cocurrent flows are interesting, they result in minimum heat transfer when compared to countercurrent flows. Countercurrent flows, however, can strip the film from the surface, depending on the properties of the fluid external to the film. Since the external fluids are typically a gas or a vapor, the velocities when stripping occurs are normally quite high. Nevertheless, this is a common problem in cooling towers and other devices, and in the case of cooling towers can lead to the need for excessive make-up water and a highly visible plume. Usually the falling film develops a wavy interface, followed by the formation of larger waves on its surface prior to entrainment of liquid in the gas stream. The waves can be initiated by either Tollmein–Schlichting or Kelvin–Helmholtz instabilities. Ostrach and Koestel (1965) discussed these and other instabilities associated with two-phase flows. The Tollmein–Schlichting waves are associated with transition from laminar to turbulent flows while the Kelvin–Helmholtz instabilities are interfacial phenomena resulting from the shear at the interface due to relative velocity differences. The latter are applicable to otherwise laminar flows.

Ishii and Grolmes (1975) discuss entrainment of liquid into the gas stream. For the case of vertical falling films in countercurrent gas flow, possible causes of entrainment are shearing droplets from the top of roll waves and the formation of large-amplitude bulges in the liquid. Unstable films are particularly troublesome in wetted wall columns (which are simply vertical pipes with a gas flowing up the center and an annular film flowing down the surface). Such devices have been reviewed by Bharathan (1988). Tien and Liu (1979) outline an overview of the theory and experiment. Subsequently, McQuillan et al. (1985) and Bankoff and Lee (1986) reviewed these apparatuses and established a data bank of experimental flooding points. Stefan and Mayinger (1990) studied such systems at high gas pressure.

Heat and mass transport to falling films were reviewed by Seban (1978) and others (Faghri, 1983; Faghri and Saban, 1985). He discussed heating at the wall, evaporation, absorption, and the effects of film thickness for laminar and turbulent flows, but omitted interfacial shear effects. Experimental work since Seban's review include that of Segev et al. (1981) and Lee and Bankoff (1983). Theoretical studies were conducted by Jacobs and Fletcher (1988) and Jacobs and Dolan (1994) of the counterflow falling film problem for laminar flows with heat transfer from the gas to a film flowing over an adiabatic wall. Thus, their models apply to packed beds and other devices where the supporting surfaces are only to provide for the formation of the film. (In fact, the packing continuously reforms the film in lengths sufficiently small so as to maximize the local heat transfer coefficient on an individual packing element.) The first paper used integral methods and was applicable for only very small and large values of the gas velocity. The asymptotic solutions indicated that for a given countercurrent velocity a minimum would occur in the heat transfer coefficient. The second paper utilized the boundary layer equations for the film and the Navier–Stokes equations for

the external gas stream, and was able to define the extent of the phenomenon. The nature of the flow is shown in Figures 4.23.1a and b. Comparison of the results are shown in Figure 4.23.2. It is clear that both analyses predict a region of minimum heat transfer. Figure 4.23.3 shows a comparison of the mean interfacial friction coefficient, and with Figure 4.23.2, indicates an overprediction of drag and an under-prediction of heat transfer by the integral model. The results indicate that a gas velocity of at least 10 times that of the mean film should be used, but that the velocity should be less than that necessary to cause entrainment. The heat transfer in the gas liquid film system is controlled by the gas-side heat transfer for the case of sensible heat transfer.

No solution currently exists for the wavy film countercurrent flow situation. Subject to the lack of experimental data, it is recommended that one assume that the surface waves should only influence the heat transfer internal to the film. For situations where the thermal penetration is less than the film thickness, the average Nusselt number for the internal resistance is

$$\mathrm{Nu} = \sqrt{\frac{6}{\pi}}\mathrm{Re}^{1/2}\mathrm{Pr}^{1/2} \tag{4.23.1}$$

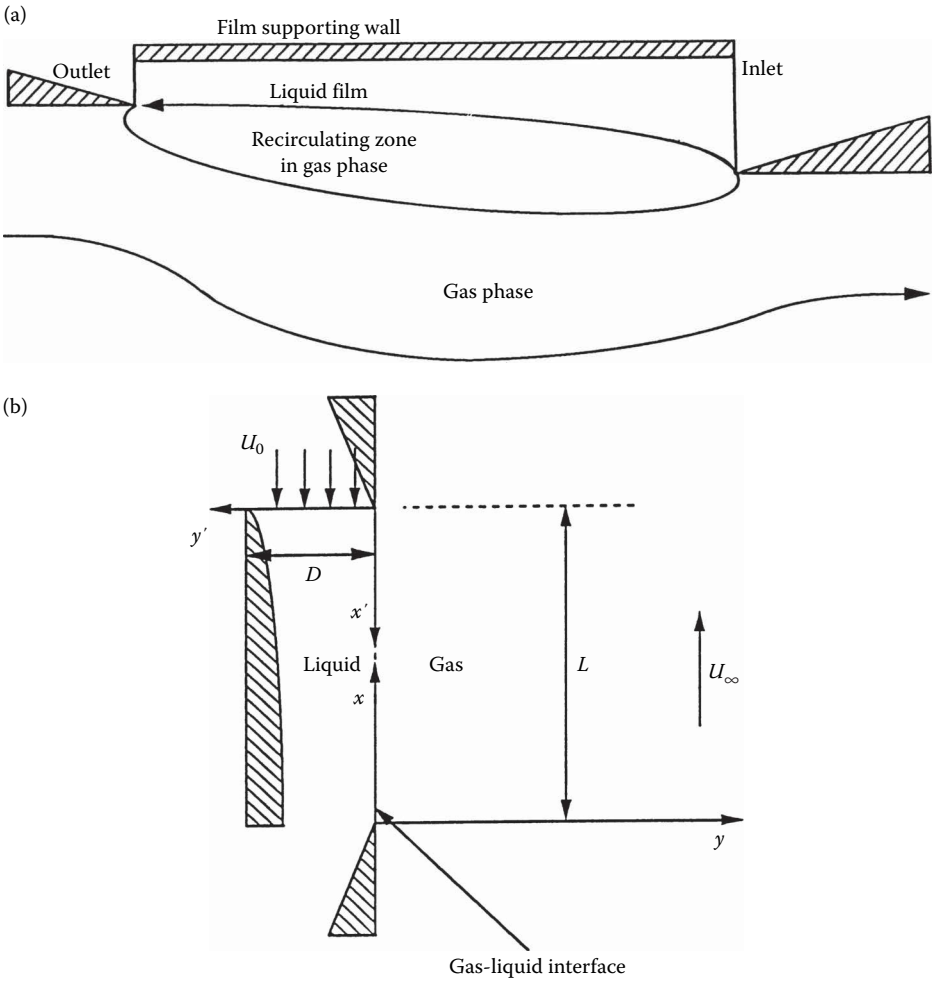

FIGURE 4.23.1 (a) Flow of gas over falling liquid film with decreasing thickness. (b) Geometry used in mathematical model for falling film and gas regions. (From Jacobs, H.R. and Dolan, S.M., *J. Energy, Heat Mass Transfer*, 16, 77, 1994. With permission.)

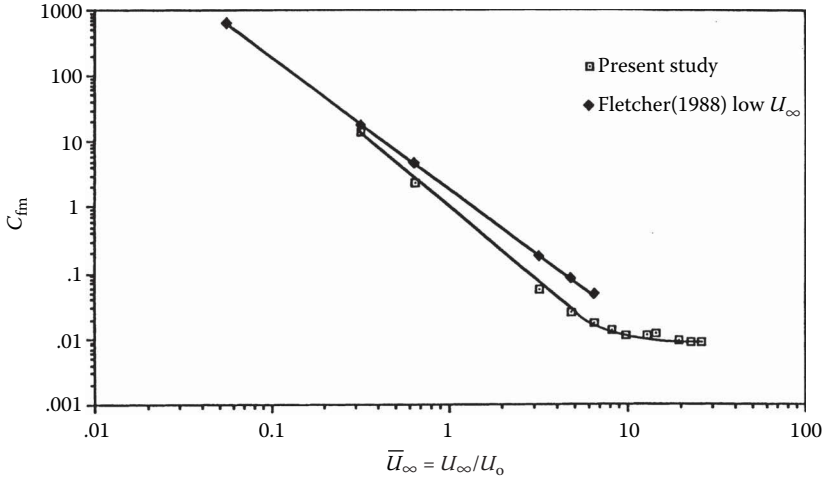

FIGURE 4.23.3 Effect of U_∞ changes on frictional drag.

where $\mathrm{Re} = uD/v$ is the film thickness and u is the mean film velocity. For a wavy film, the heat transfer coefficient will be increased by 15% (Levich, 1962) based on an assumed similarity to gas absorption. Similarly for turbulent films, mass transfer analogs should offer some assistance although there exist few controlled experiments (Levich, 1962).

Heat Transfer to Jets and Sheets

In many types of process equipment (Figure 4.23.4), the apparatus is simply a vessel containing a few partial trays which are solid or perforated. The trays have a lip so as to hold a quantity of liquid sufficient to provide the needed pressure head to form a series of jets or a sheet of fluid falling under gravity. Such devices are used in humidifiers and direct contact condensers or as mass transfer devices in dealing with gases or vapors (List, 1982).

In such equipment the heat transfer process is described as heat transfer to jets and sheets rather than films, as the fluid is not supported where the primary heat transfer takes place (on the jets and

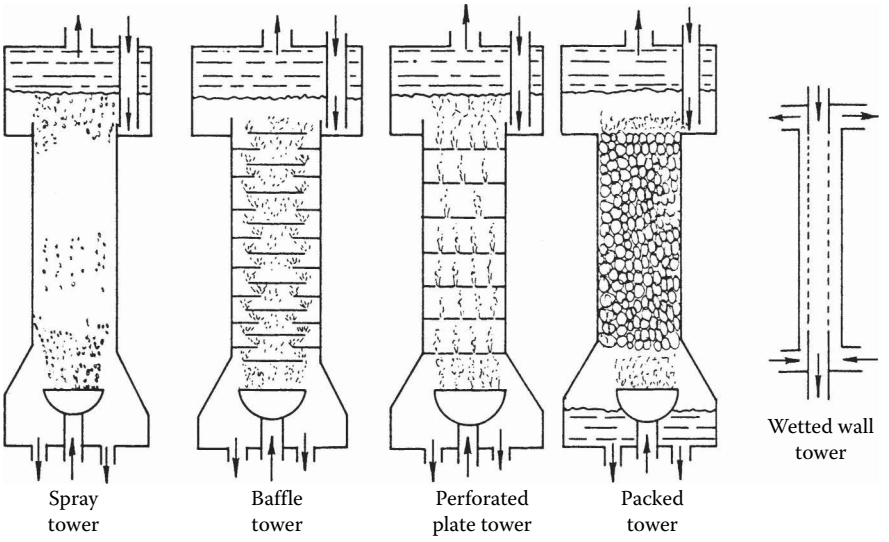

FIGURE 4.23.4 Schematic of various types of direct contact counterflow devices.

sheets). The series of trays act as mixers. The liquid is caught on a tray and leaves it at its mean temperature. The reforming of jets or sheets provides for a higher heat transfer coefficient than would occur for a stream that fell the entire length of the column and, thus, requires a shorter column to accomplish the required energy transfer. The major disadvantage is a greater pressure loss in the device than for an empty vessel (which is called a spray column).

Typically, the hydrodynamics of a jet or sheet can be assumed to be either a slug flow or fully developed. Thus, the analysis of the heat transfer via the energy equation follows that of a Graetz problem where only the axial component of the advection term and the conduction term across the jet or sheet remain. External to the jet or sheet the heat transfer coefficient must be determined. In most cases, values for flow over a solid surface can be used. The flow over a jet or sheet in most column designs is crossflow and, thus, the external heat transfer coefficient is independent of axial location. This allows one to adapt the Graetz-type solutions to solving for the mean axial temperature of the jet or sheet, as was done by Jacobs and Eden (1986). For liquid jets or sheets exposed to a gas or vapor, especially for sensible heat transfer, the external resistance to heat flow may be controlling, and it may be possible to assume negligible gradient across the jet or sheet. Otherwise, the fully developed internal thermal resistance can be used for axial lengths greater than the thermal developing region; however, to minimize the internal resistance requires the use of shorter jets or sheets and requires the distance between trays to be less than the thermal entrance length, as predicted by the Graetz solution. For turbulent flows in the liquid, the maximum heat transfer would neglect the internal resistance altogether. Where the external thermal resistance is not controlling and the stream is turbulent, it is advisable to use a Graetz-type solution with an effective thermal conductivity given by

$$k_{\in \mathrm{H}} = k + \frac{\rho c \in_{\mathrm{t}}}{\mathrm{Pr}_{\mathrm{l}}} \tag{4.23.2}$$

The above discussion applies to smooth, laminar surfaces. As with thin films, waves will eventually occur on the surface of these streams, leading to a better mixing in the jets or sheets. The wavy regime typically decreases the internal resistance by as much as 15%. Eventually, the jets and/or sheets will break down into drops or a spray in a manner similar to that discussed in Section 4.18. While it is possible to have a jet break down into a fine spray, if the jet Reynolds number is sufficiently

high, a freely falling jet will typically break down into drops that are twice the diameter of the jet or twice the thickness of a sheet. In many instances this does not provide a sufficient increase in surface area to result in higher heat transfer rates than would occur in a continuous sheet, although internal mixing may increase. Thus, an analysis for a continuous jet or sheet may be applicable even after breakup.

Sensible Heat Transfer to Dispersed Media: Drops, Particles, Bubbles

Sensible heat transfer to disperse media from a continuous phase is dependent upon the proximity of other particles, drops, or bubbles and to their own geometry, as well as their velocity through the continuous surrounding media and its thermal properties. For solid particles, the heat transfer is generally described in terms of an equivalent sphere. An equivalent diameter is obtained from

$$D_{\text{equiv}} = \frac{6V}{A_s} \tag{4.23.3}$$

For drops and bubbles, the problem is more difficult than for solid particles, as they are easily distorted, subject to both breakup and coalescence, and may have significant internal circulation depending on how they are formed (Rose and Kintner, 1966; Sideman and Isenberg, 1967; Sideman and Taitel, 1964; Sirignano, 1983; Sundararajan and Ayyaswamy, 1984, 1985a,b). Close proximity to other drops or bubbles, as associated with volume fraction or holdup equaling 5% or greater, will make drops that would otherwise distort tend to remain spherical. Further, the presence of impurities tends to stabilize the interfaces of bubbles with the surrounding media no matter whether the impurities are in the dispersed or continuous phase. Thus, models of drops within swarms, based on transport in single bubbles typically overpredict heat and mass transfer since they overpredict drop or bubble distortion and internal circulation. Drop dynamics based on drag for single spheres will be in error, as the drag will vary for drops in a swarm due to differences in the surrounding flow. In the midst of the array the spheres have a greater drag, but at the front the drag can be less than for a single sphere and the drag at the rear can be higher than that within the array for staggered or random arrays. For inline arrays, the drag can be greatest at the front of a column, leading to a bunching up of particles.

For holdups less than 5%, assuming rigid spheres, the expression of Ahmad and Yovanovich (1994) for external to the sphere heat transfer is recommended:

$$\mathrm{Nu_D} = 2.0 + \frac{0.775\mathrm{Re_D^{1/2}Pr^{1/2}}\Big/\sqrt{2\gamma+1}}{\left[1+\left(\dfrac{1}{(2\gamma+1)^3\,\mathrm{P_r}}\right)^{1/6}\right]} \tag{4.23.4}$$

where:

$$\gamma = \frac{1.0}{\mathrm{Re_D^{1/4}}} \quad \text{for} \quad \gamma < 1 \tag{4.23.5}$$

and $\gamma = 1.0$ for $\gamma > 1$.

For holdups greater than 5%, Wilson and Jacobs (1993) recommended for isothermal spheres in the midst of a swarm:

$$\mathrm{Nu_D} = \left\{1 - 0.186\left(\phi - 0.42\right)\right\}\left(0.877\mathrm{Re_D^{1/2}} + 0.152\mathrm{Re_D^{2/3}}\right)\mathrm{Pr}^{1/3} \tag{4.23.6}$$

where the velocity is the superficial velocity through the bed. This expression compares well with the correlation of Whitaker (1972) for a densely packed bed as well as for single spheres.

Similarly, Evans (1994) studied the heat transfer to particles at the leading and trailing edge of a hexagonal array of spheres. Using a partial spherical shell with slip at the surface to define the effect of the surrounding particles, he showed the effect mentioned earlier for random arrays. Sirignano (1993) has studied inline arrays for up to three particles deep and showed the effects mentioned earlier for such particles. While inline effects may apply to a single column of bubbles, the hydrodynamic instability of such a flow makes the staggered array of Evans (1994) more practical in attempting to model the flows. Analogy between heat and mass transfer in packed beds has been explored by Roberson and Jacobs (1990) and Thomson and Jacobs (1984).

An experimental model for the behavior of drops or particles in swarms was presented by Wagner and Stichlmair (1997). They provide the following expressions for swarm velocity relative to the continuous phase as a function of the Archimedes number, Ar, void fraction, and so-called fluid number, K_f:

$$\frac{\mathrm{Re}_{ss}}{K_f^{0.086}} = \frac{4.55\,\mathrm{Ar}\left(1-\epsilon_d\right)^{4.65}\Big/K_f^{0.1}}{\left[15.6+\mathrm{Ar}\left(1-\epsilon_d\right)^{4.65}\Big/K_f^{0.1}\right]^{1.5}} \tag{4.23.7}$$

where $\mathrm{Re}_{ss} = \dfrac{W_{ss} D_p \rho_c}{\mu_c}$, $\quad K_f = \sigma^3 \rho_c^3 \Big/ \left(\mu_c^4 g \Delta\rho\right)$, $\quad \mathrm{Ar} = d_p^3 \rho_c \Delta\rho g / \mu_c^2$

and W_{ss} is the superficial velocity of the multiphase system.

Figure 4.23.5 presents a comparison of experimental data with the correlation of Equation 4.23.7, and Figure 4.23.6 shows the flooding limit obtained.

The internal to the drop or particle heat transfer is based on the one-dimensional conduction problem in a sphere. This, of course, must be modified for internal circulation and geometrical distortion. Grace (1983) provides a mapping of drop distortion for single drops of a pure fluid in a

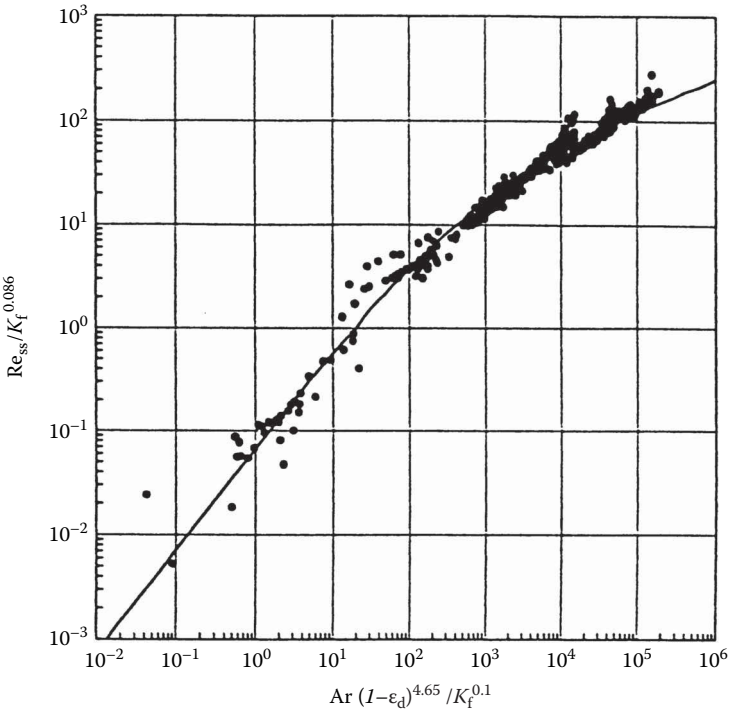

FIGURE 4.23.5 Comparison of Equation 4.23.7 with experimental data.

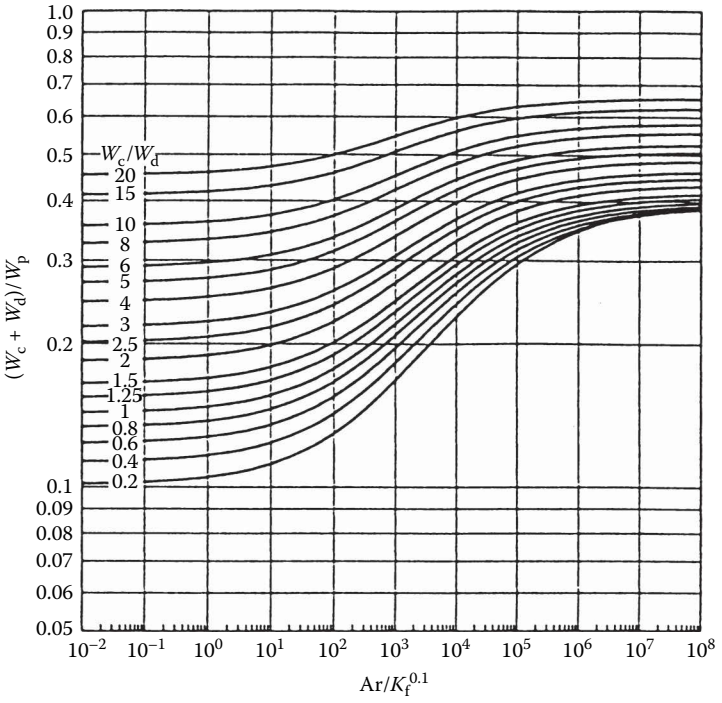

FIGURE 4.23.6 Flooding rates.

second pure immiscible fluid, as shown in Figure 4.23.7. Impurities, however, tend to immobilize the interface and the proximity of other drops will reduce any recirculation behind the drops and return them to sphericity. Jacobs and Eden (1986) provide for a correction to the molecular diffusivity which can account for both internal circulation and distortion in drops in a swarm or dense array as shown in Figure 4.23.8. For a single column of bubbles, Calderbank and Korchinski (1956) also provide an effective thermal diffusivity based on studies of bromobenzene in glycerol. Jacobs and Eden's studies were for isobutane in a geothermal brine.

For rapidly internally circulating drops, a number of investigators have used the Hadamard (1911) model for flow inside a sphere. Of these models, Sideman (1966) recommends

$$\mathrm{Nu}_{\mathrm{di}} = 2 + 1.13\left(\mathrm{Pe}K_{\mathrm{v}}\right)^{0.5} \tag{4.23.8}$$

where

$$K_{\mathrm{v}} = 1 - \frac{1.45\left(2 + 3\mu_{\mathrm{d}}/\mu_{\mathrm{c}}\right)}{1 + \dfrac{\rho_{\mathrm{d}}\mu_{\mathrm{d}}^{1/2}}{\rho_{\mathrm{c}}\mu_{\mathrm{c}}^{1/2}}}\mathrm{Re}_{\mathrm{cD}}^{1/2} \tag{4.23.9}$$

and subscripts c and d refer to the continuous and drop fluid properties, respectively.

The drop temperature is predicted from

$$\frac{\rho_{\mathrm{d}} C_{\mathrm{pd}} D}{6}\frac{\mathrm{d}T_{\mathrm{d}}}{\mathrm{d}t} = U_0\left(T_{\mathrm{d}} - T_{\mathrm{c}}\right) \tag{4.23.10}$$

where U_0 is the overall surface-based heat transfer coefficient. When the drop is not strongly circulating the spherical conduction problem must be solved. The temperature distribution in

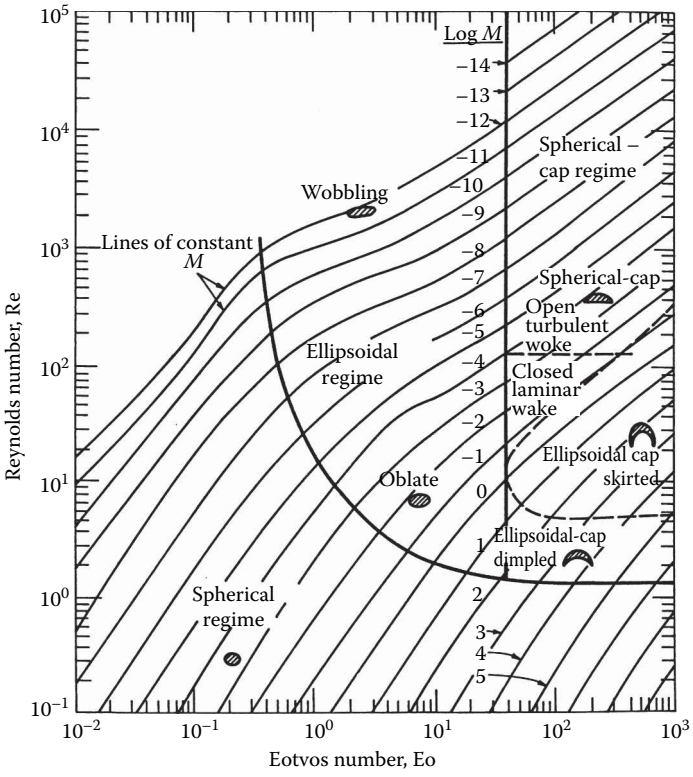

FIGURE 4.23.7 Distortion map as a function of Reynolds and Eötvos numbers. (From Grace, J.R., *Handbook of Fluids in Motion*, Butterworths Group, Ann Arbor, MI, 1983. With permission.)

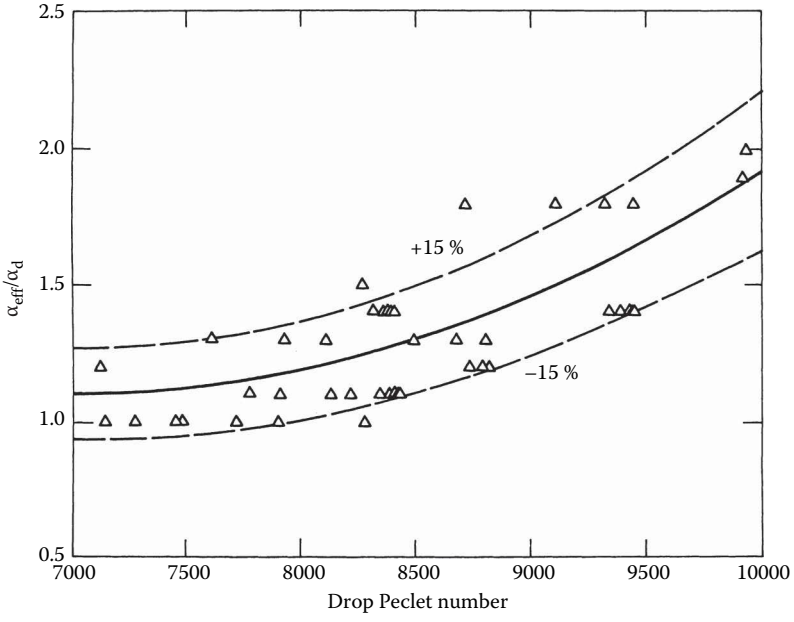

FIGURE 4.23.8 Ratio of effective thermal diffusivity as a function of drop Peclet number. (From Jacobs, H.R. and Eden, T.J., *Proceedings of 8th International Heat Conference*, Vol. 6, 3013, 1986. With permission.)

a sphere subject to a constant heat transfer coefficient and fixed continuous phase temperature is given by

$$\frac{T-T_\infty}{T_0-T_\infty}=2\sum_{n=1}^{\infty}\frac{\mathrm{Bi}\sin\mu_n e^{-\mu_n F_0}}{\left(\mu_n-\sin\mu_n\cos\mu_n\right)}\frac{\sin\left(\mu_n r/R\right)}{\mu_n r/R} \tag{4.23.11}$$

where T_0 is the initial sphere temperature, Bi is the Biot modulus, F_0 is the Fourier modulus, and $\mu_n=\lambda_n R$. Here μ_n are the zeros of $\mu_n \cos \mu_n=(1–\mathrm{Bi}) \sin \mu_n$. Solution of Equation 4.23.11 can be obtained from the so-called Heisler charts, or calculated.

In the time interval 0 to t, the ratio between the total heat transfer q from or to the sphere, and its initial internal energy $q_i=4/3R\ c(T_0-T_\infty)$ is

$$\frac{q}{q_i}=6\sum_{n=1}^{\infty}\frac{\sin\mu_n-\mu_n\cos\mu_n}{\mu_n^3\left(\mu_n-\mu_n\cos\mu_n\right)}\left(1-e^{-\mu_n^2F_0}\right) \tag{4.23.12}$$

Use of Equation 4.23.11 or 4.23.12 with values of α_{eff} and an appropriate heat transfer coefficient allows for the prediction of sensible heat transfer to individual drops or particles for low holdup. Equation 4.23.11 can be used as the Kernel in a Duhamel's superposition integral to solve for the temperature of a drop moving through a continuous phase, the temperature of which is variable with the trajectory of the drop or particle.

Direct Contact Heat Transfer with Change of Phase

Evaporation and Boiling

In Section 3 the topics of phase change from a vapor to a liquid and the reverse are introduced. These topics apply to direct contact heat transfer as well; however, the effects of solid surfaces do not come into play. The interface where the heat transfer, and thus the mass transfer to a different phase, takes place is between two independent mass streams.

At the beginning of Section 3.4.1, Carey introduces the concept of metastable liquids and the role of surface tension. Consider a gas bubble in a liquid. Carey shows that if the gas is a saturated vapor and the liquid is the same fluid, that the liquid must be superheated or in a metastable state if the pressure balance, including surface tension effects, is to be in equilibrium.

For pure liquids, where there exists a continuous phase with temperature sufficiently greater than the saturation temperature of a second fluid immiscible with the first, it is possible to demonstrate the existence of metastable states. If several subcooled drops of a fluid are injected into a second, the drops will have a pressure greater than the surroundings. The drops will gradually heat and will rise to a temperature equal to or nearly equal to the continuous phase. If the temperature is below the Spinodal limit (maximum superheat limit for a liquid) of the drops, nothing may happen. For example if the drops are pentane and the fluid is pure water, the drops may rise to the surface after a period of time and then evaporate. If the water temperature is near the Spinodal lmit, the drops will rise, but before reaching the surface may instantaneously vaporize in an explosive way. The presence of impurities in either phase will cause the drops to vaporize and form two-phase bubbles below the surface. The impurities act as nucleation sites for the phase change just as impurities in a metal or surface flaws serve as nucleation sites for boiling from solid surfaces. Some early experiments to illustrate boiling nucleation were with mercury films on a surface with an oil as the vaporizing medium. They were used to illustrate the need for nucleation sites. Thus, although the thermodynamics of direct contact boiling is related to conventional boiling, the effect of the interfaces between liquids makes them different and metastable states perhaps play a more important role. In most industrial situations, impurites are present and alter the situation for direct contact boiling.

Four basic problems are encountered in direct contact boiling/evaporation. These are (1) boiling at the interface between two parallel streams, (2) evaporation of drops of a spray from an immiscible

liquid, (3) evaporation of drops within a liquid or gas/vapor mixture, and (4) the evaporation of the continuous phase around the dispersed phase. The first problem is related directly to film boiling and follows its analyses. The second problem is of interest due to a number of things. First, if the interfacial properties are such that the liquid drops wet the liquid below them, there will exist a metastable state with the liquid in the drops having their phase change only from their upper surfaces. Such a situation was addressed by Kodres et al. (1980, 1981) who showed photographically the difference between this situation and that of Liedenfrost boiling, where the drop is held above the surface by the vaporizing film. (See *Numerical Heat Transfer*, 3:21–34, 1998.) Development of a model for the evaporation rate must be accomplished numerically and depends on the fluid properties (Prakash and Sirignano, 1980; Rangel and Sirignano, 1987).

The evaporation of a drop in a gas stream is dependent upon the nature of the gas phase. For the evaporation of a drop into a gas made up primarily of different substances; for example, a fuel drop in air combustion products requires the solution of the mass diffusion problem coupled with the heat transfer. The same is true of water drops in an air stream as related to the design of cooling towers discussed in Section 4.13. However, the evaporation of drops into a superheated stream of its own vapor is considerably easier to analyze, depending on the drop size. Carey and Hawks (1995) report for the evaporation of large drops in their own vapor

$$\mathrm{Nu}_\mathrm{D} = 2\frac{\ln\left(\mathrm{Ja}_\mathrm{v}-1\right)}{\mathrm{Ja}_\mathrm{v}} \tag{4.23.13}$$

where $J_{\mathrm{av}} = e_{\mathrm{pv}}\left(T_\infty - T_\mathrm{R}\right)/h_{\mathrm{fg}}$ and for microdrops

$$\mathrm{Nu}_\mathrm{D} = 2\frac{\ln\left(\mathrm{Ja}_\mathrm{v}-1\right)}{\mathrm{Ja}_\mathrm{v}}\left[1+\frac{0.4\,\mathrm{Ja}_\mathrm{v}}{1+10\,\mathrm{Ja}_\mathrm{v}^2}\left(\frac{K_{\mathrm{np}}}{0.001+K_{\mathrm{nD}}}\right)\cdot\sigma_\mathrm{T}\left(1+\gamma\right)\left(9\gamma+5\right)K_{\mathrm{nD}}+\sigma_\mathrm{T}\left(1+\gamma\right)\right] \tag{4.23.14}$$

where K_n is the mean free path of a molecule divided by the drop diameter, γ is the ratio of specific heat, and ϕ_r is the accommodation coefficient. The reader is referred to Sanders and Dwyer (1987) for further review of individual droplet processes. They present a comprehensive numerical model of single-droplet dynamics with and without combustion. Their studies include mass transfer with accelerating and decelerating drops. They solve the complete Navier–Stokes equations, energy equations, mass conservation equations, and equations of state.

The last evaporation/boiling model deals with droplets vaporizing in an immiscible liquid. Such a system was investigated by Coban and Boehm (1986) and by numerous others for application to desalination, geothermal power production, and production of electricity using solar ponds, etc. A volatile fluid is injected into a hot immiscible continuous stream. Unlike evaporation within a gas stream, here the vapor stays with the drop. The problem has been studied by Klipstein (1963), Simpson et al. (1974), Sideman (1966), and Raina and co-workers (1982, 1984a,b, 1985), and Battya et al. (1983). The models are all single-drop/bubble studies and are assumed to strongly depend on the external heat transfer and surface tension effects. In most of the systems studied, a drop of hydrocarbon was placed in water, the temperature of which was well above the boiling point of the hydrocarbon. For such systems, the surface of the two-phase bubble is wetted by the hydrocarbon liquid. This suggests that the hydrocarbon must reach a degree of superheat before evaporation occurs, but not the explosive condition close to the Spinodal line. Various models assume that the liquid settles to the bottom of the drop, as in the early models of Sideman, or to totally wet the walls with a uniform film. The former models do not reproduce well the experimental results while the latter model, first proposed by Simpson, does. It results in

$$h_0 = \frac{2.57\left(\dfrac{D(t)}{D_0}\right)^{1/6}}{1+0.206\left(\dfrac{D_t}{D_0}\right)^{5/12}}\frac{K_\mathrm{w}}{\mathrm{m^2K}} \tag{4.23.15}$$

This equation predicts an increasing heat transfer in the early stages of evaporation and a decrease in the latter stages.

The Sideman (1966) model depended only on the external heat transfer coefficient and fraction of the bubble surface wetted by the remaining liquid. It predicts the heat transfer decreases with time as it ignores heat transfer through the vapor. Coban and Boehm (1986) account for heat transfer through the vapor as well as directly to the liquid, resulting in

$$\mathrm{Nu}_{\mathrm{lD}} = 2\mathrm{Pe}_{\mathrm{c}}^{1/3}\left\{0.466\left(\pi - B + \sin\frac{\mathrm{d}B}{\mathrm{d}t}\right)^{2/3} + \frac{5K_{\mathrm{dv}}}{R}(1-0.466)\left(\pi - B + \sin\frac{\mathrm{d}B}{\mathrm{d}t}\right)^{2/3}\right\} \quad (4.23.16)$$

where c indicates the continuous phase, d the drop, and l and v are properties of the liquid and vapor, respectively. The above model assumes no sloshing of the liquid and B is the segment angle defining the surface of the liquid in the bottom of the drop. The expression is for the overall heat transfer.

The last evaporation phenomenon addressed is for a hot liquid drop or particle in a subcooled liquid with subsequent vaporization of the coolant. Kazimi et al. (1974) dealt with this as a transient film boiling problem but neglected the effects of both gravity and continuous phase motion. Dhir and Purohit (1977) solved the problem of subcooled film boiling from spheres including buoyancy effects. They predict

$$\mathrm{Nu}_{\mathrm{Dv}} = \mathrm{Nu}_0 + \mathrm{Nu}_{\mathrm{nc}}\frac{\mathrm{PrSc}}{\mathrm{Pr_l Sh}\mu} + \frac{\mathrm{Pr_v}\sigma}{\mathrm{Sh}}\frac{\left(T_{\mathrm{w}}^4 - T_{\mathrm{SAT}}^4\right)D}{h_{\mathrm{fg}}\mu_{\mathrm{v}}} \quad (4.23.17)$$

where

$$\mathrm{Nu}_0 = 0.8\left(\frac{g\rho_{\mathrm{v}}\left(\rho_2 - \rho_{\mathrm{v}}\right)h_{\mathrm{fg}}D^3}{M_{\mathrm{v}}k_{\mathrm{v}}\left(T_{\mathrm{w}} - T_{\infty}\right)}\right)^{1/4} \quad (4.23.18)$$

and

$$\mathrm{Nu}_{\mathrm{nc}} = 0.9\left(\frac{g\rho_{\mathrm{L}}c_{\mathrm{pL}}B_0\left(T_{\mathrm{SAT}} - T_{\infty}\right)D^3}{\mu_{\mathrm{L}}K_{\mathrm{L}}}\right)^{1/2} \quad (4.23.19)$$

for the average Nusselt number for a sphere in a quiescent pool.

For forced flow over a sphere or a falling sphere

$$\mathrm{Nu} = \mathrm{Nu}_0 = 0.8\mathrm{Re}_{\mathrm{cD}}^{1/2}\left[1 + \frac{\mathrm{ScPr}v}{\mathrm{ShPr_L}\mu_{\mathrm{c}}}\right] \quad (4.23.20)$$

where $\mathrm{Sc} = \dfrac{C_{\mathrm{pL}}\left(T_{\mathrm{SAT}} - T_{\infty}\right)}{h_{\mathrm{fg}}}$ and $\mathrm{Sh} = \dfrac{C_{\mathrm{pr}}\left(T_{\mathrm{w}} - T_{\infty}\right)}{h_{\mathrm{fg}}}$.

For boiling in cryogenic fluids, Hendricks and Baumeister (1969) investigated boiling of nitrogen and helium from a sphere. They show a dependence on the Bond number, $\mathrm{Bo} = (P_{\mathrm{L}} - P_{\mathrm{r}})g\,R^2/(\sigma gc)$, where σ is the surface tension. The results are shown in Figure 4.23.9, where Nu′ and Nu − 2 and $Rd' = \dfrac{h_{\mathrm{fg}} + 0.5C_{\mathrm{p}}\Delta T}{C_{\mathrm{p}}\Delta T}$.

Direct Contact Condensation

Direct contact condensation occurs in many industrial processes including reflux columns and in separators as well as in open feedwater heaters, etc. Jacobs (1988a) provides a significant discussion in his review article on *Direct Contact Heat Transfer for Process Technologies*. The first industrial

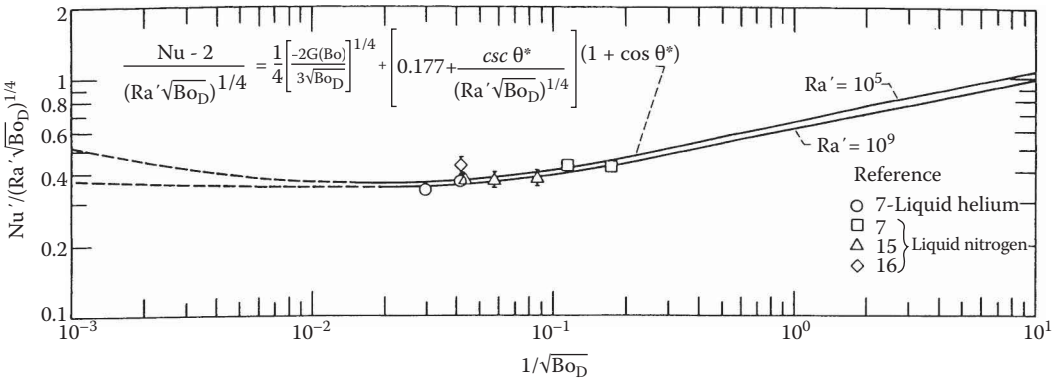

FIGURE 4.23.9 Experimental and predicted results for film boiling off submerged spheres. (From Hendricks, R.C. and Baumeister, K.J., Film boiling from submerged spheres, NASA, Washington, DC, 1969.)

use of direct contact condensers was in steam engines and dates back prior to the turn of the century. The first design article was written by Hausbrand and was published in English in 1933. In a review of the literature, Jacobs and Fannar (1977) categorized direct contact condensers as being "drop type," "jet and sheet type," and "film type."

Drop type refers to condensation on a spray of coolant that is injected into a chamber filled with vapor or a gas-vapor mixer with the intent to condense the vapor. The coolant can be the same fluid as the vapor or could be immiscible with the condensate. Kutateladze (1952) was the first to recommend the drops be assumed spherical and that the heat transfer is dominated by the transient conduction within the drops when dealing with a pure vapor. This assumption is reasonable in most situations as injectors used in direct contact condensers produce drops in the size range of 0.25–2.5 mm in diameter. Such drops fall at sufficiently slow velocity that they remain spherical with little or no internal circulation. The Kutateladze model neglects the added mass. While such an analysis is appropriate for a Jakob number tending to infinity or time to zero, it overpredicts the heat transfer. Jacobs and Cook (1978) developed a theoretical model that accounted for the added mass and predicts the experiments of Ford and Lekic (1973) exactly.

The model development shows that the final to initial drop size is given by

$$R_f / R_1 = \left(1 + \frac{1}{\mathrm{Ja}}\right)^{1/3} \tag{4.23.21}$$

where

$$\mathrm{Ja} = \frac{\rho_L h_{fg}}{\rho_d C_{pd} \left(T_{SAT} - T_0\right)} \tag{4.23.22}$$

in which the subscripts L and d refer to the condensate liquid and drop, respectively. Thus, one can deal with a drop being of a different fluid than the condensate. Their solution solves the problem of conduction in a sphere subject to the boundary condition

$$q'' = \frac{k_c \left(T_{SAT} - T_{RI}\right)}{R(t) - \mathrm{Ri}} \tag{4.23.23}$$

The nondimensional radius at time t is given as

$$\frac{T_{\text{mean}}(t)}{T_{\text{SAT}}-T_i}=1+\frac{6}{\pi}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp\left(-n^2\pi^2\,\frac{4at}{D_0^2}\right) \tag{2.23.24a}$$

This is a solution of a spherical Stefan-type problem assuming that the condensate film is thin. It is appropriate for large values of Ja. In the limit as Ja tends to infinity

$$\frac{R(t)}{R_1}=1+\frac{3}{\text{Ja}}\int_0^{R_i}\left(\frac{r}{R_1}\right)^2\frac{\left(T_{(r,t)}-T_i\right)}{\left(T_{\text{SAT}}-T_i\right)}\frac{\mathrm{d}r}{\text{Ri}} \tag{4.23.24b}$$

For conditions where there are noncondensibles present, it is necessary to solve the flow field external to the drops. Such studies have been conducted by Chung et al. (1981a,b; 1984a,b) and by Huang and Ayyaswamy (1987a,b) who also included the effects of internal circulation. They found the latter to have negligible effects, except at extremely high velocities or low interfacial tension. Celata et al. (1990) attempted to form uniform drops by application of a high-frequency acoustic field. At Re as low as 100, but for Pe of 1000 to 5000, they found heat transfer coefficients higher than predicted for infinite Pe. The best fit to their data was obtained using Equation 4.23.24; however, even it underpredicted the early temperature rise, indicating even stronger mixing than predicted by the Hadamard model for flow inside a sphere.

The influence of noncondensibles on condensation rates is not unlike that predicted for boundary layer type problems, with as little as 5% noncondensibles reducing the heat transfer by as much as 50% to 100%. More studies of this influence are needed.

In addition to accurately predicting the performance of a spray type (drop type condenser), it is required to have data on drop size distribution for a given spray nozzle. Brown (1951) and Isachenko and Kushnyrev (1974) present some work, but more is needed. For example, in order to design a barometric condenser the vapor velocity must not exceed the terminal velocity of the smallest drop; yet to fully utilize the cooling capacity of the spray, the size of the largest drops must be known. From a practical view, this means that the diameter of the condenser for a simple spray column is set by the smallest drops and its height by the largest.

Collapsing Bubble Condensation

Direct contact condensation can be accomplished by injecting a jet of bubbles into a continuous liquid coolant. Depending on the jet velocity, the jet can break down quickly or remain coherent for some time. If the jet is injected at close to sonic velocities, the latter is true. Of course, the vapor can bubble through in a series of bubble trains as well. Thus, single vapor bubbles as well as jets have been studied. Jet flow is impacted by its orientation with gravity, with vertical jets foreshortened or lengthened depending on whether gravity is opposing or favorable. Horizontal jets are typically curved due to buoyancy effects. The first definitve study was by Weimer et al. (1973). Chen and Faeth (1982, 1983) and Sun (1985) used sophisticated two-fluid numerical models to analyze jet collapse, yet they do not adequately predict the heat transfer between the phases (Eden, 1995). Thus, dependence on experimental studies is still required.

The study of bubble collapse is not only of interest as it applies to condensers, but also for other applications. Sideman and Moalem-Maron (1982) reported a wide range of experimental data. Floreschuetz and Chao (1965) modeled a drop collapsing in its own vapor. Jacobs et al. (1978) were the first to account for the internal resistance of the condensate in the collapse of a saturated vapor bubble in an immiscible liquid. They show that the collapse rate for a pure vapor rising at a constant velocity is

$$\frac{D(t)}{D_0}=\left[1-0.901\left(\text{Re}_L\text{P}_r\right)^{1/2}\phi\,\text{Ja}^*\,\frac{\rho_f}{\rho_v}F_{0L}\right] \tag{4.23.25}$$

where

$$\phi = \sqrt{\left(C_1^2 + C_1\right)} - C_1 \tag{4.23.26}$$

and

$$C_1 = 0.75 \frac{\left(\rho k C_p\right)_f}{\left(\rho k C_p\right)_1} \tag{4.23.27}$$

Jacobs and Major (1982) dealt with bubbles containing a mixture of vapor and a noncondensible gas. They showed that for small bubbles less than or equal to 3.5 mm in radius, the heat transfer was controlled by diffusion, but larger bubbles have good internal circulation due to distortion and oscillation and their analysis can be accomplished by assuming perfect mixing during the collapse.

The effect of adjacent bubbles in a collapsing train was dealt with by Moalem-Maron et al. (1972). Golafshani (1983) improved on the model, using the more sophisticated model of Jacobs and Major (1982). For pure vapor bubbles they found little influence based on the models, indicating that the external thermal resistance dominated the heat transfer.

Despite the relative acceptance of the theories, Johnson et al. (1983) and Sudhoff (1982) found that experiments with bubble trains are plagued by a so-called persistent bubble. Johnson et al. carried out experiments in a very deep heat exchanger. The visual observations indicated that the persistent bubble finally disappears and they conclude that this is due to absorption of the non-condensible gases present by the surrounding liquid. So far, no other investigators have offered hypotheses to explain this phenomenon; however, if the arguments of Johnson et al. are valid, it may be possible that a heat exchanger could be designed with a depth such that condensation may be accomplished and noncondensible gases readily separated.

Condensation on Jets and Sheets

Barometric condensers are designed in the form of spray columns, baffle tray columns, or sieve tray columns. When designed as spray columns, a nozzle forms a coarse spray as discussed in the preceding section. When designed as a baffle tray column, the coolant flows into a tray, and then over its lip in a sheet to the tray below, and subsequently to the next tray and so forth until it and the condensate form a pool at the bottom of the condenser.

In a sieve tray column, the coolant leaves the tray through perforations as a series of jets. Both sheets and jets can break down into lesser streams and/or drops as discussed by Bogy (1979). The jets are laminar but instabilities can make them wavy or even turbulent prior to breaking into drops. If the jets or sheets remain laminar or just wavy, they can be analyzed as a Graetz-type problem similar to the analysis for sensible heat transfer. Hasson et al. (1964a,b) applied such analyses to condensing steam on sheets and fan jets with reasonable success. Jacobs and Nadig (1987) solved the problems for an axisymmetric jet or a sheet including both the resistance of the added condensate mass and the effects of noncondensibles for the vapor and coolant being the same or immiscible fluids. They presented curves of coolant capacity utilization rather than heat transfer coefficients for design purposes. Results for steam-water are presented in Figures 4.23.10a and b. Knowing the noncondensible concentration, and the degree of utilization, the Graetz number and, thus, the length of the sheet can be determined. Extension of this work to wavy or turbulent flow is desirable; however, it is likely that waves will not increase the heat transfer by more than 15% based on the sensible heating information reported earlier for jets and falling films.

When as little as 2% noncondensibles are present, the heat transfer is controlled by the external diffusion of vapor to the interface, thus turbulence in the liquid will also have small effects.

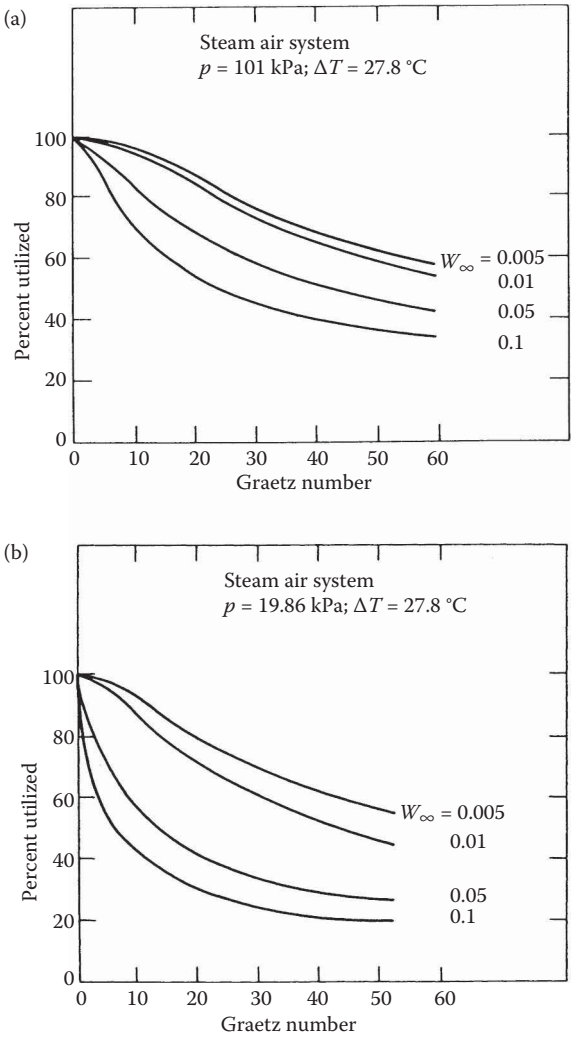

FIGURE 4.23.10 (a) Effect of W_∞ on percent coolant utilized for condensation on a sheet, $P=10$ kPa and (b) effect of W_∞ on percent coolant utilized for condensation on a sheet, $P=19.86$ kPa. (From Jacobs, H.R. and Nadig, R., *ASME J. Heat Transfer*, 109, 1013, 1987. With permission.)

Liu et al. (1989) carried out experiments with round jets, which ultimately broke down and formed drops whose diameter were twice that of the jet. Their results, shown in Figures 4.23.11a and b indicate that the heat transfer for condensation was little different than if the jet had not fragmented. This was because although the surface area was greater, the rate of diffusion was smaller, thus negating the former. Kim and Mills (1989a,b) studied condensation on turbulent jets and noted that the external to the jet heat transfer resistance governed, as noted above for sheets.

Direct Contact Condensation Falling Films

In addition to the barometric condensers mentioned in the preceding subsections, some condensers have been designed as packed beds. The packing can be varied from structured to nonstructured types and be made of a variety of materials. The materials are chosen so that the coolant

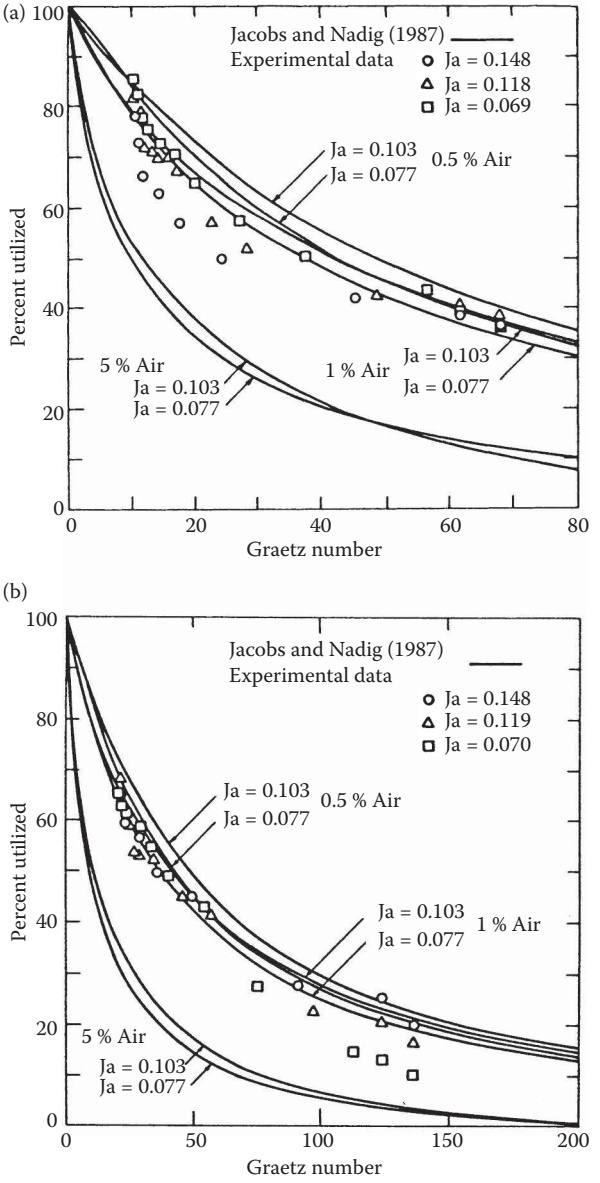

FIGURE 4.23.11 (a) Percent coolant utilized for 12.7 mm head of water and (b) percent coolant utilized for 50.8 mm head of water. (From Liu, T.L., Jacobs, H.R., and Chen, K., *ASME J. Heat Transfer*, 111, 585, 1989. With permission.)

wets the packing and flows across it as a thin film which is reformed as it drips from one level of packing to the next in a manner analogous to condensate dripping from one tube to the next in a surface condenser.

The modeling of falling films of coolant with subsequent condensation are similar to those for sensible heat transfer mentioned previously, but considerably more complicated, especially with noncondensibles present. Seven equations must be solved simultaneously. Even for a pure vapor the problem is difficult, as shown by Jacobs and Bogart (1980), Rao and Sarma (1984), etc. Jacobs and Nadig (1983) deal with noncondensibles being present as well as the coolant and condensate being immiscible.

Jacobs et al. (1982) studied film condensation on a thin film flowing over a sphere. Using their results, they present a correlation for the mean fluid temperature leaving the sphere as

$$\frac{T_m - T_{SAT}}{T_0 - T_{SAT}} = 0.03\ \mathrm{Ja}^{-0.4}\,\overline{R}^{-1/2}\mathrm{Re}^{1/3}\mathrm{Pr}^{0.36} \tag{4.23.28}$$

for the coolant and condensate being the same. In the above, $\overline{R}$ is $R\Big/\left(\frac{v^2}{g}\right)^{1/3}$ and R is the radius of the sphere.

The results showed very good agreement when compared to the experimental data of Finklestein and Tamir (1976).

Repeated layers of spheres with reforming films which flow onto the succeeding layer with a new T_0 equal to T_m at the base of the previous sphere provide a model for a packed bed of spheres.

Jacobs et al. (1979) and Bharathan and Althof (1984) carried out experiments with a variety of packings and relative flow rates of vapor and coolants that account for a nonstagnant vapor. Celata et al. (1989) studied steam condensation on a turbulent film of water. They indicate that laminar models can be used when modifying the liquid thermal conductivity as

$$k_{eff} = k_f\left(0.21\mathrm{Re}^{0.34}/\mathrm{Pr}^{0.24}\right) \tag{4.23.29}$$

Direct Contact Heat Transfer with Solidification

Direct contact with solidification is found in several applications including the manufacture of small beads where a molten spray is injected into a coolant. Typical of this is the formation of lead and steel shot for shotguns. It is also used in freezing of food, freeze-desalting of brine, and freeze-coating of thin films on wires. Johnson et al. (1973) investigated freeze-desalting by injecting a cold refrigerant into brine. Ice formed at the interface and was recovered with the refrigerant. Cheung and Cha (1987) and Cheung (1990) studied freeze-coating of a moving wire with the intent of forming a uniform coating. These problems are all similar to condensation problems assuming, for example, condensation on a drop or condensation on a jet or sheet with the velocity in the stream being slug flow. The difference in the analysis is that the Jakob number is replaced by the Stefan number. Freezing of liquid drops follows the Stefan problem in conduction, depending on the circulation within the drops and external shear. For metal drops, the high surface tension eliminates the circulation and the solution is in fact a spherical Stefan problem. Of course, no analytical solution exists and numerical or integral methods must be used to solve the nonlinear problem.

Summary

The length of this section on direct contact heat transfer does not provide for a complete development of the subject. However, the references cited in the text will provide further insight to the multitude of complex problems that are direct contact in nature. The reader has been referred to other sections within the text as well. Of particular importance are the development of models for multiphase flow. So-called two-fluid models are often used to determine the heat transfer in direct contact systems. These models are typically one-dimensional Eulerian models. However, when dealing with one or more dispersed phases in a continuum, a so-called Lagrangian–Eulerian model also is used. The author and others have developed computer codes to deal with a range of such problems; nonetheless, continued work is needed, especially for problems where the holdup of the dispersed phase is large.

4.24 HEAT TRANSFER IN THE PRESENCE OF SYNTHETIC JETS

Mangesh Chaudhari and Amit Agrawal

Introduction

A synthetic jet is synthesized directly from the fluid of the system in which it is embedded. It is commonly formed from a small closed cavity having a diaphragm at one end and a small opening at the other. In the process of jet formation, the fluid is alternately sucked into and ejected from the cavity due to vibration of the diaphragm (Figure 4.24.1). Owing to zero net mass addition to the system, the synthetic jet is also known as a zero-net-mass-flux (ZNMF) device. At low actuating frequency (less than the jet formation frequency) of vibration of the diaphragm, the fluid enters the cavity during the suction stroke and ejected out from the cavity during the ejection stroke, without any jet formation. However, an increase in the excitation frequency increases the rate of suction and ejection of fluid from the cavity, and beyond a certain frequency (the jet formation frequency) the fluid vortices detach from the cavity surface and travel into the surrounding medium. Further increase in the excitation frequency increases the formation rate of vortices; and these vortices coalesce with each other in the medium to form a synthetic jet. However, there is an upper limit on frequency until which the synthetic jet forms.

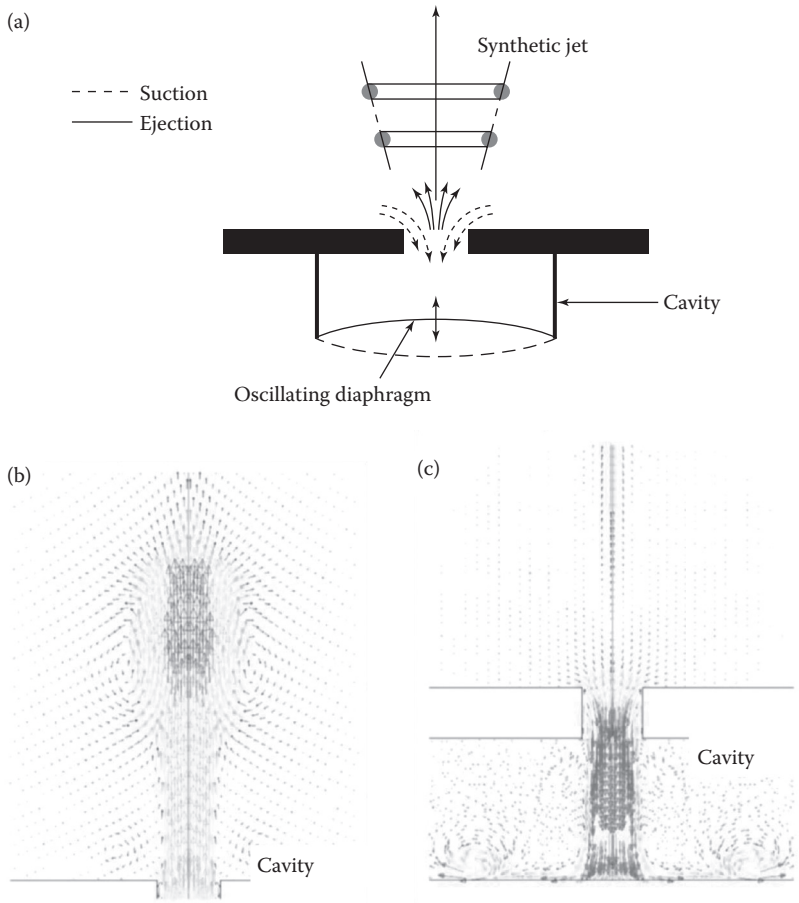

FIGURE 4.24.1 (a) Schematic of synthetic jet operation showing the suction and ejection strokes, respectively. (b) and (c) Velocity vectors obtained from computational fluid dynamics calculations by Jain et al. (2011), showing vortex formation during the suction and ejection strokes, respectively. (From Jain, M. et al., *Sens. Actuators, A,* 165, 351–366, 2011. With permission.)

The aforementioned feature obviates the need for input piping or complex fluidic packaging and makes synthetic jets ideally suited for low-cost batch fabrication using micromachining techniques. Owing to the pulsating nature of the flow, the entrainment of fresh ambient fluid into the jet is high. This leads to a relatively large mass flux downstream of the orifice and a relatively large heat transfer coefficient. The use of "synthetic jet" to drive the air is a relatively new approach for electronics cooling, and its usefulness has been explored in previous studies (Mahalingam and Glezer, 2005; Pavlova and Amitay, 2006; Arik, 2007; Chaudhari et al., 2010a).

Owing to the vortical nature of the flow during the suction and ejection processes, no potential core exists in the synthetic jet, which makes this flow different as compared to a normal jet. It has been further observed that there is substantial mixing of the fluid near the orifice of a synthetic jet; and that the turbulence intensities are about four times higher than that of a normal jet. These features make the use of synthetic jet for cooling of a hot surface attractive; their use for cooling of compact devices has also been explored.

Electronic cooling is an area where the use of synthetic jet has been actively explored. Besides cooling, synthetic jets have a number of other potential engineering applications, such as boundary-layer separation control, jet vectoring, better mixing of fuel in the engine combustion chamber, creation of local turbulence, and vehicle propulsion. A synthetic jet is therefore a promising novel technique having some unique characteristics (better mixing, zero net mass flux, etc.), which makes them particularly useful for several engineering applications.

Flow Characteristics of Synthetic Jet

The synthetic jet is formed in a stagnation fluid due to vibration of a diaphragm in a closed cavity having one or more openings at some other end of the cavity. Owing to the oscillatory nature of the flow, calculation of Reynolds number is not straightforward. The Reynolds number of the synthetic jet is calculated as (Smith and Glezer, 1998):

$$\mathrm{Re} = \frac{U_o d}{\upsilon} \tag{4.24.1}$$

where d is the orifice diameter, υ is the kinematic viscosity, and U_o is the average orifice velocity during the ejection part of the cycle. The last parameter is calculated from measurement (using, for example, a hotwire) of the instantaneous streamwise velocity ($u(t)$) at the exit and centerline of the orifice, as

$$L_o = \int_0^{\tau/2} u(t)\,\mathrm{d}t \tag{4.24.2}$$

$$U_o = L_o f \tag{4.24.3}$$

where L_o is the stroke length, f is the excitation frequency (or inverse of time period τ), and t is time. Various researchers have explored the heat transfer and flow characteristics of synthetic jets both experimentally and numerically. Initial studies were geared toward understanding the flow physics of synthetic jet, and later their heat transfer characteristics were explored. Schlieren imaging, particle image velocimetry, hot wire anemometry, thermal imaging, liquid crystals, and interferometery are some of the measurement techniques used for the study of synthetic jet (Smith and Glezer, 1998; Zhang and Tan, 2007; Chaudhari et al., 2009; Qayoum et al., 2010; Bhapkar et al., 2014). The study has been carried out for both planar and axisymmetric synthetic jets using different actuators (such as piezoelectric and electromagnetic). Lumped element modeling (LEM) (Gallas et al., 2003) and similarity analysis (Agrawal and Verma, 2008) of a synthetic jet have been carried out in the

literature. It was noticed that the synthetic jet formation is governed by the jet Strouhal number (or Stokes number) and found to be different for planar and axisymmetric jets (Holman et al., 2005).

Broadly, the following set of events takes place from the time of starting the actuator and as the excitation frequency is increased. The smoke required in the experiments is generated using an incense stick (*agarbatti*) and images are captured using a digital camera.

1. When the actuator is off, there is no flow from the orifice and the smoke from the incense stick rises vertically upward (not shown). When the actuator is excited at a very low frequency (around 1 Hz), initially there is a continuous suction and ejection of the smoke in the form of vortex rings from the orifice, due to the movement of the diaphragm. However, the vortex rings generated during the ejection stroke are sucked back into the cavity during the suction stroke; so effectively, the vortex rings do not come out of the cavity. The effect of the pressure waves generated by the oscillatory diaphragm can however be seen as a disturbance to the otherwise undisturbed smoke line flowing in the vertical direction (Figure 4.24.2a). Although clearly visible to the naked eye, the sucking back of the vortices is rather difficult to photograph. The generation and suction of vortices are similar to those shown in the numerical simulations (Figure 4.24.1c).
2. As the excitation frequency is increased, the frequency of vortex formation also increases, but still the vortices that are formed are eventually sucked back into the cavity. This occurs until a frequency of approximately 6–8 Hz is reached. Interestingly, the frequency of excitation seems to be reflected in the smoke line as a corresponding frequency of disturbance. Eventually, a critical frequency (at about 9 Hz), termed as the starting point for the synthetic jet to form, is reached. At this point, for the first time, the vortex ring crosses the smoke line and propagates in the horizontal direction (not shown). Due to increase in the momentum of the vortex ring, it is able to overcome the suction created during the backward movement of the diaphragm.
3. On a further increase of frequency (to about 20 Hz), the vortex rings are expelled out of the orifice (Figure 4.24.2b). The vortex-shedding frequency increases with the excitation frequency, along with the momentum of the rings. The rings now travel some distance in the horizontal direction beyond which they become indistinguishable from the ambient fluid. Initially, the distance between the rings is large but it reduces with an increase in the excitation frequency. The vortex rings lose their momentum in the far field, and eventually coalesce with the rings ejected in the previous forcing cycle.

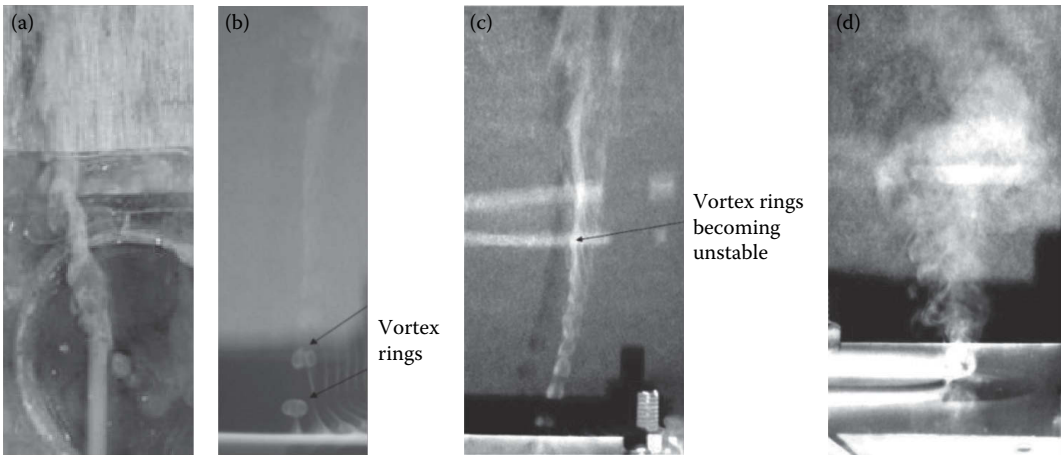

FIGURE 4.24.2 Flow visualization images showing the various stages of synthetic jet. (a)–(d) correspond to a gradual increase in the excitation frequency. See text for details.

4. As the frequency is further increased (to 20–30 Hz), coalescence starts taking place much closer to the orifice and slowly it takes the form of a continuous jet that appears laminar in appearance even in the far field. At a frequency of about 40 Hz, instabilities are seen to set up in the far field of the jet (Figure 4.24.2c). Due to these instabilities, the flow seems to become helical intermittently, and the laminar structure of the jet breaks down. The absence of potential core is also evident from the image.
5. Increasing the frequency further to about 100 Hz increases the instabilities and eventually a turbulent jet is seen to form (Figure 4.24.2d). The turbulence intensity of this jet increases with a corresponding enhancement in the dissipation of smoke in the flow field. Different length scales corresponding to eddies of different sizes can be discerned.

Smith and Glezer (1998) and Mallinson et al. (2001) observed that there is large entrainment in the near field of both planar and axisymmetric synthetic jets, due to the oscillating nature of the flow. The synthetic jet is found to be wider, slower, and having more momentum as compared to a continuous jet in the near field, while in the far field the characteristics of synthetic and continuous jets are similar in several aspects (Smith and Swift, 2003; Agrawal and Verma, 2008). The synthetic jet flow characteristics have been studied for different flow and geometrical parameters of the cavity (Chaudhari et al., 2009) using an electromagnetic actuator. The geometrical parameters of the cavity include the depth of cavity, orifice diameter, shape of orifice, and number of orifices. Hotwire anemometer is used for measurement of suction and ejection velocity. The ejection velocities are found to be larger as compared to the suction velocities. The ratio of ejection to suction average velocities decreases monotonically with frequency—from about 2.3 to 1, for 3 mm orifice diameter (Chaudhari et al., 2009). Note that this ratio is dependent on the orifice diameter, as the orifice diameter increases the ratio decreases suggesting a relative decrease in the ejection velocity. A lower bound and an upper bound on the formation frequency of a synthetic jet are also observed from Figure 4.24.3. Also, two resonant frequencies have been identified out of which the first resonance frequency (in the range of 250–300 Hz) seems almost independent of both the cavity depth and orifice diameter, whereas the second resonance frequency was found to be dependent on the cavity height and it decreased with an increase in cavity height. Also, the second resonance peak dampens out with an increase in the orifice diameter. The first resonance frequency is independent of all the configurations of the actuator known as diaphragm resonance frequency, and the second resonance frequency depends on the cavity volume termed as Helmholtz resonance frequency. These resonance frequencies can be varied as per the requirements, by proper selection of the actuator as well as the cavity volume. Turbulence intensities were found to be larger (ranging around 3–4) for different orifice diameter and almost independent of the cavity volume and frequencies for the same actuator (Chaudhari et al., 2009). As compared to the normal jet, the synthetic jet turbulence intensities are very high near the orifice, i.e., the fluid mixing takes place at a faster rate, which leads to the use of a synthetic jet for cooling of surfaces in compact devices.

Chaudhari et al. (2009) observed that the input power requirement for a synthetic jet is about 1.4–1.6 W. Interestingly, the power requirement at the resonance frequency is slightly lower (by about 10%) as compared to that at the other frequencies. The issue of noise generation due to the operation of the synthetic jet has been addressed by Bhapkar et al. (2013, 2014). Noise levels between 48–68 dB have been measured by them, which are well within the comfort limit. Operating the synthetic jet cavity at the resonance frequency is found to be beneficial from several aspects: high ejection velocity, low noise generation, low input power requirement, and high heat transfer coefficient. The reason for this observation stems from the fact that a part of the input power supplied to the actuator is consumed in moving the diaphragm, while the remaining amount is dissipated through noise and other losses. A larger amount of noise at frequencies other than the resonance frequency and at higher excitation voltages can therefore be expected.

It was noticed that the synthetic jet spreads rapidly along the direction of the minor axis of the rectangular orifice, while along the major axis the synthetic jet initially contracted before spreading

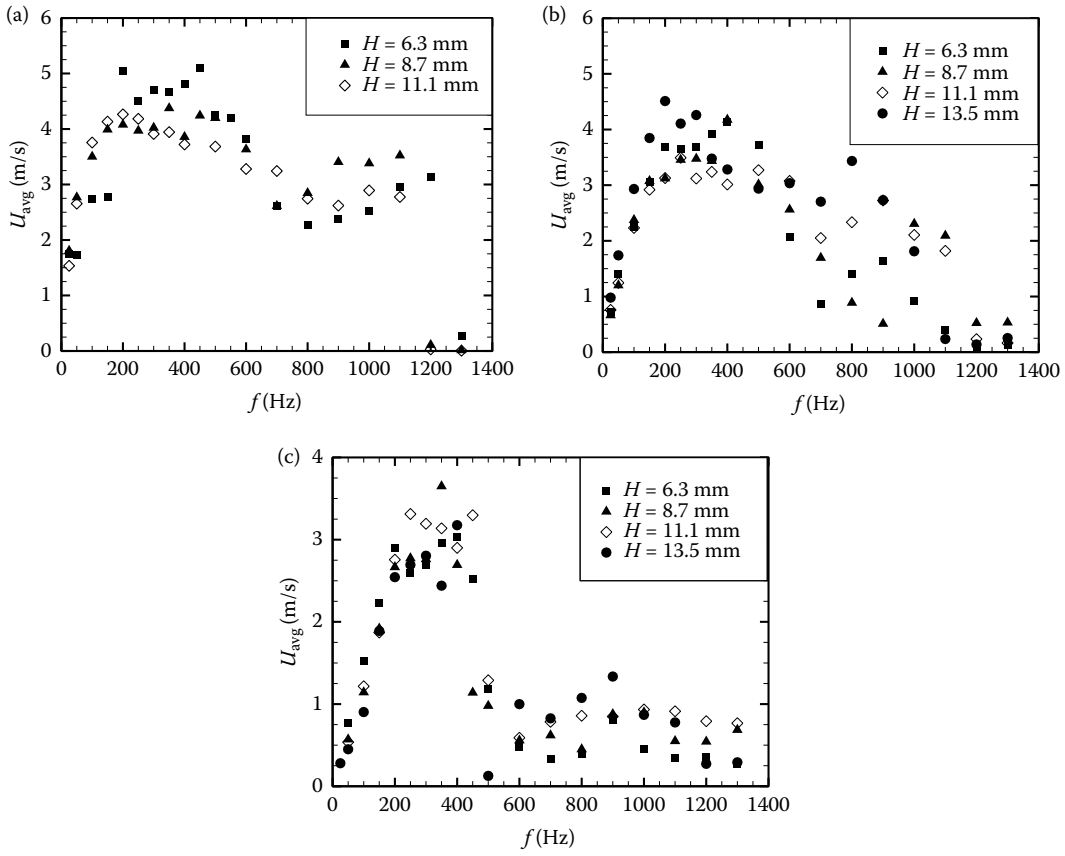

FIGURE 4.24.3 Variation of average velocity with excitation frequency for different cavity depths and orifice diameters. The orifice diameters are: (a) 3 mm, (b) 5 mm, and (c) 8 mm. (From Chaudhari, M. et al., *Exp. Therm. Fluid Sci*., 33, 439–448, 2009. With permission.)

slowly. The cooling region was observed to be wider with a synthetic jet than with a continuous jet, as deduced from the local temperature distribution (Zhang and Tan, 2007).

Heat Transfer Characteristics

The flow behavior of synthetic jet suggests that it can be employed for enhancing the heat transfer rate from a surface. The hot surfaces can be cooled by employing a synthetic jet parallel to the surface (such as in a duct or microchannel) or by impinging on a surface. The study was carried out to measure the performance of impinging synthetic jet for cooling of electronic components. The experiments were conducted for different excitation frequencies at different orifices to impinging surface distances. Synthetic jet gives optimum cooling performance at orifice to a surface distance of six times the orifice diameter (Figure 4.24.4), for all Reynolds numbers investigated in Pavlova and Amitay (2006) and Chaudhari et al. (2010a).

The vortices of the synthetic jet impinging on the surface individually are responsible for enhancing the heat transfer from the surface; after impingement these vortices break down into smaller secondary vortices to increase the rate of heat transfer. The maximum heat transfer coefficient with synthetic jet is found to be 4–11 times that of the natural convection heat transfer coefficient (Arik, 2007; Chaudhari et al., 2010a). The exponent of Reynolds number for the maximum Nusselt number is found to vary between 0.6 and 1.4 (Figure 4.24.4), which is larger as compared to a continuous jet (~0.5).

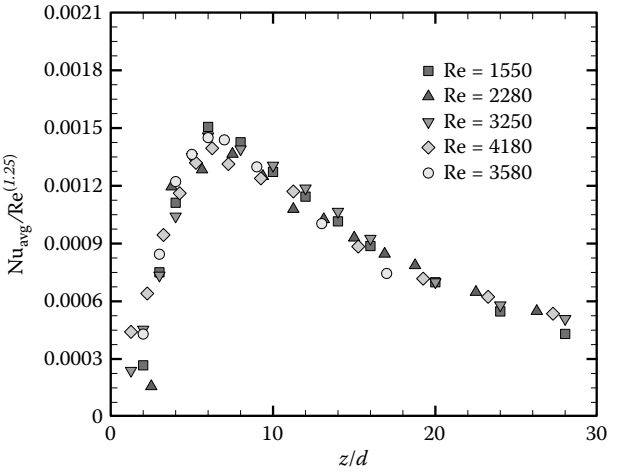

FIGURE 4.24.4 $Nu_{avg}/Re_{1.25}$ vs z/d showing dependence of Nusselt number on Reynolds number. (From Chaudhari, M. et al., *Int. J. Heat Mass Transfer,* 53, 1057–1069, 2010a. With permission.)

Note that the data for different Reynolds numbers collapse well on to a single curve with a maximum scatter of 3% around the mean value. Due to the high exponent of Reynolds number, synthetic jets are expected to perform substantially better at high Reynolds number as compared to a continuous jet.

The heat transfer performance of the continuous jet is found to be better at the lower axial distances as compared to the synthetic jet for the same Reynolds number. The fresh fluid input is provided by the continuous jet at all axial distances but for the synthetic jet at lower axial distances the same fluid is sucked and ejected, which degrades the cooling performance of the synthetic jet (Chaudhari et al., 2010a). Based on the experimental data for the circular orifice synthetic jet, the following correlation has been proposed to calculate the average Nusselt number:

$$\frac{\mathrm{Nu_{avg}}}{\mathrm{Pr}^{0.333}} = 7.624(\mathrm{Re})^{0.792}\left(\frac{L}{d}\right)^{-2.186}\left(\frac{R}{d}\right)^{2.258}\left(\frac{z}{d}\right)^{-0.632} \tag{4.24.4}$$

In the above correlation, d is orifice diameter, L is enclosure size, ($2R$) is heater size, and z is axial distance between orifice and surface. The above correlation is valid for: Re = 1150–4180, L/d = 7.86–22, R/d = 1.5–4, and $z/d > 3$ (Chaudhari et al., 2010a). A general correlation for the stagnation point heat transfer performance of an impinging synthetic jet is obtained for a wide parameter range, incorporating the effect of Reynolds number ($500 < \mathrm{Re} < 1500$), jet-to-surface spacing ($2 < z/d < 16$), and stroke length ($2 < L_0/D < 40$) (Persoons et al., 2011),

$$\mathrm{Nu_0} = 0.1676\mathrm{Re}^{0.686}\mathrm{Pr}^{0.4} f(H) \tag{4.24.5}$$

where, $f(z) = \dfrac{1+1.108\left(\dfrac{z/d}{5.21}\right)^2}{1+\left(\dfrac{z/d}{5.21}\right)^{2.487}}$.

The cooling performance of the impinging synthetic jet has been studied for different sizes and shapes of orifice (viz., square, rectangular, and elliptical with different aspect ratios, oval and diamond). It has been observed that a square orifice performs better as compared to the circular and rectangular

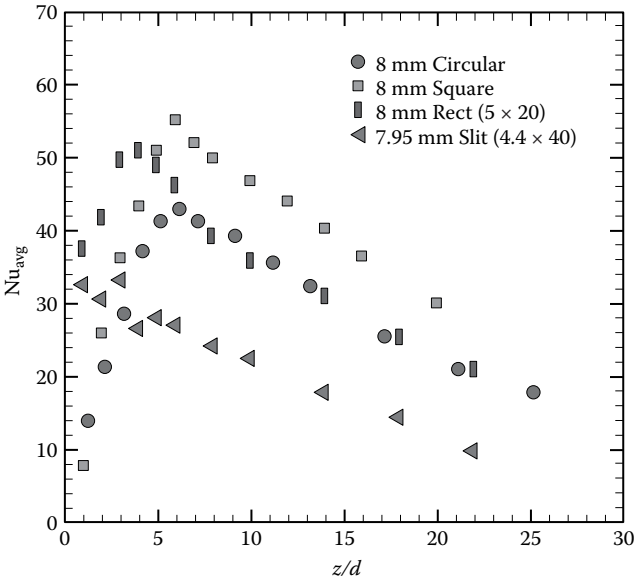

FIGURE 4.24.5 Variation of average Nusselt number with the normalized axial distance for different shapes of orifice having same hydraulic diameter with excitation frequency of 200 Hz. (From Chaudhari, M. et al., *Exp. Therm. Fluid Sci.*, 34, 246–256, 2010b. With permission.)

orifices for the same hydraulic diameter due to the larger mass flux (Chaudhari et al., 2010b) as shown in Figure 4.24.5. Further, a rectangular orifice gives better cooling performance as compared to the other shapes of orifice with the same hydraulic diameter at lower axial distances. For rectangular orifices, at lower axial distances, there is no recirculation and the shape of the orifice is retained as the flow emerges from the orifice; therefore, covering larger surface area for cooling. The following correlation from the experimental data for all orifice shapes is proposed by Chaudhari et al. (2010b):

$$\frac{\mathrm{Nu}_{\mathrm{avg}}}{\mathrm{Pr}^{0.333}} = 0.014(\mathrm{Re})^{0.841}\left(\frac{L}{d}\right)^{1.514}\left(\frac{R}{d}\right)^{-1.725}\left(\frac{z}{d}\right)^{-0.607} \tag{4.24.6}$$

The above correlation is valid for: $L/d = 7.86–22$, $R/d = 1.5–4$, $z/d = 3–25$, and $\mathrm{Re} = 600–4200$. The diamond and oval shape orifices give 17% and 7%, respectively, increase in heat transfer as compared to a circular orifice of the same hydraulic diameter (Bhapkar et al., 2014; Mangate and Chaudhari, 2015).

Multiple-orifice, single-cavity impinging synthetic jet cooling performance has also been explored for different locations and number of satellite orifices with respect to a center orifice. Further results are available for different Reynolds numbers and normalized axial distance (Chaudhari et al., 2011). The maximum heat transfer coefficient with multiple-orifice, single-cavity is found to be 30% higher as compared to a single orifice synthetic jet. Further, two peaks of the Nusselt number are observed with respect to normalized axial distance (z/d) for multiple-orifice single-cavity impinging synthetic jet, as shown in Figure 4.24.6. The first peak is located at $z/d = 2$, and the second peak is at $z/d = 9$. The appearance of the first peak is particularly significant as it can be utilized in space-constrained applications. The two peaks are observed for 1, 2, and 4 number of satellite orifices along with the center orifice due to the enhanced circulation of the fluid. However, for 8 number of satellite orifices, a ring is formed around the center orifice, which restricts entrainment of the fresh fluid and only a single peak is observed. The first peak shows a larger increase in Nusselt number with respect to the baseline value of no satellite orifice as compared to the second

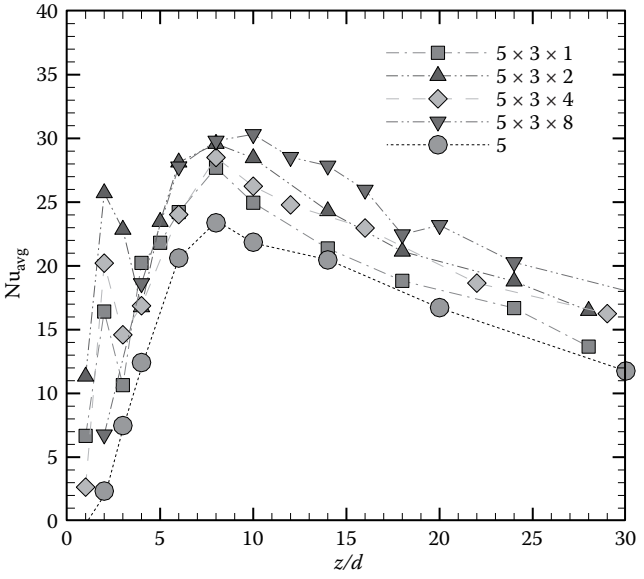

FIGURE 4.24.6 Comparison of average Nusselt number for 5 mm center orifice and different satellite holes around center of same pitch along the normalized axial distance for Re=2600. (From Chaudhari, M. et al., *Int. J. Heat Mass Transfer*, 54, 2056–2065, 2011. With permission.)

peak. There are a sharp increase and a sharp decrease of the average Nusselt number at around $z/d=2$ for the satellite orifices of 1, 2, and 4 number. The two satellite orifices along with the center orifice give maximum cooling performance at $z/d=2$, which is required in the cooling of compact devices. The number of satellite orifices with the center orifice plays an important role to get the two peaks of Nusselt number. Multiple satellite orifices without the center orifice cover the maximum surface area, which gives better performance as compared to a single center orifice. According to requirements, a proper configuration can thus be selected with different number of satellite holes and with/without the center orifice.

Besides improvement in the value of heat transfer coefficient and appearance of an additional peak, the benefit with multi-orifice, single-cavity synthetic jet is a slight reduction in the input power requirement as compared to a single center orifice synthetic jet. The power consumption is reduced due to a reduction in the resistance to flow, owing to a larger number of openings as compared to a single center orifice. The reduction in power consumption in conjunction with the larger heat transfer coefficient with multi-orifice synthetic jet suggests that they can be beneficially employed in cooling systems.

Other than employing synthetic jets in impinging mode, studies related to flow in microchannels and server ducts have been carried out, where the synthetic jet flow is parallel to the hot surface. Lee et al. (2012) numerically studied the flow and heat transfer characteristics in a microchannel using the synthetic jet. Cross flow in addition to the synthetic jet flow removes the hot spots from the electronic components. A synthetic jet can thus be effectively used for the local cooling of electronic components of a blade server (Chaudhari et al., 2012). The heat transfer characteristics of an inclined impinging synthetic jet have also been carried out for different angle of inclinations ($\theta=40°$–$90°$). The normal impingements ($\theta=90°$) resulted in the maximum value of the heat transfer coefficient for all orifice to surface spacings (Bhapkar et al., 2013).

From an application point of view, the utility of the synthetic jet has been explored by studying the thermal performance of heat sinks. Also, use of the synthetic jet in the duct (as a blade server) has been explored. It was observed that approximately 40% more heat dissipation occurred with the synthetic jet-based heat sinks as compared to that with a steady flow from a ducted fan blowing air

through the heat sink. The average heat transfer coefficient in the channel flow between the fins was 2.5 times that of the steady flow in the duct at the same Reynolds number. The thermal effectiveness of the synthetic jet heat sinks is more than twice of the fan-heat sink combination at the same power (Mahalingam and Glezer, 2005). The shape of the orifice with the same hydraulic diameter of the synthetic jet has a negligible effect on the thermal performance of the heat sink. A commercial fan that covers the entire surface of heat sink performs better than the single orifice synthetic jet (Chaudhari et al., 2012).

4.25 TEMPERATURE AND HEAT TRANSFER MEASUREMENTS

Robert J. Moffat and Tadhg O'Donovan

There are two different kinds of materials to consider with respect to experimental methods: the unit operations of measurement (transducers and their environmental errors) and the strategy of experimentation. This section deals only with the unit operations: transducers, their calibrations, and corrections for environmental errors.

Temperature Measurement

An International Practical Temperature Scale (IPTS) has been defined in terms of a set of fixed points (melting points of pure substances) along with a method for interpolating between the fixed points. The IPTS agrees with the thermodynamic temperature scale within a few Kelvin over most of its range. The IPTS is the basis for all commerce and science, and all calibrations are made with respect to the IPTS temperature. The scale is revised periodically.

Accurate calibrations are not enough to ensure accurate data, however. If a sensor has been installed to measure a gas temperature or a surface temperature, any difference between the sensor temperature and the measurement objective due to heat transfer with the environment of the sensor is an "error." In most temperature-measuring applications, the environmental errors are far larger than the calibration tolerance on the sensor and must be dealt with just as carefully as the calibration.

Thermocouples

Any pair of thermoelectrically dissimilar materials can be used as a thermocouple. The pair need only be joined together at one end and connected to a voltage-measuring instrument at the other to form a usable system. A thermocouple develops its signal in response to the temperature difference from one end of the pair to the other. The temperature at one end, known as the reference junction end, must be known accurately before the temperature at the other end can be deduced from the voltage.

Thermocouples are the most commonly used electrical output sensors for temperature measurement. With different materials for different ranges, thermocouples have been used from cryogenic temperatures (a few Kelvin) to over 3000 K. In the moderate-temperature range, ambient to 1200°C, manufacturer's quoted calibration accuracy can be as good as ±3/8% of reading (referred to 0°C) for precision-grade base metal thermocouples. Broader tolerances apply at very high temperature and very low temperatures. Thermocouple signals are DC voltages in the range from a few microvolts to a few tens of microvolts per degree Centigrade. Because of their low signal levels, thermocouple circuits must be protected from ground loops, galvanic effects, and from pickup due to electrostatic or electromagnetic interactions with their surroundings. Thermocouples are low-impedance devices. Multiple channels of thermocouples can be fed to a single voltage reader using low-noise-level scanners or preamplifiers and electronic multiplexers.

The alloys most frequently used for temperature measurement are listed in Table 4.25.1. These alloys have been developed, over the years, for the linearity, stability, and reproducibility of their EMF vs. temperature characteristics and for their high-temperature capability.

Calibration data for thermocouples are periodically reviewed by the National Institutes of Science and Technology based on the then-current IPTS. Values in Table 4.25.1 illustrate the approximate levels, which can be expected, and are from the National Bureau of Standards Monograph 125. Maximum temperatures listed in this table are estimates consistent with a reasonable service lifetime. Allowable atmosphere refers to the composition in contact with the thermoelements themselves. Accuracy estimates are provided for two levels of precision: standard grade and precision grade, where these data are available.

Noble metal and refractory metal thermocouples are often used with substitute lead wires, as a cost-saving measure. These lead wires, described in Table 4.25.2, are cheaper and easier to handle than the high-temperature thermocouples. They have the same temperature–EMF characteristics as their primary thermoelements, but only over the range of temperatures the lead wires will usually encounter (up to a few hundred degrees Centigrade). Except for the substitute alloys, thermocouple extension wires have the same composition as thermocouple wires, differing only in the type of insulation and the accuracy of calibration, which is not held as closely for extension wire as for thermocouple-grade wire.

Any instrument capable of reading low DC voltages (on the order of millivolts) with 5–10 μV resolution will suffice for temperature measurements. Galvanometric measuring instruments can be used, but, since they draw current, the voltage available at the terminals of the instrument depends not only on the voltage output of the thermocouple loop but also on the resistance of the instrument

and the loop together. Such instruments are normally marked to indicate the external resistance for which they have been calibrated. Potentiometric instruments, either manually balanced or automatically balanced, draw no current when in balance, hence can be used with thermocouple loops of any arbitrary resistance without error. High-input impedance voltmeters draw very low currents and, except for very high resistance circuits, are not affected by the loop resistance.

Thermocouple Theory

Equation 4.25.1 is the general form describing the EMF generated in a two-wire thermocouple (Moffat, 1962). The same form can be derived from either the free-electron theory of metals or from thermodynamic arguments alone: the output of a thermocouple can be described as the sum of a set of terms, one arising in each wire in the circuit.

The junctions do not generate the EMF: they are merely electrical connections between the wires. For a two-wire circuit,

$$\mathrm{EMF} = \int_0^L \varepsilon_1 \frac{dT}{dx}\,dx + \int_L^0 \varepsilon_2 \frac{dT}{dx}\,dx \tag{4.25.1}$$

where

ε_1 and ε_2 = the total thermoelectric power of materials 1 and 2, respectively, mV/°C. The value of ε is equal to the sum of the Thomson coefficient and the temperature derivative of the Peltier coefficient for the material.
T = temperature, °C
x = distance along the wire, m
L = length of the wire, m

This form for expressing the output of a two-wire circuit applies regardless of whether the wires are uniform in composition or not. If a circuit contained four wires (two thermocouple wires and two extension wires), then Equation 4.25.1 would be written with four terms, one for each length of wire.

When the wire is uniform in composition and both wires begin at ($\boldsymbol{T}_0$) and both end at ($\boldsymbol{T}_\mathbf{L}$), the two terms can be collected into one integral:

$$\text{EMF} = \int_{T_0}^{T_\text{L}} (\varepsilon_1 - \varepsilon_2)\,\text{d}T \tag{4.25.2}$$

The EMF–temperature (*E–T*) tables produced by NIST and others are "solutions" to Equation 4.25.2 and can be used only when the following three conditions are met:

1. The thermoelectric power, ε, is not a function of position, i.e., the wires are homogeneous;
2. There are only two wires in the circuit;
3. Each wire begins at $\boldsymbol{T}_\mathbf{0}$ and ends at $\boldsymbol{T}_\mathbf{L}$.

When the circuit consists entirely of pairs of materials, Equation 4.25.2 can be used directly as the basis for understanding the source of the EMF. As an example, consider the three-pair system shown in Figure 4.25.1. For that circuit, Equation 4.25.2 would have three terms: one for each pair. The total EMF generated by the circuit would be the sum of the EMFs generated in the thermocouple pair and in the extension wire pair. The pair of copper wires would not contribute to the net EMF, assuming the two copper wires were perfectly matched. The EMF contributed by each pair would be proportional to the temperature difference from end to end of that pair, as shown in Equations 4.25.3 and 4.25.4.

$$\text{EMF} = \int_{T_1}^{T_2} (\varepsilon_{\text{cn}} - \varepsilon_{\text{cu}})\,\text{d}T + \int_{T_2}^{T_3} (\varepsilon_+ - \varepsilon_-)_{\text{LEADS}}\,\text{d}T + \int_{T_3}^{T_4} (\varepsilon_+ - \varepsilon_-)_{\text{TC}}\,\text{d}T \tag{4.25.3}$$

$$\text{EMF} = 0 + (T_3 - T_2)\,(\varepsilon_+ - \varepsilon_-)_{\text{LEADS}} + (T_4 - T_3)\,(\varepsilon_+ - \varepsilon_-)_{\text{TC}} \tag{4.25.4}$$

Most thermocouple circuits consist only of pairs of wires and can be understood in terms of these two equations, but some require a more detailed treatment. A graphical method of analysis is available, based on Equation 4.25.1.

The temperature–EMF calibrations of the more common materials are shown in Figure 4.25.2 derived from NBS Monograph 125 and other sources. This figure provides the input data for a simple graphical technique for describing the EMF generation in a circuit. Each curve in Figure 4.25.2 represents the output that would be derived from a thermocouple made of material X used with platinum when the cold end is held at 0°C and the hot end is held at $\boldsymbol{T}$.

Those elements commonly used as "first names" for thermocouple pairs, i.e., Chromel (Chromel–Alumel), iron (–constantan), copper (–constantan), have positive slopes in Figure 4.25.2.

The simplest thermocouple circuit for temperature measurement consists of two wires joined together at one end (forming the "measuring junction") with their other ends connected directly to a measuring instrument, as shown in the upper portion of Figure 4.25.3. The EMF generation

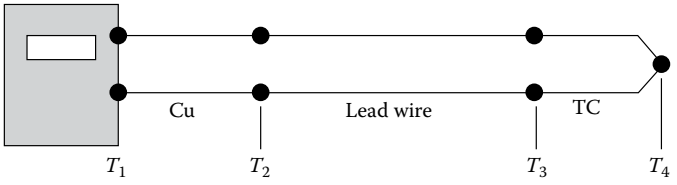

FIGURE 4.25.1 A three-pair circuit.

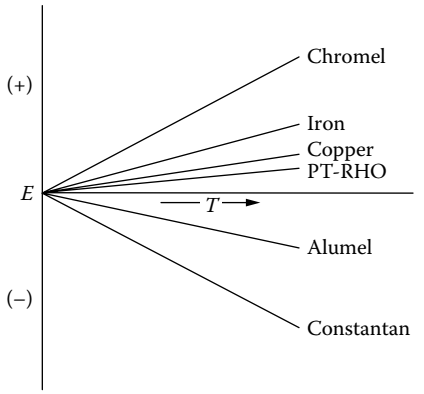

FIGURE 4.25.2 *E–T* calibrations for several common thermocouple materials.

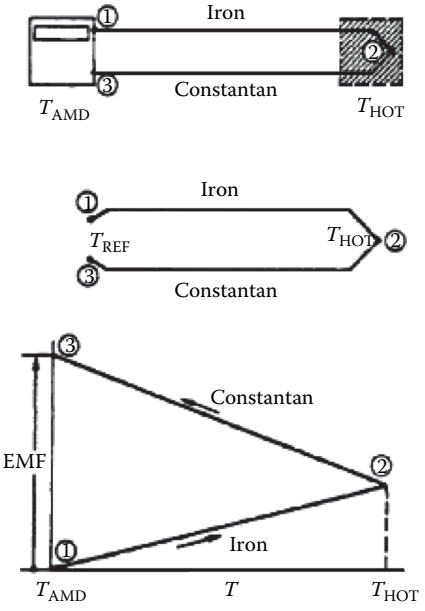

FIGURE 4.25.3 *E–T* diagram of a thermocouple using an ambient reference.

in this circuit is graphically represented in the lower portion, an ***E–T*** diagram, using the data in Figure 4.25.2. The ***E–T*** diagram is used for examining the EMF generated in the circuit, to be certain that it arises only from the desired thermocouple materials, and that all segments of the circuit are properly connected. The ***E–T*** diagram is not used for evaluating the output—that is done using the tables after the circuit has been shown to be correctly wired.

To construct an ***E–T*** diagram, first sketch the physical system considered and assign a number to each "point of interest" on that sketch and a temperature. On ***E–T*** coordinates, locate point 1 at 0/mV and at its assigned temperature. Then start a line from point 1, moving toward the temperature of point 2, and copying the shape of the calibration curve of the iron wire (see Figure 4.25.2). From 2 to 3, use the constantan calibration curve. The difference in elevation of points 1 and 3 describes the net EMF generated in the circuit between points 1 and 3, and describes the polarity. When point 3 lies physically above point 1 in the ***E–T*** diagram, it is, by convention, electrically negative with respect to point 1.

The simple triangular shape shown in Figure 4.25.3 identifies a proper circuit. Any thermocouple circuit whose ***E–T*** diagram is equivalent to that is appropriate for temperature measurement and its EMF may be interpreted using the conventional tables. Any circuit whose ***E–T*** diagram is not equivalent to the pattern circuit should be rewired.

Thermocouples generate their signal in response to the temperature difference between the two ends of the loop. For accurate measurements, the temperature of the "reference junction" must be known. Laboratory users often use an ice bath made from a good-quality Dewar flask or vacuum-insulated bottle of at least 1 pt capacity, as shown in Figure 4.25.4. The flask should be filled with finely crushed ice and then flooded with water to fill the interstices between the ice particles. The reference thermocouple is inserted into a thin-walled glass tube containing a small amount of silicone oil and submerged six or eight diameters into the ice pack. The oil assures good thermal contact between the thermocouple junction and the ice–water mixture. The tube should be sealed at the top to prevent atmospheric moisture from condensing inside it, which would cause corrosion when using iron–constantan thermocouples. Figure 4.25.5 shows in iron–constantan thermocouple circuit with an ice bath. The individual thermocouple wires are connected to copper wires in the ice bath,

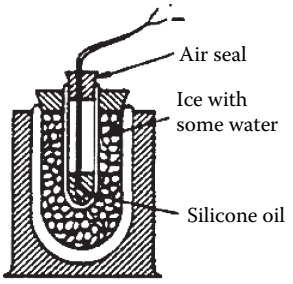

FIGURE 4.25.4 Characteristics of a good ice bath.

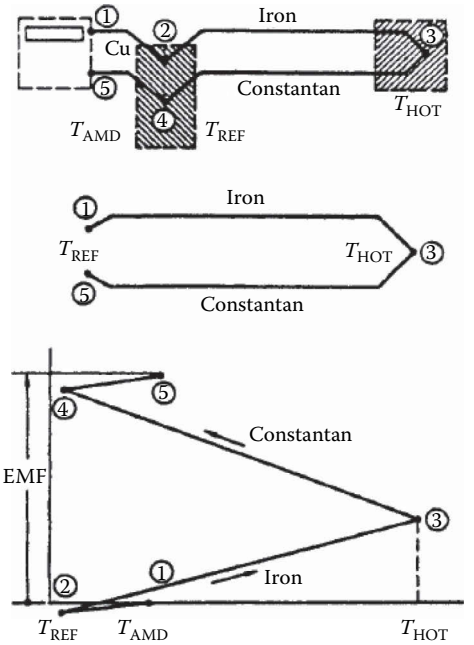

FIGURE 4.25.5 A thermocouple circuit using an ice bath reference and its *E–T* diagram.

and the two copper wires taken to the voltmeter. The lower portion of this figure shows the ***E–T*** diagram for this circuit, and proves that the output of this circuit is entirely due to the temperature difference from end to end of the iron–constantan loop: the two copper wires do not contribute to the output.

Calibration

Thermocouple calibrations are provided by the wire manufacturers to tolerances agreed upon industry-wide, as summarized in Table 4.25.1. These tolerances include two components: the uncertainty in the average slope of the calibration curve of the wire, and the effects of local inhomogeneities in the wire. It is difficult to improve the accuracy of a thermocouple by calibrating it. For a truly significant calibration, the thermocouple would have to be exposed to the same temperature during calibration, at every point along it, as it would encounter in service. In an oven calibration, most of the signal is generated in the material at the mouth of the oven, as could be recognized by considering the temperature gradient distribution along the wire. The material inside the oven contributes little or nothing to the signal.

Thermistors

Thermistors are electrical resistance temperature transducers, made from a semiconducting material or a doped polycrystalline ceramic; their electrical resistance varies inversely, and exponentially, with temperature. The resistance of a 5000 Ω thermistor may go down by 200 Ω for each degree Centigrade increase in temperature in the vicinity of the initial temperature. Interrogated by a 1.0 mA current source, this yields a signal of 200 mV/°C. As a consequence of this large signal, thermistors are frequently used in systems where high sensitivity is required. It is not uncommon to find thermistor data logged to the nearest 0.001°C. This does not mean that the data are accurate to 0.001°C, simply that the data are readable to that precision. A thermistor probe is sensitive to the same environmental errors that afflict any immersion sensor: its accuracy depends on its environment.

Thermistor probes can be used between –183°C (the oxygen point) and +327°C (the lead point), but most applications are between –80°C and +150°C. The sensitivity of a thermistor (i.e., the percent change in resistance per degree Centigrade change in thermistor temperature) varies markedly with temperature, being highest at cryogenic temperatures.

Thermistor probes range in size from 0.25-mm spherical beads (glass covered) to 6-mm-diameter steel-jacketed cylinders. Lead wires are proportionately sized. Disks and pad-mounted sensors are available in a wide range of shapes, usually representing a custom design "gone commercial." Aside from the unmounted spherical probes and the cylindrical probes, there is nothing standard about the probe shapes.

Calibration

Thermistor probes vary in resistance from a few hundred ohms to megaohms. Probe resistance is frequently quoted at 25°C, with no power dissipation in the thermistor. The commercial range is from about 2000 to 30,000 Ω. Representative values of the sensitivity coefficient (% change in resistance per degree Centigrade) are given in Table 4.25.3 and resistance values themselves, in Table 4.25.4.

Proprietary probes are available that "linearize" thermistors by placing them in combination with other resistors to form a circuit whose overall resistance varies linearly with temperature over some range. These compound probes can be summed, differenced, and averaged as can any linear sensor. Modern manufacturing practices allow matched sets to be made, interchangeable within ±0.1°C.

Thermal Characteristics

Thermistor probes are generally interrogated using a low current, either AC or DC. A level of about 10 μA would be typical. With a probe resistance of 10 K Ω, 0.01 W must be dissipated into

TABLE 4.25.3
Thermistor Temperature Coefficient Variations with Temperature

Temperature, °C	Condition	$\Delta R/R$, %
–183	Liquid oxygen	–61.8
–80	Dry ice	–13.4

327	Melting lead	–1.4

TABLE 4.25.4
Thermistor Resistance Variation with Temperature

Temperature, °C	Resistance, Ω	Temperature, °C	Resistance, Ω
–80	1.66 M	0	7355
–40	75.79 K	25	2252
–30	39.86 K	100	152.8
–20	21.87 K	120	87.7
–10	12.46 K	150	41.9

TABLE 4.25.5
Representative Thermal Dissipation Constants for Two Thermistor Probe Designs

Environment	1.0-cm Disk	5.0-cm Cylinder
Still air	8 mW/°C	1 mW/°C
Still oil	55	—
Still water	—	3.5
Oil at 1 m/s	250	—

its surrounding material. This current results in the probe running slightly above the temperature of the medium into which it is installed: the "self-heating" effect. Since thermistors are often used where very small changes in temperature are important, even small amounts of self-heating may be significant.

The self-heating response is discussed in terms of the "dissipation constant" of the probe, in milliwatts per degree Centigrade. The dissipation constant depends on the thermal resistance between the thermistor and its surroundings. For fluid-sensing probes, the self-heating varies with velocity and thermal conductivity, while for solid immersion probes, it varies with the method of attachment and type of substrate.

Dissipation constants for representative probes are given in Table 4.25.5. The self-heating effect must be considered in calibration as well as in use.

The transient response of a thermistor is more complex than that of a thermocouple and, size for size, they are not as well suited to transient measurements.

Thermistor probes are sold with calibration tables of resistance vs. temperature at some specified accuracy, on the order of ±0.1 or 0.2 K, depending on the grade of probe purchased. These tables are

typically in increments of 1 K. For computer interpretation, they should be fit to the Steinhart–Hart form[2] and the coefficients determined for least error.

$$\frac{1}{T} = A_0 + A_1 \ln(R) + A_3 \ln(R^3) \tag{4.25.5}$$

Resistance Temperature Detectors

The terms resistance temperature detector (RTD) and resistance thermometer are used interchangeably to describe temperature sensors containing either a fine wire or a thin film metallic element whose resistance increases with temperature. In use, a small current (AC or DC) is passed through the element, and its resistance measured. The temperature of the element is then deduced from the measured resistance using a calibration equation or table lookup.

RTDs are used both for standards and calibration laboratories and for field service. Field-service probes are generally encased in stainless steel protective tubes with either wire or film elements bonded to sturdy support structures. They are made to take considerable physical abuse. Laboratory standard-grade probes are often enclosed in quartz tubes, with the resistance wire mounted in a strain-free manner on a delicate mandrel.

High-quality resistance thermometers have been used as defining instruments over part of the range of the IPTS. Because of this association with high-precision thermometry, resistance thermometers, in general, have acquired a reputation for high precision and stability. Commercial probes, however, are far different in design from the standards-grade probes, and their stability and precision depend on their design and manufacture.

RTDs are often recommended for single-point measurements in steady-state service at temperatures below 1000°C, where longtime stability and traceable accuracy are required and where reasonably good heat transfer conditions exist between the probe and its environment.

They are not recommended for use in still air, or in low-conductivity environments. RTDs self-heat, which causes an error when the probes are used in a situation with poor heat transfer. They are not recommended for transient service or dynamic temperature measurements unless specifically designed for such service. The probes tend to have complex transient characteristics and are not amenable to simple time-constant compensation.

Physical Characteristics

The physical characteristics of any given resistance thermometer represent a compromise between two opposing sets of requirements. For accuracy, repeatability, and speed of response, a delicate, low-mass sensing element is desired, supported in a strain-free manner in good thermal contact with its surroundings. For durability, a rugged sensor is indicated, mounted firmly to a sturdy structure inside a robust, sealed protection tube.

Both the short-term calibration (resistance vs. specimen temperature) and the long-term stability (drift) are directly affected by the mechanical configuration of the probe. The electrical resistance of the sensing element is a function of its temperature and state of mechanical strain (Figure 4.25.6).

The sensing elements used in field-service RTD probes range from thin metallic films deposited on rectangular ceramic wafers ($0.5 \times 1.0 \times 2.0$ mm) with pigtail leads (0.25 mm diameter and 2.5 cm long) to glass-encapsulated, wire-wound mandrels (4 mm in diameter and 2.0 cm long), again with pigtail leads. Bonding the sensor to its support provides good mechanical protection to the element, but subjects the element to strain due to thermal expansion. As long as this process is repeatable, the calibration is stable.

Electrical Characteristics

RTDs are available commercially with resistances from 20 to 20,000 Ω with 100 Ω being common. Bifilar windings are frequently used in wire-wound elements, to reduce the electrical noise pickup.

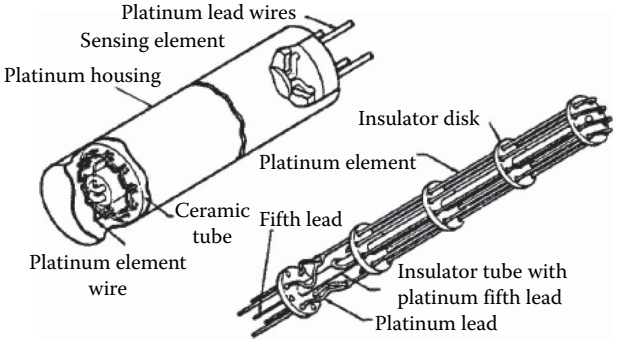

FIGURE 4.25.6 Slack-wire platinum resistance thermometer.

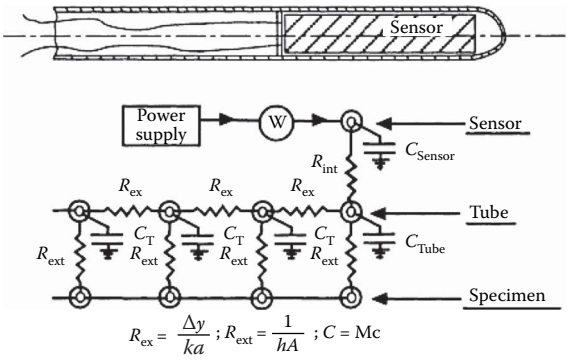

FIGURE 4.25.7 Thermal circuit representation of a typical resistance thermometer.

This is more important in the quartz-jacketed probes than in those with stainless steel protection tubes. Twisted pair lead wires are recommended.

Thermal Characteristics

Figure 4.25.7 shows a simplified cross section of a typical resistance thermometer and a thermal circuit, which can be used to discuss its behavior. In forming such a thermal circuit model, each element of the probe is described by its resistive and capacitive attributes following conventional heat transfer practice. The principal components are

- The external thermal resistance per unit length
- The thermal capacitance of the protective tube per unit length, $\boldsymbol{C_T}$
- The radial internal thermal resistance between the sensor and the protective tube, $\boldsymbol{R_{int}}$
- The capacitance of the sensor element and its support, $\boldsymbol{C_{sensor}}$
- The axial internal thermal resistance of the stem, per unit length, $\boldsymbol{R_T}$

This circuit can be used to predict the temperature distribution within the probe both at steady state and during transients and can be refined, if needed, by subdividing the resistance and capacitance entities.

Steady-State Self-Heating

Interrogating an RTD by passing a current through it dissipates power in the element, shown in Figure 4.25.7 as $\boldsymbol{W}$, which goes off as heat transfer through the internal and external resistances. This self-heating causes the sensing element to stabilize at a temperature higher than its surroundings

and constitutes an "error" if the intent is to measure the surrounding temperature. The amount of the self-heating error depends on three factors:

- The amount of power dissipated in the element
- The internal thermal resistance of the probe, as a consequence of its design
- The external thermal resistance between the surface of the probe and the surrounding material

The self-heating temperature rise is given by Equation 4.25.6:

$$T_{sens} - T_{surr} = W(R_{int} + R_{ext}) \tag{4.25.6}$$

The internal thermal resistance of a probe, $\boldsymbol{R_{int}}$, measured in degree Centigrade per Watt, describes the temperature rise of the sensing element above the surface temperature of the probe, per unit of power dissipated. The internal thermal resistance can be deduced from measurements of the sensor temperature at several different current levels when the probe is maintained in a well-stirred ice bath, where the external thermal resistance is very low. The slope of the apparent temperature vs. power dissipated line, °C/W, is the internal thermal resistance. When an RTD is used in a gas or liquid, the external resistance between the probe and its surroundings must be estimated from standard heat transfer data. The external resistance is $1/(\boldsymbol{hA})$, °C/W.

A typical cylindrical probe exposed to still air will display self-heating errors on the order of 0.1°C–1.0°C per mW (commercial probes of 1.5–5 mm in diameter). At 1 m/s air velocity, the self-heating error is reduced to between 0.03°C and 0.3°C. In water at 1 m/s velocity, the self-heating effect would be reduced by a factor of four or five compared to the values in moving air, depending on the relative importance of the internal and the external thermal resistances.

Calibration and Drift

The relationship between resistance and temperature must be determined for each probe or acquired from the manufacturer. Generally speaking, the reported values will require interpolation.

The resistance–temperature characteristic of a probe may drift (i.e., change with time), while the probe is in service. Manufacturers of laboratory-grade probes will specify the expected drift rate, usually in terms of the expected error in temperature over an interval of time. Two sample specifications are "0.01°C per 100 h" for a low-resistance, high-temperature probe (0.22 Ω at 0°C, 1100°C maximum service temperature) and "0.01°C per year" for a moderate-resistance, moderate-temperature probe (25.5 Ω at 0°C, 250°C maximum service temperature). The drift of the resistance–temperature relationship takes place more rapidly at high temperatures.

Infrared Thermography

Advances in infrared thermal imaging technology, of all the temperature measurement techniques, have been the most significant in recent years. There is now even an add-on device for smart phones to convert the camera to a thermography device. The spatial and temporal resolution of this non-invasive technique has increased to 15 μm and in excess of 500 Hz respectively.

Surface temperatures and gas temperatures can be deduced from radiation measurements. Surface-temperature measurements are based on the emitted infrared energy, while gas-temperature measurements use specific emission lines from the gas itself or from a tracer inserted into the gas. Radiation devices, such as pyrometers for surface-temperature measurement systems (single-point), are commercially available, at low cost, which can measure temperature to ±1.5% of reading or 1.5°C (whichever is greater), above 0°C, if the emissivity of the surface is known. The device referenced requires a spot size of 1.9 cm diameter, viewed from 95 cm. Spectroscopic gas-temperature measurements can be accurate to ±3 or 4% of reading, but require a significant investment in effort as well as equipment (on the order of 1– 2 years and $100,000–$200,000). Several techniques based on Raman scattering have been used in combustion systems. Planar-laser-induced fluorescence has shown considerable promise as one of the newer methods.

Infrared emission from a surface is described by two laws: the Stefan–Boltzmann law describing the total emitted radiation as a function of temperature, and Planck's law describing its distribution as a function of temperature. These laws form the basis for all radiation-based surface-temperature detectors.

Early radiometers focused the total infrared energy on a thermopile bolometer and used the temperature rise across its calibrated heat loss path to measure the incident energy flux. Solid-state photon detectors have replaced thermopile bolometers as the detector of choice. Such a detector will respond to any photon having energy above a certain level (specific to the detector). Since the energy of a photon is inversely proportional to its wavelength, detectors respond to all wavelengths below some value. Modern detectors use band-pass filters to limit the wavelength band of photons admitted to the detector and rely on Planck's law to infer the temperature from the energy flux:

$$E_{b,\lambda} = \frac{C_1 \lambda^{-5}}{e^{C_2/\lambda T} - 1} \tag{4.25.7}$$

where

$E_{b,\lambda}$ = radiated power at the wavelength λ, W/m²
T = temperature, K
$C_1 = 3.743 \times 108$, W μm⁴/m²
$C_2 = 1.4387 \times 104$, μm K

Commercial radiation temperature detectors use different wave bands for different temperature ranges, with different detectors for each band. The emissivity of the surface must be known, as a function of temperature, in the wavelength band used by the detector.

Radiation detectors are vulnerable to interference from four sources: low signal-to-noise ratio at low temperatures (below a few hundred degrees Centigrade); radiation from the surroundings reflecting into the detector (also usually more important at low temperatures); low spatial resolution (also more evident at low temperatures); uncertainty in the emissivity of the surface (at all temperatures); and absorption of radiation into water vapor and CO_2 in the line of sight (at any temperature).

A fiber-optic blackbody temperature detector system is offered by the Luxtron Corporation for standards room and field service above 300°C. The unit consists of a blackbody capsule fiber-optically coupled to a filtered, band-limited photon detector. The accuracy of 0.01°C–0.1°C is claimed, depending on temperature level.

A fluoroptic temperature-measuring system is also offered by the same company, for use only at lower temperatures (–200°C to +450°C). This system uses an ultraviolet-stimulated phosphor on the end of an optical fiber as its sensor. The fluorescent signal from the phosphor decays with time, and its "time constant" is a function of temperature. The accuracy of ±0.5°C is claimed for measurements within ±50°C of a calibration point, or ±1°C within 100°C.

Temperature-Sensitive Paints, Crayons, and Badges

Temperature-sensitive paints, crayons, and badges are available from several suppliers (Omega Engineering, Inc., Stamford, CT, and others in Germany and Japan). Each undergoes an irreversible change (e.g., a change in color or a change from solid to liquid) at one specified temperature. With a range of paints, temperatures from ambient to about 1500°C can be covered. The accuracy generally quoted is about ±1% of level, although melting standards are available to ±0.5°C.

The phase-change materials melt at well-defined temperatures, yielding easily discernible evidence that their event temperature has been exceeded. When more than one phase-change paint is applied to the same specimen, there can be interference if the melt from the low-melting paint touches the high-melting material. Color change materials do not interfere, but are more difficult to interpret. The calibration of high-temperature paints (both phase change and color change) may shift when they are used on heavily oxidized materials, due to alloying of the oxide with the paint. Recommended practice is to calibrate the paints on specimens of the application material. The event

temperature that will cause transformation depends on the time at temperature: short exposure to a high temperature often has the same effect as long exposure to a lower temperature.

The paints and crayons are nonmetallic and, therefore, tend to have higher emissivities for thermal radiation than metals. They should be used only over small areas of metallic surfaces, compared with the metal thickness, or else their different emissivities may lead to a shift in the operating temperature of the parts.

The principal disadvantages of the paints and crayons are that they require visual interpretation, which can be highly subjective, and they are one-shot, irreversible indicators that respond to the highest temperature encountered during the test cycle. They cannot record whether the peak was reached during normal operation or during soak-back.

Liquid crystals can be divided into three groups, depending on their molecular arrangements: (1) smectic, (2) nematic, and (3) cholesteric. Most of the temperature-sensitive liquid crystals now in use are cholesteric: made from esters of cholesterol. Their molecules are arranged in planar layers of molecules with their long axes parallel and in the plane of the layer. The molecules in each layer are rotated with respect to those in its neighboring layers by about 15 min of arc in a continuous, helical pattern along an axis normal to the layers.

The colors reflected from cholesteric liquid crystals are thought to be due to Bragg diffraction from the aligned layers. The "wrap angle" between adjacent layers increases with temperature; hence, the color of the liquid crystal shifts toward short wavelengths (toward blue) as the temperature is raised. The color can also be affected by electric fields, magnetic fields, pressure, shear stress, and some chemical vapors.

Warm cholesterics are colorless liquids and they pass through a series of bright colors as they are heated through their "color-play" temperature band. The first color to appear is a deep red, followed by yellow, green, blue, and violet. Further heating yields a colorless liquid again. This cycle is reversible and repeatable, and the color–temperature relationship can be calibrated.

Liquid crystals selectively reflect only a small fraction of the incident light; hence, to enhance the brightness of the color image, they must be backed up with black paint or a nonreflecting surface.

A typical calibration is shown in Figure 4.25.8 for liquid crystals painted over black paint on an aluminum calibration strip. The upper part of Figure 4.25.8 describes the color variation, while the lower part shows the imposed linear temperature distribution. The hot end is blue, the cold end is red. Color-play intervals range from 0.5°C to 10.0°C. Liquid crystals whose color-play interval is on the order of 0.5°C–2.0°C are often referred to as narrow-band materials, while those whose interval extends to 5.0°C–10°C are called wide band. Narrow-band images are easy to interpret by eye. Wide-band images show only subtle variations of color for small changes in temperature, and accurate work requires digital image handling or multiple images taken with different filters.

Several different narrow-band liquid crystals can be mixed together to make a single, multi-event paint covering a wide range of temperatures, provided their color-play intervals do not overlap. Such a mixture yields a set of color-play bands, one for each component.

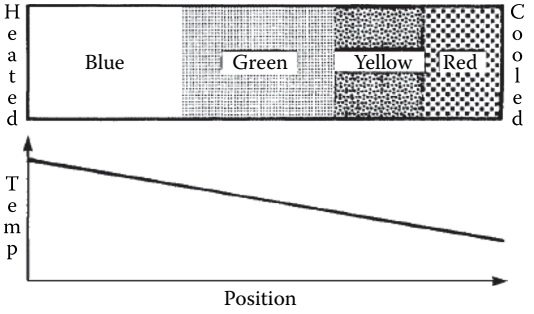

FIGURE 4.25.8 Schematic representation of a calibration strip.

Calibration

Liquid crystals are sold by event temperature and color-play bandwidth, with a nominal accuracy of ±1°C on the event temperature. In many applications, especially if the image is to be visually interpreted, no further calibration is needed.

The accuracy attainable with a liquid crystal is related to the width of the color-play interval. With narrow-band material (a color-play interval of about 1.0°C), visual interpretation can be done with an uncertainty of 0.25°C–0.5°C. With digital image interpretation, spectrally controlled lighting and appropriate corrections for reflected light interference, the uncertainty can be held below 0.25°C.

Early users reported that the perceived color of a liquid crystal depended on both the lighting angle and the viewing angle. This dependence can be eliminated by using a light source along the line of sight (coaxial viewing and illumination).

Multiple-Event Paints

Several narrow-band paints can be mixed together to make a single paint with all the characteristics of each component, if their color-play intervals do not overlap. Each component retains its original calibration and acts independently of the other components.

Figure 4.25.9 shows the image from a five-event paint used to map the adiabatic wall temperature isotherms around a heated block in mixed convection. The outermost isotherm is 30°C, and the events are spaced apart at 5°C intervals. Determination of the temperatures from a multiple-event image requires that the temperature be known at one point in the image.

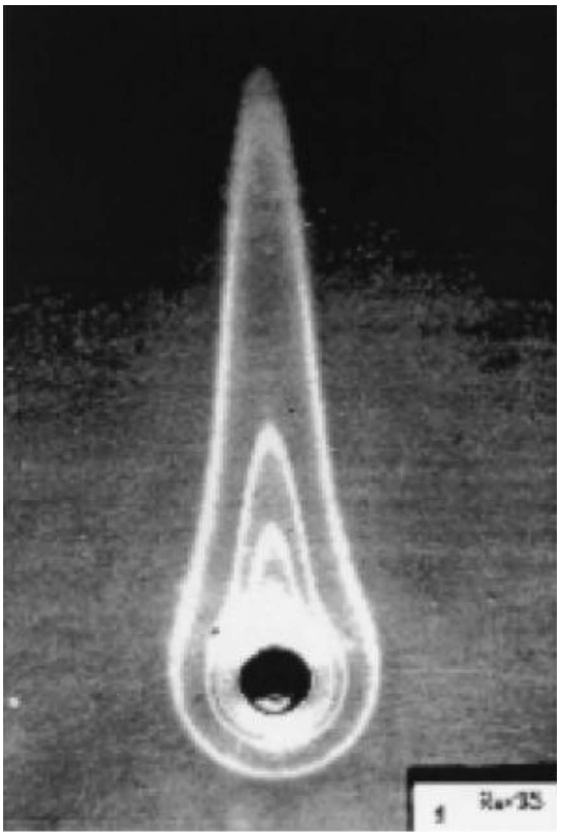

FIGURE 4.25.9 Multi-event liquid crystal used to visualize the isotherm pattern above a heated spot in mixed convection.

Liquid Crystals in Water

Liquid crystals can be used to mark the temperature distribution in water and some other liquids by adding a small quantity of encapsulated liquid crystal material to the liquid and photographing the color distribution using planar lighting. Velocity and temperature distributions can be determined by photographing the liquid crystal particles using a known exposure time. The temperature is deduced from the particle color, and the velocity by the length of the streak its image forms. Figure 4.25.10 shows the velocity and temperature distributions in a shear-driven, water-filled cavity 30 s after the impulsive start of belt motion. In this view, the belt is at the top of the image, and moved from left to right. The water was stably stratified initially, with the top being 4°C hotter than the bottom. This technique was demonstrated by Rhee et al. (1984) and has been used by several workers.

Image Processing

Several schemes have been proposed to remove the subjectivity from the interpretation of liquid crystal images. Akino et al. (1989), and others have processed RGB video images of narrow-band images using multiple filters to extract images of specified isochromes, related to temperatures through a calibration. Hollingsworth et al. (1989) processed RGB images of wide-band images using chromaticity coordinates (hue, saturation, and intensity) and extracted temperature at each pixel, rather than along isochromes.

Heat Flux Measurement

Heat flux to or from a surface can be measured directly, using heat flux meters, or inferred from an overall energy balance, or inferred from temperature–time measurements at the surface or within the body. There are no primary standards for heat flux measurement.

Three general classes of heat flux meters are in common use: slug calorimeters, planar heat flux gauges (sometimes called Schmidt–Boelter gauges), and circular foil gauges (sometimes called Gardon gauges). Sensitivities range from microvolts per kW/m^2 to millivolts per W/m^2. Planar gauges can be used for radiant or convective heat loads. Circular foil gauges should be used only for radiant loads.

Thus far both temperature and surface heat flux measurement techniques described have largely been limited to steady-state or low-speed transient measurements. To advance our understanding

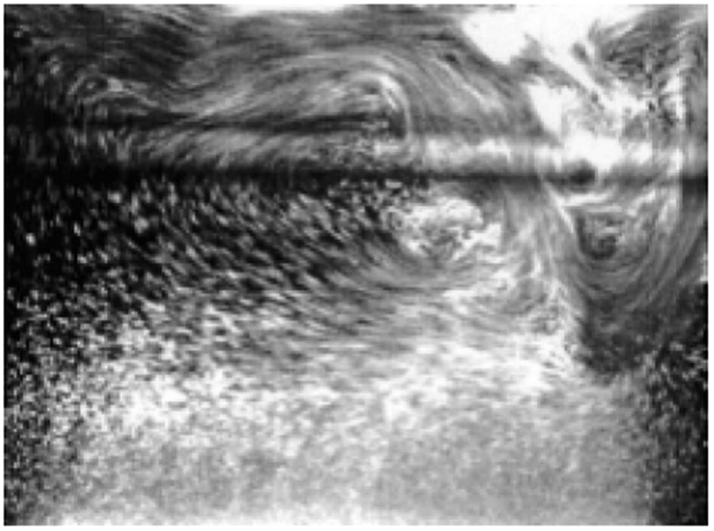

FIGURE 4.25.10 Liquid crystal visualization of the velocity and temperature distribution in a water-filled tank.

of convective heat transfer in many applications, it is important to shed new light on the complex coupling of surface heat flux and local fluid velocity. While several fluid flow measurement techniques, such as laser Doppler velocimetry (LDV), particle image velocimetry (PIV), and hot-wire anemometry (HWA) can resolve velocities at rates of up to 100 kHz, temperature and heat flux measurements are more limited; fine-wire thermocouples have reported maximum frequency response in the region of 330 Hz. This section will also describe the current state-of-the-art and potential of techniques such as infrared thermal imaging and hot-film anemometry to improve the temporal resolution of temperature and surface heat flux measurement techniques.

Slug Calorimeter

The slug calorimeter is an energy balance transducer consisting of a known mass of material instrumented so that its temperature can be measured. A simple version is shown in Figure 4.25.11. If losses are negligibly small and the mass and the specific heat are constant, the instantaneous heat flux is deduced from

$$\dot{q}''_{\text{in}} A = Mc \frac{\partial T}{\partial t} \tag{4.25.8}$$

where

T = average temperature of the slug, °C
M = mass of the slug, kg
c = specific heat, J/kg-°C
A = face area, m^2
τ = time

The variation of slug temperature with time is used to infer net heat transfer rate to the gauge. Slug calorimeters are used mainly when the heat flux, or the heat transfer coefficient, is expected to be relatively constant. They are of less value when the input flux changes arbitrarily because of the inaccuracies inherent in differentiating the signals.

Planar Heat Flux Gauge

Planar heat flux gauges use Fourier's law to deduce the heat flux from a steady-state measurement of the temperature difference across a thin sheet of thermally insulating material. The planar gauge geometry is shown in Figure 4.25.12. The working equation for a planar gauge is

$$\text{EMF} = N\varepsilon\Delta T = \frac{N\varepsilon t}{k}\dot{q}'' \tag{4.25.9}$$

where

N = number of junction pairs
ε = thermoelectric power of the thermoelement, mV/°C
t = thickness of the insulator, m
k = conductivity of the insulator, W/m·°C
$\dot{q}''$ = heat flux through the gauge, W/m^2

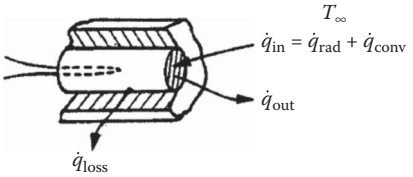

FIGURE 4.25.11 A simple slug calorimeter.

FIGURE 4.25.12 A typical planar heat flux gauge.

The figure shows one thermocouple junction on the top and one on the bottom surface of the insulator. Most gauges use multiple junctions (thermopile). The thermoelements may be wire (down to 0.025 mm diameter) or thin films deposited on the insulator (10–20 Å). The assembly is usually sandwiched between two sheets of protective material to form an integral unit. Up to 150°C application temperature, these units are often made of Kapton, and provided with a contact adhesive. They may be as thin as 0.15 mm overall.

Gauges should not be removed and reinstalled without recalibration, as the act of removing them from the surface may delaminate the gauge, changing its thermal resistance, and therefore its calibration.

Hot-Film Anemometry

While this technique is not currently commercially available, it has been used by researchers since at least the 1980s, by adapting set-ups similar to those employed for hot wire anemometry fluid velocity measurement. A hot-film sensor typically consists of a nickel sensor element on a thin polyimide film and is should be flush-mounted on a heated surface. The sensor element forms one arm of a Wheatstone bridge and as the electrical resistance of the film increases with temperature, a decade resistor is used to set and maintain the film at, or above the temperature of the surrounding heated surface. The power or heat dissipated from the surface can then be measured by monitoring the temperature-dependent resistance of the sensor and the voltage across the sensor:

$$q_{\text{dissipated}} = \frac{R_{\text{film}}}{(R_1 + R_{\text{probe}})^2} \times E^2 \tag{4.25.10}$$

where

R_1 = bridge resistor in line with probe
$R_{\text{probe}} = R_{\text{film}} + R_{\text{sensor\_leads}}$
E = voltage

The setup can respond at frequencies up to 100 kHz but the accuracy of the technique is limited by a number of factors. Firstly, to achieve a measureable signal, it is important for the sensor to operate at a temperature in excess of the surrounding surface. This introduces an error to the technique, which is proportional to the "overheat"; typical "overheat" values range from 1°C to 20°C. There are two proposed correction techniques for this error. The first relies on a calculation of the conduction losses across the substrate and adhesive layer but accuracy is compromised by the ability to measure the temperature locally and to estimate the distance across which the temperature difference occurs. The second considers the sensor signal under adiabatic test conditions, but as these tests are not simultaneous, it is thereafter difficult to ascertain the time-resolved surface heat flux.

A further aspect to be considered is the "effective surface area" of the film element. Lateral conduction from the sensor element heats the substrate locally, increasing the heated area above that of the element. The effective surface area of the sensor therefore is the equivalent area of the sensor at the elevated overheat temperature; this can range up to a factor of 10 times the geometric surface area, depending on the overheat and convective heat flux range. Studies by Scholten and Murrary (1996), and O'Donovan et al. (2011) have shown that these combined effects can lead to a significant uncertainty in the time-average heat flux measurement (up to 25%) but with some optimization of sensor overheat, uncertainties of less than 6% have been reported.

Liu and Sullivan (1996), Scholten and Murray (1998), and O'Donovan and Murray (2007) have successfully demonstrated that the technique can resolve surface heat flux measurements at high

temporal resolution. These studies have reported on the time-varying effects of vortices shedding from cylinders in cross-flow and impinging from air jets on the boundary layer. The correction techniques presented are based on time-averaged and steady-state measurements and the influence on the magnitude of the local heat flux measurements is, as yet, unresolved. Further experimental and numerical modeling strategies are required to perfect this technique and develop it for commercial readiness.

Calibration

Calibration of the hot-film sensor for heat flux applications is done by reference to a known/established point, such a front stagnation of a heated cylinder in crossflow. Calibration requires both a heated and adiabatic test for each overheat considered to ascertain the effective surface area of the sensor.

Circular Foil Gauges

A circular foil gauge consists of a thin circular disk of metal supported by its edge from a structure of constant and uniform temperature. The circular foil gauge is often called a Gardon gauge. A constantan foil is often used, with a copper support structure. Two copper wires complete the circuit: one attached to the center of the foil disk and one to the support structure. The copper–constantan thermocouple thus formed produces an EMF determined by the temperature difference from the center of the foil disk to its rim. That temperature difference is directly proportional to the average heat flux on the disk. A cross-sectional view of a circular foil gauge is shown in Figure 4.25.13.

The working equation for a circular foil gauge is

$$\text{EMF} = \varepsilon \frac{R^2}{4kt} \dot{q}'' \tag{4.25.11}$$

where

ε = thermoelectric power, mV/°C
R = radius of the disk, m
k = thermal conductivity of the disk, W/m·°C
t = thickness of the disk, m
q'' = heat flux absorbed by the disk, W/m^2 (must be uniform)

The output signal is thus directly proportional to the heat flux on the disk. Cooling passages are frequently built into the support structure to maintain the edge of the disk (the heat sink for the foil disk) at a constant temperature.

Calibration

Calibration of the Gardon-type heat flux meters is most easily done by comparison, using a radiation calibrator.

Planar gauges can be calibrated either by conduction or radiation, but the results will depend on the calibration method for some gauges.

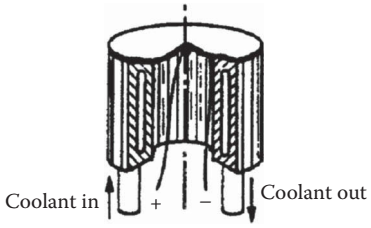

FIGURE 4.25.13 A water-cooled circular foil gauge (Gardon gauge).

Sensor Environmental Errors

Temperature sensors generate signals in response to their own temperatures, but are usually installed to measure the temperature of some fluid or solid. There is heat transfer between the sensor and all of its surroundings, with the result that the sensor usually equilibrates at some temperature different from the fluid or solid it is installed in. This difference is considered an error in the measurement.

Similarly, heat flux gauges are generally installed so one can infer the heat flux, which would have been there had the gauge not altered the system behavior. But heat flux gauges do disturb the system, and the heat flux at the gauge location, when the gauge is there, may be significantly different from that which would have been there without the gauge. This system disturbance effect must also be considered an error.

Steady-State Errors in Gas-Temperature Measurement

All immersion-type temperature sensors (thermocouples, resistance detectors, and thermistors) are subject to the same environmental errors, which are frequently larger than the calibration errors of the sensors. Large probes are usually affected more than small ones; hence, RTDs and thermistors (selected by investigators who wish to claim high accuracy for their data) are more vulnerable to environmental errors (due to their larger size and their self-heating errors). This aspect of accuracy is sometimes overlooked.

Sensor installations for gas-temperature measurements should be checked for all three of the usual steady-state environmental errors: velocity error, radiation error, and conduction error. The same equations apply to all sensors, with appropriate dimensions and constants.

$$\text{Velocity error:} \quad E_v = (1-\alpha)\frac{V^2}{2g_c J c_p} \tag{4.25.12}$$

$$\text{Radiation error:} \quad E_r = \frac{\sigma\varepsilon}{h}(T_{sens}^4 - T_{surr}^4) \tag{4.25.13}$$

$$\text{Conduction error:} \quad E_c = \frac{T_{gas} - T_{mount}}{\cosh\left[L\sqrt{\dfrac{hA_c}{kA_k}}\right]} \tag{4.25.14}$$

where

E_v = velocity error, °
α = recovery factor, —
V = velocity, ft/s
g_c = universal gravitational constant
J = Joules constant, Btu/ft²
c_p = specific heat, Btu/lbm, °F
and E_r = radiation error, °R
σ = Stefan–Boltzmann constant
ε = emissivity
h = heat transfer coefficient, Btu/s ft², °F
T_{sens} = indicated temperature, °R
T_{surr} = surrounding temperature, °R
E_c = conduction error, °R
T_{gas} = gas temperature, °R
T_{mount} = mount temperature, °R
L = length of exposed junction, ft
h = heat transfer coefficient, Btu/s ft², °F
A_c = heat transfer area, ft²

k = thermal conductivity, Btu/s ft
A_k = conduction area, ft^2

Velocity error depends upon the recovery factor, which varies with the Prandtl number of the fluid. The Prandtl numbers of most liquids are greater than 1; hence, the recovery factor α is greater than 1 and probes tend to read higher than the stagnation temperature in high-speed liquid flows. With thermistors and RTDs in liquids, the self-heating effect and the velocity error both tend to cause high readings. In gases, where the Prandtl number is less than 1, the two effects are of opposite sign and may partly cancel each other.

Radiation and conduction errors vary inversely with the heat transfer coefficient. Both tend to be larger for larger-diameter probes since, all other factors remaining the same, the heat transfer coefficient will be lower for a large-diameter probe. This results in larger radiation and conduction errors. In liquids, radiation error is not a problem, but velocity error and conduction error may both be significant. Conduction error becomes a problem in liquid-temperature measurements when thermowells are used. The depth of immersion of the well is frequently too short to eliminate conduction error.

Steady-State Errors in Solid and Surface-Temperature Measurements

When probes are used to measure solid temperature by inserting them into a hole in the specimen, they are subject to conduction errors proportional to their size and conductivity. A general rule of thumb is to keep the insertion depth at least 20 times the diameter (or wall thickness) of the probe. This assumes a close-fitting hole, backfilled with a material with higher thermal conductivity than air. For more-exact advice regarding a specific installation, a careful thermal circuit analysis of the installation should be developed, and its results used to guide the selection of diametrical clearance, backfill materials, and penetration depth.

A thermocouple attached to a hot surface surrounded by cooler fluid will exchange heat with the fluid by convection and with the surrounding solids by radiation. Heat lost from the thermocouple must be made up from the surface by conduction, which will result in a cold spot at the point of attachment.

Figure 4.25.14 shows the system disturbance error caused by a surface-attached thermocouple, as a fraction of the maximum possible error for the installation. If the surface is irradiated (e.g., by heating lamps), the irradiation will raise the surface temperature, but will also affect the system disturbance error. The effect on the system disturbance error caused by turning on the irradiation is similar to that of raising the temperature of the surrounding fluid to a new value, T_∞°,

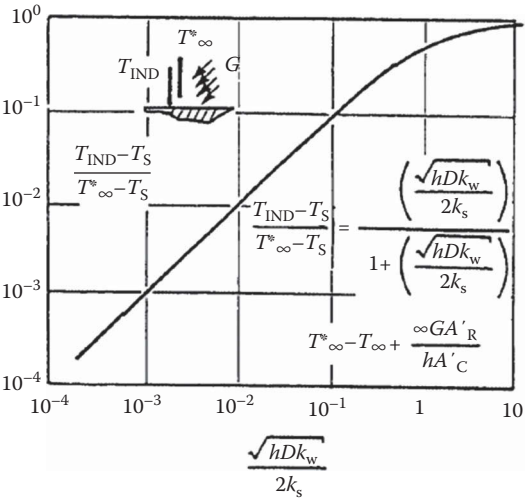

FIGURE 4.25.14 System disturbance errors caused by an attached thermocouple (worst case).

where

T_{ind} = indicated temperature from an otherwise error-free thermocouple, °C
T_s = undisturbed substrate temperature, °C
T_∞° = effective fluid temperature, °C
h = heat transfer coefficient, TC to fluid, W/m, °C
D = outside diameter of TC, m
k_w = effective thermal conductivity of TC, W/m, °C
k_s = thermal conductivity of the substrate, W/m, °C

The effective gas temperature is defined in terms of the incident irradiation and the heat transfer coefficient as

$$T_\infty^\circ = T_\infty + \frac{\alpha G A_R}{h A_C} T_\infty^* \tag{4.25.15}$$

where

T_∞ = actual gas temperature, °C
α = absorptivity of the TC for thermal radiation
G = incident thermal radiation flux, W/m^2
A_R/A_c = ratio of irradiated surface to convective surface
h = heat transfer coefficient between the TC and the gas, W/m °C

Steady-State Errors in Heat Flux Gauges for Convective Heat Transfer

If the gauge is not flush with the surface, it may disturb the flow, and if it is not at the same temperature as the surface, it will disturb the heat transfer. Thus, the gauge may properly report the heat flux, which is present when the gauge is present, but that may be significantly different from the heat flux that would have been there if the gauge had not been there.

For planar gauges, both effects are usually small. The thermal resistance of such a gauge is generally small, and they are thin enough to avoid disturbing most flows. Circular foil gauges pose a more serious problem, since they are often cooled significantly below the temperature of the surrounding surface. Dropping the wall temperature at the gauge location can significantly increase the local heat load in two ways: one due to the fact that, for a given value of h, a cold spot receives a higher heat load from the gas stream. The second effect arises because the value of the heat transfer coefficient itself depends on the local wall temperature distribution: a local cold spot under a hot gas flow will experience a higher heat transfer coefficient than would have existed had the surface been of uniform temperature.

Evaluating the Heat Transfer Coefficient

The heat transfer coefficient is a defined quantity, given by

$$h = \frac{\dot{q}''_{conv}}{(T_o - T_{ref})} \tag{4.25.16}$$

where

h = heat transfer coefficient, W/m^2, °C
$\dot{q}''_{conv}$ = convective heat flux, W/m^2
T_o = temperature of the considered surface, °C
T_{ref} = temperature used as reference for this definition, °C

Different reference temperatures are conventionally used for different situations:

- T_∞: The free-stream temperature. Used for isolated objects of uniform temperature in a uniform free stream, where an average value of h is desired, which describes the overall heat transfer between the object and the flow. Also used in boundary layer heat transfer analyses where local values of h are needed to deal with locally varying conditions.

- T_m: The mixed mean fluid temperature. Used for internal flows where the intent of the calculation is to describe the changes in mixed mean fluid temperature (e.g., heat exchangers).
- $T_{adiabatic}$: The adiabatic surface temperature. Used for isolated objects or small regions of uniform temperature in either internal or external flows, where the overall thermal boundary conditions are neither uniform heat flux nor uniform temperature.

For a given data set, the value of the heat transfer coefficient will depend on the reference temperature chosen, and h should be subscripted to inform later users which reference was used: e.g., h_∞, h_m, or $h_{adiabatic}$.

Direct Methods

The two most commonly used methods for measuring the heat transfer coefficient are both derived from the same energy balance equation:

$$hA(T_o - T_{ref}) = \dot{e}_{in} + \dot{q}_{cond,in} + \dot{q}_{rad,in} - Mc\frac{dT}{d\tau} \tag{4.25.17}$$

where

h = the heat transfer coefficient, W/m, °C
A = the area available for convective transport, m^2
T_{ref} = the reference temperature used in defining h, °C
T_o = the average surface temperature over the area A, °C
$\dot{e}_{in}$ = externally provided input, W
$\dot{q}_{cond,in}$ = net energy conducted in, W
$\dot{q}_{rad,in}$ = net energy radiated in, W
$Mc\ dT/d\tau$ = rate of increase of thermal energy stored within the system, W

Steady State

In the steady-state method, the transient term is zero (or nearly so), and h is determined by measuring the input power and the operating temperature, and correcting for losses. Equation 4.25.17 can be applied to differentially small elements or to whole specimens. The considered region must be reasonably uniform in temperature, so the energy storage term and the convective heat transfer term use the same value.

For tests of isolated objects, or embedded calorimeter sections, steady-state tests usually use high-conductivity specimens (e.g., copper or aluminum) with embedded electric heaters. The resulting value of h is the average over the area of the specimen. The Biot number, hL/k, for the specimen should be low (on the order of 0.01 or less) if only one temperature sensor is used in the specimen, so the surface temperature can be determined from the embedded sensor.

If a single heated element is used within an array of unheated elements, the resulting heat transfer coefficient is implicitly defined as $h_{adiabatic}$ and should be identified as such. Heat transfer coefficients measured with single-active-element tests cannot be used with the mixed mean fluid temperature.

When the variation of h over a surface is required, one common steady-state technique is to stretch a thin foil (stainless steel, or carbon impregnated paper, or gold deposited on polycarbonate) over an insulating substrate, and electrically heat the foil surface. Liquid crystals or infrared techniques can be used to map the surface temperature, from which the heat transfer coefficient distribution can be determined. The "heated foil with liquid crystal" approach was used by Cooper et al. in 1975 to measure heat transfer coefficients, and has since been used by many others. Hippensteele et al. (1985) have made extensive use of the foil technique in studies of gas turbine heat transfer. An example of their work on the end wall of a turbine cascade is shown in Figure 4.25.15. Hollingsworth et al. (1989) used a stainless steel foil heater for a study in air for an electronics cooling application, illustrated in Figure 4.25.16.

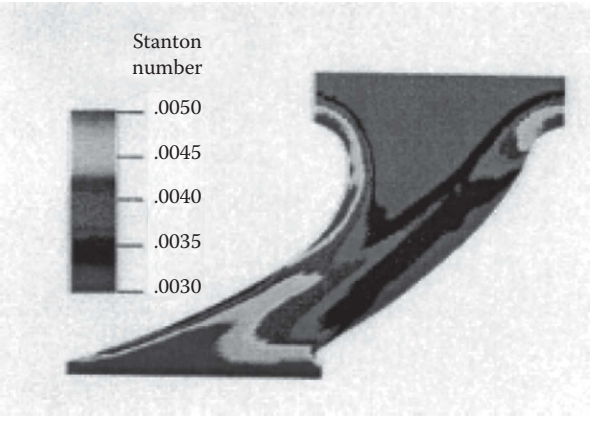

FIGURE 4.25.15 Heat transfer coefficient distribution on the end wall of a turbine cascade. (From Hippensteele, S.A. et al., NASA Technical Memorandum 86900, March, 1985. With permission.)

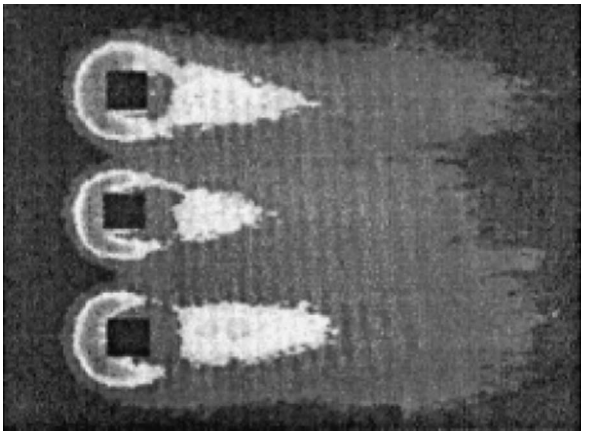

FIGURE 4.25.16 Visualization of the heat transfer coefficient distribution on a heated plate around three unheated cubes.

Advances in imaging and thermal imaging technology now enable measurements in excess of 500 Hz. The limiting factor for the response time of the experimental setup therefore is more likely to be the thickness and material properties (thermal conductivity and capacitance) of the foil. In order to resolve the time-varying heat transfer coefficient, it is explained by Golobic et al. (2009) that the time constant ($\delta^2 \rho c_p / k$) for the foil (including paint/coating) should be much less than the required measurement timescale. A finite difference that considers an energy balance across each pixel (foil volume) can resolve the time-varying heat transfer coefficient at high temporal resolution.

Another steady-state technique that reveals the distribution of h on the surface was introduced by den Ouden and Hoogendoorn (1974). It used a uniform and constant-temperature substrate (a tank of warm water or a copper block) covered with a layer of known thermal resistance (a plate of glass or a thin layer of epoxy). The surface was painted with liquid crystals (or visualized using infrared imaging) and the surface-temperature distribution determined. The inner (uniform) and outer (measured) temperature distributions are then used as boundary conditions to a three-dimensional conduction solver that calculates the total heat flux at each point on the surface. The total heat flux is corrected for radiation to yield the net convective transport at each point, from which h can be determined.

This method appears to have an advantage in accuracy over the heated foil technique because of the more accurate handling of substrate conduction.

Transient Lumped Parameter Systems

In the lumped parameter transient method, the specimen is assumed to be uniform in temperature at every instant through the transient. The power, $\dot{e}_{in}$, in Equation 4.25.17 is usually zero, although that is not necessary (one could simply change the power level at time zero to initiate the transient). At time zero, a transient is initiated, and the response curve recorded.

The data can be interpreted, and the validity of the first-order assumption tested at the same time by plotting $(T-T_{final})/(T_{initial}-T_{final})$ on the log scale of semilog coordinates, with time on the algebraic scale. If the line is straight, then the system is first order and the characteristic time can be determined from any two points on the line by

$$\tau = \frac{(t_2 - t_1)}{\ln\left\{\dfrac{T_{fin} - T_1}{T_{fin} - T_2}\right\}} \tag{4.25.18}$$

where

τ = characteristic time, Mc/hA, s
t_1 = time at the first instant
t_2 = time at the second instant
T_1 = specimen temperature at the first instant, °C
T_2 = specimen temperature at the second instant, °C
T_{fin} = specimen temperature after a long time (fluid temperature), °C

The heat transfer coefficient is extracted from the time-constant definition.

Indirect Methods

An increasingly popular method is the extraction of h from surface-temperature variations after a step in flow temperature using an inverse calculation method. The simplest inverse method assumes one-dimensional conduction into an infinitely thick plate of constant material properties. Even highly irregular geometries can be studied with this technique, if the streamwise extent of the specimen is small and the testing time is short. A short time interval is necessary so the penetration of the thermal wave is limited to a thin layer near the surface. The short streamwise extent is necessary so the temperature response of the surface upstream does not alter the thermal step applied to the downstream surface. This technique has been used to determine the heat transfer coefficient distribution on the inside walls of passages of irregular shape, by making the passage in a transparent material.

Naphthalene Sublimation

The equations for mass diffusion are similar to those for heat transfer, except for replacing the Prandtl number in the heat transfer equation by the Schmidt number in the diffusion equation. Thus, one could expect that the distribution of the mass transfer coefficients on a surface would mimic the distribution of the heat transfer coefficients.

The most commonly used analog technique is naphthalene sublimation. As early as 1940, the mass transfer/heat transfer similarity was used to estimate the heat transfer coefficient distribution. Naphthalene is a solid material that sublimes at a reasonable rate in air at ambient temperature. Specimens can be cast in naphthalene with good precision, and the recession of the surface mapped as a function of position and time using automated or semiautomated measuring equipment. The surface recession over a known interval of time is a measure of the mass transfer rate, from which the mass transfer coefficient can be deduced.

Naphthalene experiments are generally done at a uniform temperature; hence, a uniform vapor pressure exists at the surface. This corresponds to the heat transfer situation of heat transfer from a uniform temperature surface. No counterpart of the uniform heat flux situation has been produced using naphthalene, nor have there been experiments corresponding to variable wall temperature.

Naphthalene sublimation experiments do not suffer from any counterpart of the conduction heat transfer in the substrate. Conduction makes it difficult to work near discontinuities in wall temperature in a heat transfer experiment. Details of the fine structure of mass transfer near obstructions and discontinuities can be resolved in naphthalene experiments, but those details might not exist in a heat transfer process. The Prandtl number of air is much lower than the Schmidt number of naphthalene diffusing in the air; hence, thermal conduction would tend to blur out sharp gradients in the temperature field more than diffusion would blur out gradients in naphthalene concentration.

The Schmidt number of naphthalene in air is about 2.5, far different than the Prandtl number of air (0.71); hence, the mass transfer coefficient deduced from a naphthalene experiment is not numerically equal to the heat transfer coefficient which would have existed at those conditions. The usual recommendation is to adjust for the Prandtl number of Schmidt number using a relation of the form:

$$\mathrm{St}\,\mathrm{Pr}^{2/3} = f\{\mathrm{Re}\} = \mathrm{Sh}_j \mathrm{Sc}_j^{2/3} \tag{4.25.19}$$

based on laminar results. That recommendation has not been seriously tested by experiments in turbulent and separated flows. By using nominal values of the Schmidt number and Prandtl number, the heat transfer Stanton number would be 2.3 times higher than the measured Sherwood number and an uncertainty of 10% in that ratio would alter the inferred heat transfer coefficient by 23%.

System Performance Matching. Sometimes the "effective average heat transfer coefficient" for a system is inferred from the overall behavior of the system, e.g., estimating h from the effectiveness of a heat exchanger. Values deduced by this means cannot be expected to agree well with direct measurements unless a very sophisticated system description model is used.

4.26 FLOW MEASUREMENT

Jungho Kim, S.A. Sherif, and Alan T. McDonald

Introduction

Flow measurements are perhaps the most common type of measurements made. Many types of flow measuring devices are available. The choice of meter type depends on the required accuracy, range, cost, ease of reading or data reduction, and service life. The simplest and cheapest device that gives the required accuracy should be chosen.

Flow measurement can be classified into four broad types: (1) direct methods, (2) flow restriction methods, (3) linear flow meters, and (4) traversing methods. Each of these is discussed in the following subsections.

Direct Methods

Tanks can be used to determine the flow rate for steady liquid flows by measuring the volume or mass of liquid collected during a known time interval. If the time interval is long enough, flow rates may be determined precisely by using tanks. Compressibility must be considered in gas volume measurements. It is not practical to measure the mass of gas, but a volume sample can be collected by placing an inverted "bell" over water and holding the pressure constant by counterweights. No calibration is required when volume measurements are set up carefully; this is a great advantage of direct methods.

Restriction Flow Meters for Flow in Ducts

Most restriction flow meters for internal flow (except the laminar flow element) are based on acceleration of a fluid stream through some form of nozzle, shown schematically in Figure 4.26.1. Flow separating from the sharp edge of the nozzle throat forms a recirculation zone shown by the dashed lines downstream from the nozzle. The main flow stream continues to accelerate from the nozzle throat to form a vena contracta at location 2 in Figure 4.26.1 and then decelerates again to fill the duct. At the vena contracta, the flow area is a minimum, the flow streamlines are essentially straight, and the pressure is uniform across the channel section. The theoretical flow rate is

$$\dot{m}_{\text{theoretical}} = \frac{A_2}{\sqrt{1-\left(A_2/A_2\right)^2}}\sqrt{2\rho\left(p_1 - p_2\right)}. \tag{4.26.1}$$

Equation 4.26.1 shows the general relationship for a restriction flow meter: Mass flow rate is proportional to the square root of the pressure differential across the meter taps. This relationship limits the flow rates that can be measured accurately to approximately a 4:1 range.

Several factors limit the utility of Equation 4.26.1 for calculating the actual mass flow rate through a meter. The actual flow area at Section 2 is unknown when the vena contracta is pronounced (e.g., for orifice plates when D_t is a small fraction of D_1). The velocity profiles approach uniform flow only at large Reynolds numbers. Frictional effects can become important (especially downstream from the meter) when the meter contours are abrupt. Finally, the location of the pressure taps influences the differential pressure reading, $p_1 - p_2$.

The actual mass flow rate is given by

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1-\left(A_2/A_2\right)^2}}\sqrt{2\rho\left(p_1 - p_2\right)}, \tag{4.26.2}$$

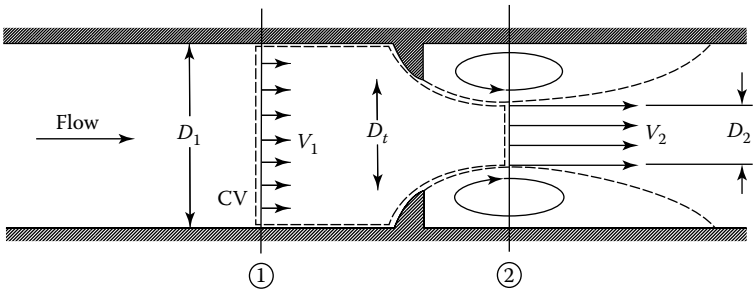

FIGURE 4.26.1 Internal flow through a generalized nozzle, showing control volume used for analysis.

where C is an empirical discharge coefficient.

If $\beta = D_t/D_1$, then $(A_t/A_1)^2 = (D_t/D_1)^4 = \beta^4$, and

$$\dot{m}_{\text{actual}} = \frac{CA_t}{\sqrt{1-\beta^4}}\sqrt{2\rho(p_1 - p_2)}, \tag{4.26.3}$$

where $1/(1-\beta^4)^{1/2}$ is the velocity correction factor. Combining the discharge coefficient and velocity correction factor into a single *flow coefficient*,

$$K \equiv \frac{C}{\sqrt{1-\beta^4}} \tag{4.26.4}$$

yields the mass flow rate in the form:

$$\dot{m}_{\text{actual}} = KA_t\sqrt{2\rho(p_1 - p_2)}. \tag{4.26.5}$$

Test data can be used to develop empirical equations to predict flow coefficients vs. pipe diameter and Reynolds numbers for standard metering systems. The accuracy of the equations (within specified ranges) is often adequate enough to use the meter without calibration. Otherwise, the coefficients must be measured experimentally.

For the turbulent flow regime ($Re_D > 4000$), the flow coefficient may be expressed by an equation of the form:

$$K = K_\infty + \frac{1}{\sqrt{1-\beta^4}}\frac{b}{\text{Re}_{D_1}^n}, \tag{4.26.6}$$

where subscript ∞ denotes the flow coefficient at infinite Reynolds numbers and constants b and n allow for scaling to finite Reynolds numbers. Correlating equations and curves of flow coefficients vs. Reynolds number are given for specific metering elements in the next three subsections following the general comparison of the characteristics of the orifice plate, flow nozzle, and venturi meters in Table 4.26.1 (see Fox and McDonald, 1992).

Flow meter coefficients reported in the literature have been measured with fully developed turbulent velocity distributions at the meter inlet. When a flow meter is installed downstream from a valve, elbow, or other disturbance, a straight section of pipe must be placed in front of the meter. Approximately 10 diameters of straight pipe upstream are required for venturi meters and up to 40 diameters for orifice plate or flow nozzle meters. Some design data for incompressible flow are given in the following subsections. The same basic methods can be extended to compressible flows.

TABLE 4.26.1
Characteristics of Orifice, Flow Nozzle, and Venturi Flow Meters

Flow Meter Type	Diagram	Head Loss	Cost
Orifice		High	Low
Flow nozzle		Intermediate	Intermediate
Venturi		Low	High

FIGURE 4.26.2 Orifice geometry and pressure tap locations. (From Miller, R.W., *Flow Measurement Engineering Handbook*, McGraw-Hill, New York, 1996. With permission.)

Orifice Plates

The orifice plate (Figure 4.26.2) may be clamped between pipe flanges. Since its geometry is simple, it is low in cost and easy to install or replace. The sharp edge of the orifice will not affect the scale or suspended matter. However, suspended matter can build up at the inlet side of a concentric orifice in a horizontal pipe; an eccentric orifice may be placed flush with the bottom of the pipe to avoid this difficulty. The primary disadvantages of the orifice are its limited capacity and the high permanent head loss caused by uncontrolled expansion downstream from the metering element.

Pressure taps for the orifices may be placed in several locations as shown in Figure 4.26.2 (see Miller, 1996 for additional details). Since the location of the pressure taps influences the empirically determined flow coefficient, one must select handbook values of K consistent with the pressure tap locations.

The correlating equation recommended for a concentric orifice with corner taps is

$$C = 0.5959 + 0.0312\beta^{2.1} - 0.184\beta^{8} + \frac{91.71\beta^{2.5}}{\mathrm{Re}_{D_1}^{0.75}}. \tag{4.26.7}$$

Equation 4.26.7 predicts orifice discharge coefficients within ±0.6% for $0.2 < \beta < 0.75$ and for $10^4 < \mathrm{Re}_{D_1} < 10^7$. Some flow coefficients calculated from Equation 4.26.7 are presented in Figure 4.26.3. Flow coefficients are relatively insensitive to Reynolds number for $\mathrm{Re}_{D_1} > 10^5$ when $\beta > 0.5$.

Flow Nozzles

Flow nozzles may be used as metering elements in either plenums or ducts, as shown in Figure 4.26.4; the nozzle section is approximately a quarter ellipse. Design details and recommended locations for pressure taps are given in *ASHRAE Handbook: Fundamentals* (1981).

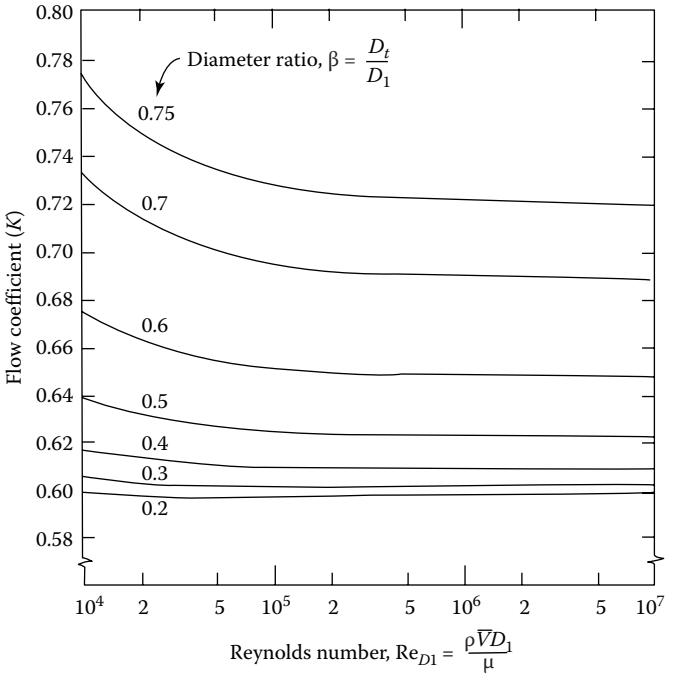

FIGURE 4.26.3 Flow coefficients for concentric orifices with corner taps.

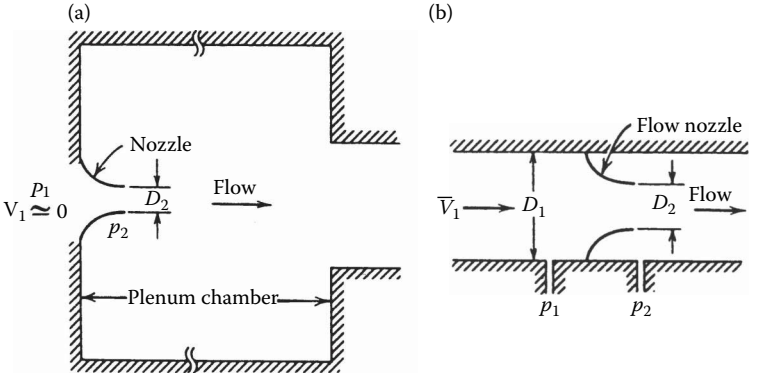

FIGURE 4.26.4 Typical installations of nozzle flow meters: (a) plenum and (b) in duct.

A similar correlating equation is available for orifice plates with D and $D/2$ taps. Flange taps require a different correlation for every line size. Pipe taps, located at $2 - 1/2\ D$ and $8D$, no longer are recommended. The correlating equation recommended for ASME long-radius flow nozzles is

$$C = 0.9975 - \frac{6.53\ \beta^{0.5}}{\mathrm{Re}_{D_1}^{0.5}}. \tag{4.26.8}$$

Equation 4.26.8 predicts discharge coefficients for flow nozzles within ±2.0% for $0.25 < \beta < 0.75$ for $10^4 < \mathrm{Re}_{D_1} < 10^7$. Some flow coefficients calculated from Equation 4.26.8 are presented in Figure 4.26.5. (K can be >1 when the velocity correction factor exceeds 1.) For plenum installation, nozzles may be fabricated from spun aluminum, molded fiber glass, or other inexpensive materials.

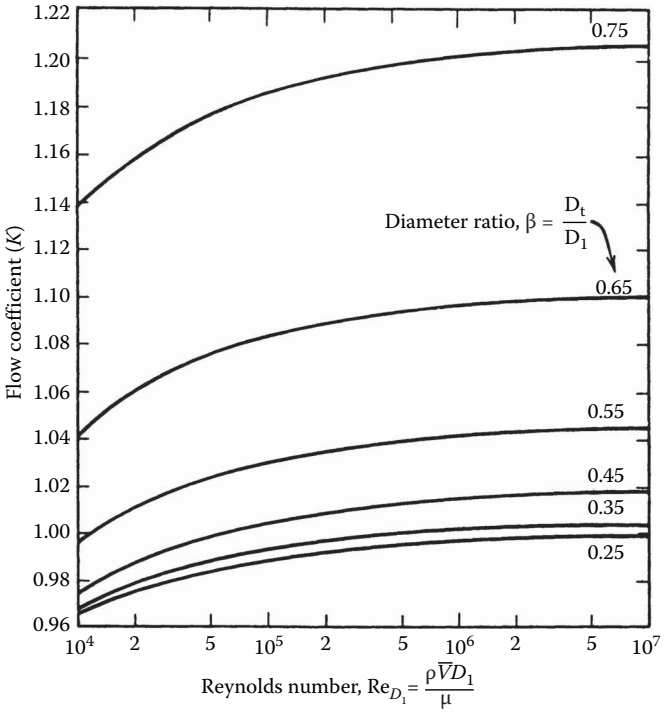

FIGURE 4.26.5 Flow coefficients for ASME long-radius flow nozzles.

Typical flow coefficients are in the range $0.95 < K < 0.99$; the larger values apply at high Reynolds numbers. Thus, the mass flow rate can be computed within approximately ±2% using $K=0.97$.

Venturi Meters

Venturi meters are generally made from castings machined to close tolerances to duplicate the performance of the standard design, so they are heavy, bulky, and expensive. The conical diffuser section downstream from the throat gives excellent pressure recovery; the overall head loss is low. Venturi meters are self-cleaning because of their smooth internal contours.

Experimentally measured discharge coefficients for venturi meters range from 0.980 to 0.995 at high Reynolds numbers ($Re_{D_1} > 2\times10^5$). Thus, $C=0.99$ can be used to calculate mass flow rate within ~±1% at high Reynolds numbers. For specific information at Reynolds numbers below 10^5, consult manufacturers' literature.

Orifice plates, flow nozzles, and venturis all produce pressure drops proportional to the flow rate squared, according to Equation 4.26.4. In practice, a meter must be sized to accommodate the largest flow rate expected. Because the pressure drop vs. flow rate relationship is nonlinear, a limited range of flow rates can be measured accurately. Flow meters with single throats are usually considered for flow rates over a 4:1 range.

Unrecoverable head loss across a metering element may be expressed as a fraction of the differential pressure across the element. These losses are shown in Figure 4.26.6.

Linear Flow Meters

The output of flow meters is typically calibrated to read a volume flow rate of a specified liquid or gas under certain conditions. For example, the volume flow rate of a liquid could be expressed in terms of liters per minute (LPM) of water, while that of a gas could be expressed in terms of standard cubic feet per minute (SCFM) of air. When using flow meters to determine flow rate at

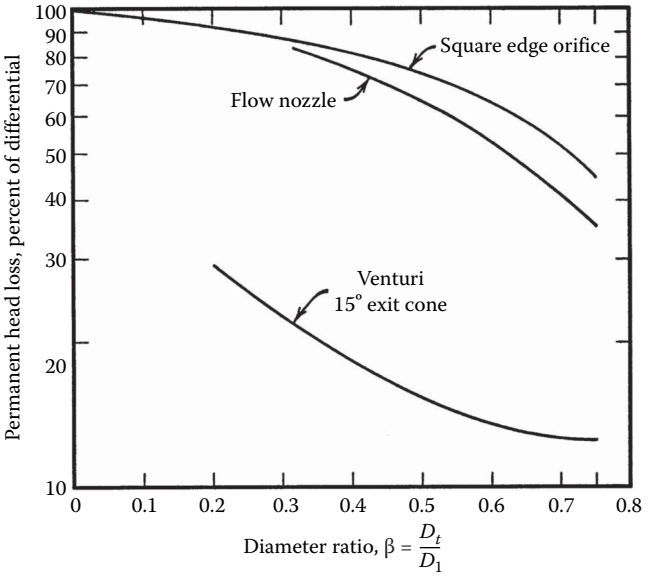

FIGURE 4.26.6 Permanent head loss produced by various flow metering elements. (From Miller, R.W., *Flow Measurement Engineering Handbook*, McGraw-Hill, New York, 1996. With permission.)

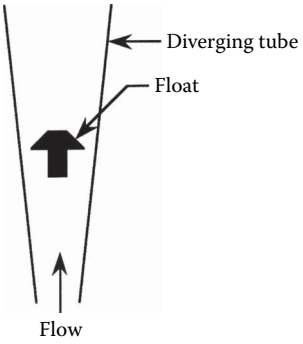

FIGURE 4.26.7 Schematic of rotameter operation.

conditions different from the calibration conditions, corrections to the output must be made to obtain the true flow rate.

Rotameters

A typical rotameter consists of a float contained within a diverging tube (Figure 4.26.7). The float is raised by a combination of drag and buoyancy. The height to which the float rises in the tube can be made to vary by varying the shape of the diverging tube—tubes with linear or logarithmic variations can easily be fabricated.

Glass tube rotameters can be used to temperatures as high as 200°C and pressures up to 20 atm, depending on the diameter of the tube. Plastic tube rotameters are also available for use at lower temperatures and pressures. Flow rates at very high temperatures and pressures can be measured using metal tubes—detectors mounted on the outside of the tube are used to determine the float position.

Rotameters usually come with calibrations based on water or air at STP (standard temperature and pressure). The output is generally in SCFM of air or LPM of water. For measuring flow at other conditions or for other fluids, corrections must be made to determine the flow rate. The response of

a rotameter can be determined by performing a force balance on the float. The height of the float is determined by a balance between the drag force on the float and the effective weight of the float:

$$F_D = \left(\rho_{float} - \rho_{fluid}\right) g V_{float}, \tag{4.26.9}$$

where the drag force is given by

$$F_D = C_D A_{float} \frac{\rho_{fluid} u_{fluid}^2}{2}. \tag{4.26.10}$$

Combining Equations 4.26.9 and 4.26.10 and solving for the fluid velocity u_{fluid} yields

$$u_{fluid} = \sqrt{\frac{2g\left(\rho_{float} - \rho_{fluid}\right)V_{float}}{C_D A_p \rho_{fluid}}}. \tag{4.26.11}$$

The mass flow rate is given by

$$\dot{m} = \rho_{fluid} A_{meter} u_{fluid}, \tag{4.26.12}$$

where A_{meter} is the area between the float and the tube. Combining Equations 4.26.11 and 4.26.12 yields

$$\dot{m} = C\rho_{fluid} A_{meter} \sqrt{\frac{\rho_{float}}{\rho_{fluid}} - 1}, \tag{4.26.13}$$

where it has been assumed that the drag coefficient, C_D, is constant. Many floats are designed for constant C_D over a wide flow range.

Consider now the case where a given flow meter indicates the same flow rate for two different fluid flows, i.e., ammeter is constant for both cases. Then,

$$\frac{\dot{m}_1}{\dot{m}_2} = \frac{\rho_{fluid,1}}{\rho_{fluid,2}} \frac{\sqrt{\rho_{float}/\rho_{fluid,1} - 1}}{\rho_{float}/\rho_{fluid,2} - 1}. \tag{4.26.14}$$

Since $\dot{m} = \rho_{fluid}\dot{V}$,

$$\frac{\dot{V}_1}{\dot{V}_2} = \frac{\sqrt{\rho_{float}/\rho_{fluid,1} - 1}}{\rho_{float}/\rho_{fluid,2} - 1}. \tag{4.26.15}$$

For cases where $\rho_{float} \gg \rho_{fluid}$ (gas flows), Equation 4.26.15 reduces to

$$\frac{\dot{V}_1}{\dot{V}_2} = \frac{\sqrt{\rho_{fluid,2}}}{\rho_{fluid,1}}. \tag{4.26.16}$$

Example: Assume we have an oil with a specific gravity of 0.8 flowing through a rotameter with a float made of steel. The steel has a specific gravity of 8.0. If the meter was calibrated for water, what is the correction that must be made to the indicated flow rate in order to obtain the true flow rate of oil?

Solution: Because the fluid density is not negligible compared to the float density, Equation 4.26.15 must be used:

$$\frac{\dot{V}_{oil}}{\dot{V}_{water}} = \frac{\sqrt{\rho_{float}/\rho_{oil} - 1}}{\rho_{float}/\rho_{water} - 1} = \frac{\sqrt{8.0/0.8 - 1}}{\sqrt{8.0/1.0 - 1}} = 1.13.$$

The true flow rate of oil, therefore, would be 1.13 times that indicated.

Target Flow Meters

These meters measure the drag force on a disk or target placed in the flow. The meter may consist simply of a hinged disk in the flow with a dial indicator showing the amount of deflection. More sophisticated meters use a strain gauge or a bellows to measure the force. Target meters can be used in dirty flows and also to sense the flow direction. They are subject to the same corrections as for rotameters.

Turbine Flow Meters

Turbine flow meters consist of a free-running, vaned impeller mounted in a cylindrical section of a tube. A cutaway of some turbine flow meters is shown in Figure 4.26.8. The rate of angular rotation is determined by counting the number of blade passages per unit time magnetically, mechanically, optically, or by some other method. No penetrations or seals in the duct are usually required, enabling turbine flow meters to measure flow rates in corrosive or toxic liquids. They are generally used for liquid flows, and are characterized by high accuracy and wide dynamic range. Reading accuracies of 0.5% over a 30:1 range are common. If units with ball bearings are used, they should be inspected occasionally to check for bearing wear. The life of the unit can be dramatically increased by operating the unit well below the maximum rated speed, however. The response of turbine flow meters can be affected by viscosity. A field calibration should be performed when the working fluid has a viscosity significantly higher than that for water.

Paddlewheel flow meters are an inexpensive alternative to turbine flow meters when extreme accuracies are not required. The rate of rotation of a paddlewheel partially immersed in the flow is used as a measure of the flow rate. Unlike turbine flow meters, paddlewheels can be used in dirty flows.

Positive Displacement Meters

Positive displacement meters measure flow rate by separating the flow into discrete increments that are moved from one side of the flow meter to the other. An example of a positive displacement meter is shown in Figure 4.26.9. Positive displacement meters can be used to measure the flow rate of high-viscosity fluids.

Vortex Shedding Meters

When a bluff body is placed in a flow, vortices can be shed downstream of the body (Figure 4.26.10). Vortex shedding meters measure the frequency of the asymmetric pressure variations that occur on the body as the vortices are shed and relate this to the flow rate. The vortex shedding frequency is governed by the Strouhal number (St)

$$\mathrm{St} = \frac{f_s d}{V}, \tag{4.26.17}$$

where

f_s = vortex shedding frequency
d = characteristic dimension of the body
V = velocity of the flow

Experiments have shown that St is constant within 1% for Reynolds numbers between 104 and 106. The frequency is directly proportional to the velocity (and thus the flow rate) around the body in this range. These flow meters are insensitive to dirty flows and can be used under a wide variety of conditions because they have no moving parts.

Thermal Mass Flow Meters

These determine flow rate of clean gases by passing the fluid through a precision tube that is heated in one section; then, the temperature of the tube wall upstream and downstream of the heated section is measured (Figure 4.26.11). The difference in temperature between the two sensors is a measure of the mass flow rate. Calibration is usually performed using nitrogen and a correction factor is applied for other gases.

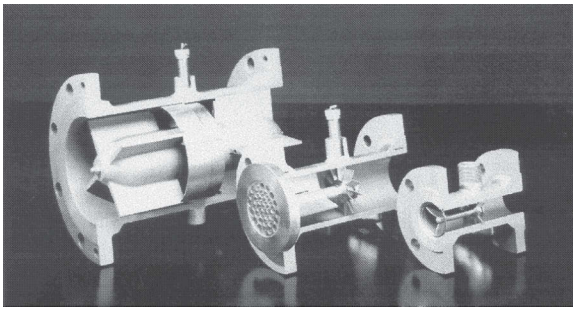

FIGURE 4.26.8 Some turbine flow meters. (Courtesy of Smith Meter, Erie, PA.)

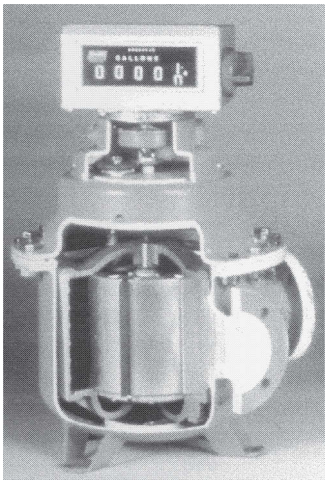

FIGURE 4.26.9 A cutaway of a positive displacement meter. (Courtesy of Smith Meter, Erie, PA.)

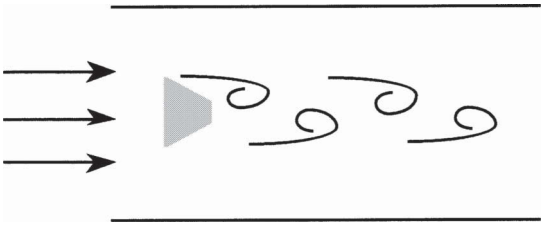

FIGURE 4.26.10 Vortices shedding off a body placed in a moving stream.

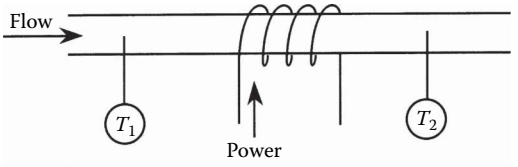

FIGURE 4.26.11 Schematic of thermal mass flow meter operation.

An alternate scheme measures the temperature of the gas; power is supplied to the downstream sensor such that its temperature is kept at a fixed amount above the upstream sensor. The feedback circuit needed to do this is similar to that used in hot-wire anemometry. The amount of power supplied to the downstream sensor is a measure of the gas flow rate. The advantages of these meters are that they give a direct indication of the flow rate without requiring corrections for temperature or pressure variations, they have no moving parts, and are noninvasive.

Ultrasonic Flow Meters

These meters determine flow rate by measuring the Doppler shift of an ultrasonic signal due to the movement of particles in the flow (Figure 4.26.12). Particles or bubbles in the fluid are usually required. Recently, meters have been developed that can measure the flow of clean fluids by measuring the velocity of turbulent swirls in the liquid. The meter is noninvasive, and can measure flow rate of dirty fluids or slurries.

The transit time method relies on measuring the difference in the time it takes for a signal to traverse the flow in one direction compared to a signal traveling in the opposite direction. Because the difference in transit times are so small, the time difference is usually measured as a phase difference between the two sound signals. When the particles move at flow speed, the frequency shift is proportional to flow speed. For a suitably chosen path, output is proportional to volume flow rate. Ultrasonic meters may require calibration in place. One or two transducers may be used.

Laminar Flow Elements

A laminar flow element (LFE) operates by passing a gas through a bundle of tubes or a honeycomb (Figure 4.26.13). The small diameter of these flow passages in the matrix laminarize the flow, and the pressure drop between the inlet and exit of the tubes is measured. If the flow passages were circular, the pressure drop across the element would be

$$\Delta P = \frac{128\mu l \dot{V}}{\pi D^4}, \tag{4.26.18}$$

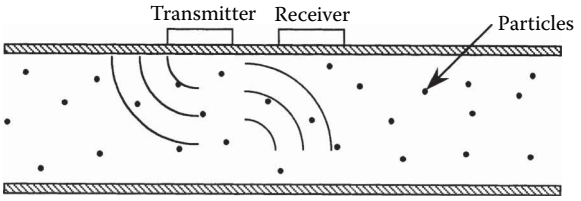

FIGURE 4.26.12 Schematic of an ultrasonic flow meter.

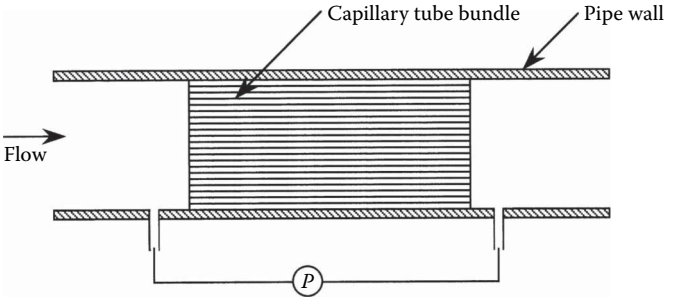

FIGURE 4.26.13 Schematic of a laminar flow element.

which is linear with the volumetric flow rate. Because the flow passages are not necessarily circular, calibration of the flow meter is usually required. Corrections are also needed for changes in fluid viscosity and temperature. The gas must be clean. The LFE may be used with reasonable accuracy over a 10:1 flow rate range. An LFE costs approximately as much as a venturi, but is much lighter and smaller. Thus, the LFE is widely used in applications where compactness and extended range are important.

Coriolis Meters

These meters are true mass flow meters. The concept behind Coriolis meters is shown in Figure 4.26.14. Consider the case where the flow moves through a U-tube that is vibrated at its resonant frequency using an electromagnetic coil. If fluid flows into the tube when the tube is moving upward, the fluid needs to be accelerated and will cause the tube to bend down. The fluid that has traveled around the bend at this time already has an upward momentum and needs to be decelerated, causing this part of the tube to bend upward. The tube, therefore, will twist in the opposite direction during the downward motion. The difference in velocity of the two legs of the vibrating tube is a measure of the mass flow rate. The density of the fluid flowing in the tube can be measured by measuring the change in resonant frequency of the tube. The instrument measures mass flow rate directly and, thus, is ideal for two-phase or liquid–solid flow measurements. Pressure drop across the coriolis meter may be high, but its useful flow rate range is 100:1.

Electromagnetic Flow Meters

Electromagnetic flow meters create a magnetic field across a pipe. When a conductive fluid passes through the field, a voltage is generated at right angles to the field and velocity vectors. Electrodes placed on a pipe detect the resulting signal voltage, which is proportional to the average axial velocity when the profile is axisymmetric. The minimum flow speed should be above ~0.3 m/s, but there are no restrictions on the Reynolds number. The flow rate range normally quoted is 10:1.7

Traversing Methods

In situations such as in air handling or refrigeration equipment, it may be impractical or impossible to install a fixed flow meter; but it may be possible to measure flow rate using a traversing technique.

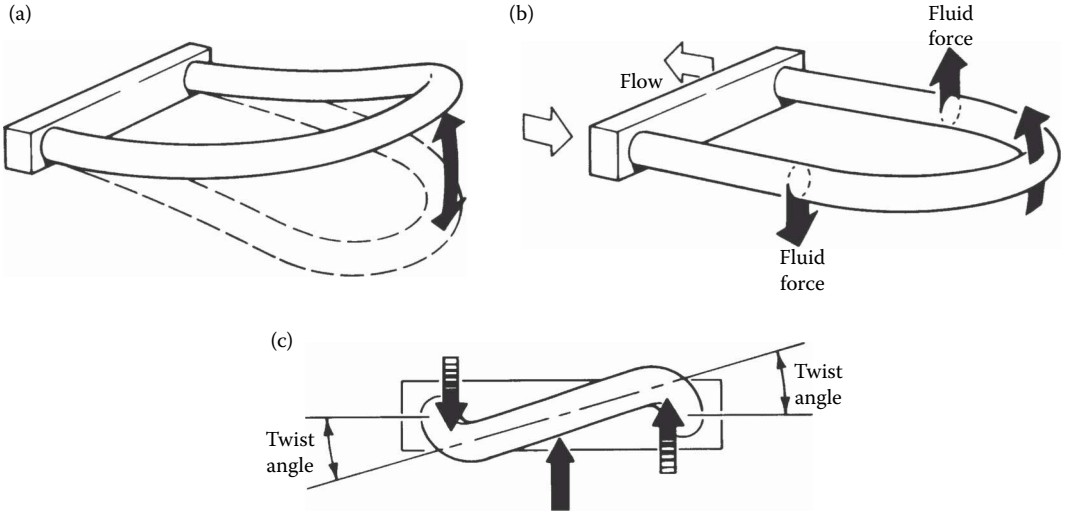

FIGURE 4.26.14 Principle of operation of a Coriolis meter: (a) vibrating flow tube, (b) fluid forces reacting to vibration of flow tube, and (c) end view of flow tube showing twist. (Courtesy of Micro Motion Inc., Boulder, CO.)

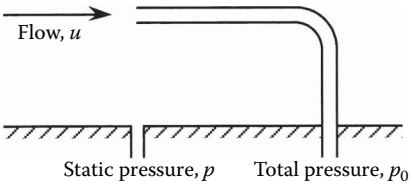

FIGURE 4.26.15 Basic total pressure probe setup.

To measure flow rate by the traversing method, the duct cross section is subdivided into segments of equal area. The fluid velocity is measured at the center of each area segment, and the volume flow rate for each segment is approximated by the product of the measured velocity and segment area. Flow rate through the entire duct is the sum of these segmental flow rates. Methods for measuring the flow velocity are discussed in the following subsections.

Pressure Probes

Perhaps the simplest and least expensive method of measuring velocity is through the use of Pitot probes. Consider the stagnating flow shown in Figure 4.26.15. Applying Bernoulli's equation to the flow between a point far upstream of the probe and the probe tip, assuming an incompressible flow, yields

$$p_0 = p + \frac{1}{2}\rho u^2. \tag{4.26.19}$$

The total pressure sensed by the tube (p_0) is greater than the free stream pressure (p) by the dynamic head $1/2\rho u^2$. The free stream velocity (u), thus, can be determined by measuring the static and total pressures. Equation 4.26.19 can be applied to flows whose Mach number (Ma=u/a) is <0.2 with <0.5% uncertainty. The speed of sound is given by

$$a = \sqrt{\gamma R_g T}\,, \tag{4.26.20}$$

where T is the static absolute temperature of the flow, R_g is the real gas constant, and γ is the ratio of specific heats. When the flow Mach number exceeds 0.2, the density of the fluid along the stagnation streamline changes and compressibility effects must be taken into account. For $0.2 < \mathrm{Ma} < 1.0$, the relation between velocity and pressure difference is given by

$$\mathrm{Ma}^2 = \frac{2}{\gamma - 1}\left[\left(\frac{p_0}{p}\right)^{\frac{\gamma-1}{\gamma}} - 1\right]. \tag{4.26.21}$$

When the flow is supersonic, the flow adjusts to the stagnation condition through a bow shock off the tip of the Pitot probe (Figure 4.26.16). The relationship between the static pressure ahead of the shock (measured by a static pressure tap) and the total pressure behind the shock (indicated by the probe) is given by

$$\frac{p_1}{p_{2,0}} = \frac{\left(\frac{2\gamma}{\gamma+1}\mathrm{Ma}_1^2 - \frac{\gamma-1}{\gamma+1}\right)^{\frac{1}{\gamma-1}}}{\left(\frac{\gamma+1}{2}\mathrm{Ma}_1^2\right)^{\frac{\gamma}{\gamma-1}}}. \tag{4.26.22}$$

Equation (4.26.22) can be solved to determine the Mach number and, hence, the flow velocity ahead of the shock.

Although the measurement of velocity using pressure probes is relatively straightforward, there are many situations where the ideal situation indicated in Figure 4.26.15 does not occur. Some factors that influence the measurement are

- Alignment of the probe with the flow
- Wall effects
- Turbulence effects
- Pitot probe design
- Static pressure tap geometry
- Streamline curvature

Each of these effects is briefly discussed below.

Alignment Effects

The change in stagnation pressure due to flow misalignment for various probes is shown in Figure 4.26.17. It is seen that an open-ended tube can be misaligned by up to ±10° without error in the pressure reading, while a tube with a chamfered opening can tolerate misalignments up to ±30°.

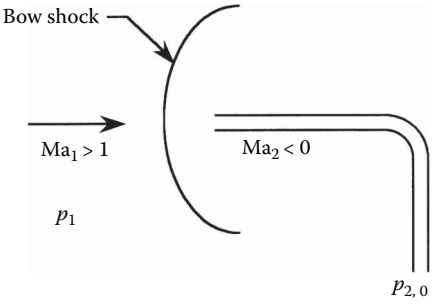

FIGURE 4.26.16 Supersonic flow around a total pressure probe.

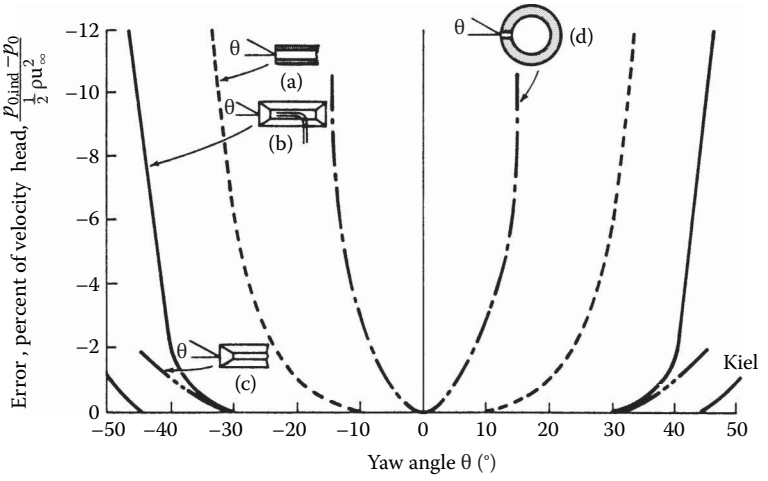

FIGURE 4.26.17 Error in stagnation pressure with changes in yaw angle for (a) open-ended tube, (b) channel tube, (c) chamfered tube, and (d) tube with orifice in the side. p_0 and $p_{0,ind}$ are the true and indicated pressures, respectively. (From Krause, L.N. and Gettleman, C.C., *ISA Proc.*, 7, 134, 1952. With permission.)

Wall Effects

The presence of a wall changes the flow around the probe, and this can result in pressure readings that are lower than when a wall is not present. For a round probe touching the wall, the velocity indicated can be up to 1.5% lower than the actual value.

Turbulence Effects

The effects of turbulence on velocity measurements are dependent on many factors such as turbulence scale and structure, fluctuation frequency, and internal geometry of the probe. The few studies that have been performed were inconclusive, with some studies indicating a decrease in the measured velocity with increasing turbulence and others indicating the opposite trend. A first-order analysis indicates that 20% turbulence intensities can result in a 2% increase in the measured velocity.

Static Pressure Taps

Static pressure taps should be drilled perpendicular to the wall; no burrs or chamfers should be present. The holes should be made as small as possible without causing excessively slow response times at the transducer.

Streamline Curvature

If the streamlines in a flow are curved (perhaps due to obstacles in the flow), then velocity and pressure gradients can occur across the channel and the static pressure obtained from a wall pressure tap may not be representative of the total pressure being measured. The local static pressure at the measuring location must either be measured or computed.

Design of Pitot-Static Probes

Pitot-static probes combine the measurement of total and static pressure in one unit. A commercially available Pitot-static probe is shown in Figure 4.26.18. The location of the static pressure

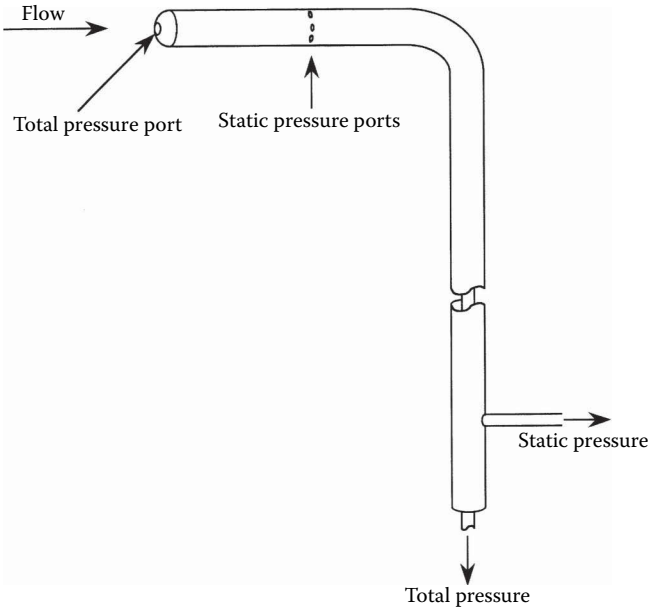

FIGURE 4.26.18 A pitot–static probe.

taps is important. The static pressure taps should be located sufficiently far downstream of the tip so that flow acceleration effects can be ignored, and sufficiently far upstream of the support so that blockage effects are small. If the static pressure taps are located eight tube diameters downstream of the tip and eight tube diameters upstream of the support, then the effects of both acceleration and blockage will be below 1%. Flow direction can be obtained using pitot probes containing multiple sensing holes. Prism probes can also be used.

Hot-Wire Anemometry

Hot-wire anemometry is used when one wishes to measure rapidly varying velocities with good spatial resolution. Velocity fluctuations up to 50 kHz can easily be obtained. Typically, a heated, thin wire is held in the flow, and the cooling effect on the wire due to the velocity of the flow is measured. The disadvantages compared to pressure probes are that they are relatively expensive, they use frail wires, and they need to be calibrated in a known flow environment. Corrections also need to be made to account for free stream temperature variations and for flow along the wire for slanted wires. There are two types of hot-wire anemometry—constant temperature and constant current.

Constant Current Anemometry

This method consists of sending a constant current through a thin wire and measuring the change in resistance of the wire with velocity. Although much simpler than the constant temperature anemometry, constant current anemometry has several disadvantages that has resulted in almost exclusive use of constant temperature anemometry today. These disadvantages include relatively low frequency response and the possibility of wire burnout at large currents and low velocities. However, they can be used when many channels of data need to be acquired, when turbulence information is not needed, or when the flow temperature needs to be measured. Numerous schemes for treating the resulting data have been published. Digital processing techniques, including fast Fourier transforms, can be used to obtain mean values and moments, and to analyze signal frequency content and correlations.

Constant Temperature Anemometry Fundamentals

The basic circuit is shown on Figure 4.26.19. The wire is represented by resistance R_w in a Wheatstone bridge. Resistors R_1, R_2, and R_c are very stable with temperature. The imbalance in

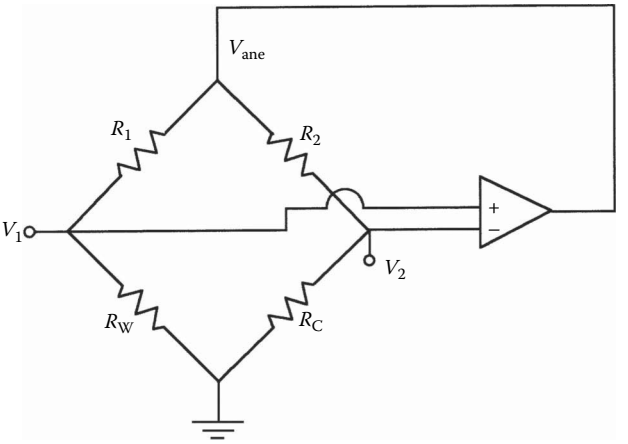

FIGURE 4.26.19 Schematic of a hot-wire circuit.

the bridge is measured using an op-amp (operational amplifier), and the op-amp outputs whatever voltage is necessary to bring the bridge back into balance. For example, consider the case where the bridge is balanced at a given flow velocity, i.e., $R_w/R_1 = R_c/R_2$ and $V_1 = V_2$. If the velocity over the wire increases, the wire temperature (and therefore its resistance) will decrease, causing the bridge to become unbalanced ($R_w/R_1 < R_c/R_2$ and $V_1 < V_2$). The op-amp senses this imbalance in the bridge and increases its output voltage causing more current to flow through the wire, bringing the bridge back into balance. The operating temperature of the wire is controlled by changing the value of R_c. The output voltage of the op-amp is a measure of the amount of cooling the wire experiences. Because the temperature of the wire does not change, the frequency response is not limited by the thermal mass of the wires and high frequency responses are possible.

Equations Governing Hot-Wire Anemometry

The cooling law is assumed to be of the form

$$\mathrm{Nu} = A_0 + B_0 \mathrm{Re}^{05}. \tag{4.26.23}$$

Multicomponent Probes

More than one component of velocity can be measured if multiple wires are present. Consider the case where a wire is inclined relative to the axis of the flow, as shown in Figure 4.26.20. The single wire probe shown in Figure 4.26.21a is often used to measure the axial component of velocity. Cross wires (Figure 4.26.21b) inclined at θ_1 and θ_2 from the normal can be used to obtain the instantaneous U and V components of velocity. The cross-correlation between u' and v' ($u'V'$), also known as the turbulent shear stress, can be obtained if the instantaneous velocities U and V are known. The wires will be sensitive to the velocities according to

$$U_{\mathrm{eff},1} = U\cos(\theta_1) + V\sin(\theta_1), \tag{4.26.24}$$

$$U_{\mathrm{eff},2} = U\cos(\theta_2) - V\sin(\theta_2). \tag{4.26.25}$$

If the effective velocities over the two wires are known along with the probe geometry, then the velocities U and V can be determined. The instantaneous velocity can be broken down into the mean and fluctuating components:

$$U = \overline{U} + u', \tag{4.26.26}$$

$$V = \overline{V} + v'. \tag{4.26.27}$$

Since

$$\overline{uv} = \overline{\left(\overline{U} + u'\right)\left(\overline{V} + v'\right)} = \overline{UV} + \overline{u'v'}, \tag{4.26.28}$$

the turbulent shear stress can be written as

$$\overline{u'v'} = \overline{uv} - \overline{UV}. \tag{4.26.29}$$

These results must be corrected to take into account the directional response of the wire, as discussed in the next subsection. Three-wire probes to measure three components of velocity are also available (Figure 4.26.21c).

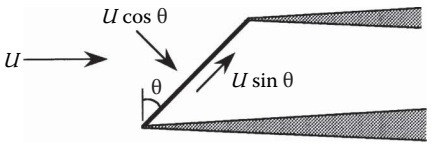

FIGURE 4.26.20 Normal and tangential components of velocity for a wire inclined to the flow.

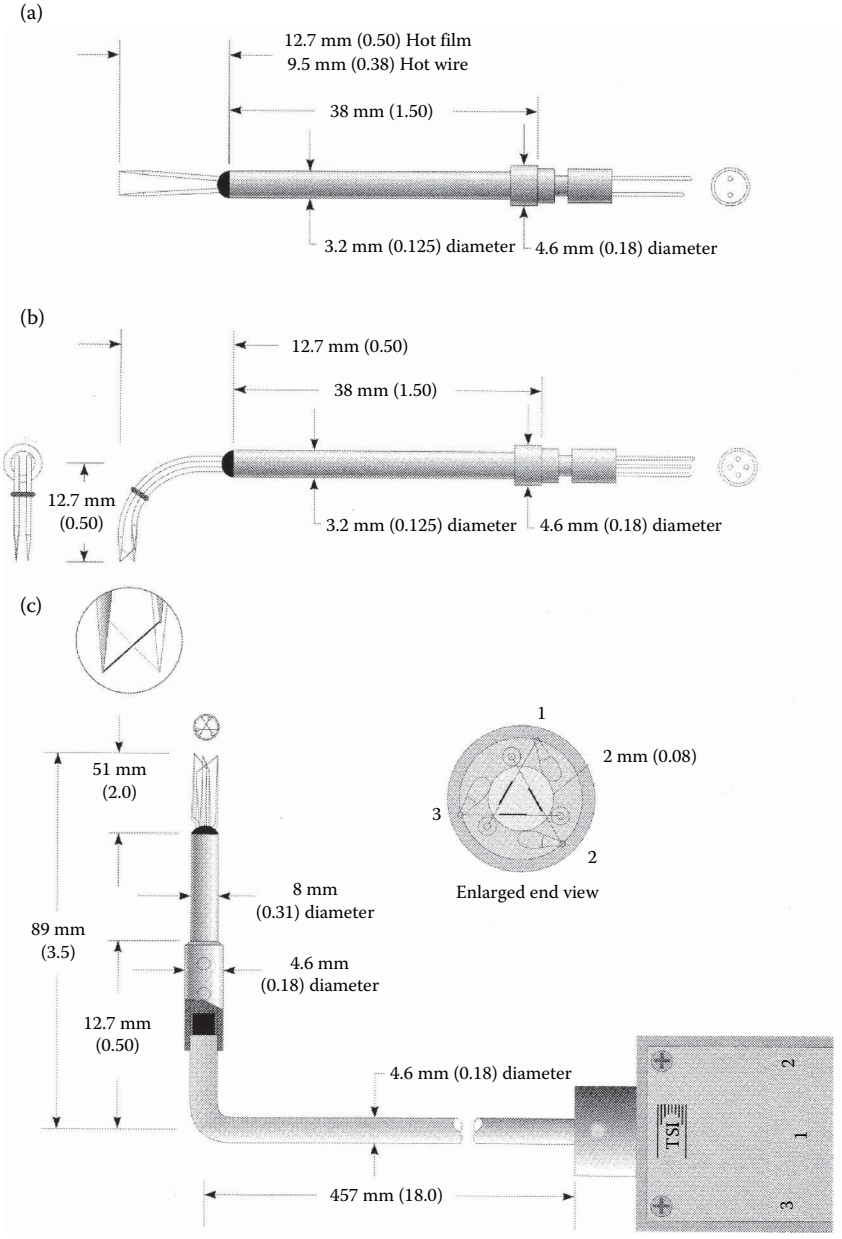

FIGURE 4.26.21 Some hot-wire probe configurations: (a) single-wire probe, (b) boundary layer cross-wire probe, and (c) triple sensor cross-flow probe. (Courtesy of TSI Inc., St. Paul, MN.)

Directional Response

For small inclinations θ to the flow, the hot wire will only respond to the velocity component normal to the wire or $U\cos\theta$. For large inclinations, a significant axial flow develops along the wire resulting in additional cooling as a result of the finite length of the wire. The equation usually used to describe this effect is based on the work by Champagne et al. (1967) and is given by

$$U_{\text{eff}}^2 = U^2\left(\cos^2\theta + k^2\sin^2\theta\right), \tag{4.26.30}$$

where k is a constant that varies linearly from 0.2 for a wire with $l/d=200$ to zero for $l/d=600$. Champagne et al. (1967) applied these results to estimate the overall error for a 45° cross wire operated at constant temperature. They found that

$$\left(\frac{\overline{u'^2}}{U^2}\right)_{\text{m}} = \left(\frac{\overline{u'^2}}{U^2}\right)_{\text{i}}, \tag{4.26.31}$$

$$\left(\frac{u'v'}{U^2}\right)_{\text{m}} = \frac{1+k^2}{1-k^2}\left(\frac{\overline{u'v'}}{U^2}\right)_{\text{i}}, \tag{4.26.32}$$

$$\left(\frac{\overline{v'^2}}{U^2}\right)_{\text{m}} = \frac{1+k^2}{1-3k^2+4k^4}\left(\frac{\overline{v'^2}}{U^2}\right)_{\text{i}}, \tag{4.26.33}$$

where the subscript m is the measured value and the subscript i is the ideal value for a wire of infinite length.

Corrections due to Temperature

Probably the most significant error when using a properly calibrated hot wire occurs as a result of drifts in the flow temperature from the calibration temperature. If the flow temperature is higher than the calibration temperature, less energy is required to keep the wire at a constant temperature for a given velocity, and the indicated flow velocity will be lower than the true flow velocity. However, a first-order correction can be made to account for the drift in flow temperature is described below. The energy dissipated by the wire is proportional to the wire-to-flow temperature difference and is also proportional to the voltage across the wire:

$$q_{\text{w}} \sim \Delta T \sim V^2. \tag{4.26.34}$$

The following equation can be used to correct for small changes in temperature:

$$V_{\text{corr}} = V_{\text{m}}\sqrt{\frac{T_{\text{w}} - T_{\text{ref}}}{T_{\text{w}} - T_{\infty}}}, \tag{4.26.35}$$

where

V_{corr} = corrected voltage
V_{m} = measured voltage
T_{w} = wire temperature
T_{ref} = temperature of the calibration flow
T_{∞} = temperature of the flow

It should be noted that the sensitivity to ambient temperature changes decreases with higher wire temperatures—the wire should be operated at the highest possible temperature.

Laser Doppler Anemometry

Laser Doppler velocimetry (LDV) uses light to measure the velocity of particles in a flow through a small volume. If the particles faithfully follow the flow, then the velocity of the particle can be assumed to be the velocity of the flow itself. LDV has numerous advantages over other methods of measuring velocity. First, it is nonintrusive so it can be used in environments that are hostile to probes or where probes excessively disturb the flow. Second, it does not depend on temperature or pressure changes in the flow. Third, it can detect flow reversals. Fourth, it can measure very high velocities if sufficiently fast electronics are available. Fifth, velocity is measured directly and is unaffected by changes in temperature, density, or composition in the flow field. LDV has been used in flows ranging from natural convection to flows in internal combustion engines and gas turbines. The disadvantages include the need for particles (seeded or naturally occurring) that follow the fluid motion, high cost, the need for optical access to the test section, and the need for careful alignment.

Principle of Operation

The basic setup for a popular type of LDV system is shown in Figure 4.26.22. A single, polarized, continuous wave laser is split into two parallel beams using a beam splitter. The beams pass through

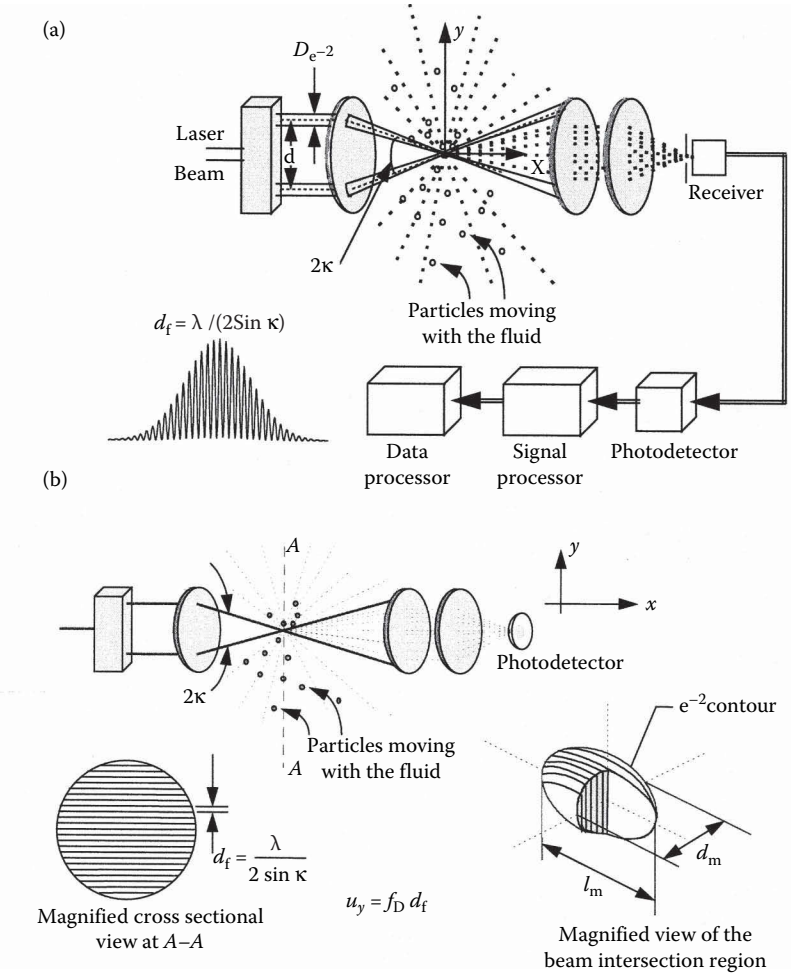

FIGURE 4.26.22 Basic setup for a two-component LDV: (a) schematic of a dual beam system and (b) details of the beam crossing. (Courtesy of TSI Inc., St. Paul, MN.)

a focusing lens that causes the beams to intersect in the focal plane of the lens, simultaneously reducing the beam diameter. The light beams approximate cylinders in the intersection region. The two beams constructively and destructively interfere with each other in the intersection regions, setting up alternating bright and dark fringes that are parallel to the axis of the laser beams. A particle moving through the measuring volume will scatter light with the intensity of the scattered light depending on whether or not the particle is in a bright or dark fringe. Only the component of velocity perpendicular to the fringes and to the axis of the laser beams will be measured. The collecting lens collects some of the scattered light and focuses it onto a photodetector that outputs a signal dependent on the light intensity. Since the spacing between the fringes can be calculated or measured, the velocity of the particle traversing the measuring volume can be determined by measuring the frequency of the signal from the photomultiplier.

Measuring Volume Dimensions

The dimensions of the measuring volume can be computed from the following relations:

$$d_{\mathrm{m}} = \frac{4 f \lambda}{\pi D_{\mathrm{e}}^{-2}}, \tag{4.26.36}$$

$$l_{\mathrm{m}} = \frac{d_{\mathrm{m}}}{\tan \kappa}, \tag{4.26.37}$$

$$d_{\mathrm{f}} = \frac{\lambda}{2 \sin \kappa}, \tag{4.26.38}$$

where

d_{m} = measuring volume diameter
l_{m} = measuring volume length
d_{f} = fringe spacing
f = focal length of the transmitting lens
D_{e}^{-2} = diameter of the laser beam at the e^{-2} intensity point entering the transmitting lens
λ = wavelength of the laser light
κ = half angle between the beams

He–Ne or argon-ion lasers are typically used. Note that in order to get a small measuring volume diameter, the focal length needs to be short, or the beam diameter needs to be large. Similar effects are seen for the measurement volume length. Ideally, one would like to have a measuring volume that is small compared to the scales of interest, with at least 10 fringes in the measuring volume.

Backscatter Mode

A configuration that is often used is shown in Figure 4.26.23. The backscatter configuration has the advantage that the optics can be made very compact, and because all the optics can be put in a single

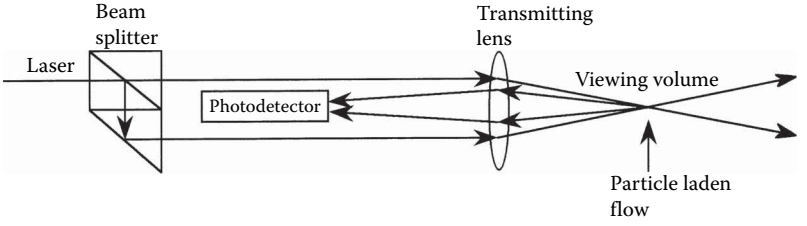

FIGURE 4.26.23 LDV configuration for backscatter.

housing, the optics need to be aligned only once. Much less light is scattered in the backward direction than in the forward direction; however, so much more sensitive photodetectors are required to detect the weaker signal.

Photodetectors

Two types of photodetectors are generally used to convert the scattered light collected by the collecting lens to an electronic signal. In the photomultiplier, photons strike a coating of photoemissive material, causing electrons to be emitted. These electrons are accelerated by a high-voltage field and impact onto a dynode that emits even more electrons. This amplification process is repeated, resulting in final gains of 10^3–10^7. Frequency responses up to 200 MHz can be obtained using photomultipliers.

Photodiodes are light-sensitive semiconductor junctions. An amplification process similar to that in photomultiplier tubes occurs in photodiodes, but gains are limited to ~10^3. The frequency response tends to be lower as well. However, photodiodes are much less expensive than photomultipliers.

Signal Processing

A typical output signal from a photodetector is shown in Figure 4.26.24. It is seen to consist of a pedestal along with the Doppler signal. Most commercial LDV systems currently on the market use fast Fourier transform or correlation methods to determine the frequency.

Particle Tracking

It is important that the particles used in the LDV system be able to follow the flow. Consider a spherical particle placed in a uniform flow. The drag force on the particle is due to the difference in speed between the particle and the carrier fluid, i.e.,

$$\text{Force} = ma = m\frac{\mathrm{d}U_\infty}{\mathrm{d}t} = \rho_\mathrm{P}\frac{\pi D_\mathrm{P}^3}{6}\frac{\mathrm{d}U_\infty}{\mathrm{d}t} = \text{Drag}. \tag{4.26.39}$$

The drag on a spherical particle is given by

$$\text{Drag} = C_\mathrm{d}\frac{1}{2}\rho_\infty\frac{\pi D_\mathrm{P}^2}{4}\left(U_\infty - U_\mathrm{P}\right)^2, \tag{4.26.40}$$

where

$$C_\mathrm{d} = \frac{24}{\mathrm{Re}_\mathrm{P}} = \frac{24\nu}{D_\mathrm{P}\left(U_\infty - U_\mathrm{P}\right)} \tag{4.26.41}$$

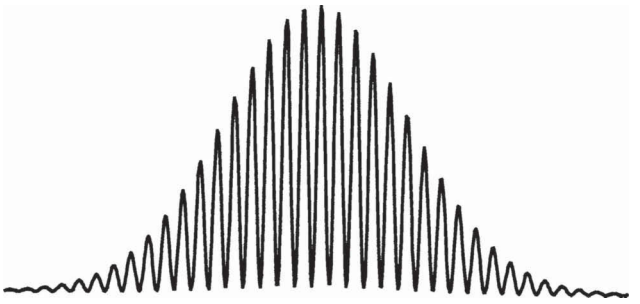

FIGURE 4.26.24 Typical photodetector signal due to scattering from a single particle. (Courtesy of TSI Inc., St. Paul. MN.)

for $0 < \mathrm{Re}_p < 100$. Combining Equations 4.26.39 through 4.26.41 and integrating yields

$$\frac{(U_\infty - U_P)}{U_\infty} = \exp(-t/K), \tag{4.26.42}$$

where

$$K = \frac{D_P^2 \rho_P}{18 \nu \rho_\infty}. \tag{4.26.43}$$

Here, K is the time constant, and represents the time it takes for the initial velocity difference between the particle and the fluid to decay by $1/e$. Particles with K small compared to the time scales of interest will faithfully follow the flow.

Flow Reversal Measurements

If the fringes are stationary, as was assumed until now, one cannot tell the direction from which the particle passes the fringes, i.e., a particle moving with a velocity U will produce the same signal as a particle moving with velocity $-U$. While the direction of the flow is unambiguous in many cases, there are other flows (recirculating flows, flows with high turbulence intensity, impinging jets, shear flows) where the flow direction is not known. This problem can be easily rectified by shifting the frequency of one of the laser beams. If one of the beams is shifted in frequency, this will cause the fringes to move as well. If the fringes move at a speed faster than the maximum absolute flow velocity, then the indicated velocity will be the flow velocity plus the fringe velocity. Zero flow velocity would correspond to the fringe velocity; negative flow velocities would correspond to the indicated velocities lower than the fringe velocity; and positive flow velocities would correspond to the indicated velocities higher than the fringe velocity.

Frequency shifting is usually accomplished by inserting an acoustic–optic Bragg cell in one of the split beams. Typical shifts are 40 MHz, i.e., a 40 MHz signal would be seen at the output of the photodetector at zero flow velocity.

Multicomponent Systems

Measurement of more than one component of velocity is more difficult than simply having two one-component systems because the signals from the two beams interfere with each other. It is necessary to be able to distinguish which pair of beams the signal came from. One can either use two pairs of beams of different color or different polarities. In the two-color method, four beams consisting of two different colors are usually used. An argon-ion laser produces both blue and green lines. This light is split and converged to form two mutually orthogonal dual-beam systems. The scattered light is collected by a pair of receiving optics/photodetector systems, one of which accepts only blue light and one of which only accepts green light. The scattered light is separated using a dichroic mirror that transmits the blue light and reflects the green light.

Particle Image Velocimetry

A relatively new method of measuring velocity at many points in the flow is by particle image velocimetry (PIV). This method enables simultaneous measurement of velocity at many points in the flow by measuring the distance that particles carried by the flow travel over a known time interval. Accuracy and spatial resolution are comparable to LDV.

Typical applications of PIV are to obtain the turbulent flow structure of complex steady flow fields where mapping is too difficult and time-consuming, and periodic flow fields where the velocity field can be obtained at different phases. An example of flow field velocity vectors obtained using PIV is shown in Figure 4.26.25.

The fundamental principle of PIV by optical imaging is the measurement of displacements δx, δy of image markers, which travel with the fluid. In PIV, the time between the marks is fixed, while

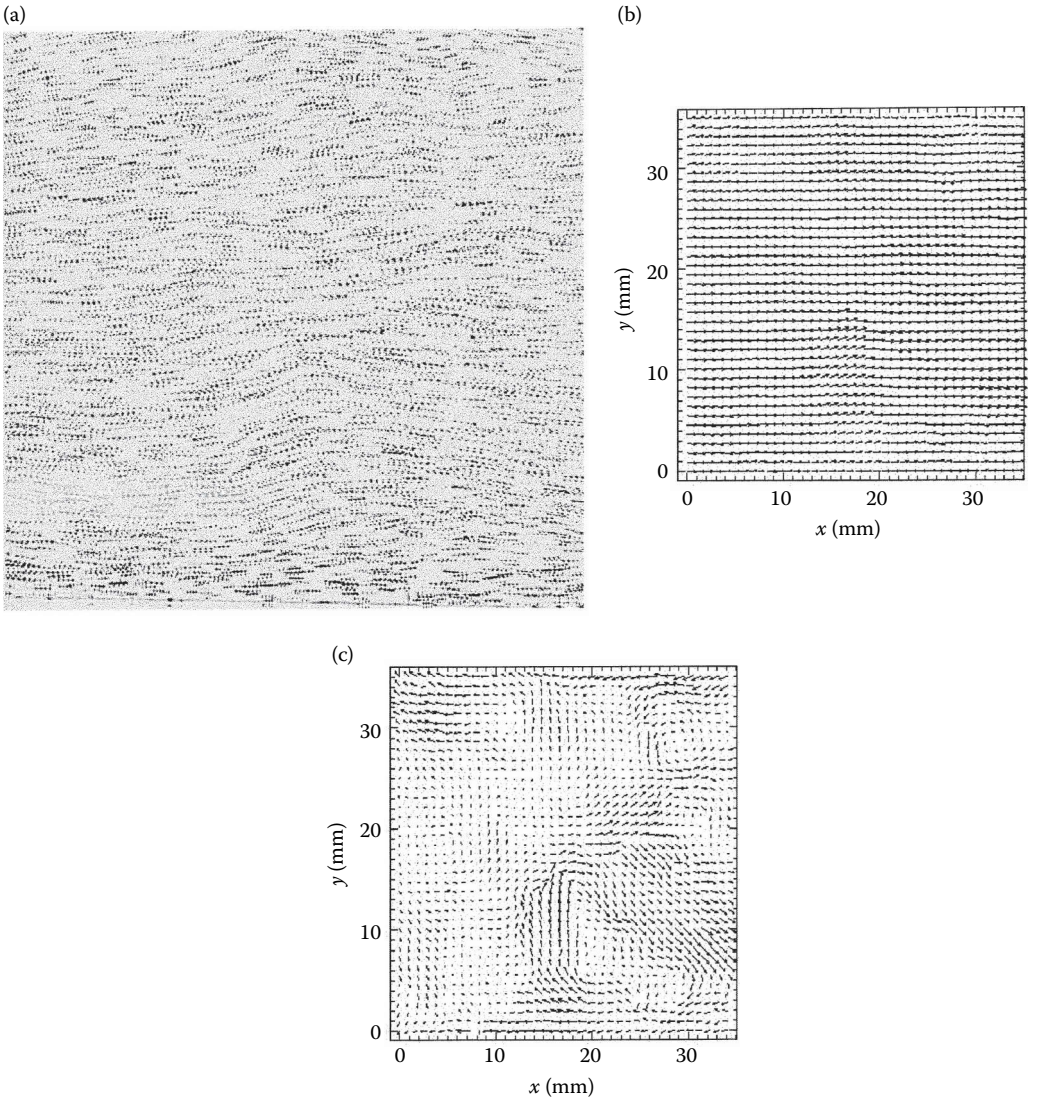

FIGURE 4.26.25 Examples of velocity vectors obtained using PIV: (a) double exposure of particles in flow field, (b) velocity vectors, and (c) velocity vectors with mean velocity subtracted out. (Courtesy of Ken Kiger, University of Maryland, College Park, MD.)

the distance between fringes is fixed in LDV. The time interval between marks in PIV must be small compared to the time scales of interest in the flow. Typical markers that have been used are H_2 bubbles, fluorescent particles, and naturally occurring small particles in liquids. The two main components of a PIV system are the imaging system that produces a double-exposed photographic image of the particles in the flow field, and the interrogation system that extracts and presents the velocity field information contained in the photograph.

Imaging System

Typically, the beam from a doubly pulsed laser is converted into a sheet of laser light using a cylindrical lens, which is then used to illuminate the markers in the flow. A camera located perpendicular to the flow records the doubly exposed image onto film. Typical light sources are pulsed lasers or shuttered continuous wave (CW) lasers. Because pulsed lasers have larger energy output than CW

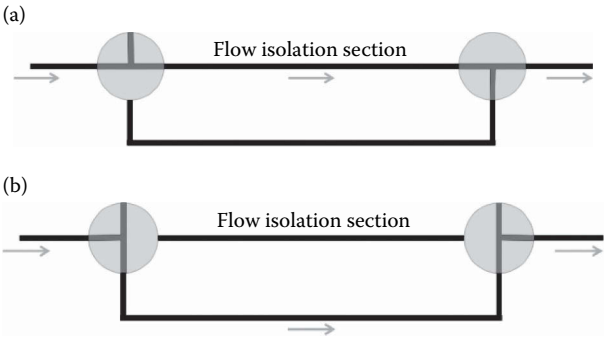

FIGURE 4.26.26 Example of (a) a double-exposed image of a particle shifted from one another, (b) the corresponding spatial autocorrelation. (Courtesy of Ken Kiger, University of Maryland, College Park, MD.)

lasers, they are generally used to illuminate small particles in the flow. Single CW laser beams swept across the flow using a rotating, faceted mirror produce a pseudo light sheet and can also be used to illuminate particles.

Film is usually necessary to resolve the markers if reasonable spatial resolution is desired. Larger markers in conjunction with high-resolution video cameras can be used, but care must be taken to ensure that the markers faithfully follow the flow. High-resolution cameras do have the advantage that near online processing of the data can be performed, however, with the appropriate digitizing and computing equipment.

The result of the imaging system is to produce two sets of markers that are displaced in time. The two sets can be on a single sheet of film, or can be recorded separately on different frames of a video camera. An example of two sets of markers is shown on Figure 4.26.26a.

Interrogation System

To obtain the velocity vectors, the doubly exposed image is first divided up into small subareas over which the average velocity vector will be computed. The size of the subareas should be as small as possible to obtain the highest number of velocity vectors; but they should not be so small that an insufficient number of particle pairs result. A good rule of thumb is to choose a subarea size that contains ~10 particle pairs. The position of each of the particles is then determined, and a spatial autocorrelation performed (Figure 4.26.26b). The location of the peaks in the spatial correlation plane yields the average particle displacement over that subarea. The largest peak results from a self-correlation and is not of interest. Two other peaks, one in the positive direction and the other in the negative direction, indicate the possible average particle displacement over that subarea.

Flow Direction

It is not possible to determine the *direction* of the velocity vector from a doubly exposed photograph alone. This is not a problem if the main flow direction is known *a priori*, but it does present problems in highly turbulent flows or if flow reversals occur. Image shifting of the second set of particles relative to the first can be used to resolve this directional ambiguity. Suppose the second set of images is shifted by a positive amount. A stationary marker will be displaced by this amount. A moving marker will have an additional displacement as a result of its movement. A shift greater than that expected at the largest negative flow velocity then eliminates ambiguity regarding flow direction since the second image is always on the positive side of the first image. This technique is analogous to using frequency shifting in LDV measurements to determine the direction of the particle movement.

Rotating mirrors and crystals have been used to produce this shift in images. More recently, cameras have been developed specifically for PIV that electronically shift the first set of images by

a certain number of pixels before acquiring the second set, eliminating any additional mechanical complexity.

Viscosity Measurements

Viscometry is the technique of measuring the viscosity of a fluid. Viscometers are classified as rotational, capillary, or miscellaneous, depending on the technique employed. Rotational viscometers use the principle that a rotating body immersed in a liquid experiences a viscous drag, which is a function of the viscosity of the liquid, the shape and size of the body, and the speed of its rotation. They are widely used because measurements can be carried out for extended periods of time.

Capillary viscometry uses the principle that when a liquid passes in laminar flow through a tube, the viscosity of the liquid can be determined from measurements of the volume flow rate, the applied pressure, and the tube dimensions. Viscometers that cannot be classified either as rotational or capillary include the falling ball viscometer. Its method of operation is based on Stokes' law, which relates the viscosity of a Newtonian fluid to the velocity of a sphere falling through it. Falling-ball viscometers are often employed for reasonably viscous fluids. Rising bubble viscometers utilize the principle that the rise of an air bubble through a liquid medium gives a visual measurement of liquid viscosity. Because of their simplicity, rising bubble viscometers are commonly used to estimate the viscosity of varnish, lacquer, and other similar media.

Void Fraction Measurement

The measurement of the void fraction (α) in a two-phase flow of liquid and gas (or vapor)—defined as the fraction of the tube cross-sectional area occupied by the gas—is important for two-phase flow closure models. Some methods that have been developed to measure α are described below.

Fast closing valve. A simple and accurate method to measure α is to use two valves to quickly isolate a section of pipe containing the two-phase flow. The void fraction is determined by dividing the volume of trapped liquid by the total trapped volume. Ball valves are generally used since their internal flow area can be made to match the tube's inner diameter to minimize flow disturbance. The valves can be rigidly linked together so they close simultaneously; fast closing solenoid-actuated valves can be used. Two three-way valves can be arranged as shown in Figure 4.26.27 such that the flow can bypass the measurement section during measurement, thereby avoiding the need for flow shutdown.

Capacitance sensor. This technique exploits the difference in the dielectric constant between liquid and gas to determine α through the change in capacitance between two conductors. The

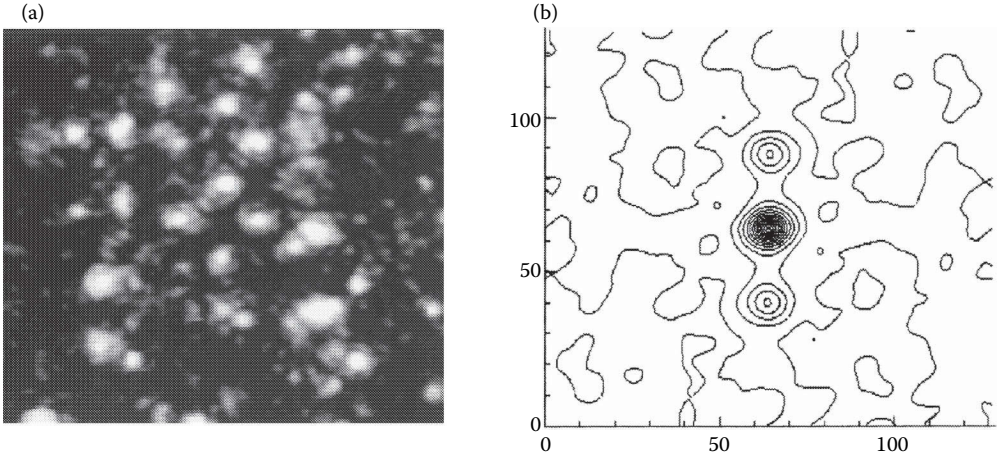

FIGURE 4.26.27 Three-way ball valve arrangement that allows the flow to be uninterrupted during measurement. (a) Straight through flow during normal operation. (b) Bypassed flow during void fraction measurement.

conductors can be deposited around the two halves of the tube or as helical strips wound around the tube. The measured capacitance has been found to be relatively insensitive to the flow pattern. Calibration of the sensor vs. void fraction is usually performed with the results expressed as the capacitance change normalized by the maximum capacitance change:

$$\alpha = f\left(\frac{C - C_1}{C_2 - C_1}\right), \tag{4.26.44}$$

where C is the measured capacitance, C_1 is the capacitance with the tube filled with Fluid 1, and C_2 is the capacitance with the tube filled with Fluid 2. Depending on the size of the conductors and the speed of the measurement, flow patterns can be identified based on time resolved measurements.

Tomography. If multiple electrodes are arranged around the circumference of the tube, the capacitance (for insulating fluids), resistance (for conducting fluid), or impedance (uses both resistance and capacitance) between any pair of electrodes can be measured using tomography. Techniques based on X-rays, gamma rays, and neutrons have also been proposed. The resolution is limited by the number of elements in the sensor array. An example of the void fraction measured using tomography is shown in Figure 4.26.28.

Conductivity wire probe. The conductivity probe exploits the difference in electrical conductivity between the liquid and gas to obtain the local void fraction in conducting liquids (Neal and Bankoff, 1963). A wire is covered with insulation except for its tip and placed in the flow. The impedance between the tip and the liquid is measured, and high and low impedance are seen when gas and liquid occupy the tip, respectively. The void fraction is given by the fraction of time the tip is occupied by gas.

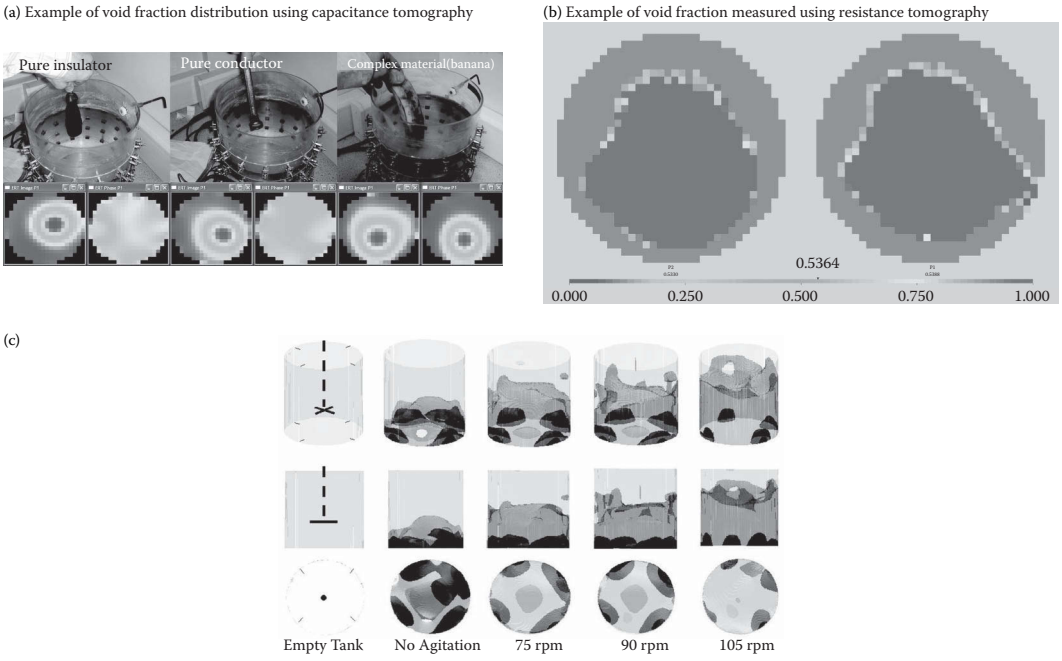

FIGURE 4.26.28 Sample results of void distribution measured using electrical capacitance tomography (top left), electrical resistance tomography (top right), and electrical impedance tomography (bottom). (Courtesy of Industrial Tomography Systems.)

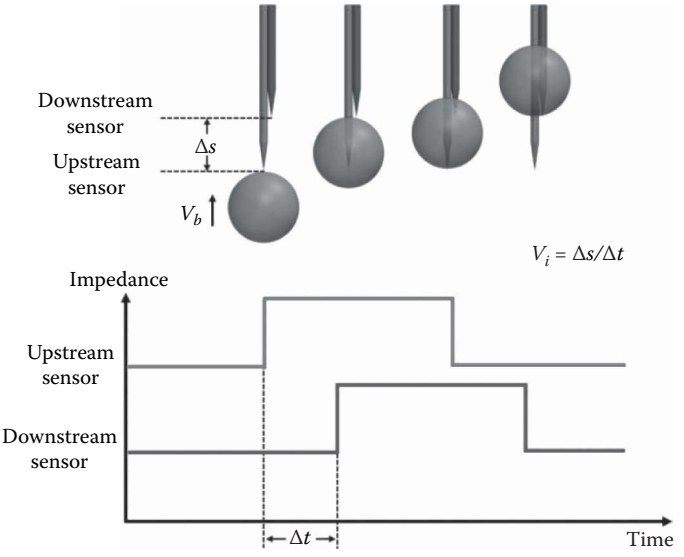

FIGURE 4.26.29 Conductivity probe measurement principle. (Courtesy of Prof. Seungjin Kim, Pennsylvania State University.)

Multiple sensors offset from each other axially and laterally can be used to obtain information about the interfacial velocity and area. For example, the interfacial velocity can be measured using the double sensor configuration shown in Figure 4.26.29 by dividing the distance between the sensors (Δs) and the measured time delay (Δt). Double and four sensor probes have been used to measure the interfacial area as well as the Sauter mean diameter and bubble frequency. Details of the measurement theory and signal processing scheme for multisensor conductivity probes including recent improvements made on the probe can be found in the literature (Kataoka et al., 1986; Kim et al., 2000; Bernard et al., 2015).

Optical probe. Optical probes are similar to conductivity probes, but depend on the index of refraction change between liquid and gas to measure the local void fraction (Abuaf et al., 1978). Typically, the tip of an optical fiber or light guide is shaped into a cone such that light traveling through the fiber is reflected back to the source by total internal reflection when gas is present. When the tip is covered by liquid, however, light is refracted into the liquid with little being reflected to the source since the probe has similar index of refraction as the liquid. The presence of bubbles and droplets as well as their arrival times and frequency can be measured in this way. If two probes are used in close proximity to each other, the velocity can also be measured.

Wire mesh sensors. The technique developed by Prasser et al. (1998, 2001) is used to measure the void fraction distribution at many points in a two-phase flow of a conducting liquid. In their sensor, two orthogonal electrode grids (a transmitter grid and a receiver grid) containing 16 sensors each are separated axially by a distance of 1.5 mm. The electrical conductivity measured using a high-speed multiplexer circuit between each of the wires in the transmitter grid and those in the receiver grid is used to determine if liquid or gas is present at each crossing point. This technique can provide detailed information regarding the local flow structure. Although the measurement is intrusive, the flow structure can be captured before the bubbles are fragmented by the wires. Development of the technique over the years has led to sensors as large as 128×128 crossing points that can be read at frame rates up to 1280 Hz. Three-layer sensors have been developed for the measurement of velocity, interfacial area density, and bubble size distribution. The reader is referred to Valasco Pena and Rodriguez (2015) for an overview of recent developments.

Defining Terms

Flow meter: Device used to measure mass flow rate or volume flow rate of fluid flowing in a duct.

Restriction flow meter: Flow meter that causes flowing fluid to accelerate in a nozzle, creating a pressure change that can be measured and related to flow rate.

Thermal anemometer: Heated sensor used to infer local fluid velocity by sensing changes in heat transfer from a small electrically heated surface exposed to the fluid flow.

Traverse: Systematic procedure used to traverse a probe across a duct cross section to measure flow rate through the duct.

4.27 APPLICATIONS OF ARTIFICIAL NEURAL NETWORKS AND GENETIC METHODS IN THERMAL ENGINEERING

Arturo Pacheco-Vega, Gerardo Diaz, Mihir Sen, and K.T. Yang

Introduction

Recent decades have seen enormous strides in technologies that can be loosely grouped together under the general term *artificial intelligence* (AI). Since, at the same time, relatively powerful desktop computers have become commonly available, applications of these methods are quickly spreading to many areas of science and engineering outside the field of computer science, especially for complex systems where more traditional methods have failed to be useful. The techniques of artificial neural networks (ANNs) and genetic methods have been shown to be particularly useful in the thermal sciences. This section is an overview of the state-of-the-art technology in this area. It is fundamentally tutorial in nature so that the reader unfamiliar with these techniques can use it as a point of departure. We will describe the methodology and scope of these methods, and then concentrate on specific applications that illustrate their use. An extensive bibliography is also provided for readers who are interested in pursuing the subject further.

Thermal systems are natural or engineered systems involving temperature differences. The engineering discipline of thermal sciences, particularly heat transfer, specifically deals with the analysis, design, and control of such systems, and has a long history of development in response to needs in a great variety of applications. Much of the advancement in the field has been the result of first-principle analyses for simpler phenomena, supplemented by experimental correlations for the more complex ones for which the first principles are either not known or the problem is too complex for their use. Unfortunately, the existing methods of analyses are no longer adequate to deal with many current applications, even though analyses are still critically needed for a variety of reasons, such as, for instance, energy efficiency, environmental concern, optimum design and control, cost, and competitiveness in the market place. While the thermal sciences as a basic engineering discipline must and should continue to develop and advance our quantitative understanding of the fundamental phenomena involved, new methods of analysis must be found in the interim, which can be used as a surrogate for such understanding. This is particularly true in the analysis and control of dynamic thermal systems. Obvious examples in this area are dynamic performance of complex heat exchangers and storage devices, network dynamics and hydronic control for heating, ventilating, and air-conditioning (HVAC) applications, dynamic thermal sensor development, thermal packaging of microelectronic devices, and thermal processing of conventional and advanced materials, just to mention a few.

AI and Its Scope

AI, though easy to recognize, is difficult to define: the word artificial is used to signify something made by humans, but intelligence itself is a more elusive concept. In fact, one can debate whether machines can actually think. Working definitions would be to say that it is "the study of how to make computers do things which, at the moment, people do better" (Rich and Knight, 1991); the "study that encompasses computational techniques for tasks that apparently require intelligence when performed by humans" (Tanimoto, 1990); "the discipline that aims to understand the nature of human intelligence through the construction of computer programs that imitate intelligent behavior" (Bonnet, 1985); or "the study of mental faculties through the use of computational models" (Charniak and McDermott, 1985). Though every definition has its drawbacks, it appears that some elements of a knowledge base, search techniques, and logical reasoning are usually involved in AI and that the techniques usually attempt a simulation of a specific aspect of human or animal behavior. There are also related and overlapping disciplines that go by other names. *Soft computing*, for

example, is a collection of techniques including fuzzy logic, neural networks, genetic algorithms, and probabilistic reasoning that are based on the idea that "intelligent systems should exploit, whenever possible, the tolerance for imprecision and uncertainty" (Bouchon-Meunier et al., 1995; Jang et al., 1997). *Knowledge engineering* and *intelligent information systems* are terms that are used when the emphasis is on the database. *Virtual reality, artificial life, machine intelligence, data mining, soft computing*, and *deep learning* are also related ideas that are being widely used. There is obviously some overlap between all these terminologies that we will not attempt to sort out here. The point is that these techniques are able to deal with complex problems that would be difficult to handle otherwise.

AI has a wide variety of applications in the natural and engineering sciences, among which are pattern recognition, decision making, system control, information processing, natural languages, symbolic mathematics, computer-aided instruction, speech recognition, vision, and robotics. These applications have spawned a large number of usable algorithms, such as optimization and search techniques, that can be used in other fields. Out of the broad set of techniques available, we will, for reasons of space, be concerned with two that have been shown to be useful in the thermal sciences: ANNs and genetic methods. We will exclude any discussion of topics such as knowledge-based techniques, fuzzy logic, and other AI methodologies.

Why AI?

At the outset, one must ask why AI techniques have any role in the thermal sciences. The answer to this lies at the core of the subject, i.e., in heat transfer. Heat transfer, like its sister discipline fluid mechanics, is based on mechanics and thermodynamics and has long been considered as one of the basic engineering sciences. At a fundamental level, it is deterministic and well understood; the equations for conduction, convection, and radiation can be easily written down, and the material properties involved can also be measured. So it is proper to discuss why AI and allied techniques are needed at all.

A major application of heat transfer is in devices such as heat exchangers, which are one of the basic components of thermal systems. A wide variety of heat exchangers exists in the market and for each it is necessary, for design and selection purposes, to know the heat transfer rate under prescribed operating conditions. In a given device exchanging heat between two fluids, the heat transfer rate depends on the flow rates and the inlet temperatures of each fluid. From the heat transfer rate, secondary quantities such as the fluid outlet temperatures can be determined. Though the governing equations can be written down, it is extremely difficult to solve them numerically under actual operating conditions. Among the reasons for this are as follows: complicated heat and fluid flow geometries, turbulence in the flow, existence of hydrodynamic and thermal entrance regions, nonuniform local heat transfer rates and fluid temperatures, secondary flows in the tube bends, vortices in the neighborhood of the tube–fin junctions, airside flow development in fin passages, heat conduction along tube walls, natural convection within the tubes and between the fins, and temperature dependence of fluid properties.

The computation must take into account the large ratio between the largest and the smallest length scales at which computations must be carried out. Accurate numerical solutions, thus, cannot be obtained with reasonable effort. As a consequence of this, we are usually forced to abandon the first-principles approach in favor of empirical information. It must be emphasized that each one of the complicating factors can be handled alone and can even be said to be understood, but their occurring together is what makes the problem difficult.

We can, therefore, for purposes of this discussion, define a *complex* system to be one that is made up of a large number of simple subsystems that interact with each other. Empirical information in the form of correlations is commonly used to help in the analysis of thermal systems that are complex. These correlations usually have little physical basis and are proposed to have the simplest form that will give the best accuracy. The vagueness in this procedure gives rise to a variety of correlations for even the most straightforward calculation such as, for example, that of turbulent heat

transfer in a duct. Furthermore, as our ability to carry out complicated calculations for the purpose of design increases, the definition of the "simplest" form changes. At this point in time, it may be said that simplicity in the correlation may no longer be of concern, but accuracy in the predictions is. In this regard, AI has much to offer. It is typically used in instances where the ultimate purpose is to detect and make use of patterns, rather than to uncover new physics.

Heat Exchangers

Since much of the following discussion will center on compact heat exchangers, we will explain this problem a little further. For the interested reader, Section 4.1 provides a detailed description of heat exchangers. Empirical information about a given heat exchanger is experimentally determined by the manufacturer and is presented to the user, i.e., the thermal system designer, in the form of the heat transfer rate as a function of the four control variables: the two flow rates and the two inlet temperatures. Being a four-variable function, it is difficult to represent completely, though partial information can be provided in the form of charts or graphs. In principle, this function depends on the geometry of the heat exchanger, the materials with which it is made, the surface conditions, the fluids used, etc. It completely characterizes the heat exchanger, and is the information that must be transferred in some form from the manufacturer to the design engineer. Since the raw experimental data would require a large amount of space for data storage, it is necessary to compress the information in some fashion for transfer from manufacturer to user, and from which it can later be accurately recovered. There are different ways in which this can be done.

In the simplest procedure, the information is compressed as two heat transfer correlations, one for the inside and another for the outside, thus characterizing the heat exchanger performance by only these two quantities. For each side, a characteristic temperature difference is assumed. However, in reality, this is found to be inaccurate; the heat transfer coefficients are known to vary considerably with flow rates and fluid properties. Furthermore, without accurate tube wall temperature measurements, which are not easy to make, it is difficult to separate the experimentally determined overall thermal resistance into its internal and external components to find each transfer coefficient separately. It is possible to assume separate correlations for the heat transfer on either side and to use a regression analysis to determine the constants. Summing the resistances, however, produces a correlation that is not linearizable and, hence, could give more than one set of constants. This is discussed in further detail later.

We can resort to dimensionless analysis to reduce the number of variables involved in the correlation. The internal and external Nusselt (or Stanton) numbers should thus depend on the corresponding Reynolds and Prandtl numbers. A correlation using nondimensional variables has the advantage that it can be used for a wide range of length scales, flow rates, and fluids. This is the most common procedure. However, loss of accuracy is the price to be paid for this generality since not all the physical phenomena involved in the heat transfer process, like the previously cited examples show, scale exactly with the limited set of nondimensional variables used. Property variations are one example; there will be a significant difference in the heat rate predictions if the manufacturer and the user assume different values of the viscosity of the liquid (the viscosity of water, for example, at 40°C is 65% of what it is at 20°C). Letting a characteristic temperature difference scale a temperature profile assumes that the profile will be similar under all conditions, which is not the case. Moreover, the user of the information, the thermal system designer, is usually interested only in the heat transfer rate and not in intermediate variables like the internal and external heat transfer coefficients. It is preferable to sacrifice generality of application and correlate the heat rate directly with respect to the other variables.

The errors that are usually present in the predictions of a heat transfer correlation are due less to errors in measurement than to data compression represented by the correlation. Accuracies of a few percent would be achievable if the predictions had the same error level as the measurements. The two approaches that we will consider in detail to resolve this problem are outlined as follows.

1. The ANN technique offers an alternative approach to the problem of information compression. It is a procedure that is usually used to predict the response of a complex physical system that cannot be easily modeled mathematically. The network is first trained by experimentally obtained input–output sets of data, after which it can be used for prediction. The manufacturer can train a network using the experimental data; the constants or parameters of the trained network can then be transferred to the user who can calculate the performance of the heat exchanger under any other flow rate or inlet temperature condition.
2. The search for the correlation that best fits the data can be carried out using genetic methods. Given a specific form of the correlation, the constants therein can be obtained through the use of a genetic algorithm (GA). Extending the idea farther, the best correlation function itself can be selected among a restricted class by genetic programming (GP). The objective is not that the form of the correlation be simple—just that its predictions be accurate.

Artificial Neural Networks

In this subsection, we will discuss the ANN technique, which is generally considered to be a subclass of AI, and its application to the analysis of complex thermal systems (Yang, 2008). Applications of ANNs have been found in such diverse fields as philosophy, psychology, business and economics, sociology, science, as well as in engineering. The common denominator is the complexity of the field.

The technique is rooted in and inspired by the biological network of neurons in the human brain that learns from external experience, handles imprecise information, stores the essential characteristics of the external input, and generalizes previous experience (Eeckman, 1992). In the biological network of interconnecting neurons, each receives many input signals from other neurons and gives only one output signal, which is sent to other neurons as part of their inputs. If the sum of the inputs to a given neuron exceeds a set threshold, normally determined by the electric potential of the receiver neuron that may be modified under different circumstances, the neuron fires and sends a signal to all the connected receiver neurons. If not, the signal is not transmitted. The firing decision represents the key to the learning and memory ability of the neural network.

The ANN attempts to mimic the biological neural network: the processing unit is the artificial neuron; it has synapses or interneuron connections characterized by synaptic weights; an operator performs a summation of the input signals weighted by the respective synapses; an activation function limits the permissible amplitude range of the output signal. It is also important to realize the essential difference between a biologic neural network and an ANN. Biological neurons function much slower than the computer calculations associated with an artificial neuron in an ANN. On the other hand, the delivery of information across the biological neural network is much faster. The biological one compensates for the relatively slow chemical reactions in a neuron by having an enormous number of interconnected neurons doing massively parallel processing, while the number of artificial neurons must necessarily be limited by the available hardware.

In this subsection, we will briefly discuss the basic principles and characteristics of the multilayer ANN, along with the details of the computations made in the feedforward mode and the associated backpropagation algorithm that is used for training. Issues related to the actual implementation of the algorithm will also be noted and discussed. Specific examples on the performance of two different compact heat exchangers analyzed by the ANN approach will then be shown, followed by a discussion on how the technique can also be applied to the dynamic performance of heat exchangers as well as to their control in real thermal systems. Finally, the potential of applying similar ANN techniques to other thermal system problems and their specific advantages will be delineated.

Methodology of ANNs

The interested reader is referred to the text by Haykin (1994) for an account of the history of ANN and its mathematical background. Many different definitions of ANNs are available; the one proposed by Schalkoff (1997) is that an ANN is a network composed of a number of artificial neurons. Each neuron has an input/output characteristic and implements a local computation or function. The output of any neuron is determined by this function, its interconnection with other neurons, and external inputs. The network usually develops an overall functionality through one or more forms of training; this is the learning process. Many different network structures and configurations have been proposed, along with their own methodologies of training (Warwick et al., 1992).

Feedforward Network

There are many different types of ANNs, but one of the most appropriate for engineering applications is the supervised, fully connected multilayer configuration (Zeng, 1998) in which learning is accomplished by comparing the output of the network with the data used for training. The *feedforward* or *multilayer perceptron* is the only configuration that will be described in some detail here. Figure 4.27.1 shows such an ANN consisting of a series of layers, each with a number of nodes. The first and last layers are for input and output, respectively, while the others are the hidden layers. The network is said to be fully connected when any node in a given layer is connected to all the nodes in the adjacent layers.

We introduce the following notation: (i, j) is the jth node in the ith layer. The line connecting a node (i, j) to another node in the next layer $i+1$ represents the synapse between the two nodes. $x_{i,j}$ is the input of the node (i, j), $y_{i,j}$ is its output, $\theta_{i,j}$ is its bias, and $w^{i,j}_{i-1,k}$ is the synaptic weight between nodes $(i-1, k)$ and (i, j). The total number of layers, including those for input and output, is I, and the number of nodes in the ith layer is J_i. The input information is propagated forward through the network; J_1 values enter the network and J_I leave. The flow of information through the layers is a function of the computational processing occurring at every internal node in the network. The relation between the output of node $(i-1, k)$ in one layer and the input of node (i, j) in the following layer is

$$x_{i,j} = \theta_{i,j} + \sum_{k=1}^{J_{i-1}} w^{i,j}_{i-1,k} y_{i-1,k} \tag{4.27.1}$$

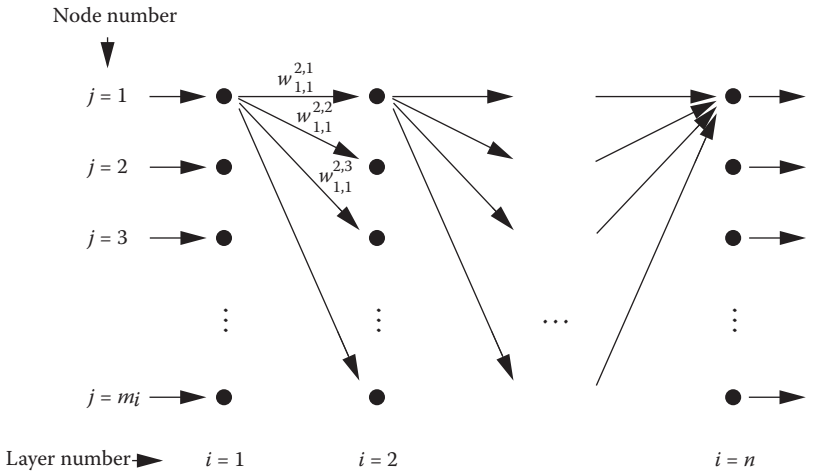

FIGURE 4.27.1 Schematic of a fully connected multilayer ANN.

Thus, the input $x_{i,j}$ of node (i, j) consists of a sum of all the outputs from the previous nodes modified by the respective internode synaptic weights $w_{i-1,k}^{i,j}$ and a bias $\theta_{i,j}$. The weights are characteristic of the connection between the nodes and the bias of the node itself. The bias represents the propensity for the combined incoming input to trigger a response from the node and presents a degree of freedom, which gives additional flexibility in the training process. Similarly, the synaptic weights are the weighting functions that determine the relative importance of the signals originated from the previous nodes.

The input and output of the node (i, j) are related by

$$y_{i,j} = \phi_{i,j}(x_{i,j}) \tag{4.27.2}$$

where $\phi_{i,j}(x)$, called the *activation* or *threshold* function, plays the role of the biological neuron determining whether it should fire or not on the basis of the input to that neuron. A schematic of the nodal operation is shown in Figure 4.27.2. It is obvious that the activation function plays a central role in the processing of information through the ANN. Keeping in mind the analogy with the biological neuron, when the input signal is small, the neuron suppresses the signal altogether, resulting in a vanishing output, and when the input exceeds a certain threshold, the neuron fires and sends a signal to all the neurons in the next layer. This behavior is determined by the activation function. Several appropriate activation functions have been studied (Haykin, 1994; Schalkoff, 1997). For instance, a simple step function can be used, but the presence of noncontinuous derivatives causes computing difficulties. The most popular one is the logistic sigmoid function

$$\phi_{i,j}(\xi) = \frac{1}{1+e^{-\xi/c}}$$

for $i > 1$, where c determines the steepness of the function. For $i = 1$, $\phi_{i,j}(\xi) = \xi$ is used instead. The sigmoid function is an approximation of the step function, but with continuous derivatives. The nonlinear nature of the sigmoid function is particularly beneficial in the simulation of practical problems. For any input $x_{i,j}$, the output of a node $y_{i,j}$ always lies between 0 and 1. Thus, from a computational point of view, it is desirable to normalize all the input and output data with the largest and smallest values of each of the data sets.

Training

For a given network, the weights and biases must be adjusted for known input–output values through a process known as training. The backpropagation method is a widely used deterministic training algorithm for this type of ANN (Rumelhart et al., 1986). The central idea of this method is to minimize an error function by the method of steepest descent to add small changes in the direction of minimization. This algorithm may be found in many texts on ANN (for instance, Rzempoluck, 1998), and only a brief outline will be given here.

In usual complex thermal system applications where no physical models are available, appropriate training data come from experiments. The first step in the training algorithm is to assign initial values to the synaptic weights and biases in the network based on the chosen ANN configuration. The values may be either positive or negative and, in general, are taken to be less than unity in absolute value. The second step is to initiate the feedforward of information starting from the input layer. In this manner, successive input and output of each node in each layer can all be computed. When

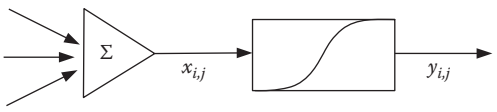

FIGURE 4.27.2 Nodal operation in an ANN.

finally $i=I$, the value of $y_{I,j}$ will be the output of the network. Training of the network consists of modifying the synaptic weights and biases until the output values differ little from the experimental data, which are the targets. This is done by means of the backpropagation method. First, an error $\delta_{I,j}$ is quantified by

$$\delta_{I,j} = (t_{I,j} - y_{I,j}) y_{I,j} (1 - y_{I,j})$$

where $t_{I,j}$ is the target output for the j node of the last layer. This equation is simply a finite difference approximation of the derivative of the sigmoid function. After calculating all the $\delta_{I,j}$, the computation then moves back to the layer $I-1$. Since the target outputs for this layer do not exist, a surrogate error defined as

$$\delta_{I-1,k} = y_{I-1,k}(1 - y_{I-1,k}) \sum_{j=1}^{J_I} \delta_{I,j} w_{I-1,k}^{I,j}$$

is used instead.

A similar error $\delta_{i,j}$ is used for the rest of the inner layers. These calculations are then continued layer by layer backward until layer 2. It is seen that the nodes of layer 1 have neither δ nor θ values assigned, since the input values are all known and invariant. After all the errors $\delta_{i,j}$ are known, the changes in the synaptic weights and biases can then be calculated by the generalized delta rule (Rumelhart et al., 1986):

$$\Delta w_{i-1,k}^{i,j} = \lambda \delta_{i,j} y_{i-1,k} \tag{4.27.3}$$

$$\Delta \theta_{i,j} = \lambda \delta_{i,j} \tag{4.27.4}$$

for $i < I$, from which all the new weights and biases can be determined. The quantity λ is known as the learning rate that is used to scale down the degree of change made to the nodes and connections. The larger the training rate, the faster the network will learn, but the chances of the ANN to reach the desired outcome may become smaller as a result of possible oscillating error behaviors. Small training rates would normally imply the need for longer training to achieve the same accuracy. Its value, usually around 0.4, is determined by numerical experimentation for any given problem.

A cycle of training consists of computing a new set of synaptic weights and biases successively for all the experimental runs in the training data. The calculations are then repeated over many cycles while recording an error quantity E for a given run within each cycle, where

$$E = \frac{1}{2} \sum_{j=1}^{J_I} (t_{I,j} - y_{I,j})^2 \tag{4.27.5}$$

The output error of the ANN at the end of each cycle can be based on either a maximum or averaged value for a given cycle. Note that the weights and biases are continuously updated throughout the training runs and cycles. The training is terminated when the error of the last cycle, barring the existence of local minima, falls below a prescribed threshold. The final set of weights and biases can then be used for prediction purposes, and the corresponding ANN becomes a model of the input–output relation of the thermal system problem.

Implementation Issues

In the implementation of a supervised, fully connected multilayered ANN, the user is faced with several uncertain choices that include the number of hidden layers, the number of nodes in each layer, the initial assignment of weights and biases, the training rate, the minimum number of training data sets and runs, the learning rate, and the range within which the input–output data are

normalized. Such choices are by no means trivial, and are rather important in achieving good ANN results. Since there is no general sound theoretical basis for specific choices, past experience and numerical experimentation are still the best guides, despite the fact that much research is now going on to provide a rational basis (Zeng, 1998).

On the issue of number of hidden layers, there is a sufficient, but certainly not necessary, theoretical basis known as the Kolmogorov mapping neural network existence theorem as presented by Hecht-Nielsen (1987), which essentially stipulates that only one hidden layer of artificial neurons is sufficient to model the input–output relations as long as the hidden layer has $2J_1 + 1$ nodes. Since in realistic problems involving a large set of input parameters, the nodes in the hidden layer would be excessive to satisfy this requirement, the general practice is to use two hidden layers as a starting point, and then add more layers as the need arises, while keeping a reasonable number of nodes in each layer (Flood and Kartam, 1994).

A slightly better situation is in the choice of the number of nodes in each layer and in the entire network. Increasing the number of internal nodes provides a greater capacity to fit the training data. In practice, however, too many nodes suffer the same fate as the polynomial curve-fitting routine by collocation at specific data points in which the interpolations between data points may lead to large errors. In addition, a large number of internal nodes slows down the ANN both in training and in prediction. One interesting suggestion given by Rogers (1994) and Jenkins (1995) is that

$$N_t = 1 + N_n \frac{J_1 + J_I + 1}{J_I}$$

where N_t is the number of training data sets, and N_n is the total number of internal nodes in the network. If N_t and J_I are known in a given problem, this equation determines the suggested minimum number of internal nodes. Also, if N_n, J_1, and J_I are known, it gives the minimum value of N_t. The number of data sets used should be larger than that given by this equation to ensure the adequate determination of the weights and biases in the training process. Other suggested procedures for choosing the parameters of the network include the one proposed by Karmin (1990) that involve first training a relatively large network that is then reduced in size by removing nodes which do not significantly affect the results, and the so-called radial Gaussian system, which adds hidden neurons to the network in an automatic sequential and systematic way during the training process (Gagarin et al., 1994). Also available is the use of evolutionary programming approaches to optimize ANN configurations (Angeline et al., 1994). Some authors (see, for example, Thibault and Grandjean, 1991) present studies of the effect of varying these parameters.

The issue of assigning the initial synaptic weights and biases is less certain. Despite the fact that better initial guesses would require less training efforts, or even less training data, such initial guesses are generally unavailable in applying the ANN analysis to a new problem. The initial assignment then normally comes from a random number generator of bounded numbers. Unfortunately, this does not guarantee that the training will converge to the final weights and biases for which the error is a global minimum. Also, the ANN may take a large number of training cycles to reach the desired level of error. Wessels and Barnard (1992), Drago and Ridella (1992), and Lehtokangas et al. (1995) suggested other methods for determining the initial assignment so that the network converges faster and avoids local minima. On the other hand, when the ANN needs upgrading with additional or new experimental data sets, the initial weights and biases are simply the existing ones.

During the training process, the weights and biases continuously change as training proceeds in accordance with Equations 4.27.3 and 4.27.4, which are the simplest correction formulas to use. Other possibilities, however, are also available (Kamarthi et al., 1992). The choice of the training rate λ is largely by trials. It should be selected to be as large as possible, but not too large to lead to nonconvergent oscillatory error behaviors. Finally, since the sigmoid function has the asymptotic limits of [0, 1] and may thus cause computational problems in these limits, it is desirable to normalize all physical variables into a more restricted range such as [0.15, 0.85]. The choice is somewhat

arbitrary. However, pushing the limits closer to [0, 1] does commonly produce more accurate training results at the expense of larger computational efforts.

Application of ANNs to Compact Heat Exchangers

In this subsection, the ANN analysis will be applied to the prediction of the performance of two different types of compact heat exchangers, one being a single-row, fin–tube heat exchanger (called heat exchanger 1), and the other a much more complicated multirow, multicolumn fin–tube heat exchanger (heat exchanger 2). In both cases, air is either heated or cooled on the fin side by water flowing inside the serpentine tubes. Except at the tube ends, the air is in a cross-flow configuration. Details of the analyses are available in the literature (Diaz et al., 1996, 1998b, 1999b; Pacheco-Vega et al., 1999, 2001a). For either heat exchanger, the normal practice is to predict the heat transfer rates by using separate dimensionless correlations for the air- and waterside coefficients of heat transfer based on the experimental data and definitions of specific temperature differences.

Heat Exchanger 1

The simpler single-row heat exchanger, a typical example being shown in Figure 4.27.3, is treated first. It is a nominal 18 in. × 24 in. plate fin–tube type exchanger manufactured by the Trane Company, with a single circuit of 12 tubes connected by bends. The experimental data were obtained in a variable-speed, open wind-tunnel facility shown schematically in Figure 4.27.4. A PID (proportional-integral-derivative)-controlled electrical resistance heater provides hot water and its flow rate is measured by a turbine flow meter. All temperatures are measured by type T thermocouples. Additional experimental details can be found in the thesis by Zhao (1995). A total of $N = 259$ test runs were made, of which only the data for $N_t = 197$ runs were used for training, while the rest were used for testing the predictions. It is advisable to include the extreme cases in the training data sets so that the predictions will be within the same range. For the ANN analysis, there are four input nodes, each corresponding to the normalized quantities: air flow rate $\dot{m}_a$, water flow rate $\dot{m}_w$, inlet air temperature T_a^{in}, and inlet water temperature T_w^{in}. There is a single output node for the normalized heat transfer rate $\dot{Q}$. Normalization of the variables was done by limiting them within the range [0.15, 0.85]. Coefficients of heat transfer have not been used since that would imply making some assumptions about the similarity of the temperature fields.

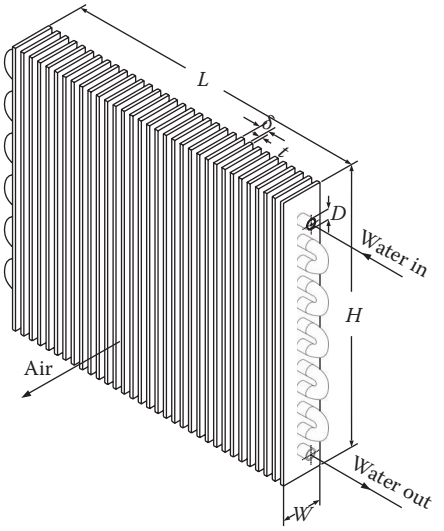

FIGURE 4.27.3 Schematic of compact heat exchanger 1.

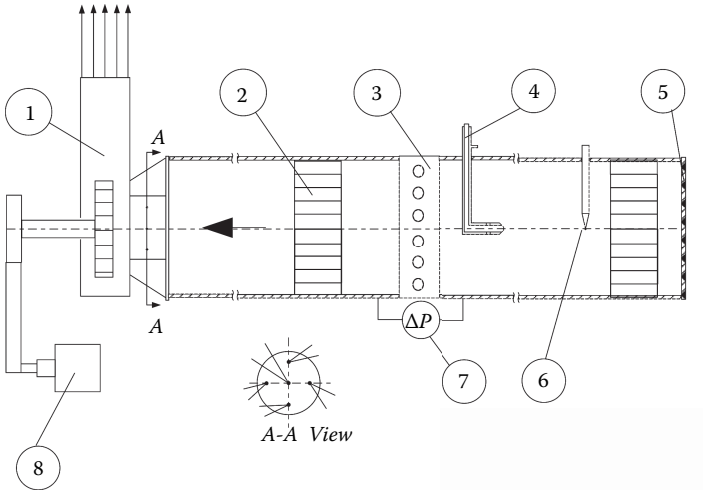

FIGURE 4.27.4 Schematic of test facility: (1) centrifugal fan, (2) flow straightener, (3) heat exchanger, (4) Pitot static tube, (5) screen, (6) thermocouple, (7) differential pressure gauge, (8) motor. View A–A shows the placement of five thermocouples.

Fourteen different ANN configurations were studied, as shown in Table 4.27.1. As an example, the training results of the 4-5-2-1-1 configuration, with three hidden layers with 5, 2, and 1 nodes, respectively, are considered in detail. The input and output layers have 4 nodes and 1 node, respectively, corresponding to the four input variables and a single output. Training was carried out to 200,000 cycles to show how the errors change along the way. The average and maximum values of the errors for all the runs can be found, where the error for each run is defined in Equation 4.27.5. These errors are shown in Figure 4.27.5. It is seen that the maximum error asymptotes at about 150,000 cycles, while the corresponding level of the average error is reached at about 100,000. In either case, the error levels are sufficiently small.

After training, the ANNs were used to predict $N_p = 62$ testing data, which were not used in the training process; the mean and standard deviations of the error for each configuration, R and σ, respectively, are shown in Table 4.27.1. R and σ are defined as

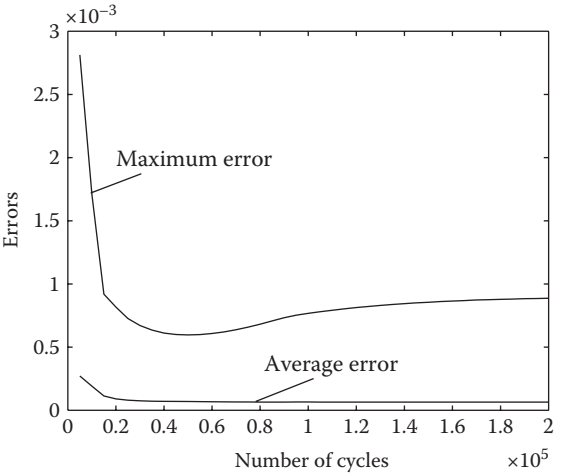

FIGURE 4.27.5 Training error results for configuration 4-5-2-1-1 ANN.

TABLE 4.27.1
Comparison of Heat Transfer Rates Predicted by Different ANN Configurations for Heat Exchanger 1

Configuration	R	σ
4-1-1	1.02373	0.266
4-2-1	0.98732	0.084
4-5-1	0.99796	0.018
4-1-1-1	1.00065	0.265
4-2-1-1	0.96579	0.089
4-5-1-1	1.00075	0.035
4-5-2-1	1.00400	0.018
4-5-5-1	1.00288	0.015
4-1-1-1-1	0.95743	0.258
4-5-1-1-1	0.99481	0.032
4-5-2-1-1	1.00212	0.018
4-5-5-1-1	1.00214	0.016
4-5-5-2-1	1.00397	0.019
4-5-5-5-1	1.00147	0.022

$$R = \frac{1}{N_p}\sum_{r=1}^{N_p} R_r \tag{4.27.6}$$

$$\sigma = \sqrt{\sum_{r=1}^{N_p}\frac{(R_r - R)^2}{N_p}} \tag{4.27.7}$$

where R_r is the ratio $\dot{Q}^e / \dot{Q}^p_{ANN}$ for run number r, $\dot{Q}^e$ is the experimental heat transfer rate, and $\dot{Q}^p_{ANN}$ is the corresponding prediction of the ANN. R is an indication of the average accuracy of the prediction, while σ is that of the scatter, both quantities being important for an assessment of the relative success of the ANN analysis. The network configuration with R closest to unity is 4-1-1-1, while 4-5-5-1 is the one with the smallest σ. If both factors are taken into account, it seems that 4-5-1-1 would be the best, even though the exact criterion is of the user's choice. It is also of interest to note that adding more hidden layers may not improve the ANN results. Comparisons of the values of R_r for all test cases are shown in Figure 4.27.6 for two configurations. It is seen, that although the 4-5-1-1 configuration is the second best in R, there are still several points at which the predictions differ from the experiments by more than 14%. The 4-5-5-1 network, on the other hand, has errors confined to 3.7%.

The effect of the normalization range for the physical variables was also studied. Additional trainings were carried out for the 4-5-5-1 network using the different normalization range of [0.05, 0.95]. For 100,000 training cycles, the results show that $R = 1.00063$ and $\sigma = 0.016$. Thus, in this case, more accurate averaged results can be obtained with the range closer to [0, 1].

We also compare the heat transfer rates obtained by the ANN analysis based on the 4-5-5-1 configuration, $\dot{Q}^p_{ANN}$, and those determined from the dimensionless correlations of the coefficients of heat transfer, $\dot{Q}^p_{cor}$. For the experimental data used, the least-square correlation equations have been given by Zhao (1995) and Zhao et al. (1995) to be

$$\varepsilon Nu_a = 0.1368 Re_a^{0.585} Pr_a^{1/3} \tag{4.27.8}$$

$$Nu_w = 0.01854 Re_w^{0.752} Pr_w^{0.3} \tag{4.27.9}$$

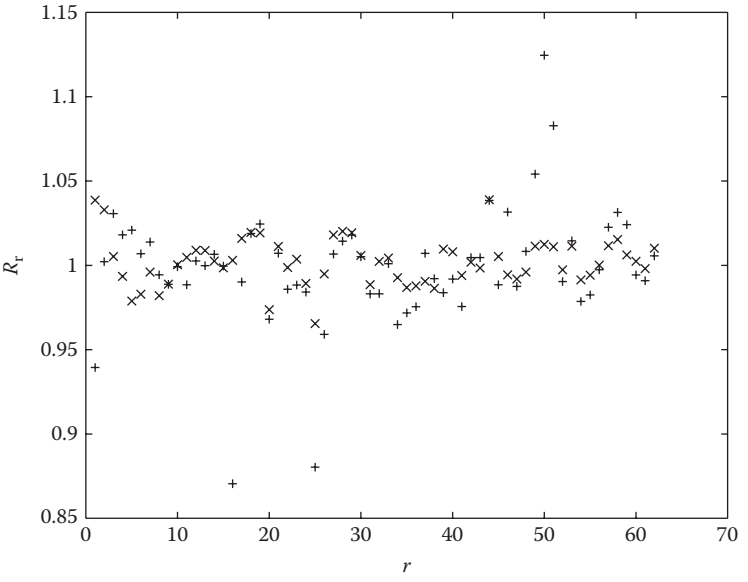

FIGURE 4.27.6 Ratio of heat transfer rates R_r for all testing runs (× 4-5-5-1; + 4-5-1-1) for heat exchanger 1.

applicable for $200 < \mathrm{Re_a} < 700$ and $800 < \mathrm{Re_w} < 4.5 \times 10^4$, where ε is the fin effectiveness. The Reynolds, Nusselt, and Prandtl numbers are defined as follows,

$$\mathrm{Re_a} = \frac{V_a \delta}{\nu_a}; \mathrm{Nu_a} = \frac{h_a \delta}{k_a}; \mathrm{Pr} = \frac{\nu_a}{\alpha_a}$$

$$\mathrm{Re_w} = \frac{V_w D}{\nu_w}; \mathrm{Nu_w} = \frac{h_w D}{k_w}; \mathrm{Pr} = \frac{\nu_w}{\alpha_w}$$

where the subscripts a and w refer to the air- and waterside, respectively, V is the average flow velocity, δ is the fin spacing, D is the inside diameter of the tube, and ν and k are the kinematic viscosity and thermal conductivity of the fluids, respectively. The correlations are based on the maximum temperature differences between the two fluids. The results are shown in Figure 4.27.7, where the superscript e is used for the experimental values and p for the predicted. For most of the data, the ANN error is within 0.7%, while the predictions of the correlation are of the order of ±10%. The superiority of the ANN is evident.

These results suggest that the ANNs have the ability of recognizing all the consistent patterns in the training data including the relevant physics as well as random and biased measurement errors. It can perhaps be said that it catches the underlying physics much better than the correlations do, since the error level is consistent with the uncertainty in the experimental data (Zhao, 1995). However, the ANN does not know and does not have to know what the physics is. It completely bypasses simplifying assumptions such as the use of coefficients of heat transfer. On the other hand, any unintended and biased errors in the training data set are also picked up by the ANN. The trained ANN, therefore, is not better than the training data, but not worse either.

Heat Exchanger 2

A second demonstration of the ANN analysis is on a multirow multicolumn compact heat exchanger shown schematically in Figure 4.27.8. Detailed heat and mass transfer measurements for this heat exchanger with different fin spacings and a wide range of operating conditions were carried out and the data reported by McQuiston (1978b). The air- and waterside thermal resistances were decoupled by using a high Reynolds number turbulent flow on the water side such that the waterside

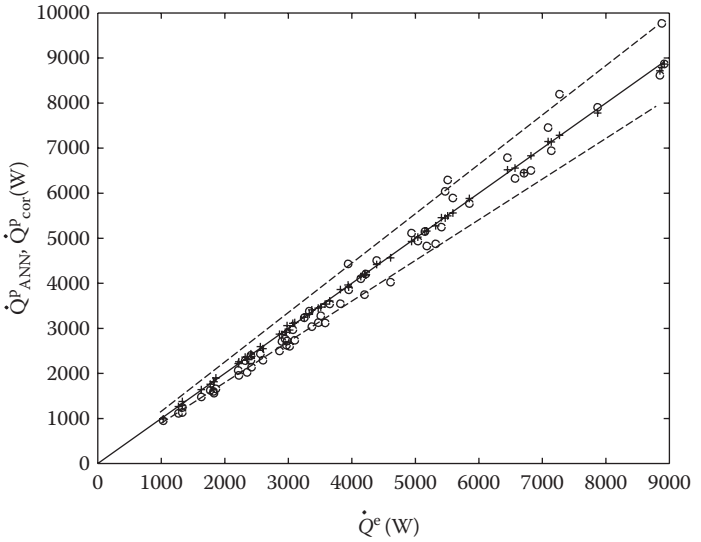

FIGURE 4.27.7 Comparison of 4-5-5-1 ANN (+) and correlation (o) predictions for heat exchanger 1.

coefficients of heat transfer were much higher than those on the air side; the waterside resistance could be estimated and subtracted from the overall thermal resistance to yield the resistance of the air side only. Details of the experimental facility and instrumentation can be found in McQuiston (1978b). The types of heat exchangers tested were for air-conditioning applications and, therefore, under certain operating conditions, condensation would occur. The heat transfer data were analyzed depending on whether the airside surface was dry, covered with droplets of water in dropwise condensation, or with water films in filmwise condensation. All physical dimensions are shown in Figure 4.27.8; the only geometrical quantity that was allowed to vary was the fin spacing, as it is the most important physical variable in such heat exchangers. On the other hand, the experimental data covered a wide range of operating conditions on the air side. McQuiston (1978a) correlated his data in terms of three airside heat transfer coefficients, nondimensionalized as Colburn j factors. These are the sensible heat j_s, the latent heat j_m, and the total heat j_t defined by

$$j_s = \frac{h_a}{G_c c_{p,a}} \mathrm{Pr}_a^{2/3}$$

$$j_m = \frac{h_{m,a}}{G_c} \mathrm{Sc}_a^{2/3}$$

$$j_t = \frac{h_{d,a}}{G_c} \mathrm{Sc}_a^{2/3}$$

where h_a is the heat transfer coefficient, and $h_{m,a}$ and $h_{d,a}$ are the mass transfer coefficients associated with the j factors, G_c is the air flow mass flux, $c_{p,a}$ is the specific heat of air, and Sc_a is the Schmidt number of air defined by $\mathrm{Sc}_a = \nu_a / D_a$, where ν_a is the kinematic viscosity of air and D_a is the mass diffusivity of water vapor in air. The j factors were correlated as functions of Reynolds numbers Re_D and $Re\delta$ and the geometrical factors $(4/\pi)(x_a/D_h)(x_b/D)\sigma_f$ and $\delta/(\delta - t)$, where

$$\mathrm{Re}_D = \frac{G_c D}{\mu_a}$$

$$\mathrm{Re}_\delta = \frac{G_c \delta}{\mu_a}$$

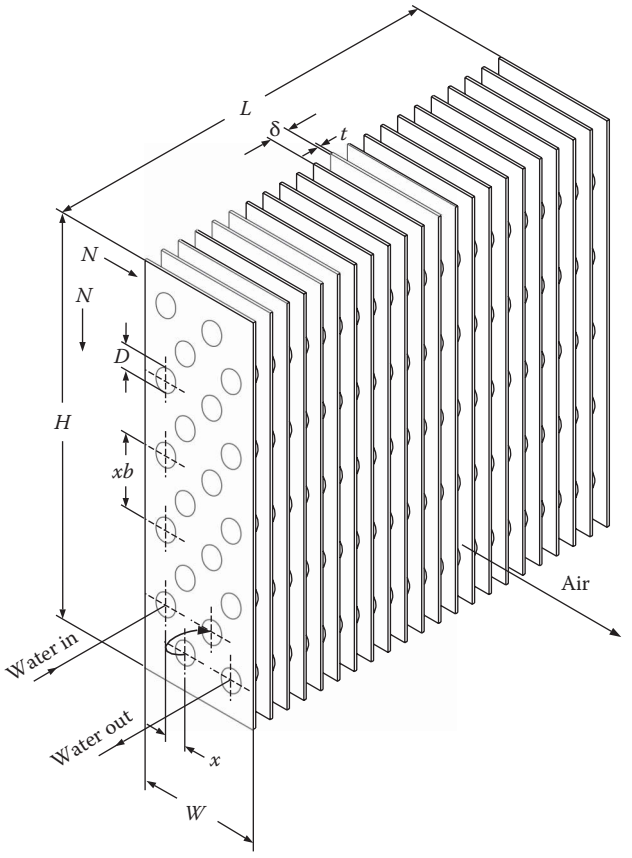

FIGURE 4.27.8 Schematic of compact heat exchanger 2. Dimensions are $L=12$ in., $D=0.392$ in., $t=0.006$ in., $x_a=0.866$ in., $x_b=1$ in., $N_r=4$, $N_c=5$, 0.071 in. $< \delta <$ 0.0250 in.

D is the outside diameter of the tube, δ is the fin spacing, and μ_a is the dynamic viscosity of air. Also x_a and x_b are the two tube-center distances shown in Figure 4.27.8, D_h is the hydraulic diameter, t is the fin thickness, and σ_f is the ratio of the free-flow area of air to the frontal area.

The McQuiston (1978a) correlations are

$$j_s = 0.0014 + 0.2618\mathrm{Re}_D^{-0.4}\left(\frac{4}{\pi}\frac{x_a}{D_h}\frac{x_b}{D}\right)^{-0.15} f_s(\delta) \tag{4.27.10}$$

$$j_t = 0.0014 + 0.2618\mathrm{Re}_D^{-0.4}\left(\frac{4}{\pi}\frac{x_a}{D_h}\frac{x_b}{D}\right)^{-0.15} f_t(\delta) \tag{4.27.11}$$

where

$$f_s(\delta) = \begin{cases} (0.9 + 4.3\times10^{-5}\,\mathrm{Re}_\delta^{1.25})\left(\dfrac{\delta}{\delta - t}\right)^{-1} & \text{dropwise condensation} \\ 1.0 & \text{dry surface} \\ 0.84 + 4.0\times10^{-5}\,\mathrm{Re}_\delta^{1.25} & \text{film condensation} \end{cases} \tag{4.27.12}$$

and

$$f_t(\delta)=\begin{cases}(0.80+4.0\times10^{-5}\,\mathrm{Re}_\delta^{1.25})\left(\dfrac{\delta}{\delta-t}\right)^4 & \text{dropwise condensation}\\ 1.0 & \text{dry surface}\\ (0.95+4.0\times10^{-5}\,\mathrm{Re}_\delta^{1.25})\left(\dfrac{\delta}{\delta-t}\right)^2 & \text{film condensation}\end{cases} \tag{4.27.13}$$

The ranges of validity are number of rows $N_r=4$, $100 < \mathrm{Re}_D < 4000$, 3/8 in. $< D <$ 5/8 in., 1 in. $< x_b <$ 2 in., 4 fins/in. $< l/\delta <$ 14 fins/in., and 200 ft/min $< V <$ 800 ft/min. Gray and Webb (1986) used these and other data to find

$$j_s = 0.14\mathrm{Re}_D^{-0.328}\left(\frac{x_b}{x_a}\right)^{-0.502}\left(\frac{\delta-t}{D}\right)^{0.0312} \tag{4.27.14}$$

for the dry-surface conditions in the ranges $500 < \mathrm{Re}_D < 24{,}700$, $1.97 < x_b/D < 2.55$, $1.97 < x_a/D < 2.58$, $0.08 < (\delta-t)/D < 0.64$, and $1 < N_r < 8$. Either correlation, i.e., Equations 4.27.10 and 4.27.11 or Equation 4.27.14, can be used to determine the total heat transfer rates under the dry-surface conditions, while those in Equations 4.27.10 and 4.27.11 are for the sensible and total heat transfer rates under wet-surface conditions.

Several ANN configurations were tried, and the best results were given by the fully connected 5-5-3-3 ANN configuration shown in Figure 4.27.9. The five input nodes correspond to the variables: inlet air dry bulb temperature $T_{a,db}^{in}$, inlet air wet bulb temperature $T_{a,wb}^{in}$, inlet water temperature T_w^{in}, the airflow Reynolds number Re_D, and the fin spacing δ. The three output nodes correspond to j_s, j_t, and the total heat transfer rate $\dot{Q}_t$. The j factors were not necessary for the heat rate predictions and were computed merely for the purpose of comparison. All variables were normalized in the same way as in the previous example. The two j factor predictions can be directly compared with the computed data given by McQuiston (1978a). A total of 327 experimental runs were reported by McQuiston (1978b), of which 117 runs were associated with observed dropwise condensation, 91 were related to dry-surface conditions, and the remaining 119 were with filmwise condensation. The data were analyzed in two different ways. First, each of the three surface conditions was analyzed separately to train three ANNs using the respective data sets. Second, the entire 327-run data sets were combined to train an ANN. The purpose here was to determine whether the network based on training data separated by some physical condition would perform better than another trained with the combined data set.

The errors obtained by these four ANNs are shown in Table 4.27.2. The errors indicated are root-mean-square values of the percentage difference between the predicted and experimental data for 800,000 training cycles. For dropwise condensation, the error is of the order of 3.3% in j_s, 3.9% in j_t, and only 1.4% in the total heat transfer rates. From the discussions in the previous example, this result is somewhat expected, since both j_s and j_t are not expected to include all the essential physics, while $\dot{Q}_t$, being a physical quantity itself, the ANN better recognizes the true relationship between $\dot{Q}_t$ and the physical input data. It is seen that this is also true for the dry surface and the surface with film condensation. It is also of interest to note that the ANN gives much better prediction for dry surfaces than for wet. This is perhaps also expected, since the physical phenomena with condensation are more complex. On the other hand, when the ANN is trained by the entire set of experimental data without separating them according to surface conditions, the errors all increase. This indicates that the ANN has more difficulty in differentiating between the different physics involved. However, it must be added that an error of 5% or less can still be counted as a relatively good prediction. It is even more remarkable to note that the predictions for $\dot{Q}_t$, which is what the user of the information is ultimately interested in, have errors only of the order of 2.7%.

Table 4.27.3 shows comparisons between the predictions of ANNs and the dimensionless correlations given earlier for j_s. Table 4.27.4 is a similar comparison for j_t. It is seen that despite the fact that

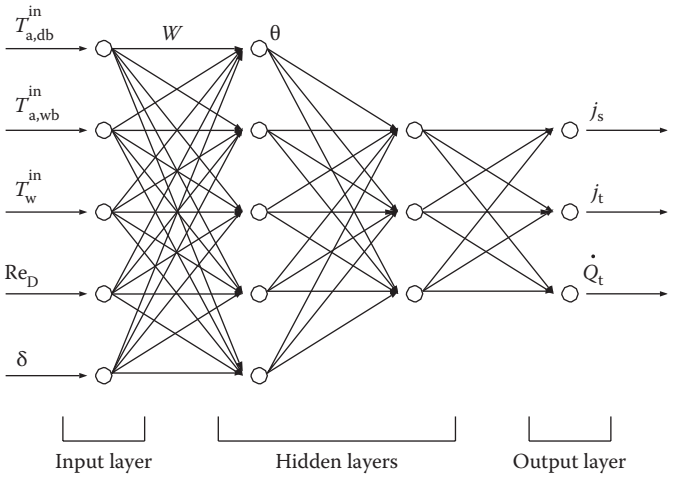

FIGURE 4.27.9 Schematic of a 5-5-3-3 ANN for heat exchanger 2.

TABLE 4.27.2
Percentage Errors in j_s, j_t, and $\dot{Q}_t$ for Heat Exchanger 2

Surface	j_s	j_t	$\dot{Q}_t$
Dropwise condensation	3.32	3.87	1.446
Dry surface	1.002	1.002	0.928
Filmwise condensation	2.58	3.15	1.960
Combined	4.58	5.05	2.69

the Gray and Webb (1986) correlation indeed performs better than those of McQuiston (1978a) under the dry-surface conditions, all the correlation predictions are much worse than those from the ANN. Actual comparisons of the j_t factors under both wet-surface conditions between the McQuiston correlations and the ANN results are shown in Figures 4.27.10 and 4.27.11, where the superscripts p and e on the j factors refer, respectively, to ANN predictions and the experimental data. This example shows that the ANN is able to predict the total heat transfer well, even for the fairly complex case of a heat exchanger in which there may be condensation phase change on the air side.

Separation of Data for Training and Testing

One of the main issues during the implementation of the ANN model of a complex system is the choice of the minimum number of training data sets and runs, since the goal is to build the best possible model over the widest parameter range of operating conditions. The data can be separated in different ways into training and testing; the usual approach is to use a fraction of the total available data during each stage of the process. This has two disadvantages: first, the data set available for training is smaller than the total amount of information available so that the predictions are not the best possible, and second, if the training data do not include the extreme values, the predictions fall in the extrapolated range and are hence less reliable. The issue of extrapolation and its impact on the reliability of ANNs, as modeling tools of complex systems, has been studied by Pacheco-Vega et al. (2001b) for the case of limited experimental data in heat exchangers.

The case of separating the data for training and testing is analyzed next by considering the data reported by McQuiston (1978b) for the heat exchanger 2 discussed in the previous section. Additional details are in Pacheco-Vega et al. (2001a). The ANN chosen is a 5-5-3-1 configuration,

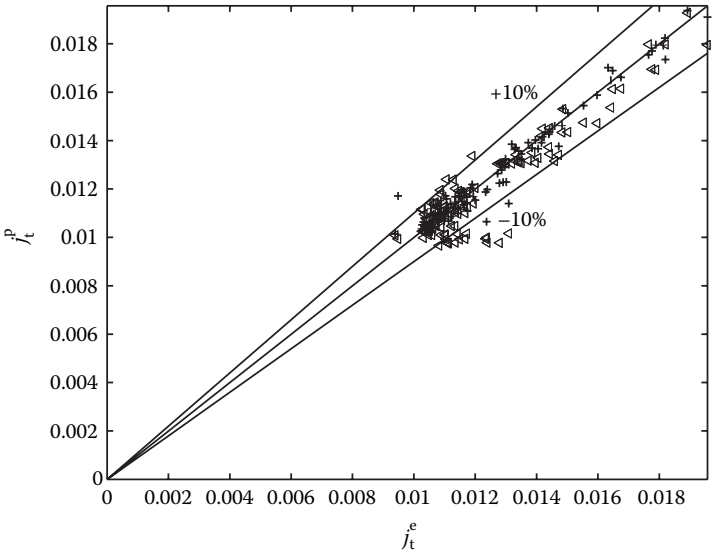

FIGURE 4.27.10 Experimental vs. predicted j_t for heat exchanger 2 with dropwise condensation. ANN: (+); McQuiston: (◁).

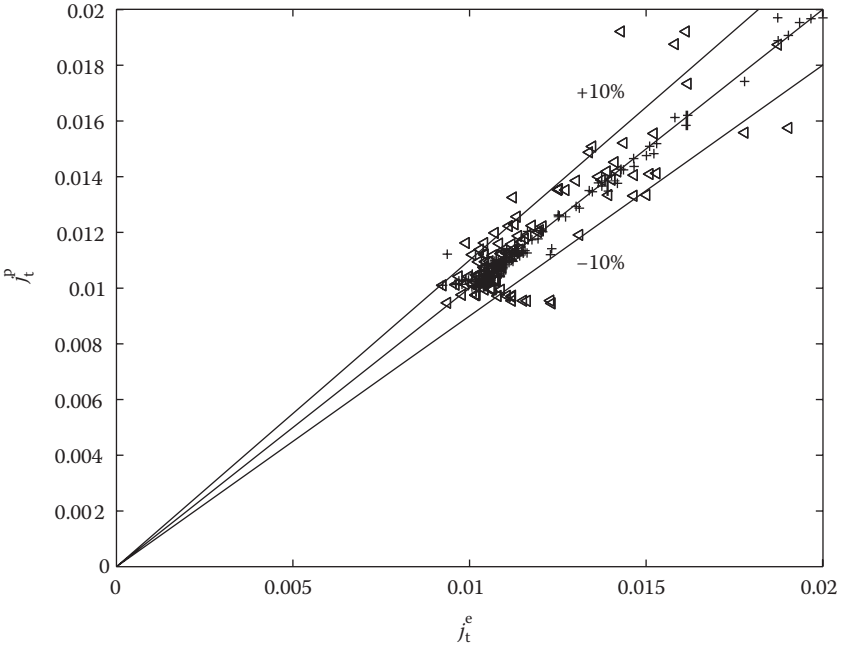

FIGURE 4.27.11 Experimental vs. predicted j_t for heat exchanger 2 with film condensation. ANN: (+); McQuiston: (◁).

similar to the one schematically shown in Figure 4.27.9—the only difference being that the fourth layer has only one output, the heat rate. The procedure is outlined as follows:

- The $M = 327$ available sets of experimental data are first randomly sorted to avoid introducing any bias in the selection process and their order is then fixed.

TABLE 4.27.3
Percentage Errors in j_s Predictions for Heat Exchanger 2

Surface	ANN	McQuiston	Gray and Webb

Dropwise condensation	3.87	7.55	—
Dry surface	1.002	14.57	11.62
Filmwise condensation	3.15	14.98	—
Combined	5.05	—	—

- From the set, only the first M_a are chosen for training and the rest $M_b = M - M_a$ kept aside. The fraction used for training is defined as $P_s = M_a/M$.
- For the M_a data sets, the rms values of the relative output errors

$$S_{\dot{Q}} = \left[\frac{1}{M_a} \sum \left(\frac{\dot{Q}^p - \dot{Q}^e}{\dot{Q}^e} \right)^2 \right]^{1/2}$$

  are calculated at each cycle of the training process in order to evaluate the performance of the network and to update the weights. The number of cycles providing a reasonably low level of error, $S_{\dot{Q}}$, in the training process is fixed for the entire process.
- After the training is finished, three different data sets are then tested: (1) the same M_a data that were used for training are tested, (2) the M_b data left out of the training process are tested, and (3) the complete M data sets are tested. In each case, the percentage error between the predicted and experimental values is calculated, being E_a, E_b, and E, respectively.
- Finally, without reordering the M data sets, the procedure described here is repeated for different values of the percentage of splitting, i.e., $P_s = 10\%$, 20%,…, 90%, 95%, and 99%.

Note that the exact shape of the error vs. P_s curve depends on the initial order of the data sets, but some general features can be identified. To remove the influence of the initial random ordering of the data sets, and get the overall characteristics of the error, the curves are calculated ten times and the results averaged.

Figure 4.27.12 shows the average error in prediction calculated in the three different ways described earlier as a function of the training fraction P_s. The error bars illustrate the standard deviations, σ_a, σ_b, and σ corresponding to E_a, E_b, and E, respectively, that resulted from the 10 different curves. From this figure, it can be seen that as P_s increases, on average, the prediction errors for all three cases asymptote to approximately the same values. For any P_s, E_a is always small since the training and testing data are identical. At small values of P_s, E_b and E are both very large indicating that an insufficient fraction of the data has been used for training. As M_a is increased, better predictions are obtained. Beyond $P_s = 60\%$ approximately, the differences in the prediction errors for all

data sets are small. The same trend is observed for σ_s, which become smaller as $P_s \rightarrow 100\%$, indicating that the prediction is somewhat insensitive to the initial random ordering of the data. Near the end, however, at $P_s = 99\%$ for example, σ_b becomes large again because now M_b is very small and the error depends greatly on the data set that is picked for testing. It is thus possible to deduce that, in this case at least, if more than 60% of the available data is used for training, the results will be essentially the same. However, it is always better to use all of the available data for training, and use the same for testing. This gives us the best prediction over the widest parameter range.

Thermal System Dynamics and Control Using ANNs

In many practical thermal systems, the operations are time dependent. A dynamic situation occurs either when a disturbance is introduced into the system or when the conditions change with time; in either case, the thermal system will respond in a time-dependent manner. In many instances, there is a need to quantitatively know what these responses may be. Ideally, this calls for dynamic system models that relate the outputs to the inputs. Unfortunately, again because of the complexity of practical thermal systems, only very few attempts at developing such models have been made and only for simple cases (Cohen and Johnson, 1956; Mozley, 1956; Thal-Larsen, 1960; Gartner and Harrison, 1965; Yamashita et al., 1978; Schmidt and Willmott, 1981; Spiga and Spiga, 1992). This is understandable since modeling is difficult even in static cases. On the other hand, in many applications, such as HVAC systems and industrial thermal processes, the control strategy is often based on the dynamic system or process models to achieve robustness and optimality. The usual PID controllers are simply not sufficient, as they often require manual supervision. Another difficulty with the dynamic thermal system models, even in those cases where they do exist, is that they are incapable of accommodating the degradation of system components over time and, hence, they may become less adequate as time goes on. One good example is the effect of fouling in heat exchanger pipes. Interestingly enough, ANNs can offer solutions to all these problems. A broad discussion on ANN-based dynamic system modeling techniques has been given by Ayoubi (1997).

Dynamic Model

The central issue in developing ANN-based dynamic models for thermal systems is the addition of time as a variable for both training and predictions.

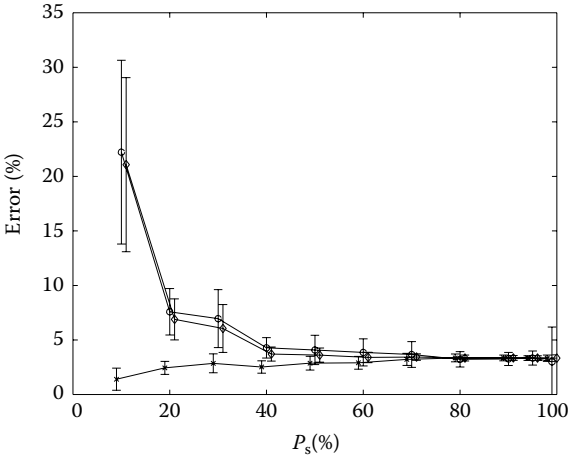

FIGURE 4.27.12 ANN prediction errors vs. percentage of data used for training; –×– error E_a using training data; –o– error E_b using data not used for training; –◇– error E using complete data. Error bars indicate standard deviations. The E_a and E curves have been shifted horizontally by –1% and 1%, respectively, for clarity.

This can be done in two different ways as shown in Figures 4.27.13. In the first methodology, depicted in Figure 4.27.13a, we train the ANN in the same way that we train it for steady state problems, where $f(t)$ corresponds to a time-dependent forcing function and t is time, which is included as an additional input variable. The main problem with using this method to predict the dynamic behavior of a system is that time needs to remain within the range used for training the ANN. Extrapolation with respect to the training data lowers the accuracy of the prediction due to activation-function saturation. The other method, shown in Figure 4.27.13b, differs with respect to the first one in the fact that no explicit information about time is provided to the network. In this methodology, used in Diaz et al. (1998a,b, 1999a, 2000a,b, 2001b,c), values of the variables at time t are provided as inputs to the network and the values of the same variables at time $t+\Delta t$ are used as the outputs. The time step Δt does not need to stay constant over time, though it should be chosen so that incremental values of all the variables remain small. The trainings are successively carried out over as many Δts as needed to cover the entire time horizon. Once trained, the ANN can predict the values of the input variables for an instant Δt later. For higher order dynamical systems, the past information at several previous instants in time might be required in order to obtain an accurate prediction with the ANN.

For a demonstration of this method, the heat exchanger 1 situation discussed earlier is again considered. The ANN to be trained had a 3-5-2 configuration. Dynamic data were obtained by varying the water inlet temperatures by changing the heater settings while keeping the other variables, the mass flow rates of both fluids and the air inlet temperature, all constant. The input to the ANN were $T_w^{in}(t)$, $T_a^{out}(t)$, $T_w^{out}(t)$ and the output were $T_a^{out}(t+\Delta t)$ and $T_w^{out}(t+\Delta t)$. Training data were obtained from experiments in which the water inlet temperature was varied in small increments of 5.56°C from 32.2°C up to 65.6°C. For testing the predictions of the ANN, three additional sets of experiments were performed.

1. The system was first brought up to a temperature of 60°C and the heater was then set at 37.8°C. The resulting sudden decrease of the air and water outlet temperatures is shown in Figure 4.27.14. The ANN predictions are excellent. The slight oscillations in the measured water outlet temperatures were likely due to local turbulence in the flow.
2. In the second set of experiments, the water inlet temperature was ramped up manually. The corresponding results are in Figure 4.27.15, which shows the same excellent prediction by the ANN.
3. The final set of experiments was designed to observe if the ANN could predict the system behavior when an input variable different from the one in the training data is used. The changes in the air and water outlet temperatures were measured when the mass flow rate of air was first increased to a value greater than the one in the training data, and then decreased to a lower value. The results are shown in Figure 4.27.16 where the decrease is

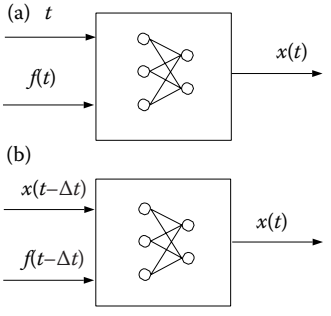

FIGURE 4.27.13 Two training methods for dynamic problems.

seen around $t = 10$ s, and the increase at $t = 120$ s. The predictions, as expected, are not very good. It is remarkable, though, that the ANN approach still predicts the correct overall trends and that the errors are small.

Dynamic Control

In the usual dynamic control systems for industrial processing and HVAC systems, the common practice is to use a feedback control involving a system model, sometimes known as the plant model, in conjunction with a standard PID controller. Such a control system, unfortunately, requires constant attention and manual supervision to achieve optimality. Although there are automatic tuning algorithms available (Zhuang and Atherton, 1993), these controllers still require a certain level of human supervision. As previously discussed, there are many advantages in

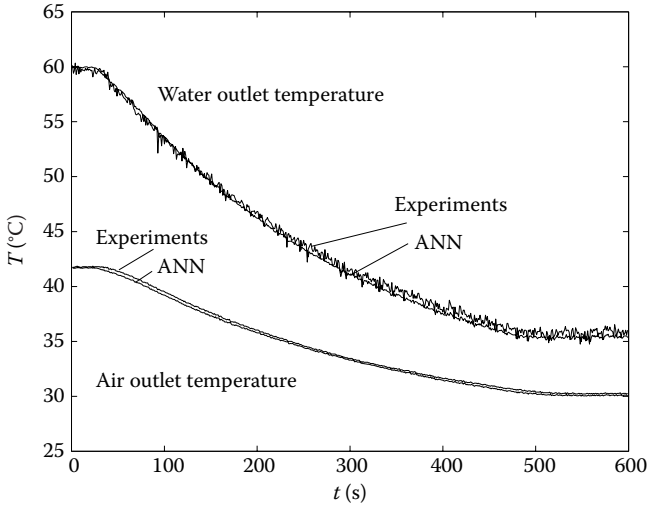

FIGURE 4.27.14 ANN dynamic prediction for sudden cooling.

using a plant model based on ANNs; control strategies have been developed along these lines. There is the technique of direct inverse control that utilizes an inverse system model (Hunt et al., 1992), which is then cascaded with the controlled system so that the composed system results in an identity mapping between the desired response and the controlled system output. Thus, the network acts directly as the controller in such a configuration. An extension to this strategy that incorporated an orthogonal weight estimator routine was given by Pican et al. (1998). Then there is the technique of internal model control (IMC) (Psichogios and Ungar, 1991; Hunt et al., 1992) where a forward system and inverse model are used directly as elements within the feedback loop. The system model is placed in parallel with the real plant, and the difference between the system and model outputs is used as a feedback signal, which is then processed by a controller subsystem in the forward path. In the IMC strategy, a separate linear filter is often introduced to provide desirable robustness and tracking response to the closed-loop system. The IMC has been widely applied in process-control systems.

A third dynamic-control strategy is known as predictive control in which an ANN model predicts the future plant response over the specific time horizon (Hunt et al., 1992; Ayoubi, 1997; Jeannette et al., 1998). The predictions supplied by the network are passed to a numerical optimization routine, which attempts to minimize a specified performance criterion in the calculation of a suitable control signal. One further possibility is to train another ANN to mimic the action of the optimization routine. The advantage here is that the outer loop consisting of the plant model and the optimization routine is no longer needed when training is complete, thus greatly simplifying the control system operation. Finally, mention should be made of the adaptive control strategies (Brown and Harris, 1994; Narendra and Mukhopadhyay, 1996), which have been under very active development in the past decades, and have specific important applications in the area of thermal systems.

ANNs with IMC

IMC consists of having a model of a plant M in parallel with the real system P, as shown in Figure 4.27.17. The difference between the outputs of P and M is used as the feedback for a controller C that is located in the forward path of the control scheme. The training procedure of such a control system using ANNs has two steps.

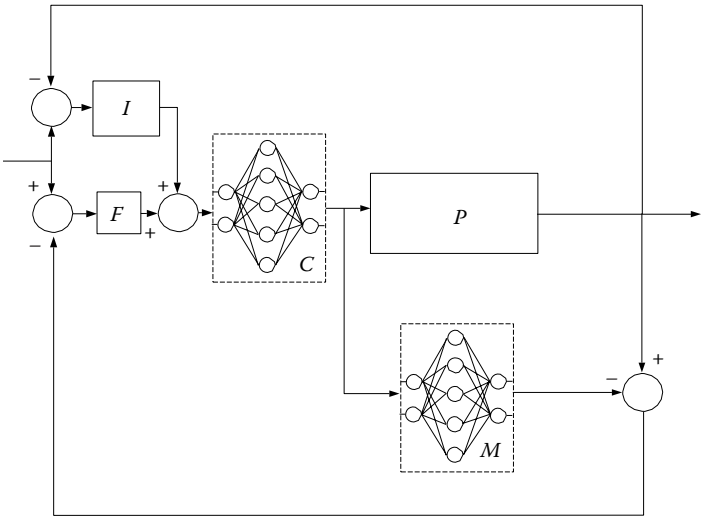

FIGURE 4.27.17 General IMC structure plus integral control.

- We first train an ANN to learn the dynamics of the process by providing known input and output data sets. This is *M*.
- Then, another ANN is trained to learn the inverse dynamics of the process and to function as a nonlinear controller *C*. It is trained to invert the model *M* instead of trying to learn the inverse dynamics of the actual process. By training in this way, we make sure that we invert the steady state gain of the model so that the offset can be eliminated.

For our experiments, we consider the heat exchanger 1 configuration described earlier, where we trained the plant model *M* with information related to $T_{\text{out}}^{\text{a}}$ and $\dot{m}_a$. These data were obtained by taking measurements of the system subject to small increments in the set point temperature. The controller *C* is obtained by using a synthetic signal, which is the desired value of the air speed. This signal is supplied to *M* to give a certain value of $T_{\text{out}}^{\text{a}}$, which is then supplied as the input to the controller. The training algorithm adjusts the weights of *C* to reduce the error between the synthetic signal and the controller output.

Since the ANNs only provide an approximation to the behavior of the actual plant, we used a one parameter filter *F*, following the suggestion of Nahas et al. (1992), preceding the controller in the forward path to account for plant–model mismatch. An integral control path *I* was also added in parallel with *F* to help obtain an offset-free controlling action. There are two constants that have to be chosen by trial and error, the first for the integral controller and the other for the filter. As a large percentage of the controllers that are currently being used correspond to proportional-integral (PI) and PID schemes, standard PI and PID controllers were used to compare the performance with the ANN controller.

Comparison with PID: Step Change in Set Point

The first test was designed to observe the performance of the controller subject to a step change in the value of the set point temperature $T_{\text{out}}^{\text{a}}$. The system was taken up to a point in which the outlet air temperature was near 32°C. The controller was turned on for 40 s until the temperature remained within a band of ±0.1°C. The set point was then increased to 36°C. Both controllers performed well and behaved in a similar way when controlling the system at large values of air speed. However, on approaching the lower end of air speeds, the system became very hard to control for two reasons. One is the effect of the delay involved, and the other is the high sensitivity of $T_{\text{out}}^{\text{a}}$ to $\dot{m}_{\text{a}}$ at low air speeds. This test brings the system from a very easy-to-control point at 32°C to a hard-to-control

state at 36°C. The results are shown in Figure 4.27.18. It is seen that although the ANN controller has a slightly larger overshoot, it presents less oscillations and it is able to bring the system to a stable condition. On the other hand, both PI and PID controllers oscillate significantly more and are not able to bring the system to a steady state, but keep T_{out}^{a} within 36 ± 0.1°C by constantly adjusting the air speed. Thus, the ANN controller uses less energy and is more stable by keeping the system steady instead of generating an oscillatory controlling action.

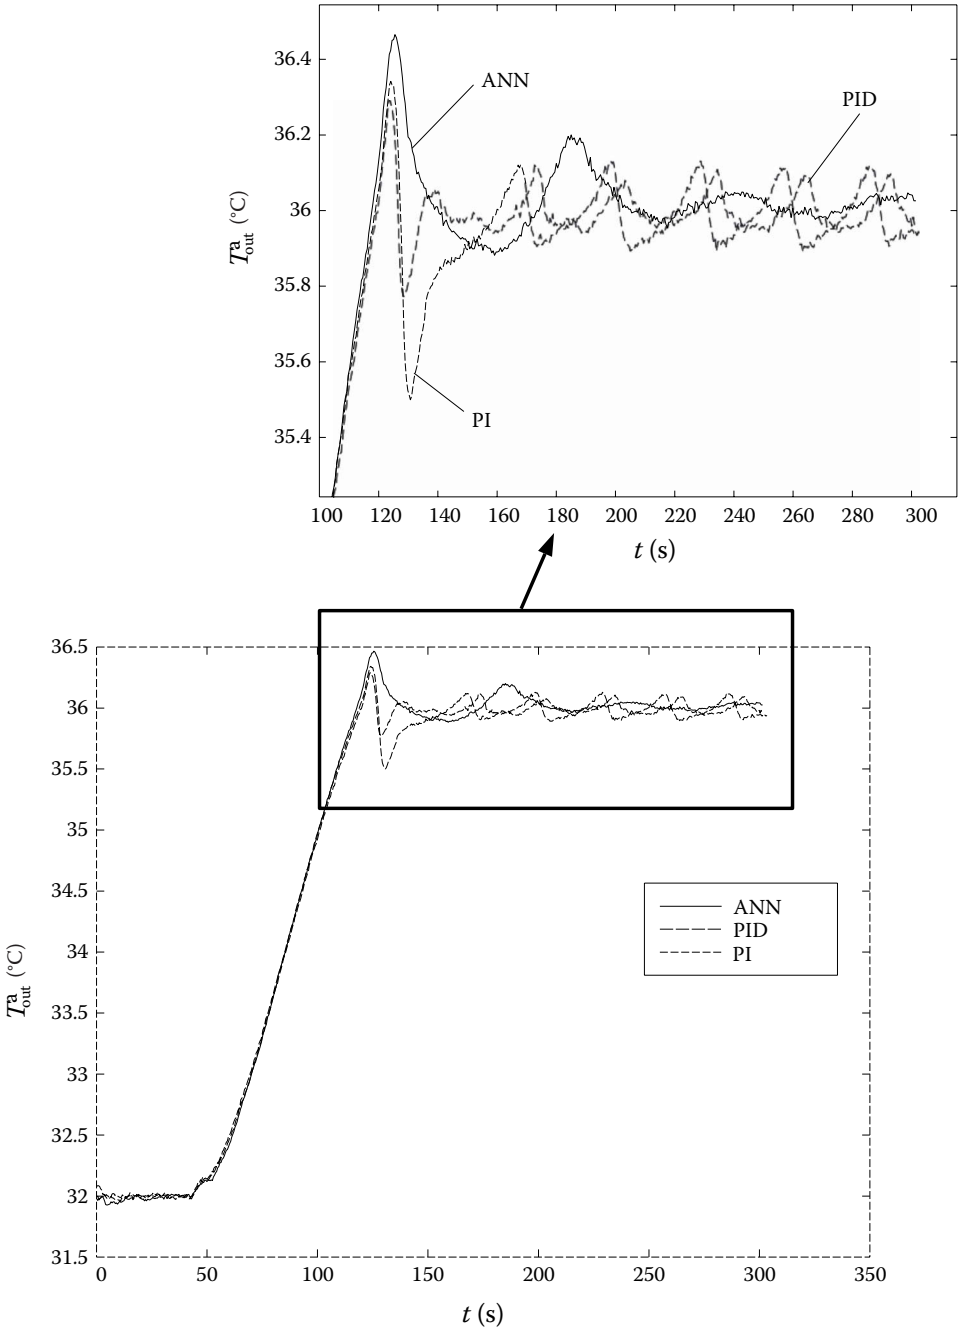

FIGURE 4.27.18 Change in the setpoint temperature. —, ANN; – –, PID; ---, PI.

Comparison with PID: Disturbance Rejection

We now analyze the disturbance rejection capabilities of the control system. In this test, a disturbance is applied to the plant in the form of a pulse in the following way. Once the system is at steady state operation, one of the valves on the water side was completely shut down for a short time. Once again, the controllers were tested at a state that was hard to control, i.e., with $T^{a}_{out} = 36°C$ and a low air speed. The PI controller showed the worst performance and is left out of the comparison shown in Figure 4.27.19. Figure 4.27.19a shows the change in the water flow rate, which is the disturbance itself; the water flow is shut down between $t=40$ s and $t=70$ s. After the disturbance pulse, the controller brings the system back to steady state. Figure 4.27.19b,c shows the change in T^{a}_{out} and $\dot{m}_a$, respectively. Once again it can be seen that the PID is not able to bring the system to a steady state condition while the oscillations of the ANN controller are quickly damped out. It can be seen in Figure 4.27.19c that the PID controller, in trying to control the temperature, generates an oscillatory air speed.

Neurocontroller as an Iterated Map

For a static ANN, the input and output variables are time-independent. In a digitally controlled time-dependent system, however, the variables are functions of time, which are sampled periodically with a constant time interval Δt. Here we are interested in a control methodology that brings the single-input–single-output thermal system to a given steady state. We are thus interested in a single variable to be controlled, $y(t)$, and a single control variable, $x(t)$, where t is time. A trained ANN can be used to predict $y^{i+1}=y((i+1)\Delta t)$ knowing $y^{i}=y(i\Delta t)$ if the system satisfies an unknown

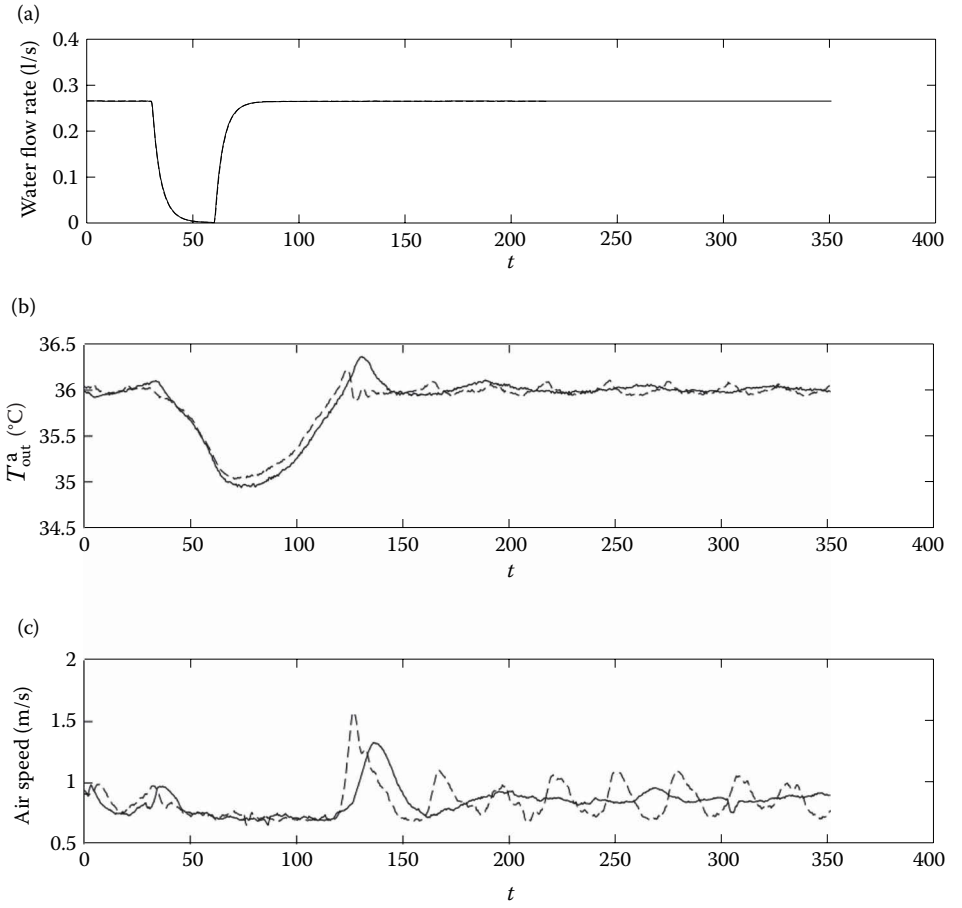

FIGURE 4.27.19 Disturbance rejection. —, ANN; – –, PID.

differential equation of first order. If the equation is of higher order, one can, in principle, include sufficient time derivatives of a vector version of $y(t)$ to reduce all scalar equations in its components to first order. In practice, this is difficult since analog signals corresponding to derivatives may not be readily available. However, a finite difference approximation of the derivatives shows that, provided Δt is small enough, this is equivalent to adding information about y at previous instants in time, i.e., y^{i-1}, y^{i-2}, etc., as many as needed. Previous values of $x^i = x(t)$ may also be needed for systems of higher order. A memory unit, which is part of the computerized control system, stores y^i and x^i to provide information on previous instants to the ANN.

A vector $\mathbf{u}$ of dimension n will be defined such that on the input side of the ANN $\mathbf{u}^i = (y^{i-n+1}, y^{i-n+2}, \ldots, y^{i-1}, y^i)$, and on the output side $\mathbf{u}^{i+1} = (y^{i-n+2}, y^{i-n+3}, \ldots, y^i, y^{i+1})$. The overall effect of the control system is that of a nonlinear map

$$\mathbf{u}^{i+1} = \mathbf{F}(\mathbf{u}^i) \tag{4.27.15}$$

For closed-loop operation, a controller generates the control variable $x(t)$. The controller is modeled by

$$x^i = g(y^i, y^{i-1}, \ldots, x^{i-1}, x^{i-2}, \ldots, y^*) \tag{4.27.16}$$

and the ANN by

$$y^{i+1} = f(y^i, y^{i-1}, \ldots, x^i, x^{i-1}, x^{i-2}, \ldots) \tag{4.27.17}$$

where y^* is a reference value of the controlled variable. Once again the map represented by Equation 4.27.15 applies where $\mathbf{u}^i = (y^{i-n+1}, y^{i-n+2}, \ldots, y^{i-1}, y^i, x^{i-m+1}, x^{i-m+2}, \ldots, x^{i-1}, x^i)$.

Consider the nonlinear map Equation 4.27.15 for open-loop control, or a similar map obtained by using Equations 4.27.16 and 4.27.17 in closed-loop control. The fixed points $\bar{\mathbf{u}}$ map to themselves and are hence solutions of $\bar{\mathbf{u}} = \mathbf{F}(\bar{\mathbf{u}})$. A nonlinear map can have more than one fixed point with different stability characteristics. To study the stability of a given fixed point, the map is linearized around it to get

$$\mathbf{u}^{i+1} - \bar{\mathbf{u}} = \mathbf{J}(\mathbf{u}^i - \bar{\mathbf{u}})$$

where $\mathbf{J}$ is the Jacobian of $\mathbf{F}$ evaluated at the fixed point. The spectral radius of $\mathbf{J}$, denoted by r, is the largest of the absolute values of its eigenvalues. If $r < 1$, the images of the map converge to the fixed point and it is stable; otherwise it is unstable (Hale and Kocak, 1991).

Closed-Loop Control

The control strategy used for closed-loop operation is based on internal model control (Hunt et al., 1992). It consists of a model M of a plant in parallel with the plant P itself, as shown in Figure 4.27.17. The difference between the outputs of P and M is used as the feedback for a controller C that is located in the forward path of the control scheme. The training procedure of such a control system using ANNs has two steps. An ANN is first trained to learn the dynamics of the process by providing known input and output data sets; this is M. Then, another network C is trained to learn the inverse dynamics of M to function as a controller. Further details of the control scheme are in Diaz et al. (2001b).

In the experiments, M was trained with information related to $y(t) = T_{\text{out}}^{\text{air}}(t)$ and $x(t) = U(t)$. The data were obtained by taking measurements of the system subject to small increments in the set point temperature. The controller C was obtained by using a synthetic signal, which is the desired U. This was supplied to M to give a y, which was the input to the controller. The training algorithm adjusted the weights of C to reduce the error between the synthetic signal and the controller output.

Since the ANNs only provide an approximation to the behavior of the actual plant, a filter F (Diaz et al., 1999a, 2001a, 2004) was used preceding the controller in the forward path to account for plant–model mismatch. An integral control path I was also added in parallel with F to help obtain an offset-free controlling action.

The controller obeys the relationship

$$x^i = g(x^{i-2}, x^{i-1}, y^{i-2}, y^{i-1}, y^i, T_{\text{ref}})$$

and the model

$$y^{i+1} = f(x^{i-2}, x^{i-1}, x^i, y^{i-2}, y^{i-1}, y^i)$$

where $x(t) = U(t)$. T_{ref} is the desired set point temperature of $T_{\text{out}}^{\text{air}}$. Thus, the map is

$$\begin{aligned} u_1^{i+1} &= u_2^i \\ u_2^{i+1} &= g(u_1^i, u_2^i, u_3^i, u_4^i, u_5^i, T_{\text{ref}}) \\ u_3^{i+1} &= u_4^i \\ u_4^{i+1} &= u_5^i \end{aligned} \tag{4.27.18}$$

$$u_5^{i+1} = f(u_1^i, u_2^i, g(u_1^i, u_2^i, u_3^i, u_4^i, u_5^i, T_{\text{ref}}), u_3^i, u_4^i, u_5^i) \tag{4.27.19}$$

where $\mathbf{u}^i = (x^{i-2}, x^{i-1}, y^{i-2}, y^{i-1}, y^i)$. Equation 4.27.18 must be computed before Equation 4.27.19. The Jacobian of this map is

$$\mathbf{J} = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 \\ \mu_1 & \mu_2 & \mu_3 & \mu_4 & \mu_5 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ \lambda_1 & \lambda_2 & \lambda_3 & \lambda_4 & \lambda_5 \end{bmatrix}$$

where $\mu_k = \overline{\partial g / u_k^i}$.

To illustrate the difference between stable and unstable behaviors of the system, two different controllers, C_1 and C_2 with $r < 1$ and $r > 1$ respectively, were trained. The weights for the stable controller were found using the stabilization algorithm proposed here. The reference temperature was chosen to be $T_{\text{ref}} = 34.0°\text{C}$. The flow rates and temperatures in the test facility were first adjusted to get $T_{\text{out}}^{\text{air}}$ as close to T_{ref} as possible, and then the controller was turned on. Figure 4.27.20 shows the response of the two controllers. For the stable controller C_1, $T_{\text{out}}^{\text{air}}$ oscillates a few times but eventually goes to T_{ref}. On the other hand, for otherwise identical conditions, controller C_2 takes the system to the maximum air speed, $U_{\max}$, where it remains without accomplishing the control task.

Additional Applications of ANNs in Thermal Engineering

In the past, applications of ANN to engineering problems have been attempted in structural engineering and engineering mechanics (Zeng, 1998). Tentative studies of applying ANN to problems in thermal systems have a relatively short history. With the exception of neural network systems and control systems applied to HVAC systems, the studies have been somewhat sporadic and in only some distinct areas of application. For heat transfer data analysis and correlation, an ANN-based

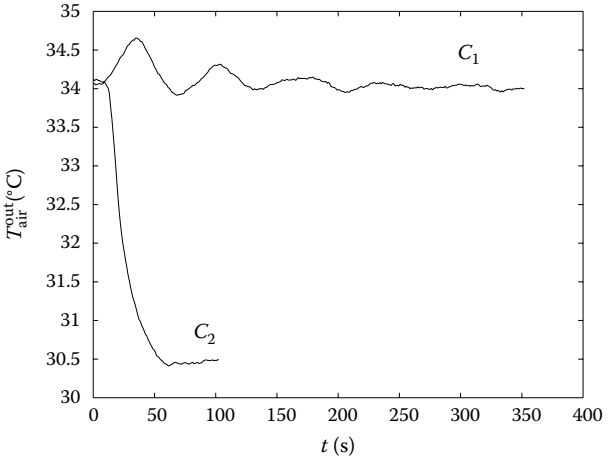

FIGURE 4.27.20 Performance of controllers C_1 and C_2, closed-loop control.

methodology was proposed by Thibault and Grandjean (1991) and a similar methodology was introduced by Jambunathan et al. (1996) to predict coefficients of heat transfer in convective-flow systems using liquid crystal thermography. Both steady and unsteady heat conduction problems were treated by ANN in studies by Gobovic and Zaghloul (1993), Yentis Jr. and Zaghloul (1994), and Kuroe and Kimura (1995). Kaminski et al. (1996) gave an interesting description of the thermal deterioration process based on a combined ANN and GA analysis. An ANN was also used to identify the location and strength of unknown heat sources by sparse temperature measurements (Momose et al., 1993). In addition, an ANN-based attempt was made to predict measured intrinsic thermodynamic properties (Normandin et al., 1993), including those of new refrigerants (Sozen et al., 2010).

ANN analyses have also been utilized to study and predict the performance of specific thermal devices and systems. Good estimates of the thermal storage loads and the dynamic system operation of typical thermal storage systems were obtained by Ferrano and Wong (1990) and Ito et al. (1995). Heat exchanger performance and control were studied by Diaz et al. (1996, 1998b, 1999b), Lavric et al. (1994, 1995), Bittanti and Piroddi (1997), Pacheco-Vega et al. (2001a,b) and, more recently, Ruiz-Mercado et al. (2009). Several industrial applications of ANN were also demonstrated, in a fluidized-bed dryer (Zbicinski et al., 1996), in a liquid-sodium reflux-pool boiler solar receiver (Fowler et al., 1997), in a steel annealing furnace (Pican et al., 1998), and in the design of a chemical injection-system retrofit fuzzy control system in a thermal power plant (Moon and Cho, 1996). Other specific applications include manufacturing and materials processing involving microelectronic manufacturing (Mahajan and Wang, 1993), a coordinate grinder (Yang et al., 1995), rapid thermal processing control (Fortuna et al., 1996), sensors and sensor analysis involving thermal image processing (Naka et al., 1993), and blast furnace probe temperatures (Bulsari and Saxin, 1995).

On the other hand, there is a coherent body of published literature dealing with the analysis and control of HVAC systems. Such systems are generally quite large and rather complex, and robust optimal control is essential in assuring their satisfactory operation. In current practice, many HVAC control processes utilize the standard PID control strategy, which, however, is not always autonomous and often requires constant manual supervision in order to achieve optimal control. Interest in the application of ANNs to the control of HVAC systems is due to its high potential of achieving an improvement. Since the appropriate theoretical dynamic model of the HVAC system is difficult to obtain, the role of ANN is to provide such a model from existing experimental data on the system operation. Several studies are available dealing with the modeling of HVAC systems, including ANN-based nonlinear HVAC model computations (Mistry and Nair, 1993), models for building energy use and HVAC system identification (Kreider et al., 1992, 1995; Chow and Teeter, 1997),

and system models for district heating (Waldemark et al., 1992). The first proof of the possibility of utilizing an ANN model as a part of the control system was given by Curtiss et al. (1993), and subsequent studies showed how the control systems including the ANN models could be implemented (Alessandri et al., 1994; Carriere et al., 1994). It is interesting to note in an experimental study how well one such ANN-based control system performed in a simple hydronic HVAC system, compared to the performance of the standard PID control (Jeannette et al., 1998).

Adams et al. (1990) optimized the protection of feedwater heaters. Leitch and Quek (1992) worked on an architecture for integrated process supervision. Kos (1993) took an ANN approach to thermal placement in power electronics. Terry and Himmelblau (1993) did data rectification and gross error detection in a steady-state process via ANNs. Huang and Nelson (1994) also applied this technique to determine the delay time for a HVAC plant to respond to control actions. Ding and Wong (1990) controlled a simulated hydronic system using an ANN. Dhar et al. (1995) used an ANN with wavelet basis functions to predict hourly heating and cooling energy use in commercial buildings with the temperature as the only weather variable. Inoue et al. (1995) studied thermal comfort and climate control. Kawashima et al. (1995) did a 24 h thermal load prediction. Li et al. (1996) developed a fault diagnosis method for heating systems using neural networks. Matsumoto et al. (1997) studied the effect of pin fin arrangement on endwall heat transfer. Takemori et al. (1991) worked on a neural network air-conditioning system for individual comfort. Dounis et al. (1992) implemented an AI technique in thermal comfort control for passive solar buildings.

All the studies mentioned here represent tentative attempts to apply the ANN analysis to thermal system problems. Since good results have been obtained so far, there is no reason why the ANN approach cannot be applied to many other thermal problems with equal success, particularly in the analysis of dynamic systems and their control.

General Discussion of ANNs

It must be emphasized that the implementation of ANN predictions in an industrial setting is really very simple and straightforward. For instance, once the network is trained for a given device by the manufacturer, it can simply be transmitted to the intended customer by giving him or her the sets of weights and biases and the corresponding software for the appropriate network configuration. The customer can then independently carry out the neural computing. An example of the weights and biases for heat exchanger 1 for the 4-2-1 ANN configuration is given in Table 4.27.5. It should be mentioned that the training process of an ANN is somewhat computing intensive, even though not excessive in terms of the computing resources available today, and all computations can be readily handled by personal workstations. However, once the training is completed, the predictions using the finalized sets of synaptic weights and biases can be carried out on any personal computer.

There are several inherent and excellent attributes of the ANN approach, which the traditional analysis, including the dimensionless correlations of the experimental data, simply does not have. The neural network, by its ability for pattern recognition, is capable of capturing all the relevant physics, but some of this physics is often not accounted for in the common data correlations by dimensionless parameters. It should be realized, too, in this regard, that since the effects of properties, which represent part of the physics, are expected to show up in the input–output relations in the training data for the ANN, there is no need to explicitly use such properties in the ANN analysis, while such use is necessary in the traditional analysis. Unfortunately, in many applications such properties, which may be either intrinsic or apparent, may not be known or not known accurately, and thus may often lead to difficulties. Furthermore, the complexity in the physics is not an issue in the ANN approach, while such complexity is often the critical barrier in the traditional analysis. Also, it is a relatively simple matter, by continuing training with new data, to adapt to changing conditions, a situation which often exists in real-world applications. The traditional analysis is not capable of doing so, since the physical mechanisms responsible for such changing conditions are not known. In addition, dynamic thermal-system models, which are needed for developing optimal

control strategies, are difficult to develop by the traditional analysis even for simple systems; they are readily accessible by the ANN approach. On the other hand, there are several shortcomings relative to ANN implementations, but these can be remedied by adequate numerical experimentation, past experience in similar applications, or continuing research in the field of ANN.

The attractiveness of the ANN approach has been demonstrated in the preceding subsections by considering the static and dynamic performances of typical compact heat exchangers. Such heat exchangers are already in common use today, and the traditional analysis has not yet produced satisfactory theories to predict their behavior. Even though the applications of the ANNs have been demonstrated here by considering them as examples, the potential applications in other thermal systems are essentially unlimited—thermal systems still have not been analyzed by the ANN approach to any large extent. In order to promote its application to thermal science and engineering problems, it would be desirable to look at application areas in which the ANN approach would make significant impacts. In this regard, the most significant areas lie where the lack of physical models, system complexities, and unavailability of properties or constitutive relations represent critical barriers to the advancement of the field in terms of product development, process development and control, manufacturing, sensitivity and risk analyses, and other similar areas which involve simulation, design, and control. This is particularly imperative in those areas where there are plenty of experimental data that can be used to train the networks. To give some indication to this vast potential, several examples of critical technology areas can be mentioned for the applications of the ANN approach.

Thermal Networks

The focus so far has been on components, especially on heat exchangers. However, even if the behavior of a single heat exchanger could be accurately predicted, it would be difficult to do so for a large network of these devices as are commonly used in practice. Thermal networks, as used in heating and cooling systems in a single building or in a collection of buildings, may consist of chilled water for cooling purposes, steam for heating, air for ventilation or, more commonly, a combination of these. Current design is heavily based on overspecification so that it is not unusual to find simultaneous heating and cooling to obtain the desired comfort level, especially during periods

of change in weather. A hydraulic network may consist of a large number of interconnected pipes with valves, heat exchangers, pumps, and other components online. The simplest network problem consists in determining the flow in each branch of the network. Methods based on the solution of the nonlinear pressure drop and flow rate network equations have been developed to solve this problem. The control of the flow in a given branch by change of pump or valve parameters is a more difficult problem. Though one can in principle resolve the network for the new conditions, this could be time-consuming for a large network and, thus, difficult to use in real time. In addition the exact, current state of the network and its physical properties may not be known for computational purposes. Thus, for example, the heat transfer coefficients at a heat exchanger will be affected by fouling, which will in turn change its ability to transfer heat. It is possible that the response of the network be simulated by an ANN. This ANN can be trained by using experimental data so that the response of changing any parameter can be found. One of the advantages is that this can be done online so that changes in system performance are reflected in the simulation.

Thermal Processing of Materials

In almost all materials processing operations involving thermal effects, the most critical information is the direct relationship between the desired characteristics of the end product, such as, for instance, material microstructure defect elimination and the processing parameters. Physical models that provide such relationship are either not available or, if available, involve either apparent properties or constitutive relations, which are not available. In the latter case, the lack of such information essentially nullifies the usage of such models. The ANN analysis simply bypasses all these uncertainties and leads immediately to the direct quantitative relationship between the desired end-product characteristics and the processing parameters. This advantage becomes particularly significant in dealing with new engineering materials, foods, and pharmaceutical and biological materials.

Environmental and Safety Studies

There are many complex thermal systems dealing with environmental and safety control in buildings, factories, mines, and the like. HVAC and indoor pollution systems and fire protection systems are good examples. Despite the recent advances made in the control of HVAC systems by means of the ANN approach, much more needs to be done, especially in the area of simulating realistic dynamic conditions involving, for instance, time delays. Performance-oriented risk analysis of fire hazards is drawing much attention, but very little is known concerning the realistic assessment of likely dynamic fire-and smoke-spread scenarios, which are needed in risk analysis and also in the design of fire mitigation systems for enclosed habitat spaces such as high rises and mines. The capability of the ANN approach needs to be explored and exploited to deal with such complex dynamic systems.

Tribological Systems

In all systems of any size involving relative motions of components in contact, friction inevitably occurs and produces heat, wear, or both. To minimize or control friction, theories or models are needed for the physical, chemical, and other phenomena occurring at the surfaces of contact or interfaces. Such models would necessarily depend on the physical structure and properties at these interfaces. Such theories or models are either not available or difficult to apply because of the unknown characterization of these interfaces, even though the methods of preparing such interfaces and the lubricant used are known. ANNs, in general, are capable of catching all the relevant physics and recognizing the unique surface characterization, and then incorporating such characterizations into the ANN-based input–output relation.

Reactive Systems

One major barrier to our knowledge of reacting systems from molecular–biological systems in single cells to large scale reactors to combustion phenomena is the lack of reaction kinetics and the corresponding energy transport information. Models are impossible without such information. For the ANN

analysis, such information can again be bypassed and, therefore, is not needed in the analysis. The effects of the reaction kinetics are reflected in the output data used in the training of the ANN and, therefore, they are accounted for in the trained ANN, which then becomes the model of the reactive system.

Multiphase Phenomena and Systems

In systems involving components of multiple phases such as mixtures of liquids and gases, liquids and solids, solids and gases, binary gas mixtures (Diaz and Campo, 2009) and all three phases in turbulent pipe flows with heat transfer and multicomponent heterogeneous mixtures in food processing, the extreme complexity prevents the development of reasonable models for use in simulation, optimization, and control. Attempts to correlate the data would not be particularly fruitful either because of the large data scatter due to unknown parameters. This type of complex system is a natural for ANN-based analysis, modeling, and dynamic control, as recently demonstrated by the application of ANNs to predict the convective heat transfer in evaporative processes and small-scale units (Romero-Mendez et al., 2014, 2016).

Inverse Problems and Parameter Estimation

The importance of solving inverse problems and problems in parameter estimation has long been recognized in many engineering applications, and this importance has also received ever-increasing attention in the field of thermal systems. The application of ANN analysis to such problems is not new, but should be emphasized. As is already obvious, the inputs and outputs of an ANN, especially in dynamic systems, can be switched as in the case of an inverse ANN model.

Genetic Algorithms (GAs)

Evolutionary programming, of which genetic algorithms and programming are examples, allow programs to change or evolve as they compute. GAs, specifically, are based on the principle of Darwinian selection. One of their most important applications in the thermal sciences is in the area of optimization of various kinds.

Optimization by itself is fundamental to many applications. In engineering, for example, it is important to the design of systems; analysis permits the prediction of the behavior of a given system, but optimization is the technique that searches among all possible designs of the system to find the one that is the best for the application. The importance of this problem has given rise to a wide variety of techniques that help search for the optimum solution. There are searches that are gradient-based and those that are not. In the former, the search for the optimum solution, as for example, the maximum of a function of many variables, starts from some point and directs itself in an incremental fashion towards the optimum; at each stage, the gradient of the function surface determines the direction of the search. Local optima can be found in this way, the search for global optimum being more difficult. Again, if one visualizes a multivariable function, it can have many peaks, any one of which can be approached by a hill-climbing algorithm. To find the highest of these peaks, the entire domain has to be searched; the narrower this peak the finer the searching "comb" must be. For many applications, this brute force approach is too expensive in terms of computational time. Alternatives, like simulated annealing, are techniques that have been proposed, and the GA is one of them.

In what follows, we will provide an overview of genetic algorithm and programming. A numerical example will be explained in some detail. The methodology will be applied to one of the heat exchangers discussed earlier. There will be a discussion on other applications in thermal engineering and comments will be made on potential uses in the future.

Methodology of GAs

GAs are discussed in detail by Holland (1975, 1992), Mitchell (1997), Goldberg (1989), Michalewicz (1992), and Chipperfield (1997). One of the principal advantages of this method is its ability to pick

out a global extremum in a problem with multiple local extrema. For example, we can discuss finding the maximum of a function $f(x)$ in a given domain $a < x < b$. In outline, the steps of the procedure are the following.

- First, an initial population of n members, $x_1, x_2, \ldots, x_n \in [a, b]$ is randomly generated.
- Then, for each x, a fitness is evaluated. The fitness, or effectiveness, is the parameter that determines how good the current x is in terms of being close to an optimum. Clearly, in this case, the fitness is the function $f(x)$ itself, since the higher the value of $f(x)$, the closer we are to the maximum.
- The probability distribution for the next generation is found based on the fitness values of each member of the population. Pairs of parents are then selected on the basis of this distribution.
- The offsprings of these parents are found by crossover and mutation. In crossover, two numbers in binary representation, for example, produce two others by interchanging part of their bits. After this, and based on a preselected probability, some bits are randomly changed from 0 to 1 or vice versa. Crossover and mutation create a new generation with a population that is more likely to be fitter than the previous generation.
- The process is continued as long as desired or until the largest fitness in a generation does not change much any more.

The procedure can be easily generalized to a function of many variables.

Let us consider a numerical example that is shown in detail in Table 4.27.6. Suppose that one has to find the x at which $f(x)=x(1-x)$ is globally a maximum between 0 and 1. We have taken $n=6$, meaning that each generation will have six numbers. Thus, for a start, six random numbers are selected between 0 and 1. Now we choose n_b,which is the number of bits used to represent a number in binary form. Taking $n_b=5$, we can write the numbers in binary form normalized between 0 and the largest number possible for n_b bits, which is $2^{n_b-1} = 31$. In one run, the numbers chosen and written down in the first column of the table labeled $G=0$, are 25, 30, 28, 19, 3, and 1, respectively. The fitnesses of each one of the numbers, i.e., $f(x)$, are computed and shown in the second column. These values are normalized by their sum and shown in the third column as $s(x)$. The normalized fitnesses are drawn on a roulette wheel in Figure 4.27.21. The probability of crossover is taken to be 100%, meaning that crossover will always occur. Pairs of numbers are chosen by spinning the wheel, the numbers having a bigger piece of the wheel having a larger probability of being selected. This produces column four marked $G=1/4$, and shuffling to produce random pairing gives column five, marked $G=1/2$. The numbers are now split up in pairs, and crossover applied to each pair. The

10011	0.2373	0.3762	10011	10011	00011	00011
00011	0.0874	0.1386	00011	11110	11011	11011
00001	0.0312	0.0495	11100	00011	00110	00100

first pair [0 0 0 1 1] and [1 1 1 0 0] produces [0 0 0 1 0] and [1 1 1 0 1]. This is illustrated in Figure 4.27.22a, where the crossover position is between the fourth and fifth bit; the bits to the right of this line are interchanged. Crossover positions in the other pairs are randomly selected. Crossover produces column six, marked as $G=3/4$. Finally, one of the numbers, in this case the last number in the list [0 0 1 1 0], is mutated to [0 0 1 0 0] by changing one randomly selected bit from 1 to 0, as shown in Figure 4.27.22b. From the numbers in generation $G=0$, these steps have now produced a new generation $G=1$. The process is repeated until the largest fitness in each generation increases no more. In this particular case, values within 3.22% of the exact value of x for maximum $f(x)$, which is the best that can be done using 5 bits, were usually obtained within 10 generations.

Applications of GAs to Compact Heat Exchangers

The following analysis is based on the data collected on a single-row heat exchanger referred to earlier as heat exchanger 1. In the following, a set of $N=214$ experimental runs provided the database. The heat rate is determined by

$$\dot{Q} = \dot{m}_a c_{p,a} \left(T_a^{out} - T_a^{in} \right) \tag{4.27.20}$$

$$= \dot{m}_w c_w \left(T_w^{in} - T_w^{out} \right) \tag{4.27.21}$$

For prediction purposes, we will use functions of this type

$$\dot{Q} = \dot{Q}(T_w^{in}, T_a^{in}, \dot{m}_a, \dot{m}_w)$$

The conventional way of correlating data is to determine correlations for inner and outer heat transfer coefficients. For example, power laws of the following form

$$\varepsilon \mathrm{Nu}_\mathrm{a} = a\mathrm{Re}_\mathrm{a}^\mathrm{m}\mathrm{Pr}_\mathrm{a}^{1/3} \tag{4.27.22}$$

$$\mathrm{Nu}_\mathrm{w} = b\mathrm{Re}_\mathrm{w}^\mathrm{n}\mathrm{Pr}_\mathrm{w}^{0.3} \tag{4.27.23}$$

are common. The two Nusselt numbers provide the heat transfer coefficients on each side and the overall heat transfer coefficient, U, is related to h_a and h_w by

$$\frac{1}{UA_\mathrm{a}} = \frac{1}{h_\mathrm{w}A_\mathrm{w}} + \frac{1}{\varepsilon h_\mathrm{a}A_\mathrm{a}}$$

To find the constants a, b, m, n, the mean square error

$$S_U = \frac{1}{N}\sum\left(\frac{1}{U^\mathrm{p}} - \frac{1}{U^\mathrm{e}}\right)^2 \tag{4.27.24}$$

must be minimized, where N is the number of experimental data sets, U^p is the prediction made by the power-law correlation, and U^e is the experimental value for that run. The sum is over all N runs.

This procedure was carried out for the data collected. It was found that S_U had local minima for many different sets of the constants, the following two being examples.

Correlation	*a*	*b*	*m*	*n*
A	0.1018	0.0299	0.591	0.787
B	0.0910	0.0916	0.626	0.631

Figure 4.27.23 shows a section of the S_U surface that passes though the two minima, *A* and *B*. The coordinate z is a linear combination of the constants a, b, m, and n such that it is zero and unity at the two minima. Though the values of S_U for the two correlations are very similar and the heat rate

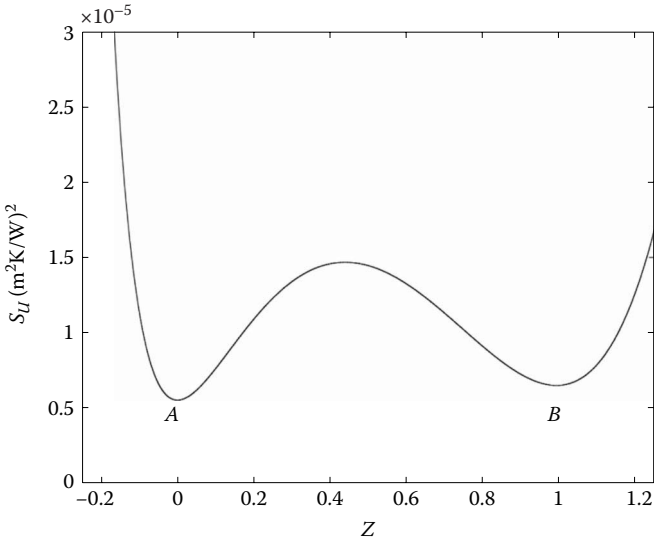

FIGURE 4.27.23 Section of $S_\mathrm{U}(a, b, m, n)$ surface.

predictions for the two correlations are also almost equally accurate, the predictions on the thermal resistances on either side are different. Figure 4.27.24 shows the ratio of the predicted air- and waterside Nusselt numbers using these two correlations. R_a is the ratio of the Nusselt number of the airside predicted by Correlation *A* divided by that predicted by Correlation *B*. R_w is the same value for the waterside. The predictions, particularly the one on the water side, are very different.

There are several reasons for this multiplicity of minima of S_U. Experimentally, it is very difficult to measure the temperature at the wall separating the two fluids, or even to specify where it should be measured, and mathematically, it is due to the nonlinearity of the function to be minimized. This raises the question as to which of the local minima is the "correct" one. A possible conclusion is that the one which gives the smallest value of the function should be used. This leads to the search for the global minimum, which can be done using the GA.

For these data, Pacheco-Vega et al. (1998) conducted a global search among a proposed set of heat transfer correlations using the GA. The experimentally determined heat rate of the heat exchanger was correlated with the flow rates and input temperatures, with all values being normalized. To reduce the number of possibilities, the total thermal resistance was correlated with the mass flow rates in the form

$$\frac{T_w^{in} - T_a^{in}}{\dot{Q}} = f(\dot{m}_a, \dot{m}_w) \tag{4.27.25}$$

The functions that were used are indicated in Table 4.27.7. The GA was used to seek the values of the constants associated with each correlation, the objective being to minimize the variance.

$$S_Q = \frac{1}{N}\sum\left(\dot{Q}^p - \dot{Q}^e\right)^2 \tag{4.27.26}$$

where the sum is over all *N* runs between the predictions of a correlation, $\dot{Q}^p$, and the actual experimental values, $\dot{Q}^e$. Since the unknowns are the set of constants, *a*, *b*, *c*, and sometimes *d*, a single binary string represents them; the first part of the string is *a*, the next is *b*, and so on. The rest of the GA is as in the numerical example given before. The results obtained for each correlation are also summarized in the table in descending order of S_Q. The last column shows the mean square error σ

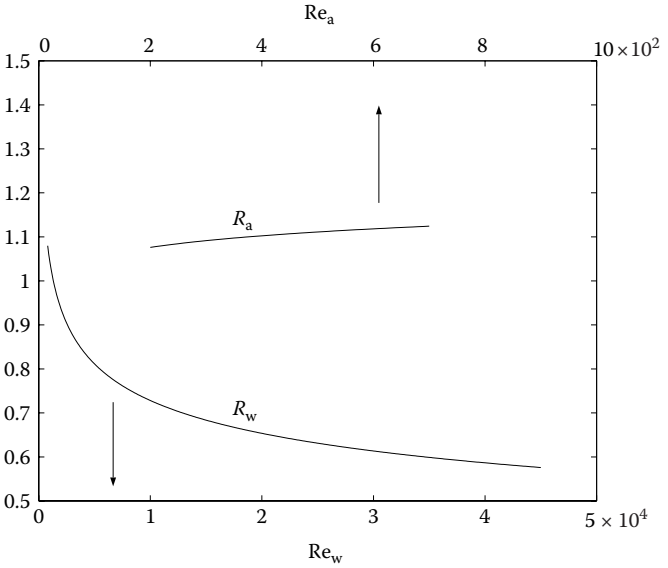

FIGURE 4.27.24 Ratio of the predicted air- and water-side Nusselt numbers.

TABLE 4.27.7
Comparison of Best Fits for Different Correlations

Correlation	*f*	*a*	*b*	*c*	*d*	σ

Linear	$a - b\dot{m}_w - c\dot{m}_a$	2.3087	0.8533	0.8218	—	0.2118
Quadratic	$a - b\dot{m}_w^2 - c\dot{m}_a^2$	1.8229	0.6156	0.5937	—	0.2468

defined in a manner similar to Equations 4.27.6 and 4.27.7. The parameters used for the computations are population size 20, number of generations 1000, bits for each variable 30, probability of crossover 1, and probability of mutation 0.03.

Some correlations are clearly seen to be superior to others. However, the difference in S_Q between the first- and second-place correlations, the power law, and inverse logarithmic, which have mean errors of 2.5% and 3.3%, respectively, is only about 8%, indicating that either could do just as well in predictions even though their functional forms are very different. In fact, the mean error in many of the correlations is quite acceptable. Figure 4.27.25 shows the predictions of the power-law correlation vs. the experimental values, all in normalized variables. The prediction is seen to be very good. The quadratic correlation on the other hand, is the worst in the set of correlations considered, and Figure 4.27.26 shows its predictions. It must also be remarked that, because of the random

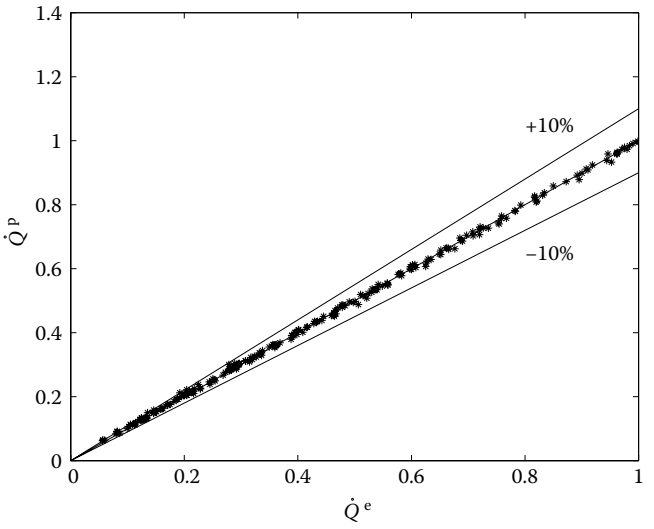

FIGURE 4.27.25 Experimental vs. predicted normalized heat flow rates for a power-law correlation. The straight line is the line of equality between prediction and experiment, and the broken lines are ±10%.

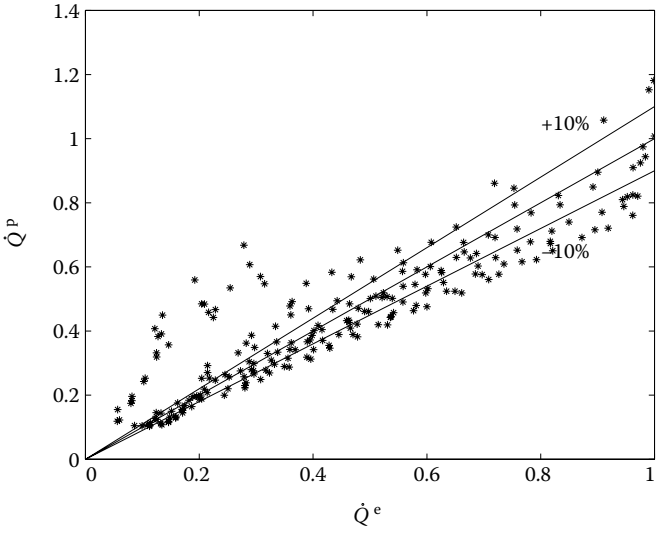

FIGURE 4.27.26 Experimental vs. predicted normalized heat flow rates for a quadratic correlation. The straight line is the line of equality between prediction and experiment, and the broken lines are ±10%.

numbers used in the procedure, the computer program gives slightly different results each time it is run, changing the lineup of the less appropriate correlations somewhat.

Additional Applications of GAs in Thermal Engineering

Though the GA is a relatively new technique in relation to its application to thermal engineering, there are a number of different applications that have already been successful. Davalos and Rubinsky (1996) adopted an evolutionary genetic approach for numerical heat-transfer computations. Shape optimization is another area that has been developed. Fabbri (1997) used a GA to determine the optimum shape of a fin. The two-dimensional temperature distribution for a given fin shape was found using a finite-element method. The fin shape was proposed as a polynomial, the coefficients of which have to be calculated. The fin was optimized for polynomials of degree 1 through 5. von Wolfersdorf et al. (1997) did shape optimization of cooling channels using GAs. The design procedure is inherently an optimization process. Androulakis and Venkatasubramanian (1991) developed a methodology for design and optimization that was applied to heat exchanger networks; the proposed algorithm was able to find local solutions where gradient-based methods failed. Abdel-Magid and Dawoud (1995) optimized the parameters of an integral and a proportional-plus-integral controller of a reheat thermal system with GAs. The fact that the GAs can be used to optimize in the presence of variables that take on discrete values was put to advantage by Schmitt et al. (1996) who used it for the design of a compact high-intensity cooler.

The placing of electronic components as heat sources is a problem that has become very important recently from the point of view of computers. Queipo et al. (1994) applied GAs to the optimized cooling of electronic components. Tang and Carothers (1996) showed that the GA worked better than some other methods for the optimum placement of chips. Queipo and Gil (1997) worked on the multiobjective optimization of component placement and presented a solution methodology for the collocation of convectively and conductively air-cooled electronic components on planar printed wiring boards. Meysenc et al. (1997) studied the optimization of microchannels for the cooling of high-power transistors. Inverse problems may also involve the optimization of the solution. Allred and Kelly (1992) modified the GA for extracting thermal profiles from infrared image data that can be useful for the detection of malfunctioning electronic components. Jones et al. (1995)

used thermal tomographic methods for the detection of inhomogeneities in materials by finding local variations in the thermal conductivity. Raudensky et al. (1995) used the GA in the solution of inverse heat conduction problems. Okamoto et al. (1996) reconstructed a three-dimensional density distribution from limited projection images with the GA. Wood (1996) studied an inverse thermal field problem based on noisy measurements and compared a GA and the sequential function specification method. Li and Yang (1997) used a GA for inverse radiation problems. Castrogiovanni and Sforza (1996, 1997) studied high-heat flux-flow boiling systems using a numerical method in which the boiling-induced turbulent eddy diffusivity term was used with an adaptive GA closure scheme to predict the partial nucleate boiling regime.

Genetic Programming

The GP technique (Koza, 1992, 1994) is an extension of the GA procedure in which computer codes take the place of numbers. Developed originally to automatically generate computer programs, in the context of thermal engineering applications, it can be used, for example, in symbolic regression to search within a set of functions for the one which best fits experimental data. The procedure is similar to that for the GA, except for the crossover operation. If each function is represented in tree form, though not necessarily of the same length, crossover can be achieved by cutting and grafting. A typical representation of the function $5x\cos(5x+1)$ is illustrated, for example, in Figure 4.27.27a, while Figure 4.27.27b, shows the result of the crossover operation on the two functions $5x(x+1)$ and $x(5x+1)$ to give $5x(5x+1)$ and $x(x+1)$. The crossover points may be different for each parent. In general, as shown in the figures, branch nodes may be mathematical operators (such as sin, cos, exp, log, +, −, *, /, ∧), or may be Boolean (such as AND, OR, and NOT) or conditional (IF-THEN-ELSE, etc.) operators. Leaf or terminal nodes x_j, $j=1, \ldots, N_v$, on the other hand, are the variables in a particular problem, or constants $\mathbf{C} \in \mathbb{R}$ to be determined as part of the solution.

Computer Representation

A key element in GP is the representation of functional forms conserving a correct syntax, since both the crossover and mutation operations directly lean on it. Such representation depends on the programming language being used for its coding. For instance, due to the natural way of portraying these tree structures, GP was ordinarily coded in LISP (Koza, 1992; Sette and Boullart, 2001). However, to increase speed in the computations, other object-oriented programming languages like C or C++ have also been used. Recently, Cai et al. (2006) introduced a GP algorithm coded in MATLAB by taking advantage of the fact that MATLAB enables handling different data types in a

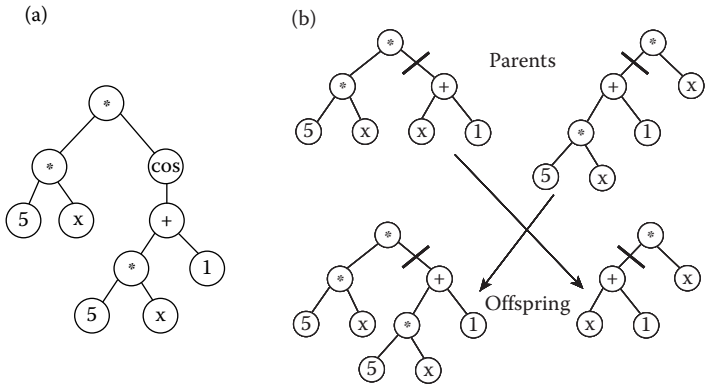

FIGURE 4.27.27 Function representation as (a) parse tree and (b) crossover in GP. (a) Function is $5x\cos(5x+1)$. (b) Parents are $5x(x+1)$ and $x(5x+1)$, and offspring are $5x(5x+1)$ and $x(x+1)$.

straightforward manner, such that the syntactically-correct crossover operation can be achieved. In their code, trees representing the functions are stored as rectangular arrays, an example of which, for the crossover of functions $5x(x+1)$ and $x(5x+1)$ considered before, is illustrated in Figure 4.27.28. An important advantage of using arrays is that the "size" L_f, of the function can be easily computed as the product of the number of rows and the number of columns of the smallest rectangular layout, which, for symbolic regression in a variety of applications is key as an objective may be to find the smallest heat transfer correlation that provides the highest accuracy. As an example, the size of the functions mentioned earlier is, respectively, $L_f=4\times3=12$ and $L_f=4\times4=16$.

Fitness and Penalty

If GP is used to perform symbolic regression, then the objective is to minimize the variance of the error between predictions and the data. Thus, the fitness is naturally defined as the reciprocal of the variance

$$F_f = \left(\frac{1}{N} \sum_{i=1}^{N} \left[f^t(x_j)_i - f^p(x_j, \mathbf{C})_i \right]^2 \right)^{-1}$$

between the target data $f^t(x_j)$ for $i=1, \ldots, N$, and the values predicted by the candidate functions $f^p(x_j)$ for $i=1, \ldots, N$. In heat transfer applications, f is either a transfer conductance or a dimensionless form of the heat transfer coefficients. A potential problem with using the fitness directly as defined here, however, is that it may generate functions of complicated forms with many terms. To prevent large functions and favor more compact ones, the fitness may be penalized according to their corresponding size. Although this can be done in many ways, McKay et al. (1997) has proposed to use a logistic sigmoid penalty function $g(L_f)$, with prescribed parameters a_1 and a_2, to define a penalized fitness Q_f, as

$$Q_f = F_f g(L_f) \tag{4.27.27}$$

$$g(L_f) = \frac{1}{1+\exp[a_1(L_f - a_2)]} \tag{4.27.28}$$

The effect that a_1 and a_2 have on the results from GP is illustrated in a later section.

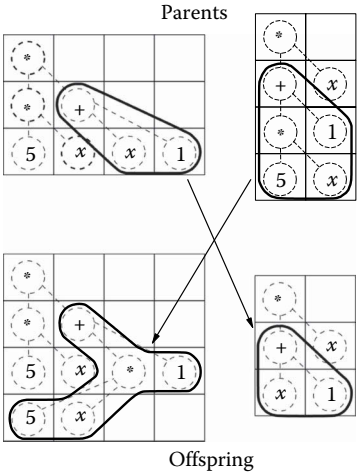

FIGURE 4.27.28 Crossover of functions represented as arrays: parents are $5x(x+1)$ and $x(5x+1)$, and offspring are $5x(5x+1)$ and $x(x+1)$.

Methodology of GP

The steps of the procedure are the following.

- First, an initial set of M correlations coded as parse trees is randomly generated from the chosen sets of functional operators and terminals. For the subsequent generations, the old population is used.
- Then, for each f, the value of the fitness is calculated.
- The probability distribution for the next generation, on the basis of which parents are chosen for replacement, is calculated from the fitness values.
- As in the GA procedure, once the parents are selected, crossover and mutation are applied according to preselected probabilities p_c and p_m, respectively.
- Once the optimum functional form is determined, the final step of each iteration in GP is the application of the GA to seek for the optimum values constants in it.
- Once crossover and mutation have been applied to the complete population, and the optimum set of constants are determined, a new population that keeps the fittest member of the previous generation is created.
- The process is repeated until some criterion based on convergence or maximum number of generations, G_{max}, is achieved.

Since GP is a probabilistic technique, every run gives a slightly different answer. To understand this inherent variation, it is useful to perform multiple runs along with a statistical analysis of the results.

Applications of GP to Compact Heat Exchangers

The procedure is illustrated by its application to experimental data obtained from tests on the heat exchanger 2 described in an earlier section. Though the data included operating conditions for which either dry surface, dropwise or film condensation would occur, only the dry-surface data were considered by Cai et al. (2006) for the analysis. From the measurements, the correlation originally proposed by McQuiston (1978a) is given in Equation 4.27.10, with $f_s(\delta)=1$ in Equation 4.27.12; i.e.,

$$j_s = 0.0014 + 0.2618\mathrm{Re}_D^{-0.4}\left(\frac{4}{\pi}\frac{x_a}{D_h}\frac{x_b}{D}\right)^{-0.15} \tag{4.27.29}$$

where j is the sensible Colburn j factor, defined earlier as $j_s = h_a \mathrm{Pr}_a^{2/3} / G_c c_{p,a}$, Re_D is Reynolds number, and the term in parenthesis is a nondimensional geometrical parameter representing an airside area ratio.

To perform symbolic regression for these data, the fitness function was defined as

$$F_j = \left(S_j\right)^{-1} = \left(\frac{1}{N}\sum_{i=1}^{N}\left(j_{s,i}^{e} - j_{s,i}^{p}\right)^2\right)^{-1}$$

where $j_{s,i}^{e}$, $i=1, \ldots, N$, are the measurements and $j_{s,i}^{p}$, $i=1, \ldots, N$, are the predicted values from each of the M correlations in the population. The algorithm seeks a correlation function and the corresponding constants that maximize F_j (or minimize S_j), with $M=100$, $G_{max}=800$, $p_c=0.8$, and $p_m=0.2$; $x_1=\mathrm{Re}_D$, and $x_2 = \frac{4}{\pi}\frac{x_a}{D_h}\frac{x_b}{D}$ are the variables in the terminal set. To build Q_j as in Equation 4.27.27, the values used in Equation 4.27.28 are $a_1=0.2$ and $a_2=30$.

A typical evolution of the algorithm is shown in Figure 4.27.29, where the two curves correspond to the values of unpenalized and penalized fitnesses, F_j and Q_j respectively, obtained from the best correlation found in each generation. The figure shows that because Q_j rejects good candidate

correlations that are large in size, the values of F_j are larger than those of Q_j. In addition, though both curves follow similar paths, only that of Q_j keeps increasing as the best correlation from the previous generation is based on Q_j, rather than F_j; this means that a correlation that has a large F_j but is also large in size, may not be preserved for the subsequent iteration.

The following are two examples of the correlations that result from the procedure:

$$j_s = \frac{1.82}{103.81 + 0.0299\ \mathrm{Re_D} + \frac{4}{\pi}\frac{x_a}{D_h}\frac{x_b}{D}}$$

$$j_s = \frac{66.39 - \frac{1.7824}{\pi}\frac{x_a}{D_h}\frac{x_b}{D}}{3881.61 + \mathrm{Re_D}}$$

Though these correlations are different in form, and their sizes, L_j, are 10 and 16 respectively, their RMS errors in predictions of the j factor are less than 0.1% (6.32% and 6.24%), indicating that either could be used. This multiplicity of solutions in functional space, similar to that in the parameter space of an assumed form (Pacheco-Vega et al., 2001a), was also noticed by Pacheco-Vega et al. (2003a) using artificial data. After several runs of the procedure, a slightly more complex correlation, with L_j=24, that provides better predictions is

$$j_s = \frac{2205.32}{1.39\times10^5 + 24.16\ \mathrm{Re_D} + \left(\frac{4}{\pi}\frac{x_a}{D_h}\frac{x_b}{D}\right)\mathrm{Re_D}} \tag{4.27.30}$$

A comparison of the RMS percentage error in j_s from the correlations obtained with GP against that developed by Pacheco-Vega et al. (2003b) using global regression with the same functional form as that of Equation 4.27.29, and against Equation 4.27.29 itself, is shown in Table 4.27.8 in descending order of magnitude. From the results, it is possible to observe that regardless of differences in accuracy, all the correlations found by the GP method give a smaller error than that of Equation 4.27.29. On the other hand, the table illustrates that even though the global-regression-based correlation is the best possible that can be obtained from the assumed functional form, Equation 4.27.30 is seen to give a slightly smaller error.

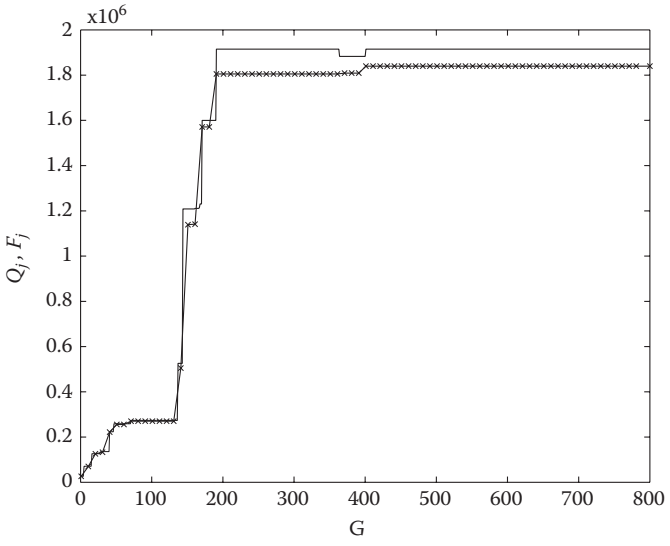

FIGURE 4.27.29 Evolution of fitness and penalized fitness with generation number. (–) fitness function F_j, (–×–) penalized fitness Q_j.

TABLE 4.27.8
Comparison of RMS Errors in j_s for Heat Exchanger 2

Prediction Method	Error (%)
Equation 4.27.29 McQuiston	14.74
Pacheco-Vega et al. (2003b)	6.21
Equation 4.27.30	6.18

A comparison between the experimentally-determined j factor and that predicted from Equation 4.27.30 is illustrated in Figure 4.27.30. The predictions from Equation 4.27.29 are also included as a reference. As expected, the scatter in the predictions from the GP-based correlation is much smaller.

Effect of Penalty Parameters

In limiting the size of the correlations for practical thermal engineering applications, it is possible to choose different penalty functions, $g(L_f)$, in Equation 4.27.27. Using the sigmoidal form as in Equation 4.27.28, however, prevents the fitness in Equation 4.27.28 from becoming either unbounded or singular thus avoiding computational problems, but the choice of a_1 and a_2 has an effect on the results. This effect was analyzed and reported by Cai et al. (2006), with different values of a_1 and a_2, maintaining one variable fixed while changing the other. Three runs were made for each a_1, a_2 value and the results are presented next.

Figure 4.27.31 presents the results for a_1 constant and varying a_2, with Figure 4.27.31a showing the penalty function vs. correlation size, and Figure 4.27.31b illustrating the corresponding penalized fitness values. The result of each run is also marked on them. As can be seen from the figures and Equation 4.27.28, the parameter a_2 provides a nominal size of the correlation by simply shifting the penalty function horizontally. A larger a_2 enables a larger correlation size with a smaller error to be selected. The choice of a_2 is subjective in that a smaller error is to be preferred, but at the expense of functional complexity.

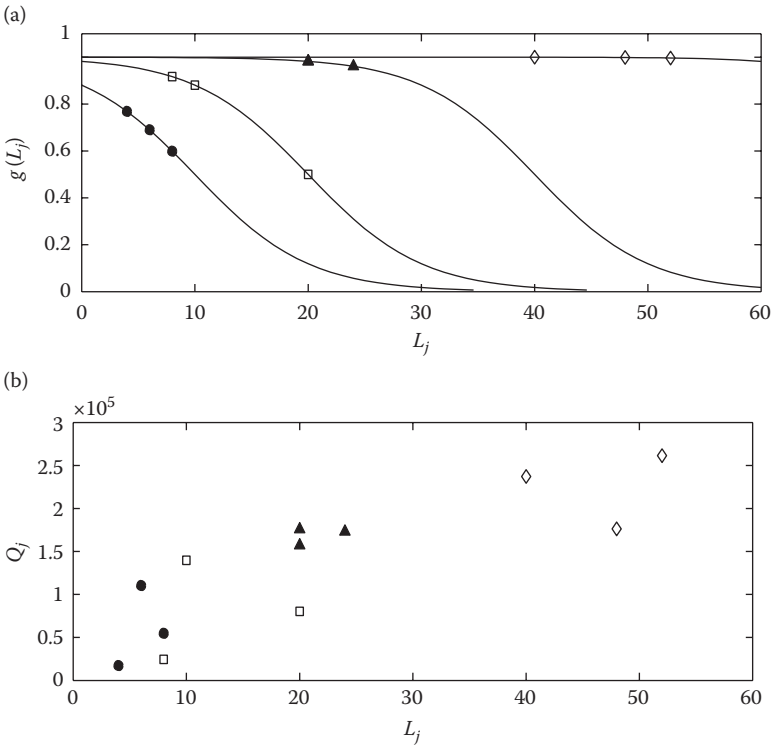

FIGURE 4.27.31 (a) Penalty and (b) penalized fitness functions vs. correlation size for different a_2: (•) 10, (□) 20, (▲) 40, (◊) 80.

The results for variable a_1 and constant a_2 are shown in Figure 4.27.32, with Figure 4.27.32a illustrating the penalty function and Figure 4.27.32b the penalized fitness function. In this case, a_1 is a measure of the slope of the penalty function and determines how strongly a large functional form of the correlation is penalized. From the figures, it is clear that for small values of a_1, the penalty function changes smoothly providing a gradually increasing rejection of large correlations, while for the large values, the fitness curve shows a sudden onset of rejection. Though the choice of a_1 is subjective, an intermediate value for a_1 is appropriate for finding relatively compact well-fitted correlations.

Additional Applications of GPs in Thermal Engineering

Applications involving GP are rarer than those of the GA. Lee et al. (1997) studied the problem of correlating the critical heat flux (CHF) for upward water flow in vertical round tubes under low-pressure and low-flow conditions. Correlations were developed for two types of conditions, namely, inlet and local. In these, the data included the tube diameter, fluid pressure, and mass flux, along with either the heated length and the subcooling enthalpy for the earlier or the critical quality for the latter. Genetic programming was used as a symbolic regression tool to find the functional form and the constants in it that provided the best accuracy. The final correlations that were found had predictions better than those in the literature. In a different study, the modeling of solid oxide fuel cell systems with semi-empirical equations was performed by Chakraborty (2009). Given the data for fixed and dynamic loads, the GP technique was used to find the correlation functions that could accurately describe the electrochemical and thermal properties of solid-oxide fuel-cell stacks. The results from the GP-based models for the static current–voltage behavior, and the transient response

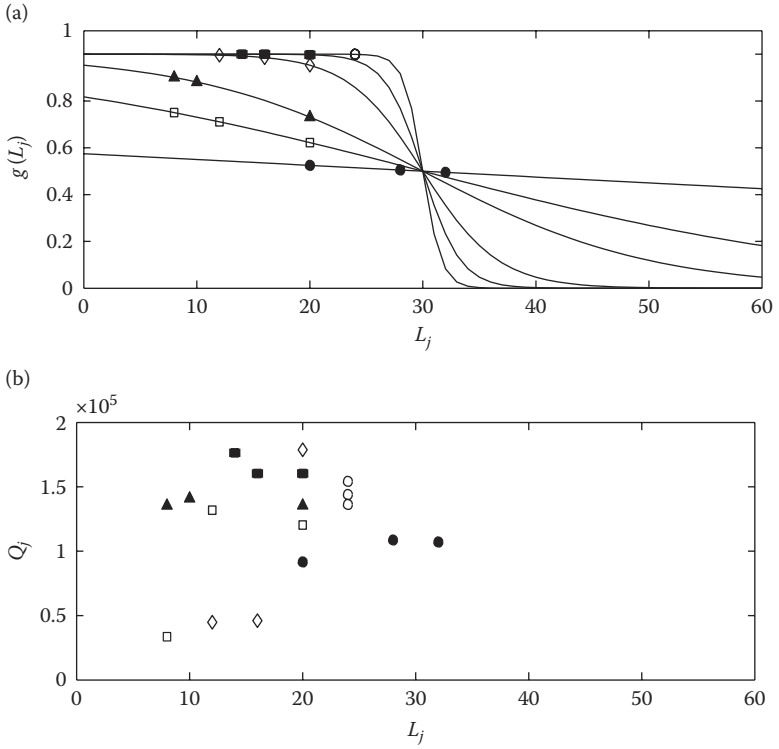

FIGURE 4.27.32 (a) Penalty and (b) penalized fitness functions vs. correlation size for different a_1: (•) 0.01, (□) 0.05, (▲) 0.1, (◊) 0.3, (■) 0.6, (o) 1.2.

under changing load conditions, were more accurate that the state-of-the-art radial basis function neural network. On the other hand, Lee and Tong (2011) conducted a study on the development of reliable models towards forecasting energy consumption from experimental data. The investigation focused on combining the residual modification information with GP sign estimation to improve a "grey" forecasting model. The energy consumption in China was considered to demonstrate the effectiveness of the proposed GP-based forecasting model.

An experimental investigation of helically finned tubes was reported by Zdaniuk et al. (2011) with the idea of investigating the performance of two correlation techniques to be used for system optimization. From the data collected, empirical correlations for the friction factor f and the Colburn j factor were developed by symbolic regression and used to find the geometric parameters and operating conditions, which would maximize heat transfer enhancement efficiency index. The results from the GP-based models were better suited for optimization purposes than those of an ANN approach. A similar study that introduced a new correlation based on GP to describe choke performance in both critical and subcritical flow conditions in pipeline flow regimes was conducted by Kaydani et al. (2014). The GP correlation equation was developed using field data collected from various Iranian oil well pipelines, and its accuracy compared to several other empirical models. A statistical analysis of the results from the symbolic-regression-based model show that for either flow condition, it can be applied effectively yielding high accuracy for choke performance pipeline forecasting.

In a recent paper, Liu et al. (2015b) followed the idea first proposed by Cai et al. (2006) to integrate the GP technique with the GA for deriving more accurate heat transfer correlations. Three different experimental data sets, corresponding to a shell-and-tube heat exchanger with continuous helical baffles, a single row heat exchanger with helically finned tubes and a finned oval-tube heat

exchanger with double rows of tubes, respectively, were considered for their study. In each case, the final correlation functions were found to be more accurate in predicting their thermal behavior than currently used models. Based on the aforementioned work, Liu et al. (2015a) proposed a method for synthesizing both economic cost and energy benefit aspects of the sinter cooling bed. The predictions were based on correlation equations derived by symbolic regression for the annual energy gains as functions of the parameters of operation. A bi-objective optimization of the sinter cooling bed was finally performed to achieve the optimal conditions in reference to both waste heat utilization and economic cost. The advantage of the GP method in seeking an optimum functional form was exploited in these applications.

General Discussion of GAs and GPs

The evolutionary programming method has the advantage that, unlike the ANN, a functional form of the relationship is obtained. Genetic algorithms, GP, and symbolic regression are relatively new techniques from the perspective of thermal engineering, and we can only expect the applications to grow. There are a number of areas in prediction, control, and design where these techniques can be effectively used. One of these, in which progress can be expected, is in thermal-hydronic networks. Networks are complex systems built up from a large number of simple components; though the behavior of each component may be well understood, the behavior of the network requires massive computations that may not be practical. Optimization of networks is an important issue from the perspective of design, since it is not obvious what the most energy-efficient network, given certain constraints, should be. The constraints are usually in the form of the locations that must be served and the range of thermal loads that are needed at each position. A search methodology based on the calculation of every possible network configuration would be very expensive in terms of computational time. An alternative based on evolutionary techniques would be much more practical. Under this procedure, a set of networks that satisfy the constraints would be proposed as candidates for the optimum. From this set, a new and more fit generation would evolve and the process repeated until the design does not change much. The definition of fitness, for this purpose, would be based on the energy requirements of the network.

Concluding Remarks

AI is a broad term and many of its techniques have not been reviewed here. Reviews like those of Culp et al. (1990) on the impact of AI within the HVAC industry, and Cahill (1994) and Paoletti and Sciubba (1997) on the use of a knowledge-based expert system for the design of complex thermal systems like power plants, should be consulted. Other examples on the use of AI in thermal engineering are the following. Rasmussen et al. (1990) identified the distillation process dynamics comparing process knowledge and black box-based approaches. Gao et al. (1990) worked on the synthesis of optimized heat exchanger networks. Fujii and Lutzenhiser (1992) used intelligent systems in residential air-conditioning and natural cooling systems. Loveday and Virk (1992) applied the technique to buildings. Dregalin and Nazyrova (1993) introduced AI elements to heat power engineering. Sandberg et al. (1995) studied an intelligent distributed heater used for industrial applications. Yang et al. (1996) developed an analysis of intelligent control strategies of a thermal energy storage air-conditioning system. These papers indicate some of the wide variety of approaches that can be considered in thermal engineering.

Despite the tremendous strides made in advancing our knowledge base in the field of thermal science and engineering in the last 100 years or so, researchers in the field have often felt apprehensive that their hands were tied by the relatively limited though popular approaches in the traditional analysis of thermal phenomena: solving the governing first principles or modeling equations and finding the necessary correlations from experimental data. Even with the ever-increasing computing resources, which have become available, difficulties still exist since the systems are much

more complex, and the need is to respond more quickly to the applications and challenges of the fast-changing world of technology. The AI community provides some possible solutions, and it is surprising that there has not been much more concerted effort in the thermal-science research community to seek the application of these new approaches, which have the potential for addressing these needs. This section has discussed two of these techniques, the ANN and the genetic algorithmic approaches, that are beginning to take root now. The purpose here has been to introduce the reader to these methodologies, and it is up to him or her to apply them and similar procedures to a broader set of problems. AI techniques are well suited to complex problems, and thermal engineering presents many examples of this. It is not a substitute, but rather a complement, for incisive physical insight and first-principle analyses.

ACKNOWLEDGMENTS

We are grateful for the contributions our collaborators X. Zhao and R.L. McClain have made to our understanding of the subject. We are also thankful for the financial support of the late D.K. Dorini to the Hydronics Laboratory where most of our work has been carried out, and that of the Mexican Council of Science and Technology (CONACyT) and the Organization of American States for support.

4.28 THERMAL ASPECTS OF PAPER MAKING

Martine Rueff and Evelyne Mauret

Introduction

Paper making is a very ancient process that aims at producing fibrous materials, used in the everyday life, and characterized by an incredibly diversity of applications. However, papers are largely composed of cellulosic fibers issued from plant biomass only (mainly wood but also perennial and annual plants) even if some other fibers can be used for imparting very specific properties (synthetic, mineral, and animal fibers). So, paper and board are bio-based and recyclable materials, which make them perfectly suited to meet the requirements of a sustainable world.

Industrialization of paper making began in the nineteenth century with the invention of the internal sizing based on the use of rosin added to the fiber suspension in acidic conditions, in 1807. This treatment aimed at decreasing the surface energy of the fibers, allowed the elimination of a gluing operation previously performed on dry paper sheets, this operation being manual to a large extent. The first paper machines including a drying section equipped with heated cylinders thus appeared around 1820. Of course, from the nineteenth century, important modifications of the paper making unit operations (disintegration, refining, forming, pressing, drying, etc., operations) were conducted to improve the productivity of the paper machine and the quality of paper. The use of wood as the main source of cellulosic fibers instead of rags was also an important step and radically changed the way paper was manufactured. During the twentieth century, the development of new treatments of the fiber suspension in neutral or alkaline conditions allowed the use of calcium carbonate as mineral fillers, among other things. This was also a drastic change in the monitoring of the paper machines. From 1970, the progressive closing of the water circuits and the increasing use of recycled fibers were other important features in the evolution of the paper making practices. Today, changes are made in a more incremental way and the optimization of the process is made to limit the impact on our environment and the production costs; the main aim is to decrease the amounts of water, raw materials, and energy used for manufacturing paper. In that sense, the drying section of a paper machine is of utmost importance because it contributes largely to intensive energy consumption.

In the first section of this chapter, we will briefly describe the paper making process and the specific role of drying. Then, the kinds of cellulosic wood fibers used in paper making will be presented, as well as how these fibers interact with water. Finally, the main properties of the paper are described with a special focus on the effect of drying on some properties.

The second section is devoted to the description of the drying from a more formal point of view. A brief description of drying is made, including the driving forces and the physical phenomena taking place. This section will focus then on the multicylinder drying section, its organization, and the main equipment, which play a role on heat transfer and the economy of the process. Finally, physical properties of the paper constituents, in relation with drying, will be presented.

The Paper Making Process

From Pulp Disintegration to Drying and Reeling

This section is only a brief introduction to paper making. This process is described on a very broad basis and only the Fourdrinier paper machine, which is the most common paper machine, is considered. Interested readers may refer to more developed introduction (Scott et al., 1995; Gavelin and Smook, 1998; Rojas and Hubbe, 2004; Lundell et al., 2011) or to specialized literature (Jokio, 1999; Paulapuro, 1999; Ek et al., 2009; Karlsson, 2009; Holik, 2013).

Paper is produced from an aqueous suspension of lignocellulosic fibers mainly obtained from wood (softwood and hardwood species) by a process that combines batch and continuous unit

operations. In most cases, fibers are received as pulp bales. These commercial bales are disintegrated in pulpers in order to form a fibrous suspension as homogeneous as possible. Pulpers are tanks equipped with bottom-mounted turbines: They provide high shearing effects to the suspension and allow breaking bonds between fibers thus disrupting flakes of pulp. Pulpers work at about 40–50 g/L consistency, preferably in batch conditions so that the disintegration duration can be adapted to the properties of the pulp. Nevertheless, because of increasing production rates, some installations switch to continuous mode. This has a negative impact on the quality of the fiber suspension and leads to a poor dispersion. Whatever the operating mode considered, it should be kept in mind that the fibers used in paper making exhibit high aspect ratios and, for this reason, have a high propensity to flocculate (see Table 4.28.1). Obtaining a perfectly dispersed suspension is thus not possible apart from very low fiber concentrations (below 1 g/L), which are not representative of the conditions encountered in a paper machine.

The stored pulp suspension then undergoes a mechanical treatment, called refining, whose objective is to modify the properties of the fibers in order to meet the end-use requirements regarding the considered grade of paper. Refining induces external and internal fibrillation of the fibers resulting from the compression and shear forces acting during the operation. This leads to an increase of the swelling and the conformability/flexibility of the fibers, their specific surface area, and the production of cellulosic fines. Cellulosic fines are small-sized elements whose largest dimension is less than approximately 100 μm (the upper limit ranges between 75 and 200 μm according to the definition). Refining also induces a decrease of the fiber length. So, owing to the physical modifications undergone by the fibers, refining significantly influences the physical and mechanical properties of paper, much more than the other operations in the paper making process. Generally, refining is a continuous process involving disk refiners with grooved plates (see Figure 4.28.1). The flow of the fiber suspension is forced in between the plates—one rotating (the rotor plate) and one stationary

TABLE 4.28.1
Morphological Properties of Softwood and Hardwood Fibers

	Length (mm)	Width (μm)	Aspect Ratio (Length/Width)
Softwood	2–4	20–40	50–200
Hardwood	1–2	14–40	30–90

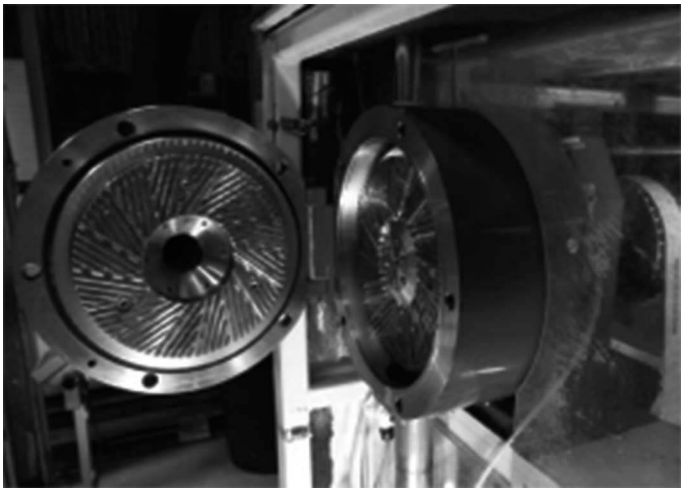

FIGURE 4.28.1 A disk refiner(©CHEZIERE).

(the stator plate). During the operation, the two plates are nearly in contact with gap clearance ranging from about 100 to 200 μm. The design of the disks (bar pattern, groove depth, bar spacing, etc.) and the refining conditions (pressure, flow rate, concentration, gap clearance between the disks, rotational frequency, etc.) are very important and directly impact the compression and shear forces acting on the fiber flocs as well as the energy consumption.

It is worth noting that many paper grades are made from blends of pulps: virgin or recycled pulps, mechanical or chemical pulps, hardwood or softwood pulps, etc. Whenever possible, and because the fibers issued from different sources have different properties, the pulps are disintegrated and refined separately.

After these two steps of disintegration and refining, the pulps are blended in the desired proportions and diluted to low concentrations (ranging from 5 to 10 g/L in most cases) by using water recovered from the sheet-forming section. The diluted pulp is then subjected to several stages of cleaning (centrifugal cleaning and pressure screening) and enters the headbox. The headbox is a fluid disperser device designed to create high levels of turbulence and shear and ensuring two main actions: the rupture of the fiber flocs and the homogeneous and regular delivery of the fiber suspension onto an endless moving wire that constitutes the dewatering fabric. On this fabric, a wet web is formed by filtration of the deposited suspension (see Figure 4.28.2). This web is drained by gravity, thanks to dynamic devices (foils, and possibly rolls at low-speed paper machines) and wet suction boxes until the wet line. Then, a diphasic flow of water and air takes place through the formed sheet, and the drainage is made by dry suction boxes. During the sheet formation, huge quantities of water (named white water) are removed and collected in specific trays from where it is pumped and partly reused for dilution purposes (this circuit constitutes the so-called short loop of the paper machine). The dryness of the wet web increases continuously during the sheet formation and reaches approximately 20% at the end of the moving wire before entering the press section.

It is worth noting here that many papers contain inorganic components in significant quantities. Chemical additives are also added into the fiber suspension from the disintegration stage to the headbox (Eklund and Lindström, 1991; Roberts, 1996; Scott, 1996; Neimo, 1999). The added amount of mineral fillers (ground calcium carbonate, clay, talc, etc.) depends on the paper grade and varies from 0 (blotting papers, tissue, etc.) to 20% approximately (printing and writing papers, for instance). In some specific cases such as decorative papers, higher quantities of inorganic compounds (up to 50%) are added and, quite often, pigments are used for these grades (titanium dioxide,

FIGURE 4.28.2 The forming section of a pilot paper machine (the wet line is visible).

precipitated calcium carbonate). Using the words pigment or filler is a pure convention for papermakers: pigments, which are more refined than fillers in terms of purity, specific surface area, optical properties, are by far more expensive and only used for high added-value papers when introduced into the fibrous suspension. Fillers are generally less expensive than virgin pulps and their introduction allows decreasing the production costs and improving certain properties of the paper (optical properties and printability, for instance). The chemical additives play an important role by improving the productivity of the paper machine (processing chemicals) and the end-use properties of the paper (performance additives). Retention and drainage agents are by far the most important processing chemicals. The combined introduction of cationic and anionic polyelectrolytes, which constitute the most common system used, allows monitoring the retention in small-sized elements (cellulosic fines, mineral fillers, and pigments) during the sheet formation on the forming fabric. Indeed, at this stage, the drainage of large amounts of water combined with the pressure pulsations induced by the drainage elements (rolls, foils, suction boxes) leads to a loss in fine elements. A large fraction of these elements are recycled with the white water in the short loop of the paper machine. Nevertheless, this loss contributes to lengthen the nonsteady periods when changes in the production operating conditions occur and then to decrease the productivity; it also causes an asymmetrical distribution of components in the thickness of the paper sheet, to cite a few of the numerous effects of low retention levels. The increase in the flocculation level of the fiber suspension allows for an entrapment of the finest elements in the formed flocs, which can be easily retained on the fabric. It also has a positive effect on the drainage rate of the suspension that may result in an increase of the production rate. On the other hand, the use of such additives negatively impacts the quality of the sheet formation (mass distribution) and that of the produced paper. In the case of overdosage, the presence of large flocs, from which water cannot be easily removed, may lower the dryness of the wet web entering the press section and such heterogeneities lead to the creation of defects in the paper sheet during pressing. Consequently, it appears that the optimal level of flocculation is a subtle balance influenced by the properties of the fibers, the conditions of turbulence in the headbox, the intensity of the pressure pulsations during the sheet formation, as well as the properties of the chemicals and their dosage in a given application (Eklund and Lindström, 1991; Scott, 1996; Neimo, 1999; Rojas and Hubbe, 2004; Hubbe et al., 2009).

After forming, the web is conveyed from the formation fabric to the press section where it passes through a series of nips formed by two rolls running under pressure to remove a significant fraction of the remaining water. Porous belts, called felts, support the sheet in the nips and contribute to dewatering (see Figure 4.28.3). The dryness increases again and, depending on the properties

FIGURE 4.28.3 Example of a press section of a pilot paper machine (the rolls, the nip, the belt, and the paper sheet are visible).

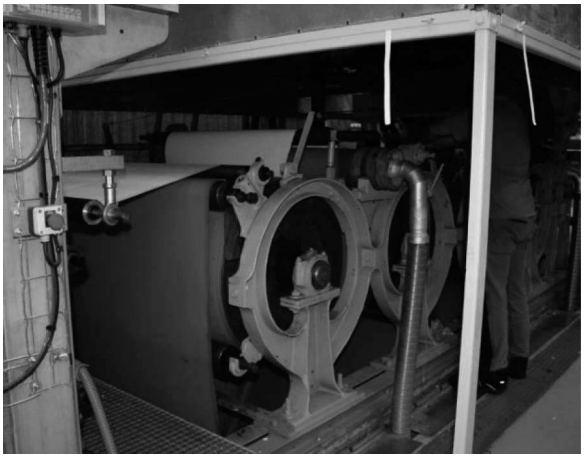

FIGURE 4.28.4 Example of a drying section of a pilot paper machine.

of the wet web and the technology used, is comprised between 40% and 50% at the end of the press section.

The final section corresponds to the drying stage. In most cases, rotating steam-heated cylinders fed with low pressure steam are used for drying (see Figure 4.28.4). Steam pressure is generally below 6 bar and so the surface temperature of the dryers does not exceed 130°C. Dryer fabrics are used in order to improve the contact area between the wet sheet and the drying cylinders and, as will be explained later, the drying fabrics may be used to carry the web in the paths between two cylinders. Paper drying is then predominantly based on conduction heat transfer but convection also plays a role, particularly during the travel of the sheet between two cylinders. There is indeed a relative movement between the web and the surrounding air and the drying section is ventilated to extract the water vapor evaporated from the sheet. Combining forced convection (impingement drying) to contact drying on drying cylinders is also a method to improve the capacity of a multi-cylinder drying section. Different technical solutions are available on the market. Though radiation heat transfer (infrared drying) may also be considered in order to improve the drying capacity of a paper machine, and thus its performance, it is in fact rarely implemented in the conventional drying section. It is more often used to even out the moisture profile before online surface treatment or at the end of the drying section as an alternative to remoisturizing the web, for instance. In this case, systems equipped with low power density infrared, acting over 150 mm width, may be used. The main application of infrared in paper making is to perform contactless drying after surface treatment. The dryness of the sheet after drying is generally comprised between 92% and 95%, each grade having specific targets. The drying operation will be described in detail in the third section of this chapter.

Finally, the paper enters the reel section where it is rolled up. The obtained parent roll is removed from the reeling machine and transferred to other places where the next operations can be conducted. It is worth noting that some finishing operations aiming at improving paper surface properties may also be performed online. In order to summarize the description of the paper making process, which transforms a fibrous suspension into a dry paper, a very simplified drawing of the paper machine is shown in Figure 4.28.5.

To conclude, and before describing the finishing and converting operations, it is important to point out here that the characteristics of the paper machines mainly depend on the grade of the paper produced and particularly on its basis weight. Paper machines can run at velocities ranging from 300 m/min (for carton boards, for instance) to 1500 m/min (for printing papers) or even at higher velocities. Their size may also vary considerably in terms of width and length. Paper machine may be from 50 to 150 m long, the drying section being the longest, up to 100 m long in certain cases.

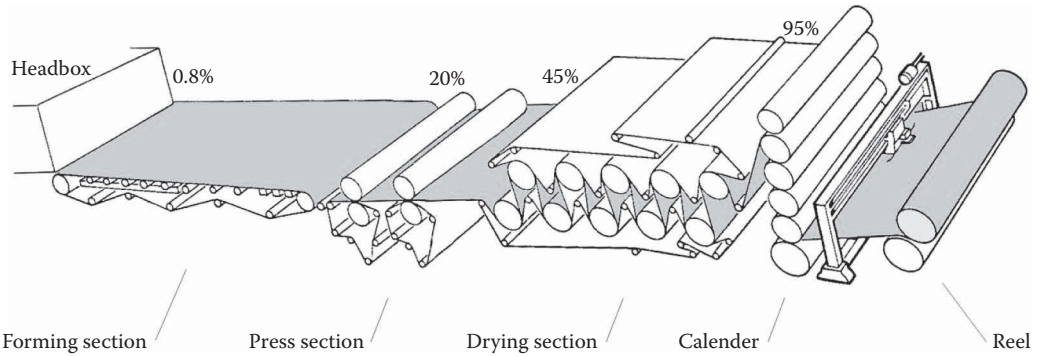

FIGURE 4.28.5 Very simplified drawing of a paper machine.

Paper sheets from 1 to 10 m wide can be produced. On modern paper machines, production rates can thus reach 40 tons/h. The paper making process involves the use of huge quantities of water: working at a low concentration is required in order to limit flocculation of the suspension resulting from the relatively high aspect ratio of the lignocellulosic fibers. Paper making can thus be viewed as a process allowing the removal of water from a fiber suspension. As a first approximation, 200 kg of water per kg of fibers are drained in the forming section, whereas the amount of removed water is close to 2 kg/kg and 1 kg/kg in the press section and the drying section, respectively (Ghosh, 2011; Karlsson, 2009, Chap. 2, p. 40). In most cases, the water is recycled in the process and, today, most paper machines allow producing paper with reduced consumption of water, generally $<5\ m^3$ of water per ton of paper produced. Certain paper machines work with fully closed circuits and the water consumption is reduced to nearly zero. Table 4.28.2 summarizes the amounts of water present at different locations of the paper machine.

The energy consumption of a paper machine is high and generally varies between 200 and 600 kWh/ton of paper produced for electricity and between 1300 and 1800 kWh/ton for thermal energy (McIvor et al., 1999; Molin et al., 2010). The largest consumption of thermal energy is in the drying section that represents about 40% of the total capital costs of a paper machine (Ghosh, 2011).

Finishing and Converting Operations

Sizing, coating, and calendering are considered as finishing operations. Generally, sizing consists of applying to the paper surface a thin aqueous layer of starch that may contain mineral pigments. To this purpose, the dried sheet passes through two soft rolls of the so-called size press and the size solution is metered in the nip. The amount deposited is generally comprised between 2 and 10 g of dry matter per square meter of paper. The objective is to improve the properties of paper

TABLE 4.28.2
Examples of Involved Quantities of Water and Dryness at Different Locations of the Paper Machine

	Dryness (%)	Moisture Content (kg/kg Dry Matter)	Cumulated Fractions of Eliminated Water (%)
Headbox	0.8	124	0
Wet line	2	49	60.5
Dry suction boxes	14	6	95.2
Couch roll	20	4	96.8
Press section	40	1.5	98.8
Drying section	95	0.05	>99.9

by increasing its strength and limiting dusting problems. This operation also decreases the surface porosity and, consequently, slows down the penetration rate of liquids into the sheet. Specific chemicals can also be added to decrease the surface energy of paper. A great number of paper grades undergo such a treatment from printing papers to liners or fluting media. Compared to sizing, coating aims at modifying the surface properties of the sheet in a more drastic way. The formulation of the deposited dispersion is complex: it is made of water, mineral pigments, binders (polymer emulsions, water-soluble polymers), and additives (thickeners, dyes, optical brightening agents, etc.). Coated papers are printing grades (magazines, paper boards, etc.), mainly because the printing quality is significantly improved after coating and calendering resulting in very good properties in terms of surface smoothness, brightness, opacity, surface energy, among others. Coaters are based on several techniques (roll coater, air-knife coater, blade coater, etc.) depending on the required properties, the targeted quantity deposited during the coating, etc. The basis weight of the dry coated layer ranges from 10 to 30 g/m² and, when necessary, several coating layers can be deposited so that the final basis weight can reach more than 100 g/m². Both sizing and coating operations require the presence of a devoted drying section combining contact-free drying devices to preserve the wet coating layer, which could adhere on the dryer shell (infrared and air dryers) and conventional drying cylinders (Hung et al., 2014).

Calendering, which is based on a mechanical treatment, also aims at improving the quality of the paper surface and leveling the thickness profile. This operation is carried out on steel rolls disposed in a stack in which paper is subjected to friction and compression forces. The main operating parameters impacting the effect of calendering are the nip pressure, the number of nips, and the retention time. Supercalendering is a more intensive operation generally used for coated papers. In this case, paper passes between soft (polymer, compressed paper, or cotton) and hard (steel) rolls disposed alternately in a stack. The operation involves high pressure and the effect on paper is important: very glossy papers can be obtained by supercalendering. Calendering is generally performed on the paper sheet just before it is rolled up, whereas supercalendering is performed offline. Several other techniques of calendering exist, but they are not detailed here: softcalendering, extended-nip calendering, etc. The effect of calendering is more pronounced if the moisture content in the paper sheet is increased and if the operation is conducted at a high temperature. This is generally done by spraying water on the paper just before the nip and by heating the rolls to temperatures ranging from 80°C to 200°C, depending on the desired intensity of the operation. At such temperatures, water acts as a plasticizer and facilitates the softening of the wood polymers as well as that of the coated polymers, thus increasing the efficiency of the calendering. Most often, the calendering operation aims at modifying the surface only and not the bulk of the paper: supercalendering must be conducted so that the increase of moisture content in the paper and of the temperature remains localized at the surface of the sheet.

Depending on their use, paper or boards can be subjected to various converting treatments and, among these treatments, one operation is particularly important because it refers to a grade of paper used in everyday life. This is thermoforming on which the production of corrugated medium is based. Such an operation is performed on a corrugator fed with several sheets of paper. Some of the sheets (the fluting medium) are subjected to pressure by being pressed in between heated corrugated metal rolls, their surface temperature being around 180°C. A corrugated paper is then obtained and, once a suspension of starch granules has been deposited on the tips of the flutes, the fluting paper is joined to the liner to form a complex by gluing. This operation is repeated on the other side of the corrugated sheet to form a corrugated board.

Calendering and thermoforming of the sheet are thus ensured by the fact that paper is a thermoplastic material. The softening of paper results from the combined action of heat and water. In the dry state, the wood polymers have very close softening properties. The glass transition temperatures of amorphous cellulose, hemicelluloses, and lignin are about 200°C. When the water content increases, the glass transition temperature of the polysaccharides may reach ambient or subambient temperatures, whereas that of lignin is about 100°C (Back and Salmen, 1982; Szczesniak et al.,

2008; Paes et al., 2010; Horwath et al., 2011). For these finishing and converting operations, heat transfer through the paper thickness, moisture content, and thermal properties of the sheet, therefore, play a major role. Nevertheless, the operating temperature must be adapted to avoid thermal degradation of the fibers that begins at about 220°C (Yao et al., 2008).

The Cellulosic Fibers and Their Behavior during the Paper Making Process

As already mentioned, cellulose, hemicelluloses, and lignin are the main constituents of all wood species. The cellulose, which is a linear polymer of cellobiose, constitutes the strength-bearing component of the fiber (see Figure 4.28.6). In its pristine natural state, its degree of polymerization may be very high (10,000 or more) depending on the considered vegetal species. Intra- and intermolecule hydrogen bonds impart to the cellulose a high level of organization and crystallinity. Cellulose molecules are thus strongly linked to form supramolecular assemblies such as microfibrils in which crystalline and amorphous regions alternate. Amorphous zones result from defects occurring during the growth of the trees and contribute to a large extent to decrease the strength of such materials.

Cellulose microfibrils are embedded in an amorphous matrix of hemicelluloses whose chemical composition and structure can significantly vary from one vegetal species to another. Hemicelluloses are by far more accessible to chemicals than cellulose and consequently more reactive. They are made of branched polysaccharides of hexoses or pentoses. Hemicelluloses play a crucial role in paper making because they may bear functional groups (carboxylic groups) that can be ionized in the conventional conditions of pH used for the production of paper (that is between 5.5 and 8 in most cases), thus conferring an anionic charge to the fibers. Lignin is a very complex phenolic macromolecule whose composition also differs by species. In wood, lignin can be viewed as a binder between the fibers. It imparts rigidity to the material, but it also confers resistance to wood against microbiological attacks. The wood fibers are, therefore, formed by the association of cellulose microfibrils and matrices of hemicelluloses and lignin. The concentration of these constituents varies in the fiber cell walls, which comprise three main layers: the middle lamella at the outside of the fiber, the primary and the secondary walls (see Figure 4.28.7). The middle lamella is rich in lignin and ensures the cohesiveness between the fibers. The primary wall also contains lignin in significant quantity together with cellulose and hemicelluloses. In the primary wall, cellulose exhibits lower degrees of crystallinity and polymerization than in the secondary wall, which constitutes the thickest region of the fiber. The secondary wall is divided in three sublayers (S_1, S_2, and S_3) with different compositions and thicknesses. The sublayers are very rich in cellulose and hemicelluloses. The orientation of the cellulose fibrils varies from sublayer to sublayer and this organization largely contributes to the strength of the cellulosic fiber. The lumen corresponds to the central opening of the fiber.

The proportions of the three main components in wood are on average 40%, 35%, and 25% for cellulose, hemicelluloses, and lignin, respectively (%, w/w), as illustrated in Table 4.28.3.

Fibers used in paper making can be obtained from wood by chemical or mechanical treatment. Chemical pulping of wood consists of dissolving lignin by removing the middle lamella: it is the most efficient way to get well-separated individual fibers exhibiting good properties. Kraft pulping uses a mixture of sodium hydroxide and sodium sulfide. It is the preponderant process with more than 90% of the chemical pulps produced in the world because it is based on a very efficient chemical recovery system. The other process is the acid sulfite pulping, which is used for producing

pulps with high content in cellulose, hemicelluloses being quickly degraded in acidic conditions (see Table 4.28.4).

In the mechanical processes, fiber separation is caused by shear forces exerted on pieces of wood, which can be pretreated (by hot water, steam, or chemicals) in order to soften the lignin and facilitate the grinding process. Mechanical defibering process does not allow a good separation of the fibers: the pulp contains shives or bundles of fibers and also a high quantity of fines whose production results from the very intense shear forces occurring during the operation. The properties of the obtained pulps are thus different from those of the chemical pulps. The fibers have less affinity to water, are less flexible, and form paper with relatively poor mechanical properties. The yields of the mechanical pulping processes are high (more than 90%) when compared to those encountered in chemical pulping (about 50%) where most of the lignin and simultaneously a fraction of the hemicelluloses are dissolved.

The fibers obtained after pulping (mechanical or chemical) are more or less brown, depending on the process used. This color is mainly due to the presence of lignin and may even be more

pronounced after a kraft chemical pulping, for instance. Removing the remaining lignin or converting the chromophore groups to colorless ones is thus important when white grades of pulps are required. This is done by using oxidants (ClO_2, H_2O_2, O_2, Na_2O_2, etc.) during the bleaching operation. After the pulping and bleaching operations, the obtained pulps are pressed, dried, and packaged in the form of bales. The combined effect of the chemical pulping and bleaching decreases the degree of polymerization of the cellulose polymers to about 1000–1500.

Besides the virgin pulps, recycled pulps play a major role today. They represent more than 50% of the sources of fibers for the paper making industry: Today, this proportion exceeds 60% in Europe. Recycled papers from various sources (magazines for the low-quality grades or kraft linerboards for high-quality grades, for instance) are disintegrated in the paper mill, in pulpers working at a high consistency (around 10%, w/w). Compared to the production of paper from virgin pulps, the use of recycled fibers requires intense cleaning stages, also operating at a high consistency (between 3% and 5%, w/w). Finally, although refining is a key unit operation for virgin pulps, it is performed under very moderate conditions for recycled fibers that are characterized by their weakness. It is worth noting that recycled fibers can be composed of mechanical or chemical fibers or a mixture of these two types of fibers and also that their properties and behavior are neither easily predictable nor reproducible.

The affinity of wood fibers (and nonwood fibers as well) with water is a key parameter of the paper making process. Once immersed in water, the cellulosic fibers swell almost instantly and this affinity helps their dispersion, which is also favored by the presence of anionic charges on their surface (Eklund and Lindström, 1991; Roberts, 1996; Hubbe et al., 2007). The behavior of fibers in water depends on several factors, the most important one being their chemical composition and the accessibility of the fiber wall to water. Thus, thanks to the presence of OH groups onto cellulose and hemicelluloses, hydrogen bonds can be formed between the water molecules and the main constituents of the fiber, both at its surface and in its wall. Lignin that is more hydrophobic limits the sorption of water. Moreover, during chemical pulping, the lignin present in the primary and secondary walls is removed to a great extent. This elimination, more or less easy depending on how the lignin and the carbohydrates are bound, leads to the creation of voids or pores inside the fiber walls. These pores also favor the penetration of water. Consequently, the tendency of chemical fibers to swell in water is enhanced when compared to that of mechanical fibers, which do not undergo the same phenomena during pulping and which contain high amounts of lignin. Ionized chemical groups also promote interactions of the fibers with water molecules. Hardwood fibers are more charged than softwood fibers due to the presence of hemicelluloses containing a greater amount of carboxylic functions and they therefore exhibit a greater tendency to swelling compared to softwood. Sulfonic

acidic groups, ionized whatever the pH, must also be taken into account for certain high yield pulps; they result from the fact that wood chips can be impregnated by sodium sulfite in order to soften them and facilitate the subsequent operation of defibering. It is also important to mention here that the refining stage plays a major role: by promoting external fibrillation (thus increasing the specific surface area as illustrated in Figure 4.28.8) and internal fibrillation (which corresponds to delamination phenomena of the ultrastructure of the fibers), refining has a considerable effect on fiber swelling. Finally, increasing the pH of the suspension (which leads to an increase in the amount of ionized carboxylic groups) or decreasing the ionic strength (which limits the screening effects of the electrical charges born by the fibers) also favor the affinity of the fibers with water but to a lesser extent than refining.

Water present in the wet web is commonly referred as free and bound water even if a continuum does exist between the totally free water (capillary condensation) and the strongly bound water (adsorbed as a monolayer) as illustrated on Figure 4.28.9. In physisorption (or physical adsorption), intermolecular forces (e.g., van der Waals forces or hydrogen bonding) are responsible for adsorption; the surface is not altered chemically (chemisorption). Multilayer adsorption is frequently observed. The adsorbate uptake increases usually with increased partial pressure of the fluid and decreasing temperature. The water present far from the cellulosic surface, even in the pores of the fiber wall, must be considered as free water. On the contrary, bound water strongly interacts with cellulose and hemicelluloses at very short distance: it is present onto the surface of the fiber (outside and lumen surface) and in the fiber wall.

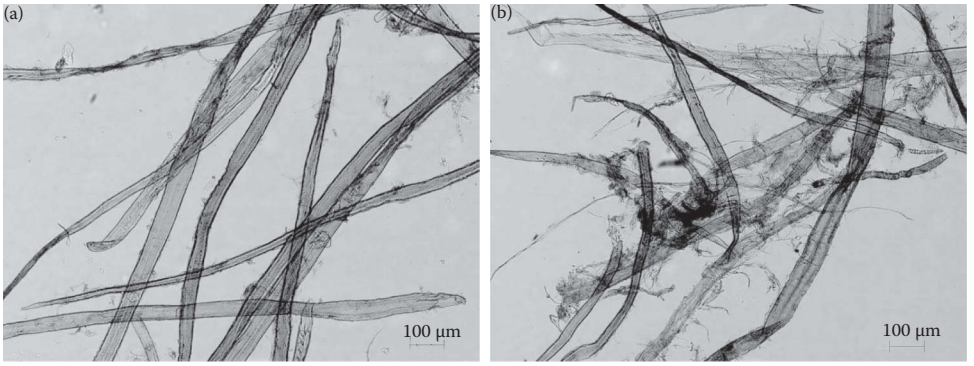

FIGURE 4.28.8 Optical photomicrographs of softwood chemical kraft fibers: slightly refined (a) and highly refined (b).

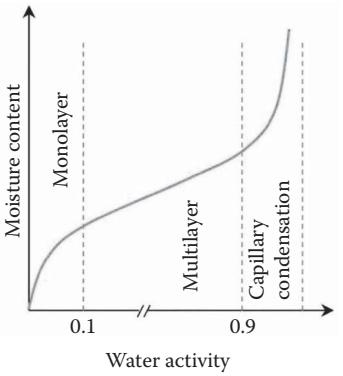

FIGURE 4.28.9 Typical shape of a sorption isotherm showing the different states of water. Activity of water is equal to the relative humidity of the ambient air (see Equation 4.28.2).

Bound and free water show different properties. Viscosity, density, and boiling point of bound water are, for instance, higher than those of free water. In contrast, the dielectric constant is lower for bound water. The free water present between the fibers is relatively easily removed from the wet web and a significant part is eliminated during the forming and pressing operations. However, the water present inside the fiber requires more energy to be removed. The swelling of the fibers may be evaluated by measuring the water retention value (WRV). It corresponds to the amount of water remaining in a small sample of pulp after centrifugation (generally at 3000 g for 10–20 min):

$$\mathrm{WRV} = \frac{\text{Weight of the centrifugated sample}}{\text{Weight of the dried sample}} - 1. \tag{4.28.1}$$

The WRV is then expressed in grams of water per gram of dried fibers. This value lies between 0.8 g/g for unrefined unbleached softwood kraft pulps and 2.0 g/g for refined bleached hardwood kraft pulps. When small-sized cellulosic elements are present in significant amounts in the pulp, the WRV increases because it also includes capillary water retained onto the surface of these elements. Thus, for values greater than 2 g/g, the WRV does not reflect the swelling of the fiber only and it must be considered with caution.

The elimination of water from the fiber wall has several consequences (Niskanen, 1999a; Hubbe et al., 2007): pressing and drying affect the cross-sectional shape of the fibers. Indeed, when the water is removed, the fibers shrink and the lateral shrinkage of the fiber is by far more important (about 15%–30%) than the longitudinal shrinkage (about 2%). Finally, removing the water from the cell wall leads to the creation of new hydrogen bonds between the cellulose chains. These bonds are often not easily broken during subsequent rehydration of the fibers. It implies that a never-dried fiber swells to a greater extent than fibers that have undergone a drying stage. This phenomenon that limits the accessibility of the wall to water is often called hornification. It also modifies the mechanical properties of the fibers. So, when a never-dried single fiber is dried under restraint, its tensile strength increases and its elongation at break decreases, which results from the rearrangement of the polymers in the cell wall (Niskanen, 1999b).

In summary, it is worth noting here that numerous parameters such as the chemical composition of the fibers, the amount of fine elements, the level of refining, the pH of the suspension, and its ionic strength have a direct impact on the swelling of the fibers and, consequently, on the specific energy consumption during its drying.

Paper: Composition, Grades, and Main Properties

A sheet of paper is a complex porous structure made of cellulosic fibers and fines and, in many cases, of mineral fillers or pigments and additives. The paper composition depends on its end-use and three main grades of paper can be considered according to Paulapuro's classification (Paulapuro, 2000): printing and writing papers (copy papers, newsprint papers, magazines, etc.), packaging papers (paper boards, corrugated board, liquid packaging boards, etc.), and specialty papers (tissue, security papers, labels, etc.). Figure 4.28.10 shows scanning electron microscope (SEM) pictures of a cardboard and a coated paper.

Paper is characterized by its basis weight and its apparent density. Typically, basis weight varies from 20 g/m² (for tissue paper, for instance) to more than 400 g/m² (for boards). The apparent density of paper is typically in the range of 0.5–1 g/cm^3, whereas the density of pure cellulose is close to 1.5 g/cm^3. Consequently, the sheet porosity, which is the ratio of the pore volume to the total volume of the paper, ranges from 0.3 to 0.7 in most cases. Papermakers often used the specific volume or bulk, which ranges from 1.2 to 2 cm^3/g. In a paper sheet, the porous network has interfiber pore sizes of the order of 0.5–10 μm (Corte, 1957).

The properties of paper are largely governed by its structure. In a paper sheet produced on an industrial paper machine, the fibers exhibit specific orientations. Due to the forming process, the

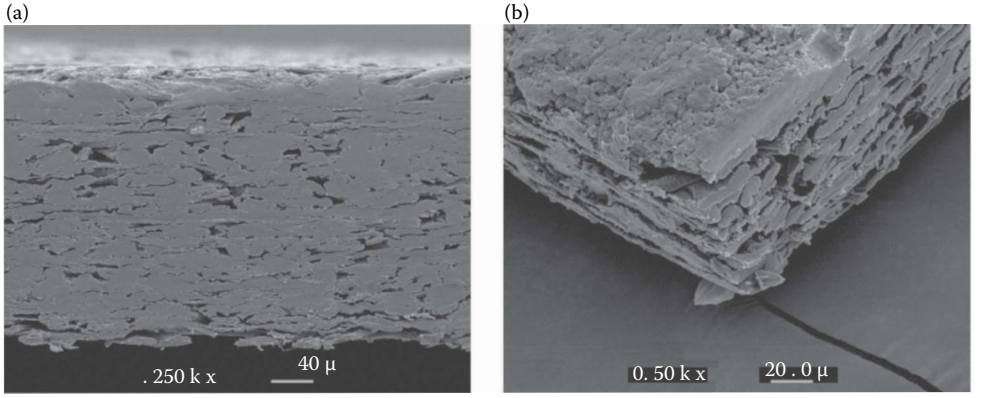

FIGURE 4.28.10 SEM pictures of cardboard (a: view of a cross section) and a high-gloss ink jet paper (b: view of the coated layer and the cross sections).

fibers are thus preferentially oriented with their main axis perpendicular to the thickness of the sheet: the paper can thus be viewed as a layered structure. Moreover, if we consider the plane of the sheet, the fibers also have a preferred orientation in the direction of the production named the machine direction. This orientation can be adjusted; it results from the difference between the velocity of the suspension leaving the headbox and that of the forming fabric. Increasing this difference leads to a more marked orientation. Fiber orientation influences the properties of paper and, depending on the tested direction, paper shows different values in terms of tensile strength, Young's modulus, tearing strength, etc. Moreover, all along its production, the wet paper sheet undergoes strains in the machine direction that results from different velocities between press section rolls, dryer rolls, etc. This strain positively impacts the main mechanical properties of paper in the machine direction. On the other hand, in the cross direction, particularly in the regions close to the edges, and in the transverse direction (or *z*-direction), the sheet can move more freely. The elimination of the water present between the fibers induces capillary forces, which contribute to hold the fibers together. The fibers come into contact as water is removed and the network thus gains strength to withstand external forces. This phenomenon, combined with the shrinkage of the individual fibers, causes a global shrinkage of the fibrous network during drying. The in-plane shrinkage may be noticeable and reach values generally between 2% and 10% in the cross direction. The magnitude of shrinkage in the *z*-direction is much greater. For instance, Wahlström (1999) measured a global shrinkage in the range from 2% to 6% in the cross direction, whereas it was between 40% and 60% in the *z*-direction. Shrinkage depends on the initial swelling of the fibers and on their specific surface area, these properties being largely influenced by the refining of the suspension. The lateral shrinkage of the fibers during drying creates shear stresses and compressive stresses (microcompressions) in the regions of bonding between fibers. Together with the fiber orientation, shrinkage thus induces differences in terms of properties between the cross direction and the machine direction. For instance, the elongation at failure obtained from a tensile test is greater in the cross direction than in the machine direction because of this anisotropic shrinkage. The existence of a shrinkage profile, as already mentioned, also explains why properties can significantly vary along the cross direction. Consequently, elongation at failure in the cross direction is greater for paper strips sampled near the edge of the sheet than that of paper strips sampled in the middle of the sheet. It should be noted that it is possible, in a paper machine, to limit, at least in part, the cross-directional shrinkage but not that in the *z*-direction.

Paper produced on a classical Fourdrinier paper machine also shows an unequal distribution of fine elements in the thickness. This originates from a nonsymmetrical forming; the use of retention agents helps to improve the distribution profile. Besides these considerations, it is important to note that paper does not consist of individual fibers homogeneously distributed in the sheet, but is made of flocs containing fibers and fine elements. Indeed, depending on the formation conditions

(intensity of the turbulence in the headbox and of pressure pulsations in the forming section, dosage of the retention, and drainage agents), the flocculation of the fibers is more or less pronounced, which affects the floc size and the quality of the sheet formation through nonuniform mass distribution. All these phenomena are detailed in Niskanen (1999b).

The mechanical strength of a paper sheet depends on numerous parameters such as the fiber strength, its aspect ratio, the number and nature of bonds between fibers as well as their distribution, which itself is impacted by the sheet formation, the stress distribution, etc. The involved bonds result from different mechanisms and, until now, their relative importance has not been totally elucidated (Lindström et al., 2005; Hubbe, 2006). Hydrogen bonding is generally considered as the most important mechanism but attractive van der Waals forces, attractive and repulsive electrostatic forces acting between charged groups, among others, must also be considered. These forces take place mainly at a molecular level and very short distances, which seems, in a first approach, incompatible with the roughness of the fibers. Nevertheless, several phenomena may justify the creation of bonds, which occur during the progressive elimination of water resulting from the drying of paper. Capillary forces thus play an important role. Their increase during drying is a driving force that pulls the fibers together thus allowing close contact and bonding. The diffusion mechanism corresponds to the extension in water of segments of macromolecules or fibrils out of the surface of the fibers. When two surfaces are brought closer together, macromolecule or fibril segments may come into contact so that bonds are created. This explains why swollen macromolecules such as hemicelluloses are crucial for obtaining paper with high strength. Mechanical entanglement of fibrils and fibers also helps to improve the strength. This discussion emphasizes the importance of the conformability and flexibility of the fibers and of the presence of fibrils at the fiber surface for an adequate formation of contact surfaces. As discussed earlier, these properties are influenced by the refining stage, which explains why this operation is fundamental in order to increase paper strength.

Because paper is a hygroscopic material, its moisture content depends on the relative humidity of the surrounding atmosphere. Relative humidity is defined as the ratio between the ambient partial pressure of water vapor, e', and the partial pressure of water vapor at saturation at the same total pressure and temperature, e'_w:

$$RH\% = \frac{e'(p,T,r)}{e'_w(p,T)} \times 100, \tag{4.28.2}$$

where e'_w depends on the total pressure of the system, p, and temperature, T. It is very close to the saturation pressure of pure water at low temperature. The partial pressure of water vapor in the air, e', depends also on the mixing ratio of the air (r is the ratio of the mass of water vapor in the air to the mass of dry air).

At equilibrium, the relative humidity of the surrounding air and the activity of water in the material are equal. Working at constant pressure (atmospheric pressure), the total pressure of the system is omitted in the variables. The activity of water in the material, a_w, which depends then on the temperature and moisture content, X, of the material, is

$$a_w(T,X) = \frac{e'(T,X)}{p_{sat}(T)}, \tag{4.28.3}$$

where e' is the partial pressure of water vapor in the material (considering the comment on pressure, this partial pressure is a function of the temperature and moisture content) and p_{sat} is the saturation pressure of pure water.

Sorption isotherms provide the relationship between the equilibrium moisture content in the paper sheet and the relative humidity of the ambient air (or water activity in the material) for a given temperature (Figure 4.28.11). The general shape of paper sorption/desorption isotherms looks like type II of IUPAC (International Union of Pure and Applied Chemistry) classification. Sorption

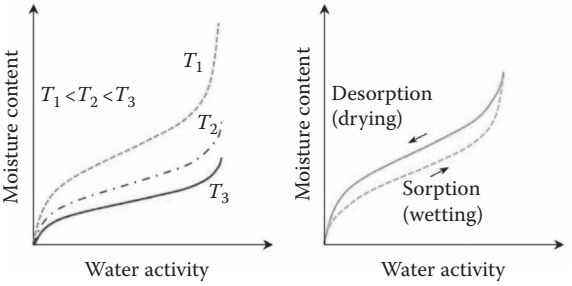

FIGURE 4.28.11 Typical shape of sorption isotherms at different temperatures (left) and hysteresis effect (right). Activity of water is equal to the relative humidity of the ambient air (see Equation 4.28.2).

isotherms may be different for water sorption and desorption, particularly during the first expositions of paper to various atmospheres (Figure 4.28.11). This hysteresis is due to the fact that a total rewetting of paper after a first drying is not possible, because of the irreversible formation of bonds between cellulose chains in the walls of the fibers. This phenomenon was already described when hornification was defined. Other aspects of the hygroscopic behavior of paper are discussed later.

The properties of paper are influenced by its moisture content and decreasing the amount of water sorbed by a paper is a way to increase most of its mechanical properties. Nevertheless, when paper becomes too dry, such as for relative humidities below 15% and moisture contents close to zero, it becomes very brittle and the mechanical properties may be significantly reduced. This phenomenon emphasizes the fact that water acts as a plasticizer in the sheet structure. Consequently, overdrying can be detrimental and this is why paper dryness above 95% should be avoided.

An increase in the moisture content of paper also induces hygroexpansion, which corresponds to the strain measured for a given change in relative humidity. This phenomenon depends on the ability of the paper to sorb water and on the degree of bonding of the fibrous network. Consequently, the composition of the paper needs to be considered: mineral fillers or addition of chemicals that limit the water sorption improve the dimensional stability of paper. The composition of the fibers themselves is also important: papers made from chemical pulps exhibit poor dimensional stability compared to those made from mechanical pulps. Increasing the refining level contributes to decrease in the dimensional stability because the degree of bonding is greater. This hygroexpansion is also largely governed by the fiber orientation in the fibrous network and its shrinkage during drying. The dimensional stability of freely dried sheets is thus drastically lower than that observed with a paper dried under restraint. Consequently, hygroexpansion is much higher in the cross direction than in the machine direction. The difference in composition of the two sides of the paper sheet leads to differences of local moisture contents and here again the two sides may have different hygroexpansion. The fact that hygroexpansion locally varies in the sheet leads to specific behaviors such as paper curl, cockles, etc., and also alter the runnability of the subsequent operations undergone by the material. Hygroexpansion is a major concern for paper producers, printers, and converters. Therefore, many investigations have focused on the sorption/desorption isotherms of paper and their link with some physical properties. One can find in the literature a comprehensive list of publications on this subject, most data concerning results at a low temperature, that is to say room temperature.

In summary, drying plays a major role in paper making. It is an energy-consuming operation and its relative share in the production costs of a paper machine ranges between 70% and 80% (Ghosh, 2011). The drying operation also impacts to a great extent the properties of the paper mainly through the anisotropic shrinkage of the sheet occurring when water is eliminated. Mechanical properties and dimensional stability are particularly influenced. Table 4.28.5 shows properties affected by drying for different grades of paper. For all these reasons, a good control of this operation is necessary to limit the increase in the production costs and to control the paper properties for its intended end use.

Drying of Paper: General Aspects

As already mentioned, drying is the final dewatering step in the paper making process, which is usually implemented when the mechanical water removal techniques have reached their limits; the moisture content of the web entering the drying section is generally between 1.0 and 1.4 kg water per kg dry matter depending on the fibrous composition, refining level of the pulp and technology used. However, in the case when high bulk is desired, moderate pressing is applied and thus drying starts at a relatively high moisture of paper. Drying is an important stage of the manufacturing process because it determines the final structure of the fibrous network and the distribution profile of the small particles. It also plays a significant role on the properties of the end product (mechanical properties, optical properties, etc.) owing to the creation of bonds between fibers and the development of stresses within the fiber walls during consolidation of the material as already mentioned in a previous section of this chapter.

Drying involves simultaneous heat and mass transfer:

- Heat transfer to the material to be dried, allowing water phase change
- Mass transfer from the bulk to the exterior of the material

Contact drying, in combination with convection drying, is the most common method in the paper making industry as shown in Table 4.28.6 (Karlsson, 2009; Polat and Mujumdar, 2014). Conventional drying is performed in a multicylinder drying section that is surrounded by a hood. Figure 4.28.12 illustrates two different organizations of dryers (double felted and single felted) that are generally seen in the drying section of a paper making plant. The reasons for these configurations will be

TABLE 4.28.6
Share of the Drying Technologies by Application

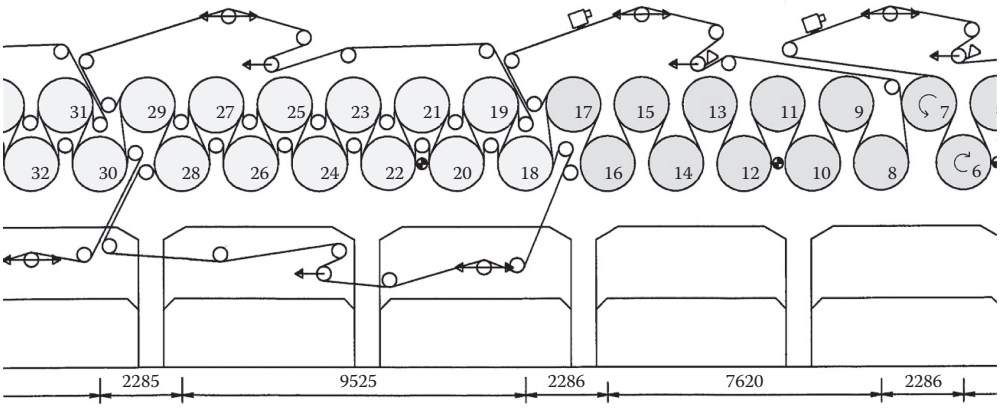

FIGURE 4.28.12 Two typical arrangements of the dryers at a paper machine.

discussed later in this section. Figure 4.28.12 also shows the travel of the paper from one dryer to the next one and the presence of fabrics, the role of which will also be described later.

Other technologies using infrared radiation or convection are used for specific purpose or grades, as shown in Table 4.28.6. The order of magnitude of evaporation rates attained in each type of dryer is reported in the same table. It should be noted that the evaporation rate can be defined by different manners. For instance, for a cylinder dryer, the surface area can be either the surface of paper in contact with the dryer or the lateral area of the dryer. The former is used in Table 4.28.6. It is noticeable that the evaporation rates obtained with all the other technologies are significantly higher than with a conventional steam-heated dryer. However, the reader should be aware that these systems are used for a specific purpose.

In addition, it should be noted that the drying section is equipped with runnability devices, ventilation systems, heat recovery exchangers, etc., and that the dryers are heated with saturated (or slightly overheated) steam; the drying section needs a steam–condensate system. None of these systems are included in Figure 4.28.12. Depending on the design of the hood, the ventilation systems, and also the operating conditions (steam temperature, air temperature, etc.), the performance of a drying section can vary to a certain extent for the same grade of paper.

This chapter is focused on the case of the multicylinder drying section only. After a brief description of the phenomena taking place during paper drying, the role of the different elements and the effect of operating parameters are explained in more detail.

The Different Stages of the Drying Process

A drying curve for contact drying of a capillary porous medium such a paper, performed under laboratory-controlled conditions, can be divided into three different periods:

- Temperature increase: The sheet temperature increases and a temperature gradient develops within the thickness of the sheet. Moisture content only slightly decreases.
- Constant evaporation rate: The wet sheet behaves like a water surface. This period lasts as long as the surface is fed with water from the bulk of the material. The main mechanisms, described by Dreshfield and Han (1956), are the following. Water evaporates at the free surface but vapor is also produced close to the hot surface. While migrating toward the free surface, this vapor is subjected to evaporation–condensation cycles. Liquid water moves toward both surfaces under the effect of capillary pressure. Sheet permeability is therefore an important parameter. Simultaneously, structural modifications take place resulting from substantial shrinkage and increase in air content.

- Decreasing evaporation rate: At a certain moment, the superficial layers in contact with the hot surface are no more saturated with water and the evaporation rate therefore decreases. The evaporation front recedes within the bulk of the material. The surface area in contact with the hot surface decreases and also the thermal conductivity of the layers close to the hot surface, increasing the resistance to heat transfer. As a consequence, the temperature of the sheet decreases until an equilibrium is reached and then it reincreases (Deshfield and Han, 1956; Jones, 1969). According to Dreshfield and Han (1956), the external conditions are less important here than that in the constant rate period. The value of the moisture content when the evaporation rate starts to decrease is called the critical moisture content. Its value depends on various parameters such as the basis weight of the web (the higher the basis weight, the higher the value of the critical moisture content; this is due to the gradients that develop within the sheet thickness), drying rate (the faster the drying, the higher the value of the critical moisture content; this is also due to the gradients within the sheet thickness), heterogeneities of the sheet, refining degree of the fibers or moisture content of the web at the commencement of drying among others. For example, laboratory experiments give values ranging between 0.3 and 0.6 kg water/kg dry matter for papers having a basis weight below 100 g/m^2 and as high as 1–1.2 kg water/kg dry matter for very heavy papers (200–800 g/m^2).
- In the case of convection drying, the same three drying regimes are encountered. During the constant rate period, the sheet is at a temperature close to the wet bulb temperature of the air.

Among the different mechanisms that may contribute to moisture movement during the drying of porous materials, that is to say liquid migration due to gravity, capillary migration, diffusion due to a concentration gradient, diffusion under the effect of a partial pressure gradient and thermomigration, capillary migration of liquid water, and diffusion of water vapor are the most important. It should be noted that, in the case of paper drying, the Fickian diffusion only is considered and not the Knudsen diffusion that occurs when the scale length of a system is comparable to or smaller than the mean free path of the particles involved. However, when the surface of paper has been coated, the Knudsen diffusion cannot be neglected in the coat because of the small pore sizes in this layer (<0.5 μm).

During the constant rate period, mass transfer is limited by the boundary layer at the free surface. The mass flux is given by

$$J_m = \frac{D_{va} \cdot M_v}{R \cdot T_p \cdot \delta_m} \cdot p \cdot \ln \frac{p - e'_a}{p - e'_p}, \tag{4.28.4}$$

where p is the pressure in the air surrounding the dryer, e'_a is the partial pressure of water vapor in the air, e'_p is the partial pressure of water vapor at the sheet surface, D_{va} is the coefficient of diffusion of water in air, T_p is the temperature of paper at the surface, and δ_m is the thickness of the boundary layer. This expression can also be written as

$$J_m = \frac{k_m \cdot M_v}{R \cdot T_p} \cdot p \cdot \ln \frac{p - e'_a}{p - e'_p}, \tag{4.28.5}$$

where k_m is the mass transfer coefficient.

The mass transfer coefficient is generally assessed using the Chilton–Colburn analogy (Bergman et al., 2011). It is expressed as

$$k_m = \frac{h^*_{pa}}{\rho_a \cdot c_{pa} \cdot Le^{2/3}}, \tag{4.28.6}$$

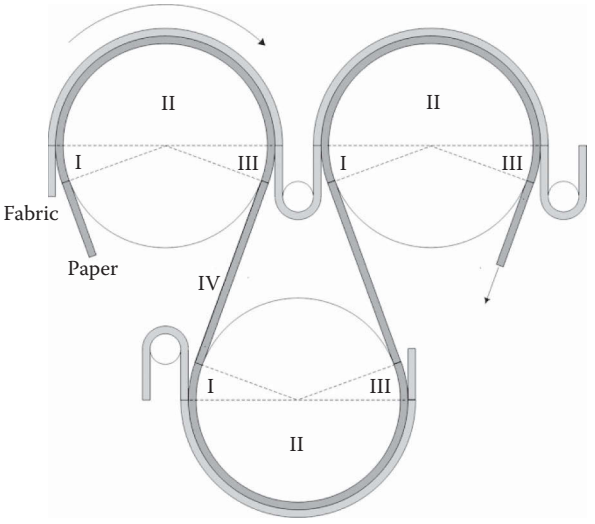

FIGURE 4.28.13 The four drying phases of paper in a drying section, as defined by Nissan (1960, 1961).

where h_{pa}^{*} is the corrective heat transfer coefficient and *Le* is the Lewis number. It should be noted that when the temperature difference between the air and the surface is small, the influence of mass transfer on heat transfer is negligible. When the temperature difference is large, for example, in impingement drying, the corrective heat transfer coefficient in the Chilton–Colburn equation is derived from the heat transfer coefficient modified thanks to Ackermann correction in order to include the effect of evaporation (Karlsson, 2009, Chap. 2, p. 58). However, most computational drying simulations nowadays include the correction factor whatever the evaporation rate (Zvolinschi et al., 2006; Roonprasang, 2008; Ghodbanan et al, 2015).

In a paper machine, the problem is more complex than in laboratory experiments. Figure 4.28.13 shows the different stages of drying as described by Nissan and coworkers (1960, 1961). It should be noted that the wrapping angles may be different in a real paper machine and that the drawing is not to scale. As shown in this figure, the drying process can be divided into four stages:

- I: The paper comes in contact with the dryer face (hot surface).
- II: The fabric covers the paper.
- III: Due to the wrapping angle of the fabric, the paper is no more in contact with this fabric.
- IV: The paper leaves the dryer and travels in the open draw.

This process is repeated as many times as there are dryers. However, the conditions may be different at each location (evolution of the temperature of the sheet and of its moisture content, temperature of the dryer, etc.). Globally, the sheet is warmed up during the phases I–III and cooled down in phase IV because of the evaporation process. Depending on the properties of the fabric, evaporation takes place when the sheet is in contact with the dryer or only in the free draw. So external factors play a role on the kinetics of drying as well as internal factors.

The heat transfer coefficient between air and paper is generally calculated from the correlation expressions for a flat plate (e.g., see Section 3.2.2 in Chapter 3 of this handbook):

- For laminar flow over a flat plate,

$$\text{when } \mathrm{Re} < 5 \cdot 10^5 : \overline{\mathrm{Nu_L}} = 0.664 \cdot \mathrm{Re_L}^{1/2} \cdot \mathrm{Pr}^{1/3}. \tag{4.28.7}$$

- For turbulent flow over a flat plate,

$$\text{when } \mathrm{Re} \geq 5 \cdot 10^5 : \overline{\mathrm{Nu_L}} = \left(0.037 \cdot \mathrm{Re_L}^{4/5} - 871\right) \cdot \mathrm{Pr}^{1/3}, \tag{4.28.8}$$

where $\overline{Nu_L}$ is the average Nusselt number, the values of the Reynolds and Prandtl numbers being evaluated at the mean film temperature. There are also other correlation expressions in the literature based on experimental work for paper machines (Karlsson, 2009) and one should be aware that simulation results should be validated experimentally.

In the drying section of a paper machine, the length of the sheet over a dryer (more than 2 m) and the relative speed between air and paper (at least 4 m/s) are generally sufficient for reaching the turbulent flow conditions. The values of the Prandtl number depend on temperature and air humidity in the surrounding air. For conditions in a conventional drying section, it ranges between 0.7 and 0.8 and the order of magnitude of the heat transfer coefficient is 20–40 W/m^2·K, depending on the machine speed and the state of air.

Other factors such as the presence of the fabric also affect the value of the mass transfer coefficient. The actual coefficient at the surrounding air interface is reduced. In drying simulations, a corrective factor called fabric reduction factor is applied.

In the paths between two cylinders, the correlations for heat transfer over a flat plate are also used. The exchange surface area is increased because the two sides of the web can be exposed to air. In recent publications (Zvolinschi et al., 2006; Ghodbanan et al., 2015), authors also use the Churchill correlation for a bank of cylinders (Bergman et al., 2011):

$$\overline{Nu_D} = 0.3 + \frac{0.62 \cdot Re_D^{1/2} \cdot Pr^{1/3}}{\left[1+\left(0.4/Pr\right)^{2/3}\right]^{1/4}} \cdot \left[1+\left(\frac{Re_D \cdot Pr^{1/3}}{282000}\right)^{5/8}\right]^{4/5}. \tag{4.28.9}$$

Global Heat Transfer Coefficient on the Drying Cylinder

The rate of heat transfer from the hot steam inside the cylinder to the paper on the outside depends on the overall temperature gradient and on the various thermal resistances present in the system:

$$Q = U \cdot A \cdot \left(T_0 - T_7\right). \tag{4.28.10}$$

As shown in Figure 4.28.14, there are a number of resistances to heat transfer in series due to

- The presence of noncondensable gases
- A film of condensate

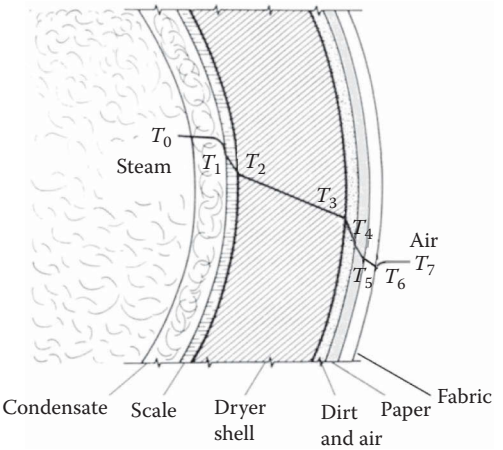

FIGURE 4.28.14 Resistances to heat transfer in paper drying on a steam-heated dryer cylinder.

- Rust and scale on the internal parts of the dryer shell
- Dryer shell
- Sheet-to-dryer contact including
  - Dirt and air between the outside surface of the dryer and the wet paper
  - Paper
  - Dryer fabric
  - Boundary layer of air

Neglecting the presence of noncondensable gases, the condensate is thus the first barrier to heat transfer. The thickness of the condensate layer is greatly affected by dryer speed; as the cylinder rotational speed increases, the contribution of the condensate layer to the overall resistance also increases.

The rust and scale deposited on the dryer shell is responsible for the second thermal resistance. Its value depends both on the nature of dryer shell and the thickness of the fouling layer. Dryers are generally made of cast iron. The thickness of the shell wall being around 25 mm, the thermal resistance due to the shell is approximately $5.3 \cdot 10^{-4}$ or 5.3×10^{-4} K m^2/W.

The third primary resistance to heat transfer is due to the contact between the outside surface of the dryer and the wet paper. Dirt on the outside of the dryer, the thin film of air that separates the dryer from the paper, and the outer surface conditions of the paper are the primary contributors to sheet-to-dryer contact resistance.

The relative contribution of each of these three resistances (condensate layer, dryer shell, and sheet-to-dryer contact) to the overall thermal resistance is greatly dependent on cylinder speed, as depicted in Figure 4.28.15. Pulkowski and Wedel (1988), for example, showed that the condensate layer is the main obstacle to increasing cylinder speeds and thus productivity.

Concerning the cylinder to paper coefficient, experimental studies performed both at the laboratory and field scales show that this heat transfer coefficient is dependent on the sheet moisture content, ranging, for instance, from about 200 W/m^2·K for a dry paper to 1000 W/m^2·K for a wet paper at 1 kg/kg moisture content. The variations are almost linear in this moisture range. However, the numerical values of the coefficients vary among authors (Wilhelmsson, 1990) and also depend on the grade of paper, etc.

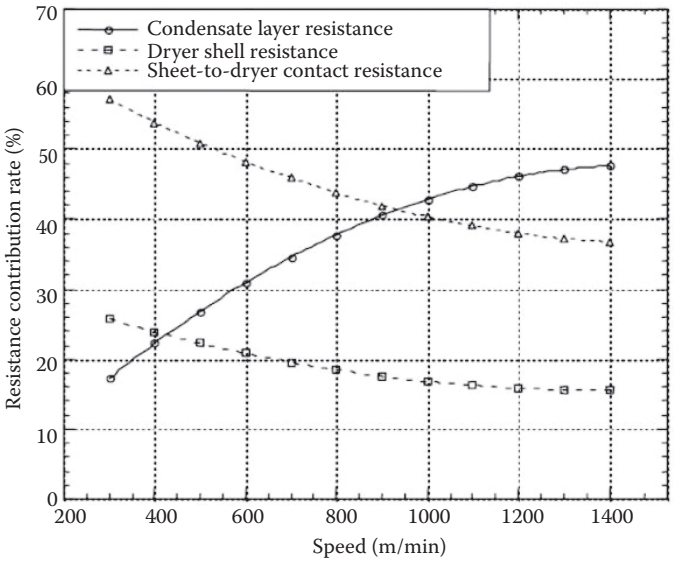

FIGURE 4.28.15 Share of the three main contributors to heat transfer resistance as a function of machine speed.

Organization of the Cylinder Dryers

In the conventional, the so-called double-tier drying section shown in Figure 4.28.12 on the left-hand side (cylinders 18–29), the steam-heated dryers are organized in two rows. The web travels alternately from one cylinder row to the other, for instance, from a cylinder in the bottom row to the next one in the top row and then to the following one in the bottom row and so on until the end of the drying section. Dryer fabrics are used to hold the sheet in close contact with the cylinders through the dryer section. Separate fabrics are used for the top and bottom rows of a dryer group, as shown in Figure 4.28.12.

In the second arrangement, displayed on the right-hand side of the same figure (cylinders 8–17), the rolls are also organized in two rows but the same fabric is used in a mechanical group of dryers. In this configuration, the web is sandwiched in between the dryer and the fabric in the top row and it is the fabric that is in contact with the dryer in the bottom row, the paper web being outside. The first "Unorun" sections were developed and commercialized around 1975 in order to allow high paper machine speeds. Sheet flutter and billowing in the early part of the drying section were indeed one of the major obstacles to achieving higher speeds with the double-tier configuration. As shown in the figure, the web is unsupported in the free draws between two drying cylinders in a double-tier group and, being relatively fragile because of its moisture content, would break under the effect of flutter. Using one fabric only was a solution to carry the web. In addition, there are more unfavorable conditions for heat transfer in the "Unorun" configuration because the fabric thermal resistance between the dryer and the paper decreases the temperature of the sheet, so the bottom row of dryers was no more heated with steam. This configuration is used at the beginning of the drying section in order to reduce production loss, before using two-tier groups when the sheet is dry enough to support the open draws.

The design of the drying section has been significantly improved over the 40 last years. In the single-tier configuration (Figure 4.28.16), there is only one row of dryers; the second one has been replaced by vacuum rolls, with smaller diameters than the cylinder dryers. This change was made for mechanical reasons to counteract the effect of the centrifugal force, which tends to pull the web apart from the dryer; this effect is significant at speed above 1200 m/min. In addition, exposing the free side of the sheet to air is favorable to mass transfer as well as the suction applied in the roll (around 1 kPa).

Modern and rapid machines are equipped with single-tier groups only. The heated groups may be in top or bottom position.

Cylinder dryers were usually 1500 mm in diameter (or less at small paper machines). With the development of single-tier drying groups, dryer diameters have been increased to 1800–2200 mm varying from one manufacturer to another. The suction rolls are smaller in diameter than the drying cylinders, with diameters depending on the manufacturers. This configuration allows increasing the wrapping angle of the fabric on the steam-heated dryers, which is beneficial for the drying process.

Initially, such new configurations were considered to be detrimental to the quality of the end paper because the same side of the sheet is in contact with the dryer surface in a given group and so

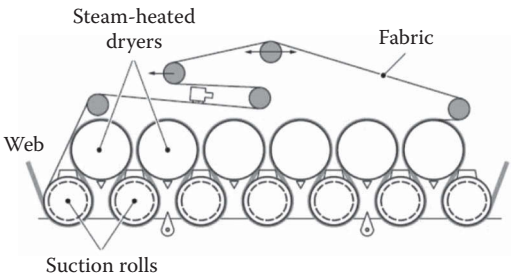

FIGURE 4.28.16 Configuration of a single-tier drying section.

gradients (moisture, temperature, etc.) could develop within the thickness of the sheet. In comparison, in the double-tier configuration, the side in contact with the lateral surface of the dryers alternates at each dryer, which reduces the gradients. Nevertheless, drying the paper on one side only for a certain period of time should be a problem for the high basis weight grades but is not so for the low basis-weight papers, which are concerned by the high production speeds. It has been found that the number of breaks in the drying section was significantly reduced (breaks decrease paper machine productivity) and that some physical properties of the sheet such as dimensional stability, tensile strength, and Young's modulus could be improved.

It should be noted that the single-felted section has been designed to enable increasing paper machine speed. As speed increases, the effect of the positive and negative nips combined with centrifugal forces caused the sheet to drop off the bottom dryer. This causes stretching and wrinkling of the sheet. Web stabilizers have specially been designed to hold the paper sheet in contact with the fabric in the draws between the dryers. The operating principle of modern devices is often based on the Coanda effect. Interested readers are referred to Rouhiainen (2008), Karlsson (2009), and Ghosh (2011) for further details.

Dryer Fabrics

This subsection is only a brief description of the role of the dryer fabrics, which are essential in different ways in the industrial process and some of their influencing properties. Interested readers could refer to, for instance, Adamur (1997) and Lang (2009a,b).The primary function of a dryer fabric is to maintain and/or improve the sheet-to-dryer contact in order to promote heat transfer. The second one is to carry the sheet and to transmit power to undriven rolls. Besides, dryer fabrics limit the cross-directional shrinkage of the paper (shrinkage was discussed in Section 4.28.2). Regarding the first function, there is always a layer of air between the sheet and the dryer that is carried by the moving sheet and dryer. The dryer fabric presses the sheet onto the dryer reducing the thickness of the air layer (as in the lubrication theory) and also minimizing any sheet lifting due to heating the sheet. Dryer felts have been used since 1820, when the paper machines were equipped with dryers. Since the 1960s, these felts have been replaced with fabrics. Dryer fabrics are nowadays woven or spiral materials constructed of synthetic monofilaments (Figure 4.28.17). Using monofilament yarns is extremely important because it allows uniform tension of the fabric in the cross direction of the paper machine owing to the good dimensional stability of monofilaments, increase life time of fabrics, cleanability of the fabric, among others. It should be noted that dryer fabrics are supplied as long strips and joining together of the two ends of the strip to form an endless belt is achieved once it is has been placed at the dryer group. Special seams are developed for this purpose; they must be resistant and should not damage the paper.

Drying fabrics must be heat resistant, rugged, and designed for both drying efficiency and runnability. In order to hold the sheet tightly in contact with the cylinders through the dryer section, adequate tension must be maintained on the fabric. Like a belt, the fabric tension exerts pressure on the paper, whose average value is proportional to the effective tension and inversely proportional to the radius of the cylinder (Karlsson, 2009, Chap. 3, p. 111; Lang, 2009a,b). However, paper is

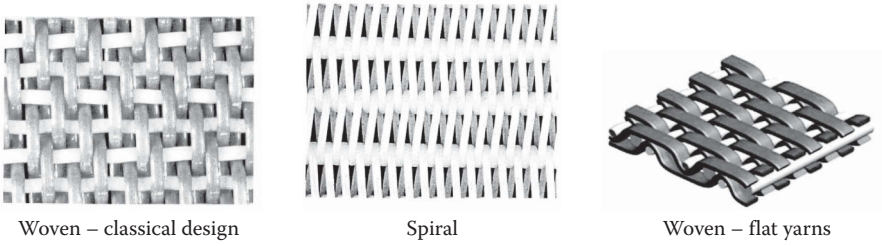

FIGURE 4.28.17 Three examples of dryer fabric patterns.

locally subjected to much higher pressure because the contact area between paper and the fabric is only a very small fraction of the area covered by the fabric (a few percent). The shape of the fabric yarns and the number of contact points are thus important parameters with regard to paper quality. The tension of a dryer fabric used to be in the 1.5 kN/m–2.2 kN/m range but higher fabric tensions (3.5 kN/m and up to 4.5 kN/m) are being utilized on high-speed paper machines to perform well. Appropriate tension values also depend on paper-related characteristics such as basis weight, permeability, and may be different from the wet end to the dry end of the drying section.

In the drying section, air must pass through the fabric. The permeability of the fabric is, therefore, an important factor. It is expressed as the flow rate of air that passes through per unit area of fabric at a given pressure drop (100 Pa which is the SI standard—permeability is expressed in $m^3/m^2 \cdot h$, or 125 Pa generally when permeability is expressed in cubic feet per square foot and per minute [cfm]). Fabric permeability is determined by the structure of the fabric and the sizes and types of yarns used. Dryer fabrics carry air into the dryer pockets due to the effect of entrained boundary layers. For the case of machines with no pocket ventilation system or poorly operating systems, the pumping of entrained boundary layer air into the pocket may reduce moisture levels and consequently improve evaporation rates. The air pumping effect is of no benefit on machines with well-designed ventilation systems and may lead to undesirable effects such as sheet flutter and breaks. The amount of boundary air carried is directly proportional to the speed of the fabric and is strongly dependent on fabric permeability. The aerodynamics of drying fabrics has been little studied (e.g., see Fagerholm, 1990; Widlund et al., 1997; Angrilli et al., 2000). The air-carrying capacity of a drying fabric is characterized by a drag coefficient. It is the ratio of the amounts of air carried, respectively, by the fabric and the reference surface (a glass plate). Typically, dryer fabrics have air drag coefficient values in the range from 2.0 to 14.7 (Adamur, 1997). The air-carrying ability of a common fabric is 2.0 on the paper side and 2.4 on the back side, and that of a flat ribbon fabric with symmetrical weave design is 1.5 (it is the same on both sides). Normally, machines run as high as fabric permeability and air-carrying characteristics as possible, but below the point that they cause sheet handling problems and also because the pocket ventilation systems are designed for a certain range of permeabilities. There is no benefit to use higher permeability fabrics.

Fabric permeability slightly affects heat transfer and thus evaporation when the sheet is in contact with the dryer but in most cases, this is not a major factor, especially with the recent paper machine designs.

Sheet surface quality can also be a limiting factor in the fabric permeability. In most conventional weave patterns, the higher the permeability, the coarser the fabric surface. A coarse fabric surface can damage the sheet surface.

Steam and Condensate Systems

The purpose of the steam and condensate system is to provide a sufficient amount of steam to the dryers and to handle the condensed steam. Dryers are organized in mechanical groups, with one fabric per group, but also in thermal groups fed at the different steam pressures. There are in general four to five thermal groups in a drying section (but the number of groups can be larger, for instance, for heavy grades or high-speed paper machines). Indeed, it is necessary to heat up the web sheet progressively and so the first dryers of the drying section run at relatively low temperatures. In addition, when the paper is wet, there is a risk of picking at the surface of the dryer if the contact temperature is too high. Once the sheet has been warmed up, water evaporates relatively easily (the drying rate depends on internal and external factors). Thus, the next dryer groups constitute the main groups of the drying section and are operated at a slightly higher temperature. Once the critical moisture content has been reached, water is more difficult to remove and it is necessary to increase the drying temperature to maintain a reasonable evaporation rate. This final stage of the drying is made in the last groups of the drying section. In practice, the dryers groups are fed with steam at different pressure, increasing from the wet end of the paper machine to the dry end.

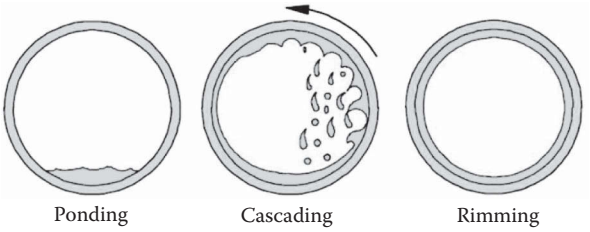

FIGURE 4.28.18 The three main condensate regimes in a steam-heated dryer.

For most printing and copying grades, the steam pressure does not exceed 0.65–1 bar in the first dryer group (Karlsson, 2009, Chap. 3, p. 116). Higher values (3–4 bar) are encountered for linerboard and corrugating medium. The steam pressure in the final groups does not generally exceed 4–6 bar, except for linerboard and corrugating medium (11 bar).

Saturated steam (or slightly superheated steam) is fed into the dryers. The steam condenses on the inner surface of the dryer and forms a layer of condensate. Depending on the speed of the paper machine, the diameter of the cylinder, and also the thickness of the condensate layer, the condensate layer behaves differently (Gavelin, 1964; Karlsson, 2009; Ghosh, 2011) as shown in Figure 4.28.18. This is explained by the balance of the forces acting: gravitational forces, centrifugal force, and frictional forces. At low speed, the condensates accumulate at the bottom of the dryer and form a pond. This is called the ponding or puddle regime. As the dryer speed increases, this pond moves in the direction of dryer rotation and widens. As the speed is further increased, the trailing edge of the pond extends over the horizontal centerline and the condensate tumbles back to the bottom of the dryer cylinder because the gravity force acting on the condensate layer when it arrives at the top of the rotating cylinder is greater than centrifugal force, the film falls down into the puddle. This is called the cascading regime. At higher speeds, the centrifugal force is sufficient and the layer can cover the inner face of the cylinder. This regime is called the rimming regime. Rimming condensate presents a resistance to the flow of heat from steam inside the dryer cylinder to the inner surface of the dryer cylinder.

As a first approximation, it can be demonstrated, from a simple force balance, that the rimming regime is attained when the speed of the dryer is equal to $\sqrt{5 \cdot g \cdot (D/2)}$, where g is the gravitational constant and D is the inner diameter of the cylinder. In practice, other factors such as the thickness of the layer of condensates must also be taken into account. The actual speed is greater. At low speeds, the rimming condensate film does not move at the same speed as the cylinder neither does its velocity constant. As the cylinder surface rises, gravity decelerates the condensate film. As the cylinder surface descends, gravity accelerates the condensate film. An oscillation is created by this alternating acceleration and deceleration. This natural oscillation produces turbulence in the rimming layer, which reduces the heat transfer resistance. The velocity of this oscillation depends on both the speed of the dryer and on the thickness of the condensate film. At high speeds, the oscillation of the condensate film is greatly reduced. As a result, the condensate layer produces a very significant reduction in the transfer of heat from the dryer cylinder, particularly in high-speed operations with thick condensate films: the condensate behaves like a stagnant film. This is why the inner surface of the dryer shells is equipped with turbulence bars (spoiler bars) in order to create microcascades in the condensate film to improve heat transfer eventually, resulting in higher drying rates.

Turbulence bars are not useful for machine speeds below 400 m/min, whereas they improve the drying rate by 5%–12% at 600 m/min and 12%–20% at 900 m/min (Karlsson, 2009, Chap. 3, p. 116).

The spacing of the bars and their cross sections are important parameters. Typically, 18 rows of bars are used in a 1.5 m diameter dryer and 21 rows of bars are used in a 1.8 m diameter dryer. High-performance bars today are 19 mm wide and 12 mm high.

The steam is fed and the condensate removed from the dryers thanks to rotary joints. There is one device per dryer fulfilling both functions except at high-speed paper machines where steam is fed at one side of the paper machine and the condensate removed at the other one. Using multiport systems could help improve the steam distribution inside the dryer and minimize the layer of condensates (Choi et al., 2001; Tim et al., 2010; Shin et al., 2011) but this development remains at the pilot stage.

Above a certain speed, the condensate cannot be removed from the dryer without creating a two-phase flow. So steam must be allowed to pass through the syphon pipe to remove the condensate (and also air and other noncondensable gases). It requires creating a pressure differential between the cylinder and the condensate header. The rate of blow through steam depends on the pressure differential and the frictional resistance of the syphon. The condensate removal tube, equipped with a special shoe, constitutes the syphon. There are two types of syphons:

- The rotary syphon that rotates with the dryer. It is convenient for relatively low speeds, e.g., 300–1000 m/min. However, as the centrifugal force that is opposed to the removal of condensates increases with the rotation speed, this type of syphon requires increasing the differential pressure as the paper machine speed, resulting in an increase of the blow-through steam. At high differential pressures, the amount of blow-through steam may be as high as 50%, or more, of the incoming steam. Therefore, rotary syphons are not suited to paper machines running at velocities more than 600 m/min.
- The stationary syphon that does not move with the dryer. In this case, the weight of the water column in the syphon pipe is the force that opposes to the removal of the condensates. Therefore, the required differential pressure is much lower than that for the rotary syphon. The value only varies little with the rotational speed of the dryer. However, the syphon shoe is more difficult to position.

Typical values of the pressure differential are 0.5–1 bar for rotary syphons and 0.15–0.25 bar for the stationary ones.

The blow-through steam must be reutilized before the condensate is returned to the boiler. The two-phase flow from a group of dryers is collected in a separator maintained at constant level where the blow-through steam is separated from the liquid. In addition, a little quantity of flash steam is produced. The condensate is pumped from the separator, and finally returns to the boiler, and the vapor is reused. In the cascade design, this vapor is reused in a group operated at a lower pressure, except of course for the first thermal group (the vapor from the first separator feeds an air/vapor heat exchanger). The vapor is mixed with some fresh steam (low-pressure steam) in a header in order to feed this group with steam. The cascade system is the predominant configuration. The disadvantage of the interconnections from the cascade configuration is that the pressures and differential pressures are not independent. This drawback can be resolved by a thermocompressor unit. A thermocompressor is an ejector that uses high-pressure steam (motive steam) from the steam header to compress low-pressure steam (here, the vapor from a separator tank) to a desired pressure. In this way, the blow-through steam can be recirculated to the same steam group, making the different steam groups independent. In this configuration makeup steam can also be used, if necessary. Adequate sizing of the thermocompressor is essential and the presence of noncondensable gases is a problem. Another disadvantage is the need for high-pressure steam and, in case of breaks or grades with low drying demand, the blow-through steam is dumped to the condenser.

The steam and condensate system is equipped with a condenser, which condenses the residual vapor before it returns to the boiler. The amount of condensed vapor is an indicator of the performance of the steam–condensate system. It should not be greater than 3% of the total steam consumption.

Hood, Ventilation, and Heat Recovery

Apart from the mechanical problems such as sheet flutter, etc., which would cause sheet breaks, the drying process is not an efficient process without combining appropriate ventilation and air exhaust

system with the dryers. Figures 4.28.12 and 4.28.13, for instance, show that many dead zones, the so-called pockets, exist in the drying section because of the sheet and/or fabric paths. A large part of evaporation from the web takes place in these zones. In order to be able to dry the paper and maintain high-evaporation rates, air must be kept reasonably dry. For this purpose, the dryers are enclosed in a hood, equipped with air systems, which have two main goals: remove the water vapor evaporated from the sheet in the dryer section and control the temperature, humidity, and air flow in the dryer pockets across the full machine width. In addition, the presence of the hood permits to maintain good working conditions in the machine room in terms of heat, humidity, and noise; protect the building and machinery from deterioration because of the humidity; and reduce emissions and mist to the outside of the mill (Gavelin, 1964; Karlsson, 2009; Ghosh, 2011).

A properly designed and operated hood air system will enable to remove vapor uniformly both in the machine and the cross directions. There are three main types of hoods: the semiopen hood, the closed hood, and the high-efficiency hood. The closed hood and high-efficiency hood completely surround the drying section and also the basement. Average values of the ventilation requirements and effect on exhaust air state are given in Table 4.28.7.

In the relatively low-speed paper machines (old machines), warm air is blown at the bottom part of the hood, below the cylinders thanks to blow rods (holes or slots). The temperature of the supply air is generally comprised between 70°C and 90°C and air velocity is slow because the objective is only to ventilate the drying section and avoid condensation in the hood.

In the recent designs of paper machines, the blow rolls or blow boxes are installed outside the pockets to blow air through the fabric. The air flow rate can reach 800 m^3/h per meter width of the paper machine and air is generally blown at a temperature comprised between 90°C and 125°C in the case of blow rolls and up to 145°C for blow boxes. This explains the differences in the properties of the exhaust air and air ratios shown in Table 4.28.7. Of course, the operating conditions of the closed and high-efficiency hoods improve the energy performance of the paper machine. At comparable evaporation rate (kg of water evaporated per time unit), the data in Table 4.28.7 show that the air exhaust flow rate will be lower with closed hoods compared with a semiopen hood, and thus the number of exhaust ventilators and the electrical power consumption will be lower. The amount of supply air is also lower for closed hoods. However, the blow boxes need high-pressure ventilators, so electrical consumption may not be different. Finally, it should be noted that the difference between the amounts of dry air in the exhaust air and supply air comes from the leakage air that is taken from the machine room (infiltration air). The machine room is conditioned and must be renewed regularly. As the amount of leakage air is lower in the case of closed hoods, another advantage of closed hoods can be pointed out.

The supply air is taken from either the outside of the building or from the machine room. It can be heated by different ways:

- In a heat exchanger, air–exhaust air, air–condensates, air–vapor (from a separator), air–steam, or
- By mixing the air stream with hot air (for instance, from a turbo blower used for the production of vacuum in the wet end) or flue gas (for instance, flue gas from infrared dryers) from another part of the mill.

TABLE 4.28.7
Ventilation Requirements at a Paper Machine Drying Section

	Semiopen	Closed	High Efficiency
Exhaust air temperature, °C	50–60	65–85	80–90
Exhaust air mixing ratio	0.04–0.06	0.12–0.14	0.16–0.18
Exhaust air per kg water evap., kg/kg	15–30	8–13	6–8
Supply air/exhaust air ratio, %	20–30	60–80	70–80

Several heat exchangers are generally installed in series, for example, air–exhaust air followed by air–vapor and then air–steam. Heat recovery from the exhaust air is possible only if the temperature is high enough. About 6% to 10%–15% of the heat at exhaust can be recovered for heating supply air (Smook, 1992; Karlsson, 2009). There are still possibilities to use the waste heat before it is released in the atmosphere.

Physical Properties of Paper Drying

Global Changes in Paper Structure during Drying

Transport mechanisms during the thermal drying of deformable porous media, including paper, are influenced by the structural changes that take place and also depend on the moisture content of the material.

The wet paper is composed of the fibrous material, liquid water that can be present inside the fibers and in the voids between the fibers and a gaseous phase (air and water vapor). Assuming that the volume of the fiber walls is strictly equal to the sum of the volumes of the dry solids and liquid water, and neglecting in-plane shrinkage, the fractions of volume occupied by the solid, liquid, and gaseous phases, expressed in percent, are given as

$$\varepsilon_s = 100 \cdot \frac{W}{\delta} \cdot \frac{1}{\rho_s}, \varepsilon_\ell = 100 \cdot \frac{W}{\delta} \cdot \frac{X}{\rho_\ell}, \varepsilon_g = 100 - 100 \cdot \frac{W}{\delta} \cdot \left(\frac{1}{\rho_s} + \frac{X}{\rho_\ell} \right), \tag{4.28.11}$$

where W is the bone-dry basis weight of the sheet, X is the moisture content, and δ is the thickness of the sheet at moisture X. It should be noted that the thickness of the wet sheet can be measured only at the laboratory scale. At the moisture content where a sheet enters the drying section, the web is no more saturated with water. The volume fraction occupied by the solids increases during drying because of the transverse shrinkage of the sheet, the gaseous volume fraction also increases, and the liquid volume fraction decreases. A typical example is shown in Figure 4.28.19. However, numerical values depend on numerous parameters, type of fibers, refining level of the fibers, pressing intensity, drying conditions, and among others. These variations affect the transport properties of the web drying, effective diffusivity of vapor, capillary flow, etc., as already discussed in the previous section, which are important for paper quality parameters. Shrinkage is largely governed by the interactions between fibers but it may be limited by the design of the dryer (Stenström, 2004).

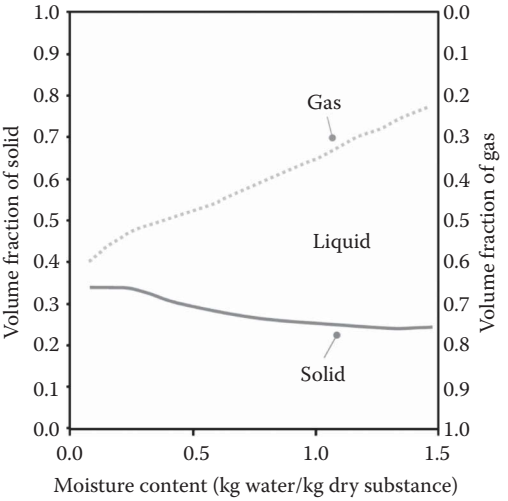

FIGURE 4.28.19 Example of variation of the fractions of volumes of the solid and gaseous phases in a paper during drying.

Specific Heat Capacity

In general, the specific heat capacity c_p of dry (air dry) paper made of pulp only is quite close to that of natural wood pulps or various vegetable fibers, wood, and cellulose, that is, about 1300–1400 kJ/kg·K. Values only slightly vary depending upon the chemical composition of fibers and also, similar to wood, depend on temperature. This is, however, generally neglected at the drying temperatures of the conventional drying sections.

As already mentioned, paper generally contains fillers, such as calcium carbonate or clay (kaolin), or, for special grades, titanium dioxide. These inorganic materials have a lower thermal capacity than the fibers, ranging from 750 to 900 J/kg·K depending on the substance and temperature. For example, the value of the specific thermal capacity of calcium carbonate may be assessed by the following expression $c_{\mathrm{p}} = 828 + 0.5T - 1.3 \cdot 10^7 / T^2$ and that of titanium dioxide by $c_p = 626 + 0.4T - 2.2 \cdot 10^6 / T^2$ (Green and Perry, 2008). The specific heat capacity of clay is 920 J/kg·K. The specific heat capacity of filler-containing paper is, therefore, a little lower than that of the fibers.

Wet paper has a greater specific thermal capacity than dry paper because of the influence of water.

The specific thermal capacity of paper is commonly calculated as the weighed sum of the specific thermal capacities of each component:

$$c_{\mathrm{p\,paper}} = x_{\mathrm{fibers}} \cdot c_{\mathrm{p\,fibers}} + x_{\mathrm{fillers}} \cdot c_{\mathrm{p\,fillers}} + x_{\mathrm{water}} \cdot c_{\mathrm{p\,water}}, \tag{4.28.12}$$

where the symbol x denotes the mass fraction of each component. The interested reader can find values of the specific thermal capacity of various wet cellulosic materials (pulps) in Shanbhag (1981).

Heat of Desorption

Paper is a hygroscopic material as already explained and depicted in Figure 4.28.11. The hygroscopic nature of the fibers also plays a role in the drying of the material. When the dryness is greater than 75%–85% (moisture content $X < 0.3 - 0.25$ kg/kg dry substance), the free water has been evaporated and the remaining water is hygroscopically bound water (physisorption), which requires more energy for its removal. Additional energy is necessary to overcome these bonding effects. For example, at 80°C and 95% dryness, 2800 kJ/kg water is needed to evaporate water from pulp compared to the latent heat of water of about 2300 kJ/kg at the same temperature. This additional energy is called the heat of (de)sorption.

The differential heat of (de)sorption, h_{s}, is the additional heat required to remove water at a given equilibrium moisture content, X:

$$h_{\mathrm{evap}}(T, X) = h_{\mathrm{s}}(T, X) + h_{\mathrm{c}}(T). \tag{4.28.13}$$

The integral heat of (de)sorption is the cumulative additional energy needed to reach a given equilibrium moisture content starting from a very large moisture content value per unit mass of water removed.

Owing to the complex and inhomogeneous structure of pulp fibers, the sorption (desorption) of water cannot be expressed by simple mathematical relations. Values are determined experimentally, either from calorimetric measurements or, more commonly, from (de)sorption isotherms, because this type of measurement is easier to perform. For several cellulosic materials, a saturation of the isosteric heat of sorption has been reported for very low equilibrium moisture contents, that is, to say below 0.04, e.g., see Leuk et al. (2016), from isotherm measurements and also from direct measurements using calorimetry. The common interpretation of these findings is that at some point below monolayer moisture, the average distance between the individual water molecules adsorbed to the surface is large enough so that there is no significant interaction between these molecules. Below this point, the adhesion interaction takes place only between the material surface and the

water molecules; therefore, the adhesion energy saturates. This is a somewhat simplistic explanation because in complex, mesoporous materials like pulp fibers there is no sharp threshold value for monolayer moisture. Nevertheless, the basic idea should still hold.

In drying calculations, even if it is not entirely correct, it is commonly assumed that the equilibrium is described by a (de)sorption isotherm, instantly attained and valid everywhere inside the web. The isotherms are used to compute the local partial pressure of water as a function of the moisture content and temperature and also the desorption energy.

Applying the Clausius–Clapeyron equation, the heat of sorption, which is related to the work needed to compress the vapor from the partial pressure e' to the saturation pressure p_{sat}, is equal to

$$h_s(T,X) = -\frac{R}{M_v}\frac{\partial \ln a_w(T,z)}{\partial(1/T)}\bigg|_{z=X}. \tag{4.28.14}$$

This method requires modeling the (de)sorption isotherms as a function of both temperature and moisture content and then calculate the first partial derivative of the model with respect to $1/T$ at constant moisture content. It should be noted that a high value of goodness of fit is not sufficient to obtain correct values of the (de)sorption heat at a low moisture content, that is to say below 0.08 kg water per kg dry substance. The most commonly used model in recent publications related to paper drying section simulation is the so-called Heikkilä formula (Heikkilä, 1993):

$$a_w(T,X) = 1 - \exp\left[-A \cdot X^B - C \cdot (T - 273.15) \cdot X^D\right],$$

where A, B, C, and D are empirical coefficients.

Other empirical models give similar quality of fit of experimental desorption data (Leuk et al., 2016) such as Anderson and McCarty formula (Anderson and McCarty, 1966)

$$a_w(T,X) = 1 - \exp\left[-(A + B \cdot T) \cdot \exp\left[-(C \cdot T + D) \cdot X\right]\right].$$

It is noteworthy that there are only few data available in the literature for the temperature range covered by the paper industrial drying process (Nelson, 1982; Karlsson, 2009; Rhim and Lee, 2009; Leuk et al., 2016).

Figure 4.28.20 displays an example of desorption energy graph as a function of moisture content for various values of the temperature. These curves clearly show that the heat of desorption significantly increases when the moisture content decreases and it decreases with temperature. From these values, the integrated desorption heat is 55 kJ/kg water at 80°C and 220 kJ/kg water at 25°C when the moisture content is decreased from 0.6 to 0.04 kg/kg dry substance. Thus, the additional heat

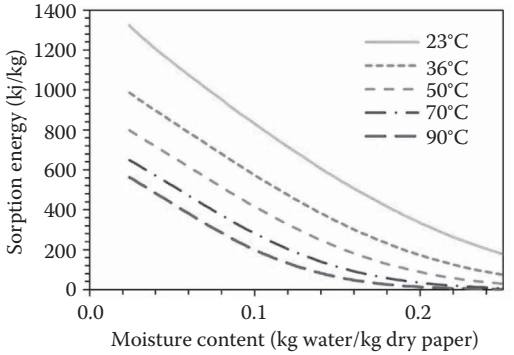

FIGURE 4.28.20 Influence of temperature on the heat of desorption of paper.

needed to desorb water accounts only for a few percent of the energy to evaporate water in industrial conditions; it is useful to recall here that the latent heat of evaporation of water is 2310 kJ/kg at 80°C and 2440 kJ/kg at 25°C. It is, however, not totally negligible and overdrying should be avoided for economic reasons in addition to its effects on the physical properties of paper.

In the case of filler-containing papers, the heat of (de)sorption should be calculated taking into account the mass fractions of the fibers and the fillers and the heat of (de)sorption of each component. The fillers used in paper making are generally not hygroscopic.

Experimental studies show that refined pulp behaves like the same untreated pulp (Seaborg and Stamm, 1931; Leuk et al., 2016), whereas bleaching or predrying decreases sorption heat (Leuk et al., 2016). However, these results do not imply that a paper made of a refined pulp behaves exactly as the paper produced from the same unrefined fibers while drying: there will be more water to remove after pressing and shrinkage will be more pronounced. In addition, it is noteworthy that, in the industrial drying process, the point when water is more difficult to remove may be reached earlier than the value obtained in quasistatic tests because of the gradients that develop in the transverse direction of the sheet (thickness) and nonuniformities in mass distribution.

Thermal Conductivity

Regarding thermal aspects, paper is an orthotropic material because of its anisotropic structure (machine, cross, and transverse directions). The thermal conductivity in the transverse direction is the most studied property, and thermal conductivity values, in the absence of other precision, are related to the property in this direction, i.e., thickness direction. This property is important for many applications where paper is relatively dry, such as copy or calendering. Dry paper is an insulating medium; its thermal conductivity ranges between 0.04 and 0.20 W/m·K. As an example, typical values collected from the literature (Kerekes and Crotogino, 1980; Burnside and Crotogino, 1984; Kartovaara et al., 1985; Lopatkiewicz et al., 2011; Lavrykov and Ramarao, 2012) are collated in Table 4.28.8.

Various parameters exert varying levels of influence on the thermal conductivity of dry (air dry) paper:

- Moisture content: This is due to the high value of water thermal conductivity (0.6 W/m·K). There is, however, no literature available on the variation of the thermal conductivity of paper as a function of moisture content in the low moisture range.

TABLE 4.28.8
Thermal Conductivity of Paper

Paper Grade	Thermal Conductivity (W/m·K)
Uncalendered paper (density 600–1000 kg/m^3, chemical pulp)	0.06–0.11
Uncalendered paper (density 400–600 kg/m^3, mechanical pulp)	0.04–0.068
Calendered paper (density 1000–1100 kg/m^3, chemical pulp)	0.105–0.16
Calendered (density 625–750 kg/m^3, mechanical pulp)	0.05–0.065
Handsheets (density 420 kg/m^3, sulfite softwood pulp)	0.016–0.02
Test liner (density 625–875 kg/m^3, unbleached recycled pulp)	0.075–0.118
Coated (density 737 kg/m^3), woodfree base	0.15
Copy paper (density 625–1260) coated or uncoated	0.08–0.18
Paper (no details)	0.04
Insulating paper for windings	0.10
Pressboard	0.19

- Temperature: Little information is available in the literature on this topic. It was shown by Lavrykov and Ramarao (2007, 2012) that thermal conductivity increases with temperature, which is consistent with the behavior of wood. However, experimental results showed a small variation only, thermal conductivity increased by 0.015 W/m·K when the temperature was increased by 100°C.
- Porosity (or density): The denser the paper, the higher the value of the thermal conductivity, owing to the decrease in air content. Interested readers should refer to the studies by Burnside and Crotogino (1984) and Hestmo et al. (2001). However, porosity and density are global parameters. They do not take into account the arrangement of the solids in the microstructure (Hestmo et al., 2001) or the possible modifications of the fibers during the densification process. In addition, it should be noted that, because refining tends to increase paper density owing to the shrinkage of fiber cross sections during drying and better interfiber bonding (relative bonded area (RBA) increases), papers made of refined pulp have a higher thermal conductivity than those made of unrefined pulps.
- Fibrous composition, nature of the pulp: The influence of the nature of the fibers is not yet completely clear, and results may not be coherent. For instance, the values measured by Kartovaara et al. (1985) do not show significant differences in thermal conductivity for papers produced with different pulps at constant sheet density, whereas Guérin et al. (2001) reported that deinked pulp fibers had a very low-thermal conductivity (0.24 W/m·K) lower than that of bleached kraft pulp (0.4 W/m·K) and thermomechanical pulp (0.58 W/m·K), which explained the relatively low thermal conductivity of papers made of deinked pulp compared to the other two products. The thermal conductivity of wood fibers in the radial direction is about 0.4–0.5 W/m·K. The low value for the deinked pulp probably means degradation of the fiber walls.
- Fiber mix: The thermal conductivity of a mixture of fibers having different values of thermal conductivity can be calculated considering it is equivalent to layers of each type of fibers combined in series (Guérin et al., 2001). In addition, only little information is available in the literature on the influence of the degree of polymerization of cellulose: From measurements performed by Lopatkiewicz et al. (2011) who determined the value of the thermal conductivity of a paper impregnated with mineral oil before (DP = 1300) and after aging (DP = 300), it seems that the degree of polymerization of cellulose is not a significant factor.
- Interfiber bonds: Experimental studies (Kartovaara et al., 1985) consisting of the breakage of interfiber bonds thanks to the tensile tests have shown that the thermal conductivity of paper did not significantly change compared to the untested paper. However, the conclusion that interfiber bonds are not an influencing parameter is valid only if the bonded area remains big enough.
- Presence of mineral fillers: Mineral fillers have a greater thermal conductivity than cellulosic fibers. For example, calcium carbonate (calcite) has a thermal conductivity around 3.5 W/m·K. Therefore, the thermal conductivity of paper increases when the filler or pigment content increases (see, e.g., Lavrykov and Ramarao, 2012) but the most influencing factors remain paper density or porosity. In addition, the location of fillers in the sheet, i.e., in between the fibers or in the pores, may also affect the thermal conductivity values.

Wet paper has a higher thermal conductivity than dry paper because the pores are partly filled with water, which creates thermal bridges within the structure. In drying, the thermal conductivity of wet paper can even be greater than that of water owing to the diffusion phenomena (evaporation–condensation) that occur:

$$\lambda_{\text{eff}} = \lambda + \lambda_{\text{diff}}. \tag{4.28.15}$$

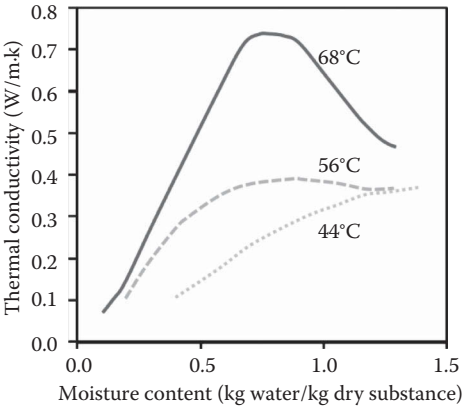

FIGURE 4.28.21 Examples of variation of the thermal conductivity of paper as a function of moisture content.

The diffusion effect is negligible at relatively low temperatures (below 50°C) and noticeable above, as shown, for example, in Figure 4.28.21. It is dominant at temperatures higher than 70°C.

Finally, it should be noted that there is no satisfactory model to predict the thermal conductivity of paper, even in the absence of diffusion, because of the complex structure of the material. Some authors refer to a lumped model considering two layers of a material where the phases in presence (solids, liquid and gas) are arranged in series in the first one and in parallel in the second one. There is, however, no robust method available to assess the relative thickness of each layer.

Conclusion

Drying is an important stage of the paper manufacturing process, which plays a significant role in determining the properties of the end product. The main phenomena taking place are understood but each case is unique, because of the diversity of the raw materials used, and the design of the drying section and the operating conditions at a paper machine. About 90% of the paper produced is dried in a multicylinder drying section that is why this chapter has mainly focused on this type of drying section.

Machine productivity, energy consumption, and product quality are major concerns today. Productivity means good runnability of the process. In that sense, many developments have been incorporated by the manufacturers to offer new solutions (single-tier drying sections, drying fabrics, ventilation systems, sheet stabilizers, etc.). Another point, which has not been developed here, is the reduction of the length of the drying section. In general, it means to be able to improve the drying rate of the cylinder dryers. The only method is to improve the contribution of convection compared to conduction. This is why the dryers may be now covered by impingement hoods (one per dryer). Heat recovery is well implemented in the paper making industry thereby leading to the sustainability. However, the process is not always optimized, diagnostics are often necessary and show that improvements are possible (Zvolinschi et al., 2006; Pettersson and Söderman, 2007; Bhutania et al., 2012).

Another aspect that has not been developed here is the modeling of paper drying. A great number of models are available having various levels of complexity depending on the modeling of the internal phenomena taking place. The relevant literature up to 1999 has been critically analyzed by Sidwall et al. (1999). A current trend is to use models that do not take into account the gradients inside the paper and apply them in a drying section simulator in order to optimize the operation of this section and minimize energy consumption.

4.29 DRYING OF MATERIALS

Pawel Wawrzyniak, Ireneusz Zbicinski, and Mariia Sobulska

Introduction

Drying is one of the most common processes encountered in real life and in industry. Solar drying of fruits, meat, and fish for food preservation was known already in antiquity. In chemical, pharmaceutical, food, ceramic, and textile industries, thermal drying is one of the unit operations controlling quality of the final product and economic efficiency of the technology. The main aim of drying is to decrease the mass of material in order to reduce costs of transportation, change and improve mechanical and physicochemical properties, and increase shelf life of a product. Drying is a complex process comprising simultaneous heat, mass, and momentum transfer accompanied by structural, mechanical, and physicochemical changes in product properties.

The chapter presents basic information about drying of materials. The most common drying techniques, types of dried materials, drying kinetics and equilibria, mechanism of moisture evaporation, and practical applications are described. Principles of the theory of drying covering the properties of humid air, wet materials, drying curves, heat and mass transfer are illustrated and discussed. On the basis of the method of heat delivery to the material (convective, contact, steam, energy field) and hydrodynamics of the gas–material system (disperse, tunnel, belt, rotary, drum, etc.), a classification of dryers is presented.

Drying is an old and well-established technology; relatively few new techniques have been successfully implemented into practice in recent years. One of the examples of novel drying methods is steam drying and disperse techniques like flame, pulse combustion, foam spray drying, which are described in the chapter.

For better understanding of the mechanism of drying process, examples of calculation of selected dryers based on heat and mass balances, equilibria, and drying kinetics are shown.

The chapter delivers also suggestions how to select an optimal drying method and specific dryer for a group of materials.

Principles of Drying

Properties of Air–Water Vapor Mixtures

In most dryers, hot air supplies the heat for evaporation and removal of evaporated moisture from the product. Dryers where heat for drying is delivered in another way are not so common due to high capital and operating costs (freeze, contact, and steam). During drying with hot air, humidification of air and air temperature drop is always observed. Therefore, thermal properties of humid air are essential for the design calculations of such dryers. Table 4.29.1 summarizes the basic thermodynamic and transport properties of an air–water system.

Psychrometry

The capacity of air for moisture removal depends on temperature and humidity. The basic concepts used in psychrometry are as follows:

Total Pressure

The total pressure of a gas mixture, such as nitrogen, oxygen, and water vapor, is made up from the sum of pressures of its constituents called partial pressures. The partial pressure of each component results from the number of moles of the constituent, temperature, and total volume of the system. The partial pressures are added to obtain total pressure.

TABLE 4.29.1
Thermodynamic and Transport Properties of Air–Water System

Property	Expression
P_v	$P_v = 100 \cdot \exp\left[27.0214 - \left(6887 / T_{abs}\right) - 5.32 \cdot \ln\left(T_{abs} / 273.15\right)\right]$
Y	$Y = 0.622 \cdot RH \cdot P_v / \left(P - RH \cdot P_v\right)$
c_{pg}	$c_{pg} = 1.00926 \times 10^3 - 4.0403 \times 10^{-2} T + 6.1759 \times 10^{-4} \cdot T^2 - 4.097 \times 10^{-7} \cdot T^3$
k_g	$k_g = 2.425 \times 10^{-2} - 7.889 \times 10^{-5} \cdot T - 1.790 \times 10^{-8} \cdot T^2 - 8.570 \times 10^{-12} \cdot T^3$
ρ_g	$\rho_g = P \cdot M_g / \left(R \cdot T_{abs}\right)$
μ_g	$\mu_g = 1.691 \times 10^{-5} - 4.984 \times 10^{-8} \cdot T - 3.187 \times 10^{-11} \cdot T^2 - 1.319 \times 10^{-14} \cdot T^3$

Source: Pakowski, Z. and Mujumdar, A.S., *Handbook of Industrial Drying*, Marcel Dekker, New York, 1995.

Dry-Bulb Temperature

Dry-bulb temperature is the temperature measured by a thermometer exposed to humid air. The tip of the thermometer should not be moist.

Wet-Bulb Temperature

Wet-bulb temperature is the temperature reached by a water surface when exposed to humid air passing over. It is usually registered by a thermometer sensor surrounded by a wet wick. The wick and, therefore, the thermo-sensor temperature decreases below the dry-bulb temperature until the rate of heat transfer from the hotter air to the wick is equal to the rate of heat transfer needed for the evaporation of water from the wick to the air stream.

Humidity

Absolute humidity (Y) is the measure of water content of the air. The absolute humidity, called sometimes the humidity ratio, is the mass of water vapor per unit mass of dry air. The units are then kg/kg and this parameter will be later called *humidity*.

Relative Humidity

Relative humidity (RH) is defined as the ratio of the partial pressure of water vapor in the air (p) to the partial pressure of saturated water vapor at the same temperature (p_v). Therefore,

$$RH = \frac{p}{p_v} \tag{4.29.1}$$

RH is often expressed as percentage:

$$RH = \frac{p}{p_v}.100\% \tag{4.29.2}$$

Air is saturated with water vapor at a given temperature and pressure when its humidity reaches maximum under these conditions. Then, the excess of liquid water appears in the form of mist or droplets. In saturation conditions, the partial pressure of water vapor in the air is equal to the pressure of saturated vapor of water at that temperature.

Enthalpy

Enthalpy as an extensive property could be calculated as the sum of partial enthalpies of dry air I_B and water vapor I_{Av}. The enthalpy of humid air I_G is related to the unit mass of dry gas.

$$I_G = I_B + Y \cdot I_{Av} \tag{4.29.3}$$

At temperature T_g, the enthalpy of dry air is

$$I_B = c_B \cdot T_g \tag{4.29.4}$$

and enthalpy of water vapor

$$I_{Av} = c_{Av} \cdot T_g + \Delta H \tag{4.29.5}$$

where c_B and c_{Av} are the mean heat capacities of dry gas and water vapor, respectively, and ΔH is the latent heat of vaporization at 0°C.

Psychrometric Chart

Humidity charts are a convenient way to store humid air data in a graphic form. One of the most popular enthalpy–humidity charts is attributed to Mollier (Figure 4.29.1). This chart, especially suitable for thermal drying calculations, plots the enthalpy of humid air vs. absolute humidity. To increase the area of unsaturated air, the oblique enthalpy line is used.

Properties of Wet Materials

Types of Materials for Drying

The objects of drying are moist bodies with different physicochemical, structural, mechanical, and other properties. Knowledge of the properties of wet materials allows for selection of appropriate drying methods and process parameters. In drying technology, three groups of materials are distinguished:

1. *Capillary porous*: low shrinkage, fragile, e.g., detergents, ceramics
2. *Colloidal*: high shrinkage, e.g., elastic gelatin
3. *Colloidal–capillary porous*: often puffing, maintain elasticity, e.g., wood, paper, leather

This classification has a conventional nature; many materials have characteristics that combine properties of the aforementioned groups. It should be kept in mind that material properties can

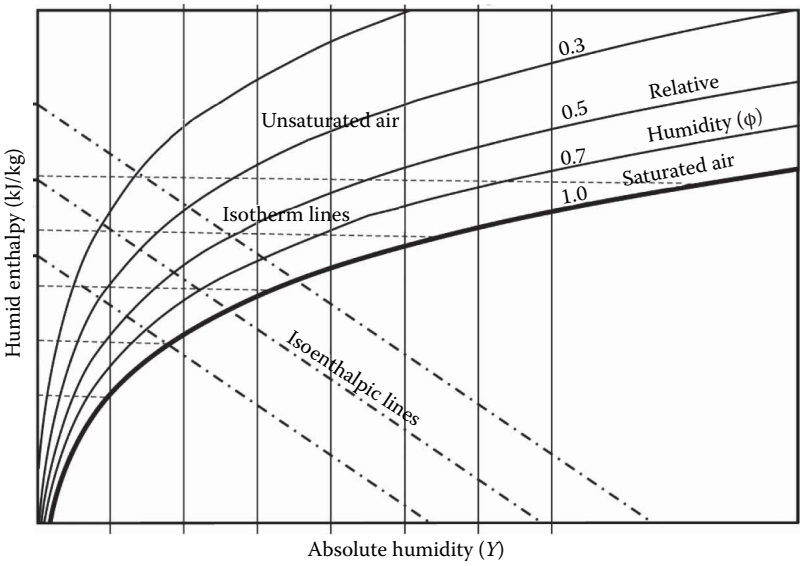

FIGURE 4.29.1 Mollier chart.

change in the drying process and one of the objectives of the drying process is to improve their properties. Broadly understood technological properties of a product depend on the type of moisture bond with the material and nature of these bonds affects the drying process. The removal of liquid from wet material is accompanied by breaking of liquid–solid bonds as a result of energy supply.

There are three groups of bonds of moisture with the material:

1. *Chemical*: Remain stable during drying process, chemically bound water cannot be removed during drying process
2. *Physicochemical*: Absorption and osmotic type bonds. Water bound due to adsorption is adsorbed mainly on inner body surfaces
3. *Physicomechanical*: Structural bonds can be removed by drying

In practice of drying, there are specific definitions of material moisture. Moisture in wet material is commonly expressed as

Absolute moisture, kg water/kg of dry material (X).

Free moisture, the moisture that is in excess in relation to equilibrium moisture. Free moisture can be removed during drying.

Equilibrium moisture (X_e, kg/kg), moisture content of the material that is in equilibrium with vapor of specified pressure and temperature. The equilibrium moisture content is the lowest moisture content to which the material can be dewatered by drying for given air temperature and humidity.

Critical moisture (X_{cr}, kg/kg), moisture content of the material at which the falling drying rate period starts due to increase in diffusion resistance of moisture flow in the material.

Drying Equilibrium

Moisture can diffuse from wet material to drying gas, if equilibrium vapor pressure over the material is higher than partial vapor pressure in the drying agent. Moisture evaporation and desorption proceeds until the system reaches the state of equilibrium (equal vapor pressure over the wet material and partial vapor pressure in the drying air). If partial vapor pressure in the ambient air is bigger than vapor pressure over the material, moisture sorption will occur, i.e., moisture will penetrate to the material by diffusion. The equilibrium moisture content in the material can be determined by a prolonged contact of the material with air at a given temperature and humidity. The relationship obtained at different air humidities at constant temperature is called sorption isotherm. An example of sorption–desorption isotherms is shown in Figure 4.29.2.

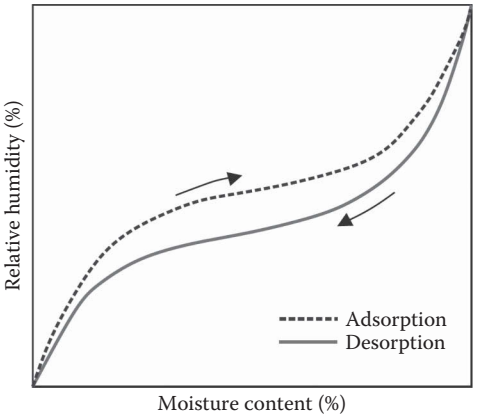

FIGURE 4.29.2 Sorption–desorption isotherms.

Figure 4.29.2 shows drying hysteresis between sorption and desorption of moisture for the same ambient air temperature. The desorption curve always has a bigger value than the equilibrium moisture sorption curve at a given temperature. Knowledge of sorption/desorption isotherms is one of the key data in drying to determine boundary values of moisture content below which the material cannot be further dried and the danger of rehydration due to moisture resorption from the air, in the case of product storage, cannot be avoided.

Drying Curves

Heat required to evaporate moisture is transferred from the drying gas. Heat transfer between the phases depends not only on material properties but also on the properties of ambient air (density, temperature, pressure, humidity, velocity, etc.). Moisture contained in the material may be in the bound or unbound form (Strumillo and Kudra, 1986). Water present in solid body capillaries, absorbed on a solid surface, or chemically bounded with a solid body falls into the category of bound moisture. Free moisture is defined as moisture that constitutes excess in relation to equilibrium moisture. During drying only unbound moisture is evaporated.

The mechanism of drying depends on the type of moisture contained in a particle. As long as unbound moisture is in the particle and the rate of moisture diffusion is sufficient to keep the state of saturation on the material surface, the particle is in the constant drying rate period (Charlesworth and Marshall, 1960).

Figure 4.29.3 shows drying curve with two characteristic drying periods: the constant drying rate period and falling drying rate period.

In the initial phase, the dried droplet has lower temperature than equilibrium temperature; as a result, in zone *A* the drying rate increases until equilibrium is reached. Typically, the initial period is so short that it is not taken into account in the considerations of drying time.

Segment *B* corresponds to equilibrium conditions, the whole amount of heat transferred to the particle from the environment is used to evaporate moisture. The evaporation rate is constant; this period is called the constant drying rate period. The rate of evaporation of moisture in this period depends on the initial concentration of dry matter; the higher concentration of the solids the lower drying rate due to decreasing equilibrium vapor pressure, which reduces the driving force of the process.

If the moisture of the material drops below a critical value (point X_{cr}), the amount of liquid reaching the surface begins to gradually decrease. As a result of an increase in diffusion resistance, the drying rate decreases. This period is called the falling drying rate period (*C*).

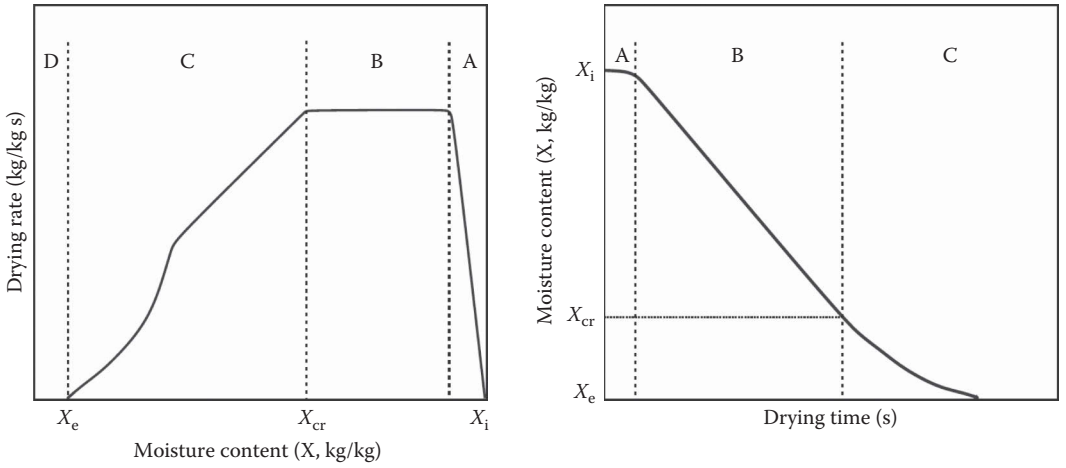

FIGURE 4.29.3 Drying rate vs. moisture content and moisture content vs. time.

The formed surface of a particle might provide an additional resistance to mass transfer and change linear shape of drying rate. The evaporation rate decreases until achieving a moisture content, which is in equilibrium with ambient air (X_e).

The mechanism of moisture removal during the falling rate drying period depends on the type of and the properties material. If the surface of the material is not porous and represents a significant resistance to the flow of moisture, the drying rate decreases and the time of moisture evaporation significantly increases.

Heat and Mass Transfer

During drying, heat of evaporation to remove water or other solvent must be provided. Heat and mass transfer occurs inside dried material and in the boundary layer between solid and drying agent. During drying, the internal structure of dried material and external conditions have various impacts in different periods of the drying process.

External Conditions

Heat may be supplied to the surface of the dried material by radiation, convection, or conduction. In most cases, all three heat transfer mechanisms are active, while one is predominant. The vast majority of drying processes is convective, hot air is used to supply energy for drying and removing water vapor. While wet material is in contact with the hot air flowing around the dried body, moisture from its surface is evaporated. Mass transfer during the evaporation of liquid is perpendicular to the direction of air flow, which affects the boundary layer. This in turn induces a change in heat transfer coefficient.

Heat and mass transfer is usually described with heat and mass transfer coefficients related to the heat and moisture flux normal to the evaporation surface, to the difference between the wall temperature or vapor pressure at the wall and reference temperature or vapor pressure.

$$q_{cw} = \alpha \cdot \left(T_w - T_{ref}\right) \tag{4.29.6}$$

$$w_{cw} = k_y \cdot \left(p_{v,w} - p_{v,ref}\right) \frac{M}{RT} \tag{4.29.7}$$

In practice, heat and mass transfer coefficients are often estimated by means of empirical correlations with the air speed, shape and size of evaporation surface, nature of the gas–vapor mixture, pressure, temperature, physical properties of the liquid, and gas component concentrations.

Internal Conditions

Drying is a diffusional process in which the transfer of moisture from the dried material to the surrounding medium is performed by surface moisture evaporation. Once some of the surface moisture evaporates, more moisture is transferred from the center of a solid to its surface. The transport of moisture within a solid is governed by a variety of mechanisms depending upon the nature and type of the solid and its form. The mechanism of moisture transport in different solids may be broadly classified into the following:

Diffusional transport of liquid or vapor
Capillary suction
Pressure induced

The type of dried materials, the structure of pores, and even rate of drying decide which mechanism is predominant. However, at different stages of drying of the same material different mechanisms may play a major role (Strumillo and Kudra, 1986).

Drying Techniques

Convective Dryers

Chamber Dryers

Scheme of a typical chamber dryer is shown in Figure 4.29.4. In most cases, chamber dryers operate in batch mode. Dried material is distributed on trays stacked inside a well-insulated drying chamber, while air circulates over the material. Usually, the stacked trays are placed on a trolley for convenient loading and unloading of the dryer. Each trolley carries the same number of trays loaded with material to be dried. Part of the moist air is recirculated with appropriately designed fans, guide vanes, or ducts. The remaining moist air continuously vented through exhaust duct is replaced with fresh air. Usually, drying times in the chamber dryers are long (from 10 to 100 h). Chamber dryers are sensitive to air flow pattern distribution over the trays as the residence time required for the slowest drying tray decides the dryer capacity.

Due to a large amount of labor to load and unload the product, the operation of chamber dryers is expensive. Chamber dryers are useful for small production lines but can be used to dry a wide range of materials, among them valuable products. In a modified design, with indirect heating of the trays, vacuum is used to remove evaporated moisture.

Tunnel Dryers

A tunnel dryer may be considered as development of the chamber dryer in which trays stacked on the trolleys move through a tunnel (long drying chamber with entrance and exit doors at opposite ends). The schematic of a tunnel dryer is depicted in Figure 4.29.5. The dried material is entering

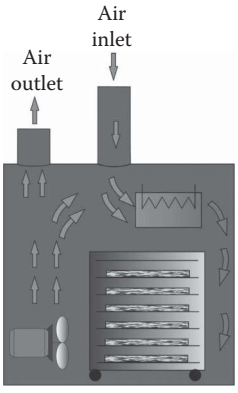

FIGURE 4.29.4 Schematic of chamber dryer.

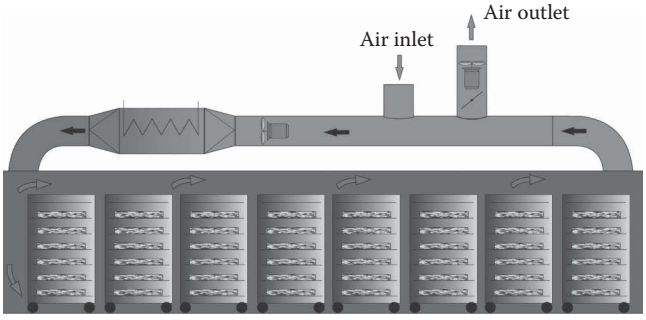

FIGURE 4.29.5 Schematic of tunnel dryer.

at one end and the product is collected at the other end of the tunnel. Trolleys with wet materials are pushed through the tunnel. In most cases, air supplying the heat for evaporation and removal of vapor circulates. Usually, part of the moist air is exhausted and replaced with fresh air. Trolleys with dried material on trays can move through the dryer either con- or countercurrently to the air flow direction. Also air cross-flow can be used but in that case the tunnel should be specially designed to control the flow path.

Tunnel dryers are often used for drying packaging materials, ceramics pottery, glass containers, etc. The drying process can be finished with sterilization of the containers. Tunnel dryers offer continuous drying of a large amount of materials.

Due to a large amount of labor to load and unload the product, the operation of a tunnel dryer is expensive. Drying rate is small, so long residence time is necessary and the process is time consuming.

Belt Dryers

Belt dryers were developed for gentle processing of materials susceptible to physical damage. Figure 4.29.6 depicts schematic of a single-belt dryer. Wet material is continuously spread as a thin layer on a usually horizontal mesh or perforated belt. The drying chamber can be divided into sections with a separate fan and heat exchanger to achieve different conditions of drying. The heat for moisture evaporation can be supplied directly or indirectly, and all heating media, such as steam, hot water, or hot gas can be used. The temperature of drying and air flow rate can be controlled separately in each section. Hot air passes through or over the material and supplies the heat for moisture evaporation and conveying humidity. The speed of a conveyer belt can be controlled, which enables easy control of drying time.

For the large depth of a dried material bed, moisture profile buildup in the layer of the material can be observed and dried material can be overheated. In order to ease the problem, the change in the air flow direction along the dryer is used. The moisture profile becomes then more uniform and the drying rate is higher. Another solution is the mixing of material on the belt. Also the application of multibelt dryers with several belts installed one above the other offers mixing of the material falling from the higher to the lower belt.

Belt dryers are fairly versatile; complex shape, relatively big, heat-sensitive, and fragile particles can be successfully processed. Schematic of a multipass band dryer is shown in Figure 4.29.7.

Superheated Steam Dryers

Drying with superheated steam is about a 100-year-old concept, but for a long time was not implemented in the industry. At the beginning of the twenty first century, the potential of this technique has been recognized again and many new research programs started (Devahastin, 2008).

Superheated steam drying (SSD) is replacing hot air in a convective drying process with superheated steam to provide energy for moisture evaporation and removal. Most constructions of the convective dryers can be used as a base for the superheated steam dryer; however, the change is not straightforward.

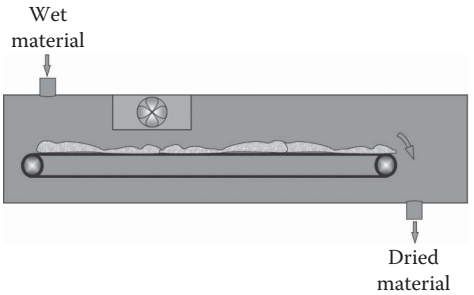

FIGURE 4.29.6 Schematic of single-belt dryer.

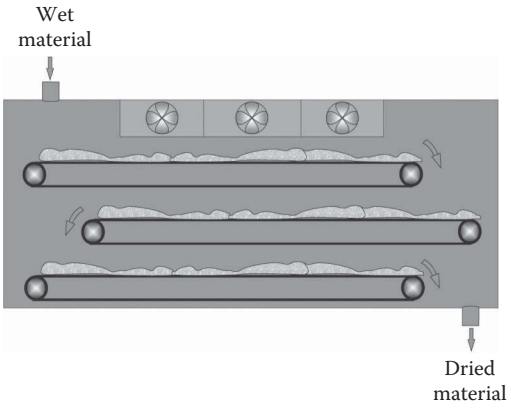

FIGURE 4.29.7 Schematic of multibelt dryer.

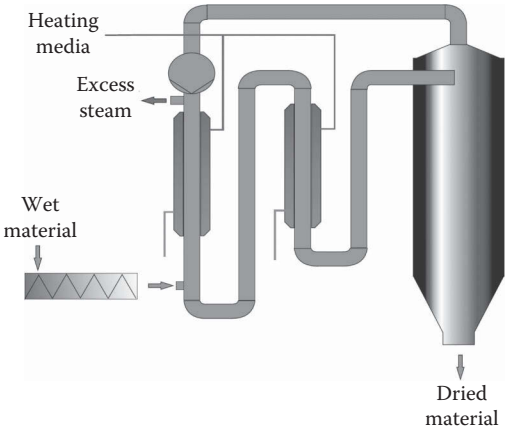

FIGURE 4.29.8 Schematic of superheated steam dryer.

SSD has a number of significant advantages over air drying. The obvious benefit is that the dryer exhaust is steam. Most of the latent heat supplied to the SSD dryer can be reclaimed by condensing the exhaust stream or by steam compression. Recovered steam can be reused in the dryer and excess can be used for other applications in the process plant. An example of a superheated steam dryer is shown in Figure 4.29.8.

Superheated steam drying eliminates the environmental problem of emission of volatile compounds produced during drying because separation of volatile organic compounds takes place at a condenser (Soponronnarit et al., 2006). The absence of oxygen in superheated steam dryers prevents oxidation or combustion reactions and eliminates the risk of fire or explosion. Lack of oxygen also inhibits oxidative reaction, which impairs the product quality (Elustondo et al., 2001). Wood chips dryer in superheated steam are softened and pelletization is improved (Pakowski et al., 2007).

Superheated steam drying can be considered as a good choice if at least one of the following conditions applies:

High-energy cost and low product value.
Product quality is significantly superior if dried in steam rather than air.
Risk of fire or explosion in the presence of oxygen is high.
Capacity and quantity of water to be removed is high.

Due to possible problems with steam condensation on the product during start-up and shutdown, steam dryers operate in continuous mode.

Disperse Dryers

Spray Dryers

Spray drying technique is commonly applied in food, chemical, ceramic, and pharmaceutical industries for mass production of powders. In spray drying, liquid feed is atomized in hot gas, dried, and collected in a form of powder, granules, or agglomerates.

First patent on spray drying (US Patent 125 406) was granted in 1872 to Samuel Percy who elaborated a concept of the process to contact dispersed liquid with hot air (Masters, 1991). Vast development of this technique was accelerated during the World War II due to high demand for dewatered powder (food, chemicals) to reduce costs of transportation. Most of existing types of spray dryers were constructed in the 40s. There are more than 500 materials already dried in spray dryers and more than 1100 patents related to this technique (Masters, 1991).

There are three stages of spray drying process (Hasheminya and Dehghannya, 2013):

1. *Atomization of feed* with pressure, pneumatic, ultrasonic or acoustic nozzles, or rotary atomizers. Figure 4.29.9 shows basic types of atomizers applied in spray drying.

   Atomization process always produces a polydisperse, log-normal particle size distribution (PSD). Typical shape of PSD with arithmetic diameter and Suter diameter characterizing the spray is shown in Figure 4.29.10. PSD occurs independently of the type of atomizer or physicochemical properties of sprayed liquid.

   In practice, for scaling-up or calculation of spray drying process, experimental distributions such as Rosin–Rammler or Nukiyama–Tanasawa are often applied (Masters, 1991). New constructions of spraying nozzles to produce narrow PSD and low velocity spray, like ultrasonic or acoustic nozzles are still under development. Up to now, no ultrasonic or acoustic nozzles have been applied in industry for mass production of powder.

   Droplets leaving the atomizer move at different speed that may lead to collisions and agglomeration. The most important parameters characterizing the spray and affecting final powder properties are atomization angle, atomization ratio (AR), and PSD. Atomization angle determines the shape of spray. Pressure nozzles are characterized by small atomization angle in comparison with pneumatic nozzles and rotary discs. One of the most important parameters determining the quality of atomization is AR, which is equal to the mass flow of atomized air to mass flow of liquid (kg/kg). The higher the AR, the smaller the droplet diameter. In practice, AR covers the range from 0.1 to 10, for AR lower than

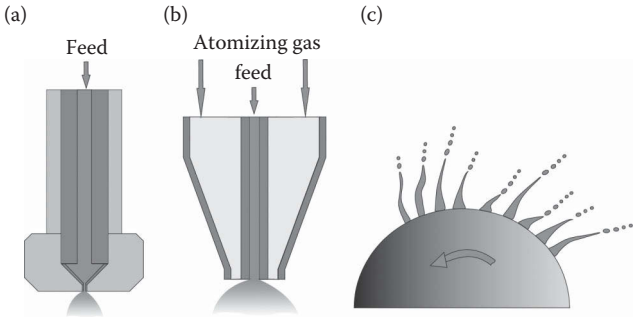

FIGURE 4.29.9 Schemes of basic types of atomizers applied in spray drying (a) pressure nozzle, (b) pneumatic nozzle, and (c) rotary disc.

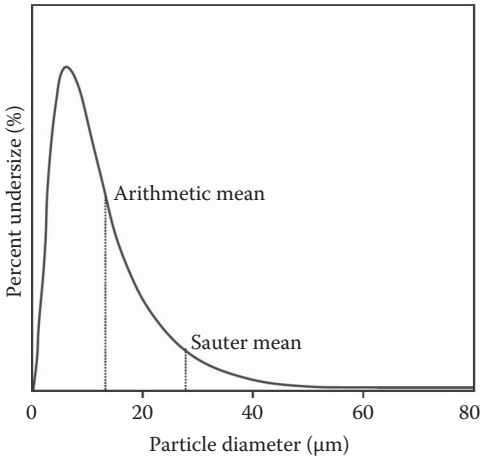

FIGURE 4.29.10 Log-normal PSD.

0.1 atomization is coarse and unstable, for AR higher than 10 no more decrease of droplet diameter can be achieved.

Atomization is accompanied by losses of volatile substances as well as flavor and aroma of dried food products (King, 1995), which occur until the formation of an impermeable layer on the particle surface. Atomization process has a significant impact on the particle size, morphology, and the organoleptic properties of the final product.

2. *Drying of droplets with hot air*

The way in which drying air is contacted with the sprayed material has a significanlt influence on the residence time of particles in the dryer and properties of the final product. Depending on sprayed material-drying agent contact, three types of spray dryers are distinguished:

Concurrent,
Countercurrent
Mixed flow

Figure 4.29.11 shows schematic diagrams of spray dryers with regard to the way of contact with drying air (Masters, 1991).

In countercurrent dryers, drying air is supplied to the dryer axially and tangentially, and the air and material being dried flow in the same direction. In countercurrent systems, raw material can be supplied into the drying chamber from the bottom or top and flows in the direction opposite to the drying air. In mixed flow dryers, the raw material is usually supplied from the top and the drying agent is fed into the drying chamber from the top and bottom.

In concurrent dryers, a so-called atomization zone is distinguished in which a stream of material penetrates the turbulent air flow and free fall zone, where the atomized material is gradually mixed with air. In the next step, the dried material is discharged from the drying chamber to cyclones where it is separated from the drying agent.

The processes of concurrent and countercurrent spray drying were developed in parallel. However, a simple construction and easy process control cause that the concurrent system is most often applied in industry. On the other hand, a better use of energy in the countercurrent system, comprising drying and agglomeration and lower production costs, also has led to a broader implementation of this system in the industry, despite the greater difficulty in controlling the process (Rahse and Dicoi, 2001). The countercurrent spray

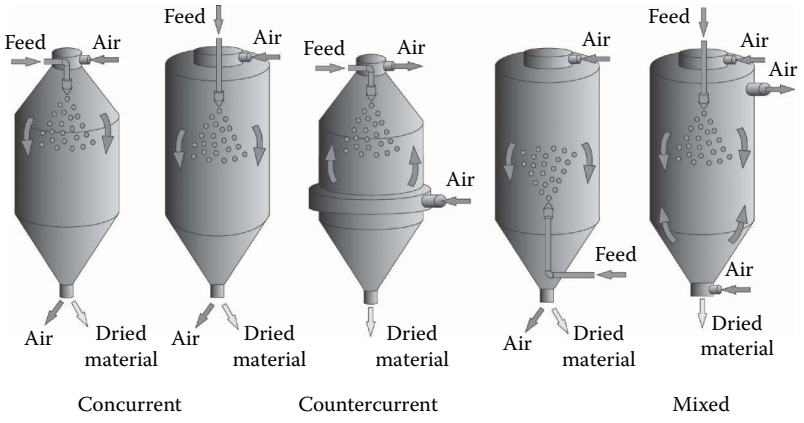

FIGURE 4.29.11 Types of spray dryers (concurrent, countercurrent, mixed).

drying method is widely used in the production of detergents, fertilizers, and certain food substances.

The countercurrent process has the following advantages over the concurrent technique:

High-energy efficiency
Intensive agglomeration, large average particle size, less dust
Control of bulk density of the powder
Drying of viscous products
Integration of upper filters
Multilevel spraying, high throughput
Lower costs of the drying process

Table 4.29.2 shows a comparison of basic powder properties dried in concurrent and countercurrent spray dryers.

Intensive agglomeration in countercurrent spray drying resulted in almost doubled average particle diameter in comparison with the concurrent process.

3. *Separation of dried powder from drying gas*

In most cases high-volume industrial dryers work in a quasi-closed system of raw material, which means that the dried product is discharged from the dryer bottom part, while particles with small diameters are separated from the stream of drying air in bag filters placed in external cyclones.

In a countercurrent system, particles entrained with the drying agent are returned to the dryer and introduced directly into the drying/atomization zone by shaking off powder

TABLE 4.29.2
Morphology of Powders Dried in Concurrent and Countercurrent Spray Dryer

Property	Concurrent Drying Process	Countercurrent Drying Process
Moisture content (%)	13	11
Bulk density (kg/m^3)	235	280
Particle diameter (μm)	170	310

Source: Taylor, T. Concurrent and countercurrent spray drying and particle morphology. Paper No. 9, *12th International Drying Symposium*, Noordwijkerhout, The Netherlands, August 28–31, 2000.

from the bag filter or by pneumatic transport of material from the cyclones. This solution can reduce the loss of material and at the same time speed up the process of agglomeration of particles in the dryer. The final purification of air usually takes place in the bag filter, where the finest particles are separated and in scrubbers where volatile impurities are removed (e.g., aromatic substances).

The spray dried materials are divided into the following three groups depending on the particle structure (Walton, 2000):

Skin forming
Agglomerate
Crystalline

Skin-forming materials are characterized by formation of an impermeable film, which covers the entire material surface, while liquid is trapped inside the particles. The particles of spray-dried materials often contain air bubbles (Verhey, 1973), which is a result of desorption of air initially present in the liquid feed or absorbed during atomization.

In view of the diversity of materials to be dried in spray dryers, it is difficult to determine general relationships presenting the kinetics of moisture removal (Masters, 1991). In a typical drying scheme, the particle stops shrinking and a solid structure is formed upon reaching the critical moisture content. From that moment particles cannot change their size, can break, agglomerate, etc.

Process conditions of spray drying have a significant effect on product morphology. Figure 4.29.12 shows the changes of bulk density of skin forming, agglomerate, and crystalline product as a function of drying air temperature (Kwapinska, 2002). Air temperature growth from 150°C to 250°C is decreased by about 75% the bulk density of the skin forming material and by approximately 30% the bulk density of the agglomerate (detergent). In the skin-forming materials, moisture is entrapped inside due to crust formation. If the particle surface is not porous, then the forming water vapor causes stretching or breaking of the crust. Temperature of the drying agent has no effect on bulk density of crystalline material.

Air bubbles in skin-forming particles as well as crashes and craters in agglomerate powder can be detected. No effect of spray drying on the morphology of crystalline material and no impact of bulk density can be found.

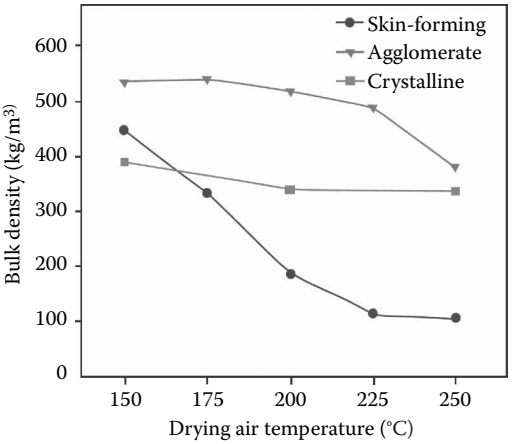

FIGURE 4.29.12 Effect of drying gas temperature on bulk density of the product (Kwapinska, 2002).

Microencapsulation

One of the most spectacular applications of spray drying is microencapsulation of products. Microencapsulation is a method of trapping an active core substance in a matrix material. This technique is used to protect specific properties of the encapsulated substance against unfavorable environmental conditions and to control release of the core material. Despite the diversity of microencapsulation techniques, spray drying is the most common method in the food industry mainly because of low cost. When removing the solvent (usually water), the process of core trapping in the matrix material proceeds at the same time. The spray drying method can be used for solutions of high viscosity, such as emulsions, pastes, and slurries. This method allows for drying of thermolabile materials without significant losses of product quality.

Microencapsulation enables extension of product shelflife, production of new flavor and aroma compositions, and improvement of nutritional values of food products. Main groups of products protected by the microencapsulation technique include spices, fats and essential oils, vitamins and minerals, bioactivators (probiotic bacteria and enzymes), and live microorganisms (acidifying bacteria and yeast) (Gibbs et al., 1999). Like in food industry, also in cosmetic industry the microencapsulation made it possible to develop production techniques in order to obtain a product with new functional properties.

Beginnings of the microencapsulation technique date back to the 30s of the 20th century (Thies, 1996). In the second half of the 20th century, the process of microencapsulation was used mainly in the food processing and pharmaceutical industries, whereas in the 1990s it was also used in cosmetic, biotechnological, and agrochemical industries (Gouin, 2004).

Analysis of the literature shows that the efficiency of microencapsulation depends on the initial temperature of the drying air, residence time, and content of the encapsulated material relative to the amount of carrier.

Table 4.29.3 gives examples of surface oil content and cardamom essential oil retention in powders at different oil concentration in the emulsion (Beristain et al., 2001).

A small ratio of matrix to core material causes a deterioration of encapsulation and increased concentration of essential oil not entrapped in the microcapsule. The highest oil retention of 83.6% was reported for the 1:4 ratio, which proves the existence of an optimum concentration of the coating material for reaching the best possible retention of the core material (Risch, 1995). On the other hand, a decrease in the retention for the oil/matrix material ratio of 1:5 was due to the shape and location of the core material in matrix material.

Fluidized Bed Dryers

A fluidized bed drying is one of the most frequently applied techniques for drying of particulate materials. High rates of heat and mass transfer cause that fluidized bed dryers are characterized by high thermal efficiency and have smaller size than other, alternative types of dryers. In fluid bed dryers thermally sensitive materials can be dried because of easy control of material temperature in

TABLE 4.29.3
Total and Surface Oil Content and Retention in Powders at Different Oil Concentrations in the Emulsion

Oil to Rubber Ratio	Oil Content in Emulsion (g oil/kg rubber)	Total Oil Content (g oil/kg rubber)	Surface Oil Content (g oil/kg rubber)	Retention (%)
1:5	166.6	111.4	1.90	66.9
1:4	200.0	167.1	2.59	83.6
1:3	250.0	185.6	8.08	74.2

different sections of the dryer. Low costs of maintenance, few moving parts, and simple devices for receiving the product are the advantages of fluidized bed drying. Its disadvantages include a limited range of materials that can be dried, e.g., this technique is not suitable for materials with high initial moisture content, with a wide range of particle sizes (polydisperse materials), and with low critical fluidization rate (Kunii and Levenspiel, 2013). Besides dryers where the classical fluidization is applied, there is a number of modifications of this technique such as vibrofluidized bed, spouted bed, or spouted bed with inert bodies.

To obtain a fluidized bed, a stream of gas should be introduced from the bottom of the dryer through a screen baffle on which the bed of particulate material is located (Figure 4.29.13). At a certain gas flow rate, the layer of material is loosened and particles move within the bed. This gas–solid particles system has many features of a fluid and so this state is called the fluidized state. Velocity at which a packed bed transfers into the fluid bed is called the critical fluidization velocity.

Further increase of the gas flow rate causes expansion of the bed. Depending on gas flow, different states of fluidization can be observed: smooth fluidization, bubbling fluidization, and turbulent fluidization. Finally, fluidization turns into pneumatic conveying and powder is carried out from the dryer. A schematic diagram of different stages of fluidization is shown in Figure 4.29.14.

In practice, the gas flow rate is maintained at a level that provides a uniform fluidization of the particles. Above the bed there is a free space (1–2 m), which allows lighter particles entrained from the bed to fall down. Fluidization of the bed of wet material develops favorable conditions for carrying out the process of drying due to good development of the interfacial contact area, which contributes to achieving high heat and mass transfer coefficients.

There are various dryers in which the fluidized bed is used. From the point of view of the type of material, fluidized bed dryers are applied to dehydrate loose materials as well as pastes, solutions,

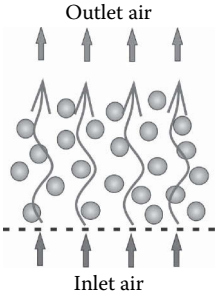

FIGURE 4.29.13 Basic mechanism of fluidized bed drying.

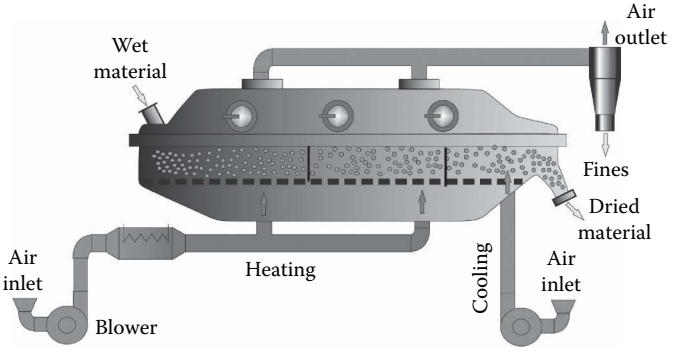

FIGURE 4.29.16 Single-stage fluidized bed dryer with rectangular cross section.

and suspensions. From the viewpoint of a drying regime, there are continuous, semicontinuous, as well as single- and multistage fluidized bed dryers. In industrial practice, the most popular are continuous dryers. Figures 4.29.15 and 4.29.16 show two typical schematic diagrams of continuous fluidized bed dryers—a classical single-stage dryer of circular cross and rectangular sections. Dryers of this type operate at a cross flow of the material and drying agent. Dried material is received directly from the dryer and dusted gas is cleaned initially in cyclones and then in bag filters. To reduce the entrainment velocity of fine particles, the diameter of a drying chamber can be expanded in the upper part (Figure 4.29.15).

Figure 4.29.16 shows a typical industrial continuous fluidized bed dryer with a rectangular cross section, divided into heating and cooling sections to maintain a predried product at a lower temperature to avoid overheating.

Baffles in the bed are used to control of residence time of particles in the dryer. Development of the fluidized bed drying technique is vibrofluidized beds. The vibrofluidized system enables uniform drying of materials with high adhesion and prone to sticking together (e.g., sugar) at high process intensity.

Pneumatic Dryers

Pneumatic drying takes place during pneumatic transport of fine particles of wet material in a hot air stream. During pneumatic drying, there is an intensive heat and mass transfer between continuous and discrete phases resulting from a significant expansion of the interfacial surface area, high

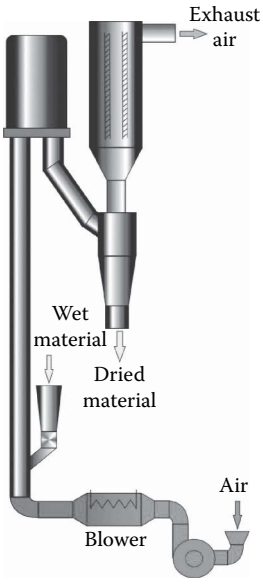

FIGURE 4.29.17 Schematic of pneumatic dryer.

heat, and mass transfer driving force (gas temperature above 500°C) and large gas flow velocities (25 m/s). A typical diagram of a pneumatic dryer is shown in Figure 4.29.17. Wet material is fed to a vertical tube in which hot air flows. Air flow velocity must be higher than settling velocity of dried material particles. The particles are entrained upwards quickly giving moisture back. Dry product is received in the cyclone and dust formed during the pneumatic transport due to abrasion of particles is collected in a bag filter or electrofilter (Borde and Levy, 2007). The residence time of material in the tube is from 1 to 5 s, which restricts the use of pneumatic dryers to materials containing mostly surface moisture. In industrial applications, the material is recirculated to prolong residence time in the dryer even to 1 min. The recommended diameter of material particles ranges from 1 to 2 mm.

Pneumatic dryers are used in many branches of chemical, ceramic, agricultural, and wood processing industries. Due to a simple construction, pneumatic dryers are characterized by low capital and operating costs as compared to other types of dispersion dryers. Owing to short residence time of material in the dryer, high inlet gas temperatures can be used and thermally sensitive materials can be dried. High temperature of the drying agent also contributes to high evaporation rates and thermal efficiency of the process. Pneumatic dryers require little space and can be installed in the open air.

A disadvantage of the pneumatic dryers is often the necessity of pretreatment of the raw material to obtain sufficiently small particles suitable for pneumatic transportation. Another problem is the abrasion of particles during pneumatic transport and high dust emission requiring efficient dust collection equipment.

Pneumatic dryers are a modern drying technique, which is continuously developed and permanently present in the industry.

Rotary Dryers

Rotary dryers are among these the most commonly used in industrial practice. Rotary dryers are characterized by simple construction, high throughput (up to hundreds tons per hour), and satisfactory thermal efficiency. Basic mechanism of the rotary drying process is as follows: material being dried is lifted due to drum rotation, then falls in the hot air stream moving in co- or countercurrent to the direction of material movement. Dried material moves along the dryer due to rotations of a slightly inclined drum.

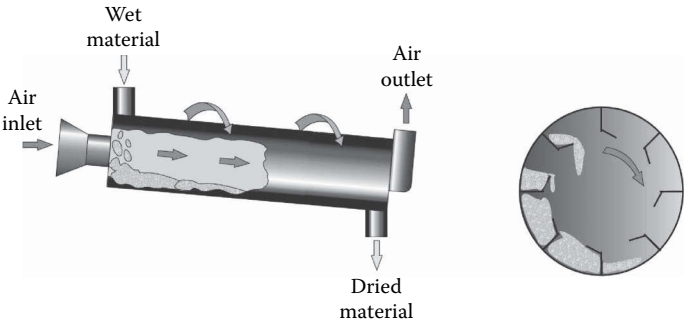

FIGURE 4.29.18 Schematic of rotary dryer.

A scheme of the rotary dryer with cross section of the kiln is shown in Figure 4.29.18.

The residence time of material in the dryer, which ranges from several minutes to about an hour in industrial conditions, depends on the speed of drum rotations (normally: several rpm), kiln inclination (up to several degrees), diameter of the drum (1–3 m), design and number of fins, load regime (normally loaded regime = 10%–12% of the dryer volume, but dryers work also in overloaded and underloaded regime), air velocity and flow direction, and also properties of the material (including moisture content). The drying time of the material must be smaller or equal to the residence time of material in the rotary kiln. Rotary dryers are applied in chemical industry (e.g., fertilizers, ores, limestone), agriculture (wood chips), for drying industrial and municipal wastes and sludges, etc. Rotary dryers, being one of the oldest dryer designs, are continually developed and find new applications due to high thermal efficiency and elasticity of the process.

Contact Dryers

In contact dryers heat for drying is supplied from the hot surface to the dried material by conduction. The contact surface may be heated up with steam, hot water, organic liquids, combustion gases, or electricity. Thermal efficiency of contact dryers is higher comparing to the convective drying because all heat from the hot surface is transferred to the wet material and there are no heat losses with exhaust air. For comparison, energy consumption of a common contact dryer is about 2800–3600 kJ/kg of water evaporated, whereas energy consumption of a convective dryer is 4000–6000 kJ/kg.

The main disadvantage of the contact drying is the higher capital costs in relation to convective drying systems; to increase throughput, the heating areas must be increased, which makes contact drying more suitable for batch operation.

Depending on the shape of a heating surface, contact dryers can be divided into drum dryers, thin-film dryers, cone dryers, chamber dryers, and agitated bed dryers. Contact dryers may operate under vacuum, e.g., in drying of heat-sensitive materials (Strumillo and Kudra, 1986).

Batch chamber contact dryers consist of a drying chamber and heating shelves where dried material is placed; the number of drying shelves depends on the dryer throughput (Figure 4.29.19a). The limitations of this type of dryers are high labor demand to load and discharge the dryer; moreover, for scaling up usually the installation of additional drying units is required.

Contact rotary dryers consist of a rotating cylindrical drying chamber with tubes installed inside, which are usually heated by steam (Figure 4.29.19b). This type of dryers might be applied when the contact of dried material with hot drying gas should be avoided due to product quality issues or when dried material is dusty and difficult to separate from the dried gas.

In the contact drum dryers, the viscous dried medium (paste or slurry) is spread on the rotating cylinder, which is heated up from the inside (Figure 4.29.19c). Depending on the construction, drum dryers are divided into single- and double-drum dryers. Different feeding methods can be applied in drum dryers: spray feed, top or bottom roller feed, “dip” feed. The choice of a suitable feeding

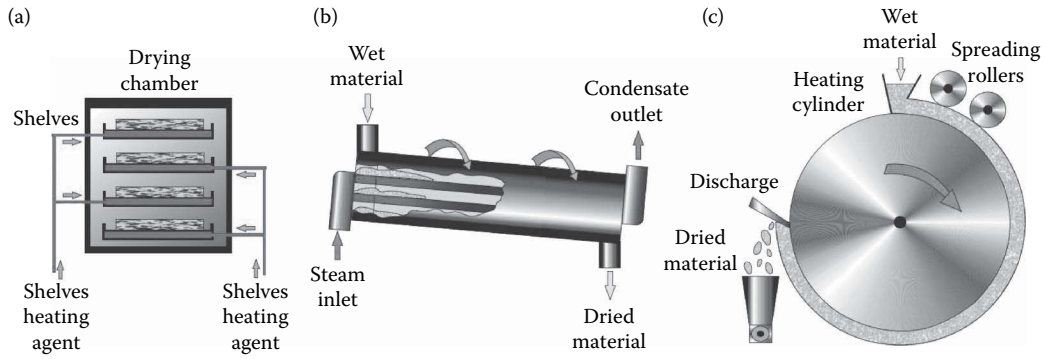

FIGURE 4.29.19 Contact dryers: (a) chamber dryer, (b) rotary dryer, and (c) drum dryer.

method depends on wet material properties such as viscosity or solids content. High heat flux and rapid moisture evaporation from the thin layer of wet material develop a porous structure of dried product making drum drying suitable for instant products. The capacity of a drum dryer is controlled by temperature of the heating surface, drum rotation speed, feeding method, and material properties (Daud, 2006).

Drying in Energy Fields

Dielectric Drying: Microwave and Radio Frequency Dryers

Dielectric drying is the drying technique were heat is generated inside the drying material due to electromagnetic energy. Depending on the frequency of electromagnetic energy, two types of dielectric drying is distinguished: microwave (MW, frequency from 300 MHz to 300 GHz) and radio frequency (RF, frequency from 3 kHz to 300 MHz).

Figure 4.29.20 shows the mechanism of dielectric drying, which can be described in the following way: polar liquids, e.g., water, absorb electromagnetic energy, which causes a change in the orientation of dipoles and heat generation due to molecular friction. Solid parts of the dried materials are not affected by the electric field; therefore, heat is generated at wet regions of the material (Zhang et al., 2016).

Dielectric properties of the wet material, strength of the electric field and frequency of the dielectric field are the main parameters which affect the rate of absorption of electric power per unit volume (Strumillo and Kudra, 1986). Energy efficiency and heating rate of MW drying depends on the dielectric property of material, which is correlated with material moisture content.

A microwave dryer usually comprises three elements (Figure 4.29.21), a magnetron where MW power is generated, waveguide transmitting the MW energy from the magnetron to dried material, and a microwave cavity where wet material is dried.

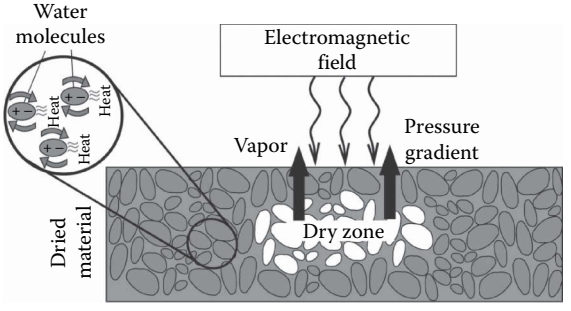

FIGURE 4.29.20 Mechanism of the microwave drying process.

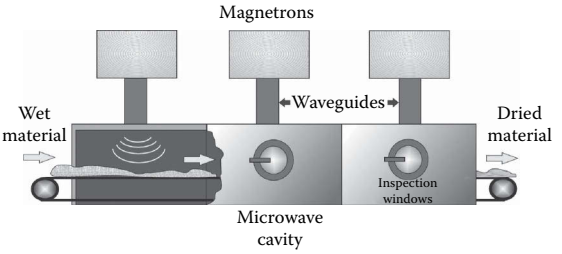

FIGURE 4.29.21 Schematic of microwave dryer.

During last decades microwave drying has found application in drying of different types of materials such as food products, pharmaceuticals, wood, ceramic, biological materials, etc. MW is suitable for materials that have good dielectric properties, i.e., ability to convert electromagnetic energy into heat.

The main advantages of MW drying are high drying rate and short drying time (Rattanadecho and Makul, 2016). The disadvantages of MW drying are high costs per unit of energy and high capital costs and nonuniform heating of dried material, which can deteriorate product quality.

Infrared Dryers

In infrared (IR), drying thermal energy is transferred from the heating elements to wet material by IR radiation (wavelength from 0.76 to 400 μm). Depending on the wavelength band, the IR radiation can be divided into three categories: near-infrared (NIR; 0.78–1.4 μm), middle-infrared (MIR; 1.4–3 μm), and far-infrared (FIR; 3–1000 μm) (Riadh et al., 2015). NIR is more efficient for thicker materials and FIR for thin materials and food products because NIR drying gives higher heat fluxes than MIR and FIR.

Figure 4.29.22 illustrates the mechanism of IR drying. The IR radiation may be reflected, absorbed, or transmitted through the product. The amount of IR energy absorbed by the product depends on the product absorption characteristics and moisture content. The mechanism of heat and moisture transport within the material is identical during the convective drying.

The scheme of an IR dryer is presented in Figure 4.29.23. IR radiators are the main elements of the dryer. In industrial practice, two types of IR radiators are commonly used: electric and gas-fired heaters. The gas-fired heaters produce temperatures in the range from 343°C to 1100°C, whereas electric heaters from 343°C to 2200°C (Krishnamurthy et al., 2008). Capital costs of electric heaters are lower but operating costs are higher comparing to the gas-fired heaters.

The IR drying technique has found wide application in industry for drying materials in the form of thin sheets, e.g., textiles, paper, building materials, paints, and coatings.

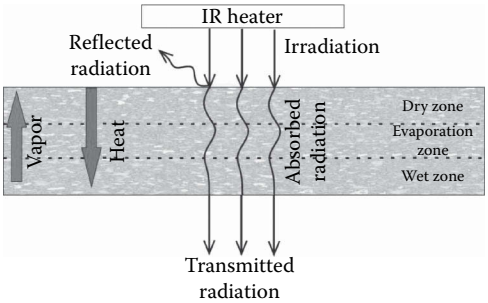

FIGURE 4.29.22 Mechanism of infrared drying process.

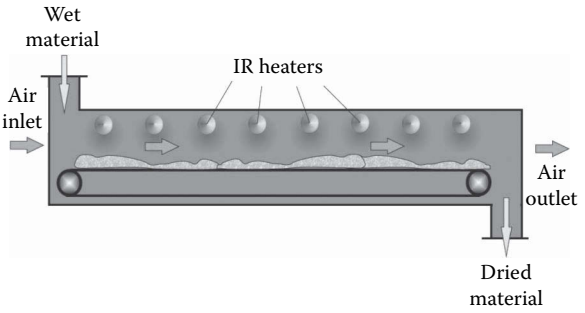

FIGURE 4.29.23 Schematic of infrared belt dryer. (From Strumillo, C. and Kudra, T., *Drying Principles, Applications and Design,* Gordon and Breach Science Publishers, New York, 1986.)

The main advantages of IR dryers is higher energy efficiency than in convective drying, reduced drying time, uniform and direct heating of the product, and low-cost technology. The disadvantages include potential fire hazards, limitation to thin layers drying and necessity to define optimal parameters, i.e., the wavelength of an IR emitter individually for each dried material. In recent years, different hybrid IR drying techniques were developed which use combination of IR with hot air, microwave, freeze-drying, vibration, etc.

Ultrasound Dryers

In ultrasound (US) drying, the energy of acoustic waves at frequencies above 20 kHz is utilized to generate air vibrations and intensify moisture evaporation. In order to enhance the dehydration process high US power intensity (>1W/cm^2) and frequencies ranging from 20 to 40 kHz are required (Witrowa-Rajchert et al., 2014). Two different types of US applications for drying intensification are described in the literature: US-assisted pretreatment of dried material and direct application of US in the drying process (Rodriguez et al., 2014, 2015). The scheme of an US dryer is presented in Figure 4.29.24. Commonly, US dryers consist of an air supplying unit, drying chamber with trays for dried material and main element—an US transducer.

Kowalski and Mierzwa (2015) described the mechanism of US drying distinguishing vibrating and heating effects of US. The propagation of acoustic wave through the gas medium generates high-frequency vibrations of air in the vicinity of dried product surface, which enhances turbulence in the evaporation zone. Additionally, the absorbed acoustic energy generates heating effect, i.e., temperature increase of dried material.

Main parameters affecting the US drying process are acoustic wave frequency, sound intensity, pressure, as well as air velocity and wet material properties (moisture content and porosity).

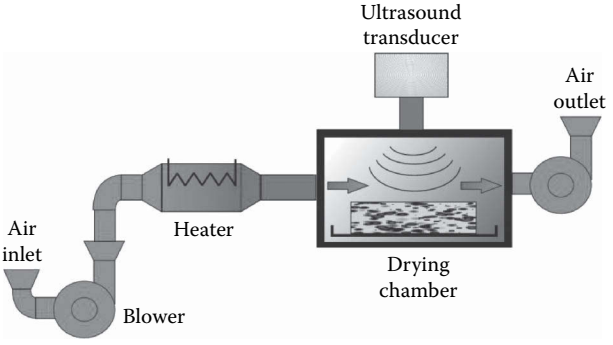

FIGURE 4.29.24 Schematic of ultrasonic dryer.

The US drying was successfully applied in the laboratory scale for drying of food materials such as fruits and vegetables (Rodriguez et al., 2014).

US drying enables one to increase the effective moisture diffusivity and mass transfer coefficient, which results in a shorter drying time. Comparison of the standard convective drying with US-assisted drying showed energy saving of up to 10% for US applications (Kowalski and Mierzwa, 2015). The demerits of US drying are immaturity of the technique, high energy cost, and destruction of cell tissues for some biological materials due to acoustic power. In the literature, there are no reports concerning the application of US drying in the industrial scale.

Vacuum Freeze-Drying

In vacuum freeze-drying, solvent is removed from the frozen material as vapor by sublimation at the pressure below triple point. The freeze-drying process includes the following steps: (1) material freezing, (2) sublimation or primary drying step where frozen "free" water is removed, and (3) secondary drying stage where the product is warmed up to remove bounded water. In the vacuum freeze-drying method, heat for drying is supplied by conduction from the heating plates or IR. In the primary drying step, the product temperature is kept below 0°C and in the secondary drying process the product temperature can be increased above 0°C, but it should be low enough to meet the product quality requirements. Material freezing is the most important step of the freeze-drying because it determines the size of ice crystals formed in the product matrix, which affects dried product morphology and drying rate (Pisano et al., 2011). Slow freezing results in the formation of large ice crystals and large pores in the material matrix.

The mechanism of freeze-drying is as follows: heat is supplied by conduction from the heated shell to the dried material, the solvent vapor is sublimating from the outer surface of the product. A thin layer of the porous dried material is formed at the surface at the beginning of the process and then rises as the sublimation front moves toward the frozen layer (Figure 4.29.25).

Freeze dryers capable of working in laboratory, pilot, or industrial scale are available on the market. Regardless of the dryer capacity all freeze dryers include the same basic elements: a drying chamber, ice condenser, and vacuum pump (Figure 4.29.26). Laboratory- and pilot-scale freeze dryers can be divided into two groups: dryers with shelves where product is placed on the heated plates located in the same chamber as the ice condenser, and dryers with flasks where product is dried in the vessels outside of the ice condenser chamber. Industrial dryers are classified using a similar principle: in single-chamber dryers the ice condenser is located at the drying chamber and in double-chamber dryers the ice condenser and drying chamber are separated. Double-chamber dryers are used when dried products have special requirements, for example, sterile pharmaceuticals.

Vacuum freeze-drying produces the best quality products in comparison to all the drying techniques. Vacuum freeze-drying, however, has high capital and operating costs. Therefore, this drying method can be suitable only for drying products of high value whose properties can be deteriorated during high-temperature drying, i.e., food products with high nutritional value, biotechnological products, pharmaceuticals, or valuable nanomaterials. The major operating cost is energy for heating, vacuuming, and condensing of the removed water.

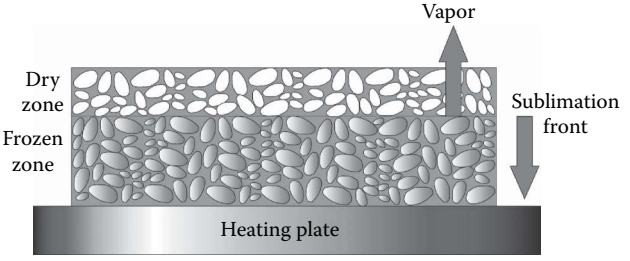

FIGURE 4.29.25 Mechanism of freeze-drying process.

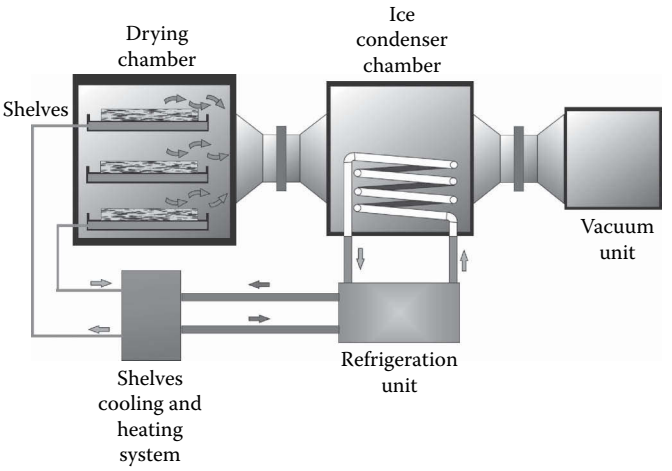

FIGURE 4.29.26 Vacuum freeze dryer with separate drying and ice condenser chambers (Liapis and Bruttini, 2007).

Atmospheric Freeze-Drying

In order to overcome the disadvantages of vacuum freeze-drying, i.e., high capital and operating costs, the atmospheric freeze-drying (AFD) technique was developed. In the AFD, the wet material is dried by convection at temperature below freezing point. As the ability of air to remove moisture is reduced when temperature decreases, the AFD is commonly carried out at temperatures ranging from –3°C to –10°C. One of the limitations of AFD is the long drying time even when comparing to vacuum freeze dryers.

Fluidized bed, tunnel and spray freeze dryers are the most common AFD systems (Reyes et al., 2010). A few authors studied drying of food products in a laboratory-scale fluidized bed atmospheric freeze dryer and find out that a moving bed intensifies heat and mass transfer and reduces drying time. The AFD technique found an application in industrial scale for drying of vegetables at AromaDry plant in Hungary (Claussen et al., 2007). Spray freeze-drying at atmospheric pressure is an emerging technique, which might reduce energy and process costs in production of pharmaceuticals comparing to conventional vacuum freeze-drying.

Special Drying Techniques

Pulse Combustion Drying

Pulse combustion drying (PCD) is the process where heat for drying and energy needed for liquid stream atomization come from intermittent combustion of gaseous fuel. The acoustic oscillations generated in the pulse combustor cause pressure and air velocity pulsations, which significantly increase the heat and mass transfer rate. Pulse combustors operate with frequency from 50 to 200 Hz, initial gas temperature is around 600°C, drying time is less than 0.1 s that enable to dry heat-sensitive products (Zbicinski et al., 2014a). The pulse combustion spray dryer has lower energy consumption (3300 kJ/kg H_2O) than a conventional spray dryer (5501 kJ/kg H_2O). The pulse combustion technique can be applied for spray dryers, fluid bed dryers, flash dryers, rotary dryers, and pneumatic dryers. Every pulse combustion dryer consists of air and fuel supplying units, pulse combustor, feeding system, drying chamber, and dried material collecting units. An example of the PCD system is presented in Figure 4.29.27. Pulse combustors available on the market may be classified as valved or valveless (mechanical or aerodynamic).

PC spray dryers are applied commercially to drying of food products, chemicals, wastes, and nano- and ceramic materials.

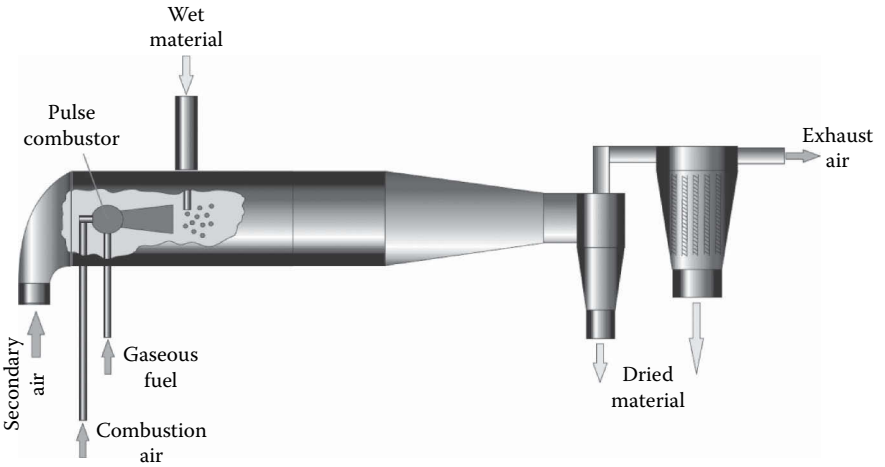

FIGURE 4.29.27 Pulse combustion spray drying system (Meng et al., 2016).

Foam Spray Drying

Foam spray drying is a modified type of the spray drying process where foaming gas is introduced into the raw material to control final product properties. Two types of the foam spray drying process are distinguished: gas desorption and gas admixing processes. In gas admixing foam spray drying, the foaming gas, for example, nitrogen, is introduced in the pipeline connecting the pump and atomizing nozzle as shown in Figure 4.29.28 (Zbicinski and Rabaeva, 2009). Feed foaming before atomization produces droplets with gas bubbles trapped inside which during contact with hot air expand producing hollow dried particles with voids.

Foam spray drying produces powders with specific properties: low bulk density, high porosity and particle size, enhanced solubility, and wettability (Zbicinski et al., 2014 b). A comparison of the bulk density of powders dried using conventional spray drying and foam spray drying methods is presented in Table 4.29.4 (Rabaeva, 2012). An increase of foaming air flow rate results in a significant reduction of the bulk density of dried products.

Flame Spray Drying

The flame spray drying (FSD) is a modification of the spray drying process where heat for drying is provided by combustion of a flammable component added to the feed. Basic principle of flame spray drying is presented in Figure 4.29.29.

Distinct features of the FSD set up is the absence of drying air heating system and presence of additional elements such as ignition system, flame detector, and safety membranes.

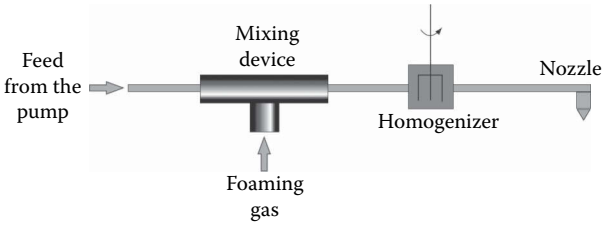

FIGURE 4.29.28 Schematic of foaming gas introduced in foam spray drying process (Zbicinski and Rabaeva, 2009).

TABLE 4.29.4

[a] Standard spray drying process.

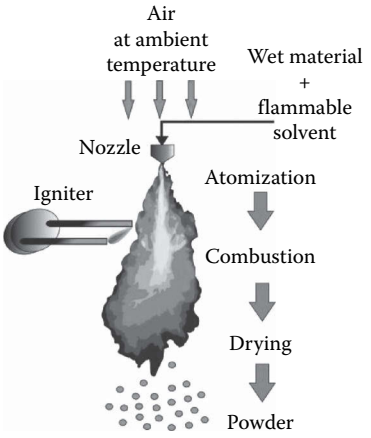

FIGURE 4.29.29 Mechanism of flame spray drying (Piatkowski et al., 2014).

For comparison, energy consumption of the FSD process was estimated to be 23.92 MJ/kg of evaporated moisture, whereas energy consumption of an equivalent standard spray drying process with electrical heating of the drying air was 36.11 MJ/kg water (Piatkowski et al., 2015).

Comparing to the standard spray drying process, dried powder obtained in FSD is characterized by reduced bulk density and increased particle diameters due to agglomeration and puffing which take place in the combustion zone. Table 4.29.5 shows a comparison of bulk density for maltodextrin powder produced using the standard spray drying process and FSD.

FSD is a new technique, without industrial applications, especially suitable for heat-resistant products.

Principles of Dryer Design

Acquisition of Drying Kinetics

An important step in the design of industrial dryers is the analysis of drying kinetics for a particular material, which can be carried out in laboratory or pilot-plant dryers. Kemp et al. (2001) distinguished four methods used to acquire experimental data on drying kinetics: periodic sampling, continuous weighing, intermittent weighing, and indirect methods. In periodic sampling, the drying process is interrupted to determine the weight of dried sample. In continuous weighing, the sample is located on a balance inside the drying chamber and sample weight loss is recorded continuously through the whole drying process. Intermitted weighing is a combination of the two aforementioned

TABLE 4.29.5

35	30	228	1021
45	30	145	793
0[a]	40	588	1358
35	40	153	937
45	40	126	849

[a] Standard spray drying process.

methods, i.e., the weight of drying sample is determined inside the drying chamber; however, at the moment of weighing, the drying process is interrupted for system stabilization. In indirect methods, data on drying kinetics are obtained from exhaust air humidity measurements.

Accurate determination of drying kinetics for disperse systems is still a challenging issue due to very short drying time. For example, drying time in an industrial-scale spray drying tower varies in the range from 1 to 10 s. Drying time in a laboratory-scale spray dryer is much longer due to large size of the analyzed droplets (from 500 to 2000 μm), therefore drying kinetics data obtained in the small scale does not represent the real spray drying kinetics (Zbicinski et al., 2005). Experimental methods for determination of spray drying kinetics can be divided into two groups: single droplet drying methods or fast drying of thin film methods. In single droplet technique, the droplet is fixed in one position due to acoustic field produced by acoustic levitator or hanged on glass filament. The data on drying kinetics of droplet are obtained from the exhaust air humidity (Groenewold et al., 2002).

In thin film method, spray drying kinetics is determined on the basis of fast drying (drying times comparable to industrial-scale drying towers) of thin layers of wet material. An example of the experimental installation, i.e., drying tunnel, elaborated for the determination of spray drying kinetics in thin film is presented in Figure 4.29.30 (Zbicinski et al., 2005). The thin layer of wet material is placed on the measuring pan mounted on a balance to record weight loss of the sample continuously during drying. Two electric heating systems provide high-temperature drying air (from 100°C to 500°C) to ensure fast drying of the sample (seconds).

The measurement of drying air temperature and humidity in the spray drying chamber is also a challenging issue as particles present in the air may hit the sensor making incorrect temperature reading. To separate gaseous phase from dispersed droplets/particles and conduct measurement in the clean air, microseparators are used (Wawrzyniak et al., 2012a).

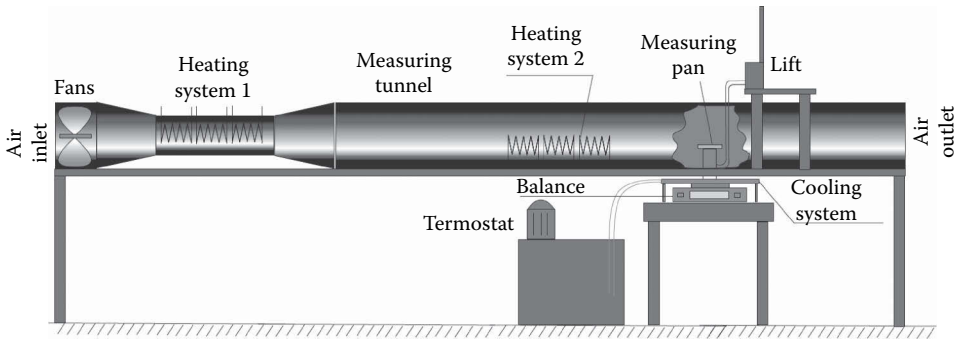

FIGURE 4.29.30 Drying tunnel for spray drying kinetics determination (Zbicinski et al., 2005).

Calculations in Drying

Drying is a complex process involving heat and mass transfer, flow of the air, water evaporation, dried material moisture diffusion, dryer geometry, and many other factors. In the steady-state operation, drying conditions are changing along the dryer, whereas in batch operation drying conditions are also changing with time.

Energy for Moisture Evaporation

During drying, moisture in the dried material is evaporated, so the heat of evaporation must be supplied. The minimum amount of energy necessary for drying process can be calculated as

$$E_{\mathrm{v,min}} = M_{\mathrm{v}} \cdot H_{\mathrm{v}} \tag{4.29.8}$$

or

$$Q_{\mathrm{v,min}} = W_{\mathrm{v}} \cdot H_{\mathrm{v}} \tag{4.29.9}$$

where

$E_{\mathrm{v,min}}$ minimum heat energy for evaporation; kJ
M_{v} evaporation load; kg
ΔH_{v} heat of vaporization; kJ/kg
Q_{v} heat supply rate; kW
W_{v} evaporation rate; kg/s

For steady state, Equation 4.29.9 takes the form

$$Q_{\mathrm{v,min}} = W_{\mathrm{s}} \left(X_{\mathrm{in}} - X_{\mathrm{out}} \right) \cdot H_{\mathrm{v}} \tag{4.29.10}$$

Heat of evaporation is the function of temperature. Considering water being the most common moisture in drying, the latent heat changes from 2501 kJ/kg at 0°C to 2256 kJ/kg at normal boiling point.

Energy for Drying

Drying always uses more energy than just the latent heat of evaporation. Considering a continuous convective dryer using hot air as a drying agent, the amount of energy necessary for heating the inlet air can be calculated with

$$Q_{\mathrm{heating}} = W_{\mathrm{g}} \cdot c_{\mathrm{pg}} \left(T_{\mathrm{g,in}} - T_{\mathrm{g,a}} \right) \tag{4.29.11}$$

where

$T_{\mathrm{g,in}}$ air temperature at the inlet of the dryer; °C
$T_{\mathrm{g,a}}$ ambient air temperature; °C

The general heat balance of a continuous dryer proposed by Kemp (2012) reads

$$W_{\mathrm{g}} \cdot c_{\mathrm{pg}} \left(T_{\mathrm{g,in}} - T_{\mathrm{g,out}} \right) \approx W_{\mathrm{s}} \cdot c_{\mathrm{ps}} \left(X_{\mathrm{in}} - X_{\mathrm{out}} \right) \cdot H_{\mathrm{v}} + W_{\mathrm{s}} \cdot c_{\mathrm{ps}} \left(T_{\mathrm{s,out}} - T_{\mathrm{s,in}} \right) + Q_{\mathrm{loss}} \tag{4.29.12}$$

Combining both equations, one can receive

$$Q_{\mathrm{heating}} = \frac{\left(T_{\mathrm{g,in}} - T_{\mathrm{g,a}} \right)}{\left(T_{\mathrm{g,in}} - T_{\mathrm{g,out}} \right)} \left[W_{\mathrm{s}} \cdot c_{\mathrm{ps}} \left(X_{\mathrm{in}} - X_{\mathrm{out}} \right) \cdot H_{\mathrm{v}} + Q_{\mathrm{s,\,sens}} + Q_{\mathrm{loss}} \right] \tag{4.29.13}$$

Equation 4.29.13 represents heat energy for a perfect adiabatic dryer. Comparing to evaporative load (Equation 4.29.12), heat lost with the exhaust gas, energy for heating the solids, and heat losses from the dryer are added.

In the last years, computational fluid dynamics (CFD) technique has found a wide application in designing of drying units, including scaling up, optimization of drying process parameters,

improvement of energy efficiency, reduction of wall deposits, etc. Commercial solvers available on the market make CFD technique a standard tool in drying modeling and scaling up.

Safety in Drying

Many dryers, especially disperse dryers, produce dust that might explode in a violent combustion reaction if it is dispersed in the air. If the dust combustion takes place within the process equipment, the heat of combustion generates a rapid development of pressure, releasing large amount of heat, and finally ends with explosion (Skjold et al., 2006). To explode, the dust–air mixture must be ignited and the concentration of dust must be between the lower (LEL) and the upper explosion limit (UEL). If the dust concentration is below LEL, the explosion will not occur because of too small amount of dust particles in the mixture to promote combustion. If dust concentration is above the UEL, there is not enough air to sustain combustion.

Procedures to determine the main parameters that describe dust explosibility (LEL, UEL, Dust Explosion Index, Minimum Ignition Energy, etc.) are given in the European Standard EN 14034.

Figure 4.29.31 shows examples of pressure distribution in an industrial spray tower for detergent drying obtained from a CFD simulations of dust–air mixture explosion (Wawrzyniak et al., 2012b). Analysis of Figure 4.29.31 shows a fast increase of pressure due to a quick propagation of shock wave in the tower (5.3 bar after 2.5 s).

Quick increase of pressure in the dryer shows how dangerous for the staff and equipment can be the results of dust explosion. The lack of safety vents or their improper configuration can lead to significant damage of equipment and even loss of life.

Explosion venting is the most common method to mitigate dust explosions. For each dryer, process or product, vent area sizing, and the efficiency of the venting system should be determined. Violence of the explosion falls as the moisture content of the dust increases; above 25%, the dust is not exposible (Barton, 2002).

Selection of Drying Method

Currently, there are many different drying methods encountered in the industry. During over 130 years of progress, each of the methods was developed to many design solutions so finally there are several hundred drying techniques in the industry.

In many cases, drying is the removal of water or other volatiles from granular or paste-like materials, but drying of solutions or liquid suspensions is also common. Analysis of the drying problem usually limits the choice of the dryer to two or three possibilities; it does not indicate the type of dryer that must be used. Selection of the dryer is then made on the basis of capital and operating

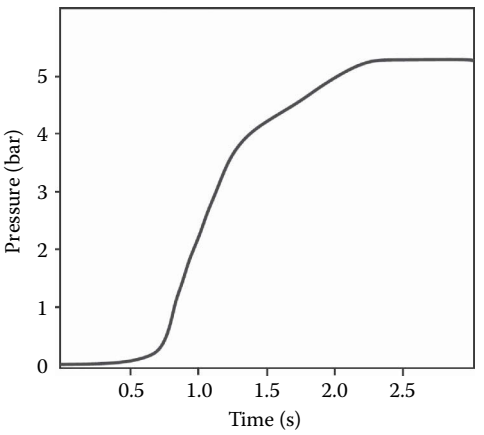

FIGURE 4.29.31 Propagation of pressure wave in the spray tower after dust explosion (Wawrzyniak, 2012).

costs. Attention must be paid, however, to the costs of the entire drying system, not just the drying unit alone. There is no universal method of dryer selection, some general rules exist, but they are not rigid and exceptions are not unusual.

Mujumdar advised to consider the following quantitative information to arrive at a suitable dryer (Mujumdar, 2007):

Dryer throughput; mode of feedstock production (batch/continuous)
Physical, chemical, and biochemical properties of the wet feed
Desired product specifications; expected variability in feed characteristics
Upstream and downstream processing operations
Moisture content of the feed and product
Drying kinetics; moist solid sorption isotherms
Quality parameters (physical, chemical, biochemical)
Safety aspects, e.g., fire and explosion hazards, toxicity
Value of the product
Need for automatic control
Toxicological properties of the product
Turndown ratio, flexibility in capacity requirements
Type and cost of fuel, cost of electricity
Environmental regulations
Space in plant

An example of classifications of drying methods based on type of dryer operation, way of heat transfer to the material, and form of dried material is shown in Figure 4.29.32.

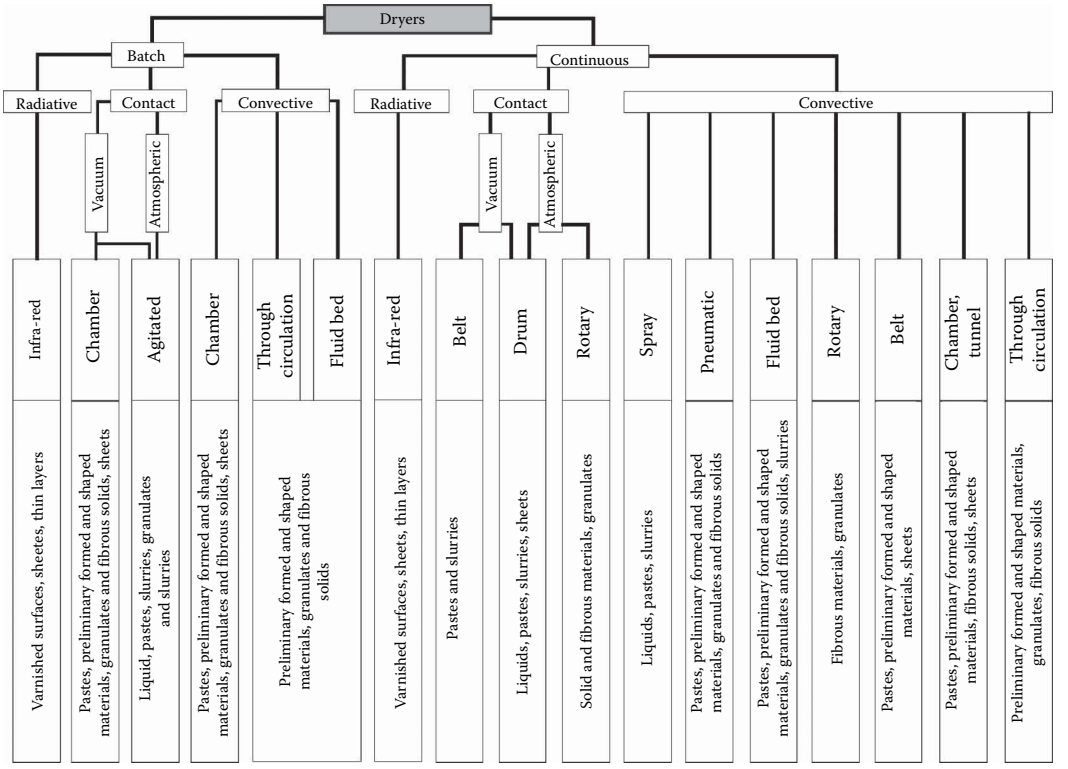

FIGURE 4.29.32 Classification of drying methods. (From Strumillo, C. and Kudra, T., *Drying Principles, Applications and Design,* Gordon and Breach Science Publishers, New York, 1986.)

Batch dryers are used when product capacity is below 200 kg/h, whereas continuous equipment is appropriate for capacity greater than 1 ton/h. The dryer should operate safely and reliably. Capital, operating, and maintenance costs must be reasonable and energy consumption must be minimized. At the same time, all the emissions (hot air, dust) must be controlled. In some cases, an auxiliary system for dust separation could be as expensive as the dryer itself.

Nomenclature

c_{Av}	mean heat capacity of water vapor, J/(kg K)
c_B	mean heat capacity of dry air, J/(kg K)
c_{pg}	specific heat, J/(kg K)
$E_{v,min}$	minimum heat energy for evaporation, kJ
ΔH	latent heat of vaporization, J/kg
I_{Av}	enthalpy of water vapor, J/kg
I_B	enthalpy of dry air, J/kg
I_G	enthalpy of humid air, J/kg
k_g	thermal conductivity, W/(m K)
k_y	convective mass transfer coefficient, m/s
M	molar mass, kg/mol
M_v	evaporation load; kg
P_v	vapor pressure of pure water, Pa
q_{cw}	heat flux at wall, W/m^2
Q_v	heat supply rate, kW
R	universal gas constant, 8.314 J/(mol K)
RH	relative humidity, fraction
T	temperature, °C
T_w	wall temperature, °C
w_{cw}	moisture flux at wall, kg/(m^2 s)
W	flow rate, kg/s
W_v	evaporation rate, kg/s
X	total moisture content, kg water/kg dry solid,
X_{cr}	critical moisture content, kg water/kg dry solid,
X_e	equilibrium moisture content, kg water/kg dry solid,
Y	absolute air humidity, kg water vapor/kg dry air
$Q_{v,min}$	heat supply rate, kW

Greek letters

α	heat transfer coefficient, W/(m^2 K)
ρ_g	density, kg/m^3
μ_g	dynamic viscosity, kg/m s

Subscripts

a	ambient
c	convection
s	solid
v	vapor
w	Wall
Ref	Reference

4.30 HEAT TRANSFER IN ROTARY KILNS

P.S. Ghoshdastidar

Introduction

A rotary kiln consists of a long refractory lined cylindrical shell mounted at a slight incline from the horizontal plane. The kiln is slowly rotated about its longitudinal axis and the solid charge is fed into the upper end of the cylinder and heated by countercurrent or cocurrent flow of hot combustion gases. During the process, the material moves to the lower end, where it is discharged. Rotary kiln reactors are used in the production of cement and sponge iron, several chemicals such as lime, phosphates and polyphosphates, zinc white, lithopone, titanium dioxide, soda ash, alumina, catalyst, and catalyst carriers. Incineration of solid waste and drying of wet solids are also performed in such kilns. Food products can be dried by superheated steam in rotary dryers. Figure 4.30.1 shows a schematic diagram of a rotary kiln used for drying and preheating of wet solids. The cross section of a rotary kiln is shown in Figure 4.30.2. The angle, α, is called the fill angle, which signifies the region of volume containing the solid. The primary advantages of rotary kilns are its simple design and great flexibility. It can be easily adaptable to changing operating conditions such as varying kiln speed, kiln inclination angle, and mass flow rates of gas and solids. Very-high-temperature processes can be carried out in rotary kilns. Solid granules of various shapes and sizes can be handled in such reactors. The main disadvantages are (1) low space–time yield, (2) inefficient energy utilization, and (3) difficult control of temperature and composition of the reactant mixture in the middle zone of the kiln [1]. Thus, there is an urgent need for optimization of rotary kilns with respect to their length, specific power input, and production capacity.

Salient Features of a Rotary Kiln

Rotary kilns are high-temperature reactors often operating in the temperature zone above 900 K. The required reaction temperature of the solid bed is achieved by burning gas or oil in the kiln (internally fired kilns) above the solid surface. Usually, a burner is positioned at the end of the kiln and flow of the hot combustion gas mixture takes place countercurrent to the solid movement. However, examples of externally fired kilns and cocurrent gas movement are also found in the industry. Only a small part of the cross section of the kiln (typically, 10%–20%) is occupied by the solids. Industrial rotary kilns often have very high length-to-diameter ratios. They may be as long as 200 m. The diameter of a rotary kiln can be as large as 5 m. The kiln inclination angle and kiln rotational speed normally does not exceed 5° and 5 rpm, respectively. The small inclination angle and low speed ensures long residence time of solids in the kiln, and enhanced contact of the solid with the hot gas. As regards the internal features of the kiln, refractory lining is used in order to insulate and protect the outer shell from thermal damage and save energy [2]. Kilns may often be equipped with lifters and tumblers to ease the motion of the solid particles axially and improve particle mixing [2].

Firing of Rotary Kilns

Kilns are usually fired by burning natural gas (CH_4) or fuel oil or pulverized solid fuels such as coal or petroleum coke. Sometimes a combination of all of these is also used [2]. Because of high temperature in the kiln the thermal radiation becomes the dominant heat transfer mode. Hence, fuels having high luminosity due to soot formation during combustion are preferred. Natural gas is normally the last choice of fuel selection except in places with strict environmental regulations on CO_2 emissions because of its high cost and transparent nature of its flame. Most rotary kilns use coal or petroleum coke as the main fuel for combustion.

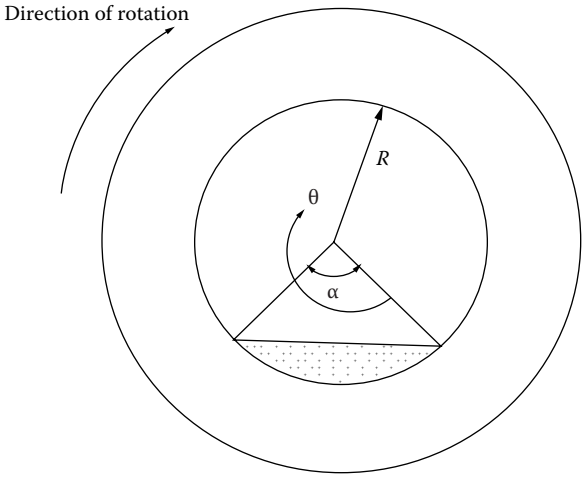

FIGURE 4.30.2 Cross section of a rotary kiln. (From Ghoshdastidar, P.S., Agarwal, A., *ASME J. Therm. Sci. Eng. Appl.*, 1, 024501, 2009. With permission.)

Phenomenon within the Solid Bed

The solid bed is composed of granular materials of various sizes and shapes. The bed is heated by the gas as well as the hot kiln wall. Heat transfer path consists of particle-to-particle conduction and radiation and interstitial gas-to-particle convection. However, transverse motion of the particles themselves results in energy transport by convection that can be a dominant heat transfer mode. Thus, modeling of heat transfer in the solid bed is a challenging task. Most simulations consider the solid bed as well mixed in the transverse plane and at a uniform temperature for the sake of simplicity.

Transverse Bed Motion

Based on the rotational speed of the kiln, the bed motion in the transverse plane can be classified into the following main categories:

1. *Centrifuging*: This is an extreme condition visualized at critical and high speeds in which all the bed materials rotate with the drum.

2. *Cascading*: This also occurs at high speeds. In this mode the height of the leading edge of the particles rises above the bed surface and granules cascade or shower down on the free surface.
3. *Rolling*: At very low rotational speeds the bed slips against the wall. In this mode, mixing is maximum. There are two distinct regions, namely, the shearing region, called the active layer, constituted by the particles near the free surface, and the passive or plug flow region at the bottom having zero shear rate. Most rotary kilns operate in the rolling mode. A rolling bed is usually flat and subtends an angle with the horizontal, called the *angle of repose*. The active layer is thinner than the passive layer because particles there move faster.

Mixing in the Solid Bed

In the rolling mode, most of the mixing (and dissociation reactions in case of chemical production) occurs in the active layer of the bed cross section. A deeper active region induces better mixing of solid particles. Increasing the kiln speed increases the depth of the active layer. It has been experimentally observed that particles move forward down the kiln through the active region [2]. Because the kiln inclination angle is small and far below the angle of repose the forward movement is not sustained by the component of gravity in the axial direction alone. Actually, the rotational speed also plays a significant role in the axial motion of the granules. For every revolution, the bed material makes several circulations in the cross section, thereby producing the axial motion [2]. Increased kiln rpm results in enhanced mixing but results in less residence time of the material in the kiln. Thus, the operator of the kiln has to strike a right balance between the two opposite effects and therein lies the need for optimization in kiln design.

Axial Velocity of Solid Particles

The axial motion of a solid particle is dependent on the kiln inclination angle and transverse motion, which in turn is dependent on the kiln rotational speed. Ghoshdastidar and Agarwal [3] showed the derivation of an expression for the axial velocity, V_z, of the solids in the kiln, based on the velocity vector diagram of a solid particle. Figure 4.30.3 shows the diagram for $\phi = 5°$.

The expression for V_z is written as

$$V_z = U \tan \varphi \tag{4.30.1}$$

where U is the circumferential speed (m/s) of the kiln and ϕ is the kiln inclination angle in degrees.

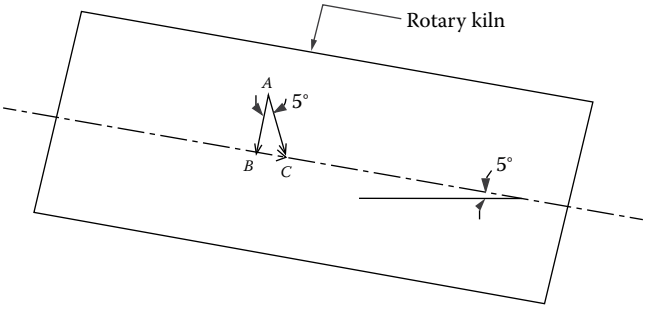

FIGURE 4.30.3 Velocity vector diagram for a solid particle in a rotary kiln. (From Ghoshdastidar, P.S., Agarwal, A., *ASME J. Therm. Sci. Eng. Appl.*, 1, 024501, 2009. With permission.)

Note that

$$U = \frac{\pi DS}{60} \tag{4.30.2}$$

where S is the kiln rotational speed (rpm).

Several other expressions for axial velocity of the solids are also found in the literature [2].

Heat Transfer Processes in a Rotary Kiln

Figure 4.30.4 shows a schematic of heat transfer processes in a rotary kiln.

The refractory wall elements are alternately heated and cooled by the hot gas and solid, respectively. Hence, quasi-steady heat conduction is present. The gas is transferring heat to both inside wall surface and solid bed by convection and radiation. The solid is heated by the gas as well as by the hot wall. The gas convection is usually turbulent. The modeling of gas convection is challenging because of the irregular geometry of the flow cross section. The wall to solid heat transfer is generally modeled using a contact heat transfer coefficient. The outer wall is losing heat by both convection and radiation. Cartesian coordinates are used because the refractory thickness is much smaller than the kiln diameter.

Rotary Kiln Modeling: Various Approaches

From the description of heat transfer processes in a rotary kiln, it is evident that modeling of rotary kilns is quite complex. The assumption of well-mixed freeboard and bed led to the development of one-dimensional (1D) model that predicts the axial solids and gas temperature distribution from the inlet to the outlet of the kiln by solving ordinary differential equations as proposed by Sass [4]. A quasi-three-dimensional (3D) model combines both an axial model (1D]) and a cross-sectional model (two-dimensional [2D]). The surface heat flux determined from the 1D model is used as a thermal boundary condition for the cross-sectional model. The 2D model is employed to determine the temperature distribution in the solid bed material and the kiln wall over axial segments. Very few models have the capability of predicting kiln length for a given set of input parameters. In the next section, modeling of a rotary food dryer is given in some detail. This is a quasi-3D model that predicts the kiln length and calculates axial solids and gas temperature distributions. However, the solid bed and gas temperatures have been considered as lumped in each axial segment.

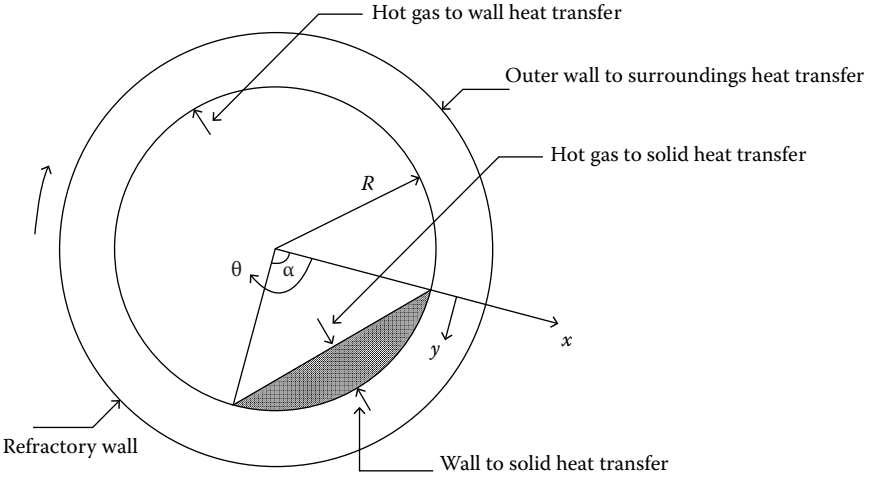

FIGURE 4.30.4 Schematic cross section of a rotary kiln showing heat transfer processes.

Drying of Food Products in a Rotary Kiln

In this section, the model of a rotary kiln used for drying and preheating of apple and carrot pieces with superheated steam at 1 bar developed by Sinhal et al. [5] is presented. The advantages of superheated steam as a drying medium are (1) energy recovery through condensation of surplus steam and (2) drying of food products in a sterilized atmosphere. The input data for the food dryer of Sinhal et al. [5] are listed in Table 4.30.1.

The dryer can be considered to comprise three zones. In the first zone, the food pieces are heated to the saturation temperature of the entrained water. In the middle zone, the water evaporates at constant temperature until the food pieces are completely dry. In the third or the last section, the dry solids are heated to some prescribed temperature and are released from the kiln.

TABLE 4.30.1
Input Data for the Food Dryer

1. Rotary Kiln	
a. Diameter (inner)	2.29 m
b. Refractory	
i. Thickness	0.23 m
ii. Thermal conductivity	0.6057 W/m K
iii. Specific heat	692.56 J/kg K
iv. Density	3000 kg/m^3
v. Emissivity	0.9
c. Rotational speed[a]	5 rpm
d. Angle of inclination[a]	5°
2. Solid	
a. Inlet temperature	288.6 K
b. Outlet temperature	413 K
c. Mass flow rate (dry)[a]	0.3 kg/s
d. Percent water with respect to dry solid (by weight)[a]	19
e. Emissivity	0.95
3. Gas (superheated steam at 1 bar)	
a. Outlet temperature[a]	416 K
b. Mass flow rate[a]	3.9 kg/s
c. Specific heat	2060.4 J/kg K
4. Water	
a. Latent heat of vaporization	2.26×10^6 J/kg
b. Specific heat (vapor)	2083.2 J/kg K
c. Specific heat (liquid)	4211.2 J/kg K
4. Heat transfer coefficients	
a. Contact heat transfer coefficient	150 W/m^2 K
b. Convective heat transfer coefficient from the kiln wall to surrounding	10 W/m^{2}K
5. Ambient temperature outside the kiln	300 K

[a] Base values.

Problem Formulation

Thermal Radiation among Hot Gas, Refractory Wall, and Solid Surface

Because the temperature involved is high thermal radiation plays a significant role in the exchange of heat among the hot gas, the inner wall of the kiln and the solid surface. The wall is divided into the surface elements to form an enclosure as shown in Figure 4.30.5. Each axial segment is further subdivided into 20 circumferential elements of equal size and five solid surface elements.

The surfaces are assumed to be diffuse and gray. It is assumed that the surface elements exchange radiation only with surfaces of the same axial segment because the segment lengths (Δz in Figure 4.30.5) are sufficiently long.

The theory of Hottel [6] is used to calculate radiation heat transfer in a gray enclosure containing a gas which emits, absorbs, and transmits radiation. Thus, in an enclosure having N surfaces at different temperatures, the net heat loss/gain, q_j, at a particular surface can be expressed as

$$q_j = \frac{\varepsilon+1}{2}\left[A_g F_{gj}\varepsilon_g(T_g)E_{bg} + \sum_{i=1}^{N} A_i F_{ij}\tau_g(T_i)E_{bi} - E_{bj}A_j\right] \tag{4.30.3}$$

where E is the emissive power (in W/m^2) and ε is the emissivity of the enclosure walls. Equation 4.30.3 is valid for $\varepsilon > 0.8$. The emissivity of the refractory wall is taken as 0.9 [7]. The emissivity of the solid (apple or carrot) is taken as 0.95 [8]. ε_g (T_g) and τ_g (T_i) are emissivity and transmissivity of the gas at T_g and T_i, respectively. For the calculation of the gas emissivity and other characteristics, Mean Beam Length Theory is used (Holman [6]). The temperature of the solid surface element is assumed to be uniform in each axial segment.

The view or shape factors between 20 surface elements and five solid surface elements are determined assuming the surface as infinite parallel strips [9]. The formulas for shape factor calculation are shown next [10].

Calculation of Shape Factors

The shape factors between the circumferential elements and solid surface elements are determined assuming the surfaces as infinite parallel strips. Surfaces (1) and (2) in Figure 4.30.6 are strips perpendicular to the XY plane. The shape factor F_{1-2} is given by Hottel (Jacob [9]) as follows:

$$F_{1-2} = \frac{\sin\phi' - \sin\phi''}{2} \tag{4.30.4}$$

where ϕ' is the angle subtended by the bottom point of surface (2) with the normal to surface (1), and ϕ'' is the angle subtended by the top point of surface (2) with the normal to surface (1). Both angles are measured clockwise from the normal to surface (1).

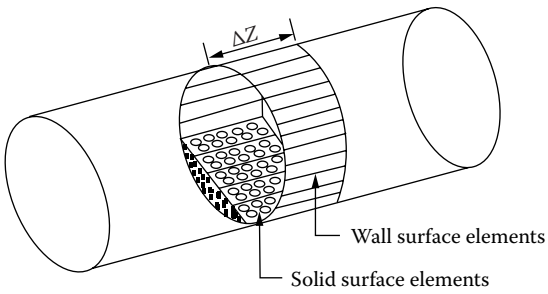

FIGURE 4.30.5 Section of the kiln showing surface elements of the wall and the solid. (From Sinhal, K. et al., *ASME J. Therm. Sci. Eng. Appl.*, 4, 011009, 2012. With permission.)

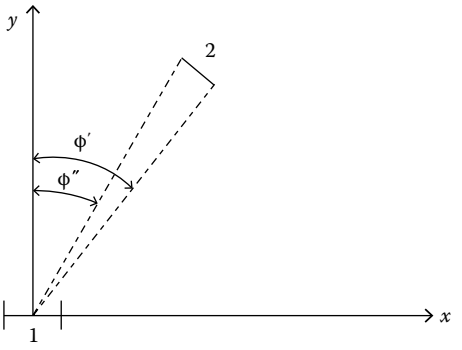

FIGURE 4.30.6 Shape factor between infinite parallel surfaces. (From Sinhal, K. et al., *ASME J. Therm. Sci. Eng. Appl.*, 4, 011009, 2012. With permission.)

Shape Factors between the Elements of the Kiln Wall

Equation 4.30.4 is written in terms of the circumferential location of the two surfaces. For the notations shown in Figure 4.30.7, the shape factor between surfaces (1) and (2) is given by

$$F_{1-2} = \frac{\Delta\theta \cos\beta}{4} \tag{4.30.5}$$

where $\Delta\theta$ is the arc angle of surface (2) in radian. The angle β is defined as

$$\beta = \frac{\pi - |\theta_2 - \theta_1|}{2} \tag{4.30.6}$$

where θ_1 and θ_2 are the circumferential positions of surface elements (1) and (2), respectively, with respect to the reference axis. For convenience, the reference axis is chosen perpendicular to the solid surface. Because of the absolute bracket in Equation 4.30.6, the shape factors F_{1-2} and F_{2-1} are equal for the same $\Delta\theta$ as required by the reciprocity relations of the shape factors.

Shape Factors between Elements of the Kiln Wall and Solid Surface

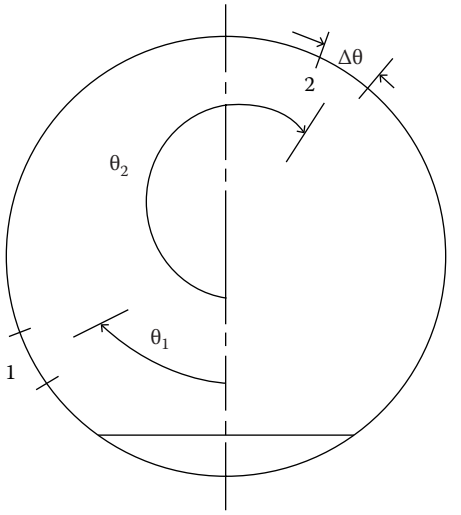

FIGURE 4.30.7 Shape factor nomenclatures when both surfaces are on refractory wall.

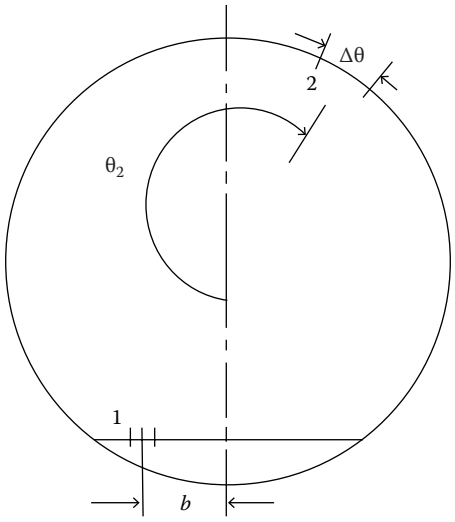

FIGURE 4.30.8 Shape factor nomenclatures when one surface is on refractory wall and other on solid.

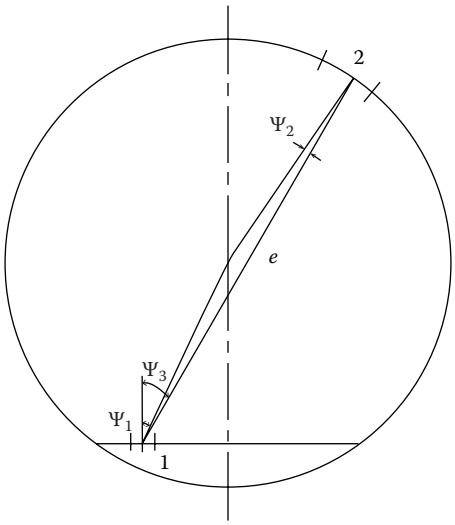

FIGURE 4.30.9 Parameters for shape factor equation.

In Figure 4.30.8, surface (1) is a solid surface element and surface (2) is a refractory wall element. Surface (1) is located at a distance b from the reference axis and θ_2 is the circumferential angle for surface (2). Angle α is the fill angle of the solid material. Additional terms that are shown in Figure 4.30.9 are needed to determine the shape factor.

The shape factor F_{1-2} is given by

$$F_{1-2} = \frac{D \cos \psi_1 \cos \psi_2 \Delta\theta}{4e} \tag{4.30.7}$$

where D is the inside diameter of the kiln. The angles ψ_1 and ψ_2 are shown in Figure 4.30.9 and are, respectively, the angles between the normal to surfaces (1) and (2) and the ray extending between

the surfaces. The distance e is the length of this ray. Expressions for ψ_1, ψ_2, and e in Equation 4.30.7 are related by expressions in the following equations:

$$\psi_3 = \tan^{-1}[2b/D\cos(\alpha/2)] \tag{4.30.8}$$

$$C = \frac{D\cos(\alpha/2)}{2\cos\psi_3} \tag{4.30.9}$$

$$e = \left[C^2 + D^2/4 - CD\cos(2\pi - \theta_2 + \psi_3)\right]^{1/2} \tag{4.30.10}$$

$$\psi_2 = \sin^{-1}[C\sin(2\pi - \theta_2 + \psi_3)/e] \tag{4.30.11}$$

$$\psi_1 = \theta_2 - \psi_2 - \pi \tag{4.30.12}$$

Calculation of Gas Radiation Properties

The composition (by volume) of hot gas for the rotary kiln used in this study is superheated steam (100% H_2O). The pressure inside the kiln is assumed to be 1 bar. Because water vapor is a radiatively participating medium, using the mean beam length theory [6], the emissivity and transmissivity of the superheated steam as a function of temperature are calculated.

Gas Convection

Brimacombe and Watkinson [11] have indicated that in a rotary kiln operating at solid temperatures up to 1100 K gas convection may be significant. In the present work, the gas flow is turbulent. The convective heat transfer coefficient is estimated using Dittus–Boelter correlation in each axial segment assuming isothermal wall and hydrodynamically and thermally fully developed flow.

Conduction Heat Transfer in the Refractory Wall

In the present study, only heat conduction in the radial direction of the wall is taken into account as the circumference and the length of the kiln are much greater than the thickness of the kiln.

The coordinate system is shown in Figure 4.30.4. Because the kiln thickness to diameter ratio is small, Cartesian coordinates are used. The energy equation for the wall is

$$U\frac{\partial T}{\partial y} = a_{\text{rf}}\frac{\partial^2 T}{\partial x^2} \tag{4.30.13}$$

where U is the circumferential velocity of the wall and a_{rf} is the thermal diffusivity of the refractory.

Elements exposed to the gas are heated by the radiation as well as convection. Heat transfer from the hot wall to the solid bed is determined from

$$q_j = h_{\text{cs}}A_{j\text{i}}(T_{j\text{i}} - T_{\text{s}}) \tag{4.30.14}$$

where q_j is the heat transfer rate, h_{cs} is the contact heat transfer coefficient between the refractory wall and the solid, $A_{j\text{i}}$ is the inner surface element area, $T_{j\text{i}}$ is the inner refractory wall surface temperature, and T_{s} is the solid temperature. Because, the heat transfer coefficient, h_{cs}, is not available, an estimated value is used.

The contact heat transfer coefficient from kiln wall to solid is estimated by Sass [4] as

$$h_{\text{cs}} = h_{\text{CONV}} + h_{\text{RAD}}$$

where

$$h_{\text{CONV}} = 118.266(\dot{m}_{\text{g}}/A)^{0.67}$$

$$h_{\text{RAD}} = \sigma f\varepsilon_{\text{s}}(T_{\text{wall}} + T_{\text{s}})(T_{\text{wall}}^2 + T_{\text{s}}^2)$$

Here, $\dot{m}_g$ is the mass flow rate of gas (kg/s), A is the cross-sectional area of kiln (m^2), f is the correction factor taken as 0.5, ε_s is the emissivity of solid mass, T_{wall} is the mean temperature of inner surface of rotary kiln (in K), and T_s is the temperature of solid mass (in K) and σ is the Stefan–Boltzmann constant having a value of 5.67×10^{-8} W/m^2 K^4. In the present problem, the contact heat transfer coefficient is estimated to be 150 W/m^2 K.

The boundary condition for the outer surface of the refractory wall is the heat loss by convection and radiation. In the present investigation, convective heat transfer coefficient, h_c, is taken as 10 W/m^2 K considering air is blowing over the kiln and using the relevant graphs of Suryanarayana et al. [12]. The radiation heat transfer coefficient is calculated from

$$h_r = \sigma\varepsilon_{rf}(T_{jo}+T_\infty)(T_{jo}^2+T_\infty^2) \tag{4.30.15}$$

where T_{jo} and T_∞ are the outer wall temperature and ambient temperature in kelvin, respectively.

The combined heat loss from the outer surface is written as

$$q_j = (h_c + h_r)A_{jo}(T_{jo}-T_\infty) \tag{4.30.16}$$

where A_{jo} is the area of the outer surface element.

False transient approach is used to solve Equation 4.30.13. The alternative direction implicit finite-difference scheme has been used to march ahead in time. Because the initial temperature distribution of the refractory wall is not known, an arbitrary temperature is assumed at all grid points in the refractory wall. The solution converges when there is no further change in the temperature at each grid point as $t \to \infty$. This temperature distribution represents the steady-state temperature distribution of wall.

Energy Transport in Solid

The solid is considered to be well mixed, and small rotational speed of the kiln gives rise to rolling bed. The gas is also assumed to be well mixed in each transversal section as the flow is highly turbulent. Thus, only the axial solid and gas temperatures are computed.

Mass and energy balances on an element of solid contained in an axial segment either in the first or in the third section of the kiln give the expression for $T_{s,z+\Delta z}$ (Equation 4.30.19). The same performed on an element of the wet solids contained in an axial segment in the second section of the kiln produces the expression for the rate of evaporation, $\dot{m}_v$ (Equation 4.30.20). In the second section, the temperature of the solids remains constant at the saturation temperature of water. The end of the second section is indicated where the cumulative $\dot{m}_v$ is equal to the total predetermined rate of evaporation of water.

Because there are five elements on the surface of the solid, total radiation heat transfer q_1 is

$$q_1 = \sum_{j=1}^{5} q_j \tag{4.30.17}$$

Similarly, the heat transfer, q_2, from the refractory inner wall, is given by

$$q_2 = \sum_{j=1}^{5} h_{cs}A_j(T_{ji}-T_s) \tag{4.30.18}$$

Sections 1 and 3 (Figure 4.30.10)

Energy in:

$$\dot{m}_s C_{ps}T_{s,z} + \dot{m}_{w,s}C_{pl}T_{s,z} + q_1 + q_2$$

Energy out:

$$\dot{m}_s C_{ps} T_{s,z+\Delta z} + \dot{m}_{w,s} C_{pl} T_{s,z+\Delta z}$$

From energy balance,

$$T_{s,z+\Delta z} = T_{s,z} + \frac{q_1 + q_2}{\dot{m}_s C_{ps} + \dot{m}_{w,s} C_{pl}} \tag{4.30.19}$$

Section 2 (Figure 4.30.11)
Energy in:

$$\dot{m}_s C_{ps} T_{s,z} + \dot{m}_{w,s,z} C_{pl} T_{s,z} + q_1 + q_2$$

Energy out:

$$\dot{m}_s C_{ps} T_{s,z+\Delta z} + \dot{m}_{w,s,z+\Delta z} C_{pl} T_{s,z+\Delta z} + \dot{m}_v (C_{pl} T_{s,z} + h_{fg})$$

For this section,

$T_{s,z} = T_{s,z+\Delta z} = 373$ K = Saturation temperature of water at 1 bar

From energy balance,

$$\dot{m}_v = \frac{q_1 + q_2}{h_{fg}} \tag{4.30.20}$$

Energy Transport in Gas

Mass and energy balances on an element of hot gas contained in an axial segment in the first or third section of the kiln give the expression for $T_{g,z+\Delta z}$ (Equation 4.30.21). The same performed on an element of the hot gas contained in an axial segment of the second section of the kiln produces another expression for $T_{g,z+\Delta z}$ (Equation 4.30.22).

Sections 1 and 3 (Figure 4.30.10)

Energy in:

$$\dot{m}_g C_{pg} T_{g,z+\Delta z} + \dot{m}_{w,g} C_{pv} T_{g,z+\Delta z}$$

Energy out:

$$\dot{m}_g C_{pg} T_{g,z} + \dot{m}_{w,g} C_{pv} T_{g,z} + q_r$$

where $q_r = \sum_{j=1}^{25} q_j$

It may be noted q_j that includes both radiation and convection.

From the mass balance,

$$\dot{m}_{w,s} = \dot{m}_{w,g}$$

From energy balance,

$$T_{g,z+\Delta z} = T_{g,z} + \frac{q_r}{\dot{m}_g C_{pg} + \dot{m}_{w,g} C_{pv}} \tag{4.30.21}$$

Section 2 (Figure 4.30.11)
Energy in:

$$\dot{m}_{\mathrm{g}} C_{pg} T_{\mathrm{g},z+\Delta z} + \dot{m}_{\mathrm{w,g},z+\Delta z} C_{pv} T_{\mathrm{g},z+\Delta z} + \dot{m}_{\mathrm{v}} C_{pv} T_{\mathrm{s},z}$$

Energy out:

$$\dot{m}_{\mathrm{g}} C_{pg} T_{\mathrm{g},z} + \dot{m}_{\mathrm{w,g},z} C_{pv} T_{\mathrm{g},z} + q_r$$

From mass balance,

$$\dot{m}_{\mathrm{w,g},z+\Delta z} = \dot{m}_{\mathrm{w,g},z} - \dot{m}_{\mathrm{v}}$$

From energy balance,

$$T_{\mathrm{g},z+\Delta z} = \frac{\dot{m}_{\mathrm{g}} C_{pg} + \dot{m}_{\mathrm{w,g},z} C_{pv}}{\dot{m}_{\mathrm{g}} C_{pg} + \dot{m}_{\mathrm{w,g},z} C_{pv} - \dot{m}_{\mathrm{v}} C_{pv}} T_{\mathrm{g},z} + \frac{q_r - \dot{m}_{\mathrm{v}} C_{pv} T_{\mathrm{s},z}}{\dot{m}_{\mathrm{g}} C_{pg} + \dot{m}_{\mathrm{w,g},z} C_{pv} - \dot{m}_{\mathrm{v}} C_{pv}} \tag{4.30.22}$$

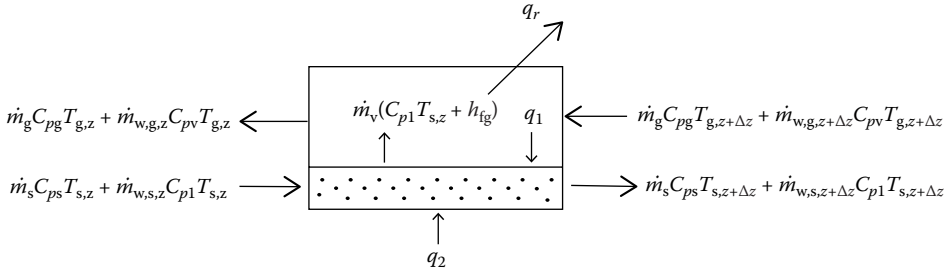

FIGURE 4.30.11 Energy transport in the solid and gas in an axial segment in the second section of the kiln. (From Sinhal, K. et al., *ASME J. Therm. Sci. Eng. Appl.*, 4, 011009, 2012. With permission.)

Basic Solution Methodology

The solution is initiated at the inlet of the kiln and proceeds to the exit. For solving the heat transfer problem, the kiln is divided into segments of equal length Δz, in the axial direction. Input data

required for the computer program are shown in Table 4.30.1 for superheated steam at 1 bar as drying medium. The property values of superheated steam are taken from Ghoshdastidar [8]). The solids properties have been calculated from the correlations given by Choi and Okos [13] based on the percent composition and temperature of apple and carrot [5]. The density and specific heat of apple at the inlet of the kiln (at 288.6 K) are 1437 kg/m^3 and 2080 J/kg K, respectively. The corresponding values for carrot are 1428 kg/m^3 and 2094 J/kg K, respectively. The source of kiln wall property data is the work of Ghoshdastidar et al. [7].

A mixture density relation is used to calculate the effective density of wet solids. The speed of rotation and the kiln inclination angle in Table 4.30.1 are typical of rotary dryers (van't land [14]).

Based on a grid independence test, the optimum number of grid points for apple drying is 25×11, the first number indicating number of grid points in the circumferential direction and the second in the radial direction. For carrot drying, the optimum number of grid points is 25×16. The axial segment length, Δz, is 1.3 m for apple drying and 1.2 m for carrot drying.

Results

Figure 4.30.12 shows axial solid and gas temperature distribution for apple and carrot for the input data in Table 4.30.1. The result shows no difference between the two. This may be due to little difference in density and specific heat. The predicted kiln length to dry and heat the apple pieces from 288.6 to 413 K is 93.6 m. The corresponding prescribed kiln length for carrot is 86.4 m. The inlet steam temperature required for both is 460 K. The higher kiln length for apple drying and preheating may be attributed to its higher density and hence, lower fill angle compared to carrot. Hence, there is less radiation heat transfer from the wall. The time to complete the drying and heating process is 29.8 min for apple and 27.5 min for carrot (drying and preheating time = kiln length/axial velocity, V_z of the solids).

Summary

This chapter presents a short overview of rotary kiln reactors widely used in chemical, metallurgical, and drying industry, emphasizing on the heat transfer processes occurring within it. The physics of transverse bed motion and mixing within the solid bed have been discussed. An expression for

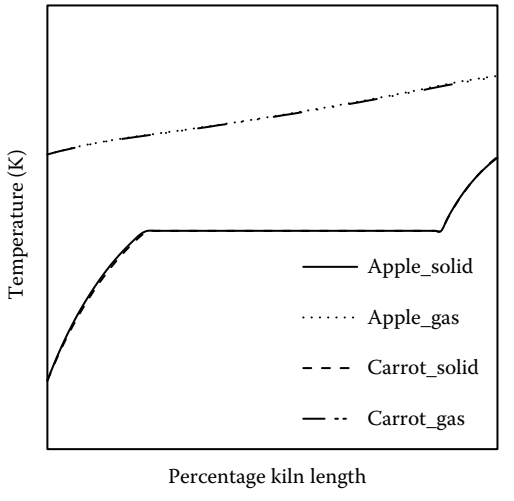

FIGURE 4.30.12 Axial solid and gas temperature distributions versus percent kiln length for apple and carrot drying based on the input data in Table 4.30.1. (From Sinhal, K. et al., *ASME J. Therm. Sci. Eng. Appl.*, 4, 011009, 2012. With permission.)

the axial velocity of solid particles has been given. Various approaches used to model rotary kilns have been introduced. Finally, a detailed numerical simulation of drying and preheating of food products such as apple and carrot with superheated steam in a rotary kiln has been presented in order to make the readers appreciate the enormous complexity and challenges in modeling rotary kilns. The main difficulties in the modeling of rotary kilns appear to be the estimation of contact heat transfer coefficient, modeling of gas convection, as well as integration of transverse solid bed motion in the overall heat transfer model.

4.31 HEAT TRANSFER IN GLASS MANUFACTURING PROCESSES

Naveen Tiwari and Rajappa Tadepalli

Introduction

Glass is one of the oldest man-made materials still in use without interruption since the recorded history. The applications of glass are widespread in today's day-to-day life starting from window glass at home or in cars, glass bottles and other glasswares, and electric components. The modern technologies demand enormous supply of glass, for example, radiation shield for nuclear technologies, glass fibers for communication, etc. Glassmaking is an integrated manufacturing process where raw minerals are transformed into a variety of finished products within a single manufacturing setup. It is an energy intensive process as it involves high temperatures at various stages of the process. This chapter discusses the concepts of heat transfer involved during the steps of glass production.

The fundamental operations to form useful glass objects appear very simple and have been practiced for more than 3000 years. With industrialization and increased consumption of glass, the manufacturing process has been streamlined. Figure 4.31.1 shows a typical process flow sheet of manufacturing a glass product in current practice. As indicated the raw materials are crushed and put through high-temperature processes. Melting of the raw materials takes place at around 1500°C. The subsequent process is to cool the melt to form a solid. When a melted substance is cooled below the melting point, crystallization is expected to occur. In glass, the cross-linkage between tetrahedron SiO_4 structures needs to be broken in order to form crystal nuclei which can only happen at low temperatures. However, at low temperatures, the high viscosity of the melt impedes the restructuring of new molecules, thus preventing the crystal growth. In general, the tendency to crystallize (or "devitrification" in the context of glass) decreases with the increasing rate of cooling and with the number of components in the glass batch. The devitrification is only desirable in glass-ceramics which is not discussed here. The "glassy" state is in continuation of the liquid state with no discontinuities in physical properties and structural arrangements. The glasses are therefore sometimes referred to as "supercooled liquids."

Composition and Its Effect on Properties

The majority of the glasses in use today are silicate based in which chief component is SiO_2, and other components are added to impart various desired characteristics to the glass. For example, lime, CaO, and small amounts of alumina (Al_2O_3) and Magnesia (MgO) improve the chemical durability of the glass. Some metal oxides can also be added to incorporate color in the glass product. For glass products that are desired to be photosensitive oxides of metals such as gold, silver, or copper are introduced into the glass composition in addition to other optical sensitizers and thermal-reducing agents. Glass products for which optical design is an essential requirement for the application better transparency, control over refractive index and freedom from defects such as bubbles and stones is necessary. Thus the glass must have a good degree of homogeneity, and the annealing should be done under conditions that will reduce internal strains in order to make an optically stable glass. Further, during the melting process components such as soda, boric oxide, and lead oxide evaporate to a certain extent from the glass melt. The change in the composition which is caused in this way must be compensated for by corrections to the raw feed if the physical properties of the glass are to be maintained. Changes in composition caused by solution of furnace envelope (refractory) must also be corrected.

In addition to change the desired properties of the glass product, they also affect the physical properties of the glass melt that affect its processing during manufacturing. Table 4.31.1 shows the effect of the glass composition on the liquidus temperature, the temperature at which crystallization

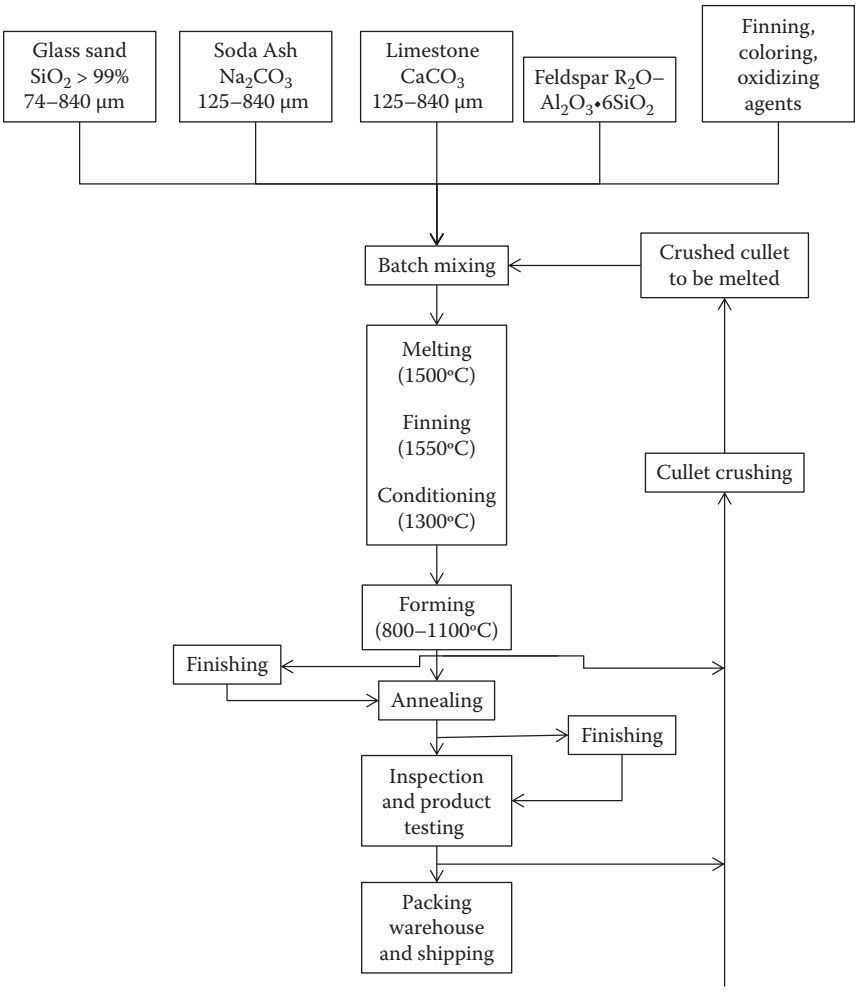

FIGURE 4.31.1 General flow of glass manufacturing. (Redrawn from Rawson, H., *Phys. Technol.*, 5, 91–114, 1974.)

may start happening provided the cooling rate is slow enough for that to initiate. It is worthy to note that the liquidus temperature can be depressed from 1710°C for pure silica to about 800°C in the presence of other metal oxides.

An important property to consider while manufacturing process is the viscosity of the melt as it continuously varies from the molten to the lowest temperature at which desired structural changes can be made. Figure 4.31.2 shows the viscosity (μ) as a function of temperature for glasses with different compositions. These curves are typically fit by the following expression:

$$\log(\mu) = -A + \frac{B}{T - T_0}, \tag{4.31.1}$$

where the constants A, B, and T_0 are determined by curve fitting for the respective glass melt. The viscosity data as a function of temperature for different compositions is important in order to assess the balance between the desired product properties versus the challenges during melting, fabrication, and annealing operations.

Similarly specific heat capacity at constant pressure C_p (J/mol/K) is a function of temperature given by Equation 4.31.2 where the coefficients are given for the respective components. Specific

heat is an intensive property and thus the net C_p of the mixture can be obtained by summating the C_p values of all the components weighted by their respective mole fractions. The values of the coefficients and their validity range are given as follows:

$$C_{pi} = a_i + b_i T + c_i / T^2 + d_i + T^{1/2}. \tag{4.31.2}$$

In the next sections, we present some details of glass manufacturing process focusing on the heat transfer aspects of it.

Melting Process

Glass is mostly melted in a continuous process in large furnaces made up of refractory blocks. The furnaces are heated from above by the flames created by burning a fuel. There are smaller versions of the furnace called pots and batch or day tanks that are used for manufacturing small amounts of glass, particularly for special composition and properties. The holding capacity of batch-type units is of a few tons, while that for the continuous tanks or furnaces ranges from about 1 to 1500 tons. The outputs from such large continuous furnaces go up to several tons of glass per day. Typically natural gas, fuel oil, and raw producer gas are the economical fuels used in the industry. In last few years, the use of electrical energy in the glass melting process as a supplement to conventional heating means is increasing. The benefits that it provides are ease of application and better control though electrical heating costs are higher.

Figure 4.31.3 shows a schematic for the working of a continuous tank for melting glass. The tanks are generally rectangular in shape. As shown in the figure, the compartment into which the batch or raw material is introduced is the "melting end," and is the bigger compartment, while the smaller compartment is called the "working end" where the glass is cooled and distributed for use. These two compartments are separated by a permanent "bridge" wall or by floating refractory baffles. The lower part of the furnace called "bath," where the melted glass is present, is constructed of a refractory block. The role of the refractory block is to minimize the heat losses due to conduction and radiation. Also, the material should be inert to the chemicals involved in glass manufacturing, and should be able to withstand the high temperatures involved. In order to meet these requirements, the refractories may be made of fireclay with addition of burned flint clay, or the typical refractory aluminous compositions. Above the walls of the furnace, combustion takes place in a crown that also covers the furnace from the top. The crown consists of an arched roof made up of silica brick resting upon side walls of silica, or fusion cast refractory. Batch is introduced mechanically by either a screw or by a pusher bar near the back of the melting end. The "doghouse," a slanted projection, is provided near the entrance to assist in introducing the batch into the furnace. In the melting end of the furnace, this batch is heated until the fluxes melt, and the sand and other ingredients dissolve.

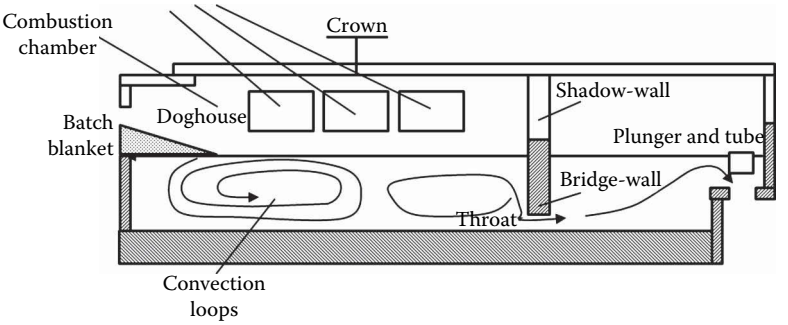

FIGURE 4.31.3 Schematic showing the melting and working compartments of the furnace. The two compartments are divided by the bridge wall.

Due to the gases such as Carbon dioxide and water vapors released during the reactions in the melt as well as air trapped in the voids of the batch, several tiny bubbles are produced in the melt due to which the molten glass is initially a foamy mass. Most of the gas bubbles are eliminated at the high temperature of the melting end. While the molten glass passes through a hole, or throat, in the bridge wall the remaining foam or scum is skimmed off from the surface of the molten glass, which is then cooled and distributed by the working-end compartment. Due to the heating of the top by the flames, cooling by side walls and addition of cold batch thermal gradients develop inside the melt. These thermal gradients lead to the formation of natural convection currents that help in making the melt homogeneous. In the work of Curlet et al. (1984), the Grashof number (ratio of buoyancy force to viscous force) is of the order of 10^5 indicating significant natural convection currents. The homogenization inside the furnace thus prevents the partially melted glass from entering into the work compartment. At such elevated temperatures, the solution of the refractory blocks may form in the glass melt leading to undissolved refractory stones, inhomogeneous glass, and bubbles. With the lower-viscosity glasses, such difficulties may limit the melting temperature used to bring the batch into solution.

When melting of sand and other batch components is completed along with the elimination of bubbles, the molten glass is cooled until its viscosity has increased to the value suitable for fabrication. In continuous furnaces, the glass melt is first cooled in the working chamber, which is maintained at a temperature between 100°C and 200°C lower than that in the melting chamber. Subsequently, the molten glass flows from the working compartment to the forming equipment through the refractory channels called "forehearths." The final cooling to desired temperature takes place at these forehearths. The uniformity in temperature is ensured such that the glass exhibits a uniform viscosity in the forming operation. Mechanical stirring by using refractory screws is one method to make the temperature homogeneous as natural convection is not very strong in this region. The forehearths' construction varies greatly and depends upon the machine to be supplied with the glass melt.

Figure 4.31.4 shows the melting chamber of the furnace where batch blanket is being introduced at the top of the melt. The granular batch mixture is usually dispensed on the surface of the melt; a picture of the real process is shown in Figure 4.31.5. Due to the lower density of the mixture, it floats on the surface of the melt until it gets transformed into glass melt. Heat is transferred from the combustion space, where fuels are being burnt, to the top of the batch blanket primarily by radiation. The amount of heat flux from the combustion space to the top of the batch blanket and to the surface of the glass melt depends on the position in the furnace. Radiation heat from the combustion space consists of wavelengths between 600 and 4500 nm and the heat flux is typically of the order of 300–500 kW/m^2. The radiation from the flames is a function of flame thickness, flame emissivity, and flame temperature. The crown also participates in this radiation heat transfer by emission and reflection of flame radiation. The highest radiation heat flux is observed

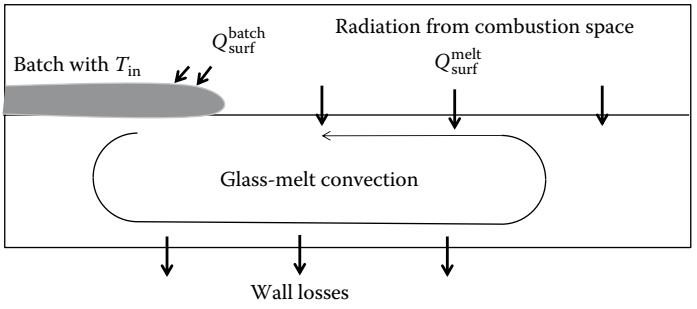

FIGURE 4.31.4 Heat flux from combustion space to glass and batch surface. (Redrawn from Krause, H., Krause, D., *Mathematical Simulation in Glass Technology*, Springer, Berlin and Heidelberg, 2002.)

FIGURE 4.31.5 The batch being introduced on top of the glass melt in the melting chamber of furnace. (Courtesy of Saint-Gobain Glass.)

at the locations with the highest flame temperatures, and to the relatively cold batch-blanket surface. The glass melt flowing underneath this blanket also transfers heat to the batch by radiation and conduction from the bottom. It is to be noted that the unreacted batch has a high reflectivity. Furthermore, the batch is a poor conductor of heat and thus develops high-temperature gradients upon heating. High heat flux densities are therefore realized due to high-temperature gradients at the start of heating. As the hot dissociation gases are released at this hot batch-bottom side the inner parts of the batch blanket are also heated up due to the rising gases. The heat penetration into the batch material thus depends on several factors such as the thermal conductivity of the batch, the nature of the reactions (endothermic or exothermic), and the nature of the released gases. The batch blanket undergoes phase change during these thermal processes. Due to the chemical and thermal processes, the composition and density are changed. The batch-to-melt conversion consists of a series of sequential and parallel chemical reactions and the conversion rate is mass transfer and heat transfer limited. It is fair to say then that the degree of batch-to-melt conversion is dependent on the local temperature T_b of the melt and also on the thermal history of the glass batch. As the heating, reactions and melting proceeds the batch parameters, such as porosity, density, conductivity, and reactivity, also change with time. The energy balance for the batch blanket can be given by

$$\frac{\partial(\rho_b C_{p,b} T_b)}{\partial t} + \nabla \cdot (\rho_b v_b C_{p,b}) = \nabla[k_b \nabla T_b] + S(T,t) + hA_f(T_{gas} - T_b), \tag{4.31.3}$$

where ρ_b is the density of the glass batch (kg/m^3); $C_{p,b}$ is the heat capacity of the glass batch (J/kg/K) that will depend on its constituents and can be computed using Table 4.31.2 (conversion needs to be done from molar to mass basis); k_b is the temperature-dependent effective batch heat conductivity (W/m/K) that depends on the constituents, porosity, and gas convection; S is the net heat sink rate due to all the chemical reactions involved (J/m^3/s), h is the heat transfer coefficient between the batch and enclosed gases (W/m^2/K); A_f is the specific heat transfer area between the batch and enclosed gases (m^2/m^3); T_{gas} is the temperature of the gases enclosed in the batch (K); T_b is the temperature of the glass batch (K); and t is time (s). The last term in Equation 4.31.3 is often neglected and the effect of released gases on the heat transfer is taken into account by defining an effective thermal conductivity $k_b(T,t)$, which can be determined by experiments. For the batch blanket, the convection terms are usually omitted from the left-hand side assuming a small contribution to energy transport due to bulk motion. The term S as a function of time and temperature is derived from laboratory tests using the complete batch. It should be mentioned that the effective batch heat conductivity k_b also takes into account the fraction of the liquid phase present in the partly molten glass batch as it moves into the furnace. In the work of Faber et al. (1991), experimental technique to measure the effective thermal conductivity and the challenges are presented.

The energy distribution in the glass melt is also governed by Equation 4.31.3, where the properties such as density and specific heat capacity are that for the melt. Further, the contribution from the convection cannot be neglected in the glass melt. The source term in general also includes the contribution due to radiation in the glass which is a semitransparent medium for the radiative heat transfer. This mode of transport in semitransparent media such as glass melts generally complicates the analysis. The contribution due to the radiation transport is typically modeled by the radiative transfer equation (RTE) for participating medium, in which the change in radiation intensity i_λ, over a distance δ is given by

$$\frac{\partial i_\lambda}{\partial \delta} = -a_\lambda i_\lambda + a_\lambda i_{\lambda b} - \sigma_{s\lambda} i_\lambda + \frac{\sigma_{s\lambda}}{4\pi} \int_{\omega_i}^{4\pi} i_\lambda(\delta,\omega)\Phi(\lambda,\omega,\omega_i)\,d\omega_i. \tag{4.31.4}$$

The right-hand side terms are loss by absorption, gain by emission, loss by scattering, and, finally, gain by scattering, respectively. In the Equation, $a\lambda$ is the absorption coefficient of the medium, $\sigma_{s\lambda}$ is the scattering coefficient, ω is the solid angle, and Φ is the scattering distribution function that depends on the both incident and scattering direction.

Note that all coefficients appearing in this equation depend on the wavelength of the radiation, and that has a strong implication for analyzing the radiation transport in glass melts, for example, the absorption coefficient for glass is shown in Figure 4.31.6 as a function of wavelength and temperature. Several integrodifferential equations need to be solved for radiation transport due to contributions from several wavelengths which need advanced numerical algorithms. Also as expected, before computations can be carried out the radiation characteristics of the glass melt as a function of wavelength must be accurately known. The presence of sand particles and bubbles may even further complicate the analysis. The boundary conditions need to be well-defined for reflection, refraction, and absorption at primary melt to reacting batch, primary melt to melt in the tank volume, and primary melt to combustion space. More details on radiation modeling in semitransparent media can be found in Frank and Klar (2010). In order to avoid such complexities associated with the analysis of radiation, the Rosseland approach is frequently used (another approach is to use a two-band model for absorption coefficient as mentioned in Roychowdhury and Srinivasan (1994)). In this approach, an effective thermal conductivity coefficient is defined by taking into account the contribution of radiation as

$$\lambda_{eff} = \lambda_{conduction} + \lambda_{radiation}, \tag{4.31.5}$$

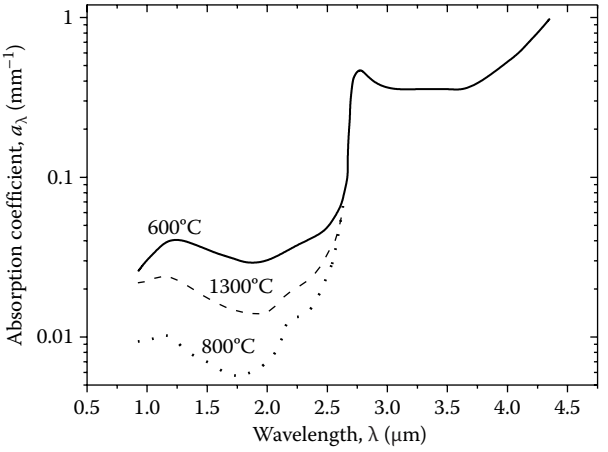

FIGURE 4.31.6 Absorption coefficient for window glass as a function of wavelength of the radiation. (Redrawn from Rawson, H., *Phys. Technol.*, 5, 91–114, 1974.)

where

$$\lambda_{\text{radiation}} = \frac{16}{3}\frac{n^2\sigma_{\text{SB}}T^3}{a_{\text{Ross}}}. \tag{4.31.6}$$

This apparent conductivity is then used in the Fourier equation of heat conduction. In the above equations, n is the refractive index, σ_{SB} is the Stefan–Boltzmann constant, and a_{Ross} is a gray absorption coefficient that can be computed from the spectral absorption of the glass melt. The effective thermal diffusivity for soda-lime silicate glass melt was experimentally measured by Van Zee and Babcock (1951), as function of temperature, and can be converted to give the effective thermal conductivity (see Pilon et al., 2006) as given in Equation 4.31.7

$$\lambda_{\text{eff}} = 213 - 0.37T + 1.66\times10^{-4}T^2, \tag{4.31.7}$$

where T is the temperature in K and the expression is valid above 1000 K (the melt will exist above this temperature anyway). The typical wavelength range of radiation in glass melting is 0.5–5 μm. Furthermore, the sand-grain diameters are smaller than 500 μm, gas bubbles range from a few microns to millimeters, and the cullet pieces are in the range of millimeter to centimeter. Due to such large sizes as compared to the radiation wavelength, diffraction and refraction need to be taken into account. Significant scattering due to bubbles and sand particles causes the melt to behave as an opaque medium, and the above analysis can be further simplified.

Fining and Bubble Dynamics

The glass-melt furnace is like a large chemical reactor where in the very first stage a large number of chemical reactions occur at different temperatures and in different phases. This stage occurs primarily in or around the batch blanket. The glass melt is left with incompletely dissolved sand grains or grains of other refractory oxides after the reactions are over in addition to the dissolved gases, and gas bubbles. In the next stage of the melting process, the residual grains are completely dissolved in the melt. Stirring of the melt is desired at high temperatures to enhance the process of dissolution. The freshly molten glass contains dissolved gases, smaller and large bubbles, and dissolved polyvalent ions. At high temperatures, above a certain fining onset temperature level, the polyvalent ions get converted to lower redox state and gases such as oxygen or SO_2 are generated in the melt. These fining gases, owing to their low solubility, diffuse toward the bubbles present in the melt. Inside the bubbles, the original gas is diluted by the fining gases. Fining gases and other dissolved gases start to diffuse into the bubbles, driven by the difference in the equilibrium pressure of these gases in the melt and the partial pressure in the bubbles. The bubbles thus growing in size ascend to the glass-melt surface with a velocity proportional to the square of the diameter and proportional to the reciprocal value of the glass-melt viscosity, in accordance with the Stokes law. The bubble-removal and gas stripping process from the melt is called fining. It requires temperatures above the fining onset temperature and almost no mixing in the melt to avoid the dispersion of the ascending bubbles throughout the whole melt. In the final stages of fining (refining), slow cooling of the melt occurs. Now, the residual tiny bubbles or the bubbles that have grown in size can completely dissolve in the melt. This dissolution (also called secondary fining) requires an increasing solubility as the melt cools down. Bubbles containing gases dissolving chemically in the melt (e.g., O_2, CO_2, SO_2) can be reabsorbed because the solubility of these gases in the melt will increase as temperature reduces. The dissolution rates of these gases and bubbles also depend on the diffusion coefficients of the gases in the melt, and as expected these values decrease with temperature reduction. This implies that the dissolution of bubbles mainly occurs in a certain temperature range. Below these temperatures, the dissolution rates become too small and the bubbles "freeze-in" in the rigid glass.

After this stage, the melt is conditioned to the viscosity level required for forming of the glass product. The viscosity should be uniform prior to forming in order to obtain a uniform glass distribution during blowing, pressing, drawing, or floating of the glass. Proper control of the glass-melt viscosity and the uniformity of the viscosity in the feeder are essential prerequisites for an optimum forming process. In the next section, description of the thermal processes and their importance is described in one of the forming processes called the float process.

Heat Treatment for Glass Transformation

Heat-treatable float glasses can be broadly classified into two categories, namely, annealed float glasses (clear or tinted glass) and coated glasses (low emissivity, solar control, and enameled/ceramic-frit printed). Before the heat treatment of glass, preprocessing steps such as cutting the glass into desired size, edge grinding, and washing are essential. The main heat treatment process depends on the amount of residual stress imparted onto the glass and can be classified as

1. Thermal tempering
   a. Convection tempering
   b. Bend tempering

2. Heat strengthening
   Typically heat strengthening increases the strength of annealed glass by a factor of two and tempering imparts a 4× increase in strength of the annealed glass. In addition, chemical tempering by ion exchange method, i.e., exchange of K (larger) ion with Na (smaller) ion is a possible option to impart higher strength to the glass. However, it is a slow batch process and is not suited for large-scale industrial applications.

The processing flow diagram for heat treatment of various types of glasses is shown in Figure 4.31.7.

A comparison of glass performance after heat treatment with various processes is shown in Table 4.31.3.

For reference, the residual stress profile comparison of glasses after different heat-treatment processes is shown in Figure 4.31.8.

Thermal tempering, being the most widely used process for toughening the glass, is covered in some detail in this chapter.

A typical tempering furnace model is shown in Figure 4.31.9 with different sections.

Glass is heated up to 600°C–700°C, depending on the glass thickness and is soaked at the tempering temperature for approximately 40 s/mm of thickness (for clear glass), followed by quenching with air jets. The nonlinear thermal expansion of the glass creates a gradient in density of the glass across thickness due to the difference in thermal gradient during cooling.

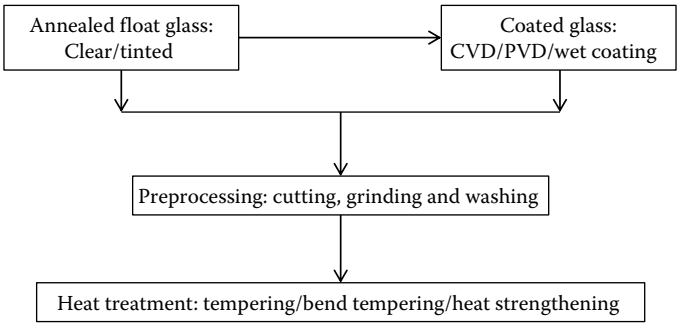

FIGURE 4.31.7 Glass processing heat-treatment flow.

TABLE 4.31.3
Comparison of Glass Performance vs. Various Heat-Treatment Processes

Parameter	Annealed Glass	Heat-Strengthened Glass	Tempered/Safety Glass
Glass strength	Bend strength: 30–40 MPa Compression strength: 1800–2200 MPa Tensile strength: 20–70 MPa Brittle and very strong in compression, Low toughness	Moderate bend strength of ~50 MPa	Very high bend strength ~120 MPa
Resistance to thermal shock	Low thermal shock resistance.	Moderate resistance to thermal shock ~100°C	Higher resistance to thermal shock ~ 200°C
Residual stress	Evenly distributed low residual stress ~15–20 MPa	Residual stress 47–52 MPa	Residual stress 78–92 MPa
Breakage pattern	Sharp, knife-like fragmentation pattern	Edge-to-edge and some fragments	Numerous small fragments

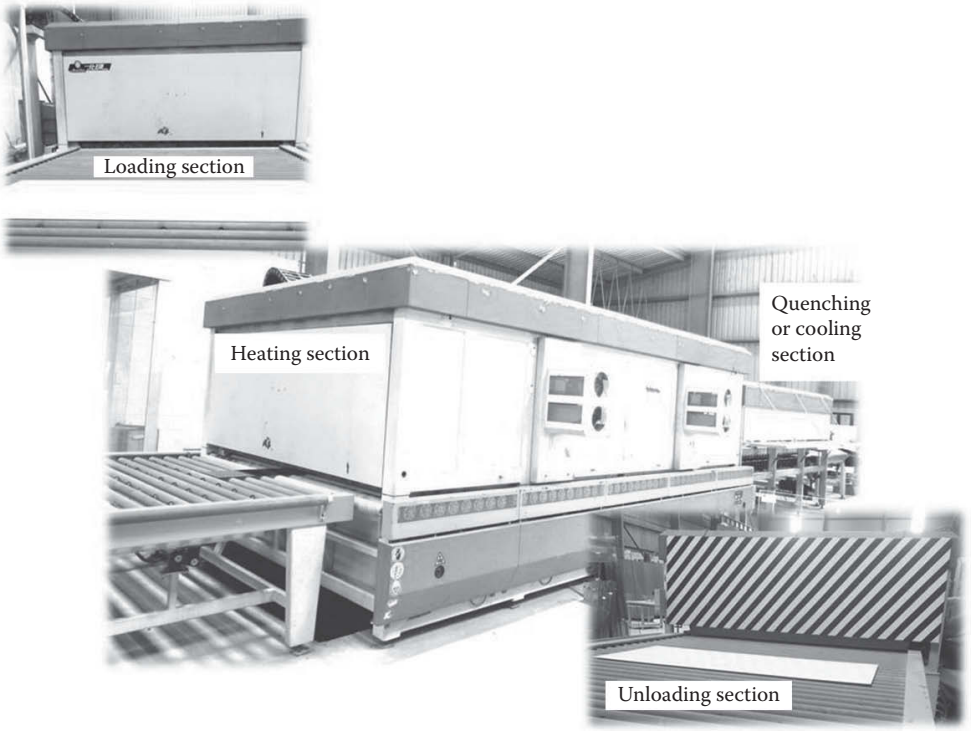

FIGURE 4.31.9 Model depicting different zones of tempering furnace. (From Glass-academy.in. With permission.)

Below T_g thermal expansion of glass is practically three times lower than that above T_g, as shown in Figure 4.31.10.

The stress during tempering develops when the glass is cooled from 670°C to 470°C and the glass is not viscous enough to move freely. When cooled rapidly, the surface experiences a higher

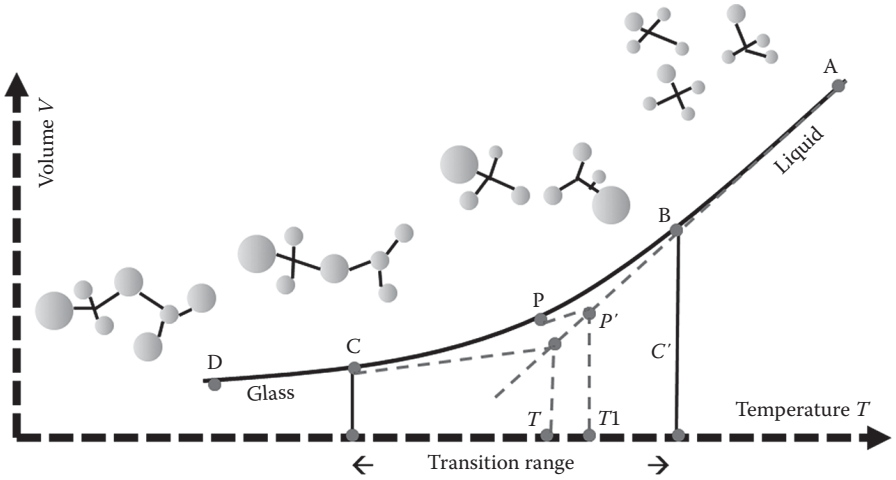

FIGURE 4.31.10 Graphical representation of thermal expansion coefficient of glass vs. temperature. (From Glass-academy.in. With permission.)

thermal gradient than the mid plane of the glass due to low-thermal conductivity of the glass. This differential rate of cooling induces a density gradient through the thickness of the glass. Rapid quenching solidifies the surface of the glass and the molecules are not free to move. But the molecules in the bulk are free to move and hence rearrange themselves resulting in a density increase.

The following modes of heating are typically used during thermal tempering:

1. Radiation
   a. Open coil heating element
   b. Framed heating element

2. Convection
   a. Combination radiation/forced convection
   b. High convection
   c. Dual chamber system with convection preheating

Details of these modes of thermal tempering are discussed now.

Radiation Tempering

Heating of glass takes place by means of radiation heat transfer from heating coils located above and below the glass as shown in Figure 4.31.11. Upon heating, the ceramic rollers get heated up and aid in heating the bottom of the glass through conductive heat transfer between roller and glass. The heating

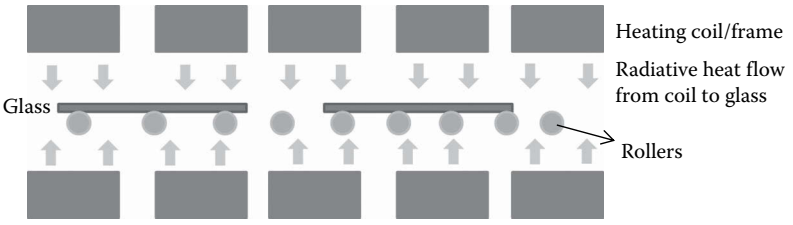

FIGURE 4.31.11 Schematic diagram of radiation tempering furnace heating setup. (From Glass-academy.in. With permission.)

elements can be an open coil arrangement or framed heating element. In open coil arrangement, the heating is not focused and the glass is kept away (20–100 cm) from the coil to avoid overheating. Framed heating elements, on the other hand, have focused heating and therefore, lower temperature is used compared to the open coil arrangement. The main drawback of these types of furnaces is that they cannot be used to heat-treat low-emissivity coated glass due to selective reflection of Infrared radiation.

Convection Tempering

In this model of tempering, the heating takes place by three modes:

1. Radiation heat transfer from heater, rollers, other surfaces and glass itself
2. Convective heat transfer to glass by hot air inside the furnace
3. Conductive heat transfer between ceramic roller and glass

The advantage of these types of furnaces over radiation furnace is that they can be used to heat-treat low-emissivity and other sensitive glasses due to relatively lower intensity and more uniform heating profile.

Various techniques for heat treatment can be deployed for convection tempering and a few examples are detailed below.

a. Combination of radiation and forced convection

The top heating chamber of the furnace is equipped with convection air jets. Heat transfer between top and bottom is maintained the same resulting in better optical quality of heat-treated glass as shown in Figure 4.31.12.

b. High convection

Heating of the air is achieved by gas or electrical heating elements and the hot air is blown against the glass by means of blowers and air nozzle arrangement thus eliminating the effect of emissivity of the glass as shown in Figure 4.31.13. Heating of glass by radiation is reduced and the peak temperature is achieved faster.

c. Dual chamber system with convection preheating

In this case, the first chamber is equipped with high convection preheating followed by forced convection in the second chamber as shown in Figure 4.31.14. This type of two-stage heating will eliminate glass bending during tempering.

The main parameters influencing thermal tempering are heating time, temperature inside the furnace, glass transfer speed, oscillation speed, distance of nozzles in chiller and percentage of nozzle opening or air pressure inside the furnace. Heating time depends on the glass thickness, also it varies according to the furnace type. Heating time for convection furnace is ~40–45 s/mm thickness of glass, and is ~15% higher for radiation tempering compared to convection furnace. The tempering temperature depends on the tint of the glass, since the heat absorption varies with the tint of the glass. Figure 4.31.15 shows the comparison of tempering temperature vs. tint of glass.

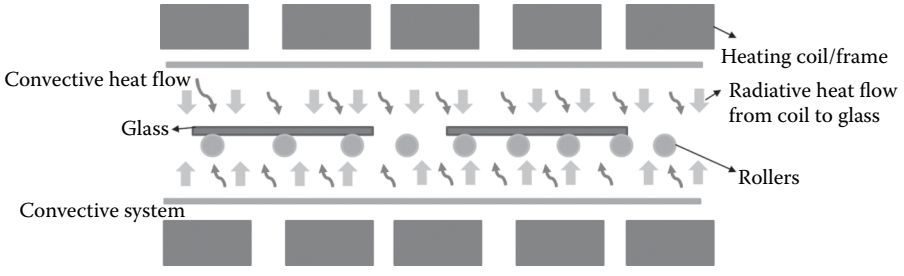

FIGURE 4.31.12 Schematic representation of combination of radiation/forced convection system. (From Glass-academy.in. With permission.)

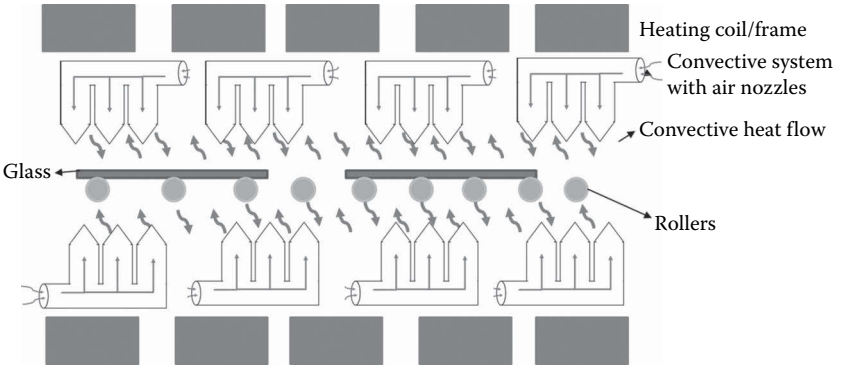

FIGURE 4.31.13 Schematic representation of highly convective system with air nozzles. (From Glass-academy.in. With permission.)

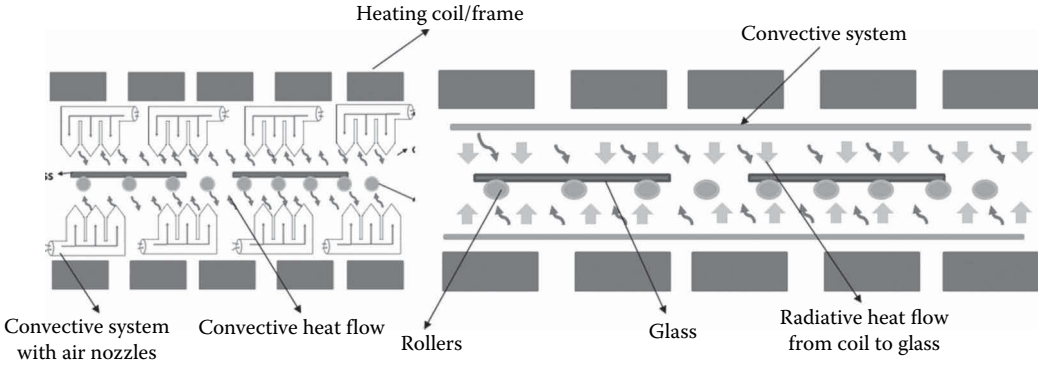

FIGURE 4.31.14 Schematic representation of dual chamber system. (From Glass-academy.in. With permission.)

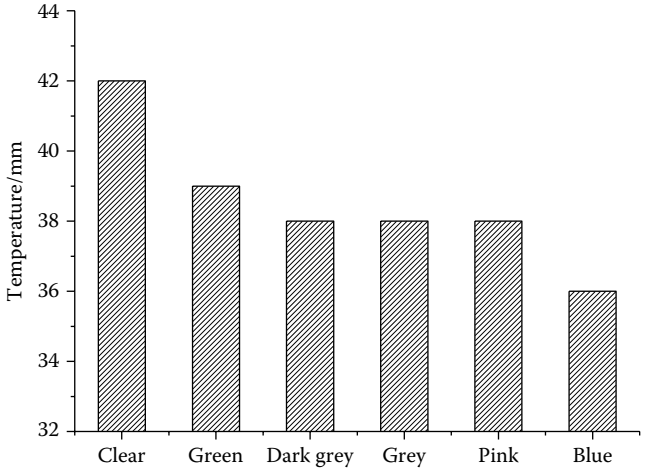

FIGURE 4.31.15 Heating requirement per mm of glass vs. tint of glass. (From Glass-academy.in. With permission.)

Heat Strengthening

Heat strengthening is almost the same process as thermal tempering except that cooling is much slower than that in the regular tempering. Thus the residual stress developed is half of that generated during thermal tempering (~45 MPa). The fragmentation structure is almost the same as that of annealed glass and the strength is twice that of the annealed glass. Heat strengthened glass is used when optical distortion requirement is very stringent, owing to its flatter surface compared to tempered glass. The residual stress comparison of heat strengthened and tempered glass is shown in Figure 4.31.16.

Heat Transfer during Tempering

During tempering, the glass is exposed to radiation emitted by radiant heaters, rollers and other surfaces inside the furnace. Also, the glass is emitting radiation, and the emission increases when glass gets hotter. Convection heat transfer between hot air and glass affects both surfaces. In addition, conductive heat transfer between glass and rollers takes place during the process. The velocity of glass is equal to the circumferential speed of the rollers. The heat transfer phenomena in a tempering furnace are represented in Figure 4.31.17.

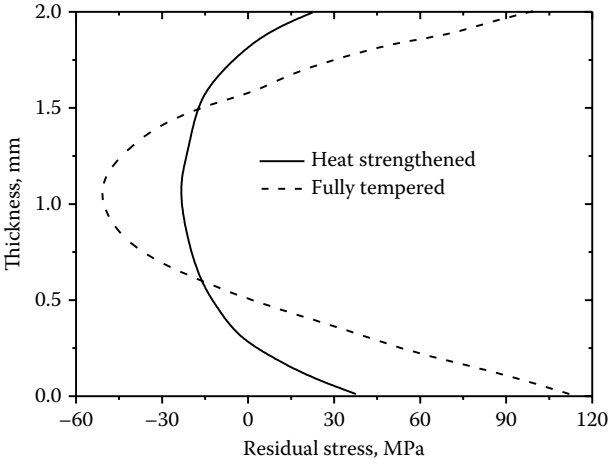

FIGURE 4.31.16 Residual stress comparison of fully tempered and heat-strengthened glass. (From Glass-academy.in.)

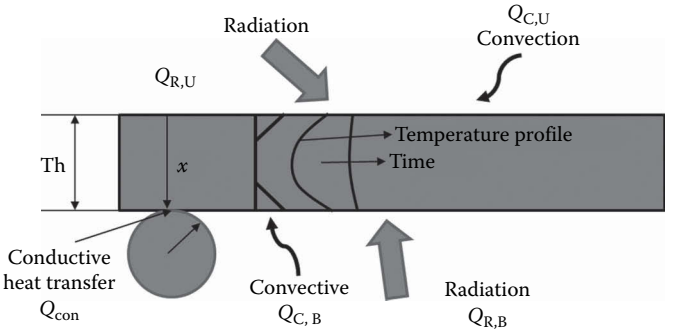

FIGURE 4.31.17 Heat transfer phenomena in a tempering furnace. (From Rantala, M. Heat transfer phenomena in float glass heat treatment processes. PhD Thesis, Tampere University of Technology, Finland, 2015. With permission.)

The equation representing the overall heat transfer phenomena as shown in Figure 4.31.17 is given by

$$\rho C_p \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial Q_R}{\partial x}, \tag{4.31.8}$$

where ρ is the density, C_p is the specific heat, and k the thermal conductivity of the glass, respectively. Further, *x is* a measure of the distance into the glass from its top surface and t is the overall time elapsed in the tempering line.

From Equation 4.31.8, the overall heat transfer through the glass in a tempering line can be classified into two categories. First, glass behaves like a lumped mass storing the overall incident heat on its surface from conduction by rollers $\left(k\frac{\partial T}{\partial x}\right)$, and radiation heat transfer from its surroundings $\left(\frac{\partial Q_R}{\partial x}\right)$ as given in Equation 4.31.8. $\rho C_p \frac{\partial T}{\partial t}$ is the overall heat stored by the glass (as lumped mass), hence resulting in an increase in its temperature *T*.

Further, an increase in glass temperature T would result in heat transfer from its surface into the ambient of tempering line via radiation and convection (with the surrounding air). The Equations representing net heat transfer by convection and radiation from glass surface are represented in Equations 4.31.9 and 4.1.10. Equation 4.31.9 represents the heat transfer from glass top surface ($x=0$) facing the tempering line. The net heat from this surface is transferred through radiation ($Q_{R,}$ $x=0$) and convection (Q_C,$x=0$). Further Equation 4.31.10 represents the heat transfer from bottom surface ($x=L$) of glass resting on the rollers. The net heat transfer from this surface is through radiation (Q_R,$x=L$), convection (Q_C,$x=L$), and conduction (Q_{Con},$x=L$) to the rollers:

$$k\frac{\partial T}{\partial x}(0,t) = Q_{R,U} + Q_{C,U}, \tag{4.31.9}$$

$$-k\frac{\partial T}{\partial x}(L,t) = Q_{R,B} + Q_{C,B} + Q_{Con}. \tag{4.31.10}$$

Representing the overall conduction heat transfer at surface $x=0$ and $x=L$ from Equations 4.31.9 and 4.31.10 in Equation 4.31.8, the net temperature of the glass in the tempering line can be estimated. The temperature, along with other parameters, determines the extent of strengthening via residual stress generation, as detailed in the chapter.

Summary

A short overview is presented in this chapter on manufacturing of glass with focus on application of heat transfer concepts. Glass manufacturing is evidently a high-temperature process in which raw material is melted, followed by reactions involving the components of the raw mixture and cooling of the melt. Radiative heat transfer plays a dominant role during melting and thermal annealing as the temperatures involved are very high. Temperature variation between the bulk of the melt and its surface generates natural convection within the melt. This convection helps to improve its quality by bringing the tiny bubbles that are formed in the melt to the surface. It also leads to better mixing of the raw material introduced at the surface with the bulk melt. After melting and cooling, thermal treatment is required to manufacture glass for a given specific application. In this chapter, float glass manufacturing is presented as an example and the thermal tempering process is discussed in some detail.

4.32 SOLAR HYDROGEN AS A "RENEWABLE REDUCTANT": POINTS AND COUNTERPOINTS

Raj Ganesh S. Pala

Introduction and Scope

Unlike most of the previous energy crises [1], which were more often than not, driven by artificial constraints on the *supply side* of fuels, the energy crisis of the future will be driven by significant increase on the *demand side*. It is not only the overall population, but also the longevity of people that is increasing and this is coupled to rising prosperity, all of which is surely bound to increase the demand for energy [2,3] Energy *per se* is not the problem as Earth is inundated with solar energy [4–6], but the quintessential search in energy science and engineering is for *energy conversion* technologies that are *environmentally sustainable*. Solar energy falling on Earth has to be converted to more usable forms like electrical energy or mechanical energy, and as this energy has significant diurnal and seasonal variation, energy conversion technologies like solar cells are often connected to energy storage technologies like batteries [4,5]. Energy storage technologies are more critical in countries like India, wherein even if electrical grid connectivity exists, certain electrical grids are often operated only during the night to meet the requirement during nights (especially in the form of energy for lighting). This imposes the constraint wherein solar photons are only available during the daytime and even if the solar photons are utilized to generate electricity via solar cells, it is impossible to store the generated electricity, for later use at night, if inexpensive energy storage technologies are unavailable.

From the time humans discovered fire, they have come to depend on burning carbon containing oxidizable biochemical or chemical feedstocks to obtain energy. These feedstocks were generated naturally over millions of years using solar energy and biomass, but are being consumed due to human activity at exceptionally faster rates, compared to the natural timescale for their generation. While the gradual drift has been from carbon-rich fuel feedstocks like wood to coal to petroleum to carbon-poor fuel feedstocks like natural gas, the generation of CO_2, which is correlated to the harmful greenhouse effect, will not stop unless zero-carbon fuels are utilized. While nuclear energy may offer a solution to near zero-CO_2 generating pathways for energy needs [3], its boon of it being *very high energy density*, also proves to be its bane and it is not clear if the socio-economical and political challenges of nuclear energy will be surmounted in the near future. If hydrogen can be generated using renewable energy and using renewable feedstocks, hydrogen as a *renewable fuel* can be "burnt" either thermochemically via hydrogen turbine/internal combustion engine to obtain mechanical energy or electrochemically via a fuel cell to obtain electrical energy [4,5].

Hydrogen, in addition to being an energy carrier and source of energy, can also be viewed as a "*renewable reductant*" to mitigate/chemically reduce/chemically fix/chemically store the CO_2 that has been generated due to the dramatic increase in energy demands following the Industrial Revolution. *For hydrogen to be a "renewable reductant," it has to be generated via a near-abundant feed like water, and via renewable sources like solar energy.* The hydrogen so generated can be reacted with CO_2 to generate useful chemicals like methanol, which can, in turn, be used for generating other commodity chemicals like ethylene via the methanol-to-olefin process [7].

Solar-based hydrogen generation can be achieved via two broad electrochemical methods. In the "indirect" electrochemical method, an electrolyzer is utilized to drive the endothermic water splitting process and generate hydrogen and oxygen, with the energy required for electrolysis supplied by solar cells [4]. There are certain advantages in this process—physicochemically, as the solar energy absorption and current generation is undertaken by a solar cell, this device can be optimized independently of a second device, the electrolyzer, which takes the current/voltage/electrical power from the solar cell and generates hydrogen/oxygen. The feasibility of both these technologies—solar

cells and electrolyzers—has been demonstrated at industrial scales for the generation of electrical power and hydrogen/oxygen, respectively, albeit not being the cheapest method for generating electrical power/hydrogen/oxygen.

In the second "direct" electrochemical method, solar light falls onto the electrode(s) of an electrolyzer, which generates the necessary potential for splitting water. Such a process, broadly referred to as the "photoelectrochemical" (PEC) process [8–14], has captured the imagination of chemical scientists and engineers for more than four decades and has been a Holy Grail problem, waiting to be the elixir for sustainable energy [15,16], if the device is made with inexpensive Earth-abundant elements [17,18] via low-cost manufacturing techniques. This elusive search toward an engineered "photochemical" solution predates the last four decades and has been seen as a panacea for the Faustian bargain of relying on carbon-based energy feedstocks even a century ago [19,20]. The allure of this process is partly because of its *apparent* simplicity [8–14] and partly because of the possibility presented by Nature, which has mastered solar energy-based generation of carbohydrates from the simplest of raw materials—carbon dioxide and water—via intricate self-organization and self-assembly of biomacromolecules [16,21].

Due to the relatively low energy density of solar radiation, all solar technologies involve large-area devices. To obtain a feel for the areas involved, let us consider an order of magnitude analysis to estimate the areas involved in the indirect method of hydrogen generation via electrolyzer powered by solar cells. Large-area electrodes are required for generating H_2 that is to be used for reducing all the CO_2 generated in a given year. As these electrodes can be vertically stacked, they will not occupy large land area, but significant area is required if inexpensive solar cells are to power these electrolyzers. For the year 2014, the global CO_2 emissions were ~35.9 Gt ($= 34\times10^{12}$ kg), which amounts to 0.816×10^{15} g mol. Suppose, we convert CO_2 to methanol via the following reaction: $CO_2+3H_2 \rightarrow CH_3OH+H_2O$, thereby requiring 2.448×10^{15} mol of H_2 per year. Let us assume that electrocatalysts made from Earth-abundant materials are used for the production of H_2, and that the efficiency of H_2 production is 68.3% ($\eta = 1.23/1.8$). Let us also assume that amorphous Si solar cells having an energy efficiency of 10% are to power these electrolyzers. Since the solar power flux is 100 mW/cm^2, the current density obtained from the electrolyzer, powered by amorphous Si solar cells, will be 5.55 mA/cm^2 ($0.1\times0.683\times100\,/\,1.23$ mA/cm^2). The total mol of H_2 produced in a year, assuming six hours of continuous solar light in a day, per square km will be 226.75×10^7 ($0.5\times5.55\times10^{-3}\times365\times6\times3600\times10^{10}/96{,}485$ mol). As 2.448×10^{15} mol of H_2 is required for converting CO_2 to methanol, the area of solar panels required to power the water electrolyzer will be 1,079,729 km^2. Hence, a land area of 1,295,675 km^2 (1.2 times the solar panel area) will be required, which is approximately equal to the land area of the state of New Mexico!

Land area requirement for direct PEC H_2 generation processes has been estimated in solar insolation rich regions [22] and in the vicinity of refineries [23], wherein the hydrogen generated can be used for other petrochemical processes without the need for expensive hydrogen storage devices.

While photocatalytic (PC) routes have been explored for many chemical systems like photoreduction of CO_2 and wastewater treatment [4,12], most of the work has been focused on the direct water splitting. The scope of this review chapter will be restricted to photoelectrochemically driven low-temperature water splitting alone; no attempt has been made to address other approaches to renewable hydrogen [21]. The chapter is designed to serve as a qualitative introduction to the field, but is also intended to give pointers on issues that have been addressed less extensively. In addition, the chapter has carefully chosen references to books and recent reviews of the field, wherein the subject matter is discussed at a much greater depth. In the section on physicochemical principles of photoelectrochemical systems, we review the elementary principles of photoelectrochemical systems. In the section on model identification and refinement, we discuss some common methods to discern the models that have been proposed for PEC systems. The issues of efficiency and process design are addressed in "Aspects of Efficiency Metrics, Photoreactor Design, and Process Design." Materials are central to the realization of PEC technologies and aspects of material design are discussed in "Realizable Efficiencies are via Materials: Some Hope, Some Hype, and the New Hope."

The section "Roads Less Travelled: Some Challenges in Attaining the Holy Grail" has certain personal and speculative viewpoints on different aspects of PEC systems that I feel have not been adequately addressed. The chapter ends with "Concluding Remarks."

Physicochemical Principles of PEC Systems

Energetics of Water Splitting

A water electrolyzer/electrolytic cell as well as a water splitting PEC system/photocatalytic semiconducting particle are engineered to drive the following endothermic reaction:

$$H_2O \rightarrow \frac{1}{2}O_2 + H_2, \Delta G = 237 \text{ kJ/mol} \quad \text{(R1)}$$

This overall *redox* reaction is a combination of a reduction reaction:

$$2H^+ + 2e^- \rightarrow H_2 \quad \text{(R2)}$$

and an oxidation reaction:

$$H_2O \rightarrow \frac{1}{2}O_2 + 2H^+ + 2e^- \quad \text{(R3)}$$

The oxidation and reduction reaction occurs at a solid–liquid material interface, in regions often referred to as the anodic electrode surface of an electrolytic cell (or anodic surface sites of a single particle) and cathodic electrode surface (or cathodic surface sites of a single particle). In addition to the nature of the reaction occurring at these surfaces (or surface sites of a single particle), these surfaces (or surface sites of a single particle) are characterized by their distinct electrochemical potential. Without a highly technical discussion on the nature of electrochemical potential, which requires an extended detour to the fundamentals of electrochemistry [24,25], it is useful to develop qualitative insights via classical electrostatics.

In electrochemical reactions, the electrode potentials play a role akin to temperature in a thermochemical reaction, in the sense that the variation of electrode potentials modulates electron transfer between the electrode and electro-active species in the electrolyte, thereby controlling the rate of the electrochemical reaction. Modulation of *rates/kinetics* is possible as electrode potentials modulate the *energetics/thermodynamics* of the electro-oxidation and electro-reduction reactions.

As the overall reaction (Equation R1) is endothermic and considering reaction R3 at "zero electrode potential," the energetics does not favor dissociation of water. However, as the electrode potential is made positive (or shifted to an *anodic* potential), the dominant effect of the *positive* electrode potential is in stabilizing the electron appearing on the right-hand side of Equation R3. Greater positive potential favors water splitting to a greater extent; *negative* potential (or shifting to a *cathodic* potential) has the opposite effect and it destabilizes the electron appearing on right side of Equation R3. The more endothermic the overall reaction is, greater will be the electrical bias, which is the difference between the positive and negative electrode potential, required to drive the overall reaction. The free energies of the reaction are measured in kJ/mol, but V_{bias} (defined as $V_{bias} = V_{cathode} - V_{anode}$) is in volts, and both are connected by the equation $\Delta G_{reaction} = -nFV_{bias}$, where n = number of moles of electrons involved in the electrochemical reaction and F = Faraday constant = 96,485 C/mol. In the case of water splitting reaction, $V_{bias} = -1.23$ (as $V_{cathode}$ is negative with respect to V_{anode}) and $n = 2$.

Typically, in an electrolytic cell, the anodes and cathodes are metallic in nature, with their primary purpose being to change the energetics of the electro-oxidation and electro-reduction reactions. In addition, different metallic electrodes can chemically interact with the reactants/products in a different manner and hence, have different "*electrocatalytic*" properties [26].

In contrast to electrically biased electrolytic cells for water splitting, a PEC water splitting cell has at least one of the electrodes made of a semiconductor material. In contrast to metals, which have unoccupied electronic states for "small" energy electronic excitations, semiconductors, lack unoccupied electronic states for "small" excitations [27]. Here, "small" energies are of the order of characteristic energy scale kT, where k is the Boltzmann constant, T is the temperature of the material [27], and kT at room temperature is ~25 meV. In a semiconductor, the lowest unoccupied electronic state is separated from the highest occupied state by a band gap, which is much larger than kT. The highest "very closely" spaced set of energy levels of filled electronic states is called the valence band and the lowest very closely spaced energy levels of empty electronic states is called the conduction band. Here, "very closely" spaced indicates that the separation between electronic energy levels is much less than the characteristic energy scale kT. The highest energy level of the valence band is called the valence band maximum (VBM) and the lowest energy level of the conduction band is called the conduction band minimum (CBM). The difference between CBM and VBM is called the band gap. The band gap of Si is 1.12 eV (which is much larger than kT at room temperature); the band gap of typical semiconductors that have been explored in the context of PEC is given in Refs. [8] and [12] amongst others. The distribution in energies of the photons is dependent on the black body spectrum of the sun [8] and if the semiconductor has a small band gap, it absorbs more solar photons. However, not all of these photons can contribute toward water splitting.

The minimum V_{bias} required for splitting water in an electrolyzer is 1.23 V; but in addition to this, other losses like the ohmic drop in the electrolyte and losses associated with overcoming the electrochemical reaction activation barrier [24,26] are lumped together under various overpotentials [24,26]; the sum of these various overpotentials amounts to about 0.4 V. Hence, a typical electrolyzer operates at a potential of $V_{op} = 1.63$ V so as to have appreciable reaction rates and current density.

PEC systems are very similar to a simple electrolytic cell, but it contains at least one semiconductor electrode. The two electrodes are physically separated by an electrolyte, but are electrically connected. When light is incident on the semiconducting electrode, a potential is generated in the semiconductor electrode and if this potential bias is of the order $V_{op} = 1.63$ V of an electrolytic cell, then there will be sufficient water splitting activity. But alas, there would have not been the frenetic activity in the field of PEC over the last four decades if the generated photopotential were so high.

In contrast to PEC systems, water splitting can be attempted via a single semiconductor particle too; we will refer to such systems as *photocatalytic* (*PC*) water splitting semiconducting particles (Figure 4.32.1). When light falls on such particles, potential bias is generated within these particles such that some parts of the particle are anodically biased and some other parts are cathodically biased. The anodic surface sites of the PC particles host the oxidation reaction (Equation R3) and the cathodic surface sites host the reduction reaction (Equation R2).

Band Bending in the Semiconductor–Electrolyte Interface

When a voltmeter is connected between two different metals, it measures the difference between the highest energy level of the electron (called the Fermi level) in the different metals. Fermi level is a thermodynamic quantity with rigorous microscopic interpretation from statistical mechanics and it takes into account the effect of temperature/chemical nature of the material [27]. Lower the Fermi level of a metal, greater is the energy required to remove an electron from the metal; this energy is called the work function of the material. When two metals are electrically connected to each other, electrons will flow from the metal that has lower work function (or greater Fermi level) to the metal that has higher work function (or lower Fermi level) till the Fermi level of the two metals equalizes.

In a similar manner, the Fermi level of the semiconductor can be measured with respect to other metals or other semiconductors. For an n-type semiconductor, the Fermi level is closer to and just below the CBM and for a p-type semiconductor, the Fermi level is closer to and just above the VBM. In an undoped semiconductor, the Fermi level is exactly in the middle of the band gap, despite there being no electronic energy level in the band gap [24].

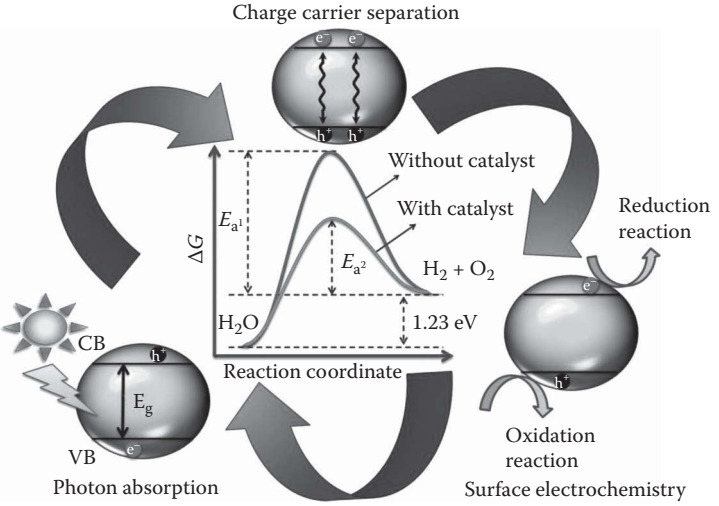

FIGURE 4.32.1 Coupling between the three fundamental physicochemical processes in a photocatalytic system.

In the electrochemical literature, the electronic energy level of redox couple in the electrolyte is given by the Nernst equation [24]; this redox energy level of the electrolyte is indicative of the tendency to transfer charges. A more positive redox level will more easily get reduced by accepting electrons from a redox level that has less positive redox level.

In a PEC cell, there is at least one interface between a semiconductor electrode and the electrolyte and in a *tandem*-PEC cell, both the electrodes are made of semiconductors. The electronic energy levels between the semiconductor and the electrolyte can be compared using a common scale; it is to be noted that the Fermi level of a semiconductor is functionally the same as the redox electrochemical potential of an electrolyte [2]. Further, when an electrical contact between the semiconductor and the electrolyte is established, charges are transferred from the higher electrochemical potential to the lower electrochemical potential. Such a transfer of charges induces bending of electronic bands in the semiconductor, which is very crucial for the separation of e^-/h^+ (Figure 4.32.2).

Dynamics of Charge Transfer between the Semiconductor and the Electrolyte

When an *n*-type semiconductor is exposed to light, it will absorb photons that have energies of the order of the band gap or greater. As these absorbed photons provide the energy for driving the endothermic water splitting reaction and as the band gap sets the bound for minimum energy for the photon that can be absorbed by the semiconductor, the band gap in turn has to be at least >1.23 V. Upon photon absorption, an electron is excited to the CBM and a hole (which is a missing electron) is at the VBM.

As the energy levels near the semiconductor surface are bent due to the lack of electroneutrality (Figure 4.32.2), the hole is "driven up" along the VBM to the surface of the semiconductor and reacts with water molecules to form O_2 and protons. Thus, the *n*-type semiconductor serves as the anode, performing oxidation, in the PEC cell. For this charge transfer to take place, the redox level of the H_2O/O_2 couple should be higher than the bent VBM of the semiconductor so that the hole can move up from the bent VBM level of the semiconductor to the occupied redox levels in the electrolyte.

As the valence band of a semiconductor has greater contribution from orbitals from the anions of the semiconductor, the more electronegative the anions, the deeper are the VBM levels and more facile is the transfer of the hole from the VBM to the less electronegative O from the water molecule. This has important consequences in terms of trade-off between band engineering to increase solar

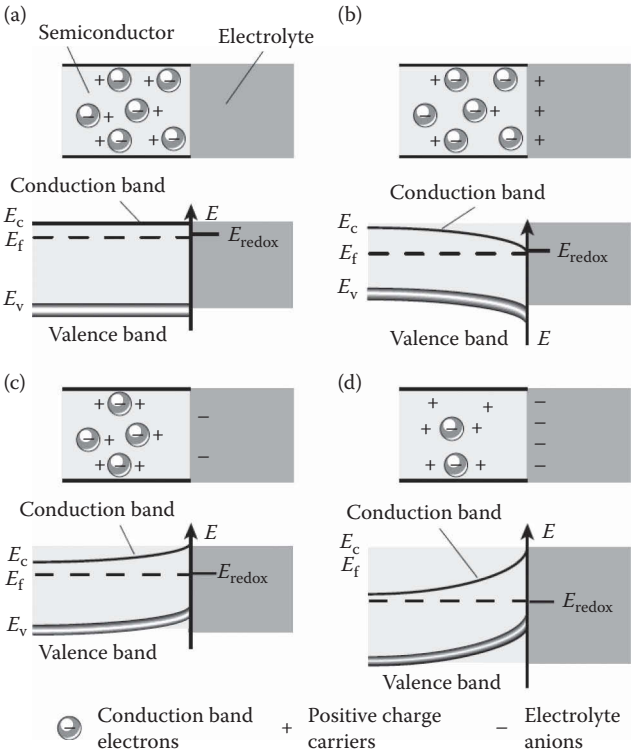

FIGURE 4.32.2 Different band-bending scenarios depending on the differences in the fermi level of the semiconductor and the redox level of the electrolyte. (Adapted from Gratzel, M., *Nature*, 414(6861): 338–344, 2001. With permission.)

photon absorption and ease of hole transfer. If the semiconductor is made of less electronegative anions, the VBM might move up and this will decrease the band gap and increase solar photon absorption, but, in turn, the driving force for hole transfer will also be decreased.

The electron along the CBM is "driven down" because of band bending and driven away from the semiconductor–electrolyte interface. *Note that band bending provides the driving force for the movement of the electrons and holes in the opposite direction.* Electron from the conduction band is transferred to the "counter electrode" (which is a metal in Figure 4.32.2), and cathodic reduction of the proton is performed at the surface of the metal electrode. The energy of the electron ejected from the counter electrode is determined by the CBM of the semiconductor photoanode and hence, for the reduction of a proton to occur at the metallic counter-electrode, the CBM level of the semiconductor should be higher than the empty energy levels available on the proton. As the orbitals of the cation make a greater contribution to the conduction band of the semiconductor, less electropositive cations will decrease the band gap, increase photon absorption, and decrease the driving force for electron transfer at the counter electrode.

Typically, the V_{bias} generated when light is incident on the semiconductor does not provide sufficient potential to split water. Hence, in addition to the photopotential generated due to exposure to light, an external electrical bias is applied in a manner similar to that of an electrolytic cell. However, the applied electrical bias is expected to be smaller than 1.6 V, which is the order of magnitude of bias in an electrolytic cell. More the generated photopotential upon light incidence, lesser will be the applied external electrical bias, and more efficient the solar energy harvesting using a PEC system.

In this section, we have attempted to provide an elementary discussion of the three physicochemical processes occurring in PEC systems—photoabsorption, electron–hole separation, and surface

electrochemistry. The physicochemical processes are much richer and many more intricate details can be added to this description to provide a quantitative description of PEC systems. The overall goal of such a description is to obtain a quantitative relationship for photocurrent as a function of solar intensity and electrical bias. These have been presented in many books and reviews in the past (see, e.g., Refs. [8,9,28,29]).

Model Identification and Refinement

The three processes central to PEC/PC—photoabsorption, electron–hole separation, and surface electrochemistry can be measured and modeled to varying degrees of certainty and success. Measurement of photoabsorption and rate of PECs reactions can be made rather conclusively [8,24]. Advancements in density functional theory (DFT) [26,30–46] have made it possible to screen a large number of materials for appropriate band gap, band edges and surface electrocatalytic properties. As of now, DFT provides the most accurate energetics for the material systems being considered for PEC/PC applications. Given this accuracy, it would be very useful to develop mathematical models via a bottom-up approach starting from the energetics based on electronic structure DFT calculations all the way to phenomenological mathematical quantities relevant to the measured photocurrents. While such advances have been made for electrochemical systems [47–49], accurate multiscale models for PEC systems has been beyond the reach of such approaches.

The most challenging aspect of PEC is to unambiguously quantify and model electron–hole separation. In this context, electrochemical impedance spectroscopy (EIS) has played an important role in yielding insights into these processes and on the dynamics of charge transfer [50,51]. In contrast to DFT, which is typically used for modeling "ideal" bulk and surface solids, EIS is used for modeling "real" experimental systems [50,51]. EIS has played an important role in discriminating between the competing models and have established the crucial role of surface states in PEC [48,52]. While the complexity of the system often demands more than one electrical circuit that fits the EIS data well, ascertaining the validity of the models via DFT seems very promising [51].

Absorption of light creates quasi-Fermi levels, which are hard to measure quantitatively. However, the "on-set potential" under light has been utilized as an approximation for quasi-Fermi levels in PEC systems [53]. Material design based on this strategy can be challenging because band positions of the materials are sensitive to impurities, defects, and surfaces [54]. Nevertheless, much progress has been made in aligning the energy levels of various molecules and semiconductors [55].

Aspects of Efficiency Metrics, Photoreactor Design, and Process Design

At a fundamental level, solar-based H_2 generation is a method for energy harvesting/energy conversion and the efficiency of this process can be captured by solar to hydrogen (STH) conversion efficiency [14,29,56]. The STH efficiency of a PEC water splitting system is defined for systems exposed to solar irradiance (1 Sun, Air Mass (AM) 1.5 global conditions) under zero bias conditions and these conditions ensures that no additional electrical bias is applied between working and counter electrodes. In order to avoid chemical potential bias, the working and counter electrodes are at the same pH and the electrolyte should not contain any sacrificial donors or acceptors. Quantitatively, STH efficiency calibrates the ratio of the chemical energy of the hydrogen produced to the incident solar energy:

$$\mathrm{STH(based\ on\ collected\ H_2\ gas)} = \frac{(\mathrm{mmol\ H_2/s}) \times (237\ \mathrm{kJ/mol})}{(P_{\mathrm{total}})(\mathrm{mW/cm^2}) \times \mathrm{Area(cm^2)}}_{\mathrm{AM1.5\,G}} \times 100 \qquad \text{(R4)}$$

Note that in this equation, Gibbs free energy per mole of H_2 is $\Delta G^\circ = 237$ kJ/mol. The precise definition of AM 1.5 G are available in many text books (see, e.g., Ref. [21]). Typically, the extent of H_2 generated is monitored by mass spectrometry or gas chromatography. It is important to ensure

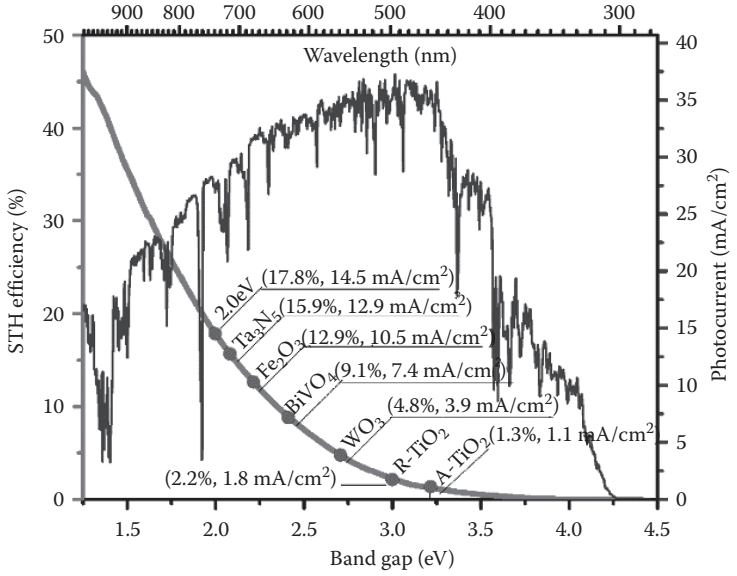

FIGURE 4.32.3 Plot of STH efficiency vs. material band-gap for important photo-materials: Right axis represents theoretical maximal photocurrent (j_{max}) and left axis represents STH efficiency are plotted against material band gap (E_g). (Reprinted from Li, J. and Wu, N., *Catal. Sci. Technol.*, 5(3), 1360–1384, 2015. Copyright © 2014, Royal Society of Chemistry with permission.)

that both H_2 and O_2 are evolved in stoichiometric proportions; deviations suggest corrosion of the electrode or other side reactions.

The short-circuit photo current (j_{SC}, mA/cm^2) can also be used to compute STH efficiency.

$$\text{STH (based on current)} = \frac{(j_{SC}\ \text{mA/cm}^2)\times(1.23\ \text{V})\times\eta_F}{(P_{total})(\text{mW/cm}^2)}\Bigg|_{\text{AM 1.5 G}}\times 100 \tag{R5}$$

where η_F is the Faradaic efficiency [24].

The most easily quantifiable factor that is correlated to the STH efficiency is the band gap of the material as the band gap determines the maximum theoretical photocurrent (j_{max}) (Figure 4.32.3). This might also be one of the reasons why most emphasis has been placed on modulating the band gap even though electron–hole recombination and surface electrochemistry also play a significant role in determining the STH efficiency. While many strategies have indeed succeeded in increasing the solar photon absorption, there has not been concomitant increase in the STH efficiency; one of the reasons might be that strategies to increase solar photon absorption have a deleterious effect on e^-/h^+ recombination [58].

As PEC systems have many coupled physiochemical processes, STH efficiency convolutes all these coupled processes and in order to deconvolute the efficiency of different processes, the following metrics are commonly used:

1. Applied bias photon to current efficiency (ABPE)
   In most semiconducting electrodes, unless external electrical bias is applied, significant current densities are not registered. Applying an electrical bias affects the extent of band bending and is expected to have a significant effect on e^-/h^+ separation and hence, the efficiency [9]. Such changes in efficiencies can be calibrated by ABPE, which is defined as:

$$\text{ABPE} = \frac{|j|(1.23 - V_{bias})}{P_{Sun}} \tag{R6}$$

where $|j|$ is the photocurrent density, V_{bias} is the electrical bias of the working electrode with respect to the counter electrode and not with respect to the reference electrode [59,60], and P_{Sun} is the incident solar power density. It is also important to thoroughly understand the difference between a "2-electrode" and "3-electrode" measurement [59,60].

2. Incident photon to current efficiency (IPCE)
While STH/ABPE does not differentiate between photons of different wavelengths, IPCE calibrates the efficiency of photons of different wavelengths, hence different energies, to generate photocurrent. It is defined as:

$$\mathrm{IPCE} = \frac{\dfrac{\mathrm{Electrons}}{\mathrm{cm^2 s}}}{\dfrac{\mathrm{Photons}}{\mathrm{cm^2 s}}} = \frac{j_{ph}\left(\dfrac{\mathrm{mA}}{\mathrm{cm^2}}\right)\times 1239.8(\mathrm{V}\times\mathrm{nm})}{P_{mono}\left(\dfrac{\mathrm{mW}}{\mathrm{cm^2}}\right)\times\lambda(\mathrm{nm})} \tag{R7}$$

where $1239.8(\mathrm{V}\times\mathrm{nm})$ arises from multiplying the Planck's constant (h) and the speed of light (c). While IPCE deconvolutes the effect of photons of different wavelengths, it does not deconvolute the three processes of photon absorption, e/h separation, and surface electrochemistry.

3. Absorbed photon to current efficiency (APCE)
To deconvolute optical processes like reflection and transmission from the overall PEC processes, APCE calibrates the photocurrent generated for every absorbed photon (of a particular wavelength), assuming that each absorbed photon generates an e/h pair. Thus, APCE convolutes only the efficiency of e/h separation and surface electrochemistry and is defined as

$$\mathrm{APCE} = \frac{j_{ph}\left(\dfrac{\mathrm{mA}}{\mathrm{cm^2}}\right)\times 1239.8(\mathrm{V}\times\mathrm{nm})}{P_{mono}\left(\dfrac{\mathrm{mW}}{\mathrm{cm^2}}\right)\times\lambda(\mathrm{nm})\times(1-10^{-A})} \tag{R8}$$

where A is the absorbance of the sample estimated from Beer's law [relates A to the logarithmic ratio of measured output light intensity (I) to initial light intensity (I_0)].

4. Intrinsic solar to chemical conversion (ISTC) efficiency
ISTC aims to calibrate the effectiveness of a photoelectrode even when the electrical bias is more than 1.23 V [56]; measurements are made within the 3-electrode system. ISTC is defined as

$$\mathrm{ISTC} = \frac{\eta_F\times 1.23\ (\mathrm{V})}{V_{dark}(\mathrm{V})}\times\frac{j_{photo}\left(\dfrac{\mathrm{mA}}{\mathrm{cm^2}}\right)\times V_{photo}(\mathrm{V})}{P_{solar}\left(\dfrac{\mathrm{mW}}{\mathrm{cm^2}}\right)}, \tag{R9}$$

where V_{photo} is the photo-voltage and is the difference between the voltage required to produce a particular current density in dark and light conditions. The voltage required to produce the same current density under illumination and η_F is the Faradaic efficiency [24]. Compared to ABPE, ISTC is more useful in terms of the solar energy conversion to Faradaic current when electrical bias is >1.23 V for some materials (please note that ABPE is not defined in this range).

When efficiency is less than 100%, as is always the case in any energy conversion device, it is important to have an insight into what possible factors contribute to losses in efficiency. In electrochemical literature [24], different "overpotentials" are indicative of physicochemical factors that contribute toward the loss of available free energy in an electrochemical energy conversion device.

Losses like concentration and activation overpotentials for water splitting are well documented in the electrochemical literature and these amount to at least 0.4 V; such losses may be present in PEC systems, but to a lesser extent as the current densities involved are smaller in PEC systems compared to a water splitting electrolytic cell. In addition to the losses mentioned earlier, there will also be collection losses as not all the products are being collected; both ohmic and collection losses might be more challenging in scaled-up photoreactors.

Many aspects of reactor and process design have been documented recently [22,23,61–63]. Among the photoreactors analyzed, the simplest and least expensive design is a slurry type reactor containing semiconducting photocatalytic particles. However, the main trade-off in this design is that the combustible mixture of hydrogen and oxygen is present in the same compartment. Pressure-swing absorption can be used for separating H_2 and O_2 mixtures from the reactor [22]. Analysis suggests that photocatalytic slurry-type reactors can be competitive with hydrogen generated from steam-reforming processes, *provided significant improvements are achieved in terms of the photocatalysts* [22].

It is beneficial to locate a solar-based hydrogen generation facility at places where there is high solar insolation. However, such places may not be sites where hydrogen is used. Due to these reasons, solar-based hydrogen economy may require additional technologies like hydrogen storage devices or fuel cells; these technologies are expensive and have not been implemented at large scales in an economical manner. In contrast to the solar-based hydrogen generation, the steam methane reforming route to generating H_2 is typically undertaken at the sites where H_2 is required. In light of these arguments, the process economics for 1 ton of solar hydrogen generation by locating the photoreactors in the vicinity of major petrochemical plants has been analyzed [23]. The solar insolation of these plants are different, but all of these plants have extensive and increasing need for H_2 [23]. The role of carbon credits was also taken into account and was used to evaluate the extent to which this will contribute to the process economics of solar-based hydrogen generation when contrasted with the steam methane reforming process that generates CO_2, but it was found that at the present levels of carbon credits, this does not significantly affect the process economics. While the critical factor that will determine the process economics is the efficiency of PC/PEC materials, we do feel, this process design of integrating solar-based hydrogen generation into traditional petrochemical complexes might be the first viable implementation of PC/PEC system [23], if these technologies are to be implemented at large scales in the future.

Realizable Efficiencies Are via Materials: Some Hope, Some Hype, and the New Hope

Literally thousands of materials have been explored in the context of PEC; it is not only impossible to review these results in this chapter, but also unnecessary as review of materials has been done many times over in many reviews [2,8–10,12,14,29,61,64–70]. Instead we focus on two classes of materials that have always posed considerable, but unrealized promise.

Titania: Black, White, and Colored

Sometimes a single class of materials, like Si for photovoltaics, zeolites for the petrochemical industry, changes the landscape of the entire field. Titania or functionalized titania, from the time of its use as a photoanode by Fujishima and Honda in 1972 [71], has appeared to be a "messiah material" for PEC, but that promise has not fructified. The main strengths of titania are that it is very stable in the electrolyte, inexpensive, non-toxic, and fairly abundant. However, the disadvantage of titania is that it is a high band gap semiconductor because of which it absorbs very little solar energy. Pure titania is "white." In addition, it does not have significant electrocatalytic activity compared to typical oxygen evolution electrocatalysts like RuO_2 and IrO_2 [72,73]. To alleviate the optical absorption, various kinds of doping [65,74,75] and sensitization strategies [2,76] have been employed. Photosensitization involves adsorption or ligation of a dye with greater

photoabsorption cross section than titania [2,76]. Doping has often involved anions that are less electronegative than oxygen, cations that are less electropositive than titanium, and, in general, such dopants introduce mid-gap states, all of which tend to increase absorption cross section. Introduction of aliovalent dopants or reduction of titania can also introduce vacancies and all this makes titania colored. In the extreme, certain treatments via hydrogenation can make it "black," which is indicative of very high photoabsorption cross section [75]. However, higher photoabsorption cross section comes at the cost of concomitant increase in e^-/h^+ recombination, due to which darker shades of titania have not showed significant improvement in overall efficiency. This points toward the fact that two of the physicochemical phenomena—photoabsorption and e^-/h^+ separation—are strongly coupled [58].

Silicon: Slender and Stable

As silicon (Si) is the main workhorse of the entire photovoltaic science and engineering, it is natural to explore its utility in PEC systems [77]. The main challenge, when it comes to PEC, is that Si is unstable in aqueous electrolytes of most pH and gets corroded, forming an insulating silica layer; numerous strategies are being attempted to overcome this issue [77]. These remedial procedures include coating Si surface with a stable overlayer like metal oxides, metals, organic compounds, and other functional groups [77]. In addition, the band gap of Si is 1.1 eV and hence, a single photon excitation from VBM to CBM does not provide the driving force (which must be ~1.6 eV) for water splitting. However, when used in a "tandem" configuration, where two Si-based photoelectrodes absorb one photon as a photocathode (wherein Si surface is stable) and one photon as a surface passivated Si photoanode, they can overcome the driving force for water splitting [78]. Also, the nanostructuring of Si, which is of much importance in a variety of modern nanostructured semiconductor devices [79], has been explored. The rationale behind the design of Si nanowires is to decrease the distance that the electronic carriers (at least one of them, either the electrons or the holes) have to travel before they can be utilized for surface electrochemistry.

In addition, Si nanowires have also been combined with titania nanowires to implement a "Z-scheme" [80], but such a design, while it enhances e^-/h^+ separation, will still be limited by photoabsorption cross section of titania.

Organic–Inorganic Perovskite: Let Us Wrap It Up

Organic–inorganic perovskite (OIP) materials are crystalline materials that have a composition ABX_3, wherein "A" is a small organic cation, "B" is a (typically a Group 14) metal like Pb, and "X" is a halogen. The most well studied OIP is methylammonium lead triiodide; OIP seems to pose revolutionary changes in the field of solar-based materials technology [81,82]. Many OIPs are anticipated to possess properties very relevant to good optoelectronic materials such as having an appropriate band structure for significant light absorption, long carrier lifetime, low carrier effective mass, very good electron and hole transport properties, relatively benign electronic defects, and most importantly, the fabrication of these materials is relatively inexpensive and requires ingredients that are Earth abundant [81,82]. The progress in these systems has been so rapid, it has even reached popular and well-respected financial news outlets [83]. The central challenges toward a wide-scale implementation of these materials are the presence of leachable Pb in the crystal framework, hysteresis, and most critically, chemical instability in the presence of moisture [82,84]. When a material is sensitive to moisture, it degrades very easily under electrolytic conditions relevant to the PEC systems. *Hence, compared to the photovoltaic applications, the PEC applications of OIP have been rather limited and have relied on wrapping up perovskites with a protective layer involving metals, polymers, "conformal" coatings, or with other functional groups* [85–87]. In any case, the science of OIP is very rich and engineering consequences of OIP are enormous; this class of materials will be explored thoroughly for its utility in PEC systems.

Roads Less Travelled: Some Challenges in Attaining the Holy Grail

Engineered e^-/h^+ Separation

Of the three physicochemical factors mentioned, optical absorption, e^-/h^+ separation, and surface electrochemistry, increasing photoabsorption cross section has been the most emphasized, probably because of the emphasis on improving titania; this has not led to a successful material. Even if an inexpensive material absorbs just 10% of the solar photons, but if all these photons can be collected toward generating H_2, we still may have a successful PEC material; in this process, being able to separate the generated electron and hole to the surface is rather crucial.

Of late, there has been a more focused demonstration of engineered e^-/h^+ separation and this often involves the formation of heterostructures with appropriate staggering of band positions so as to facilitate the migration of electron–holes in the opposite directions. While the arguments are based on band alignments at the interface of the heterostructures and impedance changes, a much more detailed experimental and computational study should be undertaken to unfold the nature of the interface. Many of the interfaces that are formed do not have an epitaxial relationship and hence, it is expected that there will be dislocations/broken bonds and associated electronic defects. It is not clear how these will influence e^-/h^+ separation and it is possible that phenomenon like pinning of electronic states, in a manner analogous to Fermi level pinning might occur at the interface.

We are addressing this problem using "isomaterial native/non-native heterostructures" [88–90]. Non-native and "native" bulk structures differ in their discrete translational symmetry—for e.g., in titania, rutile is the native structure and anatase is a non-native structure and the commercial P-25 Degussa heterostructures used as a heterogeneous catalysts might be a commonly occurring isomaterial native/non-native heterostructures. The rationale, in the context of PEC, is that the formation of an interface between a native and non-native crystal structure, but with same chemical composition (and hence, "isomaterial") may decrease electronic defects that harm carrier transport [90].

Decoupling PEC, Electrochemical, and Heterogeneous Catalytic Metrics

While photoelectrocatalysts, electrocatalysts, and heterogeneous catalysts all are functional materials aimed at catalyzing chemical reactions, it is useful to compare the level to which the active sites are characterized quantitatively in heterogeneous catalysis, electrocatalysis, and in PC/PEC. Even though heterogeneous catalysts are themselves complex, the complexity of these materials is less than electrocatalysts and photocatalysts. Significant efforts have been spent in heterogeneous catalysis, with considerable success, to identify active sites at a molecular level and to characterize the activity in terms of the turnover frequency [91] and at the level of single-site heterogeneous catalytic sites [92]. Similarly, considerable knowledge on how to identify and characterize active sites at a molecular level has also been achieved [93]. However, when it comes to PC/PEC, part of the activity depends on "optical active sites" and partly on the "surface electrochemical active sites." In addition, strategies used for enhancing optical cross section will not only influence e^-/h^+ separation but also surface electrochemistry. For instance, numerous dopants have been used for enhancing the optical absorption of titania, but it is also known in the heterogeneous catalysis community that dopants have influence in the Mars–Van-Krevelen mechanism [94,95] and also induce non-Mars–Van-Krevelen oxidation mechanisms [95,96]. Hence, it is quite possible that the changes in PEC activity is not just due to dopant-induced changes in optical cross section, but can also be due to dopant-induced changes in surface electrochemistry, and this issue has not been adequately quantified. We feel that as PEC is a strongly coupled physicochemical phenomena, it is important to decouple the interlinked effects to test the effectiveness of different material design strategies.

Are All Potentials Created Equally?

Despite enormous effort and research over the past four decades, we feel that measurements and models for photopotentials developed are still inadequately standardized, especially considering that photopotential is a very fundamental quantity. Some models for photopotential infer the

magnitude of the photopotential primarily based on band edges [37], whereas many other estimates are based on quasi-Fermi levels [97]. It is also not clear whether the photopotential is entirely determined by thermodynamics factors or based on other kinetic factors; such issues have been explored in dye-sensitized solar cells more thoroughly [98]. Also, it is not clear if the *photopotential* generated upon exposure to sunlight amounts to an additional *electrochemical potential*, although the measurement of open-circuit voltage [29] and the definition of intrinsic solar to chemical conversion [56] suggests this to be the case. As photopotential is a strong indicator of the driving force for water splitting, it would be useful to characterize this very fundamental physicochemical property as accurately as possible.

Heavily Doped Semiconductors

In the context of optoelectronics devices, what is *chemically* pure is *electronically* impure as just a few percent of chemical dopants/vacancies make a semiconductor heavily doped. In a heavily doped semiconductor, the depletion width decreases significantly and with it, the driving force that exists at the semiconductor–electrolyte interface to separate e^-/h^+ is also much suppressed. While the theory of heavy doping is well developed in the context of semiconductor devices, it has been addressed to much lesser extent in PEC systems and this gap needs to be filled for more fundamental understanding of PEC principles.

Interfacial Structure and Dynamics of Surface State

It can be anticipated that the crystal coordination structure near the electrolyte interface may be different from the bulk crystal structure. For instance, computations suggest ZnO, which is fourfold coordinated in the bulk, can form a sixfold coordinated structure near the electrolyte interface [99]. These "near-surface non-native structures" are hard to characterize experimentally, but if proved, they will have important consequence in terms of band alignments, band–band bending, and surface electrochemical properties. In general, the interfacial structure is expected to be rough. The transition from being a semiconductor to an electrolyte might be gradual, and it is not clear how this will influence the band bending and other fundamental properties of PEC systems. While recent DFT studies have advanced our understanding of surface states [51], the picture is still a static picture wherein the changes in surface atomic structure to diffusion of reactants/products is not taken into account. If such changes are incorporated, it may be possible to obtain a more detailed dynamic view of surface states and their influence on PEC processes.

Concluding Remarks

The endeavor of a chemical approach to solar energy-driven generation of renewable fuels/chemicals/hydrogen has been rich in science, promised immense engineering consequence, and has had infrequent unraveling of "breakthrough" materials; all these have kept the quest of solar-based hydrogen alive for more than four decades. Within this period, it is not uncommon to observe that a generation of scientists who have entered the field anew pose a surreal recycle of questions, whose answers may have been partially reposed by an earlier generation of scientists, who have moved on to the other fields. The apparent simplicity is beguiling as it hides the complex convolution of physicochemical events that a single material interface is supposed to accomplish. From classical semiconductor materials like Si to the newest class of materials, the organic–inorganic perovskites, materials are being investigated via newer avatars (like nanostructures) with the hope that the three fundamental properties—optical absorption, electron–hole separation, and surface electrochemistry—which are intricately coupled, are better optimized within a single material interface. However, it is not clear whether too much is being asked from a single material interface. A partial decoupling of the aforementioned three physicochemical events is possible via solar cells driving an electrolyzer, and this has been a possibility for some time now for achieving significant amount of solar-based hydrogen, but for the economics and a probable lack of scientific intrigue. The gradual

progression in understanding is hoped to pave a natural pathway for the realization of artificial photosynthesis in the not too distant future. Even if the solar-based hydrogen does not live up to its promise as a competitive energy source, we hope that it may still serve as a source of "renewable reductant" to facilitate large-scale chemical reduction of CO_2.

ACKNOWLEDGMENTS

Almost all of the work undertaken in our group in this area is in collaboration with Dr. Sri Sivakumar, Department of Chemical Engineering, IIT Kanpur and his contributions to our work have been invaluable. Discussions with professor B. Viswanathan, National Center of Catalysis Research, IIT Madras have always been enlightening. Some parts of the work have been performed in collaboration with professors. Malay Das and K. Muralidhar, Department of Mechanical Engineering, IIT Kanpur. A host of students, Arun Kumar Upadhay, Dilip Kumar Behara, Babu Radhakrishnan, Gyan Prakash Sharma, Ashok Ummireddi, Gyan Maurya, Sayantan Sasmal, Sulay Saha, and Koshal Kishor continue to contribute to my understanding in this field, for which I am very thankful. This work would not have been possible without the support of the Department of Science and Technology, India and the Indian Space Research Organization.

4.33 PASSIVE AND ACTIVE SOLAR DISTILLATION

Desh Bandhu Singh and G.N. Tiwari

Introduction

Pure water, clean environment, and electricity are considered as the basic needs for the survival of human beings on the planet earth. The available sources of water are rivers, lakes, seawater, icebergs, and underground water reservoirs. Figure 4.33.1 shows the distribution of water on the surface of the earth. Water covers more than 67% of the earth's surface. However, the major portion (97%) of this world's water is salty. Less than 3% of available water on earth is freshwater. Out of this freshwater, more than 2% water is locked up in ice caps and glaciers of Polar Regions and a very small amount (only <1%) is within human reach which can be used for drinking, agriculture, and industrial purposes. This small quantity of water is believed to be sufficient to support life and vegetation on earth. However, the available freshwater is fixed on earth and its demand increases day by day due to increase in population. It leads to an essential and earnest need to get freshwater from saline/brackish water present on the planet earth.

According to the United Nations (2004) report, more than one billion people are not having access to fresh drinking water and it has been analyzed that 2/3rd population of the world will face a shortage of water from 2025 onward. As per UNICEF (2004) report, more than 1/6th people lack access to safe drinking water and more than 1/3rd people lack adequate sanitation. The driving force for the requirement of freshwater is domestic, agriculture, and industrial areas. The use of potable water resources fluctuates from country to country. Figures 4.33.2 and 4.33.3 present the use of potable water requirement in various sectors of low- and high-income group countries, respectively. High-income group countries have higher water requirement for industries and household sectors in comparison to that of low-income countries. However, agriculture sector needs the highest percentage of potable water in both low- as well as high-income group countries.

A number of water treatment technologies are available. However, distillation using solar still which takes input as sunlight is an environmental friendly alternative for getting freshwater in the far-flung area for cleaning underground brackish water (salinity ~10,000 ppm). It is a renewable, eco-friendly, easy to operate, and low-cost technology. Hence, it can be a promising solution to the problems of shortage of drinking water, energy security, and climate change.

Solar distillation systems can effectively remove many impurities ranging from salts to microorganisms. It can remove impurity of water mainly salinity, iron, manganese, fluorides, heavy metals, bacterial contamination, and pesticide/herbicide. As per World Health Organization, the allowable limit of salinity in water is 500 ppm and it can be up to 1000 ppm in special cases. The salinity level of most of the water available on earth in terms of total dissolved salts is up to 10,000 ppm. However, seawater normally has salinity in the range of 35,000–45,000 ppm. The excessive brackishness affects the taste, causes the stomach problems and other diseases. The permissible salinity limits of 500 ppm or less can be accomplished by the solar distillation system to desalinate water for remote habitation where salty or brackish water is available for survival.

The solar distillation can be useful for the places where power is not available and demand is <200 m^3/day. The setting up of water pipelines is uneconomical and delivery by truck is unreliable and expensive on the hilly area. The other desalination plants are uneconomical for low-capacity potable water demands at such places. Under these situations, solar stills which are self-sustainable can ensure regular supply of water. All conventional desalination plants need fossil fuels either directly (thermal) or indirectly (conversion to electricity). More than half the population of the world depends on desalinated seawater. This scenario is not sustainable for the future. Using solar thermal energy for desalination is environmental friendly, free, and sustainable.

Thus the purification of polluted water by solar distillation is the most prominent method. The solar distillation system can be used anywhere with lesser number of problems as it requires

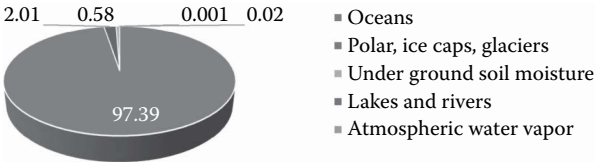

FIGURE 4.33.1 Availability of water on the earth surface (percentage).

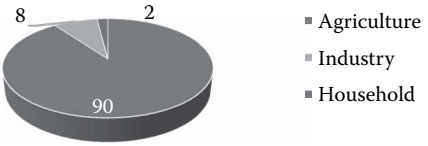

FIGURE 4.33.2 Use of freshwater requirements in low-income countries.

FIGURE 4.33.3 Use of freshwater requirements in high-income countries.

comparatively simple technology, low maintenance, and only sunshine to operate. It is suitable for places where (1) hot climatic conditions exist during major part of the year; (2) water transportation cost is high; (3) fuel supply is expensive and unreliable; (4) rainfall is <50 cm per year; and (5) only saline/brackish water is available.

Distillation Process

When the solar energy falls on the surface of brackish/saline water, the temperature of water rises; it gets evaporated and vapor is formed. Further, the vapor condenses and distillate will come as an output. This is an open cycle process as shown in Figure 4.33.4. However, solar still is based on a closed cycle.

Basic Principle of Solar Distillation

Solar distillation technology uses solar radiation as the source of heat energy to obtain potable water with the help of a device known as the solar still. It is based on the principle of greenhouse effect and evaporation/condensation of water. Figure 4.33.5 represents the schematic diagram of conventional single-slope passive solar still. It is a box-type structure made up of fiber-reinforced plastic (FRP), galvanized iron (GI) sheet, wood or concrete covered with some insulation to prevent the heat loss from the bottom and side walls. The box is covered with a glass cover which is inclined

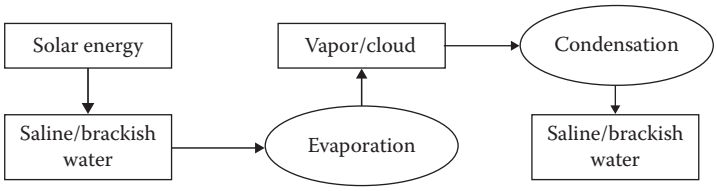

FIGURE 4.33.4 Distillation process (hydrogen open cycle).

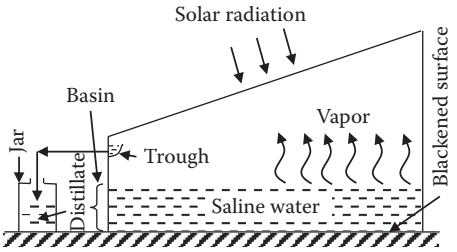

FIGURE 4.33.5 Conventional single-slope passive solar still (south oriented).

with the horizontal surface to facilitate the trickling down of water condensed on the inner surface. The condensed water at the inner surface of glass moves down due to the component of gravitational force acting along the glass cover. The bottom surface of the box is blackened from inside to absorb almost all radiation falling on it. This blackened (painted black) surface is generally known as basin liner.

The major portion of solar radiation falling on the surface of glass cover is transmitted to water mass in the basin after reflection and absorption by it. A small portion of solar radiation reaching the water surface is reflected back and absorbed by water mass and remaining portion is transmitted to basin liner where it is mostly absorbed. The attenuation of solar radiation in water mass depends on its depth and absorptivity. The temperature of basin liner increases which further transmits most of its heat to water mass by convection and a small portion of heat is lost to the atmosphere by conduction. Hence, the temperature of water increases which creates a temperature difference between water and glass surface. Heat is transferred from water surface to glass cover by three modes namely evaporation, convection, and radiation. The evaporated water undergoes film-type condensation after releasing the latent heat at the inner surface of the glass cover. The condensed water trickled down the glass cover and it is collected in a trough fixed at the lower end of the glass cover. The collected water in the trough is allowed to flow to the jar through a pipe and it is taken out for further use. Here, it should be noted that the distilled water obtained is not fit for direct use in drinking and cooking application as it lacks the minerals. However, it can be made suitable for these applications after adding the required minerals needed for human beings. The thermal energy received by glass cover by convection, radiation, and latent heat is lost to the atmosphere by convection and radiation. The daily yield from single-slope passive solar still may vary from 0.5 L/m^2 (winter) to 2.5 L/m^2 (summer).

The advantages of solar distillation system/solar still over other desalination technologies are as follows:

1. It contains no moving parts to run the system in passive mode.
2. It is an easy and cost-effective technology to provide potable water for the domestic and commercial level.
3. It requires only solar energy for its operation which is renewable and nonpolluting.
4. No skilled labor is required for its operation and maintenance.
5. It is possible to manufacture and repair locally.
6. It gives a sense of satisfaction in owning a trusted and easy to use water treatment plant.
7. It is very useful for remote settlements where only saline water is available.
8. It is self-sustainable and it can also meet electricity requirement up to certain extent when operating in active mode integrated with the photovoltaic (PV) module.

However, a solar distillation system has some demerits also which sometimes may limit the use of technology for large-scale production. It includes (1) dependency on weather for input energy, (2) requirement of large solar collection area for commercial use, (3) low interest of producer, (4) low

efficiency, (5) comparatively higher initial investment, (6) need of frequent filling and flushing of solar still, and (7) requirement of system to be robust as it is installed in open space.

The application of solar distillation technology includes (1) production of potable water as well as DC electric power for remote areas where electricity has not reached so far, (2) hospitals, (3) automobile garage, (4) workshops, (5) laboratories, (6) educational institutions, and (7) cleaning of kitchen utensils and mechanical parts.

Material Requirement of Solar Still

Although, the local material can be used for manufacturing solar still if we need a cheaper and insulating material and want to facilitate necessary repairs. However, solar still manufactured from such material will not last long. Also, a high-quality material will increase the cost of solar still but at the same time, it will survive for a longer time. In such case, one should introspect whether one need an inexpensive and short-lived solar still that requires replacement or repair every few years, or manufacture something more durable and long lasting with the hope that the distilled water produced will be cheaper in the long run.

The material used for making the solar still should be able to bear a long life and it should also be inexpensive enough so that it can be replaced after degradation. It must be strong enough to bear minor earth movements and wind pressure. It should be nontoxic. It should not release vapors or encourage an unpleasant taste to the water at elevated temperatures. It should be corrosion resistant against saline water and distilled water. It should be compact enough and easy to handle so that it can be carried by local transportation. The film-type condensation should occur at the inner surface of glass cover as the formation of water droplets there will reduce the intensity of radiation falling on the surface of water because water droplets act as a mirror which will reflect the solar intensity. Solar still may be constructed using concrete/cement, GI sheet, FRP with the top cover of transparent material like glass, plastic, etc.

Classification of Solar Distillation System/Solar Still

Solar still also known as solar distillation system is a device that converts saline/brackish water into potable water with the help of solar energy. It imitates the natural distillation process with the difference that it operates in a closed loop. It can be classified into two parts namely passive solar still and active solar still. Saline or brackish water is directly fed into the basin in passive solar stills (Kudish et al., 1982; Delyannis and Delyannis, 1983; Tiwari et al., 1986; Yadav and Tiwari, 1987; Clark, 1990) but for active solar stills, there is an additional source of heat to provide thermal energy. This thermal energy is added to the saline/brackish water into the basin of passive solar still to increase the rate of evaporation.

The additional source of heat may be included through collector/concentrator (Rai and Tiwari, 1983; Fernandez and Chargoy, 1990; Lawrence and Tiwari, 1990; Zaki et al. 1992; Kudish et al., 2003) or waste heat energy from any industrial plant (Tleimat and Howe, 1966), etc. Further, it can be divided into two parts namely single-slope and double solar still on the basis of its structure and positioning. The orientation of single-slope solar still is due south and for double-slope solar still orientation of one glass cover is due east and other is kept due west to collect maximum solar radiation. The orientation of single-slope solar still is due south for the southern globe and due north for the northern globe. The complete classification of solar distillation systems has been given in Figure 4.33.6.

The double-slope solar still (passive) may be symmetrical or unsymmetrical. In symmetrical-type double-slope solar still (passive), both glass covers have the same area and their angles of inclination with horizontal are also the same. However, the orientation of solar still glass covers is dissimilar. No external energy is given. In unsymmetrical-type double-slope solar still (passive), both glass covers do not have the same area and the angle of inclination with horizontal is not the same.

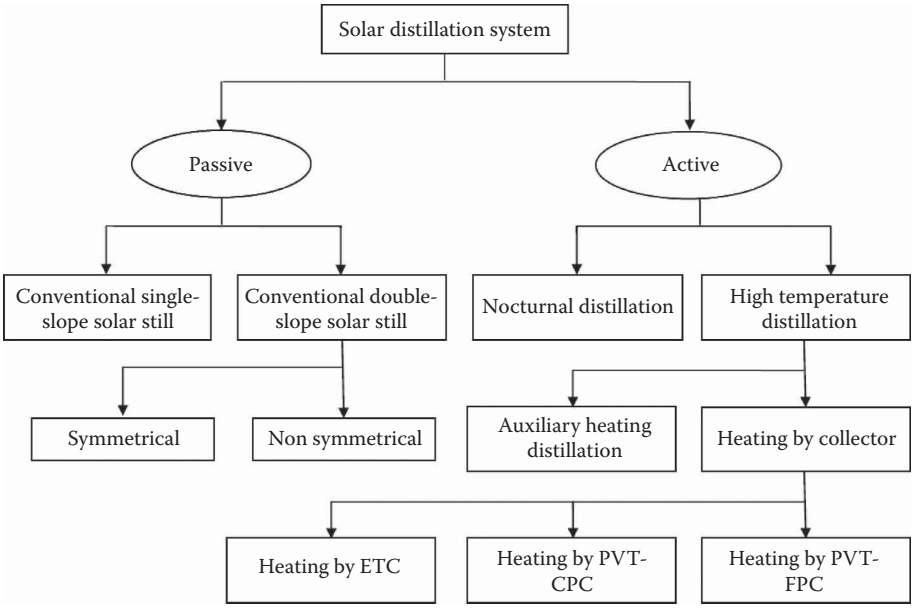

FIGURE 4.33.6 Classification of solar distillation system.

The active solar still can be divided into two parts namely nocturnal distillation and high-temperature distillation. In nocturnal distillation, solar energy is used in day time and waste thermal energy of industrial plant is used at night when the solar energy is not available. Waste heat from heat treatment plant (food, chemical and textile industry, etc.) is transmitted to the solar still with the help of heat exchanger.

Further, high-temperature distillation is divided into auxiliary heating distillation and heating by collectors (photovoltaic thermal (PVT)). The flat plate collector (FPC) may be alone or it may be fully or partially covered by photovoltaic (PVT-FPC). Further, PVT-FPC may be integrated with parabolic concentrator in which case, it is known as photovoltaic thermal-compound parabolic concentrator (PVT-CPC) collector. FPC is alone used for thermal energy generation which is supplied to the solar still. To develop a self-sustainable system, FPC is fully or partially covered by PV due to which both thermal energy and electrical energy are generated. Thermal energy is supplied to solar still and some part of electrical energy is used to run the pump for water circulation. The rest part of the electrical energy may be used for storage/other application. PVT-FPC is integrated with parabolic concentrator to reflect the beam radiation to receiver area.

Historical Background

Historically the earliest documented work on solar distillation is that of Arab alchemists in the 16th century (Mouchot, 1869). According to Arab alchemists, polished Damascus concave mirrors could be used for solar distillation. Wide earthen pots were used for distillation (Della Porta, 1589). These earthen pots were kept in sunlight to receive the solar radiation to heat, water got evaporated and condensate was collected into the container placed underneath (Nebbia and Menozzi, 1966). In 1862, Lavoisier, a French chemist, made use of large glass lenses fitted on supporting structure with an aim to converge solar energy on to the distillation flask filled with water. Mouchot (1869) has also described the use of silver- or aluminum-coated glass reflectors to concentrate solar energy for distillation purpose.

The solar still was first designed and constructed in 1872 by Carlos Wilson in Northern Chile. It was actually a basin-type solar still designed to produce potable water for meeting the drinking

water needs of the mining community in residing in Las Salina area. The system was constructed using a series of wooden bays (each of dimension 1.14 m × 61.0 m) making up an overall surface area of about 4700 m^2. The top portion was covered with glass and the bottom portion was painted black with logwood dye and alum for increasing the absorption of sunlight. The bays were filled with saline water and the same was allowed to evaporate due to solar radiation falling on it through the glass. It then condensed over the glass cover and trickled down into the container kept to store distilled water. This device worked satisfactorily for almost four decades and the daily yield of about 4.9 kg/m^2 was attained in summer season (Harding, 1883).

Not much work on solar distillation was documented between the 1880s and the end of First World War due to slow research progress in the field of solar energy. Then, with the revitalization of interest, a number of solar-based systems viz. roof type, V-covered, tilted wick, inclined tray, suspended envelope, tubular stills, etc., were reported. Solar concentrators made of metal-coated reflectors were developed for solar distillation applications (Kausch, 1920). Further, Pasteur, in 1928, reported the use of a number of concentrators to reflect the solar radiation on to a water-filled copper boiler. The steam from the boiler was then allowed to flow to the distilled water collector through a water-cooled condenser. Use of aluminum-coated cylindrical parabolic reflectors for focusing the solar energy on evacuated water tubes was reported in the literature (Abbot, 1938). An efficiency (explained in Section 4.33.9.3) of as high as 80% could be attained. Boiling of water in tubes, however, created certain problems. During Second World War, an air inflated still made of plastic was developed by Telkes (1945) for US defense forces. US Navy used as many as 200,000 of these stills during the war.

As a next stage, the forced air circulation in stills was tried with an aim to increase the vapor condensation rate so that higher distillate might be obtained. Many researchers studied the exploitation of latent heat of vaporization in multieffect systems and preheating the brine to increase the distillate output. Many researchers have suggested the integration of desalination of water with electric power generation to increase the overall operating efficiency of the plant.

The basin-type solar stills, also called greenhouse roofs, are in an advanced stage of evolution. A number of researchers have reported the effect of design, operational, and climatic parameters on the performance of such stills. Cooper investigated the performance of basin-type still and concluded that the maximum efficiency of such a system that could be achieved is 60% (Cooper, 1969a,b, 1973a,b). Frick proposed a mathematical model based on sine wave heat flow assumption and employed thermic circuits and Sankey diagrams for modeling (Frick, 1970). Hirschman and Roefler (1970) studied the relationship between of heat capacity and the performance of still considering periodic insolation. Further, Baum et al. (1970), Nayak et al. (1980), and Sodha et al. (1980) have also presented the periodic and transient analysis.

Recently, many other types of solar stills have also been proposed and studied. Talbert et al. (1970) presented a review on the solar still. Delyannis and Delyannis (1973) presented the review of major solar distillation units around the world. Oltra (1972) investigated multieffect solar stills. A tilted tray or inclined–stepped solar stills were proposed by Howe (1961) and Akhtamov (1978). Frick and Sommerfeld (1973), Sodha et al. (1981), and Moustafa et al. (1979) studied the tilted, wick-type and multiple wick-type solar distillation systems. Norov et al. (1975) and Menguy et al. (1980) have investigated the solar film covered still and wiping spherical stills. Soliman (1976), Malik and Tran (1973), and Malik et al. (1982) investigated indirectly heated solar stills. Researchers have also investigated several designs including reflectors, the effect of heat-storing materials, climatic, operational, and design parameters with modifications in the conventional-type solar stills for the last 40 years with significant improvement in terms of yield, efficiency, and reported several studies.

A review on passive solar still till 1982 was done by Malik et al. (1982) and it was updated up to 1992 by Tiwari (1992), which also incorporate active solar still. Rai and Tiwari (1983) studied the active solar still in forced mode theoretically for the first time and found that the daily yield was 24% higher than conventional solar still. At the same time, Zaki et al. (1983) studied the active solar still under natural circulation mode for the first time and reported a maximum increase in yield of

33% in comparison to conventional solar still. Tiwari and Dhiman (1991) investigated the solar still augmented with collectors experimentally and the thermal model was validated with experimental results. The heat exchanger was used in the basin for transferring the thermal energy of collector fluid (water) to water in the basin and they found the rise in yield by 12% if the length of the heat exchanger was increased by 100% (6–12 m). Lawrence and Tiwari (1990) developed an empirical relation for internal heat transfer coefficient on the basis of theoretical results for such systems. Hamadou and Abdellatif (2014) provided for heating the solar still at its bottom by a circulating heat transfer fluid and reported a considerable increase in productivity. They found that doubling the heat transfer fluid rate effected 9% improvement in distilled water yield. The relation between distilled water production and the heat transfer fluid rate is thus nonlinear.

The optimum number of collectors for maximum yield in the case of solar still coupled with collectors is 8 m^2 as the increase in gain becomes lower than thermal loss (Kumar and Tiwari, 1998). They have reported that the daily yield and overall thermal efficiency decline if basin area is increased which occurs because of the large heat content storage capacity for a given depth of water. Tiris et al. (1998) investigated basin-type solar still augmented with two flat plate solar collectors experimentally and reported an average increase of 100% in the yield of active solar still in comparison to conventional solar still. The productivity of active solar still decreases with increase in water depth; however, it increases with the increase in solar flux (Badran and Al-Tahainesh, 2005). Tripathi and Tiwari (2005) investigated the active solar still for the effect of water depth on internal heat and mass transfer and concluded that convective heat transfer depends on water depth. They also reported that the yield was higher during the off-sunshine hours than day time if the depth of water is more due to the heat content of water mass. Badran et al. (2005) studied single stage basin-type solar still augmented with FPC and reported 52% increase in yield in comparison to conventional solar still. Dwivedi and Tiwari (2010) investigated double-slope active solar still under natural circulation mode experimentally and reported that the thermal efficiency was lower and exergy efficiency was higher in comparison to conventional double-slope solar still.

Sinha et al. (1994) studied active solar distillation system as an investment alternative to a solar hot water system and concluded that the annual operating cost of the solar water heater was higher than that of the solar still. However, the cost of hot water was much less than the cost of distilled water. Kumar and Sinha (1996) studied the double-slope solar still integrated with nontracking-type cylindrical parabolic concentrator and concluded that the yield obtained was higher than FPC-coupled solar still. Kumar et al. (2000) found that for maximum annual yield, the optimum collector inclinations of a flat plate collector and still glass cover are 20° and 15°, respectively, for New Delhi climatic condition. Lourdes et al. (2002) made a comparative study of solar still integrated with solar pond, FPC, evacuated tube collector (ETC), compound parabolic collector, and parabolic trough collector for direct steam generation (DSG) and concluded that DSG was a promising technology for solar-assisted sea water desalination. Zuriat and Abu-arabi (2004) investigated the regenerative solar still and reported that the productivity of the regenerative solar still was marginally affected by the thickness of water at the top of the first condensing cover and the amount of water flowing per unit time going into the second effect. Tiwari and Tiwari (2005) calculated the annual performance of solar stills at different water depth and inclinations of condensing covers. Further, Tiwari et al. (2007) did the thermal modeling of basin-type solar still integrated with FPC, concentrating collector, ETC, and ETC with pipe and reported an overall thermal efficiency as 13.14%, 17.57%, 17.22%, and 18.26%, respectively. They found their average exergy efficiency in the range of 0.59%–1.82%. Abdel-Rehim and Lasheen (2007) studied solar still using heat exchanger and tracking concentrator experimentally and found an increase in productivity by 18% as compared to conventional solar still.

El-Sebaii et al. (2009) studied theoretically the performance of active single-basin solar still with a sensible storage material and concluded that daily productivity of the solar still with storage was 23.8% higher than that when it was used without storage. They used sand as the storing material. Arslan (2012) investigated the performance of various designs of active solar stills under closed

cycle mode experimentally and concluded that the circular box active solar still design produced highest overall daily efficiency. Taghvaei et al. (2014) investigated experimentally the long-term (more than 2 days) effects of water depth on the performance of active solar stills and recommended the higher depth of water in the basin for practical use of solar still. Lilian et al. (2014) have developed a solar distillation system in which a partly immersed slowly rotating low-weight hollow drum was led within the cavity of the solar still. They found an average improvement in water yield by 20%–30% in comparison to simple solar still. Rajaseenivasan et al. (2014) investigated solar still integrated with FPC and the basin of solar still was distributed into small sections. They found 60% increment in yield as compared to conventional solar still.

The integration of PVT with FPC results in the increase in efficiency of solar cell and utilization of residual thermal energy for distillation. The advantage is that comparatively higher electricity will be produced by PV module due to lower temperature and the system becomes self-sustainable. Hendrie (1979) presented a theoretical model on PVT systems using conventional thermal collector techniques. Bhargava et al. (1991) investigated the effect of air channel depth, length, air mass flow rate, and part of absorber plate area covered by solar cells (packing factor, PF) on a single pass. They concluded that the overall electrical efficiency of the PV module can be enhanced by increasing the packing factor and reducing the temperature of the PV module by withdrawing the thermal energy associated with the PV module. Tiwari et al. (2011) have reviewed various PV modules and their applications, especially PVT solar distillation system and thermal modeling for overall thermal energy and exergy analysis. Estahbanati et al. (2015) carried out a study to predict the effect of number of stages on productivity of multieffect active solar still in both the modes viz. continuous and noncontinuous. They concluded that the distillate production varies with number of stages in a quadratic fashion as we switch from noncontinuous to continuous mode, for instance, a five-stage system would produce 25% more freshwater in continuous mode than in noncontinuous mode.

Kumar and Tiwari (2008, 2009, 2010) designed and validated the solar still integrated with PVT-FPC and concluded that the yield of active solar still increased by more than 3.5 times than the passive solar still. They found the payback period of active solar still in the range of 3.9–23.9 years. The work of Kumar and Tiwari (2010) was further extended by Singh et al. (2011) for double-slope solar still. Eltawil and Omara (2014) investigated the performance of solar still by incorporating PVT, FPC, and hot air and found an increase in productivity by 51%–148% in comparison to conventional solar still. Calise et al. (2014) designed a novel poly-generation system employing photovoltaic/thermal collectors, absorption chiller, multieffect distiller, storage tank, auxiliary heater and balance of plant devices for seawater desalination in European Mediterranean countries, known to be rich in renewable sources but poor in fossil fuels and water resources. Tiwari et al. (2015) and Singh et al. (2016) designed, fabricated, and validated the single-slope PVT-FPC active solar distillation system and concluded that the thermal efficiency was lesser than the system proposed by Kumar and Tiwari (2010) and Singh et al. (2011). However, exergy efficiency and overall thermal efficiencies were found to be higher. Saeedi et al. (2015) have studied the optimization of PVT solar still taking energy efficiency as objective function and found the optimum value of mass flow rate and number of collectors as 0.044 and 7 kg/s. They used simulation technique for optimization. Singh et al. (2016) have presented the theoretical analysis of the effect of energy matrices on life cycle cost analysis of single- and double-slope passive solar stills for the same basin area under similar climatic condition and concluded that single slope performs better than double-slope on the basis of annual exergy gain, annual energy output, thermal efficiency, exergy efficiency, life cycle conversion efficiency (LCCE), energy payback time (EPBT) based on exergy, energy production factor (EPF) based on exergy and exergo-economic parameter. However, double performs better than single-slope passive solar stills on the basis of annual productivity, EPBT based on energy and EPF based on energy. Recently, Singh and Tiwari (2016) have studied single- and double-slope solar stills integrated with N identical partially covered PVT-CPC water collectors at 0.14 m water depth, optimum number of collectors

and mass flow rate for the same basin area under similar climatic condition to assess the life cycle cost by incorporating the effect of energy payback period. They have concluded that single slope performs better than double-slope PVT-CPC active solar distillation system on the basis of energy matrices and cost of water.

Heat Transfer in Solar Still

The performance of solar still is affected by all heat exchanges that define temperature of water, basin liner, inner surface of glass cover, outer surface of glass cover and yield. Here, it is interesting to note that there are two opposing phenomena. On one hand, the aim is to store maximum energy to increase the temperature like basin. On other hand, the aim is to lose maximum energy so that maximum production of distillate in the solar still can be ensured. The energy flow diagram of a conventional single-slope solar still with its equivalent thermal circuit diagram is shown in Figure 4.33.7 in which $\dot{q}$ and C represent rate of heat transfer and heat capacity, respectively. The various heat transfers and heat capacities at different stages such as water-glass, glass-ambient are water-ambient are considered in electrical analogy. The fraction of solar intensity at different components of solar still unit (Tiwari et al., 1989) can be written mathematically as follows:

Fraction of solar intensity absorbed by glass cover, $\alpha'_g = (1-R_g)\alpha_g$

Fraction of solar intensity reflected by water mass, $R'_w = (1-R_g)(1-\alpha_g)R_w$ Fraction of solar intensity absorbed by water mass, $\alpha'_w = (1-R_g)(1-\alpha_g)(1-R_w)\alpha_w$. Fraction of solar intensity absorbed by basin liner, $\alpha'_b = (1-R_g)(1-\alpha_g)(1-R_w)(1-\alpha_w)\alpha_b$. Fraction of solar intensity lost to the ambient through water and glass cover, $(1-R_g)(1-\alpha_g)(1-R_w)(1-\alpha_w)(1-\alpha_b)$, where R and α represent the reflectivity and absorptivity, respectively; g, w, and b are suffix for glass cover, water mass, and basin liner, respectively.

However, if attenuation of solar intensity within water mass is considered, then α'_w and α'_b is expressed as follows:

$$\alpha'_w = (1-R_g)(1-\alpha_g)(1-R_w)\left[1-\sum \mu_j \exp(-\eta_j d_w)\right]$$

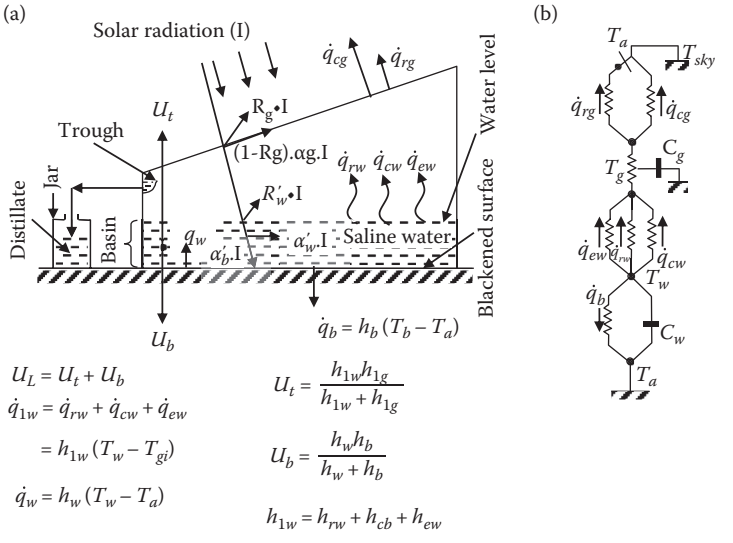

FIGURE 4.33.7 (a) Energy flow diagram of a conventional single-slope solar still and (b) equivalent thermal circuit diagram of conventional single-slope solar still.

where $\sum \mu_j \exp(-\eta_j d_w)$ is the attenuation factor in which d_w is the depth of water.

$$\alpha_b' = (1-R_g)(1-\alpha_g)(1-R_w)\alpha_b\left[\sum \mu_j \exp(-\eta_j d_w)\right]$$

Hence, the fraction of solar intensity lost to the ambient through water and glass cover if attenuation of solar intensity within water mass is considered is expressed as

$$(1-R_g)(1-\alpha_g)(1-R_w)(1-\alpha_b)\left[\sum \mu_j \exp(-\eta_j d_w)\right]$$

The heat transfer mode in the case of solar still can be divided as external and internal. The external heat transfer mode consists of conduction, convection, and radiation. It occurs at the outer surface of glass cover, bottom, and side insulation. The internal heat transfer mode takes place by radiation, convection, and evaporation. It occurs between water surface and inner surface of glass cover. The evaporative heat transfer is responsible for solar distillation. Convection and radiation are losses.

External Heat Transfer

(a) Top loss heat coefficient

The temperature in the glass may be assumed to be uniform due to the small thickness of glass. The rate of heat transfer from the glass cover to the outside atmosphere ($\dot{q}_g$) can be written as

$$\dot{q}_g = \dot{q}_{rg} + \dot{q}_{cg} \tag{4.33.1}$$

where

$$\dot{q}_{rg} = \epsilon_g \sigma\left[(T_{go}+273)^4 - (T_{sky}+273)^4\right] \tag{4.33.2}$$

$$\dot{q}_{rg} = h_{rg}\left(T_{go} - T_a\right) \tag{4.33.3}$$

with

$$h_{rg} = \frac{\epsilon_g \sigma\left[(T_{go}+273)^4 - (T_{sky}+273)^4\right]}{(T_{go}-T_a)} \tag{4.33.4}$$

$$\dot{q}_{cg} = h_{cg}\left(T_{go} - T_a\right) \tag{4.33.5}$$

Putting values of $\dot{q}_{rg}$ and $\dot{q}_{cg}$ in Equation 4.33.1, we get

$$\dot{q}_g = h_{1g}\left(T_{go} - T_a\right) \tag{4.33.6}$$

where

$$h_{1g} = h_{rg} + h_{cg} \tag{4.33.7}$$

The empirical relation for h_{1g} can be discussed for the following cases:

Case (i): The expression for h_{1g} is given by

$$h_{1g} = 5.7 + 3.8\,V$$

where V is the velocity of wind (m/s). This expression incorporates the effect of free convection and radiation from the glass cover as explained by Watmuff et al. (1977).

Case (ii): In this case, the radiation and convection losses are evaluated separately. The radiative heat transfer coefficient (h_{rg}) can be calculated using Equation 4.33.4. The convective heat transfer coefficient (h_{cg}) can be evaluated from the relation

$$h_{cg} = 2.8 + 3.0\,V \tag{4.33.8}$$

However, there is no significant change in the performance of the solar still by considering h_{1g} as represented either by Case (i) or Case (ii).

(b) Bottom and side loss coefficient

Heat is also lost from the water in the basin to the ambient through the insulation and consequently by convection and radiation from the bottom or side surface of the basin. The bottom loss coefficient (U_b) can be expressed as

$$U_b = \left[\frac{1}{h_w} + \frac{1}{h_b}\right]^{-1} = \left[\frac{1}{h_w} + \frac{L_i}{K_i} + \frac{1}{h_{cb} + h_{rb}}\right] \tag{4.33.9}$$

The side heat loss coefficient (U_e) can be written as

$$U_e = \frac{U_b A_{ss}}{A_s} \tag{4.33.10}$$

If A_{ss} is very small in comparison to A_s, for small depth of water, U_e can be neglected. Here, A_{ss} is surface area in contact with water and A_s is the area of basin of solar still. The rate of heat loss per m^2 from basin liner to the ambient can be written as

$$\dot{q}_b = h_b (T_b - T_a) \tag{4.33.11}$$

where

$$h_b = \left[\frac{L_i}{K_i} + \frac{1}{h_{cb} + h_{rb}}\right]^{-1} \tag{4.33.12}$$

Internal Heat Transfer

a. Radiative loss coefficient

In this case, the water surface and the glass cover are considered as infinite parallel planes. This approximation is valid for small inclination of the glass cover and for large width of distiller unit. The rate of radiative heat transfer ($\dot{q}_{rwg}$) from the water surface to the glass cover for these infinite parallel planes is given by

$$\dot{q}_{rwg} = \epsilon_{\text{eff}} \sigma \left[(T_w + 273)^4 - (T_{gi} + 273)^4\right] \tag{4.33.13}$$

$$\dot{q}_{rwg} = h_{rwg} (T_w - T_{gi}) \tag{4.33.14}$$

where h_{rwg} is the radiative heat transfer coefficient from water surface to the glass cover and it is given by

$$h_{rwg} = \epsilon_{\text{eff}} \sigma \left[(T_w + 273)^2 + (T_{gi} + 273)^2\right][T_w + T_{gi} + 546] \tag{4.33.15}$$

Here, it should be noted that water and glass are considered to be parallel surfaces and hence the radiation shape factor is 1. Also, $\frac{1}{\epsilon_{\text{eff}}} = \frac{1}{\epsilon_w} + \frac{1}{\epsilon_g} - 1$.

b. Convective loss coefficient
Heat transfer takes place across humid air in the solar distillation unit by free convection. It is caused by the effect of buoyancy due to variation of density in humid fluid. The variation in density is due to the temperature gradient in the fluid. Hence, the heat transfer rate from water surface to the glass covers by convection ($\dot{q}_{cwg}$) in upward direction through humid fluid can be expressed as

$$\dot{q}_{cwg} = h_{cwg}\left(T_w - T_{gi}\right) \tag{4.33.16}$$

The coefficient h_{cwg} can be evaluated by the relation given by Dunkle (1961) as

$$h_{cwg} = 0.884\left[\left(T_w - T_g\right) + \frac{(P_w - P_{gi})(T_w + 273)}{268.9\times10^3 - P_w}\right]^{1/3} \tag{4.33.17}$$

c. Evaporative loss coefficient
The evaporative heat transfer rate from water surface to glass cover can be written as

$$\dot{q}_{ew} = h_{ewg}(T_w - T_{gi}) \tag{4.33.18}$$

The value of evaporative heat transfer coefficient can be obtained by the relation given by Cooper (1973a,b) as

$$h_{ewg} = 16.273\times10^3 h_{cwg}\frac{\left(P_w - P_g\right)}{\left(T_w - T_g\right)} \tag{4.33.19}$$

where

$$P\left(T\right) = \exp\left(25.317 - \frac{5144}{T + 273}\right) \tag{4.33.20}$$

The value of h_{ewg} can be more realistic for larger value of $(T_w - T_{gi})$. The total heat transfer coefficient (h_{1w}) can be can be evaluated as

$$h_{1w} = h_{rwg} + h_{cwg} + h_{ewg} \tag{4.33.21}$$

where h_{rwg}, h_{cwg}, and h_{ewg} can be evaluated using Equations 4.33.15, 4.33.17, and 4.33.19, respectively.

Overall Heat Transfer

a. Top loss coefficient
The rate of heat loss in the upward direction of a solar still can be expressed as

$$\dot{q}_t = U_t(T_w - T_a) \tag{4.33.22}$$

where U_t is the top loss coefficient from the water surface to the ambient air and it can be written as

$$U_t = \left[\frac{1}{h_{1g}} + \frac{1}{h_{1w}}\right]^{-1} \tag{4.33.23}$$

b. Bottom loss coefficient
The rate of heat loss through the bottom of insulation from water to the ambient air can be written as

$$\dot{q}_b = U_b(T_w - T_a) \tag{4.33.24}$$

where U_b is the bottom heat loss coefficient and it is given by

$$U_b = \frac{h_w h_b}{h_w + h_b} \tag{4.33.25}$$

The rate of total heat lost per m^2 from the water surface to the ambient through the top and bottom of the system ($\dot{q}_{\text{loss}}$) can be calculated as

$$\dot{q}_{\text{loss}} = U_L(T_w - T_a) \tag{4.33.26}$$

where U_L is the overall heat transfer coefficient and it is given by $U_L = U_t + U_b$.

Modified Internal Heat Transfer

The convective heat transfer coefficient from water surface to inner glass cover surface of a conventional solar still is calculated by Equation 4.33.17 given by Dunkle (1961). However, this expression has some limitations. Firstly, this equation is valid only for normal operating temperature ≅ 50°C in a solar still and temperature difference of 17°C. Secondly, it is independent of cavity volume due to $n = 1/3$. Thirdly, it is valid only for parallel evaporative and condensing surfaces. In the new design of solar still, the operating temperature is higher and limitations mentioned above are not satisfied. Hence, there is a need to find new methodology to get the value of convective heat transfer coefficient. In this regard, Kumar and Tiwari (1996b) have proposed the methodology to evaluate convective heat transfer coefficient using linear regression analysis. This methodology is as follows:

The hourly distillate output per m^2 from a distillate unit is given by

$$\dot{m}_{ew} = \frac{\dot{q}_{ew} \times 3600}{L} = \frac{16.273 \times 10^3 h_{cw}\left(P_w - P_g\right) \times 3600}{L} \tag{4.33.27}$$

(from Equation 4.33.18 and 4.33.19)
where

$$h_{cw} = \frac{\text{Nu}\ K_f}{d_f} = \frac{K_f}{d_f} C\left(\text{GrPr}\right)^n \tag{4.33.28}$$

Putting the value of h_{cw} in Equation 4.33.27, one gets the following expression.

$$\frac{\dot{m}_{ew}}{R} = C\left(\text{GrPr}\right)^n \tag{4.33.29}$$

where $R = 16.273 \times 10^3 h_{cw}\left(P_w - P_g\right)\dfrac{K_f}{d_f}\left(\dfrac{3600}{L}\right)$.

Equation 4.33.29 represents the equation of straight line and it can be expressed as

$$y = ax^b \tag{4.33.30}$$

where $y = \dfrac{\dot{m}_{ew}}{R}$; $x = \text{GrPr}$; $a = C$; and $b = n$.

Now, taking ln on both sides of Equation 4.33.30, it can be expressed in the form of straight line equation as follows:

$$y' = b'x' + a' \tag{4.33.31}$$

where $y' = \ln(y)$; $b' = b$; $x' = \ln x$; and $a' = a$.

Using linear regression analysis, coefficients a' and b' in Equation 4.33.31 can be expressed as

$$b' = \frac{N\left(\sum x'y'\right) - \left(\sum x'\right)\left(\sum y'\right)}{N\left(\sum (x')^2\right) - \left(\sum x'\right)^2} \tag{4.33.32}$$

$$a' = \left(\frac{\sum y'}{N}\right) - b'\left(\frac{\sum x'}{N}\right) \tag{4.33.33}$$

Here, N is the number of experimental observations under steady-state condition. In a quasi-steady-state condition, N becomes $(N+1)$. After calculating b' and a' from Equations 4.33.32 and 4.33.33, respectively, C and n can be evaluated using the following expressions.

$$C = \exp(a') \text{ and } n = b'$$

Once, values of C and n are known, one can evaluate convective heat transfer coefficient from Equation 4.33.28.

Thermal Modeling of Solar Stills

Single and double-slope PVT-CPC active solar stills are shown in Figures 4.33.8 and 4.33.9, respectively. Assumptions for writing energy balance equation for single-slope and double-slope PVT-CPC active solar stills (Singh and Tiwari, 2016) are as follows:

1. The partially covered PVT-CPC water collector and solar stills are in quasi steady state.
2. The losses due to resistance in the solar cells are negligible. These are the losses occurring as a result of the interconnections and bus bar in the PV module and other connecting wires. These wires are generally made up of aluminum or copper which have very low electrical resistivity (of the order of 10^{-8} Ω-m). So, i^2r losses are negligible in comparison to the other thermal losses or heat transfers in the system. Hence, neglecting the ohmic losses will not affect the thermal performance of the solar cell in greater extent.
3. The heat capacity of solar cell, glass cover, absorbing, and insulation material of collector and solar stills is negligible as heat losses due to heat capacity are low in comparison to the other rate of heat transfer in the system. The amount of heat loss in solar cell can be written as $m \cdot c_p \cdot \Delta T$, where m represents the mass of solar cell, c_p represents specific heat capacity at constant pressure of solar cell material (silicon), and ΔT represents the difference of average cell temperature and ambient temperature. The mass of solar cell

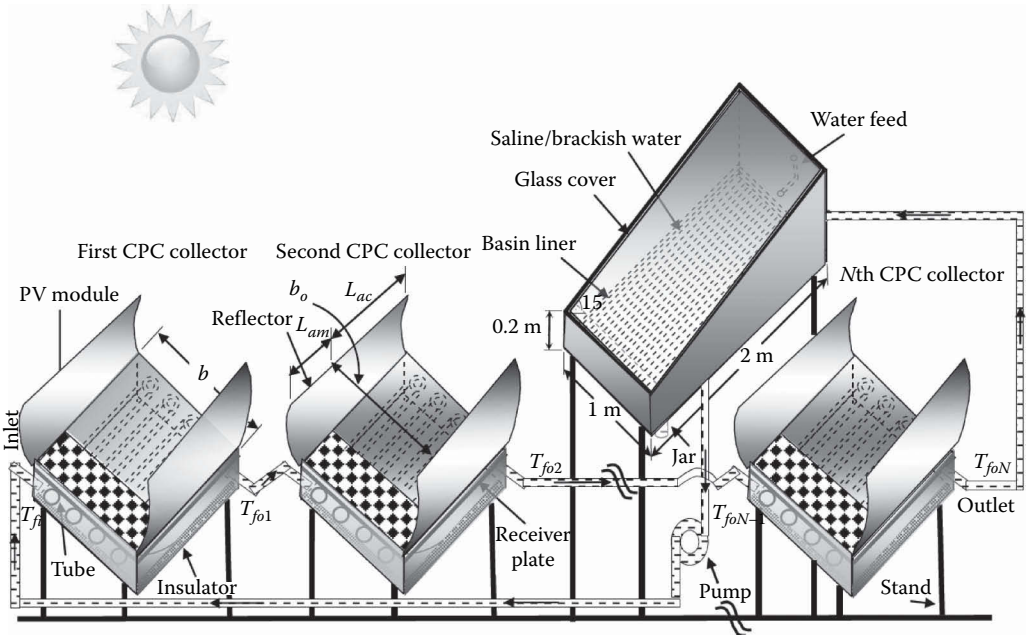

FIGURE 4.33.8 Schematic diagram of single-slope PVT-CPC active solar still.

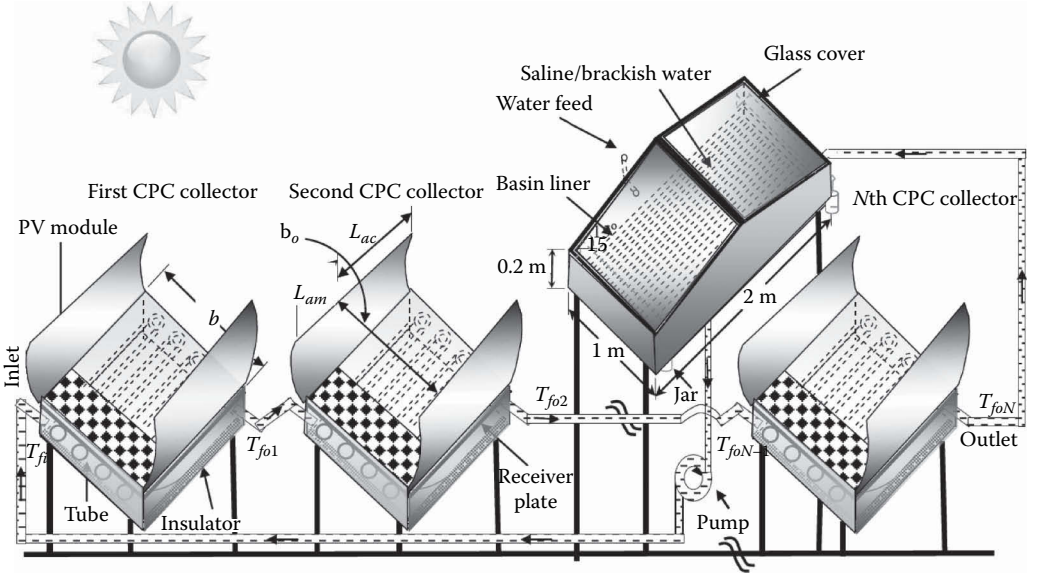

FIGURE 4.33.9 Schematic diagram of double-slope PVT-CPC active solar still.

(0.156 m×0.156 m×0.0002 m) comes out to be ~0.0113 kg taking the density of silicon as 2.33×10^3 kg/m^3. The value of c_p for silicon (Si) at room temperature is 0.705 kJ/kg K and average value of ΔT in the month of June for the system is 44.87 K (Singh and Tiwari, 2016). Therefore, heat loss due to heat capacity in solar cell comes out to be 0.36 kJ which is 0.0012% of the heat output from solar still because heat output from solar still is of the order of 10^4kJ. Further, the amount of heat loss due to heat capacity of glass cover is given by $m \cdot c_p \cdot \Delta T$, where m represents mass of glass cover, c_p represents specific heat capacity

of glass at constant pressure, and ΔT represents the temperature difference between inner surface and outer surface. The average value of temperature difference between inner and outer surfaces of glass cover is 2.84 K in the case of PVT active solar still as reported by Kumar et al. (2010). Mass of glass cover in solar still comes out to be 20.70 kg taking glass density as 2500 kg/m^3. The heat consumed by glass is 49.38 kJ taking c_p of glass as 0.84 kJ/kg K, whereas daily heat output of the system is of the order of 10^4kJ. So, heat consumed by glass due to its heat capacity comes out to be 0.17% in comparison to the amount of heat output from the solar still. In the similar way, heat consumed by absorbing and insulating materials corresponding to their heat capacities can also be computed which will come out negligibly small. Hence, the amount of heat loss due to heat capacities of solar cell, glass, absorbing, and insulating materials can be neglected as they are not going to affect the result in greater extent.

4. Solar stills are vapor leakage proof. If leakage occurs, the steady-state condition no longer exists and energy equation will become too complex due to transient condition. Hence, the leakage of vapor has been neglected as it will not affect the result much and steady-state condition exists.
5. The level of water in the basin is constant. The maximum daily yield of the solar distillation system is 30.36 kg as reported by Singh and Tiwari (2016). The corresponding change in level of water comes out to be 0.015 m during 24 h. The variation in daily yield is 0.25% as reported by Tiwari et al. (2009) if water level changes by 15.38% (0.11–0.13 m) in the case of active solar still. Hence, the small change in level of water can be neglected.
6. No stratification (i.e., no layered configuration) of water occurs in the basin of active solar stills as there is a continuous stirring of water due to its circulation by pump throughout the system which results in mixing of water.
7. The film-type condensation occurs at the inner surface of glass. A small inclination with horizontal is provided to glass for facilitating the same as the component of gravitational force $(mg\sin\theta)$ will act along the surface in the downward direction which will help in trickling down the condensate. Here, θ is the angle of inclination of the glass with horizontal. Also, the inner surface of glass is cleaned to prevent the droplet formation. Further, if the film-type condensation does not take place then water droplets will form at the inner surface of glass cover which will act as mirror and some portion of the solar radiation will be reflected. Hence, lesser amount of solar radiation will reach the surface of water which will adversely affect the yield. Therefore, the occurrence of film-type condensation is ensured during the design phase. However, small amount of droplets may still form which can be ignored as they are negligibly small.

N Identical PVT-CPC Active Solar Still

Useful Energy Gain for N Identical Partially Covered PVT-CPC Water Collectors Connected in Series

Following Tripathi et al. (2016), the rate of useful thermal output from N identical partially covered PVT-CPC water collectors connected in series can be expressed as,

$$\dot{Q}_{uN} = \frac{(1-K_k^N)}{(1-K_k)}(A\ F_R(\alpha\tau))_1 I_b(t) + \frac{(1-K_k^N)}{(1-K_k)}(A\ F_R U_L)_1(T_{fi} - T_a) \tag{4.33.34}$$

In their set-up, PVT-CPC water collectors are in open loop. However, collectors are in closed loop with solar still in PVT-CPC active solar still. The water from basin of solar still enters to the inlet of first PVT-CPC water collector and outlet of *N*th PVT-CPC water collector are fed to the basin of solar still. Hence, T_{fi} becomes equal to T_w.

The temperature at the outlet of *N*th PVT-CPC water collector (T_{foN}) is given by

$$T_{foN} = \frac{(A\ F_R(\alpha\tau))_1}{\dot{m}_f C_f}\frac{(1-K_k^N)}{(1-K_k)} I_b(t) + \frac{(A\ F_R U_L)_1}{\dot{m}_f C_f}\frac{(1-K_k^N)}{(1-K_k)} T_a + K_k^N T_{fi} \tag{4.33.35}$$

where $T_{fi} = T_w$. The temperature obtained at the outlet of *N*th PVT-CPC water collector is fed to the basin of solar still. Hence, $T_{wo} = T_{foN}$.

The analytical expression for the temperature-dependent electrical efficiency of solar cells (η_{cN}) of a number (N) of PVT-CPC water collectors is given by Evans (1981) and Schott (1985) as

$$\eta_{cN} = \eta_o\left[1-\beta_o(\overline{T}_{cN} - T_o)\right] \tag{4.33.36}$$

where η_o is the efficiency at standard test condition and $\overline{T}_{cN}$ is the average solar cell temperature of *N*th PVT-CPC water collector. The value of $\overline{T}_{cN}$ can be calculated using the expression developed by Tripathi et al. (2016) in which $T_{fi} = T_w$.

Energy Balance Equations for Single Slope Solar Still

Following Singh and Tiwari (2016), energy balance equation for single-slope solar still can be written as follows:

Inner surface of glass cover

$$\alpha'_g I_s(t) A_g + h_{1w}(T_w - T_{gi})A_b = \frac{K_g}{L_g}(T_{gi} - T_{go})A_g \tag{4.33.37}$$

where $\alpha'_g = (1 - R_g)\alpha_g$ represents the fraction of solar flux absorbed by the glass cover and $h_{1w} = h_{rwg} + h_{cwg} + h_{ewg}$ represents the rate of total heat transfer coefficient from water surface to inner surface of glass cover.

Outer surface of glass cover

$$\frac{K_g}{L_g}(T_{gi} - T_{go})A_g = h_{1g}(T_{go} - T_a)A_g \tag{4.33.38}$$

Here, $h_{1g} = h_{r,g} + h_{c,g}$ or $h_{1g} = 5.7 + 3.8\ V$

Water mass in basin

$$\dot{Q}_{uN} + \alpha'_w I_s(t) A_b + h_{bw}(T_b - T_w)A_b = h_{1w}(T_w - T_{gi})A_b + M_w C_w \frac{dT_w}{dt} \tag{4.33.39}$$

Here, $\alpha'_w = (1 - R_g)(1 - \alpha_g)(1 - R_w)\alpha_w$ represents the fraction of solar flux absorbed by water mass and $\dot{Q}_{uN}$ is the rate of useful thermal output from N identical hybrid PVT collectors connected in series.

Basin liner

$$\alpha'_b I_s(t) A_b = h_{bw}(T_b - T_w)A_b + h_{ba}(T_b - T_a)A_b \tag{4.33.40}$$

where $\alpha'_b = (1 - R_g)(1 - \alpha_g)(1 - R_w)(1 - \alpha_w)\alpha_b$ which is the fraction of solar flux absorbed by basin liner.

Using Equations 4.33.34 and 4.33.37 through 4.33.40, one can get the following differential equation for water temperature in basin.

$$\frac{dT_w}{dt} + a_1 T_w = f_1(t) \tag{4.33.41}$$

Values of a_1 and $f_1(t)$ of Equation 4.33.41 are given in Appendix.

The following assumptions have been made to get an approximate solution of differential equation (4.33.41).

1. The time interval (Δt) is small, i.e., ($0 < t < \Delta t$).
2. Values of T_a, $I_b(t)$, and $I_s(t)$ can be considered as average value between "0" and "t", i.e., $\overline{T}_a$, $\overline{I}_b(t)$, and $\overline{I}_s(t)$. Hence $f_1(t)$ becomes constant and its average value will be $\overline{f_1}(t)$.
3. a_1 is constant for interval Δt.

One can get the solution of Equation 4.33.41 with initial condition, $T_w = T_{w0}$ at $t=0$, as follows:

$$T_w = \frac{\overline{f_1}(t)}{a_1}(1 - e^{-a_1 t}) + T_{w0} e^{-a_1 t} \tag{4.33.42}$$

After evaluating T_w from Equation 4.33.42, one can obtain glass temperature from Equations 4.33.37 and 4.33.38 as follows:

$$T_{gi} = \frac{\alpha'_g I_s(t) A_g + h_{1w} T_w A_b + U_{c,ga} T_a A_g}{U_{c,ga} A_g + h_{1w} A_b} \tag{4.33.43}$$

$$T_{go} = \frac{\dfrac{K_g}{L_g} T_{gi} + h_{1g} T_a}{\dfrac{K_g}{L_g} + h_{1g}} \tag{4.33.44}$$

The hourly yield ($\dot{m}_{ew}$) can be expressed as

$$\dot{m}_{ew} = \frac{h_{ewg} A_b (T_w - T_{gi})}{L} \times 3600 \tag{4.33.45}$$

Here, L is the latent heat of evaporation and can be evaluated using the expression given by Fernandez and Chargoy (1990) and Toyama and Kagakuv (1972).

Above equations can be discussed for the following limiting condition:

1. For $\frac{A_a}{A_r} = 1$ and $I_b(t) = I(t)$, equations derived for single-slope PVT-CPC active solar still reduce to equations for single-slope PVT-FPC active solar still.
2. For $\frac{A_a}{A_r} = 1$, $A_{rm} = 0.625\ \text{m}^2$, $A_{rc} = 1.375\ \text{m}^2$, $I_b(t) = I(t)$, $A_b = 1\ \text{m}^2$, and $N=2$, equations derived for single-slope PVT-CPC active solar still reduce to expressions derived by Singh et al. (2016).
3. In the case of single-slope passive solar still $\dot{Q}_{uN} = 0$ as no external energy is fed to the basin of solar still. Hence, putting $\dot{Q}_{uN} = 0$, equations derived for PVT-CPC active solar still reduce to equations for single-slope passive solar still (Singh et al., 2016).

Energy Balance Equations for Double Slope Solar Still

Following Singh and Tiwari (2016), energy balance equation for double-slope solar still can be written as follows:

Energy balances for east cover

For inner glass cover

$$\alpha'_g I_{SE}(t) A_{gE} + h_{1wE}(T_w - T_{giE}) \frac{A_b}{2} - h_{EW}(T_{giE} - T_{giW}) A_{gE} = \frac{K_g}{L_g}(T_{giE} - T_{goE}) A_{gE} \tag{4.33.46}$$

Here, $h_{1wE} = h_{rwgE} + h_{cwgE} + h_{ewgE}$ which is called total heat transfer coefficient from water surface to glass cover and α'_g represents the fraction of solar flux absorbed by the glass cover.

For outer glass cover

$$\frac{K_g}{L_g}(T_{giE} - T_{goE})A_{gE} = h_{1gE}(T_{goE} - T_a)A_{gE} \tag{4.33.47}$$

where $h_{1gE} = h_{rgE} + h_{cgE}$ or $h_{1gE} = 5.7 + 3.8$ V.

Energy balances for west cover

For inner glass cover

$$\alpha'_g I_{SW}(t)A_{gW} + h_{1wW}(T_w - T_{giW})\frac{A_b}{2} + h_{EW}(T_{giE} - T_{giW})A_{gE} = \frac{K_g}{L_g}(T_{giW} - T_{goW})A_{gW} \tag{4.33.48}$$

where $h_{1wW} = h_{rwgE} + h_{cwgE} + h_{ewgE}$ which is called total heat transfer coefficient from water surface to glass cover on the west side.

For outer glass cover

$$\frac{K_g}{L_g}(T_{giW} - T_{goW})A_{gW} = h_{1gW}(T_{goW} - T_a)A_{gW} \tag{4.33.49}$$

where $h_{1gW} = h_{rgW} + h_{cgW}$ or $h_{1gW} = 5.7 + 3.8$ V.

For basin liner

$$\alpha'_b\left(I_{SE}(t) + I_{SW}(t)\right)\frac{A_b}{2} = h_{bw}(T_b - T_w)A_b + h_{ba}(T_b - T_a)A_b \tag{4.33.50}$$

Here, α'_b is the fraction of solar flux absorbed by basin liner.

For water mass in basin

$$(M_w C_w)\frac{dT_w}{dt} = \left(I_{SE}(t) + I_{SW}(t)\right)\alpha'_w\frac{A_b}{2} + h_{bw}(T_b - T_w)A_b - h_{1w}(T_w - T_{giE})\frac{A_b}{2} - h_{1w}(T_w - T_{giE})\frac{A_b}{2} + \dot{Q}_{uN} \tag{4.33.51}$$

Using Equation 4.33.34 and 4.33.46 through 4.33.51, one can get the differential equation for water temperature (T_w) in basin. Following assumptions made in solving Equation (4.33.41), one can get the solution of this differential equation with initial condition $T_w = T_{wo}$ at $t=0$ as

$$T_w = \frac{\overline{f_2}(t)}{a_2}(1 - e^{-a_2 t}) + T_{w0}e^{-a_2 t} \tag{4.33.52}$$

Equation 4.33.52 is similar to Equation 4.33.42 obtained for single-slope PVT-CPC active solar distillation system. However, constants of Equation 4.33.52 which has been obtained for double-slope PVT-CPC active solar distillation system are different. Their expressions are given in Appendix. After evaluating T_w from Equation 4.33.52, one can obtain glass temperature for double-slope PVT-CPC active solar distillation system using Equations 4.33.47 through 4.33.50 as follows:

$$T_{giE} = \frac{A_1 + A_2 T_w}{P} \tag{4.33.53}$$

$$T_{giW} = \frac{B_1 + B_2 T_w}{P} \tag{4.33.54}$$

$$T_{goE} = \frac{\frac{K_g}{L_g} T_{giE} + h_{1gE} T_a}{\frac{K_g}{L_g} + h_{1gE}} \tag{4.33.55}$$

$$T_{goW} = \frac{\frac{K_g}{L_g} T_{giW} + h_{1gW} T_a}{\frac{K_g}{L_g} + h_{1gW}} \tag{4.33.56}$$

Constants of Equations 4.33.53 through 4.33.56 are given in Appendix. After evaluating glass temperature from Equations 4.33.53 and 4.33.54 and water temperature from Equation 4.33.52, one can obtain hourly yield for east and west side in the case of double-slope PVT-CPC active solar distillation system as follows:

$$\dot{m}_{ew,E} = \frac{h_{ewE} \frac{A_b}{2} \left(T_w - T_{giE}\right)}{L} \times 3600 \tag{4.33.57}$$

$$\dot{m}_{ew,W} = \frac{h_{ewW} \frac{A_b}{2} \left(T_w - T_{giW}\right)}{L} \times 3600 \tag{4.33.58}$$

The hourly yield for double-slope PVT-CPC active solar distillation system can be calculated by adding the hourly yield obtained from east side ($\dot{m}_{ew,E}$) using Equation 4.33.57 and hourly yield obtained from west side ($\dot{m}_{ew,W}$) using Equation 4.33.58.

Above equations can be discussed for the following limiting conditions:

1. For $\frac{A_a}{A_r} = 1$ and $I_b(t) = I(t)$, equations derived for double-slope PVT-CPC active solar still reduce to equations for double-slope PVT-FPC active solar still.
2. In the case of single-slope passive solar still, $\dot{Q}_{uN} = 0$ as no external energy is fed to the basin of solar still. Hence, putting $\dot{Q}_{uN} = 0$, equations derived for double-slope PVT-CPC active solar still reduce to equations for double-slope passive solar still (Dwivedi and Tiwari, 2008).

Performance Parameters of Solar Still

The performance of solar still is analyzed by its energy, exergy, efficiency, energy matrices, productivity, exergoeconomic parameter, and enviroeconomic parameter. These parameters are as follows.

Energy Output

The energy output can be calculated with the help of first law of thermodynamics. Following Singh and Tiwari (2016), the annual overall thermal energy (E_{out}) of PVT-CPC active solar still can be written as

$$E_{\text{out}} = \frac{\left(M_{ew} \times L\right)}{3600} + \frac{\left(P_m - P_u\right)}{0.38} \tag{4.33.59}$$

Here, M_{ew}, P_m, P_u, and L are annual yield from solar still, annual power generated from PV module, annual power utilized by pump and L is latent heat. The value of M_{ew} can be computed with the help of Equations 4.33.45, 4.33.57, and 4.33.58. $(P_m - P_u)$ in Equation 4.33.59 represents net electrical energy for the whole year. It has been divided by 0.38 to get the equivalent thermal energy as electrical energy is high grade energy. The factor 0.38 corresponds to power generation efficiency for a conventional power plant (Huang et al., 2001). The expression for hourly electrical energy/electrical exergy $(\dot{E}x_e)$ can be expressed as

$$\dot{E}x_e = A_m I_b(t) \sum_{1}^{N} (\alpha \tau_g \eta_{cN}) \tag{4.33.60}$$

The daily electrical exergy can be computed by adding hourly electrical exergy for 10 h as beam intensity exists for 10 h only. The monthly electrical exergy can be evaluated by multiplying daily electrical exergy with number of clear days and addition of monthly electrical exergy for 12 months will give annual electrical exergy (P_m) used in Equation 4.33.59.

In the case of solar still integrated with N identical PVT-FPC, $I_b(t) = I(t)$. In the case of passive solar still and solar still integrated with FPC, the second term of Equation 4.33.59 will not appear.

Exergy Output

The exergy output can be computed using the first law (energy) and second law (entropy) of thermodynamics. Following Nag (2004), the hourly output thermal exergy $\dot{E}x_{\text{out}}(W)$ for single-slope active solar still can be written as

$$\dot{E}x_{\text{out},s} = A_b h_{ewg} \left[(T_w - T_{gi}) - (T_a + 273) \times \ln \left\{ \frac{(T_w + 273)}{(T_{gi} + 273)} \right\} \right] \tag{4.33.61}$$

where h_{ewg} can be computed with the help of Equation 4.33.19.

Following Equation 4.33.61, the expression of hourly exergy gain for double-slope active solar still $(\dot{E}x_{\text{out},d})$ can be written as

$$\dot{E}x_{\text{out},d} = h_{ewgE} \times \frac{A_b}{2} \times \left[(T_w - T_{giE}) - (T_a + 273) \times \ln \left\{ \frac{(T_w + 273)}{(T_{giE} + 273)} \right\} \right] + h_{ewgW} \times \frac{A_b}{2} \times \left[(T_w - T_{giW}) - (T_a + 273) \times \ln \left\{ \frac{(T_w + 273)}{(T_{giW} + 273)} \right\} \right] \tag{4.33.62}$$

The value of h_{ewgE} and h_{ewgW} can be calculated with the help of Equation 4.33.19.

The overall annual exergy gain $(G_{ex,\text{annual}})$ for single- and double-slope solar stills integrated with PVT collectors can be written as

$$G_{\text{ex,annual}} = \text{Ex}_{\text{out}} + (P_m - P_u) \tag{4.33.63}$$

Here, Ex_{out} is annual thermal exergy output obtained from solar still, P_m is annual electrical exergy obtained from N identical PVT collectors, and P_u is power required to drive the pump. In the case of single- and double-slope passive solar stills, the second term of Equation 4.33.63 does not exist as collectors and pump are absent in these cases.

The daily exergy for clear day can be calculated by adding hourly exergy for 10 h as solar intensity exists for sunshine hours only. The monthly exergy for clear days can be evaluated by multiplying

daily exergy with the corresponding number of clear days. The annual exergy can be calculated by adding monthly exergy for 12 month. Following Equation 4.33.61, the hourly thermal exergy output ($\dot{E}x_c(t)$) from N identical PVT-CPC/PVT-FPC water collectors can be written as

$$\dot{E}x_c(t) = (\dot{m}_f \times C_f)\left[(T_{foN} - T_{fi}) - (T_a + 273) \times \ln\frac{(T_{foN} + 273)}{(T_{fi} + 273)}\right] \tag{4.33.64}$$

Here, $\dot{m}_f$, C_f, T_{foN}, T_{fi}, and T_a represent mass flow rate of fluid in collector, specific heat capacity of fluid in collector, temperature at the outlet of Nth collector, temperature at the inlet of first collector and ambient temperature, respectively.

Efficiency of Solar Still

Efficiency of solar still is calculated on the basis of first law as well as second law of thermodynamics. Various efficiencies of solar still are as follows:

a. Thermal efficiency
It is calculated on the basis of first law of thermodynamics. The hourly and daily thermal efficiency (Tiwari, 2002) of partially covered PVT-CPC single-slope active solar still can be written as follows:

$$\eta_{\text{hourly,thermal}} = \frac{\dot{m}_{ew} \times L}{\left[\dot{Q}_{uN} + A_b \times I_s(t)\right] \times 3600} \times 100 \tag{4.33.65}$$

$$\eta_{\text{daily,thermal}} = \frac{\sum_{t=1}^{24} \dot{m}_{ew} \times L}{\sum_{t=1}^{24}\left[\dot{Q}_{uN} + A_b \times I_s(t)\right] \times 3600} \times 100 \tag{4.33.66}$$

where t represents time, $\dot{m}_{ew}$ is the hourly yield obtained from solar still, $I_s(t)$ is hourly solar intensity falling on solar still, $\dot{Q}_{uN}$ is the hourly useful energy gain from N identical partially covered PVT-CPC water collectors, and L is the latent heat of vaporization which can be calculated using expression given by Fernandez and Chargoy (1990) and Toyama and Kagakuv (1972).
Following Equations 4.33.65 and 4.33.66, the hourly and daily thermal efficiency of partially covered PVT-CPC double-slope active solar still can be written as follows:

$$\eta_{\text{hourly,thermal}} = \frac{\left(\dot{m}_{ewE} + \dot{m}_{ewW}\right) \times L}{\left[\dot{Q}_{uN} + \frac{A_b}{2}\left(I_{sE}(t) + I_{sW}(t)\right)\right] \times 3600} \times 100 \tag{4.33.67}$$

$$\eta_{\text{daily,thermal}} = \frac{\sum_{t=1}^{24}\left(\dot{m}_{ewE} + \dot{m}_{ewW}\right) \times L}{\sum_{t=1}^{24}\left[\dot{Q}_{uN} + \frac{A_b}{2}\left(I_{sE}(t) + I_{sW}(t)\right)\right] \times 3600} \times 100 \tag{4.33.68}$$

where $\dot{m}_{ewE}$, $\dot{m}_{ewW}$, $I_{sE}(t)$, and $I_{sW}(t)$ represent hourly yield obtained from east side, hourly yield obtained from west side, hourly solar intensity falling on east side, and hourly solar intensity falling on west side, respectively.

In the case of solar still integrated with N identical PVT-FPC, $\dot{Q}_{uN}$ represents the hourly energy gain from N identical PVT-FPC which can be obtained by putting $\frac{A_a}{A_r}=1$ and $I_b(t)=I(t)$ in Equation 4.33.34 or alternatively from Shyam et al. (2015). In the case of N identical FPC connected to solar still, $\dot{Q}_{uN}$ represents the hourly energy gain from N identical FPC. The value of $\dot{Q}_{uN}$ becomes zero in the case of single-slope passive solar still as no energy is fed to solar still.

b. Thermal exergy efficiency

The hourly thermal exergy efficiency of single- and double-slope PVT-CPC/PVT-FPC active solar still can be expressed as

$$\eta_{\text{hourly,exergy},s}=\frac{\dot{E}x_{\text{out},s}(t)}{\dot{E}x_c(t)+0.933\times\left(A_b\times I_S(t)\right)}\times 100 \tag{4.33.69}$$

$$\eta_{\text{hourly,exergy},d}=\frac{\dot{E}x_{\text{out},d}(t)}{\dot{E}x_c(t)+\left[0.933\times\frac{A_b}{2}\times\left(I_{SE}(t)+I_{SW}(t)\right)\right]}\times 100 \tag{4.33.70}$$

Here, the factor 0.933 has been obtained using the expression given by Petela (2003). It has been used to convert radiation to exergy. Following Equations 4.33.69 and 4.33.70, the daily thermal exergy efficiency of single- and double-slope PVT-CPC/PVT-FPC active solar still can be expressed as

$$\eta_{\text{daily,exergy},s}=\frac{\sum_{t=1}^{24}\left[\dot{E}x_{\text{out},s}(t)\right]}{\sum_{t=1}^{24}\left[\dot{E}x_c(t)+0.933\times\left(A_b\times I_S(t)\right)\right]}\times 100 \tag{4.33.71}$$

$$\eta_{\text{daily,exergy},d}=\frac{\sum_{t=1}^{24}\left[\dot{E}x_{\text{out},d}(t)\right]}{\sum_{t=1}^{24}\left[\dot{E}x_c(t)+\left[0.933\times\frac{A_b}{2}\times\left(I_{SE}(t)+I_{SW}(t)\right)\right]\right]}\times 100 \tag{4.33.72}$$

In the case of single- and double-slope passive solar stills, the value of $\dot{E}x_c(t)$ will be zero as no exergy is fed to the basin of solar stills in this case.

c. Electrical exergy efficiency

Following Tiwari et al. (2015), the electrical exergy efficiency of single- and double-slope PVT-CPC active solar stills can be written as

$$\eta_{\text{hourly,electrical exergy}}=\frac{\dot{E}x_e(t)-\dot{P}_u(t)}{0.933\times A_{am}\times N\times I_b(t)}\times 100 \tag{4.33.73}$$

$$\eta_{\text{daily,electrical exergy}}=\frac{\sum_{t=1}^{24}\left(\dot{E}x_e-\dot{P}_u\right)}{0.933\times\sum_{t=1}^{t=24}\left[A_{am}\times N\times I_b(t)\right]}\times 100 \tag{4.33.74}$$

where $\dot{P}_u(t)$, N, $I_b(t)$, and A_{am} are hourly consumption of pump, number of collectors, beam radiation, and aperture area of module, respectively. Hourly electrical exergy $\left(\dot{E}x_e(t)\right)$ can be computed using Equation 4.33.60. The value of beam radiation and electrical energy/exergy are zero during off-sunshine hours. In the case of PVT-FPC active solar stills,

$I_b(t) = I(t)$ and $A_{am} = A_m$. In the case of passive solar stills and FPC active solar stills, electrical exergy efficiency does not exist as no electrical output is obtained due to the absence of PV.

d. Overall exergy efficiency

Overall exergy represents the summation of thermal exergy and electrical exergy. Following Singh et al. (2016), the hourly overall exergy efficiency of single- and double-slope PVT-CPC active solar distillation system can be written as

$$\eta_{\text{hourly,overall exergy},s} = \frac{\dot{E}x_{\text{out},s}(t) + \left(\dot{E}x_e(t) - \dot{P}_u(t)\right)}{0.933 \times \left[\left(A_b \times I_S(t)\right) + (A_{am} + A_{ac}) \times N \times I_b(t)\right]} \times 100 \tag{4.33.75}$$

$$\eta_{\text{hourly,overall exergy},d} = \frac{\dot{E}x_{\text{out},d}(t) + \left(\dot{E}x_e(t) - \dot{P}_u(t)\right)}{0.933 \times \left[\left[\frac{A_b}{2} \times \left(I_{SE}(t) + I_{SW}(t)\right)\right] + (A_{am} + A_{ac}) \times N \times I_b(t)\right]} \times 100 \tag{4.33.76}$$

Following Equations 4.33.69 and 4.33.70, the daily overall exergy efficiency of single- and double-slope PVT-CPC active solar distillation system can be written as

$$\eta_{\text{daily,overall exergy},s} = \frac{\sum_{t=1}^{24}\left[\dot{E}x_{\text{out},s}(t) + \left(\dot{E}x_e(t) - \dot{P}_u(t)\right)\right]}{0.933 \times \sum_{t=1}^{24}\left[\left(A_b \times I_S(t)\right) + (A_{am} + A_{ac}) \times N \times I_b(t)\right]} \times 100 \tag{4.33.77}$$

$$\eta_{\text{daily,overall exergy},d} = \frac{\left[\sum_{t=1}^{t=24} \dot{E}x_{\text{out},d}(t) + \left(\dot{E}x_e(t) - \dot{P}_u(t)\right)\right]}{0.933 \times \sum_{t=1}^{24}\left[\left[\frac{A_b}{2} \times \left(I_{SE}(t) + I_{SW}(t)\right)\right] + (A_{am} + A_{ac}) \times N \times I_b(t)\right]} \times 100 \tag{4.33.78}$$

where values of electrical exergy and solar flux used in Equations 4.33.75 through 4.33.78 are zero during off-sunshine hours.

In the case of PVT-FPC active solar still, $I_b(t) = I(t)$, $A_{am} = A_m$, and $A_{ac} = A_c$. In the case of FPC active solar still and passive solar still, electrical component will not exist due to the absence of PVT collectors in these cases.

e. Overall thermal efficiency

Overall thermal energy represents the summation of thermal energy obtained from solar still and the thermal energy equivalent to electrical exergy obtained from PVT. The electrical exergy is divided by a factor 0.38 (Huang et al., 2001) to get the equivalent thermal energy. The hourly overall thermal efficiency of single- and double-slope PVT-CPC active solar stills can be written as

$$\eta_{\text{hourly,overall thermal},s} = \frac{\dot{m}_{ew} \times L}{\left[\dot{Q}_{uN} + A_b \times I_s(t)\right] \times 3600} \times 100 + \frac{\dot{E}x_e(t) - \dot{P}_u(t)}{0.38 \times A_{am} \times N \times I_b(t)} \times 100 \tag{4.33.79}$$

$$\eta_{\text{hourly,overall thermal},d} = \frac{\left(\dot{m}_{ewE} + \dot{m}_{ewW}\right) \times L}{\left[\dot{Q}_{uN} + \frac{A_b}{2}\left(I_{sE}(t) + I_{sW}(t)\right)\right] \times 3600} \times 100 + \frac{\dot{E}x_e(t) - \dot{P}_u(t)}{0.38 \times A_{am} \times N \times I_b(t)} \times 100 \tag{4.33.80}$$

Here, $\dot{m}_{ew}$, $\dot{m}_{ewE}$, and $\dot{m}_{ewW}$ can be evaluated using Equations 4.33.45, 4.33.57, and 4.33.58, respectively. $\dot{Q}_{uN}$ and $\dot{E}x_e$ can be evaluated using Equations 4.33.34 and 4.33.61, respectively. The work consumed by DC motor pump can be evaluated using its specification. Following Equations 4.33.73 and 4.33.74, the daily overall thermal efficiency of single- and double-slope PVT-CPC active solar distillation system can be written as

$$\eta_{\text{daily, overall thermal},s} = \left[\frac{\sum_{t=1}^{24} \left(\dot{m}_{ew} \times L \right)}{\sum_{t=1}^{24} \left[\dot{Q}_{uN}(t) + A_b \times I_s(t) \right] \times 3600} + \frac{\sum_{t=1}^{24} \left[\dot{E}x_e(t) - \dot{P}_u(t) \right]}{\sum_{t=1}^{24} \left[0.38 \times A_{am} \times N \times I_b(t) \right]} \right] \times 100 \tag{4.33.81}$$

$$\eta_{\text{daily,overall thermal},d} = \left[\frac{\sum_{t=1}^{24} \left[\left(\dot{m}_{ewE} + \dot{m}_{ewW} \right) \times L \right]}{\sum_{t=1}^{24} \left[\dot{Q}_{uN}(t) + \frac{A_b}{2} \left(I_{sE}(t) + I_{sW}(t) \right) \right] \times 3600} + \frac{\sum_{t=1}^{24} \left[\dot{E}x_e(t) - \dot{P}_u(t) \right]}{\sum_{t=1}^{24} \left[0.38 \times A_{am} \times N \times I_b(t) \right]} \right] \times 100 \tag{4.33.82}$$

where values of solar flux and electrical exergy used in Equations 4.33.73 through 4.33.76 are zero during off-sunshine hours.

Energy Matrices

Unlike efficiency, energy matrices are calculated on annual basis. Analysis of energy matrices consists of the evaluation of EPBT, EPF, and LCCE. These are an important parameter for renewable technologies as the use of technology does not make any sense if the energy produced by them during the whole life time is less than the energy used in their manufacturing (Tiwari and Mishra, 2012). These are as follows:

a. Energy payback time
   It represents the time period needed to recover the total energy exhausted in preparing the materials (embodied energy) required for fabrication of solar distillation system. Following Tiwari and Mishra (2012), it can be expressed as

$$\text{EPBT based on energy} = \frac{\text{Embodied energy } \left(E_{\text{in}} \right)}{\text{Annual energy output } \left(E_{\text{out}} \right)} \tag{4.33.83}$$

$$\text{EPBT based on exergy} = \frac{\text{Embodied energy } \left(E_{\text{in}} \right)}{\text{Annual exergy output } \left(G_{\text{ex, annual}} \right)} \tag{4.33.84}$$

   Here, embodied energy represents the amount of energy needed to manufacture the material required for solar distillation system. It consists of energy as minor part and exergy as major part. The numerical value of EPBT for solar distillation system should be as low as possible to make them cost effective. It means that the solar distillation system is better if its EPBT is lower.

b. Energy production factor
   It represents the overall performance of solar distillation system. It is defined as the reciprocal of EPBT and its ideal value on annual basis is 1. Following Tiwari and Mishra (2012), EPF for solar distillation system on annual basis can be written as

$$\text{EPF based on energy} = \frac{E_{\text{out}}}{E_{\text{in}}} \tag{4.33.85}$$

$$\text{EPF based on exergy} = \frac{G_{\text{ex,annual}}}{E_{\text{in}}} \tag{4.33.86}$$

where E_{out}, E_{in}, and $G_{ex,\text{annual}}$ are, respectively, overall annual energy output, embodied energy, and overall annual exergy gain for solar distillation system.

c. Life cycle conversion efficiency

It represents the net output of solar distillation system with respect to solar radiation falling on it for the entire life time. The ideal value of LCCE for solar distillation system is one. The system is considered better if LCCE is higher. Evaluation of LCCE considers the entire life of the system, whereas efficiency can be evaluated for a particular instant, hour or day. Following Tiwari and Mishra (2012), LCCE for PVT-CPC active solar distillation system can be expressed as

$$\text{LCCE based on energy} = \frac{E_{\text{out}} \times n - E_{\text{in}}}{E_{\text{sol}} \times n} \tag{4.33.87}$$

$$\text{LCCE based on exergy} = \frac{G_{\text{ex,annual}} \times n - E_{\text{in}}}{(\text{Annual solar exergy}) \times n} \tag{4.33.88}$$

Here, E_{sol}, n, E_{out}, E_{in}, and $G_{ex,\text{annual}}$ are, respectively, annual solar energy, life, overall annual energy output, embodied energy, and overall annual exergy gain for solar distillation system. Annual solar exergy can be calculated by multiplying E_{sol} with 0.933 (a factor obtained from the expression given by Petela, 2003).

Productivity of Solar Still

Productivity is the relationship between product and the factors used in attaining the product. It means getting more and more with less and less input of resources. It is generally expressed as the ratio of effectiveness and efficiency as per ILO (1979). One should keep in mind that yield and electricity gain can be considered as production in the case of solar still. It is not productivity. Production represents the volume, whereas productivity represents the effectiveness with which input of resources is used. Also, annual productivity should be more than 100% for a system to be feasible. Following Ashcroft (1950), Cox (1951), Benson (1952), and ILO (1979), productivity (η_p) of solar still can be written as

$$\eta_p = \frac{\text{Output of the system}}{\text{Input to the system}} \times 100 \tag{4.33.89}$$

The output consists of annual yield of water (kg) and annual electricity gained (kWh) and it can be expressed as

$$\text{Output} = R_w + R_e \tag{4.33.90}$$

where $R_w = \left(M_w \times (\text{SP})_w\right)$ and $R_e = E_e \times (\text{SP})_e$

Here, R_w, R_e, M_w, E_e, $(\text{SP})_w$, and $(\text{SP})_e$ are annual revenue (Rs.) earned from water, electricity gain, annual yield of water (kg), annual electricity gain (kWh), selling price of water (Rs./kg), and selling price of electricity (Rs./kWh), respectively. The daily yield can be evaluated by adding hourly yield for the period of 24 h. The monthly yield can be evaluated by multiplying daily yield with number of clear days observed in a month. The annual yield can be evaluated by adding monthly yield for 12 month.

The hourly electricity gain ($\dot{E}_e$) can be calculated with the help of Equation 4.33.60. The daily electricity gain can be evaluated by adding hourly electricity gain for 10 h because solar intensity exists for sunshine hours only. The monthly electricity gain can be evaluated by multiplying daily electricity gain with number of clear days observed in a particular month. The annual electricity gain can be evaluated by adding monthly electricity gain for 12 months.

Input represents the uniform end-of-year annual cost (UAC) of the solar still. UAC (Kumar and Tiwari, 2009; Tiwari and Ghosal, 2005) for a given initial investment of solar distillation systems can be expressed as

$$\text{UAC} = P_s \times F_{\text{CR},i,n} + P_s \times F_{\text{CR},i,n} \times M_s - S_s \times F_{\text{SR},i,n} \tag{4.33.91}$$

Here, P_s, S_s, and M_s are the net present cost, salvage value, and maintenance cost of the solar still, respectively. It is based on the concept of net present value. The factor $F_{\text{CR},i,n}$ is called capital recovery factor which converts the present cost into UAC and the factor $F_{\text{SR},i,n}$ is called sinking fund factor which converts the present cost into UAC (Tiwari, 2013). They can be computed as $F_{\text{CR},i,n} = \dfrac{i\times(1+i)^n}{(1+i)^n-1}$ and $F_{\text{SR},i,n} = \dfrac{i}{(1+i)^n-1}$, where i and n are the rate of interest and life of the system, respectively. Maintenance cost is generally taken as 10% of net present cost and hence value of M_s used in Equation 4.33.95 may be taken as 0.1. The first, second, and third terms used in Equation 4.33.95 are, respectively, the part of UAC corresponding to net present cost, maintenance cost, and salvage value of the solar still.

Following Equation 4.33.93, the hourly and daily productivity of solar still can be written as

$$(\eta_p)_{\text{hourly}} = \frac{[\text{Hourly yield}\times(\text{SP})_w]+[\text{Hourly electricity gain}\times(\text{SP})_e]}{\text{Hourly cost}}\times 100 \tag{4.33.92}$$

$$(\eta_p)_{\text{daily}} = \frac{[\text{Daily yield}\times(\text{SP})_w]+[\text{Daily electricity gain}\times(\text{SP})_e]}{\text{Daily cost}}\times 100 \tag{4.33.93}$$

The daily cost can be evaluated by dividing UAC with the number of clear days observed in a year and hourly cost can be evaluated by dividing daily cost with 24 h.

Here, productivity has been computed on the basis of energy. However, it should be noted that productivity can also be calculated on the basis of exergy.

Exergoeconomic Parameter for Solar Still

The evaluation of exergoeconomic parameter is an economic analysis method based on exergy/energy. It incorporates exergy/energy analysis with conventional cost analysis for improving the performance of energy systems (Tsatsaronis et al., 1993). Its aim is to estimate the cost-optimal structure and facilitate designers to find ways to enhance the performance of a system in a cost effective manner. It is considered as one of the best suitable methods for the design, analysis, and performance improvement studies of energy conversion systems. Exergoeconomic parameters (Tsatsaronis and Winhold, 1985) based on exergy loss (R_{ex}) and energy loss (R_{en}) can, respectively, be expressed as

$$R_{ex} = \frac{L_{ex,\text{annual}}}{\text{UAC}} \tag{4.33.94}$$

$$R_{en} = \frac{L_{en,\text{annual}}}{\text{UAC}} \tag{4.33.95}$$

where L_{ex}, L_{en}, and UAC are annual exergy loss, annual energy loss, and uniform end-of-year annual cost. UAC can be evaluated using Equation 4.33.99. The hourly exergy loss rate (L_{ex}) for solar still as reported by Tiwari et al. (2015) can be expressed as

$$L_{\text{ex}} = \left[(h_{cwg} + h_{rwg}) \left\{ (T_w - T_{gi}) - (T_a + 273) \ln \frac{(T_w + 273)}{(T_{gi} + 273)} \right\} \right] + \left[M_w \times c_w \left\{ (T_{wf} - T_{wi}) - (T_a + 273) \ln \frac{(T_{wf} + 273)}{(T_{wi} + 273)} \right\} \right] \quad (4.33.96)$$

where h_{cwg}, h_{rwg}, T_w, T_{gi}, M_w, c_w, T_{wf}, and T_{wi} are, respectively, convective heat transfer coefficient between water and inner glass surface, radiative heat transfer coefficient between water and inner glass surface, temperature of water, temperature of glass, mass of water in basin, final temperature of water, and initial temperature of water. The daily exergy loss can be computed by adding hourly exergy loss rate for 24 h. Monthly exergy loss can be evaluated as the product of daily exergy loss and number of clear days observed in a month. The sum of monthly exergy loss for 1 year will give annual exergy loss. Similarly, annual energy loss can be determined.

The definition of exergoeconomic parameter given by Equations 4.33.94 and 4.33.95 is appropriate if one wants to minimize the exergy/energy loss. However, it does not seem to be appropriate if one wants to compare different solar distillation systems as one need not to pay any penalty against exergy/energy loss. It happens because we do not have to pay anything for the corresponding input which is solar radiation. Also, solar radiation depends on climatic condition which cannot be controlled and hence we cannot provide the same input to different solar distillation systems while making comparison. In such case, the exergoeconomic parameter based on annual exergy/energy gain with an aim to maximize the exergy/energy gain seems to be more appropriate. So, exergoeconomic parameter based on annual exergy gain ($R_{g,\text{ex}}$) and energy gain ($R_{g,\text{en}}$) as reported by Singh et al. (2016) can be written as

$$R_{g,\text{ex}} = \frac{G_{\text{ex,annual}}}{\text{UAC}} \quad (4.33.97)$$

$$R_{g,\text{en}} = \frac{E_{\text{out}}}{\text{UAC}} \quad (4.33.98)$$

where $G_{\text{ex,annual}}$ represents annual overall exergy gain which can be computed with the help of Equation 4.33.63 and E_{out} represents annual energy gain which can be computed with the help of Equation 4.33.59.

Enviroeconomic Parameter for Solar Still

The evaluation of enviroeconomic parameter for solar still presents an approach to control the environmental pollution by providing economic incentives for attaining reductions in emissions of pollutants and encourages deploying renewable energy technology that does not emit carbon to the atmosphere. The enviroeconomic analysis is based on the price of CO_2 emission and emitted carbon quantity. Following Caliskan et al. (2012), the enviroeconomic parameter based on CO_2 emission reduction and CO_2 emission reduction price can be written as follows:

$$C_{CO_2} = c_{CO_2} \times x_{CO_2} \quad (4.33.99)$$

where C_{CO_2}, c_{CO_2}, and x_{CO_2} are enviroeconomic parameter or environmental cost reduction parameter, CO_2 emission reduction price per tCO_2, and reduction in CO_2 emission for the whole life of solar still (tCO_2), respectively.

If unit power is used by a consumer and the losses due to poor domestic appliances are around 20% and transmission and distribution losses are 40%, which is common in Indian conditions, then the power that has to be generated in the power plant is $\frac{1}{(1-0.2)(1-0.4)} = 2.08$ units. The average

carbon dioxide emission for electricity generation from coal is ~0.96 kg of CO_2 per kWh at source (Sovacool 2008). Thus, the amount of CO_2 emission for unit power consumption by the consumer is $2.08 \times 0.96 = 2$ kg.

The expression for reduction in CO_2 emission based on energy ($x_{CO_2,en}$) and based on exergy ($x_{CO_2,ex}$) for the whole life of solar still can, respectively, be written as

$$x_{CO_2,en} = (E_{out} \times n - E_{in}) \times 2 \times 10^{-3} \tag{4.33.100}$$

$$x_{CO_2,ex} = (G_{ex,annual} \times n - E_{in}) \times 2 \times 10^{-3} \tag{4.33.101}$$

where E_{out}, E_{in} $G_{ex,annual}$ and n are the annual energy available from the solar still, embodied energy, annual exergy gain and life of solar still, respectively.

Den Elzen et al. (2011) mentioned the international carbon price between 13\$/tCO_2 and 16\$/tCO_2 for the low and high pledge scenario. So, average value comes out to be 14.5\$/tCO_2. Hence, the value of c_{CO_2} can be taken as 14.5\$.

Production Cost of Water and Cost of Electricity Gain

The cost (C_w) of water production in Rs./kg and cost (C_e) of electricity gain in Rs./kWh for N identical PVT-FPC solar still (Singh et al., 2016), respectively, can be written as

$$C_w = \frac{\text{UAC} - R_e}{M_w} \tag{4.33.102}$$

$$C_e = \frac{\text{UAC} - R_w}{E_e} \tag{4.33.103}$$

If the value of (UAC$-R_w$) becomes negative, then it can be taken as zero because negative cost does not make any sense. It will make value of C_e zero which will mean that we are getting electricity at no cost. In the case of passive solar still, no electricity is produced and hence C_e will not appear there.

Passive Solar Stills

A conventional single-slope passive solar still has already been explained in Section 4.33.3. The overall thermal efficiency of this solar still varies from 5% to 40% throughout the year. It has been modified to enhance its performance by increasing heat gain in the basin resulting in higher evaporation/condensation and reducing heat losses to ambient. Some modified passive solar stills are as follows.

Modified Single-Slope Solar Still

The conventional single effect solar still has low efficiency due to poor dissipation of latent heat of the condensing vapor at glass cover surface. A modification of conventional solar still is multieffect solar still which utilizes the latent heat of condensing vapor. It consists of a number of basins which contains brackish water. The vapor evaporated from first basin releases its latent heat at the lower surface of second basin. This latent heat is used to heat the water in the second basin rather than being wasted to atmosphere. This process of transferring latent heat to the second basin placed above the first basin is called multieffect in solar still. The material used for additional basin is transparent so that radiation can be allowed to lower basin. These stills produce a larger quantity of water in comparison to convention single effect solar still for the same area of basin because latent heat of condensation of vapor is utilized to heat water. However, multieffect solar stills are costlier as they need additional material. Cooper and Appleyard (1967) designed a multieffect solar still for optimum utilization of heat energy and decreasing the losses by multiple condensation and

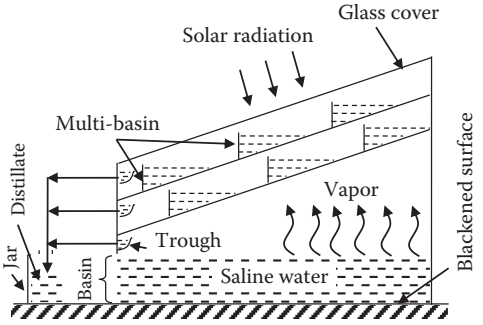

FIGURE 4.33.10 Multieffect multibasin solar still.

evaporation inside a single unit of solar still. Lobo and Araujo (1977) reported an increase in the cost of standard still per unit area by 15–25% when intermediate basins are added to it. Hence, they designed a multieffect multibasin solar still (Figure 4.33.10) to overcome this problem. They concluded that the double-effect solar still would produce 40%–55% more distillate than standard solar still at 20–25 MJ/m^2/day and cost of distillate from multieffect solar still could be 20%–25% lower because of the optimal utilization of space.

Sodha and Tiwari (1979) investigated the performance of double-basin solar still for various systems and climatic conditions. He has concluded that double basin still gives 36% higher yield than that of a single basin and observed that the yield increases rapidly as the insulation thickness is increased up to 4 cm and then it increases rather slowly. Al Mahdi (1992) predicted the effect of number of basins on the daily yield of the still. He has observed that the double basin still gives the highest peak. However, the triple and quadruple basin stills produce higher daily yield due to appreciable amounts of distillate during the night. But, addition of more than four basins does not have significant effect on yield. It may happen due to the fact that increase in temperature of water will be lesser due to higher water mass.

El-Sebaii (2005) studied the triple basin solar still and reported that the total daily yield of the still was 12.635 kg/m^2 on a typical summer day of Tanta (latitude 30° 47′ N). Tanaka et al. (2000, 2002) designed an improved single-slope solar still called single-slope single-basin multieffect solar still (Figure 4.33.11) for getting higher yield. In this case, a wetted wick is used to cover the outer portion of vertical wall to facilitate condensation on its inner surface. The condensation takes place at the inner surface of vertical wall due to its lower temperature in comparison to glass cover and latent heat is released to the vertical wall which results in heating the brine water trickling over it

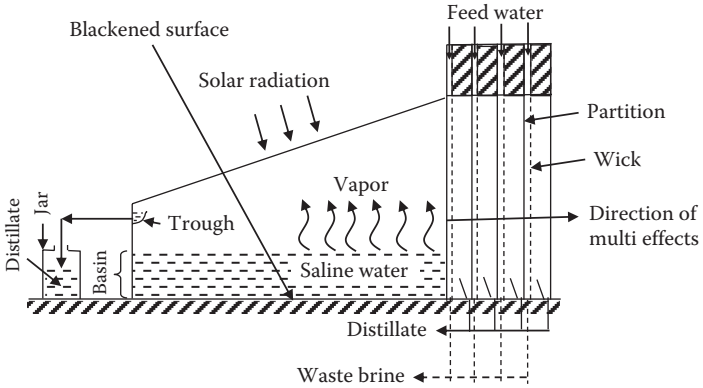

FIGURE 4.33.11 Single-slope single-basin multieffect solar still.

and further evaporation occurs. This evaporated water is condensed at other metallic wall covered with wetted wick after releasing the latent heat and this process continues.

A further improvement of single-slope solar still is regenerative-type solar still (Prakash and Kavathekar, 1986). In this case, saline water is allowed to flow over the glass surface (Figure 4.33.12, Bapeshwararao et al., 1983) which results in the improvement of yield of upper basin as well as efficiency of system. Reduction in the temperature of glass surface results in the increased circulation of air inside the still which leads to higher evaporative and convective heat transfer between water and glass (Toyama et al., 1983). Also, lower glass surface temperature increases the rate of condensation. The flowing fluid (water) over the glass cover surface is preheated before going into the basin. The glass cover temperature decreases and yield increases by intermittent flow (Madhuri and Tiwari, 1985) or continuous flow (Abu-Hijleh, 1996) of raw cooling water on the glass cover (Abu-Arabi et al., 2002). A/K Abu-Hijlew and Hasan (1997) reported that the production rate was increased by 20% when water was allowed to flow over condensing cover. Zuriat and Abu-arabi (2004) investigated the modeling and performance of regenerative solar desalination systems and concluded that the yield was increased by 34%–35% for the month of March and June for Oman weather condition.

Dutt et al. (1989) studied the effect of adding dye in the double basin still and concluded that the system efficiency was increased by 10% by adding dye in the double basin still because of increased yield due to higher increase in temperature of water. They also reported that the evaporative heat transfer coefficients were strong functions of temperature; however, variation of convective and radiative heat transfer coefficients was weak with temperature. The performance of multibasin solar still depends strongly on the mass of water in the basin. At lower mass in the basin, higher distillate is obtained because of higher increase in water temperature which results in larger difference of temperature between water surface and glass surface. Tiwari et al. (1991) studied the performance of double-basin solar still and reported that the total production of distillate was strongly dependent on depth of water in the lower basin. At lower water depth in basin, a higher yield was obtained; however, no distillation was obtained during off-sunshine hours. At higher depth of water, a lower amount of distillate was obtained, but distillation process continued for off-sunshine hours also due to heat content of water mass.

An experimental study on upward-type double-effect solar distillers with air flow through the second effect (Figure 4.33.13) was carried out by Yeh (1993). The inclination of still was 10° with the horizontal surface. A lower inclination is kept if the solar still is to be used for summer condition. He concluded that the upward-type double-effect solar distillers were more efficient than downward-type units. Hamdan et al. (1999) investigated the performance of the single, double, and triple basin

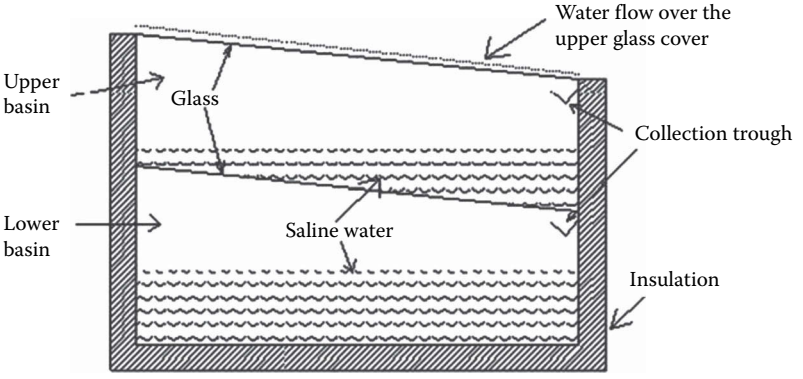

FIGURE 4.33.12 Double basin solar still with water flowing over upper glass cover. (From Bapeshwararao, V.S.V. et al., *Energy Convers. Manag.*, 23(2), 83–90, 1983. With permission.)

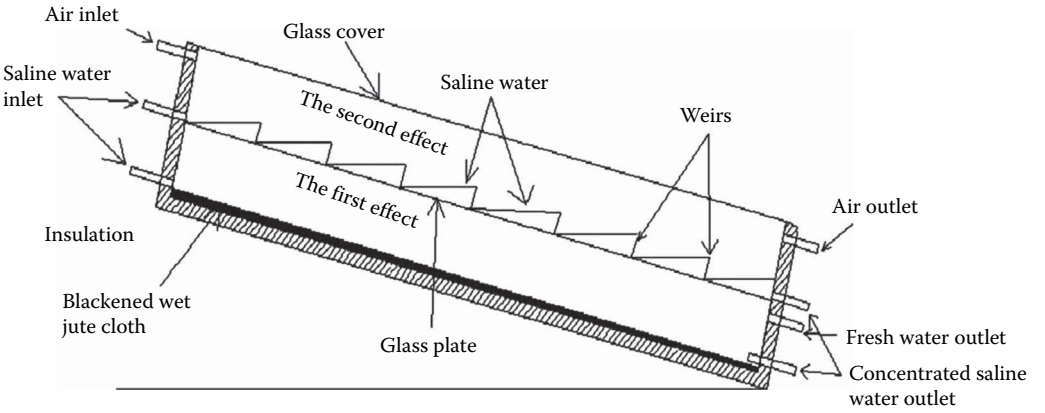

FIGURE 4.33.13 Upward-type double effect solar still. (From Yeh, H., *Energy*, 18(11), 1107–1111, 1993.With permission.)

pyramid solar stills under Jordanian climate and concluded that the triple effect solar still gave the highest daily efficiency followed by double and single effect due to similar variation in daily yield.

Cappelletti (2002) investigated experimentally the double-basin solar still (Figure 4.33.14). He designed the upper basin of the still as "V" shape and the provision was made to collect the condensed water of the lower basin in the middle. The efficiency of the still was found to be about 16% due to low temperature of the water in basin (around 50°C). Al-Hinai et al. (2002) reported the parametric investigation of a double-effect solar still and it was compared with a single effect solar still. The basin of solar still was made shallow with asphalt coating. They found an average annual yield of solar still as 4.15 and 6 kg/m^2/day for single and double-effect solar stills, respectively. Fukui et al. (2004) investigated theoretically a new maritime, life-saving, multiple-effect solar still design and concluded that the yield was increased with the use of multieffect still because of the utilization of latent heat of condensation. Al-Karaghoulia and Alnaserb (2004) investigated experimentally the performance of single and double-basin solar stills and a higher production rate was

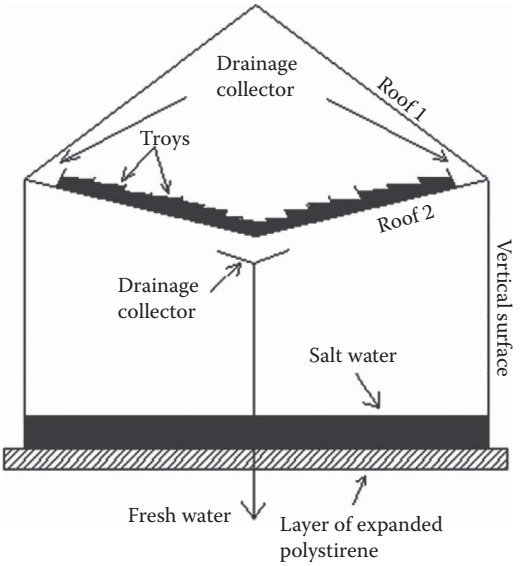

FIGURE 4.33.14 Double basin solar still. (From Cappelletti, G.M., *Desalination*, 142, 221–228, 2002. With permission.)

reported with the double basin still. It occurred because temperature of glass in the case of double basin was lower which in turn occurred due to entrapment of solar radiation in two basins in the case of double basin solar still.

They also reported that the insulation had significant effect on the productivity, especially for the double-basin type because heat losses are lower in insulation is used.

An inverted absorber solar still is another modification of single-slope solar still. It is a concentrating type of solar still and consists of a conventional solar still with a curved reflector below its metallic basin plate. Figure 4.33.15 shows the schematic diagram of inverted absorber double-basin solar still. This type of solar still receives solar radiation from top as well as from bottom. The reflector provided below the metallic basin concentrates the solar radiation on the lower portion of basin. Hence, temperature of water in this type of solar still increases at a faster rate in comparison to conventional single-slope solar still due to additional heat gain which results in higher yield. Tiwari and Suneja (1998) studied theoretically the single-basin inverted absorber single-slope solar still and reported daily yields of 5.1, 4.8, and 4.5 L/m^2 at water depths of 0.01, 0.02, and 0.03 m, respectively. Further, Sangeeta and Tiwari (1999a) studied an inverted absorber double-basin solar still to assess the effect of water depth on its and concluded that the yield of system was maximum when the depth of water was least in the lower basin. It happened due to higher increase in temperature at lower depth because heat loss corresponding to heat capacity was lower as water mass was lesser at lower depth.

Sangeeta et al. (1997) investigated the parametric study on inverted double-effect solar still and reported a 10% increase in yield if the initial water temperature was raised from 22°C to 35°C. The yield of an inverted absorber double-basin solar still was found to increase by about 99% as the absorptivity of the absorber increases from 0.55 to 0.95. It happens because loss decreases with the increase in absorptivity and more heat is transferred to water due to higher temperature difference between water mass and absorber. Sangeeta and Tiwari (1999b) studied an inverted absorber triple effect solar still and reported that the yield of inverted triple effect solar still was higher than the yield of conventional triple effect solar still because higher solar intensity was available for water mass due to reflector provided at the bottom. They also concluded that the enhancement in daily yield was significant as the number of effects increased from the first effect to the third effect. It happened due to better utilization of latent heat of condensation and better evaporation. There is a marginal increase in the yield in the case of inverted solar still if the number of basins is increased beyond seven. Also, the yield from a seven-effect inverted absorber solar still is about 4.2 times the yield from an inverted absorber single-basin solar still (Sangeeta and Tiwari, 1998).

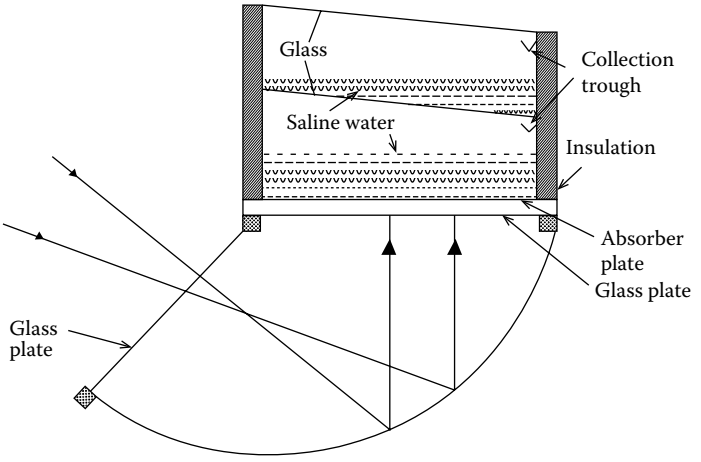

FIGURE 4.33.15 Inverted absorber double basin solar still. (From Sangeeta, S., Tiwari, G.N., *Energy Convers. Manage*., 40, 1885–1897, 1999a. With permission.)

Addition of condenser with the conventional solar still is another modification. The condensation rate is low in a simple conventional still because the inner surface of the glass cover is only area available for condensation and the difference of temperature across glass thickness is very small. Hence, an additional area for condensation is added to conventional still to increase the rate of condensation which results in higher yield. Heat capacity of the evaporation area increases due to the provision of additional area and the latent heat of condensation is used by water in upper basin of condenser area. Fath (1996) investigated the performance of a two effect solar distillation unit shown in Figure 4.33.16. In this type of solar still, the evaporated vapor from the first effect is allowed to be purged to the second effect. Fins are provided at the outer surface of the second effect cover to maintain the cover at or near-ambient temperature, and inner surface is reflective to minimize radiation losses. He reported the daily yield for the proposed unit as 10.7 kg/m^2/day under the climatic conditions of the city of Dhahran, Saudi Arabia. A higher yield is obtained due to better utilization of heat obtained from solar intensity and lower heat losses.

Madhlopa and Johnstone (2009) investigated the performance of a passive solar still with separate condenser shown in Figure 4.33.17. It consists of three basins. One basin (basin 1) lies in the

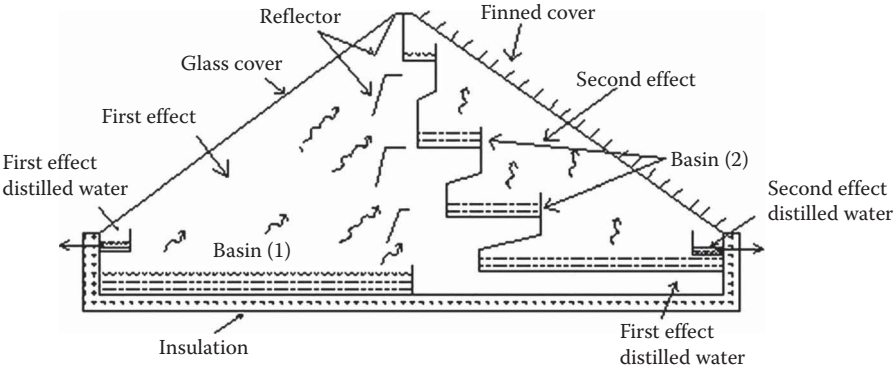

FIGURE 4.33.16 Solar still with inbuilt condenser. (From Fath, H.E.S., *Desalination*, 107, 223–233, 1996. With permission.)

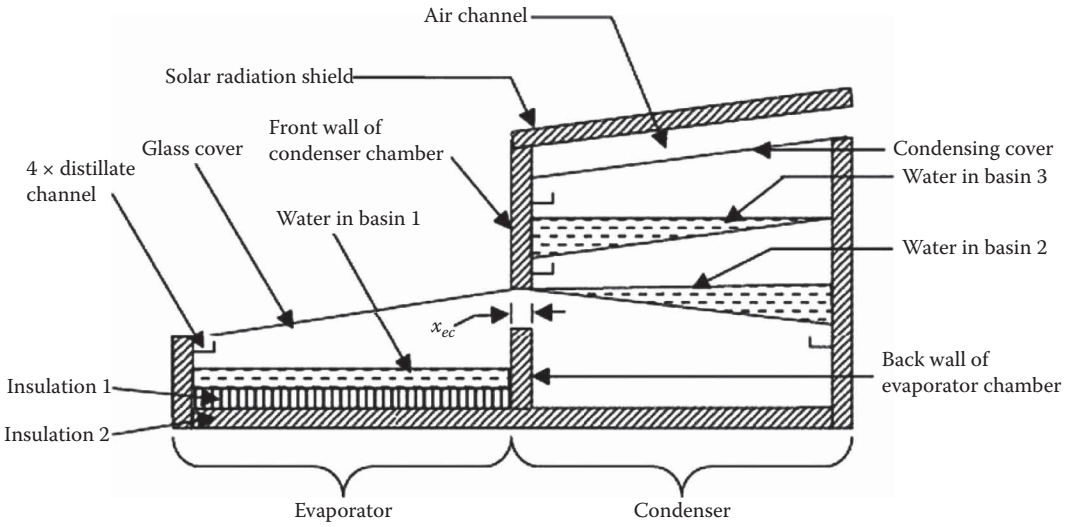

FIGURE 4.33.17 Solar still with separate condenser. (From Madhlopa, A., Johnstone, C., *Renewable Energy*, 34, 1668–1677, 2009. With permission.)

evaporation chamber and two other basins (2 and 3) lie in the condenser chamber. The evaporator basin is covered with glass cover and basin 3 is covered by an opaque condensing cover. The top part of the condensing cover is shielded from solar radiation so that the cover remains relatively cool. Some part of water vapor from the first effect condenses under the glass cover. The remainder of it flows into the condenser by purging and diffusion and condenses under the liner of basin 2. After analyzing the system, they inferred that the distillate of the still was 62% higher than that of the conventional type because of faster condensation/evaporation.

Single basin solar still with baffle absorber is another modification. In this type of solar still, aluminum or some other suitable material sheet is placed in the water mass. This plate is painted black at the top surface and thermally insulated at the bottom surface and it is commonly known as baffle. The plate floats in water and divides the unit into a shallow basin evaporative zone above the plate and heat storing zone below the plate. The plate absorbs a part of solar radiation entering the still which results in increasing the temperature of plate and heat is transferred to the brackish water in heat-storing zone by conduction. No heat transfer takes place between the two zones by convection through a gap left between the plate and side walls because hot water remains above the plate due to its lower density. Heat transfer by conduction is very small between the water above and below the plate because plate is thermally insulated at the bottom. The temperature of water above the plate becomes lower than the temperature of heat-storing zone at night. So, convection current is developed between the two zones and cold water above the plate is replaced by hot water below the plate through the gap left between the plate and side walls. This helps in the continuation of evaporation and condensation process till the temperature between water and glass is maintained during nocturnal production.

El-Sebaii et al. (2000) investigated theoretically and experimentally the effect of using aluminum plate as baffle suspended absorber in single-basin solar still and reported that the yield is about 20% higher in comparison to conventional single-slope solar still because of decrease in preheating time of the upper water column of the modified still. Further, Rahim (2003) used a painted black aluminum sheet to divide the basin water into an evaporating zone above the plate and a heat-storing zone below the plate. He reported that the system did not need any source of external power for storing and recovering processes. Srivastava and Agrawal (2013) analyzed single-slope basin-type solar still experimentally and theoretically by integrating multiple low-thermal inertia porous absorbers floating adjacent to each other. They reported about 15%–48% enhancement in yield in comparison to conventional solar still because of lower heat loss and increased thermal capacity of base fluid due to the presence of absorber plate in water mass. El-Bialy (2014) investigated experimentally the effect of basin water mass, the type of the floating absorber plate and thermal conductivity of plate on the daily productivity and efficiency of single-slope single-basin solar distiller with a floating absorber (SBDFA) under the weather conditions of Tanta, Egypt (Latitude 30° 47′ N) during typical summer days. Figure 4.33.18 shows the schematic diagram of SBDFA. The result obtained from SBDFA was compared with conventional solar still for the same weather condition. For all investigated values of the mass of water above the floating absorber, the yield of the SBDFA was found to be higher in comparison to conventional solar still under the same weather condition. The daily yield was found to be 42.2%, 15.2%, 20.1%, and 17.2% higher than conventional solar still when mica, stainless steel, aluminum, and copper were used as floating absorbers. He also indicated that SBDFA can be used for supplying potable water with reasonable amounts.

Double Slope Passive Solar Still

The cross-sectional view of double-slope solar still is shown in Figure 4.33.19. It consists of two condensing glass covers facing east and west direction and a basin which is filled with saline water to be purified. The working principle of double-slope solar still is similar to single-slope solar still. It can harness the solar radiation for the entire day unlike single-slope solar still which harnesses the solar radiation for the limited time during the day. Rubio et al. (2004) studied the performance of double-slope solar still for the climatic condition of Mexico. They developed thermal model and validated by experimental results. Further modification of double-slope solar still can be done to collect rain

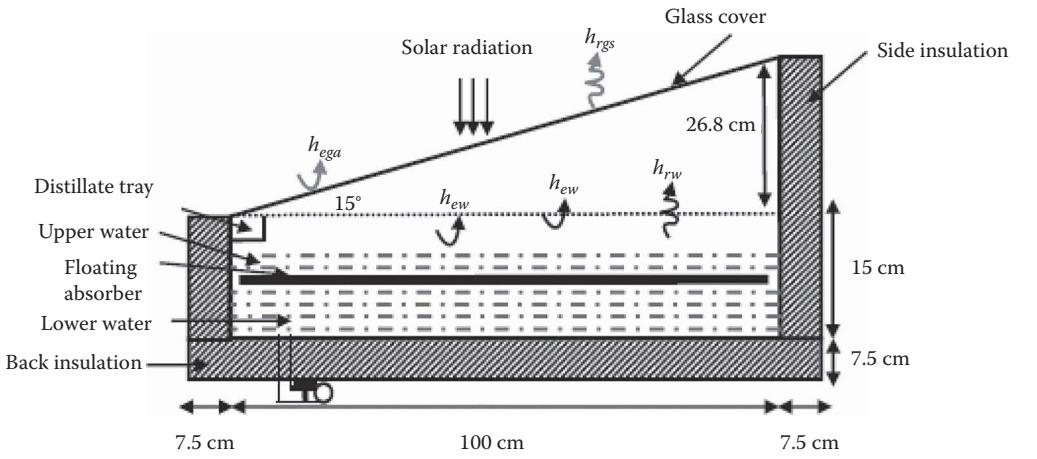

FIGURE 4.33.18 Single slope single basin solar distiller with a floating absorber. (From El-Bialy, E., *Energy*, 68, 117–124, 2014. With permission.)

water by extending the height of walls. Rain water is distilled water and can be used directly. During rainy season, solar still becomes nonfunctional due to unavailability of solar radiation. Rain water can be used during that time.

A further modification to double-slope solar still is the integration of additional basins inside the solar still. Kumar et al. (1991) investigated the effect of additional basin in double-slope solar still. Their conclusions are as follows:

1. Yield decreases with the increase in depth as the increase in temperature of water is lower at higher depth due to higher heat capacity of water mass.

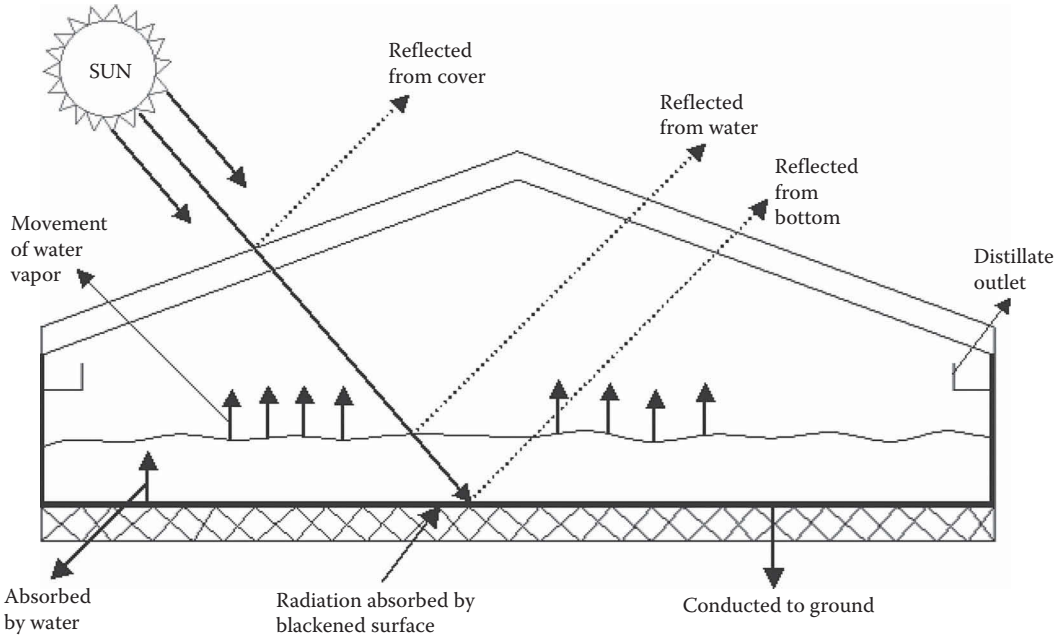

FIGURE 4.33.19 Cross-sectional view of a double slope passive solar still placed in east–west direction.

2. The daily yield increases with the decrease in depth of water in the upper basin. It happens due to better utilization of the latent heat of vaporization.
3. The lower basin produces higher distillate than upper basin.
4. Double basin solar still has higher efficiency than single-basin solar still.

A study of double-basin double-slope solar still was conducted by Rajaseenivasan et al. (2013) experimentally with diverse basin conditions. Figure 4.33.20 represents the schematic diagram of double-basin double-slope solar still. The results obtained from double-slope double basin solar still were compared with the conventional single-basin double-slope solar still. The upper basin of the double basin still was split into three compartments (each side). It was done to ensure even distribution of water mass through the entire area of the upper basin. The tests were performed with different depth of water in the basin taking mild steel pieces as energy storing material. Black cotton cloth, jute cloth, and waste cotton pieces were used as wick materials and small clay pot as porous material. They concluded that the yield of the double-basin solar still with energy storing materials in lower basin was 169.2% higher than the conventional still. Zeroual et al. (2011) and Rajamanickam and Ragupathy (2012) studied south–north oriented of double-slope passive solar still with partially cooled condenser and reported an increase of 11.82% in the yield.

Effect of Nanofluids on the Performance of Single and Double Slope Passive Solar Stills

The term nanofluid was coined by Choi (1995) for the first time. Nanofluids having water as solvent are obtained by mixing nanoparticles with water in a particular concentration along with sodium dodecyl benzene sulfonate for maintaining even suspension. They are stirred by magnetic stirrer for around 15 min and then ultrasonicated with the help of ultrasonicator. The prepared sample is then tested for the computation of stability and thermal conductivity. Zeta Potential is used for stability testing. Aluminum oxide (Al_2O_3), zinc oxide (ZnO), iron oxide (Fe_2O_3), tin oxide (SnO_2), or some other material can be used as nanoparticles. The size of particles is of the order of nanometer. The yield of solar still depends on stability and thermal conductivity of fluid. However, thermal conductivity dominates over stability and hence it is the most important factor while using nanofluid. The thermal conductivity of nanofluid can be controlled by the concentration and aspect ratio. Higher the thermal conductivity, sooner will the fluid be heated, and higher temperature difference between water surface and glass cover will be obtained which will positively affect the yield. Unlike conventional fluid used in basin, water receives heat from both basin liner and metallic nanoparticles. Elango et al. (2015) investigated the performance of single-slope passive solar still with different water nanofluids experimentally. They used nanofluids of aluminum oxide (Al_2O_3), zinc oxide (ZnO), iron oxide (Fe_2O_3), and tin oxide (SnO_2) of different concentrations. They concluded that single-slope solar still with Al_2O_3, ZnO, and SnO_2 nano-fluids had 29.95%, 12.67%, and 18.63% more production respectively than single-slope solar still with water. It happens because thermal

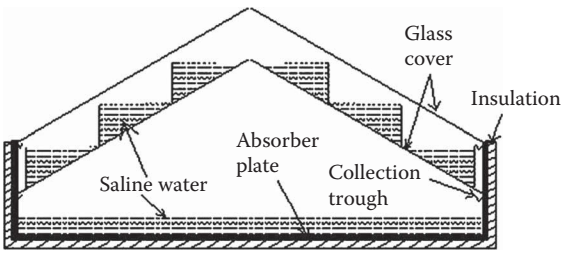

FIGURE 4.33.20 Double basin double slope solar still. (From Rajaseenivasan et al., *Desalination*, 319, 25–32, 2013. With permission.)

conductivity of Al_2O_3 nanofluid is highest followed by ZnO and SnO_2. They also observed that the payback period of nanofluid was 2.85 years which was lesser than that of the still with water as the basin fluid due to higher yield.

Sahota and Tiwari (2016a,b) investigated theoretically the performance of double-slope solar still using nanofluids. Sahota and Tiwari (2016a) investigated the effect of Al_2O_3 nanofluid on the performance of double-slope passive solar still and concluded that yield of solar still is higher by 12.2% than solar still with water at 35 kg mass of water. It happened because of increase in heat transfer coefficient and fluid temperature. They have also concluded that the daily yield increases with the increase in the concentration of nanoparticles in water because of increased surface area for heat transfer from nanoparticles to water at higher concentration of nanoparticles. Further, Sahota and Tiwari (2016b) studied theoretically the performance of double-slope passive solar still for optimized concentration (0.25%) of metallic nanoparticles namely Al_2O_3, titanium oxide (TiO_2), and copper oxide (CuO). They concluded the following on the basis of their studies.

1. The value of fluid temperature difference between nanofluid and water increases with an increase in the concentration of nanofluids because of increased surface area for heat transfer from nanoparticles to nanofluid at higher concentrations.
2. Thermal energy, exergy, thermal efficiency, and exergy efficiency are higher for Al_2O_3 nanofluid followed by TiO_2 and CuO nanofluids. It happens due to the increased thermophysical properties of Al_2O_3 nanofluid in comparison to other nanofluids under study.

Thermal–Electrical Solar Still with Boosting Reflector

Figure 4.33.21 shows the thermal–electrical solar still with boosting reflector and outside condenser proposed by Monowe et al. (2011). This solar still needs solar radiation to evaporate water from a still and a small amount of electrical energy input to run low power electrical fan (25 W/m^2 of basin area) which forces water vapor into the outside condenser. The vapor in the condenser releases its latent heat which can be used to preheat the feed water for the next batch or even for operating the still at night. This heated water can also be used for domestic purpose. Hence, loss of latent heat of condensation to the environment is minimized. The boosting reflector concentrates the solar energy to the glass. A simple railing device is provided to adjust the angle of the boosting reflector from visual observation. It can also be used to protect the glazing of the still during a hail storm or dust storm. A tank is connected to the other end of the condenser coil to collect the distilled water. Preheated saline water must be removed from the condenser every day to keep the efficiency of the still at a high level. This still is portable as saline water is charged in from the borehole reservoir using hand-operated mechanical pump.

Monowe et al. (2011) investigated the performance of thermal electrical solar still with boosting reflector and outside condenser. They have reported the efficiency of still can be as high as 77% if the preheated saline water was employed for domestic purposes. Further, efficiency can be as high as 85% if preheated saline water could be used to run the still during night times and to recharge the still by the next batch of preheated water.

Wick-Type Solar Still

A basin-type solar still takes some time to increase the temperature of water and then for evaporation of water because of heat storage due to heat capacity of water. This drawback is overcome by wick-type solar still. Figure 4.33.22 shows the schematic diagram of multi wick-type solar still (single effect). It mostly comes under inclined-type solar still. In a wick still, a water reservoir is provided at the top of the absorber and one end of a number of jute cloth pieces (wicks) are dipped into the reservoir while other ends are spread over absorber. A thin sheet of polyethylene is provided between two jute cloth pieces. The feed water flows slowly through a porous wick which is also called radiation-absorbing pad. Water gets evaporated immediately after receiving the solar

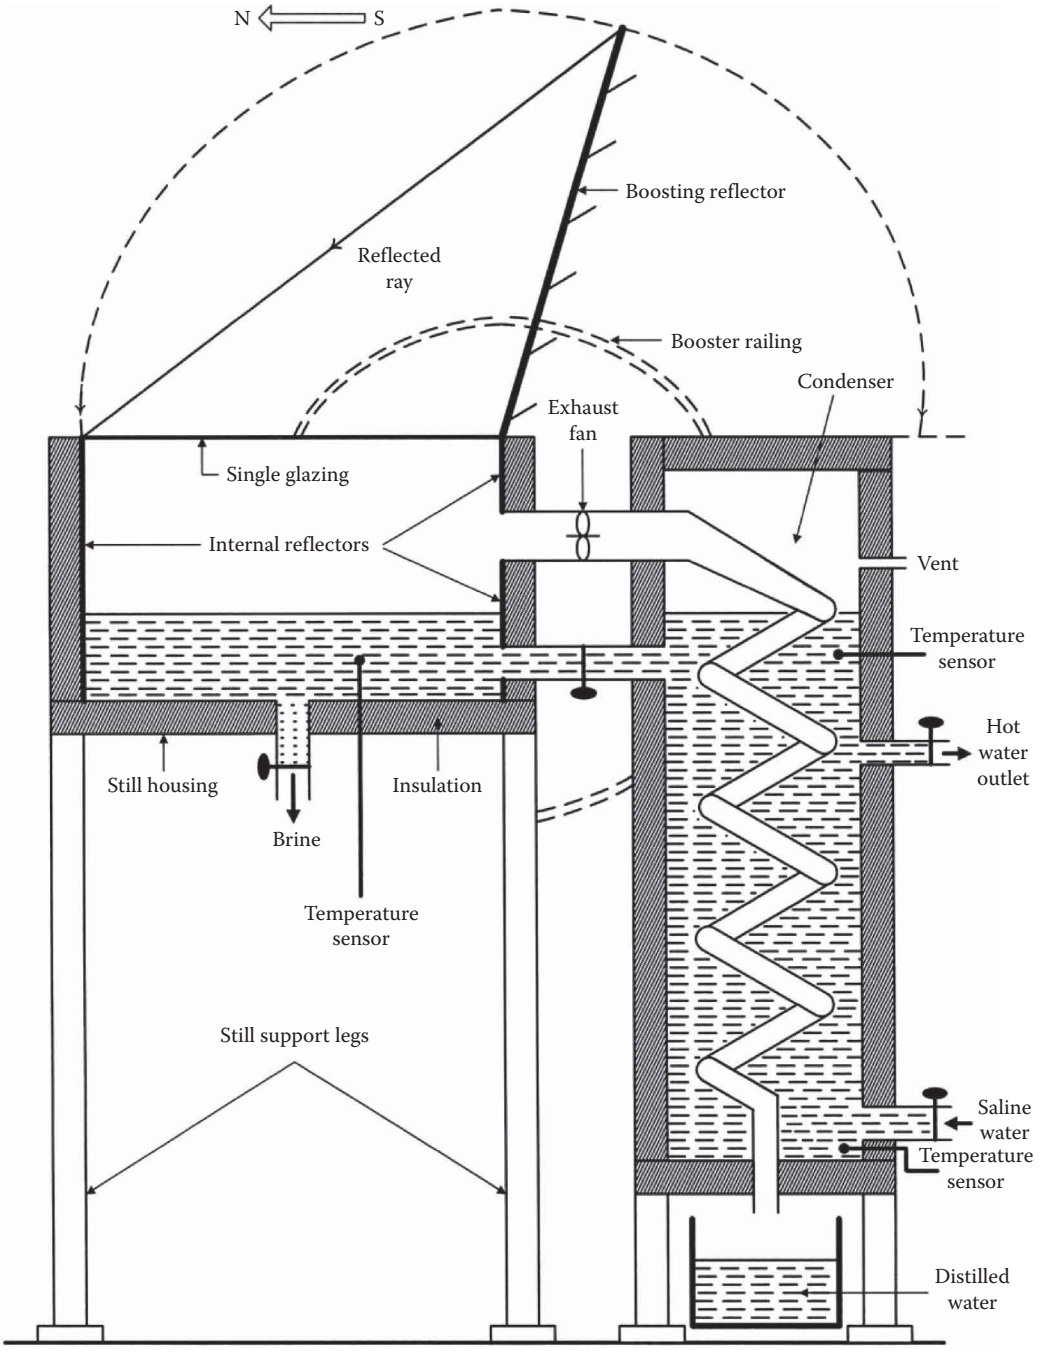

FIGURE 4.33.21 Thermal–electrical solar still with boosting reflector and outside condenser. (from Monowe P., Masale M., Nijegorodov N. and Vasilenko V., *Desalination*, 280, 332–338, 2011.)

radiation by the pad and condenses at the inner surface of glass. There are generally two advantages of wick still over basin still. First, the wick still can be made inclined so that the feed water presents a better angle to the sun. It results in the reduction of reflection. Second, depth of water is very small due to lesser feed water in the still at any time and hence the water is heated more quickly to a higher temperature. The main disadvantage of such type of still is that it does not produce distillate while

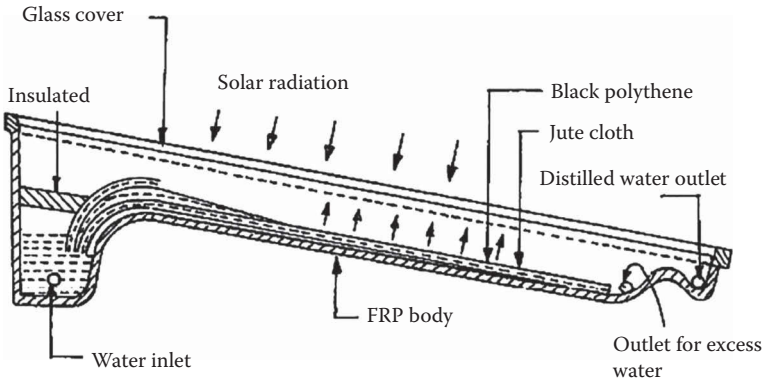

FIGURE 4.33.22 Wick-type solar still.

cloud passing or after sunset. However, basin-type solar still continues to produce distillate for some time due to heat stored in the basin water.

Sodha et al. (1981) and Tiwari and Salem (1984) investigated multiwick solar still and reported that the heat storage effect was minimized because of continuous flow of feed water through the capillary effect. The inverted multiwick double-effect solar still produced 20% higher daily yield than the conventional multieffect still. The yield was enhanced with the decrease in flow rate for a particular length of still. Also, the number of effect has a significant effect on the total yield of the still. The daily yield was increased with an increase in inlet water temperature, particularly in the second- and third-stage distillation (Tiwari et al., 1989). Singh and Tiwari (1992) studied the performance of the double-effect multiwick solar still shown in Figure 4.33.23 and reported a decreases in overall thermal efficiency with the increase in mass flow rate. Also, thermal efficiency is always higher in the first effect than that of the second effect.

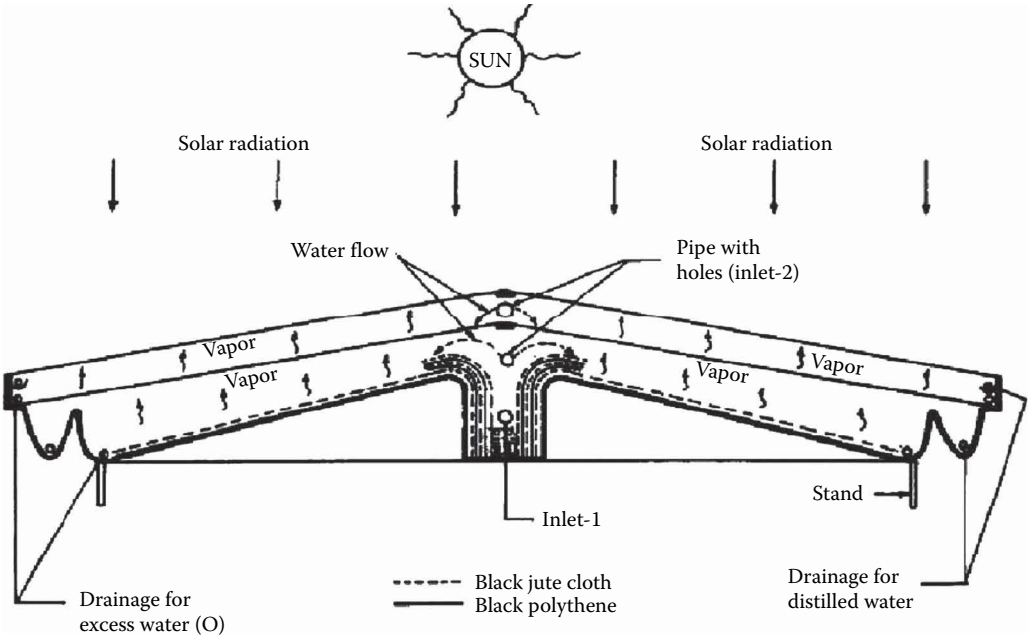

FIGURE 4.33.23 Double effect, wick-type solar still.

Yeh and Chen (1992) investigated wick-type, double-effect solar distillers with air flow through the second-effect unit experimentally. Water vapor was carried out from the second-effect unit to improve the production rate. There was a significant increase in productivity when the airflow was conducted at the optimal rate, especially for lower strengths of solar radiation. Kumar and Anand (1992) investigated the tubular multiwick solar still and found a higher distillate output of about 8%, 13%, and 18% for tubular multiwick solar still in comparison to tubular solar still, the simple multiwick solar still and conventional basin-type solar still.

Active Solar Still

If some external source is added to passive solar still to transfer thermal energy to water mass in the basin, then the solar still is called active solar still. A higher increase in the temperature of water is obtained which results in a higher temperature difference between water surface and glass cover surface. A higher evaporation is obtained as a consequence of higher temperature difference and ultimately higher distillate is produced. The thermal energy can be added to water mass either directly through solar collector/concentrator panel or indirectly through heat exchanger. Most of the passive solar stills discussed in Section 4.33.10 can be operated in active mode by integrating with source of thermal energy. This type of solar still is generally more suitable for commercial purpose as the initial investment is higher. However, it can be used for domestic purpose also.

FPC-Integrated Solar Still

The integration of FPC to basin-type solar still was proposed by Soliman (1976). The water in the basin is heated up directly by solar radiation and it also receives heat while passing through the pipe in the FPC. Pipes in FPC are provided beneath the absorber plate to gain maximum amount of solar radiation. This type of solar still operates at higher temperature of 70°C–80°C. However, the water temperature can be increased to 100°C. Some other fluids may be used in place of water like nanofluids/oils for temperature higher than 100°C. FPC-integrated solar still was also investigated by Badran et al. (2005) and reported a significant increase in yield. The yield of this solar still was 36% higher than passive solar still because of higher increase in water temperature as external heat is provided in addition to solar intensity. Further, a thermal model of FPC-integrated active solar still was developed by Rai and Tiwari (1982) and it was validated by experimental results. Performance of the system was further improved through regeneration (Bapeshwar and Tiwari, 1984; Dutt et al., 1988). In this type of solar still, water is allowed to flow over the glass cover and this preheated water is fed to basin. The glass surface temperature is reduced because of water flowing over it which results in the creation of higher temperature difference between water surface and glass surface and hence improvement in yield is obtained. The number of FPC can be optimized for getting optimum distillate output which was done by Kumar and Tiwari (1996a,b). They reported the optimum number of collectors as 10, 9, and 6 for single, double, and triple effect, respectively.

In the case of FPC-integrated active solar still, external electric source is required to run the pump and it is not self-sustainable for operation in remote areas. Hence, to make the system self-sustainable so that it can operate in remote areas also, FPC can be covered partially or fully by PV module. Such type of system is called hybrid PVT active solar still. Kumar and Tiwari (2010) designed, fabricated, and analyzed the performance of hybrid PVT-FPC single-slope active solar still. This system was equipped with PVT to operate in remote location without grid connection as the need of electrical was fulfilled by PVT output. The effective area of PV module was taken as 0.605 m2 with 36 solar cells connected in series. They integrated two FPCs in series to the basin of still. A DC motor pump was inserted between the basin and inlet to the first collector and they were connected through insulated pipe. Out of the two, only one FPC was partially covered by PV module. They conducted the experiment for different water depth and reported the maximum daily yield of system as 7.22 kg/m^2 at 0.05 m water depth. It was also observed that the system was self-sustainable to operate in remote locations. Singh et al. (2011) extended the same work for

double-slope active solar still and concluded that the yield was 1.4 times higher than that obtained for hybrid PVT-FPC single-slope active solar still. The reason being that the moderate solar intensity exists for longer period in the case of double-slope active solar still and also heat loss is lower due to lower surface area of double-slope active solar still. It was also concluded that the total cost of the system was 14% lower than hybrid PVT-FPC single-slope active solar still. It happened due to the geometrical shape of double-slope solar still as the material requirement in this case is lower if the same basin area is maintained.

The work of Kumar and Tiwari (2010) was further extended by Tiwari et al. (2015) and Singh et al. (2016). The solar still coupled with two identical partially covered PV module FPCs is shown in Figure 4.33.24a,b. Tiwari et al. (2015) investigated this active solar distillation system for exergoeconomic and enviroeconomic parameter for New Delhi climatic condition. The hourly thermal, exergy, electrical, overall exergy, and overall thermal efficiency was also computed and results were compared with the results obtained by earlier researchers. They concluded that daily thermal efficiency of this solar distillation system was less than systems designed by Kumar and Tiwari (2010) and Singh et al. (2011) because lesser area of collector is exposed to sunlight to gain thermal energy as both collectors are partially covered in this case. However, daily exergy efficiency of the system was higher than the system designed by Kumar and Tiwari (2010) but slightly lower than the system proposed by Singh et al. (2011). Further, the daily electrical exergy efficiency, the daily overall exergy efficiency and the daily overall thermal efficiency of solar distillation system under study were higher than the systems designed by Kumar and Tiwari (2010) and Singh et al. (2011). It happened because of the presence of larger area of PVT as both collectors are partially covered with PVT which produces higher electrical energy/exergy.

Singh et al. (2016) investigated active solar still integrated with two hybrid PVT collectors experimentally under the composite climate condition of New Delhi. They developed the thermal model of the system and validated with experimental results. The annual productivity was found to vary between 120.29% and 883.55% depending on the rate of interest and life of solar still. The annual productivity was obtained more than 100% which indicated that the system was feasible. There are two advantages of such type of solar still. First, it is self-sustainable to operate in remote areas where electricity has not reached so far but solar energy is available. Second, besides producing potable water, it can provide DC electrical power during sunshine hour which can be used for lighting or some other purpose.

PVT-CPC Water Collector Solar Still

Single and double solar stills integrated with N identical PVT-CPC collectors were studied theoretically by Singh and Tiwari (2016) to assess their performance by incorporating the effect of EPBT under optimized condition. They have presented the comparative analyses of single-slope PVT-CPC active solar still (Figure 4.33.8) and double-slope PVT-CPC active solar still (Figure 4.33.9) at 0.14 m water depth for the same basin area under similar climatic condition (New Delhi). They concluded the following based on their studies.

1. The optimum number of collectors and mass flow rate for these systems are 7 and 0.04 kg/s, respectively.
2. Double slope has higher daily yield than single-slope PVT-CPC active solar still if depth of water in basin is <0.19 m and vice versa. It happens because a moderate-temperature difference between water and glass surfaces exist for a longer period in the case of double-slope PVT-CPC active solar still. However, in the case of single-slope PVT-CPC active solar still, the difference of temperatures is higher but it survives for a shorter period. At higher depth, the sensible heat of water mass is a dominating factor and it is higher for single-slope PVT-CPC active solar distillation system due to higher daily solar energy.
3. The value of EPBT based on energy and exergy for double slope is lower, respectively, by 7.5% and 17.98% than single-slope PVT-CPC active solar still. Again, the value of EPF

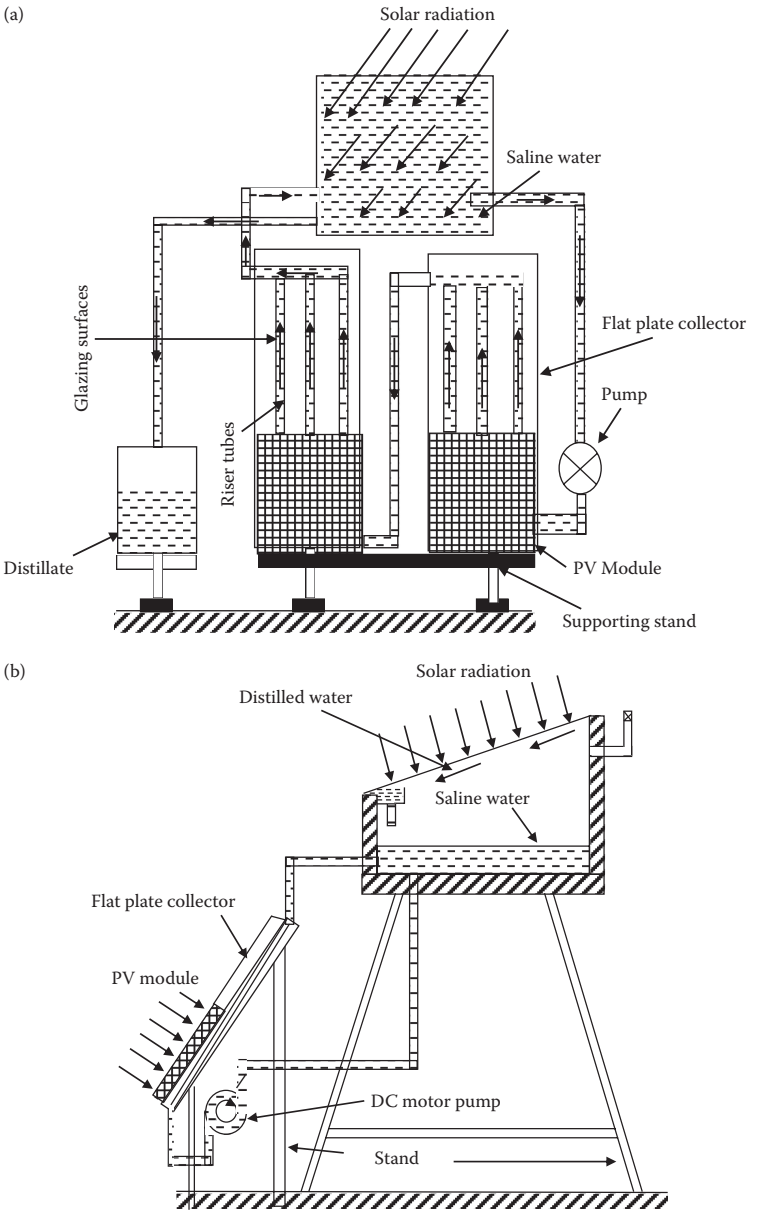

FIGURE 4.33.24 (a) Sectional top view of active photovoltaic thermal solar distillation system. (b) Sectional side view of active photovoltaic thermal solar distillation system.

based on energy and exergy for double slope is higher, respectively, by 5.12% and 12.72% than single-slope PVT-CPC active solar still. It happens because embodied energy of double slope is lower by 2.83%, but annual energy and exergy are, respectively, higher by 4.2% and 12.79% for double slope than single-slope PVT-CPC active solar still.

4. The LCCE of double slope based on energy and exergy is higher, respectively, by 5.55% and 22.22% than single-slope PVT-CPC active solar still. It occurs because overall annual energy and exergy are higher by 4.2% and 12.79%, respectively, for double slope than single-slope solar still. However, embodied energy and solar energy as well as exergy are lower by 2.83% and 1.56%, respectively, for double slope than single-slope PVT-CPC active solar still.

5. The production cost of water for single-slope PVT-CPC active solar still varies from Rs. 0.51 per kg to Rs. 2.42 per kg and for double-slope PVT-CPC active solar distillation system, the water cost varies between Rs. 0.47 and Rs. 2.21 per kg. The production cost of water for double slope is lower than single-slope PVT-CPC active solar still because yield of double slope at 0.14 m depth is higher and UAC is lower than single-slope PVT-CPC active solar still. The electricity is freely available from both single- and double-slope PVT-CPC active solar stills because revenue obtained from water is sufficient to meet the cost of system.

ETC-Integrated Solar Still

If FPC of active solar distillation system is replaced by ETC, the solar still is called ETC-integrated active solar still shown in Figure 4.33.25. ETC has two concentric tubes and there is vacuum in the annular space between tubes. The inner glass tubes are blacked at its outside surface with a selective coating to ensure the maximum absorption of solar radiation. Solar radiation incident on these tubes gets absorbed and the heat is transferred to the water inside the inner glass tube through its contact peripheral surface. ETC is inclined at some angle with horizontal (45° in this case) and the whole unit faces south to absorb maximum radiation. A pump is provided in between the basin and ETC to circulate water. Kumar et al. (2014) investigated the evacuated tube collector integrated solar still shown in Figure 4.33.25. The thermal model of the system was developed and performance of solar still under New Delhi (India) climatic condition was predicted using the thermal model. The performance of the system was optimum at mass flow rate of 0.06 kg/s and basin water depth of 0.03 m. The optimum daily yield was found to be 3.9 kg/m^2 with energy and exergy efficiencies as 33.8% and 2.6%, respectively, during typical summer day.

Climatic, Operational, and Design Parameter

The performance of solar still is affected by climatic, operational, and design parameters which are shown in Table 4.33.1.

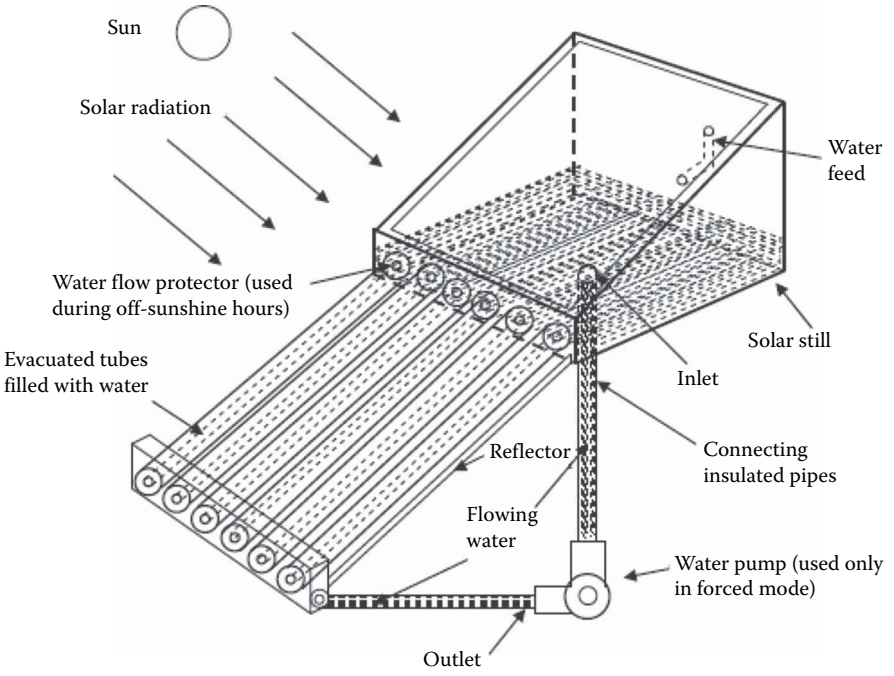

FIGURE 4.33.25 ETC-integrated solar still.

TABLE 4.33.1
Climatic, Operational, and Design Parameters

Type of parameter	Factors
Climatic parameter	Solar intensity, wind velocity, ambient temperature, humidity, and sky temperature
Operational parameter	Water depth in basin, salinity, amount of dye, and mode of operation
Design parameter	Material of construction, area of the basin, angle of inclination of condensing cover, and thickness of insulation thickness

APPENDIX

Expressions for different terms used in Equations 4.33.34 and 4.33.35 are as follows:

$$U_{tca} = \left[\frac{1}{h_o} + \frac{L_g}{K_g}\right]^{-1}; \quad U_{tcp} = \left[\frac{1}{h_i} + \frac{L_g}{K_g}\right]^{-1};$$

$$h_o = 5.7 + 3.8\,V, \ \text{W/m}^2\text{K}; \quad h_i = 5.7, \ \text{W/m}^2\text{K};$$

$$U_{tpa} = \left[\frac{1}{U_{tca}} + \frac{1}{U_{tcp}}\right]^{-1} + \left[\frac{1}{h_i'} + \frac{1}{h_{pf}} + \frac{L_i}{K_i}\right]^{-1}; \quad h_i' = 2.8 + 3\,V', \ \text{W/m}^2\text{K};$$

$$U_{L1} = \frac{U_{tcp}U_{tca}}{U_{tcp} + U_{tca}}; \quad U_{L2} = U_{L1} + U_{tpa}; \quad U_{Lm} = \frac{h_{pf}U_{L2}}{F'h_{pf} + U_{L2}}; \quad U_{Lc} = \frac{h_{pf}U_{tpa}}{F'h_{pf} + U_{tpa}};$$

$$PF_1 = \frac{U_{tcp}}{U_{tcp} + U_{tca}}; \quad PF_2 = \frac{h_{pf}}{F'h_{pf} + U_{L2}}; \quad PF_c = \frac{h_{pf}}{F'h_{pf} + U_{tpa}};$$

$$(\alpha\tau)_{1\text{eff}} = \rho(\alpha_c - \eta_c)\tau_g\beta_c\frac{A_{am}}{A_{rm}}; \quad (\alpha\tau)_{2\text{eff}} = \rho\alpha_p\tau_g^2(1-\beta_c)\frac{A_{am}}{A_{rm}};$$

$$(\alpha\tau)_{m\text{eff}} = \left[(\alpha\tau)_{1\text{eff}} + PF_1(\alpha\tau)_{2\text{eff}}\right]; \quad (\alpha\tau)_{c\text{eff}} = PF_c \cdot \rho\alpha_p\tau_g\frac{A_{ac}}{A_{rc}};$$

$$A_{rm} = b_r L_{rm}; \quad A_{am} = b_o L_{am}; \quad A_c F_{Rc} = \frac{\dot{m}_f c_f}{U_{Lc}}\left[1 - \exp\left(\frac{-F'U_{Lc}A_c}{\dot{m}_f c_f}\right)\right];$$

$$A_m F_{Rm} = \frac{\dot{m}_f c_f}{U_{Lm}}\left[1 - \exp\left(\frac{-F'U_{Lm}A_m}{\dot{m}_f c_f}\right)\right];$$

$$\left(AF_R(\alpha\tau)\right)_1 = \left[A_c F_{Rc}(\alpha\tau)_{c\text{eff}} + PF_2(\alpha\tau)_{m\text{eff}} A_m F_{Rm}\left(1 - \frac{A_c F_{Rc}U_{Lc}}{\dot{m}_f c_f}\right)\right];$$

$$(AF_R U_L)_1 = \left[A_c F_{Rc}U_{Lc} + A_m F_{Rm}U_{Lm} + A_m F_{Rm}U_{Lm}\left(1 - \frac{A_c F_{Rc}U_{Lc}}{\dot{m}_f c_f}\right)\right]$$

$$K_K = \left(1 - \frac{(AF_R U_L)_1}{\dot{m}_f c_f}\right); \quad \left(AF_R(\alpha\tau)\right)_{m1} = PF_2(\alpha\tau)_{m\text{eff}} A_m F_{Rm};$$

$$(AF_RU_L)_{m1} = A_mF_{Rm}U_{Lm};\quad K_m = \left(1-\frac{A_mF_{Rm}U_{Lm}}{\dot{m}_fc_f}\right)$$

Expressions for a_1 and $\overline{f_1}(t)$ used in Equation 4.33.41 and expressions of heat transfer coefficients used in Equations 4.33.43 through 4.33.45 are as follows:

$$a_1 = \frac{1}{M_wC_w}\left[\dot{m}_fC_f(1-K_k^N)+U_sA_b\right];$$

$$\overline{f_1}(t) = \frac{1}{M_wC_w}\left[\alpha'_{\text{eff}}A_b\overline{I_s}(t)+\frac{(1-K_k^N)}{(1-K_k)}\left(AF_R(\alpha\tau)\right)_1\overline{I_b}(t)+\left(\frac{(1-K_k^N)}{(1-K_k)}(AF_RU_L)_1+U_sA_b\right)\overline{T_a}\right];$$

$$\alpha'_{\text{eff}} = \alpha'_w+h_1\alpha'_b+h'_1\alpha'_g;\quad h_1 = \frac{h_{bw}}{h_{bw}+h_{ba}};$$

$$h'_1 = \frac{h_{1w}A_g}{U_{c,ga}A_g+h_{1w}A_b};\quad h_{1w} = h_{rwg}+h_{cwg}+h_{ewg};$$

$$h_{ewg} = 16.273\times10^{-3}h_{cwg}\left[\frac{P_w-P_{gi}}{T_w-T_{gi}}\right];$$

$$h_{cwg} = 0.884\left[(T_w-T_{gi})+\frac{(P_w-P_{gi})(T_w+273)}{268.9\times10^3-P_w}\right]^{\frac{1}{3}};$$

$$P_w = \exp\left[25.317-\frac{5144}{T_w+273}\right];\quad P_{gi} = \exp\left[25.317-\frac{5144}{T_{gi}+273}\right];$$

$$h_{rwg} = \left(0.82\times5.67\times10^{-8}\right)\left[(T_w+273)^2+(T_{gi}+273)^2\right]\left[T_w+T_{gi}+546\right];$$

$$U_s = U_t+U_b;\quad U_b = \frac{h_{ba}h_{bw}}{h_{bw}+h_{ba}};\quad U_t = \frac{h_{1w}U_{c,ga}A_g}{U_{c,ga}A_g+h_{1w}A_b};$$

$$U_{c,ga} = \frac{\frac{K_g}{l_g}h_{1g}}{\frac{K_g}{l_g}+h_{1g}};\quad h_{ba} = \left[\frac{L_i}{K_i}+\frac{1}{h_{cb}+h_{rb}}\right]^{-1};$$

$$h_{cb}+h_{rb} = 5.7\ \text{W/m}^2\text{K},\ h_{bw} = 250\ \text{W/m}^2K;$$

Expressions for a_2 and $\overline{f_2}(t)$ used in Equation 4.33.52 and expressions of different terms used in Equations 4.33.53 through 4.33.58 are as follows:

$$a_2 = \frac{1}{M_wC_w}\left[\dot{m}_fC_f(1-K_k^N)+U_bA_b+\frac{h_{1wE}(P-A_2)A_b}{2P}+\frac{h_{1wW}(P-B_2)A_b}{2P}\right];$$

$$\overline{f}_2(t)=\frac{1}{M_wC_w}\left[\begin{array}{l}\left(\frac{\alpha'_w}{2}+h_1\alpha'_b\right)A_b\left(\overline{I}_{SE}(t)+\overline{I}_{SW}(t)\right)+\frac{(1-K_k^N)}{(1-K_k)}\left(AF_R(\alpha\tau)\right)_1\overline{I}_b(t)\\+\left(\frac{(1-K_k^N)}{(1-K_k)}\left(AF_RU_L\right)_1+U_bA_b\right)\overline{T}_a+\left(\frac{h_{1wE}A_1+h_{1wW}B_1}{P}\right)\frac{A_b}{2}\end{array}\right]$$

$$A_1=R_1U_1A_{gE}+R_2h_{EW}A_{gW};\quad A_2=h_{1WE}U_2\frac{A_b}{2}+h_{EW}h_{1WW}\frac{A_b}{2};$$

$$P=\left(U_1U_2-\frac{h_{EW}^2}{A_{gE}}h_{1WW}\frac{A_b}{2}\right)A_{gW};\quad U_1=\frac{h_{1wE}\frac{A_b}{2}+h_{EW}A_{gE}+U_{c,gaE}A_{gE}}{A_{gW}};$$

$$U_2=\frac{h_{1wW}\frac{A_b}{2}+h_{EW}A_{gW}+U_{c,gaW}A_{gW}}{A_{gE}};\quad B_1=\frac{(R_2P+A_1h_{EW})A_{gW}}{U_2A_{gE}};$$

$$B_2=\frac{Ph_{1wW}\frac{A_b}{2}+h_{EW}A_{gW}A_2}{U_2A_{gE}};\quad R_1=\alpha'_gI_{SE}(t)+U_{c,gaE}T_a;$$

$$R_2=\alpha'_gI_{SW}(t)+U_{c,gaW}T_a$$

$$h_{EW}=0.034\times5.67\times10^{-8}\left[(T_{giE}+273)^2+(T_{giW}+273)^2\right]\left[T_{giE}+T_{giW}+546\right]$$

$$U_{c,gaE}=\frac{\frac{K_g}{l_g}h_{1gE}}{\frac{K_g}{l_g}+h_{1gE}};\quad U_{c,gaW}=\frac{\frac{K_g}{l_g}h_{1gW}}{\frac{K_g}{l_g}+h_{1gW}};\quad h_{1gE}=5.7+3.8V;\quad h_{1gW}=5.7+3.8\,V;$$

$$h_{1wE}=h_{rwgE}+h_{cwgE}+h_{ewgE};\quad h_{1wW}=h_{rwgW}+h_{cwgW}+h_{ewgW};$$

$$h_{ewgE}=16.273\times10^{-3}h_{c,wgE}\left[\frac{P_w-P_{giE}}{T_w-T_{giE}}\right];\quad h_{cwgE}=0.884\left[(T_w-T_{giE})+\frac{(P_w-P_{giE})(T_w+273)}{268.9\times10^3-P_w}\right]^{\frac{1}{3}};$$

$$h_{ewgW}=16.273\times10^{-3}h_{c,wgW}\left[\frac{P_w-P_{giW}}{T_w-T_{giW}}\right];\quad h_{cwgW}=0.884\left[(T_w-T_{giW})+\frac{(P_w-P_{giW})(T_w+273)}{268.9\times10^3-P_w}\right]^{\frac{1}{3}};$$

$$P_w=\exp\left[25.317-\frac{5144}{T_w+273}\right];\quad P_{giE}=\exp\left[25.317-\frac{5144}{T_{gi}E+273}\right];$$

$$P_{giW}=\exp\left[25.317-\frac{5144}{T_{giW}+273}\right];$$

$$h_{rwgE} = (0.82 \times 5.67 \times 10^{-8})\left[(T_w + 273)^2 + (T_{giE} + 273)^2\right][T_w + T_{giE} + 546];$$

$$h_{rwgW} = (0.82 \times 5.67 \times 10^{-8})\left[(T_w + 273)^2 + (T_{giW} + 273)^2\right][T_w + T_{giW} + 546];$$

Nomenclature

A_m	Area of module, m^2
A_c	Area of collector, m^2
Ag	Area of glass cover, m^2
A_b	Area of basin liner, m^2
C	Specific heat capacity, J/kg-K
F'	Flat plate collector efficiency factor, dimensionless
F_R	Heat removal factor, dimensionless
H	Heat transfer coefficient, W/m^2-K
PF_1	Penalty factor first, dimensionless
PF_2	Penalty factor second, dimensionless
$I(t)$	Incident solar intensity, W/m^2
$I_c(t)$	Incident solar intensity on collector, W/m^2
$I_s(t)$	Incident solar intensity on solar still, W/m^2
$I_b(t)$	Bean radiation incident on collector, W/m^2
I	Rate of interest, %
K	Thermal conductivity, W/m-K
L	Latent heat, J/kg
L_g	Thickness of glass, m
$\dot{m}_f$	Rate of flow of water mass in collector, kg/s
$\dot{Q}_{UN}$	Rate of useful energy transfer, kW
T	Temperature, °C
$U_{tc,a}$	Total heat transfer coefficient from solar cell to ambient through glass cover, W/m^2-K
$U_{tc,p}$	Total heat transfer coefficient from solar cell to plate through glass cover, W/m^2-K
$U_{L,m}$	An overall heat transfer coefficient from blackened surface to ambient, W/m^2-K
V_a	Velocity of air, m/s
V_{oc}	Open-circuit voltage, V
V_L	Load voltage, V
I_{sc}	Short-circuit current, A
I_L	Load current, A
h_{1w}	Total hear transfer coefficient from water surface to inner glass cover, W/m^2-K
h_{1g}	Total hear transfer coefficient from glass cover to ambient, W/m^2-K
h_{bw}	Heat transfer coefficient from blackened surface to water mass, W/m^2-K
h_{ba}	Heat transfer coefficient from blackened surface to ambient, W/m^2-K
h_r	Radiative heat transfer coefficient, W/m^2-K
h_c	Convective heat transfer coefficient, W/m^2-K
h_{ewg}	Evaporative heat transfer coefficient from water to glass, W/m^2-K
$\dot{m}_{ew}$	Hourly distillate output, kg/h
R	Reflectivity, dimensionless
FF	Fill factor, dimensionless
R_e	Annual revenue earned from electricity gain, Rs.
R_w	Annual revenue earned from distillate, Rs.
SP	Selling price, Rs.
M_w	Annual yield, kg
$\dot{E}_e$	Hourly electricity gain, kWh

(*Continued*)

E_e	Annual electricity gain, kWh
UAC	Uniform end-of-year annual cost, Rs.
$F_{CR,i,n}$	Capital recovery factor, dimensionless
$F_{SR,i,n}$	Sinking fund factor, dimensionless
P_s	Net present cost of system, Rs.
P	Initial cost of system, Rs.
C_w	Production cost of water, Rs.
C_e	Cost of electricity gain, Rs.
E_{in}	Embodied energy
E_{out}	Annual energy output
LCCE	Life cycle conversion efficiency
EPBT	Energy payback time
EPF	Energy production factor
$(G_{ex,annual})$	Annual exergy gain
R_{ex}	Exergoeconomic parameter based on exergy loss
R_{en}	Exergoeconomic parameter based on energy loss
$R_{g,ex}$	Exergoeconomic parameter based on exergy gain
$R_{g,en}$	Exergoeconomic parameter based on energy output
L_{ex}	Hourly exergy loss rate
N	Life of system
Subscripts	
A	Ambient
C	Solar cell
Eff	Effective
W	Water in solar still
F	Water in flat plate collector
G	Glass
Gi	Inner glass cover
Go	Outer glass cover
M	Module
N	Number of collectors
P	Plate
B	Blackened surface
R	Radiative
Greek Letters	
α	Absorptivity
$(\alpha\tau)_{eff}$	Product of effective absorptivity and transmittivity
β	Packing factor
β_c	Electrical efficiency
η	Efficiency
τ	Transmittivity

5.1 COMPUTER AIDED ENGINEERING

Atul Sharma

The *last fifty years* has seen tremendous evolution in computational fluid dynamics (CFD) from getting steady-state pictures to transient fluid dynamic movies of scientific-exciting flow properties and engineering-relevant parameters (Sharma, 2016); from solving the flow in lower to higher dimensions—2D to 3D; over or inside simple to complex shaped solid objects; involving single physics to multi-physics; and in a single to multiple parallelized computers. Recent advances in CFD involve its integration with other tools and its use for multiphysics simulations (incorporating structural, thermal, fluid, and electromagnetic analysis)—called *c*omputer *a*ided *e*ngineering.

The evolution has been possible mainly because of *fluid dynamicists* and *computer scientists*. Fluid dynamicists developed new or improved mathematical models and/or numerical methodologies, which could give results of acceptable accuracy in least computational time, whereas, computer scientists developed new or improved computer systems as well as programming paradigms to speedup the computations. Although presently CFD is more commonly used as an analysis tool, we can expect that CFD will be more often used as a design and optimization tool in future. This will lead to innovations in the development of the new products and improvements in the performance as well as efficiency of the existing products.

For fluid dynamics and heat transfer, we have a closed system of equations as there are three equations based on mass, momentum, and energy conservation laws and three dependent variables (pressure, velocity, and temperature). Laws of conservation of momentum and energy have a term

that describes the rate of change of momentum and energy; thus, they result in equations that are used to create fluid dynamics movie for velocity and temperature, respectively. Thereafter, we are left with the continuity equation based on the mass conservation law and pressure as a dependent variable. However, there is no rate of change of pressure term in the mass conservation law that could result in a fluid dynamic movie for pressure; in fact, the continuity equation does not have any pressure term. Thus, there is no explicit equation for pressure and the continuity equation needs to be converted into an equation for pressure. This created a lot of difficulties in handling pressure and coming up with a solution procedure for the Navier–Stokes (NS) equations in the early days of CFD. To circumvent these limitations, a pressure–velocity formulation, called as pressure correction approach, was proposed for incompressible flow; here, the continuity equation was employed as a constraint to derive the correct pressure field through a detailed iterative solution procedure.

The governing equations in fluid mechanics and heat transfer are *p*artial *d*ifferential *e*quations (PDEs), with flow properties (such as velocity, pressure, and temperature) as the dependent variables, and both spatial and temporal coordinates as the independent variables. The *exact solution* of the PDEs, subjected to certain *b*oundary *c*onditions (BCs), is a functional relationship for the flow property as a function of the spatial and temporal coordinates in a flow domain. The exact solution is continuous in both spatial and temporal coordinates. However, it is possible to obtain exact solutions for only a very few and simple problems in fluid dynamics and heat transfer, whereas a numerical solution is possible for almost all problems and is discrete in space and time. Thus, a numerical methodology requires two types of discretization: first, discretization of space and time and second, discretization of the PDEs and the BCs. The first one leads to *grid generation* for spatial discretization and time step Δt for the temporal discretization, whereas the second one leads to an *approximate algebraic formulation* for the equation discretization (PDEs and the BCs). The grid generation is a method to convert the infinite number of points in a flow domain to a certain fixed number of discrete points called grid points and determine their coordinates. The approximate algebraic formulation leads to a system of *l*inear *a*lgebraic *e*quations (LAEs), for the value of a flow property at all the grid points. Finally, the system of LAEs is solved by a solution methodology to obtain the spatial as well as temporal discrete solution for a flow property resulting in a fluid dynamic movie.

The exact solution is analogous to an infinite-resolution virtual video camera, and the numerical solution is analogous to a finite-resolution virtual video camera (Sharma, 2016). The camera results in a fluid dynamics movie for a flow property, with pixels analogous to the grid points and frame rate analogous to the time step. The numerical solution depends on the number of grid points for the spatial accuracy and on the magnitude of the time step for the temporal accuracy. The numerical solution results in a CFD software as a product, which is analogous to a virtual video camera.

The discretization method is an approximate algebraic formulation method to formulate a system of LAEs from the PDEs (Patankar, 1980) or physical-laws (proposed recently by Sharma, 2016) and BCs. Mainly, there are three discretization methods: *finite-difference method* (FDM), *finite-volume method* (FVM), and *finite-element method* (FEM); they are presented in the next three sections. FDM and FVM are more commonly used in CFD, whereas FEM is more popular in computational solid mechanics. Early development of CFD started with FDM for problems where the boundary of the computational domain corresponds to one (not any) of the three standard coordinate systems—Cartesian, cylindrical, and spherical; such problems were called simple (otherwise complex) geometry problems. Cartesian/cylindrical/spherical geometry problems were solved in a uniform or nonuniform grid, where one of the grid lines fits to the boundary of the computational domain—such a grid is called a body-fitted grid. With advances in CFD and more application to industrial problems, fitting the boundary of an computational domain to one of the standard coordinate systems was a big constraint; thus, there was a need to develop a method for computing flows in complex geometry. Initially, this was attempted with FDM on a body-fitted Cartesian grid, where the curved boundary of the computational domain was approximated as a stepped one approximating the small portions of the curved surface as either horizontal or vertical lines. However, for a very nonlinear curved domain, this led to loss of accuracy on a particular grid size or increase in

computational time (due to fine grid size needed at the boundary) to achieve a particular accuracy. Alternatively, an FDM-based method was proposed (Anderson, 1995), where certain equations were used to map the complex physical (x, y, t) domain to the simple Cartesian (ξ, η, τ) computational domain and then transform the PDEs in the complex domain to the simple domain. The resulting PDEs became quite complicated and leads to loss of computational efficiency and accuracy.

This led to the development of FVM where the governing PDEs are solved directly in the physical complex/curved domain (without transformation of domain and PDEs) on a body-fitted curvilinear structured grid. However, implementation of a staggered grid—a remedy to pressure–velocity decoupling—was found almost impossible for complex geometry; another remedy to obtain a physical solution in a colocated grid was proposed using momentum interpolation (Rhie and Chow, 1983). This was employed for quite some time with further development in the FVM-based solution that made it applicable in structured to multiblock structured to unstructured body-fitted grid systems. However, recently with more industrial applications of CFD where reasonably accurate results are desired in less computational time, there is a substantial increase in computational time for good-quality grid generation as very complex geometries as well as three-dimensional flow are commonly encountered. In terms of ease in code development, convergence characteristics of iterative solvers, memory requirement, computational cost, and computational accuracy, the Cartesian grid outweighs the body-fitted structured/unstructured grid. Thus, there is a renewed interest in the Cartesian grid (old is gold!) on *nonbody-fitted* systems instead of the earlier body-fitted grid, with a large body of work in the last decade on the Cartesian grid method.

One of the Cartesian grid methods, proposed for *f*luid–*s*tructure *i*nteraction problems, is the *immersed boundary method*, which is presented in Section 5.6. Other than the continuum methods based on the Navier-Stokes equations, the *lattice Boltzmann method* is presented in Section 5.5 as an example of mesoscale methods. Due to the large number and wide range of industrial applications, *numerical methods for two-phase flow* are gaining a lot of importance and are presented in *Section 5.7. Section 5.8* deals with *large eddy simulation of wall-bounded flow* for turbulent flows. Finally, this section on numerical methods and computational tools ends with a section on *software and computer codes.*

5.2 FINITE DIFFERENCE METHOD

Atul Sharma

Introduction

Finite-difference method (FDM) is a discretization method that uses Taylor series to convert each differential term in a partial differential equation (PDE) to a linear algebraic equation (LAE), called finite-difference equation (FDE). FDM is relatively older as compared to finite-volume method. FDM is algorithmically simple, efficient, and accurate; however, the FDM was found better suited for the simple as compared to complex geometry in a computational fluid dynamics (CFD) problem. With the advances in CFD, recently few FDM-based methods demonstrated its accurate applicability for the complex geometry as well as moving boundary problems; and created a renewed interest in the FDM. One such method is the immersed boundary method, presented in Section 5.6. In this section, an FDM based discretization as well as numerical methodology is presented for 2D steady-state heat conduction, in a Cartesian coordinate system and on a uniform grid.

Main Idea of the FDM

The algebraic formulation in FDM is based on Taylor series expansion of a flow property. Considering temperature as the flow property for the heat transfer here, the Taylor series is an *infinite series* representing temperature T at a location $x + \Delta x$, $T_{x+\Delta x}$, as an infinite sum of terms, consisting of the value and the derivatives of the function T at a *single point* x; given as

$$T_{x+\Delta x} = T_x + \left(\frac{\mathrm{d}T}{\mathrm{d}x}\right)_x \Delta x + \left(\frac{\mathrm{d}^2T}{\mathrm{d}x^2}\right)_x \frac{\Delta x^2}{2!} + \left(\frac{\mathrm{d}^3T}{\mathrm{d}x^3}\right)_x \frac{\Delta x^3}{3!} + \cdots + \left(\frac{\mathrm{d}^nT}{\mathrm{d}x^n}\right)_x \frac{\Delta x^n}{n!} \tag{5.2.1}$$

where Δx is any positive or negative spacing from the single representative location x.

For a 2D problem with x and y as the independent variables, the Taylor series expansion is given as

$$T_{x+\Delta x,y} = T_{x,y} + \left(\frac{\partial T}{\partial x}\right)_{x,y} \Delta x + \left(\frac{\partial^2 T}{\partial x^2}\right)_{x,y} \frac{\Delta x^2}{2!} + \cdots + \left(\frac{\partial^n T}{\partial x^n}\right)_{x,y} \frac{\Delta x^n}{n!} \tag{5.2.2}$$

$$T_{x-\Delta x,y} = T_{x,y} - \left(\frac{\partial T}{\partial x}\right)_{x,y} \Delta x + \left(\frac{\partial^2 T}{\partial x^2}\right)_{x,y} \frac{\Delta x^2}{2!} \cdots (-1)^n \left(\frac{\partial^n T}{\partial x^n}\right)_{x,y} \frac{\Delta x^n}{n!} \tag{5.2.3}$$

where the left-hand side (LHS) consists of T at a spacing of Δx and $-\Delta x$ from x, and same y. From *each* of the above equation, the first derivative is given as

$$\left(\frac{\partial T}{\partial x}\right)_{x,y} = \frac{T_{x+\Delta x,y} - T_{x,y}}{\Delta x} - \left[\left(\frac{\partial^2 T}{\partial x^2}\right)_{x,y} \frac{\Delta x}{2!} + \cdots\right] \tag{5.2.4}$$

$$\left(\frac{\partial T}{\partial x}\right)_{x,y} = \frac{T_{x,y} - T_{x-\Delta x,y}}{\Delta x} + \left[\left(\frac{\partial^2 T}{\partial x^2}\right)_{x,y} \frac{\Delta x^2}{2!} + \cdots\right] \tag{5.2.5}$$

Using *both* the equations, subtracting Equation 5.2.3 from Equation 5.2.2 results in an FDE for the first derivative, and adding both the equations results in an FDE for the second derivative; given as

$$\left(\frac{\partial T}{\partial x}\right)_{x,y} = \frac{T_{x+\Delta x,y} - T_{x-\Delta x,y}}{2\Delta x} - \left[\left(\frac{\partial^3 T}{\partial x^3}\right)_{x,y} \frac{\Delta x^2}{3!} + \cdots\right] \tag{5.2.6}$$

$$\left(\frac{\partial^2 T}{\partial x^2}\right)_{x,y} = \frac{T_{x+\Delta x,y} - 2T_{x,y} + T_{x-\Delta x,y}}{\Delta x^2} - 2\left[\left(\frac{\partial^4 T}{\partial x^4}\right)_{x,y} \frac{\Delta x^2}{4!} + \cdots\right] \tag{5.2.7}$$

Division of a dividend with a divisor results in a quotient and a remainder; similarly, for the right-hand side of Equations 5.2.4 through 5.2.7, the first term is called *finite-difference quotient* and the second term (within a square bracket) is called truncated term—resulting in a *truncation error*. The truncated terms in the equations show higher order derivatives multiplied by a certain power of Δx. The power of the Δx in the lowest order derivative of the truncated terms decides the order of accuracy of a finite-difference representation.

The finite-difference quotient and the order of accuracy are shown more clearly in Figure 5.2.1, for the first and second derivative. The figure shows the spatial coordinates in Equations 5.2.4 through 5.2.7 replaced by the running indices: (x, y) by (i, j), $(x + \Delta x, y)$ by $(i + 1, j)$, and $(x - \Delta x, y)$ by $(i - 1, j)$. The running indices corresponds to the element number in a 2D matrix, which is used as a data structure to store the discrete values of the temperature; discussed in the next subsection. The figure shows the various finite-difference quotients as an algebraic term. A quotient that involves one-point forward, one-point backward, and both forward and backward points is called forward,

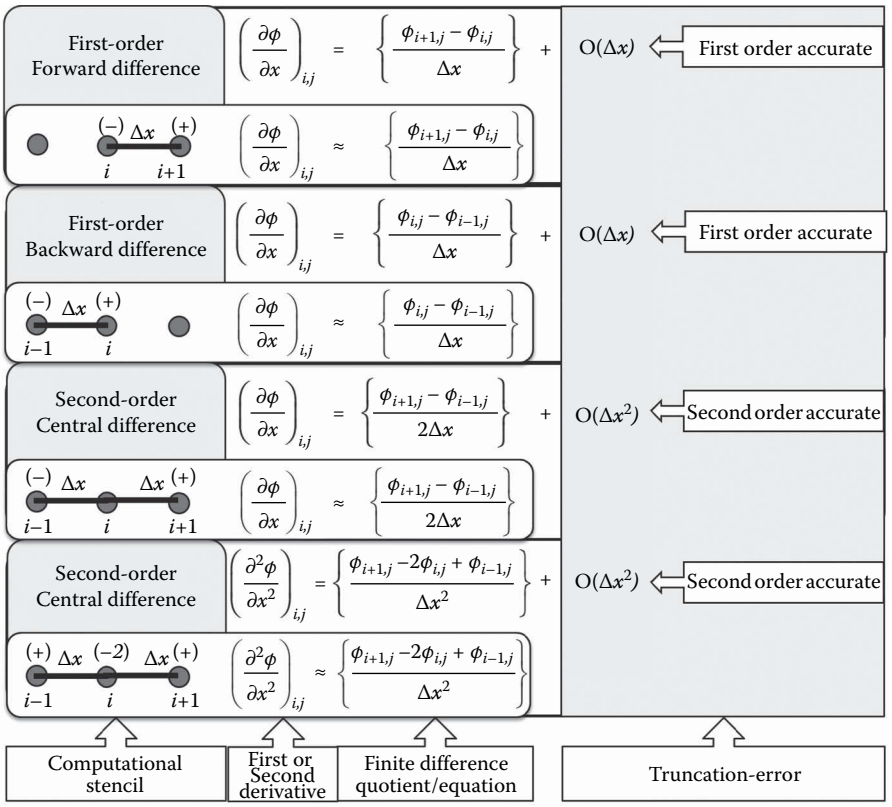

FIGURE 5.2.1 Illustration of the various types of FDM-based algebraic representation of the first and second derivatives, using Taylor series expansion.

backward, and central difference method, respectively. The points involved in the quotient are also shown schematically (joined by straight lines) in the figure, called computational stencil.

The FDEs (Figure 5.2.1) are also applicable for the derivatives in the *y*-direction, with certain replacements: $T_{i+2,j}$ by $T_{i,j+2}$, $T_{i+1,j}$ by $T_{i,j+1}$, $T_{i-1,j}$ by $T_{i,j-1}$, $T_{i-2,j}$ by $T_{i,j-2}$, Δx by Δy, and Δx^2 by Δy^2. Note that the grid point considered in the FDE for $\partial T/\partial x$ and $\partial T/\partial y$ are on a horizontal and a vertical line, with constant y and x coordinates, respectively. Further *higher order* one-sided (forward/backward) or both-sided (central) FDE can also be derived using the above procedure. Note that the procedure corresponds to the algebraic operation of the Taylor series for T at neighboring grid points.

For the first and second derivatives in the x and y directions, consider a generic FDE (Sharma 2016) as

$$\begin{aligned}\left(\frac{\partial T}{\partial x}\right)_{i,j}\Delta x,\left(\frac{\partial^2 T}{\partial x^2}\right)_{i,j}\Delta x^2 &\approx ffT_{i+2,j}+fT_{i+1,j}+cT_{i,j}+bT_{i-1,j}+bbT_{i-2,j}\\ \left(\frac{\partial T}{\partial y}\right)_{i,j}\Delta y,\left(\frac{\partial^2 T}{\partial y^2}\right)_{i,j}\Delta y^2 &\approx ffT_{i,j+2}+fT_{i,j+1}+cT_{i,j}+bT_{i,j-1}+bbT_{i,j-2}\end{aligned} \tag{5.2.8}$$

The values of the coefficients for the various neighboring temperatures in the above equation are presented in Table 5.2.1. The table shows first- and second-order forward/backward difference method for the first derivative, and second- and fourth-order central difference method for both first and second derivative. For the central difference method, note from the table that the coefficient *f* is equal to *b*, and *ff* is equal to *bb*; however, the equality is with a *change in sign* of the coefficients for the first derivative but not for the second derivative. Furthermore, the sum of the coefficients is equal to zero—the approximate representation ensures that the derivative is zero for a uniform temperature field. Finally, note that the coefficients in the table are same for the first/second derivative in the *x*-and *y*-directions.

Governing Differential Equation and Boundary Conditions

The FDM-based algebraic formulation and solution are presented in the following subsections, for 2D steady-state heat conduction with volumetric heat generation. The corresponding *governing equation* is given as

$$\text{G.E: } \frac{\partial^2 T}{\partial x^2}+\frac{\partial^2 T}{\partial y^2}+\frac{\overline{Q}_{\text{gen}}}{k}=0 \tag{5.2.9}$$

TABLE 5.2.1
The Coefficients in the General FDE (Equation 5.2.8) for the First and the Second Derivatives in *x*/*y* Direction (Sharma 2016)

Derivatives	FDM	Order of Accuracy	*bb*	*b*	*c*	*f*	*ff*
First	Forward	First			−1	1	
		Second			−3/2	2	−1/2
	Backward	First		−1	1		
		Second	1/2	−2	3/2		
	Central	Second		−1/2	0	1/2	
		Fourth	1/12	−2/3	0	2/3	−1/12
Second	Central	Second		1	−2	1	
		Fourth	−1/12	4/3	−5/2	4/3	−1/12

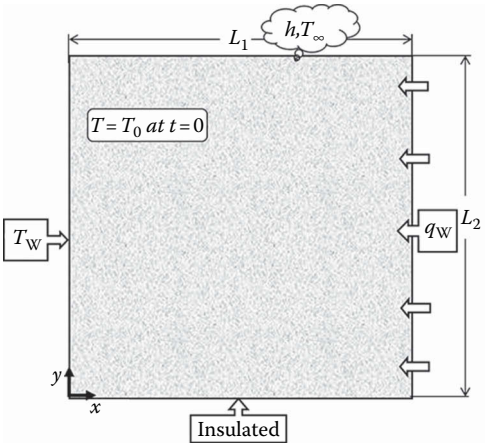

FIGURE 5.2.2 Conduction heat transfer in a rectangular plate, subjected to an initial and different types of thermal boundary conditions.

The above equation corresponds to the various heat conduction problems; however, the spatial variation in the steady-state temperature field depends on boundary conditions. Consider an example of 2D unsteady-state heat conduction in a square plate shown in Figure 5.2.2. The figure shows that the plate is subjected to the different types of thermal boundary conditions. Mathematically, the boundary conditions are classified into three types: *Dirichlet*, if the value of a flow property ($T/\vec{u}/p$) is prescribed; *Neumann*, if the gradient of the variable is prescribed; and *Robin or mixed*, if a linear combination of the variable and its gradient is prescribed at the boundary. For the example problem in Figure 5.2.2, the different types of boundary conditions (BCs) are as follows:

1. Dirichlet BC: *c*onstant *w*all *t*emperature BC at the left wall
2. Neumann BC: insulated BC at the bottom wall, and the *u*niform *h*eat *f*lux (UHF) BC at the right wall
3. Robin or mixed BC: convective BC at the top wall

The various BCs in Figure 5.2.2 are represented mathematically as

$$\begin{aligned}
&\text{BCs: At } x = 0 \Rightarrow T = T_W \\
&\text{At } x = L_1 \Rightarrow -k\left(\frac{dT}{dx}\right)_{x=L_1} = -q_W \\
&\text{At } y = 0 \Rightarrow \left(\frac{dT}{dy}\right)_{y=0} = 0 \\
&\text{At } y = L_2 \Rightarrow -k\left(\frac{dT}{dy}\right)_{y=L_2} = h(T_{y=L_2} - T_\infty)
\end{aligned} \tag{5.2.10}$$

Grid Generation

The governing equations and the BCs presented above are converted into a system of LAE, using an FDM in the next subsection. The LAEs correspond to the temperature at various discrete grid points in the computational domain—the grid points are generated by a method, presented in this subsection.

A grid generation is a method for the *spatial discretization* of the internal region of the domain as internal grid points, and the boundary region discretized as boundary grid points. The grid points are shown in Figure 5.2.3, for a simple geometry problem in a Cartesian coordinate system (Figure 5.2.2). The figure shows equispaced horizontal and vertical lines, leading to the simplest form of grid generation. The lines are called grid lines, and it is ensured that the boundary of the domain is represented by one of the grid lines—for a *body-fitted grid*.

Figure 5.2.3 shows a *uniform grid*, with the spacing between the consecutive horizontal line as Δx and the vertical line as Δy—called *grid spacing*. As discussed previously, the grid points for the application of FDM to PDE and BCs are different. Thus, the grid points are classified here into two types: boundary and internal. The figure also shows i and j as the *running indices* (consisting of integer values), which act as a tag (or address) for a grid point. The respective running indices correspond to the rows and columns of a matrix—a computationally efficient data structure to store the values of a flow property at the grid points shown in the figure. For a representative grid point (i, j), Figure 5.2.3 shows that $(i + 1, j)$, $(i - 1, j)$, $(i, j + 1)$, and $(i, j - 1)$ correspond to the adjoining east, west, north, and south neighboring grid points, respectively. The figure also shows that the respective neighboring grid points are located at $(x + \Delta x, y)$, $(x - \Delta x, y)$, $(x, y + \Delta y)$, and $(x, y - \Delta y)$.

The in-built neighboring information in the matrix makes the computer programming in CFD much easier. Using a *s*econd-order FDM on the governing PDE for a 2D steady-state conduction, it is presented below that the temperature at *any* internal grid point is represented in terms of *four* (east, west, north, and south; not all) adjoining neighboring grid points. This functional relationship is presented schematically in Figure 5.2.3, for *one* of the representative internal grid point, and is called *computational stencil*. Note that the functional dependence remains same for all the other internal grid points. Using second-order FDM for the non-Dirichlet BC, it is presented below (Equation 5.2.12) that the temperature at a boundary grid point is a function of two adjoining internal

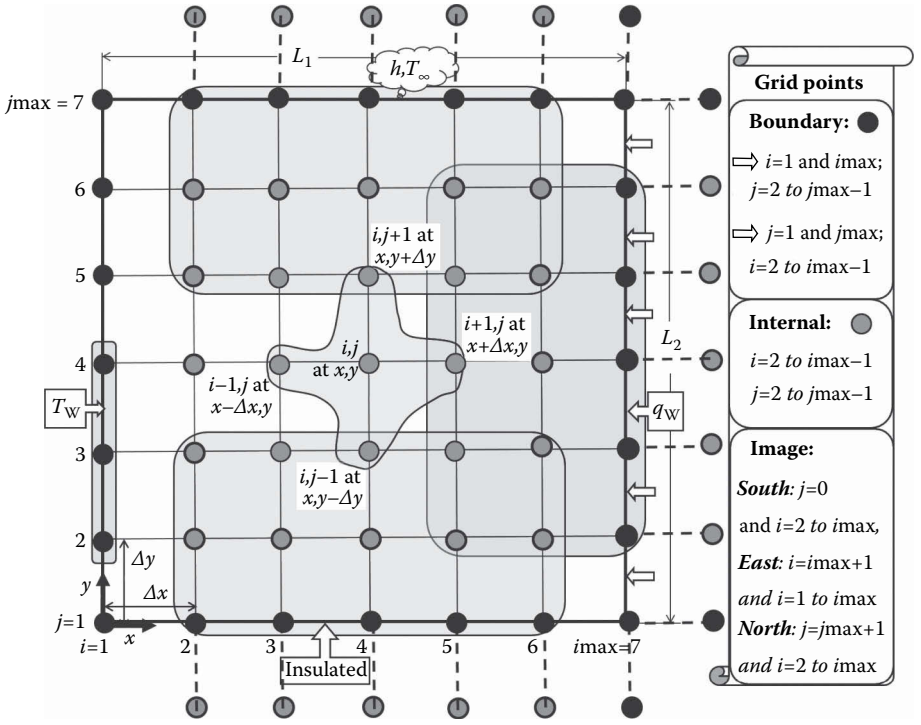

FIGURE 5.2.3 A uniform Cartesian grid generation, for an FDM. The figure also shows the various types of grid points, computational stencils (for an internal grid point and various boundary grid points), and the BCs for a 2D heat conduction problem (Figure 5.2.2).

grid points; and the temperature is constant for a Dirichlet BC. The corresponding computational stencil for the Dirichlet BC at the west boundary, and non-Dirichlet BCs at the other boundaries, are shown in Figure 5.2.3. For the grid point-by-point recursive computation, a range of values of the running indices (i and j) is shown in Figure 5.2.3; separately for the internal and boundary grid points, since their computational stencils are different. The recursive computation corresponds to scrolling through all the internal grid points for an iterative solution of the corresponding LAE, with the help of a loop in a computer program; presented below in the solution methodology.

FDM-Based Algebraic Formulation

Using the second-order FDM for both governing equations and BCs, presented in Equation 5.2.8 and Table 5.2.1, the algebraic formulation for the differential term in Equations 5.2.9 and 5.2.10 results in the FDE as

$$\text{FDE for G.E}: T_{i-1,j} + T_{i+1,j} + \beta^2 (T_{i,j-1} + T_{i,j+1}) - 2(1+\beta^2) T_{i,j} + \frac{\bar{Q}_{\text{gen},i,j} \Delta x^2}{k} = 0 \quad \text{where } \beta = \Delta x^2 / \Delta y^2 \tag{5.2.11}$$

$$\begin{aligned} &\text{FDE for BCs}: \text{At } x = 0 \quad T_{1,j} = T_{\text{W}} \equiv T_{\text{wb}} \\ &\text{At } x = L_1 \quad T_{i\text{max},j} = \frac{4T_{i\text{max}-1,j} - T_{i\text{max}-2,j}}{3} + \frac{2q_{\text{W}} \Delta x}{3k} \equiv T_{\text{eb}} \\ &\text{At } y = 0 \quad T_{i,1} = \frac{4T_{i,2} - T_{i,3}}{3} \equiv T_{\text{sb}} \\ &\text{At } y = L_2 \quad T_{i,j\text{max}} = \frac{k(4T_{i,j\text{max}-1} - T_{i,j\text{max}-2}) + 2h\Delta y T_{\infty}}{(3k + 2h\Delta y)} \equiv T_{\text{nb}} \end{aligned} \tag{5.2.12}$$

where *central difference method* is used for the second derivative in the *GE*, and the second-order *forward (or backward) difference method* for the first derivative in the *BCs*. The application of the forward difference at the south boundary, and the backward difference at the east as well as the north boundary, is decided by the one-sided forward or backward location of the internal grid points adjoining the corresponding boundary grid points (Figure 5.2.3).

For the 2D steady-state heat conduction with volumetric heat generation, on a uniform grid (with $\Delta x = \Delta y$), Equations 5.2.11 and 5.2.12 finally results in FDE as

$$\left.\begin{aligned} -T_{i-1,j} - T_{i+1,j} - T_{i,j-1} - T_{i,j+1} + 4T_{i,j} = S_{\text{T}} \\ \text{where } S_{\text{T}} = \bar{Q}_{\text{gen},i,j} \Delta x^2 / k \end{aligned}\right\} \quad \begin{aligned} &\text{for } i = 2 \text{ to } i\text{max} - 1 \\ &\text{for } j = 2 \text{ to } j\text{max} - 1 \end{aligned}$$

$$\left.\begin{aligned} T_{1,j} = T_{\text{wb}} (\text{west boundary}) \\ T_{i\text{max},j} = T_{\text{eb}} (\text{east boundary}) \end{aligned}\right\} \quad \text{for } j = 2 \text{ to } j\text{max} - 1 \tag{5.2.13}$$

$$\left.\begin{aligned} T_{i,1} = T_{\text{sb}} (\text{south boundary}) \\ T_{i,j\text{max}} = T_{\text{nb}} (\text{north boundary}) \end{aligned}\right\} \quad \text{for } i = 2 \text{ to } i\text{max} - 1$$

The boundary temperature value above is a constant for a Dirichlet BC, and gets updated (after every iteration, using Equation 5.2.12) for a non-Dirichlet BC. Since the temperature at a particular internal grid point depends on the temperature at adjoining four (not all) grid points in the domain, the system of LAEs for Equation 5.2.13 results in a *penta-diagonal* coefficient matrix. The matrix consists of five nonzero diagonal vector: one main, two lower, and two upper diagonal. The nonzero value corresponds to 4 for the main diagonal, and −1 for all the upper and lower diagonals.

For obtaining the FDE at those boundary grid points which are subjected to the non-Dirichlet BC (involves derivative of temperature), FDM involves another widely used technique—called an *image-point technique*. The technique considered image grid points outside those boundaries which are subjected to the non-Dirichlet BC, shown outside the south, east, and north boundary in Figure 5.2.3. For the south boundary ($j = 1$) in Figure 5.2.3, the second-order central difference FDM for the insulated BC is given as

$$\left(\frac{\mathrm{d}T}{\mathrm{d}y}\right)_{i,1} = \frac{T_{i,2} - T_{i,0}}{2\Delta y} = 0 \Rightarrow T_{i,0} = T_{i,2} \tag{5.2.14}$$

where $T_{i,0}$ is the temperature at the image grid point, located at a distance Δy below the south boundary for each i (Figure 5.2.3). Applying the FDE for G.E. to the south boundary grid point (Equation 5.2.11 for $T_{i,1}$), and substituting $T_{i,0} = T_{i,2}$ (Equation 5.2.14), we obtain

$$\left.\begin{aligned} T_{i-1,1} + T_{i+1,1} + 2\beta^2 T_{i,2} - 2(1+\beta^2)T_{i,1} + \frac{\bar{Q}_{\mathrm{gen},i,1}\Delta x^2}{k} = 0 \end{aligned}\right\} \text{ for } i = 1 \text{ to } i\mathrm{max} - 1 \tag{5.2.15}$$

Similarly, using the second-order FDM for both non-Dirichlet BC and GE at the east and north boundary grid points, the final FDE for the respective grid points ($T_{i\mathrm{max},j}$ and $T_{i,j\mathrm{max}}$) are given as

$$\left.\begin{aligned} 2T_{i\mathrm{max}-1,j} + \beta^2(T_{i\mathrm{max},j-1} + T_{i\mathrm{max},j+1}) - 2(1+\beta^2)T_{i\mathrm{max},j} \\ + \frac{\bar{Q}_{\mathrm{gen},i\mathrm{max},j}\Delta x^2}{k} + \frac{2q_{\mathrm{W}}\Delta x}{k} = 0 \end{aligned}\right\} \text{for } j = 1 \text{ to } j\mathrm{max} - 1 \tag{5.2.16}$$

$$\left.\begin{aligned} T_{i-1,j\mathrm{max}} + T_{i+1,j\mathrm{max}} + 2\beta^2 T_{i,j\mathrm{max}-1} - 2\left(1 + \beta^2 + \frac{\beta^2 h\Delta y}{k}\right)T_{i,j\mathrm{max}} \\ + \frac{\bar{Q}_{\mathrm{gen},i,j\mathrm{max}}\Delta x^2}{k} + \frac{2\beta^2 h\Delta y}{k}T_{\infty} = 0 \end{aligned}\right\} \text{for } i = 1 \text{ to } i\mathrm{max} - 1 \tag{5.2.17}$$

For the boundary grid points at the non-Dirichlet boundary, note that either the FDE for BCs (Equation 5.2.12) or the FDE for both GE and BCs (Equations 5.2.15 through 5.2.17; obtained by image-point technique) can be used. Both the methods are commonly used, and presented in Chapter 5 of an edited book by Muralidhar and Sundarajan (2003).

The boundary grid-point value at the corner of the domain, involved in Equations 5.2.15 through 5.2.17, are taken as T_{wb} for the south-west and north-west corner grid point ($T_{1,1} = T_{1,j\mathrm{max}} = T_{\mathrm{wb}}$); and obtained by the image-point technique for the south-east corner and north-east corner grid points (which are exposed to two non-Dirichlet BCs) as

$$\left.\begin{aligned} T_{i\mathrm{max}-1,1} + \beta^2 T_{i\mathrm{max},2} - (1+\beta^2)T_{i\mathrm{max},1} \\ + \frac{\bar{Q}_{\mathrm{gen},i\mathrm{max},1}\Delta x^2}{2k} + \frac{q_{\mathrm{W}}\Delta x}{k} = 0 \end{aligned}\right\} \text{for } i = i\mathrm{max} \text{ and } j = 1 \tag{5.2.18}$$

$$\left.\begin{aligned} T_{i\max-1,j\max} + \beta^2 T_{i\max,j\max-1} - \left(1+\beta^2+\frac{\beta^2 h\Delta y}{k}\right)T_{i\max,j\max} \\ + \frac{\bar{Q}_{\text{gen},i\max,j\max}\Delta x^2}{2k} + \frac{\beta^2 h\Delta y}{k}T_\infty + \frac{q_W\Delta x}{k} = 0 \end{aligned}\right\} \text{for } i = i\max \text{ and } j = j\max \quad (5.2.19)$$

The above equations are obtained by substituting $T_{i\max,0} = T_{i\max,2}$ in Equation 5.2.16, and $T_{i\max+1,j\max} = (2q_W\Delta x/k) + T_{i\max-1,j\max}$ in Equation 5.2.17, respectively.

Solution of the Algebraic Equations

There are two approaches for the solution of the system of LAEs: direct and indirect. *Direct method* is based on algebraic eliminations for obtaining solution in a fixed number of operations; for example, matrix inversion and Gauss elimination. *Indirect method* is used to obtain the solution asymptotically by an *iterative* procedure; for example, Jacobi and Gauss–Seidel method.

Iterative or indirect methods are generally used under four conditions (Hoffman, 1993): first, the number of equation is large (100 or more); second, most of the coefficient a_{ij} are zero (sparse matrix); third, the system of equations is diagonally dominant; and fourth, the system of equations is not ill-conditioned. A coefficient matrix is called *diagonally dominant* if the absolute value of each term on the major diagonal is equal to, or larger than, the sum of the absolute value of all the other terms in that row. These conditions are commonly encountered in CFD: the first condition due to large grid size, the second condition due to the discretization method (FDM or FVM) resulting in a LAE with sparse coefficient matrix (pentadiagonal coefficient matrix, discussed previously), and the third condition is ensured during the discretization, and the fourth condition is avoided during the discretization. Thus, it is generally more efficient in terms of computational time and storage requirements to solve the system of LAEs in CFD by an iterative than a direct method.

Jacobi and Gauss–Seidel methods are two of the simplest iterative methods; and will be presented here. For these methods, each of the LAE is converted into an explicit equation for one of the element of the unknown vector, and the values of the other elements are taken from the *previous iteration* for the *Jacobi method,* and the *improved (or latest) value* for the *Gauss–Seidel* method. The sequence of the solution of the LAEs is relevant for the Gauss–Seidel but not for the Jacobi method; this is because of the iterative solution for the system of LAEs is *simultaneous* for Jacobi and *successive* for Gauss–Seidel method. The diagonal dominance is a *sufficient* condition for the convergence of the Jacobi and Gauss–Seidel methods; for any initial guess.

Considering $N + 1$ as the *present* and N as the *previous* iteration number, and $T_{i,j}^{N+1}$ and $T_{i,j}^{N}$ as the respective iterative value, the actual *error* in the solution ($T_{i,j}^{N+1} - T_{i,j}^{\text{exact}}$) is approximated as $\Delta T_{i,j} \equiv T_{i,j}^{N+1} - T_{i,j}^{N}$ (Hoffman, 1993). This error is computed for all the N values of T and should be reduced *simultaneously* for all of them, to ensure the minimum accuracy desired (as per the value of $\in$) for the system of equations. One of the most common convergence criteria is given as

$$\left|\Delta T_{\text{for all } i,j}\right|_{\max} \le \epsilon \quad (5.2.20)$$

where the LHS represents absolute value of the maximum from all the grid-point values of $\Delta T_{i,j}$, and $\in$ is a *convergence tolerance;* corresponding to user-defined zero—say 10^{-3} or 10^{-5}. The number of iterations required to achieve convergence depends on four conditions (Hoffman, 1993): first, the dominance (in terms of magnitude) of the diagonal coefficients; second, the initial guess for the unknowns; third, the iterative method used; and fourth, the prescribed value of convergence criterion.

Concluding Remarks

Finite difference-based numerical methodology is presented in this section—starting with governing equation and boundary conditions, followed by grid generation and algebraic formulation, and ending with the iterative solution methodology.

The methodology is presented for a simpler case of 2D steady-state heat conduction, with Jacobi and Gauss–Seidel iterative method on a uniform grid. However, for the solution of various model equations in fluid dynamics and heat transfer on a nonuniform grid, similar FDM method-based methodology can be found in the book by Anderson et al. (1984), Hoffmann and Chiang (1989), and Anderson (1995). These books also present the other iterative methods; such as, conjugate-gradient method and multigrid method. The FDM-based solution can also be found in an edited book by Muralidhar and Sundarajan (2003)—Chapter 6 on stream-function vorticity method, for a 2D incompressible flow, and Chapter 7 on Marker-and-Cell method, for both heat and fluid flow in a convective heat-transfer problem.

5.3 FINITE VOLUME METHOD

Atul Sharma

Introduction

Finite volume method (FVM) is a discretization method that starts with both volume and time integral for each term of the partial differential equation (PDE); thereafter, uses certain approximations for the spatial and temporal variation of the integrand; and finally, results in the system of linear algebraic equations (LAEs). Instead of the differential form of the governing equation in the finite-difference method (FDM), the volume integral form of the equations in the FVM gives greater flexibility in handling the irregular shape of the control volumes (CVs), for complex geometry problems in computational fluid dynamics (CFD). If all the boundaries of the computational domain are aligned along *one* (not any) of the three *standard* coordinate systems: Cartesian, cylindrical, and spherical, they are called simple geometry problem; otherwise called complex geometry problem. In this subsection, an FVM-based algebraic formulation is presented for *two-dimensional* unsteady-state convective heat transfer, in a *complex geometry* CFD problem, with a curvilinear structured grid.

Governing Differential Equations

For incompressible flow, a compact *coordinate-free* conservative form of the governing PDEs is given as

$$\begin{aligned}
&\text{Continuity}: && \nabla\cdot(\rho\vec{u})=0\\
&\text{Momentum}: && \frac{\partial(\rho\vec{u})}{\partial t}+\nabla\cdot(\rho\vec{u}\vec{u})=\mu\nabla^2\vec{u}-\overrightarrow{\nabla p}\\
&\text{Energy}: && \frac{\partial(\rho c_pT)}{\partial t}+\nabla\cdot(\rho\vec{u}c_pT)=k\nabla^2T+\vec{Q}_{\text{gen}}\\
&\text{Transport}: && \frac{\partial(\rho C\phi)}{\partial t}+\nabla\cdot(\rho\vec{u}C\phi)=\Gamma_\phi\nabla^2\phi+S_\phi
\end{aligned} \tag{5.3.1}$$

where, for this generalized transport equation, $\phi=\vec{u}$, $C=1$, $\Gamma_\phi=\mu$ and $S_\phi=-\nabla p$ for the momentum equation, and $\phi=T$, $C=c_p$, $\Gamma_\phi=k$, and $S_\phi=\overline{Q}_{\text{gen}}$ for the energy equation. The Cartesian, cylindrical, and spherical coordinate versions of these Navier–Stokes equations are obtained by substituting appropriate form of the velocity vector $\vec{u}$ and the gradient operator ∇; thus, these equations are called the coordinate-free form (Muralidhar and Biswas, 2005).

Grid Generation

For an FVM, a commonly considered grid generation is presented below first for a Cartesian and then for a complex geometry. A simplest example of grid generation is shown in Figure 5.3.1, for a simple Cartesian geometry problem. A nonuniform Cartesian grid generation is shown in the figure as a procedure of drawing nonuniformly spaced horizontal and vertical lines. The lines subdivide the computational domain to subdomains, called CVs. The points located at the centroid of the CVs are called internal grid points. The figure also shows grid points located at the boundary of the domain, called boundary grid points. Similar grid generation procedure is already introduced in Figure 5.3.1 for the FDM. However, the circles in both the figures shows that the grid points are defined differently in the FDM and the FVM—at the *vertex* of the CVs for the *FDM* (Figure 5.2.3) and at the *centroid* of the CVs for the FVM (Figure 5.3.1).

Figure 5.3.1 shows a subdivision of a 2D Cartesian domain into contiguous nonoverlapping nonuniform CVs—also called *cells* in the FVM. The CVs are generated by a nonuniform Cartesian grid

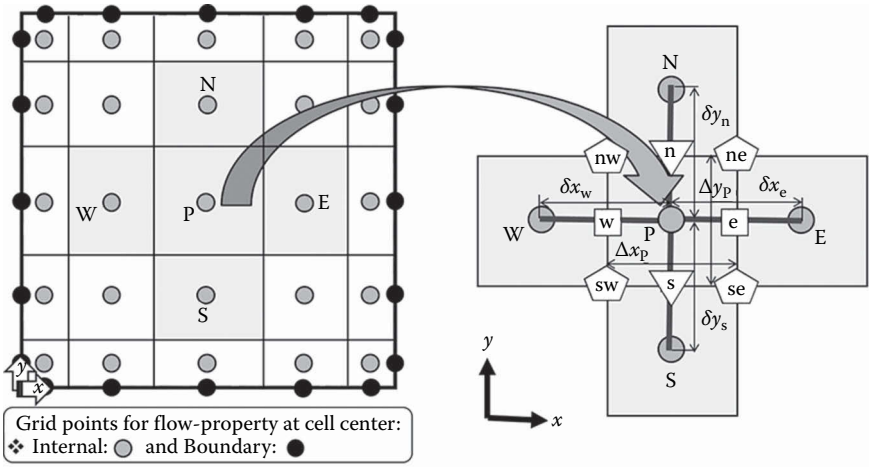

FIGURE 5.3.1 A nonuniform Cartesian grid generation, for an FVM. The figure also shows a representative Cartesian CV and its neighboring CVs.

generation method that leads to the nonuniformly spaced horizontal and vertical lines. The circles in the figure are the symbolic representation of the centroids of the CVs, which are also called *cell centers* or *internal grid points*. They are also represented by P for a representative 2D Cartesian CV; and by E, W, N, and S for the east, west, north, and south neighboring cell centers, respectively. Along with the centroid of the CVs, the figure also shows the centroids of the various faces, called *face centers*; represented by e, w, n, and s for the east, west, north, and south surfaces, respectively. They are differentiated by symbols (Sharma, 2016), as square at the vertical surfaces (for the e and w face centers), and triangle at the horizontal surfaces (for the n and s face centers). The pentagon symbol in the figure represents the corners of the representative CV and are indicated by ne, nw, se, and sw. Here, note from the figure that the capital letters (E, W, N, S) correspond to the cell centers/grid points, and small letters correspond to face centers (e, w, n, s) as well as corners (ne, nw, se, sw) of a CV.

Similar cell centers, face centers, and corners are shown in Figure 5.3.2, for a representative CV in a complex geometry problem. The grid is generated by a curvilinear grid generation method, presented in a book by Sharma (2016). Compared to the Cartesian CV for simple geometries, presented in Figure 5.3.1, Figure 5.3.2 shows that a complex CV for a complex geometry has two major differences. First, the faces for the CV are not orthogonal to each other and are not inclined along the direction of the Cartesian coordinates. Second, the lines joining the cell center P and neighboring cell centers are also not inclined along the direction of the Cartesian coordinates, do not pass through the corresponding face centers, and are not normal to the face. For the complex geometry problem, note from the figure that the domain is represented by the Cartesian coordinate system, and an FVM is presented later for the Cartesian components of the velocity field.

Main Idea of the FVM

The main idea for the FVM is that it results in algebraic formulation for the discrete heat and fluid flow field which satisfies the mass, momentum, and energy conservation laws to machine-level accuracy. The main idea in the formulation procedure for the FVM corresponds to the integral form of the governing partial differential equations, and two approximations presented later in separate subsections.

For simplicity, the main idea of the algebraic formulation is presented below for energy equation (Equation 5.3.1) and for the Cartesian CV (Figure 5.3.1). However, it is also applicable to the continuity and momentum equation (Equation 5.3.1), and for the complex CV (Figure 5.3.2) presented later.

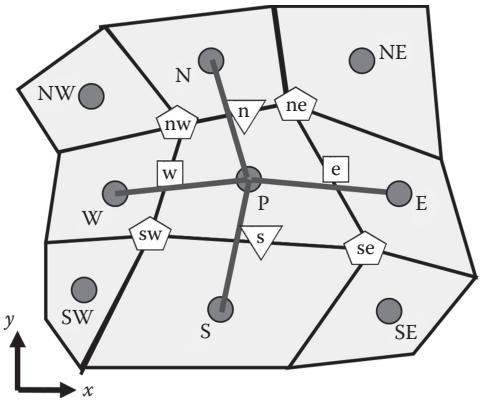

FIGURE 5.3.2 A representative complex CV for a complex geometry, with nonuniform, nonorthogonal, and curvilinear grid arrangement.

Integral Form of the Governing Equation

For an *Cartesian domain* of volume V bounded by a closed surface $\vec{S}$, the FVM starts with a volume integration of the governing partial differential equations, for a representative internal CV of volume ΔV_P (Figure 5.3.1), and a time integration between the previous time instant t and the present time instant $t+\Delta t$. This is given, for the energy equation (Equation 5.3.1), as

$$\int_{t}^{t+\Delta t}\int_{\Delta V_P}\frac{\partial(\rho c_p T)}{\partial t}\mathrm{d}V\mathrm{d}t+\int_{t}^{t+\Delta t}\int_{\Delta V_P}\nabla\cdot(\rho\vec{u}c_pT-k\overline{\overline{\nabla T}})\mathrm{d}V\mathrm{d}t=\int_{t}^{t+\Delta t}\int_{\Delta V_P}\overline{Q}_{\mathrm{gen}}\mathrm{d}V\mathrm{d}t$$

It is important to note from this integral equation that the integrands are either a volumetric term (volumetric enthalpy $\overline{\mathcal{V}_{\mathrm{T}}}=\rho c_{\mathrm{p}}T$ and volumetric heat generation $\overline{Q}_{\mathrm{gen}}$) or a flux term (enthalpy flux $\vec{h}=\rho\,\overline{\vec{u}}\,c_{\mathrm{p}}T$ and conduction flux $\vec{q}=-k\overline{\overline{\nabla T}}$). The integrands that represent a flux term are converted into surface integral—using *Gauss divergence theorem*. During this operation, one of the ∇ operator (in the integrand) pulls out, and we end up with a dot product of the remaining term of the integrand and the unit normal vector $\hat{n}$ (normal to the surface), as follows:

$$\int_{t}^{t+\Delta t}\frac{\partial}{\partial t}\int_{\Delta V_{\mathrm{P}}}(\rho c_{\mathrm{p}}T)\mathrm{d}V\mathrm{d}t+\int_{t}^{t+\Delta t}\int_{\Delta S}(\rho\vec{u}c_{\mathrm{p}}T-k\overline{\overline{\nabla T}})\cdot\hat{n}\mathrm{d}S\mathrm{d}t=\int_{t}^{t+\Delta t}\int_{\Delta V_{\mathrm{P}}}\overline{Q}_{\mathrm{gen}}\mathrm{d}V\mathrm{d}t \tag{5.3.2}$$

where $\hat{n}\,\mathrm{d}S$ represents the surface-area vector $\overline{\mathrm{d}\vec{S}}$.

Although this equation represents application of the conservation laws locally for each CV, the global conservation (for the complete domain) is built into this method. This is because the integral form of global conservation equations is obtained if we sum up this equation for all the CVs, since surface integrals over inner CV faces cancel out.

Approximations for Algebraic Formulation

Since the aim of the FVM is to obtain LAE for each CV, consisting of the cell-center temperature T_{P} and a number of neighboring cell-center values (T_{E}, T_{W}, etc.), certain approximations are needed for an algebraic representation of the integrals in Equation 5.3.2. They are broadly classified as the first and the second approximations, and are separately presented as follows.

First Approximation: Average Flux and Volumetric Term

The surface and volume integrals in Equation 5.3.2 need to be approximated using quadrature formulae. For the surface integral, it can be seen in the equation that the integrand is a flux term $\vec{f}$ (enthalpy and conduction flux), whereas, for the volume integral, the integrand is a volumetric term $\overline{\mathcal{V}}$ (volumetric enthalpy and heat generation). For both surface and volume integrals, the *I-approximation* is an approximate representation of the average value of the integrands—*the space-averaged one-point value for the spatial variation and the time-averaged one time-instant value for the temporal variation.*

For the spatial variation of the integrand, within the surface for the surface integral and inside the volume for the volume integral, the simplest one-point approximation is the midpoint rule—the space-averaged value of the integrand is approximated by its value at the centroid f of the surface for the flux term ($\vec{f}_\mathrm{f}$), and at the centroid P of the volume for the volumetric term ($\overline{\mathcal{V}}_\mathrm{P}$); the face centers f = e, w, n, and s and cell center P can be seen in Figure 5.3.1. Whereas, for the temporal variation in-between the two consecutive time instants (previous t and present $t+\Delta t$), there are three types on one-time-instant approximation—the time-averaged value of the flux is approximated by its value at previous time instant t for the explicit method, present time instant $t+\Delta t$ for the implicit method, and $t+\Delta t/2$ for the Crank–Nicolson method (follows the midpoint rule). Note that the three types of methods are considered only for the *flux* term $\vec{f}$ but not for the *volumetric* term $\overline{\mathcal{V}}$.

Thus, for a discrete representation of the integrands (general flux term $\vec{f}$ and volumetric term $\overline{\mathcal{V}}$), the *I*-approximation is given as

$$\begin{aligned}
\int_t^{t+\Delta t} \oint_{\Delta S} (\vec{f}\cdot\hat{n})\Delta S_\mathrm{f} &= \sum_{\mathrm{f=e,w,n,s}} \int_t^{t+\Delta t} \int_{\Delta S_\mathrm{f}} (\vec{f}\cdot\hat{n})\Delta S_\mathrm{f} \\
&= \sum_{\mathrm{f=e,w,n,s}} \left(\vec{f}_\mathrm{av}^{\,\mathrm{mean}}\cdot\hat{n}\right)\Delta S_\mathrm{f}\Delta t \approx \sum_{\mathrm{f=e,w,n,s}} (\vec{f}_\mathrm{f}^{\,\chi}\cdot\hat{n})\Delta S_\mathrm{f}\Delta t \qquad (5.3.3)\\
\int_{\Delta V_\mathrm{P}} \overline{\mathcal{V}}\,\mathrm{d}V &= \overline{\mathcal{V}}_\mathrm{av}\Delta V_\mathrm{P} \approx \overline{\mathcal{V}}_\mathrm{P}\Delta V_\mathrm{P}
\end{aligned}$$

where $\Delta S_{\mathrm{f=e,w,n,s}}$ is the area of the various surfaces of a CV, and ΔV_P is the volume of the CV; $\Delta V_\mathrm{P}=\Delta x_\mathrm{P}\Delta y_\mathrm{P}$, $\Delta S_\mathrm{e}=\Delta S_\mathrm{w}=\Delta y_\mathrm{P}$, and $\Delta S_\mathrm{n}=\Delta S_\mathrm{s}=\Delta x_\mathrm{P}$, for the representative Cartesian CV in Figure 5.3.1. For this equation, the subscript av represents the space-averaged value, and the superscript mean represents the time-averaged value. Note the approximate sign $\approx$ in this equation, where the average value av is represented by the centroid f = e, w, n, and s of the surfaces and the centroid P of a representative CV; the face centers f and cell center P can be seen in Figure 5.3.1 for the Cartesian CV, and Figure 5.3.2 for the complex CV. The mean value in Equation 5.3.3 is represented by the time level $\chi=n$ for the explicit method, $\chi=n+1$ for the implicit method, and $\chi=n+1/2$ for the Crank–Nicolson method. Note that $\vec{f}_\mathrm{f}^{\,n+1/2} \approx \left(\vec{f}_\mathrm{f}^{\,n}+\vec{f}_\mathrm{f}^{\,n+1}\right)\Big/2$ for Crank–Nicolson method. Also note from this equation that the time integral of the volumetric term is not considered in the *I*-approximation.

For the surface integral, this spatial approximation is second-order accurate, which can be preserved if the face-center value of the flux term $\vec{f}_\mathrm{f}$ is computed with at least second-order accuracy. For the volume integral, the spatial approximation becomes exact if the volumetric term $\overline{\mathcal{V}}$ is either constant or varies linearly within the CV; otherwise, it contains a second-order error. The time integral for this flux term is first-order accurate for the explicit and implicit method, and second order accurate for the Crank–Nicolson method.

Second Approximation: Interpolation or Extrapolation Method and Central Difference Method

For the flux term in energy equation, the integrand after the *I*-approximation in Equation 5.3.3 is $\vec{f}_{\mathrm{f}}^{\chi} \cdot \hat{n} = \vec{f}_{\eta,\mathrm{f}}^{\chi}$; where η is the outward normal direction at a surface. The integrand corresponds to *outward* enthalpy and conduction flux, at a face center f, given as

$$h_{\eta,\mathrm{f}} = \rho c_p u_{\eta,\mathrm{f}} T_{\mathrm{f}} = m_{\eta,\mathrm{f}} c_p T_{\mathrm{f}}$$

$$q_{\eta,\mathrm{f}} = -k\left(\frac{\partial T}{\partial \eta}\right)_{\mathrm{f}}$$

For the outward conduction flux $q_{\eta,\mathrm{f}}$ in the diffusion term, the *II-approximation* corresponds to FDM-based *central difference* (CD)-based representation for $(\partial T/\partial \eta)_{\mathrm{f}}$ (the normal gradient of temperature T at a face center f) in terms of the cell center values *across* the face. For the outward enthalpy flux $h_{\eta,\mathrm{f}}$ in the advection term, the *II-approximation* corresponds to an *interpolation or extrapolation method*, for the computation of face-center value of temperature T_{f} in terms of neighboring cell center values—called advection scheme.

For the Cartesian CV, shown in Figure 5.3.1, the h_η and q_η are h_x and q_x for the east surface, and $-h_x$ and $-q_x$ for the west surface; and h_y and q_y for the north surface, and $-h_y$ and $-q_y$ for the south surface. Note that η represent the outward normal to a surface, which is in the positive *x*/*y* direction for the fluxes at the east/north surface, and negative *x*/*y* direction for the fluxes at the west/south surface. The CD-based *II*-approximation for the normal gradient of temperature results in the conduction flux as

$$\begin{aligned} q_{x,\mathrm{e}}^{\chi} &\approx -k\frac{T_{\mathrm{E}}^{\chi} - T_{\mathrm{P}}^{\chi}}{\delta x_{\mathrm{e}}}, q_{x,\mathrm{w}}^{\chi} \approx -k\frac{T_{\mathrm{P}}^{\chi} - T_{\mathrm{W}}^{\chi}}{\delta x_{\mathrm{w}}} \\ q_{y,\mathrm{n}}^{\chi} &\approx -k\frac{T_{\mathrm{N}}^{\chi} - T_{\mathrm{P}}^{\chi}}{\delta y_{\mathrm{n}}}, q_{y,\mathrm{s}}^{\chi} \approx -k\frac{T_{\mathrm{P}}^{\chi} - T_{\mathrm{S}}^{\chi}}{\delta y_{\mathrm{s}}} \end{aligned} \tag{5.3.4}$$

where the δx_{e}, δx_{w}, δy_{n}, and δy_{s} are the distances between the cell centers *across* the e, w, n, and s face centers, respectively (refer Figure 5.3.1). Furthermore, for the Cartesian geometry, the enthalpy flux in the advection term is given as

$$h_{x,\mathrm{e}}^{\chi} = m_{x,\mathrm{e}} c_p T_{\mathrm{e}}^{\chi}, h_{x,\mathrm{w}}^{\chi} = m_{x,\mathrm{w}} c_p T_{\mathrm{w}}^{\chi}, h_{y,\mathrm{w}}^{\chi} = m_{y,\mathrm{n}} c_p T_{\mathrm{n}}^{\chi} \text{ and } h_{y,\mathrm{s}}^{\chi} = m_{y,\mathrm{s}} c_p T_{\mathrm{s}}^{\chi} \tag{5.3.5}$$

where the mass flux $m_x = \rho u$ and $m_y = \rho v$. Since the extrapolation or interpolation method (*II*-approximation) used to determine the temperature T_{f} in this equation depends on the direction of mass flux $m_{x/y,\mathrm{f}}$ (Patankar, 1980), the product of mass flux and temperature in the this equation is given (Sharma, 2016) as

$$\begin{aligned} & m_{x/y,\mathrm{f}} T_{\mathrm{f}} = m_{x/y,\mathrm{f}}^{+} T_{\mathrm{f}}^{+} + m_{x/y,\mathrm{f}}^{-} T_{\mathrm{f}}^{-} \Big\} \mathrm{f} = \mathrm{e,w,n,s} \\ & \text{where } T_{\mathrm{f}} = w_1 T_{\mathrm{D}} + w_2 T_{\mathrm{U}} \\ & \left.\begin{aligned} m_{x/y,\mathrm{f}}^{+} &\equiv \max(m_{x/y,\mathrm{f}}, 0) = \left|m_{x/y,\mathrm{f}}\right| \text{ if } m_{x/y,\mathrm{f}} > 0 \\ m_{x/y,\mathrm{f}}^{-} &\equiv \min(m_{x/y,\mathrm{f}}, 0) = -\left|m_{x/y,\mathrm{f}}\right| \text{ if } m_{x/y,\mathrm{f}} < 0 \end{aligned}\right\} \text{ otherwise } \quad 0 \end{aligned} \tag{5.3.6}$$

where $m_{x/y,\mathrm{f}}$ represents $m_{\mathrm{x,f}}$ at the east/west face center and $m_{\mathrm{y,f}}$ at the north/south face center. Furthermore, the temperature T_{f}^{+} is for the positive and T_{f}^{-} is for the negative *x*/*y* direction of the

fluid flow at a face center f. Also D is the downstream cell center and U is the upstream cell center: D=E and U=P if the direction of mass flux at the east face center e (refer Figure 5.3.1) is positive $m_{x,e} > 0$ and vice versa for the negative mass flux ($m_{x,e} < 0$). The various advection schemes can be found in Sharma (2016), with the weights $w_1=0$ and $w_2=1$ and $T_f^{\pm} = T_U$ (Equation 5.3.6) for the first-order-upwind (FOU) Scheme (constant extrapolation), that is, $T_e^{+} = T_P$ and $T_e^{-} = T_E$. Similarly, using the FOU scheme to determine the temperature at the other face centers, Equation 5.3.5 for the enthalpy fluxes is approximated as

$$\begin{aligned} h^{\chi}_{x,e} &\approx c_p(m^{+}_{x,e}T^{\chi}_{P} + m^{-}_{x,e}T^{\chi}_{E}), h^{\chi}_{x,w} \approx c_p\left(m^{+}_{x,w}T^{\chi}_{W} + m^{-}_{x,w}T^{\chi}_{P}\right) \\ h^{\chi}_{y,n} &\approx c_p(m^{+}_{y,n}T^{\chi}_{P} + m^{-}_{y,n}T^{\chi}_{N}) \;\;\&\;\; h^{\chi}_{y,s} \approx c_p\left(m^{+}_{y,s}T^{\chi}_{S} + m^{-}_{y,s}T^{\chi}_{P}\right) \end{aligned} \tag{5.3.7}$$

Thus, the I-approximation corresponds to the space as well as time averaged value of a flux term $\vec{f}^{\,\text{mean}}_{\text{av}}$, and space-averaged value of a volumetric term $\overline{\mathcal{V}}_{\text{av}}$; and the *II-approximation corresponds to obtaining the algebraic equation for the value or first derivative of a flow property at a face center, in terms of neighboring cell center values.*

FVM-Based Algebraic Formulation

The main idea of the FVM presented earlier for the energy equation and Cartesian CV is continued in this subsection for the Navier–Stokes (continuity, momentum and energy) equations and complex CV. Similar to the FVM for Cartesian geometry mentioned earlier, for a representative CV in an *arbitrary-shaped complex domain* of volume V bounded by a closed surface $\vec{S}$ (Figure 5.3.2), the FVM starts with the volume and the time integration of the continuity and the transport equations (Equation 5.3.1) as

$$\int_{t}^{t+\Delta t}\int_{\Delta V_P} \nabla\cdot(\rho\vec{u})\,\mathrm{d}V\,\mathrm{d}t = 0$$

$$\int_{t}^{t+\Delta t}\int_{\Delta V_P} \frac{\partial(\rho C\phi)}{\partial t}\mathrm{d}V\mathrm{d}t + \int_{t}^{t+\Delta t}\int_{\Delta V_P} \nabla\cdot(\rho\vec{u}C\phi - \Gamma_\phi\overrightarrow{\nabla\phi})\mathrm{d}V\mathrm{d}t = \int_{t}^{t+\Delta t}\int_{\Delta V_P} S_\phi\,\mathrm{d}V\,\mathrm{d}t$$

where $\phi = \vec{u}$ $C=1$, $\Gamma_\phi=\mu$ and $S_\phi=-\nabla p$ for the momentum equation, and $\phi=T$, $C=c_p$, $\Gamma_\phi=k$ and $S_\phi = \overline{Q}_{\text{gen}}$ for the energy equation. Here again, the integrand with the flux term are mass flux $\rho\vec{u}$, advection flux $\rho\vec{u}C\phi$ and diffusion flux $\Gamma_\phi\overrightarrow{\nabla\phi}$. As compared to enthalpy flux $\rho\vec{u}c_pT$ for the energy equation, the generic advection flux corresponds to x-momentum flux $\rho\vec{u}u$ for the x-momentum equation, and y-momentum flux $\rho\vec{u}v$ for the y-momentum equation. For the respective equation, the diffusion flux corresponds to viscous stress in the x- and y-direction; as compared to conduction flux for the energy equation. Using the Gauss divergence theorem for those integrands (in this integral equation) which are flux terms, we obtain

$$\begin{aligned} \int_{t}^{t+\Delta t}\oint_{\Delta S} (\rho\vec{u})\cdot\hat{n}\mathrm{d}S\mathrm{d}t &= 0 \\ \int_{t}^{t+\Delta t}\frac{\partial}{\partial t}\int_{\Delta V_P}\rho C\phi\,\mathrm{d}V\,\mathrm{d}t + \int_{t}^{t+\Delta t}\int_{\Delta S}(\rho\vec{u}C\phi - \Gamma_\phi\overrightarrow{\nabla\phi})\cdot\overrightarrow{\mathrm{d}S}\mathrm{d}t &= \int_{t}^{t+\Delta t}\int_{\Delta V_P} S_\phi\mathrm{d}V\mathrm{d}t \end{aligned} \tag{5.3.8}$$

For complex geometry, the algebraic formulation is initiated above with the coordinate-free form of the differential and integral form of the governing equations, Equations 5.3.1 and 5.3.8,

respectively. Thereafter, an FVM-based algebraic formulation is presented for the Cartesian components of velocity. Thus, for the *CVs of arbitrary/complex shape*, the *coordinate-free form* of the equations based FVM leads to the application of the momentum conservation law in the Cartesian coordinate directions: x-direction with $\varphi = u$, and y-direction with $\varphi = v$ in Equation 5.3.8. For the complex geometry problem, it is important to note that the Cartesian velocities (u and v) are obtained from the coordinate-free form, not the Cartesian form, of the momentum equation.

Applying the generic form of the I-approximation (Equation 5.3.3), an algebraic formulation of the continuity and transport equation (Equation 5.3.8) is given as

$$\sum_{\mathrm{f=e,w,n,s}} \rho\left(\vec{u}_{\mathrm{f}}^{\,n+1} \cdot \hat{n} \Delta S_{\mathrm{f}}\right) \Delta t = 0$$

$$\int_{t}^{t+\Delta t} \frac{\partial}{\partial t}(\rho C \phi_{\mathrm{P}} \Delta V_{\mathrm{P}})\mathrm{d}t + \sum_{\mathrm{f=e,w,n,s}} \left[\rho C\left(\vec{u}_{\mathrm{f}}^{\,n} \cdot \hat{n} \Delta S_{\mathrm{f}}\right)\phi_{\mathrm{f}}^{\chi} - \Gamma_{\phi}\left(\overrightarrow{\nabla \phi}_{\mathrm{f}}^{\chi} \cdot \hat{n} \Delta S_{\mathrm{f}}\right)\right] \Delta t \tag{5.3.9}$$

$$= \int_{t}^{t+\Delta t} \int_{\Delta V_{\mathrm{P}}} S_{\phi} \mathrm{d}V \mathrm{d}t$$

where ΔV_{P} is the volume of the CV, and $\Delta S_{\mathrm{f=e,\,w,\,n,\,s}}$ is the surface area at the various faces of the complex CV (Figure 5.3.2).

For the complex geometry problem, Sharma and Eswaran (2004) presented two coordinate system: global (x, y) and the local (s, t) coordinate. They are shown in Figure 5.3.3, with the local η-coordinate consisting of two nonorthogonal components: s-coordinate, along the line joining the cell centers across the surface, and t-coordinate, along the direction tangential to the surface. Note from the figure that the symbol η represents a coordinate which is normal to a surface. Since the direction of the η-coordinate varies from the one to the other surface of a complex CV, its definition is local to a surface. Thus, η-coordinate is called a local coordinate, and the Cartesian coordinate is called the global coordinate.

The Cartesian components ($\Delta S_{x,\mathrm{f}}$ and $\Delta S_{y,\mathrm{f}}$) of the surface area vector $\overrightarrow{\Delta S}_{\mathrm{f}}$ are shown in Figure 5.3.4a; the direction of the area vector corresponds to the outward normal at each surface. The figure also shows the expression for the computation of volume of the CV.

The 2D components of the vector quantities in Equation 5.3.9 are given as

$$\text{Global } x-y: \quad \vec{u}_{\mathrm{f}} = u_f + v_f; \qquad \overrightarrow{\Delta S}_{\mathrm{f}} = \Delta S_{x,\mathrm{f}} \hat{i} + \Delta S_{y,\mathrm{f}} \hat{j}$$

$$\text{Local } s-t: \quad \overrightarrow{\nabla \phi}_{\mathrm{f}} = \left(\frac{\partial \phi}{\partial s}\right)_{\mathrm{f}} \hat{s} + \left(\frac{\partial \phi}{\partial t}\right)_{\mathrm{f}} \hat{t}; \qquad \overrightarrow{\Delta S}_{\mathrm{f}} = \Delta S_{s,\mathrm{f}} \hat{s} + \Delta S_{t,\mathrm{f}} \hat{t}$$

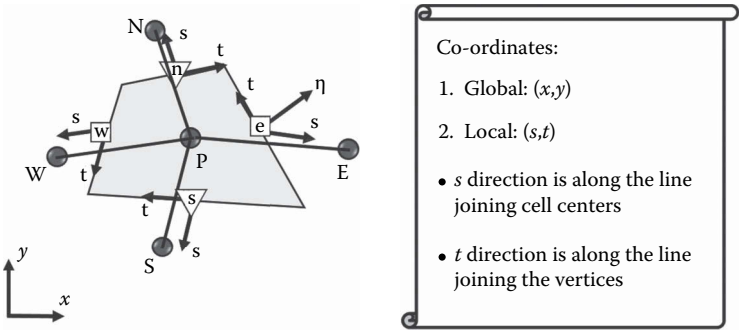

FIGURE 5.3.3 Schematic representation of the global and local coordinates, for a representative complex CV.

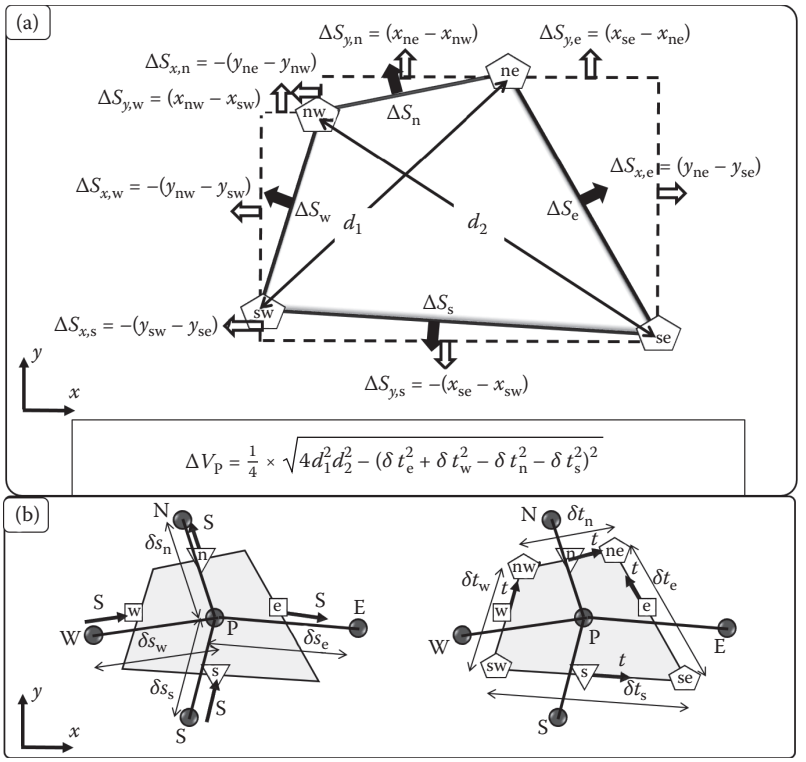

FIGURE 5.3.4 Schematic representation of the (a) surface areas $\Delta S_{x/y,f}$ and volume ΔV_P, and (b) distances between the cell centers δs_f and vertices δt_f, for a representative complex CV.

where the components for $\vec{u}_f$ and $\overrightarrow{\nabla\phi}_f$ are considered in the global x–y and local s–t coordinate system, respectively. Note that the global x–y coordinate system is considered for the computation of mass flow rate M and advection flow rate A (M and A obtained from the Cartesian velocity u/v), and local s –t coordinate is considered for the computation of diffusion D, given as

$$
\begin{aligned}
M_f^{n+1} &= \vec{m}_f^{n+1} \cdot \overrightarrow{\Delta S}_f = \rho\left(u_f^{n+1}\Delta S_{x,f} + v_f^{n+1}\Delta S_{y,f}\right) \equiv m_{\eta,f}^{n+1}\Delta S_f \\
A_{\phi,f}^{\chi} &= a_f^{\chi} \cdot \hat{n}\Delta S_f = Cm_{\eta,f}^{n}\phi_f^{\chi}\Delta S_f \equiv a_{\phi\eta f}^{\chi}\Delta S_f \\
D_{\phi,f}^{\chi} &= \vec{d}_f^{\chi} \cdot \overrightarrow{\Delta S}_f = \Gamma_\phi\left[\left(\frac{\partial\phi}{\partial s}\right)_f^{\chi}\hat{s} + \left(\frac{\partial\phi}{\partial t}\right)_f^{\chi}\hat{t}\right] \cdot \left(\Delta S_{s,f}\,\hat{s} + \Delta S_{t,f}\,\hat{t}\right) \\
&= \Gamma_\phi\left[\left(\frac{\partial\phi}{\partial s}\right)_f^{\chi}\Delta S_{s,f} + \left(\frac{\partial\phi}{\partial t}\right)_f^{\chi}\Delta S_{t,f}\right] \equiv d_{\phi\eta f}^{\chi}\Delta S_f
\end{aligned}
\tag{5.3.10}
$$

where $\vec{m}_f^{n+1} = \rho\left(\vec{u}_f^{n+1}\right)$ is the mass flux, $\vec{a}_f^{\chi} = \rho C\left(\vec{u}_f^{n}\right)\phi_f^{\chi}$ is the advection flux, and $\vec{d}_f^{\chi} = \Gamma_\phi\left(\overrightarrow{\nabla\phi}^{\chi}\right)$ is the diffusion flux. The component of respective flux in the direction η (normal to the surface) is represented as $m_{\eta,f}$, $a_{\varphi\eta,f}$, and $d_{\varphi\eta,f}$. The *II*-approximation for the mass flux corresponds to a momentum interpolation (Rhie and Chow, 1983) $m_{\eta,f}$, advection schemes for the

advection flux, and CD method for the diffusion flux. Using the two approximations, the final algebraic formulation from the continuity and transport equation are presented as follows.

Continuity Equation

After the *I*-approximation (Equation 5.3.9), the algebraic formulation for the mass source in the continuity equation (for incompressible flow) is given as

$$S_{m,P} = \sum_{\mathrm{f=e,w,n,s}} M_{\mathrm{f}}^{n+1}\Delta t = \sum_{\mathrm{f=e,w,n,s}} \rho\left(\vec{u}_{\mathrm{f}}^{n+1}\cdot\hat{n}\Delta S_{\mathrm{f}}\right)\Delta t = \sum_{\mathrm{f=e,w,n,s}} \rho u_{\eta,\mathrm{f}}^{n+1}\Delta S_{\mathrm{f}}\Delta t$$

where $u_{\eta,\mathrm{f}}$ is the outward normal velocity at the various face centers f = e, w, n, s of the complex CVs. The normal velocity is computed by a momentum interpolation method (Rhie and Chow, 1983), as the colocated (not staggered) grid is used for the complex geometry.

Transport Equations

After the *I*-approximation, the algebraic formulation for the transport equation is presented in Equation 5.39. Further application of the *II*-approximation and the resulting algebraic formulation are presented separately for the unsteady, advection, diffusion, and source terms.

Unsteady Term

The algebraic formulation for the unsteady term in Equation 5.3.9 is given as

$$\Delta V_{\phi} = \int_{t}^{t+\Delta t} \frac{\partial}{\partial t}(\rho C\phi_{\mathrm{P}}\Delta V_{\mathrm{P}})\,\mathrm{d}t \approx \rho C\Delta V_{\mathrm{P}}\frac{\phi_{\mathrm{P}}^{n+1}-\phi_{\mathrm{P}}^{n}}{\Delta t}\Delta t \tag{5.3.11}$$

where ΔV_{P} is the volume of the representative complex CV (Figure 5.3.4).

Advection Term

Advection scheme is used as the *II*-approximation, for the advection term in Equation 5.3.9. The scheme is presented for the complex geometry with the help of Figure 5.3.5 and Table 5.3.1. Advection scheme is an inward/outward direction of mass flux $m_{\eta,\mathrm{f}}$ based interpolation/extrapolation procedure. Thus, φ_{f} is expressed in terms of downstream D, upstream U, and upstream-of-upstream UU cell center values, represented by φ_{D}, φ_{U}, and φ_{UU}, respectively.

Since a face is common to two CVs, the advection scheme is presented in Table 5.3.1 for the north and east face center. *The negative value of total advection at the east face center e (of a CV P) is equal to that of the west face center* w *value of the adjoining east CV E*. The table shows a general expression for the product of the mass flux $m_{\eta,\mathrm{f}}$ and the advected variable φ_{f}, needed for computation of $A_{\phi,\mathrm{f}}^{x}$ in Equation 5.3.10. Note from the table that the equation for ϕ_{f}^{+} corresponds to positive/outward, and ϕ_{f}^{-} corresponds to negative/inward, direction of the fluid flow. This is demonstrated in the table for the east face center, where the equation for ϕ_{e}^{+} and ϕ_{e}^{-} is obtained after substituting appropriate subscript D, U, and UU in $\phi_{\mathrm{e,D}}^{\pm}$, $\phi_{\mathrm{e,U}}^{\pm}$, and $\phi_{\mathrm{e,UU}}^{\pm}$. They are also shown in Figure 5.3.5, for the FOU, CD, second-order upwind (SOU), and quadratic upwind interpolation for convective kinematics (QUICK) advection schemes. The figure and the table also show certain weights for the neighboring cell center values. Note that the equations for the weights in Table 5.3.1 correspond to a nonuniform volume of the complex CV-weighted interpolation/extrapolation procedure in the various advection schemes (Sharma and Eswaran, 2003).

Using the advection scheme, for the value of the variable φ in $a_{\varphi\eta,\mathrm{f=e,w,n,s}}$ (Equation 5.3.10), the *II*-approximation results in the algebraic formulation for the advection term in Equation 5.3.9 as

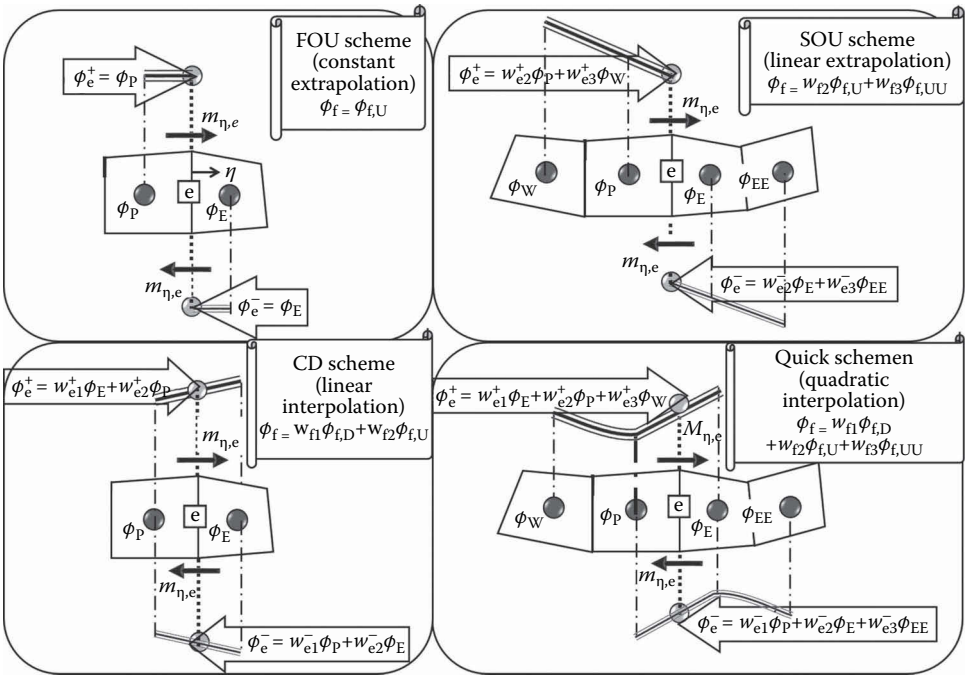

FIGURE 5.3.5 Schematic representation of various advection schemes to calculate the advected variable ϕ_f at the east face center, considering both positive/outward and negative/inward direction of the mass flux at the face. (From Sharma, A., *Introduction to Computational Fluid Dynamics: Development, Application and Analysis*, John Wiley & Sons, Chichester, UK, 2016. With permission.)

$$A_{\phi,P}^{\chi}\Delta t = \sum_{f=e,w,n,s} a_{\phi\eta,f}^{\chi}\Delta S_f \Delta t$$

$$\text{where } A_{\phi,P}^{\chi} \approx \left\{\left[m_{\eta,e}^{+,n}\phi_e^{+,\chi} + m_{\eta,e}^{-,n}\phi_e^{-,\chi}\right]\Delta S_e + \left[m_{\eta,w}^{+,n}\phi_w^{+,\chi} + m_{\eta,w}^{-,n}\phi_w^{-,\chi}\right]\Delta S_w\right\}C + \left\{\left[m_{\eta,n}^{+,n}\phi_n^{+,\chi} + m_{\eta,n}^{-,n}\phi_n^{-}\right]\Delta S_n + \left[m_{\eta,s}^{+,n}\phi_s^{+,\chi} + m_{\eta,s}^{-,n}\phi_s^{-,\chi}\right]\Delta S_s\right\}C \tag{5.3.12}$$

Diffusion Term

Using the CD method for the outward normal gradient of the variable ϕ in $d_{\phi\eta,f}^{\chi}\left[=\Gamma_\phi(\nabla\phi\cdot\hat{n})_f\right]$ (Equation 5.3.10), the *II*-approximation results in the algebraic formulation for the diffusion term in Equation 5.3.9 as

$$D_{\phi,P}^{\chi}\Delta t = \sum_{f=e,w,n,s} d_{\phi\eta,f}^{\chi}\Delta S_f \Delta t$$

$$D_{\phi,P}^{\chi} = \sum_{f=e,w,n,s} \Gamma_\phi(\nabla\phi^{\chi}\cdot\hat{n})_f \Delta S_f$$

$$\text{where } (\nabla\phi^{\chi}\cdot\hat{n})_e \Delta S_e \approx \frac{\phi_E^{\chi} - \phi_P^{\chi}}{\delta s_e}\left|\Delta S_{s,e}\right| + \frac{\phi_{ne}^{\chi} - \phi_{se}^{\chi}}{\delta t_e}\left|\Delta S_{t,e}\right| \tag{5.3.13}$$

$$(\nabla\phi^{\chi}\cdot\hat{n})_n \Delta S_n \approx \frac{\phi_N^{\chi} - \phi_P^{\chi}}{\delta s_n}\left|\Delta S_{s,n}\right| + \frac{\phi_{ne}^{\chi} - \phi_{nw}^{\chi}}{\delta t_w}\left|\Delta S_{t,n}\right|$$

$$(\nabla\phi^{\chi}\cdot\hat{n})_{\mathrm{w}}\Delta S_{\mathrm{w}} \approx \frac{\phi^{\chi}_{\mathrm{W}}-\phi^{\chi}_{\mathrm{P}}}{\delta s_{\mathrm{w}}}\left|\Delta S_{s,\mathrm{w}}\right| + \frac{\phi^{\chi}_{\mathrm{sw}}-\phi^{\chi}_{\mathrm{nw}}}{\delta t_{\mathrm{w}}}\left|\Delta S_{t,\mathrm{w}}\right|$$

$$(\nabla\phi^{\chi}\cdot\hat{n})_{\mathrm{s}}\Delta S_{\mathrm{s}} \approx \frac{\phi^{\chi}_{\mathrm{S}}-\phi^{\chi}_{\mathrm{P}}}{\delta s_{\mathrm{s}}}\left|\Delta S_{s,\mathrm{s}}\right| + \frac{\phi^{\chi}_{\mathrm{sw}}-\phi^{\chi}_{\mathrm{se}}}{\delta t_{\mathrm{s}}}\left|\Delta S_{t,\mathrm{s}}\right|$$

where the components of surface area $\Delta S_{s,\mathrm{f}}$ and $\Delta S_{t,\mathrm{f}}$ are represented in terms of their absolute values. Also δs_{f} is the distance between the adjoining cell centers, and δt_{f} is the distance between the associated vertices shown in Figure 5.3.4b. Furthermore, $\Delta S_{s,\mathrm{f=e,w,n,s}}$ and $\Delta S_{t,\mathrm{f=e,w,n,s}}$ are the local $s-t$ components of the surface area $\Delta S_{\mathrm{f=e,w,n,s}}$, calculated using the Cartesian components of the surface area. The Cartesian and local components of the surface area are correlated in terms of direction

TABLE 5.3.1
Advection Schemes for Complex Geometry (Sharma and Eswaran, 2003): Volume-Weighted Interpolation/Extrapolation-Based Equations for the Product of Mass $m_{\eta,\mathrm{f}}(\int \rho\vec{u}\,\boldsymbol{f}\cdot\hat{n})$ and Advected Variable ϕ_{f} at the East and North Face Centers

$w^{-}_{\mathrm{e},1}$	0	$\dfrac{\Delta V_{\mathrm{P}}}{\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{E}}}$	0	$\dfrac{\Delta V_{\mathrm{E}}(2\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}})}{(\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{E}})\,(\Delta V_{\mathrm{P}}+2\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}})}$
$w^{+}_{\mathrm{e},2}$	1	$\dfrac{\Delta V_{\mathrm{P}}}{\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{P}}}$	$\dfrac{2\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{W}}}{\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{W}}}$	$\dfrac{\Delta V_{\mathrm{E}}(2\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{W}})}{(\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{P}})\,(\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{W}})}$
$w^{-}_{\mathrm{e},2}$	1	$\dfrac{\Delta V_{\mathrm{E}}}{\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{E}}}$	$\dfrac{2\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}}}{\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}}}$	$\dfrac{\Delta V_{\mathrm{P}}(2\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}})}{(\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{E}})\,(\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}})}$
$w^{+}_{\mathrm{e},3}$	0	0	$-\dfrac{\Delta V_{\mathrm{P}}}{\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{W}}}$	$-\dfrac{\Delta V_{\mathrm{E}}\Delta V_{\mathrm{P}}}{(\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{W}})\,(\Delta V_{\mathrm{E}}+2\Delta V_{\mathrm{P}}+\Delta V_{\mathrm{W}})}$
$w^{-}_{\mathrm{e},3}$	0	0	$-\dfrac{\Delta V_{\mathrm{E}}}{\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}}}$	$-\dfrac{\Delta V_{\mathrm{P}}\Delta V_{\mathrm{E}}}{(\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}})\,(\Delta V_{\mathrm{P}}+2\Delta V_{\mathrm{E}}+\Delta V_{\mathrm{EE}})}$

Note: The equations are given for both positive/outward and negative/inward direction of the mass flux at the face centers. Subscript D, U, and UU correspond to the downstream, upstream, and upstream-of-upstream cell center of a face center f, respectively. The weights for the respective cell center value is represented as $w_{\mathrm{f},1}$, $w_{\mathrm{f},2}$, and $w_{\mathrm{f},3}$. Superscripts + and − correspond to $m_{\eta,\mathrm{f}} > 0$ and $m_{\eta,\mathrm{f}} < 0$, respectively. This equation for $\phi^{\pm}_{\mathrm{e}}$ and $w^{\pm}_{\mathrm{e}}$ is used to obtain similar equation for $\phi^{\pm}_{\mathrm{n}}$ and $w^{\pm}_{\mathrm{n}}$, by replacing EE, E, and W with NN, N, and S, respectively.

cosines, shown in Figure 5.3.6—for the east surface of the representative CV. The direction cosines are expressed in terms of the Cartesian coordinates of the adjoining cell center and the vertices for the surface, such as the Cartesian coordinates of E, P, ne, and se used for the computation of direction cosines seen in Figure 5.3.6.

The diffusion is represented earlier (Equation 5.3.13) in terms of adjoining cell-centered diffusion and the cross diffusion. For momentum equation, this summation represents the net viscous forces acting on the CV. In case of energy equation, it represents a gain in the conduction heat-transfer rate by the fluid inside a CV. For this equation, the cell vertex values are approximated, in terms of the four adjoining cell center values (refer Figure 5.3.2), by *volume-weighted interpolation* (Sharma and Eswaran, 2003) as

$$\phi_{ne} = \frac{\Delta V_{NE}\phi_P + \Delta V_P\phi_{NE} + \Delta V_N\phi_E + \Delta V_E\phi_N}{\Delta V_{NE} + \Delta V_P + \Delta V_N + \Delta V_E}$$

$$\phi_{se} = \frac{\Delta V_{SE}\phi_P + \Delta V_P\phi_{SE} + \Delta V_S\phi_E + \Delta V_E\phi_S}{\Delta V_{SE} + \Delta V_P + \Delta V_S + \Delta V_E}$$

$$\phi_{nw} = \frac{\Delta V_{NW}\phi_P + \Delta V_P\phi_{NW} + \Delta V_N\phi_W + \Delta V_W\phi_N}{\Delta V_{NW} + \Delta V_P + \Delta V_N + \Delta V_W}$$

$$\phi_{sw} = \frac{\Delta V_{SW}\phi_P + \Delta V_P\phi_{SW} + \Delta V_S\phi_W + \Delta V_W\phi_S}{\Delta V_{SW} + \Delta V_P + \Delta V_S + \Delta V_W}$$

Pressure as a Source Term

Using the coordinate-free form of the momentum equation, the Cartesian velocity-based algebraic formulation in Equation 5.3.12 represents x- and y-momentum flow rates, for $\phi = u$ and $\phi = v$, respectively. The respective ϕ in Equation 5.3.13 results in viscous force in the x- and y-directions. The pressure forces in the x- and y-directions, for the determination of the u and v velocities from the coordinate-free form of the momentum equation, are presented as the source term $S_u = -\nabla p \cdot \hat{i}$ and $S_v = -\nabla p \cdot \hat{j}$, respectively.

The volume and time integral of the source term are approximated as

$$-\int_t^{t+\Delta t}\int_{\Delta V_P} \nabla p \cdot \hat{i}\, dV = -\int_t^{t+\Delta t}\int_{\Delta S_f} p\hat{i} \cdot \hat{n}\, dS$$

$$\approx -\sum_{f=e,w,n,s} p_f^{n+1}\Delta S_{x,f}\Delta t = S_{u,P}^{n+1}\Delta t$$

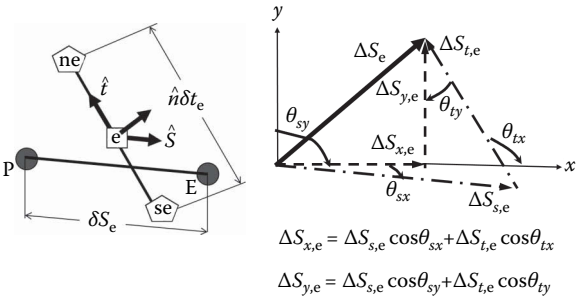

FIGURE 5.3.6 For the east face of representative complex CV, schematic representation of surface area vector and its Cartesian and local components. (From Sharma, A., *Introduction to Computational Fluid Dynamics: Development, Application and Analysis*, John Wiley & Sons, Chichester, UK, 2016. With permission.)

$$-\int_{t}^{t+\Delta t}\int_{\Delta V_{\mathrm{P}}} \nabla p\cdot\hat{j}\,\mathrm{d}V = -\int_{t}^{t+\Delta t}\int_{\Delta S_{\mathrm{f}}} p\hat{j}\cdot\hat{n}\,\mathrm{d}S$$
$$\approx -\sum_{\mathrm{f=e,w,n,s}} p_{\mathrm{f}}^{n+1}\Delta S_{y,\mathrm{f}}\Delta t = S_{v,\mathrm{P}}^{n+1}\Delta t \tag{5.3.14}$$

where Gauss divergence theorem is applied to the volume integral, as the pressure is a flux term. In this equation, the *I*-approximation is used to represent the surface-averaged pressure as p_{f} (at the face center f) and the time-averaged pressure as p^{n+1} (at present time level $(t+\Delta t)$). Furthermore, the *II*-approximation corresponds to the volume-weighted linear interpolation for p_{f} (similar to the CD method in Figure 5.3.5 and Table 5.3.1) given as

$$p_{\mathrm{f=e,w,n,s}} = \frac{\Delta V_{\mathrm{P}} p_{\mathrm{NB}} + \Delta V_{\mathrm{NB}} p_{\mathrm{P}}}{\Delta V_{\mathrm{P}} + \Delta V_{\mathrm{NB}}} \tag{5.3.15}$$

where NB = E, W, N and S for f = e, w, n, and s, respectively. Note that the Equation 5.3.14 represents the 2D Cartesian components of the total pressure force, acting on the CV.

All Terms

Substituting Equations 5.3.11 through 5.3.14 to Equation 5.3.8, the final algebraic formulation for 2D unsteady-state transport equation is given as

$$\frac{\Delta\mathcal{V}\phi}{\Delta t} + A_{\phi,\mathrm{P}}^{\chi} = D_{\phi,\mathrm{P}}^{\chi} + S_{\phi,\mathrm{P}}^{n+1}$$

$$\rho\frac{u_{\mathrm{P}}^{n+1}-u_{\mathrm{P}}^{n}}{\Delta t}\Delta V_{\mathrm{P}} + A_{u,\mathrm{P}}^{\chi} = D_{u,\mathrm{P}}^{\chi} - \sum_{\mathrm{f=e,w,n,s}} p_{\mathrm{f}}^{n+1}\Delta S_{\mathrm{fx}}$$

$$\rho\frac{v_{\mathrm{P}}^{n+1}-v_{\mathrm{P}}^{n}}{\Delta t}\Delta V_{\mathrm{P}} + A_{v,\mathrm{P}}^{\chi} = D_{v,\mathrm{P}}^{\chi} - \sum_{\mathrm{f=e,w,n,s}} p_{\mathrm{f}}^{n+1}\Delta S_{\mathrm{fy}}$$

$$\rho c_P\frac{T_{\mathrm{P}}^{n+1}-T_{\mathrm{P}}^{n}}{\Delta t}\Delta V_{\mathrm{P}} + A_{\mathrm{T,P}}^{\chi} = D_{\mathrm{T,P}}^{\chi} + \overline{Q}_{\mathrm{gen,P}}\Delta V_{\mathrm{P}}$$

where

$$A_{\phi,\mathrm{P}}^{\chi} = \left\{\left[m_{\eta,\mathrm{e}}^{+,n}\phi_{\mathrm{e}}^{+,\chi} + m_{\eta,\mathrm{e}}^{-,n}\phi_{\mathrm{e}}^{-,\chi}\right]\Delta S_{\mathrm{e}} + \left[m_{\eta,\mathrm{w}}^{+,n}\phi_{\mathrm{w}}^{+,\chi} + m_{\eta,\mathrm{s}}^{-,n}\phi_{\mathrm{w}}^{-,\chi}\right]\Delta S_{\mathrm{S}}\right\}C$$
$$+\left\{\left[m_{\eta,\mathrm{n}}^{+,n}\phi_{\mathrm{n}}^{+,\chi} + m_{\eta,\mathrm{n}}^{-,n}\phi_{\mathrm{n}}^{-}\right]\Delta S_{\mathrm{n}} + \left[m_{\eta,\mathrm{s}}^{+,n}\phi_{\mathrm{s}}^{+,\chi} + m_{\eta,\mathrm{s}}^{-,n}\phi_{\mathrm{s}}^{-,\chi}\right]\Delta S_{\mathrm{S}}\right\}C$$

$$D_{\phi,\mathrm{P}}^{\chi} = \Gamma_{\phi}\left(\frac{\phi_{\mathrm{E}}^{\chi}-\phi_{\mathrm{P}}^{\chi}}{\delta s_{\mathrm{e}}}\left|\Delta S_{s,\mathrm{e}}\right| + \frac{\phi_{\mathrm{W}}^{\chi}-\phi_{\mathrm{P}}^{\chi}}{\delta s_{\mathrm{W}}}\left|\Delta S_{s,\mathrm{w}}\right| + \frac{\phi_{\mathrm{N}}^{\chi}-\phi_{\mathrm{P}}^{\chi}}{\delta s_{\mathrm{n}}}\left|\Delta S_{s,\mathrm{n}}\right| + \frac{\phi_{\mathrm{S}}^{\chi}-\phi_{\mathrm{P}}^{\chi}}{\delta s_{\mathrm{S}}}\left|\Delta S_{s,\mathrm{s}}\right|\right)$$
$$+\Gamma_{\phi}\left(\frac{\phi_{\mathrm{ne}}^{\chi}-\phi_{\mathrm{se}}^{\chi}}{\delta t_{\mathrm{e}}}\left|\Delta S_{s,\mathrm{e}}\right| + \frac{\phi_{\mathrm{sw}}^{\chi}-\phi_{\mathrm{nw}}^{\chi}}{\delta t_{\mathrm{W}}}\left|\Delta S_{s,\mathrm{w}}\right| + \frac{\phi_{\mathrm{ne}}^{\chi}-\phi_{\mathrm{nw}}^{\chi}}{\delta t_{\mathrm{n}}}\left|\Delta S_{s,\mathrm{n}}\right| + \frac{\phi_{\mathrm{sw}}^{\chi}-\phi_{\mathrm{se}}^{\chi}}{\delta t_{\mathrm{S}}}\left|\Delta S_{s,\mathrm{s}}\right|\right) \tag{5.3.16}$$

where the transport variable at a face center $\phi_{\mathrm{f=e,w,n,s}}^{\pm}$ is presented in Table 5.3.1, and the volume-weighted pressure at the various face center p_{f} is given in Equation 5.3.15.

Concluding Remarks

FVM-based algebraic formulation is presented, for a 2D unsteady fluid dynamics and forced-convection heat transfer in a complex geometry—starting with the grid generation, and the differential and integral form of the governing equations; followed by the two approximations for the integrands in the integral equations; and ending with the resulting FVM-based approximated algebraic formulation. However, starting from the mass, momentum, and energy conservation laws instead of their differential formulation and using the two approximations (presented here), the same algebraic formulation (Equation 5.3.16) was presented recently by Sharma (2016) – called as physical law based FVM.

Due to the fact that there is no explicit equation for the pressure in an incompressible flow, the algebraic equation for the continuity equation is further converted into an equation for the pressure correction—using a pressure correction method (Sharma and Eswaran, 2003). Thereafter, the coupled system of LAEs for the velocity, pressure, and temperature are solved using a semi-explicit method (Sharma and Eswaran, 2003) or semi-implicit method (Patankar, 1980). The FVM-based solution methodology can be found in the book by Patankar (1980), Ferziger and Peric (1995), and Versteeg and Malalasekera (1995).

5.4 FINITE ELEMENT METHOD

Salil S. Kulkarni

Introduction

The finite-element method (FEM) is a numerical technique for finding approximate solutions to a wide variety of boundary value problems in engineering and science. It is probably the most popular and commonly used numerical technique when compared to other techniques like the finite-difference method, finite-volume method, and the boundary element method. This popularity of the FEM stems from its applicability to solve a wide variety of problems in solid mechanics (see, e.g., Zienkiewicz et al., 2014a), fluid dynamics (see, e.g., Zienkiewicz et al., 2014b), heat transfer (see, e.g., Gartling and Reddy, 2010), electromagnetism (see, e.g., Jin, 2014), biomechanics (see, e.g., Oomens et al., 2010), acoustics (see, e.g., Ihlenburg, 2006), etc. It is completely general with respect to the material properties and can easily handle complicated geometries subject to a variety of boundary conditions. It is applicable in multiphysics problems where there is a coupling between two or more different field variables, e.g., thermomechanical problems. The mathematical theory of the FEM well matured (see, e.g., Brenner and Scott, 2008) and the conditions under which the approximate solution approaches the actual solution, especially for linear problems, are well understood. On account of the various attributes of the FEM, which are mentioned earlier, it is widely used as an analysis tool in various fields of engineering, viz., automotive engineering, aerospace engineering, Microelectromechanical systems (MEMS) industry, biomedical engineering, electrical engineering, and civil engineering.

Papers that discuss the application of the FEM for solving heat-transfer problems first appeared in the 1960s (see, e.g., Zienkiewicz and Cheung, 1965; Wilson and Nickell, 1966). Since then, the field has fairly matured and the application of the finite element to solving problems in heat transfer is now a standard topic in many books on the FEM (see, e.g., Bathe, 1996; Hughes, 2000; Gartling and Reddy, 2010; Zienkiewicz et al., 2013). The present chapter provides a brief overview of the FEM when applied to solving heat conduction problems in stationary domains and is based on the books mentioned earlier. A brief outline of the topics discussed in the chapter is given next.

The main idea of the finite element is described in Section 5.4.2. The governing differential equations for heat conduction problems in stationary domains are discussed in Section 5.4.3. Using a simple problem, the steps involved in the derivation of the finite-element equations are described in detail in Section 5.4.4. The semidiscrete form of the finite-element equations for a general problem in transient heat conduction is given in Section 5.4.5. The linear equation solvers used in the finite equations are mentioned in Section 5.4.6. The numerical evaluation of the finite-element matrices using isoparametric elements and Gauss quadrature is discussed in Section 5.4.7. Some practical issues when using the FEM are discussed in Section 5.4.8. Finally, two example problems are solved using the FEM and are presented in Section 5.4.9.

Main Idea of the FEM

The main idea of the FEM is now explained using a simple example. Let the true temperature distribution in a rod of length L be $T(x)$ and it is as shown in Figure 5.4.1.

It is desired to find an approximation, $T_h(x)$, to the true temperature distribution, $T(x)$. In general, it is extremely difficult, if not impossible, to find a function that matches $T(x)$ everywhere over the domain $[0, L]$. The main idea of the finite element is to divide the domain $[0, L]$ into smaller nonoverlapping subdomains (elements) with the exact function being approximated with simple functions, $T_h^e(x)$, over each of the elements. Then, the approximation over the entire domain is given by $T_h(x) = \sum_{e=1}^{N} T_h^e(x)$, where N is the number of elements. For example, in Figure 5.4.1, the rod

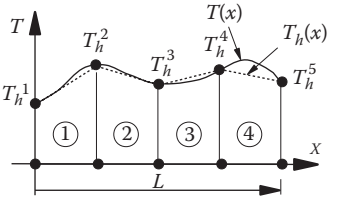

FIGURE 5.4.1 Main idea of the FEM.

is discretized into four elements. In each of the elements, the unknown function is approximated with simple (linear) functions. Then, the approximation $T_h(x)$ for the current problem is given by $\sum_{e=1}^{4} T_h^e(x)$. The basic features of the FEM can be summarized as follows:

1. The domain of the given boundary value problem is represented by a nonoverlapping collection of simple subdomains called finite elements. Each element consists of nodes, faces (in three dimensions), and edges (in two and three dimensions). This process is commonly referred to as discretization. The collection of the finite elements is called a finite-element mesh. In one-dimensional domains, the elements can be either straight or curved, in two-dimensional domains, the most common elements are either triangular or quadrilateral in shape with straight or curved edges, and in three-dimensional domains, the elements are either tetrahedral or hexahedral in shape with either straight or curved edges.
2. Over each element, the field variable, e.g., temperature, is approximated by functions of the desired type (mainly polynomials), and algebraic equations relating the physical quantities at the nodes are developed using the governing differential equations. For example, for heat conduction problems, these equations relate the temperature at the nodes to the heat flux on the element boundary.
3. The algebraic equations that are written for each element are now assembled using continuity and balance of the physical quantities. For example, for heat conduction problems, if two elements share the same edge, then the value of the temperature at the common nodes along the common edge is same for both the elements. In addition, in absence of a heat source along the edge, the outward heat flux of both the elements along the common edge is equal and opposite to each other.
4. Appropriate boundary conditions are applied and then the equations are solved for the unknown nodal quantities. The Dirichlet-type boundary conditions can be incorporated using a Lagrange multiplier approach, Nitsche's method, a penalty approach, or an elimination approach. Note that if one is dealing with a transient problem, the unknown nodal quantities are the function of time and then one has to solve a coupled set of ordinary different equations.
5. Once the equations are solved, quantities of interest, e.g., temperatures, flux, etc., are extracted, visualized, and analyzed in a process referred to as postprocessing.

Sources of Error in FEM

As mentioned earlier, the FEM is a numerical method that provides one with an approximate solution to the problem at hand. It is, therefore, essential to be aware of the sources of errors in the finite-element solution. The main sources of errors in the FEM are summarized next:

1. The division of the domain into simple classical finite elements may not be exact. For example, an attempt to represent a curved boundary with elements having straight edges leads to an error in the representation of the domain.

2. While deriving the algebraic equations for individual elements, it is usually assumed that the unknown field quantity can be represented using simple polynomials. It is possible that the actual solution may not be represented exactly using polynomials, e.g., trignometric or exponential functions.
3. The algebraic equations are frequently established using numerical integration. As the integrations may not be exact, this leads to the errors in the finite-element solution. Note that it may be possible to use symbolic computations to eliminate this error.
4. The imposition of the Dirichlet-type boundary conditions may lead to an error depending on the approach adopted to impose the boundary condition. For example, if one uses the penalty method to impose the boundary conditions, the boundary conditions are not imposed exactly and the system matrix may become ill-conditioned.
5. Additional errors may occur depending on the algorithms used for the solution of the algebraic equations.

In the next section, the governing differential equation for heat conduction in a stationary domain along with the associated initial and boundary conditions is summarized.

Governing Differential Equation

Consider a stationary three-dimensional body, Ω, with surface Γ whose temperature distribution is of interest. The surface Γ is subdivided into two disjoint surfaces, Γ_T and Γ_q such that on Γ_T the temperature is prescribed, while on Γ_q the flux is prescribed. It is assumed that the initial temperature distribution, $T_0(\mathbf{x})$, is also known. To find the subsequent temperature distribution in the body, one then solves the following (see, e.g., Bergman et al., 2011):

$$\rho C_p \frac{\partial T}{\partial t} = \nabla\cdot(\mathbf{k}\nabla T) + f \text{ in } \Omega, \tag{5.4.1}$$

subject to the following boundary conditions and initial conditions:

$$T = \overline{T}(\mathbf{x},t) \text{ on } \Gamma_T, \tag{5.4.2}$$

$$q_n = -\mathbf{n}\cdot(\mathbf{k}\nabla T) = h \text{ on } \Gamma_q, \tag{5.4.3}$$

$$T = T_0(\mathbf{x}) \quad \text{at } t = 0 \quad \text{in } \Omega. \tag{5.4.4}$$

Here, ρ is the mass density, C_p is the specific heat, T is the temperature, $\mathbf{k}$ is the conductivity tensor, f is a time, position and temperature-dependent heat source, $\mathbf{x}$ is a point in the body, $\mathbf{n}$ is an outward unit normal to the surface, and ∇ is the gradient operator. Both C_p and $\mathbf{k}$ can be functions of position and temperature. The prescribed flux boundary condition could be one of the conditions listed here or can be a combination of two or more conditions.

1. Adiabatic boundary condition: $h=0$.
2. Prescribed flux: $h = \hat{q}(\mathbf{x},t)$. Here, the prescribed flux is a function of both position and time.
3. Convection boundary condition. $h=h_c(\mathbf{x}, t)(T(\mathbf{x}, t)-T_B(\mathbf{x}, t))$. Here, $h_c(\mathbf{x}, t)$ is the known position and time-dependent convective heat-transfer coefficient, and $T_B(\mathbf{x}, t)$ is the known position and time-dependent bulk temperature.

4. Radiation boundary condition. $h = h_r'(\mathbf{x},t)\left(T^4(\mathbf{x},t) - T_S^4(\mathbf{x},t)\right)$. Here, $h_r'(\mathbf{x},t)$ is the known time-dependent radiation heat-transfer coefficient, and $T_S(\mathbf{x}, t)$ is the known time-dependent temperature of the surroundings. The radiation boundary condition is usually rewritten as

$$h = h_r(T,\mathbf{x},t)\left(T(\mathbf{x},t) - T_S(\mathbf{x},t)\right),$$

where

$$h_r(T,\mathbf{x},t) = h_r'(\mathbf{x},t)\left(T^2(\mathbf{x},t) - T_S^2(\mathbf{x},t)\right)\left(T(\mathbf{x},t) + T_S(\mathbf{x},t)\right).$$

Note that the radiation boundary condition is a nonlinear boundary condition.

The general transient heat conduction problem in a three-dimensional body is governed by Equations 5.4.1 through 5.4.4. Depending on the specific problem under consideration, one can identify it with one of the four types of problems mentioned in Table 5.4.1.

Note that a presence of a heat source that has nonlinear dependence on temperature will lead to a nonlinear problem.

Steps in the Derivation of the Finite-Element Equations

For most problems, it is not possible to solve Equations 5.4.1 through 5.4.4 exactly as the analytical solution is not available. This lack of availability of the analytical solution could be due to one or some of the following reasons: (1) complicated geometry, (2) complicated boundary conditions, and (3) complicated nature of the differential equation. In such cases, one of the numerical methods, viz., the FEM, the finite-difference method, etc., has to be used to obtain the solution. To clearly explain the steps followed in the derivation of the finite-element equations from the governing partial differential equation, one specific problem is chosen and all the necessary details of the derivation are provided. The derivation of the finite-element equations for other types of problems can be approached similarly.

There are multiple methods to derive the finite-element equations, viz., the direct method, method based on the variational approach, and the method based on the weighted residual approach (see, e.g., Zienkiewicz et al., 2013). The derivation of the finite-element equations presented in this section closely follows the approach presented in Reddy (2005). The approach is based on the application method of weighted residue to a single element, followed by the use of the divergence theorem and the Galerkin approach. This approach makes it possible to derive the finite-element equations even when a variational approach is not possible. The derivation of the elemental finite-element equations for a transient two-dimensional heat conduction in a stationary, homogeneous, isotropic media with temperature independent material properties and time- and position-dependent internal heat source is given next.

The governing partial differential equation for the problem under consideration is of the form (see Equation 5.4.1):

TABLE 5.4.1
Classification of Heat Conduction Problems

Type of Problem	Time Dependence	Radiation Boundary Condition AND/OR Temperature-Dependent Material Property
Linear steady state	X	X
Nonlinear steady state	X	✓
Linear transient	✓	X
Nonlinear transient	✓	✓

$$\rho C_p \frac{\partial T}{\partial t} = k\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) + f(x,y,t), \text{ in } \Omega. \tag{5.4.5}$$

It is assumed that on part of the boundary, Γ_T, the temperature is prescribed while on the remaining part of the boundary, and Γ_q the flux is prescribed. The initial temperature distribution, $T_0(x, y)$ is also assumed to be known. The boundary conditions and initial conditions are, therefore, written as

$$T(x,y,t) = \overline{T}(x,y,t) \text{ on } \Gamma_T \quad \text{and} \quad q_n(x,y,t) = \overline{q}(x,y,t) \text{ on } \Gamma_q, \quad T(x,y,0) = T_0(x,y) \text{ in } \Omega.$$

Figure 5.4.2 shows the domain under consideration, which is discretized using triangular finite elements. The finite-element model consists of *Nel* number of elements and *N* of nodes. Consider a typical element that is denoted by Ω^e and whose boundary is denoted by Γ^e.

The exact temperature distribution in the element, $T(x, y, t)$, is approximated using separation of variables as

$$T(x,y,t) \approx T_h^e(x,y,t) = \sum_{j=1}^{n} N_j(x,y) T_j^e(t), \tag{5.4.6}$$

where n is the number of nodes in the element, $T_j^e(t), j = 1,\ldots,n$ are the time-dependent unknown nodal temperatures and $N_j(x, y)$, $j = 1, \ldots, n$ are known as time-independent shape functions. The shape functions dictate the nature of the approximation. Because $T_h^e(x,y,t)$ is not exact, the substitution of Equation 5.4.6 in Equation 5.4.5 leads to a residual of the form:

$$R(x,y,t,T_1^e,\ldots,T_n^e) = \rho C_p \frac{\partial T_h^e}{\partial t} - k\left(\frac{\partial^2 T_h^e}{\partial x^2} + \frac{\partial^2 T_h^e}{\partial y^2}\right) - f(x,y,t) \neq 0. \tag{5.4.7}$$

Note that the residual defined in Equation 5.4.7 is a function of the location, time, and the nodal temperatures. The goal is now to find the nodal temperatures that minimize the residual is some averaged sense. The residual is first multiplied by a weighting function $w(x, y)$, followed by integrating the product over the element and then setting the integral to zero. This leads to**

$$\begin{aligned} &\int_{\Omega^e} w(x,y) R(x,y,t,T_1^e,\ldots,T_n^e)\, d\Omega^e = \\ &\int_{\Omega^e} w(x,y)\rho C_p \frac{\partial T_h^e}{\partial t} d\Omega^e - \int_{\Omega^e} w(x,y) k\left(\frac{\partial^2 T_h^e}{\partial x^2} + \frac{\partial^2 T_h^e}{\partial y^2}\right) d\Omega^e \\ &- \int_{\Omega^e} w(x,y) f(x,y,t)\, d\Omega^e = 0. \end{aligned} \tag{5.4.8}$$

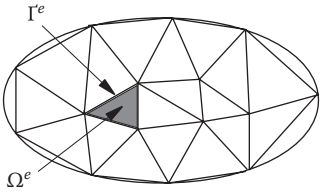

FIGURE 5.4.2 Discretization of the domain.

Equation 5.4.8 is commonly referred to as the statement of the weighted residual. Note that if one proceeds to directly evaluate Equation 5.4.8, one requires that $T_h^e(x,y,t)$ should possess continuous first derivatives with respect to both x and y. In order to reduce the continuity requirements on the approximation function, one uses the Gauss divergence theorem to obtain:

$$\int_{\Omega^e} w(x,y)\rho C_p \frac{\partial T_h^e}{\partial t} \mathrm{d}\Omega^e + \int_{\Omega^e} k\left(\frac{\partial T_h^e}{\partial x}\frac{\partial w}{\partial x} + \frac{\partial T_h^e}{\partial y}\frac{\partial w}{\partial y}\right)\mathrm{d}\Omega^e = \int_{\Omega^e} w(x,y) f(x,y,t)\ \mathrm{d}\Omega^e - \int_{\Gamma^e} w(x,y) q_n\ \mathrm{d}\Gamma^e, \tag{5.4.9}$$

where $q_n = -k\,\partial T_h^e/\partial n$. One observes that due to the use of the Gauss divergence theorem one has indeed reduced the continuity required on the approximation $T_h^e(x,y,t)$, which is now required to be only continuous. In order to obtain the required number of algebraic equations from Equation 5.4.9, in this case n, for the time derivative of the unknown nodal temperatures $T_i^e(t), i=1,\ldots,n$, one chooses n different weighting functions. The choice of $w(x, y)=N_i(x, y)$, $i=1, \ldots, n$, in Equation 5.4.9, is referred to as the Bubnov–Galerkin approximation or just Galerkin approximation. Using the Galerkin approximation and substituting $T_h^e(x,y,t) = \sum_{j=1}^{n} N_j(x,y)T_j^e(t)$ in Equation 5.4.9 leads to the following set of n coupled first-order differential equations for $T_j^e, i=1,\ldots,n$.

$$\sum_{j=1}^{n}\int_{\Omega^e} \rho C_p N_i N_j\ \mathrm{d}\Omega^e \frac{dT_j^e}{dt} + \sum_{j=1}^{n}\int_{\Omega^e} k\left(\frac{\partial N_i}{\partial x}\frac{\partial N_j}{\partial x} + \frac{\partial N_i}{\partial y}\frac{\partial N_j}{\partial y}\right)\mathrm{d}\Omega^e T_j^e = \int_{\Omega^e} N_i f(x,y,t)\ \mathrm{d}\Omega^e + \int_{\Gamma^e} N_i q_n(x,y,t)\ \mathrm{d}\Gamma^e, \quad i=1,\ldots,n. \tag{5.4.10}$$

Equation 5.4.10 can be rewritten in a vector form as

$$\mathbf{C}^e\dot{\mathbf{T}}^e + \mathbf{K}^e\mathbf{T}^e = \mathbf{f}^e(t) + \mathbf{q}^e(t), \tag{5.4.11}$$

where $\mathbf{C}^e$ and $\mathbf{K}^e$ and $n\times n$ matrix and $\mathbf{T}^e$, $\mathbf{f}^e$, and $\mathbf{q}^e$ are $n\times 1$ vectors. The matrix $\mathbf{C}^e$ is referred to as the elemental capacity matrix, the matrix $\mathbf{K}^e$ is referred to as the elemental stiffness matrix, the vector $\mathbf{T}^e$ is the vector of the unknown nodal temperatures, the vector $\mathbf{f}^e(t)$ is the vector due to the source term, and the vector $\mathbf{q}^e(t)$ is the vector of the nodal fluxes. The components of $\mathbf{C}^e$, $\mathbf{K}^e$, $\mathbf{f}^e$, and $\mathbf{q}^e$ are given by

$$C_{ij}^e = \int_{\Omega^e} \rho C_p N_i N_j\ \mathrm{d}\Omega^e, \qquad K_{ij}^e = \int_{\Omega^e} k\left(\frac{\partial N_i}{\partial x}\frac{\partial N_j}{\partial x} + \frac{\partial N_i}{\partial y}\frac{\partial N_j}{\partial y}\right)\mathrm{d}\Omega^e,$$
$$f_i^e = \int_{\Omega^e} N_i f(x,y,t)\ \mathrm{d}\Omega^e, \qquad q_i^e = \int_{\Gamma^e} N_i q_n(x,y,t)\ \mathrm{d}\Gamma^e. \tag{5.4.12}$$

The numerical evaluation of the elemental matrices and vectors is discussed in Section 5.4.7.1. Note that q_i^e given in Equation 5.4.12 is evaluated only on that part of the boundary of the body on which the flux is prescribed. This is due to the fact that the contributions to the flux vectors at the shared nodes of the common internal edge of the two adjacent elements cancel each other. This cancellation is because of the balance of flux across the shared internal edge.

From Equation 5.4.12, it is observed' that $\mathbf{C}^e=(\mathbf{C}^e)^T$ and $\mathbf{K}^e=(\mathbf{K}^e)^T$, i.e., the elemental capacity matrix and the elemental stiffness matrix are both symmetric matrices. The matrix $\mathbf{C}^e$ as defined in

Equation 5.4.12 is referred to as the consistent capacitance matrix. In practice, from the point of view of computational efficiency, one usually uses a diagonal form of the capacitance matrix. Various methods for obtaining the diagonal matrix are available in literature (see, e.g., Zienkiewicz et al., 2013). On assembly of the elemental equations using the continuity of the temperatures at the nodes and balance of flux across the internal shared element boundaries, one obtains the global set of equations as

$$\mathbf{C}\dot{\mathbf{T}} + \mathbf{K}\mathbf{T} = \mathbf{F}(t). \tag{5.4.13}$$

where

$$\mathbf{C} = \mathop{\mathbf{A}}_{e=1}^{Nel} \mathbf{C}^e, \mathbf{K} = \mathop{\mathbf{A}}_{e=1}^{Nel} \mathbf{K}^e, \mathbf{F}(t) = \mathbf{f}(t) + \mathbf{q}(t), \mathbf{f}(t) = \mathop{\mathbf{A}}_{e=1}^{Nel} \mathbf{f}^e(t), \mathbf{q}(t) = \mathop{\mathbf{A}}_{e=1}^{Nel} \mathbf{q}^e(t).$$

Note that $\dot{\mathbf{T}} = d\mathbf{T}/dt$. Here $\mathop{\mathbf{A}}_{e=1}^{Nel}$ is the assembly operator and *Nel* is the total number of elements in the model. Matrices **C** and **K** are referred to as the global capacitance matrix and the global stiffness matrix, respectively. Due to the fact that the elemental capacity matrix and the elemental stiffness matrix are both symmetric, the global capacity matrix and the global stiffness matrix are also symmetric, i.e., $\mathbf{C} = \mathbf{C}^T$ and $\mathbf{K} = \mathbf{K}^T$. Vector $\mathbf{F}(t)$ is referred to as the global load vector. Note that **C** and **K** are $N \times N$ matrices and $\mathbf{T}(t)$ and $\mathbf{F}(t)$ are $N \times 1$ vectors, where N is the total degrees of freedom in the model. For the present problem, the number of degrees of freedom is equal to the number of nodes. Equation 5.4.13 is referred to the semidiscrete finite-element model as it is obtained by discretizing the partial difference equation in only the spatial dimensions. Once the global set of equations is obtained (see Equation 5.4.13), the specified temperature boundary conditions are applied at appropriate nodes. Some of the methods used to apply the temperature boundary conditions include the elimination method, the Lagrange multiplier method, and the penalty method (see, e.g., Bathe, 1996 for details). Once the boundary conditions are applied, the resulting set of ordinary differential equations is solved to find the unknown nodal quantities.

The assembly process to form the global matrices and vectors from the elemental matrices and vectors is illustrated with a simple example shown in Figure 5.4.3.

The figure shows a discretized rectangular plate whose steady-state temperature distribution is to be found out. It is assumed that there is a distributed time independent heat source in the plate and the plate is subjected to some prescribed temperature and prescribed flux boundary conditions. As seen from the figure, the plate is discretized with two straight edge triangular elements, 1 and 2, which share a common edge. Element 1 has nodes 1–2–3, whereas element 2 has nodes 1–3–4. This node numbering is referred to as global node numbering. The three nodes of each element are also labeled 1–2–3 and are shown boxed in Figure 5.4.3. These numbers are referred to as local node numbers. Note that the elemental matrices and vectors are calculated as per the local node numbering. To aid the assembly process, an element connectivity table is formed as shown in Table 5.4.2.

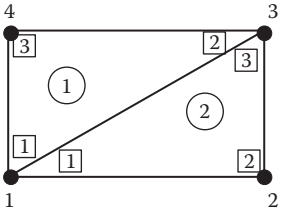

FIGURE 5.4.3 Assembly of elements.

TABLE 5.4.2
Element Connectivity for Problem Shown in Figure 5.4.3

Element No.	Local Node Numbers		
	Node 1	Node 2	Node 3
1	1	3	4
2	1	2	3

This table helps in relating the local node numbers of the element with the global node numbers. The elemental equation for element 1 in expanded form is given by (see Equation 5.4.11)

$$\begin{array}{c} \\ 1 \\ 3 \\ 4 \end{array}\begin{array}{c} \begin{array}{ccc} 1 & 3 & 4 \end{array} \\ \begin{bmatrix} k_{11}^1 & k_{12}^1 & k_{13}^1 \\ & k_{22}^1 & k_{23}^1 \\ \text{symm} & & k_{33}^1 \end{bmatrix} \end{array} \begin{bmatrix} T_1^1 \\ T_2^1 \\ T_3^1 \end{bmatrix} = \begin{array}{c} 1 \\ 3 \\ 4 \end{array}\begin{bmatrix} f_1^1 \\ f_2^1 \\ f_3^1 \end{bmatrix} + \begin{array}{c} 1 \\ 3 \\ 4 \end{array}\begin{bmatrix} q_1^1 \\ q_2^1 \\ q_3^1 \end{bmatrix},$$

where the components of the elemental matrices and the vectors are calculated using Equation 5.4.12. Here, the subscripts denote the local node numbers, and the superscript denotes the element number. Note that the components of the flux vector, i.e., q_1^1, q_2^1, and q_3^1, have to be evaluated over only those edges of the element that are on the part of the boundary of the plate where the flux is prescribed. Similarly, the elemental equation for element 2 is written as

$$\begin{array}{c} \\ 1 \\ 2 \\ 3 \end{array}\begin{array}{c} \begin{array}{ccc} 1 & 2 & 3 \end{array} \\ \begin{bmatrix} k_{11}^2 & k_{12}^2 & k_{13}^2 \\ & k_{22}^2 & k_{23}^2 \\ \text{symm} & & k_{33}^2 \end{bmatrix} \end{array} \begin{bmatrix} T_1^2 \\ T_2^2 \\ T_3^2 \end{bmatrix} = \begin{array}{c} 1 \\ 2 \\ 3 \end{array}\begin{bmatrix} f_1^2 \\ f_2^2 \\ f_3^2 \end{bmatrix} + \begin{array}{c} 1 \\ 2 \\ 3 \end{array}\begin{bmatrix} q_1^2 \\ q_2^2 \\ q_3^2 \end{bmatrix}.$$

Here, again the components of the flux vector, i.e., q_1^2, q_2^2, and q_3^2, have to be evaluated over only those edges of the element that are on the part of the boundary of the plate where the flux is prescribed. Noting that $T_1^1 = T_1^2 = T_1, T_2^1 = T_3^2 = T_3, T_3^1 = T_4$, and $T_2^2 = T_2$, one then assembles the two sets of the elemental equations to obtain the global set of equations as follows:

$$\begin{array}{c} \\ 1 \\ 2 \\ 3 \\ 4 \end{array}\begin{array}{c} \begin{array}{cccc} 1 & 2 & 3 & 4 \end{array} \\ \begin{bmatrix} k_{11}^1 + k_{11}^2 & k_{12}^2 & k_{12}^1 + k_{13}^2 & k_{13}^1 \\ & k_{22}^2 & k_{23}^2 & 0 \\ & & k_{22}^1 + k_{33}^1 & k_{23}^1 \\ & \text{symm} & & k_{33}^1 \end{bmatrix} \end{array} \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \end{bmatrix} = \begin{array}{c} 1 \\ 2 \\ 3 \\ 4 \end{array}\begin{bmatrix} f_1^1 + f_1^2 \\ f_2^2 \\ f_2^1 + f_3^2 \\ f_3^1 \end{bmatrix} + \begin{array}{c} 1 \\ 2 \\ 3 \\ 4 \end{array}\begin{bmatrix} q_1^1 + q_1^2 \\ q_2^2 \\ q_2^1 + q_3^2 \\ q_3^1 \end{bmatrix}.$$

The matrix occurring in the above equation is referred to as the global stiffness matrix, while the vectors appearing on the right side are referred to as the global load vectors. For more details about the assembly procedure, see, e.g., Reddy (2005). The global capacitance matrix that occurs in transient problems is also assembled in a similar manner.

Semidiscrete Finite-Element Model in a General Case

In this section, the semidiscrete finite-element model arising in the solution of the problem of transient heat conduction in a three-dimensional body with position and temperature-dependent material properties and time-dependent boundary conditions (see Equations 5.4.1 through 5.4.4) is presented. To develop the semidiscrete finite-element model in the general case, one essentially follows the same steps as described in Section 5.4.4. One proceeds by assuming an approximation for the temperature in a typical element of the form given in Equation 5.4.6. Following the steps outlined in Section 5.4.4, i.e., using the method of weighted residual followed by the use of Gauss divergence theorem, and finally the Galerkin method, one obtains the elemental equations as

$$\mathbf{C}^e(\mathbf{T}^e)\dot{\mathbf{T}}^e + \hat{\mathbf{K}}^e(t,\mathbf{T}^e)\mathbf{T}^e = \mathbf{F}^e(t,\mathbf{T}^e), \tag{5.4.14}$$

where

$$\hat{\mathbf{K}}^e(t,\mathbf{T}^e) = \mathbf{K}^e(\mathbf{T}^e) + \mathbf{H}^e(t) + \mathbf{R}^e(t,\mathbf{T}^e) \text{ and } \mathbf{F}^e(t,\mathbf{T}^e) = \mathbf{f}^e(t,\mathbf{T}^e) + \mathbf{q}^e(t) + \mathbf{h}_c^e(t) + \mathbf{h}_r^e(t,\mathbf{T}^e).$$

Here, $\mathbf{C}^e(\mathbf{T}^e)$ and $\mathbf{K}^e(\mathbf{T}^e)$ are the temperature-dependent elemental capacitance and stiffness matrix, respectively, and the elemental vector $\mathbf{f}^e(t, \mathbf{T}^e)$ is due to the source term. The elemental matrix $\mathbf{H}^e(t)$ and the vector $\mathbf{h}_c^e(t)$ are related to the convective boundary condition, while the elemental matrix $\mathbf{R}^e(t, \mathbf{T}^e)$ and the vector $\mathbf{h}_r^e(t,\mathbf{T}^e)$ are related to the radiation boundary condition. The components of the domain integrals $\mathbf{C}^e(\mathbf{T}^e)$, $\mathbf{K}^e(\mathbf{T}^e)$, and $\mathbf{f}^e(t, \mathbf{T}^e)$ are given by

$$C_{ij}^e = \int_{\Omega^e} \rho C_p N_i N_j \, \mathrm{d}\Omega^e, K_{ij}^e = \int_{\Omega^e} \left(\frac{\partial N_i}{\partial x} k_x \frac{\partial N_j}{\partial x} + \frac{\partial N_i}{\partial y} k_y \frac{\partial N_j}{\partial y} + \frac{\partial N_i}{\partial z} k_z \frac{\partial N_j}{\partial z} \right) \mathrm{d}\Omega^e,$$

$$f_i^e = \int_{\Omega^e} N_i f \, \mathrm{d}\Omega^e.$$

The components of boundary integrals $\mathbf{H}^e(t)$, $\mathbf{R}^e(t, \mathbf{T}^e)$, $\mathbf{h}_c^e(t)$, $\mathbf{h}_r^e(t,\mathbf{T}^e)$, and $\mathbf{q}^e(t)$ are given by

$$H_{ij}^e = \int_{\Gamma^e} h_c N_i N_j \, \mathrm{d}\Gamma^e, R_{ij}^e = \int_{\Gamma^e} h_r N_i N_j \, \mathrm{d}\Gamma^e, \tag{5.4.15}$$

and

$$h_{ci}^e = \int_{\Gamma^e} h_c N_i T_B \, \mathrm{d}\Gamma^e, \; h_{ri}^e = \int_{\Gamma^e} h_r N_i T_S \, \mathrm{d}\Gamma^e, \; q_i^e = \int_{\Gamma^e} N_i q_n \, \mathrm{d}\Gamma^e. \tag{5.4.16}$$

These integrals are to be evaluated on those portions of the boundary where the prescribed flux boundary conditions are given. Observe that $\mathbf{C}^e(\mathbf{T}^e) = (\mathbf{C}^e(\mathbf{T}^e))^T$, $\mathbf{K}^e(\mathbf{T}^e) = (\mathbf{K}^e(\mathbf{T}^e))^T$, $\mathbf{H}^e(t) = (\mathbf{H}^e(t))^T$, and $\mathbf{R}^e(t, \mathbf{T}^e) = (\mathbf{R}^e(t, \mathbf{T}^e))^T$. The numerical evaluation of the elemental matrices is discussed in Section 5.4.7.1. Note that one of the simplest approach to evaluate the coefficients of the various temperature-dependent matrices and vectors appearing in Equation 5.4.14 is to assume that the temperature is constant in the element and is equal to the average of the nodal temperatures. The material properties corresponding to this temperature are then used in the numerical evaluation of the integrals. A more accurate but computationally intensive approach is to evaluate the temperature at the Gauss points (see Section 5.4.7.3) using the element shape functions and then use it to evaluate the material properties.

On assembly of the elemental equations (see Equation 5.4.14), one obtains the global system of equations as

$$\mathbf{C}(\mathbf{T})\dot{\mathbf{T}} + \hat{\mathbf{K}}(t,\mathbf{T})\mathbf{T} = \mathbf{F}(t,\mathbf{T}), \tag{5.4.17}$$

where

$$\hat{\mathbf{K}}(t,\mathbf{T}) = \mathbf{K}(\mathbf{T}) + \mathbf{H}(t) + \mathbf{R}(t,\mathbf{T}) \text{ and } \mathbf{F}(t,\mathbf{T}) = \mathbf{f}(t,\mathbf{T}) + \mathbf{q}(t) + \mathbf{h}_c(t) + \mathbf{h}_r(t,\mathbf{T}).$$

Observe that due to the symmetry of the elemental capacity matrix and the elemental stiffness matrix, one has $\mathbf{C}(\mathbf{T}) = (\mathbf{C}(\mathbf{T}))^T$ and $\hat{\mathbf{K}}(t,\mathbf{T}) = (\hat{\mathbf{K}}(t,\mathbf{T}))^T$. Here, $\mathbf{C}(\mathbf{T})$ and $\hat{\mathbf{K}}(t,\mathbf{T})$ are $N \times N$ matrices and $\mathbf{T}$ and $\mathbf{F}(t, \mathbf{T})$ are $N \times 1$ vectors, where N is the total degrees of freedom in the model. For the present problem, the number of degrees of freedom are equal to the number of nodes. Equation 5.4.17, which is a set of coupled nonlinear first-order ordinary differential equations, is the semidiscrete finite-element model of the problem defined by Equations 5.4.1 through 5.4.4. Based on the problem classification given in Table 5.4.1, one can write a general algebraic or a semidiscrete form of the finite-element equations for each type of problem as follows:

1. Linear steady-state problem

$$\hat{\mathbf{K}}\mathbf{T} = \mathbf{F}, \tag{5.4.18}$$

   where

$$\hat{\mathbf{K}} = \mathbf{K} + \mathbf{H} \text{ and } \mathbf{F} = \mathbf{f} + \mathbf{q} + \mathbf{h}_c.$$

2. Nonlinear steady-state problem

$$\hat{\mathbf{K}}(\mathbf{T})\mathbf{T} = \mathbf{F}(\mathbf{T}), \tag{5.4.19}$$

   where

$$\hat{\mathbf{K}}(\mathbf{T}) = \mathbf{K}(\mathbf{T}) + \mathbf{H} + \mathbf{R}(\mathbf{T}) \text{ and } \mathbf{F}(\mathbf{T}) = \mathbf{f}(\mathbf{T}) + \mathbf{q} + \mathbf{h}_c + \mathbf{h}_r(\mathbf{T}).$$

3. Linear transient problem

$$\mathbf{C}\dot{\mathbf{T}} + \hat{\mathbf{K}}(t)\mathbf{T} = \mathbf{F}(t), \tag{5.4.20}$$

   where

$$\hat{\mathbf{K}}(t) = \mathbf{K} + \mathbf{H}(t) \text{ and } \mathbf{F}(t) = \mathbf{f}(t) + \mathbf{q}(t) + \mathbf{h}_c(t).$$

4. Nonlinear transient problem. This is the same as Equation 5.4.17 and is repeated here for completeness.

$$\mathbf{C}(\mathbf{T})\dot{\mathbf{T}} + \hat{\mathbf{K}}(t,\mathbf{T})\mathbf{T} = \mathbf{F}(t,\mathbf{T}),$$

   where

$$\hat{\mathbf{K}}(t,\mathbf{T}) = \mathbf{K}(\mathbf{T}) + \mathbf{H}(t) + \mathbf{R}(t,\mathbf{T}) \text{ and } \mathbf{F}(t,\mathbf{T}) = \mathbf{f}(t,\mathbf{T}) + \mathbf{q}(t) + \mathbf{h}_c(t) + \mathbf{h}_r(t,\mathbf{T}).$$

Solution Phase

Once the set of algebraic equations (see Equation 5.4.18 or Equation 5.4.19) or the semidiscrete equations (see Equation 5.4.205.4.17**) are assembled, the temperature boundary conditions are applied using, for example, the penalty method (see, e.g., Bathe, 1996 for details). A brief description of the

penalty method when it is used in linear steady-state problems is given next. Let i denote the degree of freedom, which is prescribed, i.e., $T_i = \overline{T}_i$. Then, a large constant α is added to the diagonal entry $\hat{K}_{ii}$ of the $\hat{\mathbf{K}}$ matrix and ith entry of the vector $\mathbf{F}$ is modified to $F_i + \alpha\overline{T}_i$. As a result of these modifications, the ith equation is changed to

$$(\hat{K}_{ii} + \alpha)T_i + \sum_{\substack{j=1 \\ j\neq i}}^{N} \hat{K}_{ij}T_j = F_i + \alpha\overline{T}_i.$$

Note that as α is chosen to be a very large number, the solution to the equation given earlier yields $T_i \approx \overline{T}_i$ as desired. After the boundary conditions are incorporated, the equations are then solved to obtain the solution. In case the problem is of the type given by Equation 5.4.18, the linear algebraic equations can be directly solved using the methods discussed in Section 5.4.6.1. If the problem is of type given by Equation 5.4.20, one needs to use a time integration algorithm to obtain a set of linear algebraic equations from the set of linear ordinary differential equations. Some of the most commonly used algorithms for carrying out the time integration are described in Section 5.4.6.2. If the problem is of the type given by Equation 5.4.19, then one can use a nonlinear equation solver of the type described in Section 5.4.6.3 to find the solution. If the problem is of type given by Equation 5.4.17, then one needs to combine the solvers described in Sections 5.4.6.2 and 5.4.6.3. One particular solver to solve Equation 5.4.17 is described in Section 5.4.6.4.

Linear Equation Solver

The solution of equations of the form, represented by

$$\mathbf{Ax} = \mathbf{b}, \tag{5.4.21}$$

is required when solving all the four types of problems mentioned in Section 5.4.5. Here, $\mathbf{A}$ is a $N\times N$ coefficient matrix, $\mathbf{b}$ is a $N\times 1$ right-hand side vector and $\mathbf{x}$ is a $N\times 1$ unknown vector. N depends on the degrees of freedom in the model, which for most problems in heat conduction is equivalent to the number of nodes in the model. This one-to-one equivalence between the degrees of freedom and the number of unknown hold good when the only nodal unknown is the temperature. For industrial problems, N can range from a few hundred thousand to a few millions and hence the solution of finite-element equations can require a huge computational effort. For example, if each entry of $\mathbf{A}$ is a double precision floating point number, then the storage of the full matrix $\mathbf{A}$ requires $8N^2$ bytes. If N= 100,000, a relatively small number in the present day simulations, then one needs 80 GB to store the matrix. In addition, the computational efforts (floating point operations) required to solve these systems can range from $O(N^2)$ to $O(N^3)$ depending on the type of algorithms used. Fortunately, matrix $\mathbf{A}$ has a special structure in the context of the FEM, which can be exploited to reduce the computational burden. The coefficient matrix is typically sparse and symmetric. The sparseness is due to the fact that one uses a local approximation to the unknown field variable. The matrix $\mathbf{A}$ is symmetric in those cases when one deals with self-adjoint equations and one uses the Galerkin method. The sparseness and symmetric nature of the matrix $\mathbf{A}$ translates into tremendous saving in the memory requirement as the full matrix does not have to be stored. Special data structures, which avoid the storing the numerically zero entries, are used to store the entries of the $\mathbf{A}$. The types of algorithms available in literature to solve Equation 5.4.21 arising in the context of a finite-element analysis can be broadly classified as follows:

1. *Direct solvers*: These solvers directly solve the system of equations without the need of an iterative process. They involve the following phases: (1) decomposition and (2) solution. The decomposition phase is based on some special implementation of Cholesky, QR, and LU decompositions (see, e.g., Golub and Van Loan, 2012), which exploits the sparsity of the matrix. This involves the use of graph theory to minimize the both the storage requirement

and computational effort. The decomposition phase is then followed by the solution phase which involves forward elimination followed by back substitution. More details of these methods is founds in Davis (2006). A detailed comparison of these algorithms is available (Gould and Scott, 2007). In addition to these solvers, frontal solvers (see, e.g., Irons, 1970) that are specifically tailored to exploit the assembly process of the FEM and avoid the assembly of the coefficient matrix **A** are also commonly used.

2. *Iterative solvers.* In these solvers, one starts with an initial guess $\mathbf{x}_0$ to the solution of Equation 5.4.21 and generates a sequence of approximations $\mathbf{x}_i$, which converges to the exact solution of Equation 5.4.21. The main advantage of these method is that they do not need any decompositions and primarily involve matrix vector multiplications. For symmetric positive definite matrices, one can use the conjugate gradient method (see Hestenes and Stiefel, 1952), whereas for a general matrix one can use the Generalized minimal residual method (GMRES) method (see Saad and Schultz, 1986). The rate of convergence of an iterative method is heavily influenced by the choice of the preconditioners. For symmetric positive definite matrices, some of the preconditioners that can be used include incomplete Cholesky and diagonal scaling. For a general matrix, the preconditioners that are commonly used are based on the incomplete LU factorizations. More details of the iterative methods are found in Saad (2003). The detailed survey on the types of preconditioners for large systems is given in Benzi (2002).

Time Integration Algorithm

To carry out the time integration from $t=0$ to $t=T$, one first discretizes the time interval [0, T] into Nt time intervals. Let t_1, t_2, …, $t_{Nt}=T$ denote the discrete instances where the temperature is to be obtained. Assuming that one knows the temperature up to t_n, one uses a time integration algorithm to obtain the temperature at t_{n+1}. The most commonly used algorithms for numerically integrating Equation 5.4.20 belong to the family of the generalized trapezoidal methods. The generalized trapezoidal methods are described by the following equations (see, e.g., Hughes, 2000):

$$\mathbf{C}_{n+1}\dot{\mathbf{T}}_{n+1} + \hat{\mathbf{K}}_{n+1}\mathbf{T}_{n+1} = \mathbf{F}_{n+1}, \tag{5.4.22}$$

$$\mathbf{T}_{n+1} = \mathbf{T}_n + \Delta t\dot{\mathbf{T}}_{n+\alpha}, \tag{5.4.23}$$

$$\dot{\mathbf{T}}_{n+\alpha} = (1-\alpha)\dot{\mathbf{T}}_n + \alpha\dot{\mathbf{T}}_{n+1}, \tag{5.4.24}$$

where $\mathbf{T}_n$, $\dot{\mathbf{T}}_n$, $\mathbf{T}_{n+1}$, and $\mathbf{T}_{n+1}$ are approximation to $\mathbf{T}(t_{n+1})$, $\dot{\mathbf{T}}(t_{n+1})$, $\mathbf{T}(t_{n+1})$, and $\dot{\mathbf{T}}(t_{n+1})$, respectively, $\mathbf{F}_{n+1}=\mathbf{F}(t_{n+1})$, $\hat{\mathbf{K}}_{n+1}=\hat{\mathbf{K}}(t_{n+1})$ and $\Delta t=t_{n+1}-t_n$. One particular implementation of the generalized trapezoidal methods leads to the following equation for $\mathbf{T}_{n+1}$, the unknown temperature at t_{n+1}, given the temperature $\mathbf{T}_n$ at t_n:

$$\left(\mathbf{C}+\alpha\Delta t\hat{\mathbf{K}}\right)\mathbf{T}_{n+1} = \left(\mathbf{C}-(1-\alpha)\Delta t\hat{\mathbf{K}}\right)\mathbf{T}_n + \Delta t\left((1-\alpha)\mathbf{F}_n + \mathbf{F}_{n+1}\right). \tag{5.4.25}$$

Here, α is a user-defined parameter with $0\le\alpha\le1$, which decides the accuracy and the stability of the algorithm and $\mathbf{F}_n=\mathbf{F}(t_n)$. For different values of α one obtains different algorithms, viz. $\alpha=0$ corresponds to the Forward Euler method, $\alpha=1$ corresponds to the Backward Euler method, $\alpha=1/2$ corresponds to the trapezoidal method (mid-point rule, Crank–Nicolson scheme), and $\alpha=2/3$ corresponds to the Galerkin method. The comparison of the four methods with respect to nature of the algorithm (explicit/implicit) and stability and accuracy is given in Table 5.4.3.

Nonlinear Equation Solver

The most commonly used technique to solve the problem represented by Equation 5.4.19 is the Newton–Raphson technique (see, e.g., Bathe, 1996). The basic idea of the method is to start with

TABLE 5.4.3
Comparison of the Different Time Integration Schemes

α	Method	Explicit/Implicit	Stability	Accuracy
0	Forward Euler	Explicit[a]	Conditionally stable	First order
1	Backward Euler	Implicit	Unconditionally stable	First order
1/2	Trapezoidal	Implicit	Unconditionally stable	Second order
2/3	Galerkin	Implicit	Unconditionally stable	Second order

[a] Diagonal capacitance matrix.

an initial guess of the solution and successively improve the estimate by using the first-order Taylor series expansion of the nonlinear function. To aid convergence, it is a usual practice to apply the total load in increments. The procedure to obtain the solution, $\mathbf{T}_{n+1}$ at the $(n+1)$th load increment given the converged solution, $\mathbf{T}_n$ at the nth increment using the Newton–Raphson technique is explained next. Let $\mathbf{T}_{n+1}^i$ denote the temperature at the ith iteration at load step $(n+1)$. From Equation 5.4.19, it is observed that the residue at the ith iteration, $\mathbf{R}_{n+1}^i$ is given by

$$\mathbf{R}_{n+1}^i = \hat{\mathbf{K}}_{n+1}^i \mathbf{T}_{n+1}^i - \mathbf{F}_{n+1}^i, \tag{5.4.26}$$

where $\hat{\mathbf{K}}_{n+1}^i = \hat{\mathbf{K}}(\mathbf{T}_{n+1}^i)$ and $\mathbf{F}_{n+1}^i = \mathbf{F}(\mathbf{T}_{n+1}^i)$. Using Taylor series expansion, the first-order approximation of the residue at the $i+1$th iteration is written as

$$\mathbf{R}_{n+1}^{i+1} \approx \mathbf{R}_{n+1}^i + (\mathbf{K}_T)_{n+1}^i \Delta\mathbf{T}_{n+1}^{i+1}, \tag{5.4.27}$$

where $\mathbf{K}_T = \frac{\partial \mathbf{R}}{\partial \mathbf{T}}$ is referred to as the tangent stiffness matrix. Note that at the element level, the components of a $n \times n$ tangent stiffness matrix are given by

$$R_{ab}^e = \frac{\partial R_a^e}{\partial T_b^e} = \frac{\partial}{\partial T_b^e}\left(\sum_{k=1}^{n} \hat{K}_{ak}^e T_k^e - F_a^e\right) = \hat{K}_{ab}^e + \sum_{k=1}^{n} \frac{\partial \hat{K}_{ak}^e}{\partial T_b^e} T_k^e - \frac{\partial F_a^e}{\partial T_b^e}, \quad a,b = 1,\ldots,n. \tag{5.4.28}$$

Setting the residue at the $i+1$th iterate to zero, the increment in the temperature, $\Delta\mathbf{T}_{n+1}^{i+1}$, is obtained by solving

$$(\mathbf{K}_T)_{n+1}^i \Delta\mathbf{T}_{n+1}^{i+1} = -\mathbf{R}_{n+1}^i. \tag{5.4.29}$$

Then, the temperature at the $i+1$th iterate is obtained as

$$\mathbf{T}_{n+1}^{i+1} = \mathbf{T}_{n+1}^i + \Delta\mathbf{T}_{n+1}^{i+1}. \tag{5.4.30}$$

This procedure is continued till the norm of the residue is less than some prescribed user tolerance and the norm of the increment is also less than some user prescribed tolerance. Once the converged solution is obtained, the load or the forcing is again incremented. The procedure is repeated till the entire load/forcing is applied.

The Newton–Raphson method shows a quadratic convergence rate near the true solution. As a result, it converges quickly to the true solution provided one starts sufficiently close to the true solution. The disadvantage of the method is the requirement to calculate the tangent stiffness matrix (see Equation 5.4.29) at every iteration. In addition, as the tangent stiffness matrix is not symmetric, the highly efficient symmetric linear equations solvers cannot be used. To avoid these drawbacks, a number of modifications have been suggested to the Newton–Raphson method.

These modifications include symmetric linearization (Winget and Hughes, 1985), Modified Newton method (see, e.g., Bathe, 1996), wherein the tangent stiffness matrix is calculated only at the beginning of the load increment and the quasi-Newton methods (see, e.g., Bathe, 1996), which the tangent stiffness matrix is approximated with a secant matrix whose approximation can be computed efficiently.

Transient Nonlinear Equation Solver

To carry out the time integration from $t=0$ to $t=T$, one first discretizes the time interval $[0, T]$ into Nt time intervals. Let $t_1, t_2, \ldots, t_{Nt}=T$ denote the discrete instances where the temperature is to be obtained. A solver obtained by combing the Backward Euler method (see Section 5.4.6.2) with the Newton–Raphson method (see Section 5.4.6.3) to obtain the temperature at t_i, $i=1, \ldots, Nt$ is briefly described next. One assumes that the temperature up to time t_n is known and that the temperature at time t_{n+1} is to be obtained. Next, using the time discrete form of Equation 5.4.17 coupled with the Backward Euler method, the nonlinear equation for the unknown temperature $\mathbf{T}_{n+1}$ at t_{n+1} is written as follows:

$$\mathbf{C}_{n+1}\left(\mathbf{T}_{n+1}-\mathbf{T}_n\right)=\Delta t\left(\mathbf{F}_{n+1}-\hat{\mathbf{K}}_{n+1}\right), \tag{5.4.31}$$

where $\mathbf{C}_{n+1}=\mathbf{C}(\mathbf{T}_{n+1})$, $\mathbf{F}_{n+1}=\mathbf{F}(\mathbf{T}_{n+1}, t_{n+1})$, and $\hat{\mathbf{K}}_{n+1}=\hat{\mathbf{K}}(\mathbf{T}_{n+1}, t_{n+1})$. Now, one essentially follows the procedure outlined in Section 5.4.6.3 to solve Equation 5.4.31. Note that in the present case, the residual is calculated using Equation 5.4.31. Once the converged solution is obtained at t_{n+1}, the time variable is incremented by Δt. One then repeats the procedure till one reaches time $t=T$.

Numerical Evaluation of Elemental Matrices/Vectors

The different expressions for elemental matrices and vectors given in Section 5.4.5 need to be numerically integrated over the element or its boundaries. The details of the numerical evaluation of elemental matrices and vectors are given in this section.

Isoparametric Elements

The numerical integration is carried out using the concept of isoparametric elements and is explained next. To carry out the numerical integrations, it is convenient to assume that the actual elements are obtained from some simple geometric shapes by using a coordinate transformation. The actual element (Ω^e) is usually referred to as a mapped element, and the element with the simple shape is referred to as a parent element ($\hat{\Omega}$). The integration is then carried out by using some standard integration rules over the parent element. This coordinate transformation or mapping is carried out using appropriate shape functions defined on the parent element. In case of isoparametric elements, the function to be approximated is also expressed using the same shape functions, which are used for the coordinate transformation. The basic idea of using an isoparametric element to carry to out the numerical integration is now illustrated with the help of an example. For concreteness, it is assumed that one is interested in integrating an integral of the form

$$I=\int_{\Omega^e} f(x,y)\,\mathrm{d}x\,\mathrm{d}y, \tag{5.4.32}$$

over the three-node element shown in Figure 5.4.4. The coordinate transformation from the parent element to the mapped element is assumed to be of the form

$$x(\xi,\eta)=\sum_{i=1}^{3}\hat{N}_i(\xi,\eta)x_i^e, \quad y(\xi,\eta)=\sum_{i=1}^{3}\hat{N}_i(\xi,\eta)y_i^e, \tag{5.4.33}$$

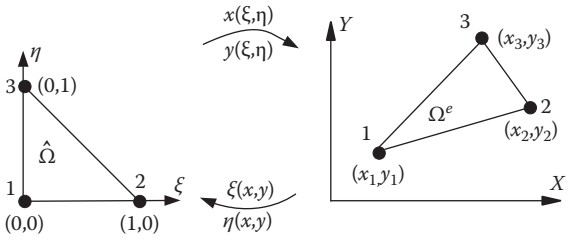

FIGURE 5.4.4 Coordinate transformation.

where the shape functions are given by

$$\hat{N}_1(\xi,\eta) = 1-\xi-\eta,\ \hat{N}_2(\xi,\eta) = \xi,\ \hat{N}_3(\xi,\eta) = \eta. \tag{5.4.34}$$

Here, ξ_i, η_i, $i=1, 2, 3$ are corner coordinates of the parent element and x_i, y_i, $i=1, 2, 3$ are the corner nodes of the mapped element. Note that the mapping between the parent element and the mapped element is chosen in such a way that it is one to one and onto, i.e., it is invertible.

The Jacobian matrix of the transformation is then given by

$$\mathbf{J} = \begin{bmatrix} \dfrac{\partial x}{\partial \xi} & \dfrac{\partial x}{\partial \eta} \\ \dfrac{\partial y}{\partial \xi} & \dfrac{\partial y}{\partial \eta} \end{bmatrix}, \tag{5.4.35}$$

while the Jacobian of the transformation is given by

$$J = \det \mathbf{J} = \frac{\partial x}{\partial \xi}\frac{\partial y}{\partial \eta} - \frac{\partial x}{\partial \eta}\frac{\partial y}{\partial \xi}. \tag{5.4.36}$$

Using the transformation and the corresponding Jacobian given in Equations 5.4.33 and 5.4.36, respectively, the integral given in Equation 5.4.32 is evaluated as

$$I = \int_{\hat{\Omega}} \hat{f}(\xi,\eta) J \, d\xi \, d\eta. \tag{5.4.37}$$

Note that because the mapping given in Equation 5.4.33 is assumed to be invertible the integrand $f(x, y)$ in Equation 5.4.32 can be written as

$$f(x,y) = f(x(\xi,\eta), y(\xi,\eta)) = \hat{f}(\xi,\eta).$$

The evaluation of the terms of the stiffness matrix is discussed next. For two-dimensional problems, the integrands in the elemental stiffness matrix consists of the derivatives of the shape functions in the mapped domain with respect to x and y. To proceed, one introduces the isoparametric element concept in which the approximation to a function in the parent domain is defined using the same shape functions, which are used for the coordinate transformation (see Equation 5.4.34). Hence, the approximation to the temperature in the parent domain, $\hat{T}(\xi,\eta)$, is written as

$$\hat{T}(\xi,\eta) = \sum_{i=1}^{3} \hat{N}_i(\xi,\eta)\hat{T}_i^e, \tag{5.4.38}$$

where $\hat{T}_i^e = T_i^e, i = 1,2,3$. Note that because the mapping given in Equation 5.4.33 is assumed to be invertible one has

$$\hat{T}(\xi,\eta) = \hat{T}(\xi(x,y),\eta(x,y)) = T(x,y).$$

Similarly one has

$$\hat{N}_i(\xi,\eta) = \hat{N}_i(\xi(x,y),\eta(x,y)) = N_i(x,y), \quad i = 1,2,3. \tag{5.4.39}$$

Using Equation 5.4.39 and the chain rule, one obtains the derivatives of the shape functions in the mapped domain with respect to x and y as

$$\frac{\partial N_i}{\partial x} = \frac{\partial \hat{N}_i}{\partial \xi}\frac{\partial \xi}{\partial x} + \frac{\partial \hat{N}_i}{\partial \eta}\frac{\partial \eta}{\partial x} \text{ and } \frac{\partial N_i}{\partial y} = \frac{\partial \hat{N}_i}{\partial \xi}\frac{\partial \xi}{\partial y} + \frac{\partial \hat{N}_i}{\partial \eta}\frac{\partial \eta}{\partial y}. \tag{5.4.40}$$

The entries $\partial \hat{N}_i/\partial \xi$ and $\partial \hat{N}_i/\partial \eta$ can be evaluated using Equation 5.4.34, while $\partial\xi/\partial x$, $\partial\eta/\partial x$, $\partial\xi/\partial y$, and $\partial\eta/\partial y$ are given by

$$\frac{\partial \xi}{\partial x} = \frac{1}{J}\frac{\partial y}{\partial \eta}, \frac{\partial \eta}{\partial x} = -\frac{1}{J}\frac{\partial y}{\partial \xi}, \frac{\partial \xi}{\partial y} = -\frac{1}{J}\frac{\partial x}{\partial \eta}, \frac{\partial \eta}{\partial y} = \frac{1}{J}\frac{\partial x}{\partial \xi}. \tag{5.4.41}$$

The entries in Equation 5.4.41 can be readily evaluated using the coordinate transformation given in Equation 5.4.33.

Element Technology

The types of elements used in a finite-element simulation play a very important role in deciding the accuracy of the solution. Elements differ in their shape in the parent domain and also by the number of nodes. Both these attributes decide the type of boundary the elements are capable of modeling accurately. More importantly, these attributes also decide the shape functions that are used to approximate the field variable within an element. The shape functions in turn decide the nature of the approximate solution that is obtained. In order to precisely define the conditions under which the obtained approximate solution converges to the true solution as the mesh is refined, one first finds a quantity referred to as the variational index, *r*. The variational index is the highest order of the derivative appearing in the element equations (see Equation 5.4.9). The convergence requirements can be stated as

1. *Completeness.* The element shape functions must represent exactly all polynomial terms of order r in the Cartesian coordinates. Note that this requirement applies to individual elements.
2. *Compatibility.* The approximation must be C^r continuous in the interior of the elements and C^{r-1} continuous at the interface of the elements. Note that the first part of this requirement applies to individual elements and the second part applies to those elements, which share a common interface.

Note that a function is said to be C^m continuous if the function and all its derivatives up to order m are continuous but its derivative of order $m+1$ is discontinuous. Observe that the variational index for the problem at hand is $r=1$ (see Equation 5.4.9). Hence, as per the convergence requirements, the shape functions must be able to represent all polynomials of degree 1 in the Cartesian coordinates and the approximation must be C^0 continuous at the interface of the elements and must be C^1 continuous in the interior of the elements. For problems with variational index 1, shape functions

that satisfy the Kronecker delta property and the partition of unit property, automatically satisfy completeness and compatibility requirements. The Kronecker delta property and the partition of unity property are explained next.

Consider a n node parent element with nodes located at $\boldsymbol{\xi}_i$, $i=1$, …, n and shape functions $\hat{N}_i(\boldsymbol{\xi}), i=1,\ldots,n$. The Kronecker delta property is given

$$\hat{N}_i(\boldsymbol{\xi}_j)=\begin{cases} 1 & \text{if } i=j, \\ 0 & \text{if } i\neq j. \end{cases} \tag{5.4.42}$$

which states that the shape function associated with node i when evaluated at node i is 1 and when evaluated at any other node is 0. The partition of unity property is given by

$$\sum_{i=1}^{n}\hat{N}_i(\xi)=1, \tag{5.4.43}$$

which states that the sum of all the shape functions evaluated at any point in the element is 1. The most common two and three-dimensional elements, which can be used in problems where a C^1 continuity is required in the interior of the element and a C^0 continuity is required at the interface of the elements are described next.

Two-Dimensional Elements

The most common two-dimensional elements used in practice are either triangular or quadrilateral in shape.

Triangular Elements

The simplest triangular element is a three-node triangular element. The parent three-node triangular element and the mapped three-node triangular element are shown in Figure 5.4.5. Note that for the parent element, $0\leq\xi\leq1$, $0\leq\eta\leq1$, and $\xi+\eta\leq1$.

As can be seen from the figure, the element is capable of representing only straight edges exactly. The shape functions of the element are linear in ξ and η and are as follows:

$$\hat{N}_1=1-\xi-\eta,\ \hat{N}_2=\xi,\ \hat{N}_3=\eta. \tag{5.4.44}$$

An improved approximation is given by a six-node triangular element. The parent six-node element and the mapped six-node element are shown in Figure 5.4.6. Nodes 4, 5, and 6 are mid-side nodes. Note that for the parent element, $0\leq\xi\leq1$, $0\leq\eta\leq1$, and $\xi+\eta\leq1$.

The shape functions are quadratic in ξ and η and are as follows:

$$\hat{N}_1=\lambda(2\lambda-1),\ \hat{N}_2=\xi(2\xi-1),\ \hat{N}_3=\eta(2\eta-1),\ \hat{N}_4=4\xi\lambda,\ \hat{N}_5=4\xi\eta,\ \hat{N}_6=4\eta\lambda, \tag{5.4.45}$$

where $\lambda=1-\xi-\eta$.

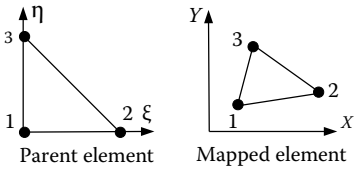

FIGURE 5.4.5 Three-node triangle.

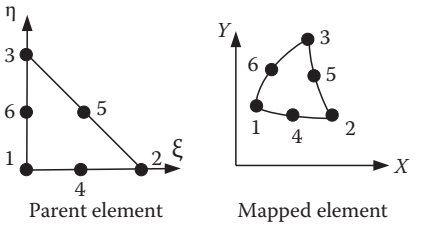

FIGURE 5.4.6 Six-node triangle.

Quadrilateral Elements

The simplest quadrilateral element is a four-node quadrilateral element. The parent four-node square element and the mapped four-node quadrilateral element are shown in Figure 5.4.7. Note that for the parent element, $-1 \le \xi \le 1$ and $-1 \le \eta \le 1$.

As can be seen from the figure, the element is capable of representing only straight edges exactly. The shape functions of the element are bilinear in ξ and η and are as follows:

$$\hat{N}_i = \frac{1}{4}(1+\xi_i\xi)(1+\eta_i\eta), \quad i = 1,2,3,4. \tag{5.4.46}$$

Here, (ξ_i, η_i) are the coordinates of the ith node. An improved approximation is given by a nine-node quadrilateral element. The parent nine-node square element and the mapped nine-node element are shown in Figure 5.4.8. Nodes 5, 6, 7, 8 are mid-side nodes. Note that for the parent element, $-1 \le \xi \le 1$ and $-1 \le \eta \le 1$. The shape functions are quadratic in ξ and η and are as follows:

$$\begin{aligned}
\hat{N}_i &= \frac{1}{4}(\xi^2+\xi_i\xi)(\eta^2+\eta_i\eta), \quad i = 1,2,3,4, \\
\hat{N}_i &= \frac{1}{2}\xi_i^2(\xi^2+\xi_i\xi)(1-\eta^2)+\frac{1}{2}\eta_i^2(\eta^2+\eta_i\eta)(1-\xi^2), \quad i = 5,6,7,8, \\
\hat{N}_9 &= (1-\xi^2)(1-\eta^2).
\end{aligned} \tag{5.4.47}$$

Three-Dimensional Elements

The most common three-dimensional elements used in practice are either tetrahedral or hexahedral in shape.

Tetrahedral Elements

The simplest tetrahedral element is a four-node tetrahedral element. The parent four-node tetrahedral element is shown in Figure 5.4.9. Note that for the parent element, $0 \le \xi \le 1$, $0 \le \eta \le 1$, $0 \le \zeta \le 1$, and $\xi + \eta + \zeta \le 1$.

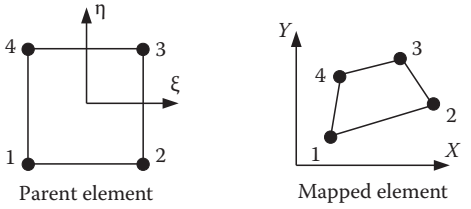

FIGURE 5.4.7 Four-node quadrilateral.

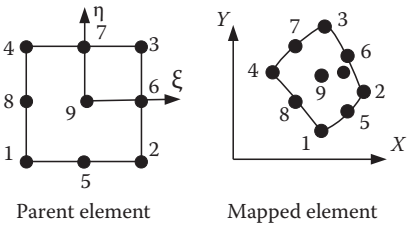

FIGURE 5.4.8 Nine-node quadrilateral.

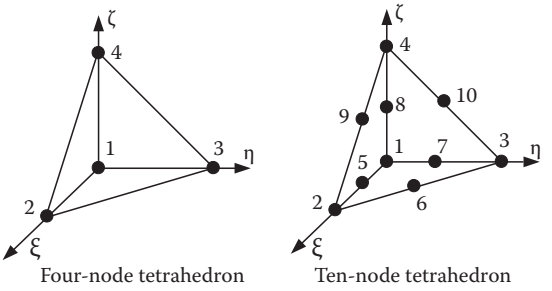

FIGURE 5.4.9 Tetrahedron elements.

The shape functions of the element are linear in ξ, η, and ζ and are as follows:

$$\hat{N}_1 = 1-\xi-\eta-\zeta,\ \hat{N}_2 = \xi,\ \hat{N}_3 = \eta,\ \hat{N}_4 = \zeta. \tag{5.4.48}$$

An improved approximation is given by a 10-node tetrahedral element. The parent 10-node element is shown in Figure 5.4.9. Note that for the parent element, $0 \le \xi \le 1$, $0 \le \eta \le 1$, $0 \le \zeta \le 1$, and $\xi+\eta+\zeta \le 1$. Here, nodes 5, 6, 7, 8, 9, and 10 are mid-side nodes. The shape functions are quadratic in ξ, η, and ζ and are as follows:

$$\begin{aligned} &\hat{N}_1 = \lambda(2\lambda-1), && \hat{N}_2 = \xi(2\xi-1), && \hat{N}_3 = \eta(2\eta-1), && \hat{N}_4 = \zeta(2\zeta-1), && \hat{N}_5 = 4\xi\lambda, \\ &\hat{N}_6 = 4\xi\eta, && \hat{N}_7 = 4\eta\lambda, && \hat{N}_8 = 4\zeta\lambda, && \hat{N}_9 = 4\eta\zeta, && \hat{N}_{10} = 4\eta\zeta, \end{aligned} \tag{5.4.49}$$

where $\lambda = 1-\xi-\eta-\zeta$.

Hexahedral Elements

The simplest hexahedral (brick) element is an eight-node hexahedral element. The parent eight-node element is shown in Figure 5.4.10. Note that for the parent element, $-1 \le \xi \le 1$, $-1 \le \eta \le 1$, and $-1 \le \zeta \le 1$. The shape functions of the element are trilinear in ξ, η and ζ and are as follows:

$$\hat{N}_i = \frac{1}{8}(1+\xi_i\xi)\ (1+\eta_i\eta)(1+\zeta_i\zeta), \quad i = 1,2,3,4,5,6,7,8. \tag{5.4.50}$$

Here, (ξ_i, η_i, ζ_i) are the coordinates of the ith node. An improved approximation is given by a 20-node hexahedral element. The parent 20-node element is shown in Figure 5.4.10. Note that for the parent element, $-1 \le \xi \le 1$, $-1 \le \eta \le 1$, and $-1 \le \zeta \le 1$. Here, nodes 9–20 are mid-side nodes. The shape functions of the element are as follows:

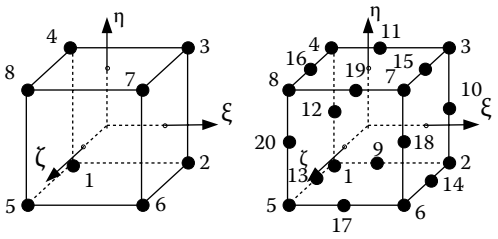

FIGURE 5.4.10 Hexahedral elements.

$$
\begin{aligned}
\hat{N}_i &= \frac{1}{8}(1+\xi_i\xi)(1+\eta_i\eta)(1+\zeta_i\zeta)(\xi_i\xi+\eta_i\eta+\zeta_i\zeta-2) && i=1,2,3,4,5,6,7,8,\\
\hat{N}_i &= \frac{1}{4}(1-\xi^2)(1+\eta_i\eta)(1+\zeta_i\zeta), && i=9,11,17,19,\\
\hat{N}_i &= \frac{1}{4}(1-\eta^2)(1+\xi_i\xi)(1+\zeta_i\zeta), && i=10,12,18,20,\\
\hat{N}_i &= \frac{1}{4}(1-\zeta^2)(1+\xi_i\xi)(1+\eta_i\eta), && i=13,14,15,16.
\end{aligned}
\tag{5.4.51}
$$

For a detailed list of the types of elements available in two and three dimensions and their properties, see, e.g., Zienkiewicz et al. (2013).

Numerical Integration

As discussed earlier, the integrations, which are to be carried out over the mapped element for calculation of various terms in the element equations, are first transformed to integrations over the parent element using appropriate coordinate transformations. These integrations are of the following type:

1. *One-dimensional integrals.* These have to be performed when solving either one-dimensional problems or while evaluating the boundary terms in two-dimensional problems. The integrals are of the form:

$$
I_1 = \int_{-1}^{+1} \hat{f}(\xi) J(\xi)\, \mathrm{d}\xi. \tag{5.4.52}
$$

2. *Two-dimensional integrals.* These have to be performed when solving either two-dimensional problems or while evaluating the boundary terms in three-dimensional problems. The integrals are of the form:

$$
I_{2a} = \int_{0}^{+1}\int_{0}^{1-\xi} \hat{f}(\xi,\eta) J(\xi,\eta)\, \mathrm{d}\xi\, \mathrm{d}\eta, \quad \text{Triangular elements}, \tag{5.4.53}
$$

$$
I_{2b} = \int_{-1}^{+1}\int_{-1}^{+1} \hat{f}(\xi,\eta) J(\xi,\eta)\, \mathrm{d}\xi \mathrm{d}\eta, \quad \text{Quadrilateral elements}. \tag{5.4.54}
$$

3. *Three-dimensional integrals*. These have to be performed when solving three-dimensional problems. The integrals are of the form:

$$I_{3a} = \int_0^{+1} \int_0^{1-\xi} \int_0^{1-\xi-\eta} \hat{f}(\xi,\eta,\zeta) J(\xi,\eta,\zeta)\, d\xi\, d\eta\, d\zeta, \quad \text{Tetrahedral elements,} \tag{5.4.55}$$

$$I_{3b} = \int_{-1}^{+1} \int_{-1}^{+1} \int_{-1}^{+1} \hat{f}(\xi,\eta,\zeta) J(\xi,\eta,\zeta)\, d\xi\, d\eta\, d\zeta, \quad \text{Hexahedral elements.} \tag{5.4.56}$$

These integrals are evaluated using an appropriately chosen numerical integration scheme. The basic idea of any integration scheme is to evaluate the integrand at a few discrete points in the domain, multiply each evaluation with a specific weighting function and finally sum all the weighted evaluations. For example, the one-dimensional integral given by Equations5.4.52 is evaluated as

$$I_1 \approx \sum_{p=1}^{N_g} \hat{f}(\xi_p) J(\xi_p) w_p, \tag{5.4.57}$$

where N_g denotes the number points where the integrand is to be evaluated, ξ_p, $p=1, \ldots, N_g$, denotes the locations of the N_g points, and w_p denotes the weight associated with point ξ_p. The most commonly used scheme to carry out the numerical integration is the Gauss integration scheme. For a one-dimensional problem, a N_g point Gauss integration scheme is able to integrate a polynomial of degree $2N_g - 1$ exactly. The locations of the sampling points and the corresponding weights to carry out the integration in one-dimensional, two-dimensional (both square and triangular) domains, and three-dimensional (both tetrahedral and hexahedral) domains are readily available in standard books (see, e.g., Zienkiewicz et al., 2013). It is important to note that as the order of the integration scheme increases, the number of function evaluations also increase, leading to an increase in the computational cost.

Practical Issues in the Use of the FEM

Some practical issues concerning the use of the FEM for analyzing problems are discussed next.

Meshing

The quality of the finite elements used in the discretization process has a profound effect on the accuracy of the solution (see, e.g., Shewchuk, 2002). The quality of the element is usually measured in terms of the element volume or area, aspect ratio, included angles, etc. Elements with large aspect ratios, large interior angles, and with high degree of distortions should be avoided.

Choice of Elements

The choice of elements dictates the order of approximation. Elements with linear and quadratic shape functions are sufficient for most types of heat conduction analysis. Higher order elements usually lead to higher accuracy at the expense of higher computational cost. In addition, the bandwidth of the stiffness matrix increases that in turn increases the computational effort to solve the system of equations.

Mesh Refinement

The usual procedure followed in performing the finite-element analysis is to first solve the problem using a relatively coarse mesh. Then based on the quality of the result, the mesh is selectively

refined to improve the accuracy of the solution in regions of interest. Mesh refinement is usually required in the regions of high gradients. The idea of mesh refinement is based on the following a priori error estimate (see, e.g., Zienkiewicz et al., 2013)

$$\| \mathbf{e} \|_E \leq Ch^p, \tag{5.4.58}$$

where $\mathbf{e} = \mathbf{T} - \hat{\mathbf{T}}$ is the difference between the true solution, $\mathbf{T}$, and the approximate solution, $\hat{\mathbf{T}}$, $\| (\cdot) \|_E$ is the energy norm, C is a constant, h is the size of a typical element in the mesh, and p is the order of approximation used. As can be seen from Equation 5.4.58, the error in the obtained solution can be reduced by either reducing the element size and/or increasing the order of approximation. Based on this observation, there are three widely used methods for mesh refinement: h-refinement, p-refinement, and h–p refinement. In h-refinement, the type of element is kept the same but the size of the element is reduced. For example, if the original mesh consisted of four-node quadrilateral, the h-refined mesh also consists of four-node quadrilaterals but with decreased size. In p-refinement, the size of the element is kept fixed but the order of approximation of the unknown function within an element is increased. For example, if the original mesh consisted of four-node quadrilateral, the p-refined mesh will consists of nine-node quadrilaterals of the same size. h–p refinement is a combination of h-refinement and p-refinement wherein not only the size of the element is decreased but also the order of approximation of the unknown function within an element is increased. Of the three methods of refinement, the h–p method is found to more effective.

Order of Gauss Integration

As discussed in Section 5.4.7.3, numerical integration is frequently used to carry out the integration of terms appearing in the elemental vectors and matrices. Because exact integration is not carried out, an error is introduced in the finite-element solution. Hence, there is a tendency to use higher order integration schemes, but this leads to a significant increase in the computational costs. Depending on the type of element that is used, one can estimate the order of Gauss integration required for the exact integration of the elemental terms if certain conditions are satisfied, namely, the material properties are constant and the mapped element is undistorted. For more discussion on the choice of the order Gauss integration, see, e.g., Bathe (1996) and Zienkiewicz et al. (2013). In practice, even if the conditions mentioned earlier are not satisfied, one still uses the estimate of the order of Gauss integration to be used based on undistorted elements and constant properties.

Note that symbolic evaluation techniques of the element matrices and vectors that avoid the use of numerical integration are a part of current research toward improving the speed and accuracy of the FEM (see, e.g., Russell and Kelly, 2013).

Choice of Solvers

As mentioned in Section 5.4.6.1, one can use either a direct solver or an iterative solver to solve the set of linear equations arising in the FEM. The choice of the solver is problem dependent. Iterative solvers require less memory compared to direct solvers as there is no fill-in. They can be considerably faster compared to direct solvers for large problems. On the other hand, direct solvers are more robust and are suitable for "difficult" problems. As mentioned before, the performance of an iterative solver is heavily dependent on the choice of the preconditioners. For some problems, it may be computationally more expensive to find a preconditioner compared to using a direct solver. In addition, the direct methods are more effective when a set of equations is to be solved for multiple right-hand side vectors. In such case, the matrix factorization needs to be calculated only once.

Examples

Two examples illustrating the use of the FEM to solve problems in heat conduction are presented next.

A Typical Two-Dimensional Problem

The purpose of this example to demonstrate in sufficient details the different steps involved in using the FEM to solve a typical two-dimensional heat conduction problem shown in Figure 5.4.11. This is an example of a linear steady-state two-dimensional problem.

The figure shows a two-dimensional body of unit thickness with a constant heat source of $f = 36$ W/m^3 that is uniformly distributed. The body is homogeneous and isotropic and the thermal conductivity is $k = 10$ W/(m °C). The temperature on the bottom edge is maintained at 50°C. The right edge is subjected to a zero flux condition, whereas there is an outward flux of 10 W/m^2 from the left edge. Convective heat transfer takes place from the top edge with constant convective heat-transfer coefficient, $h_c = 6$ W/m^2°C and bulk temperature $T_B = 10$°C.

For simplicity, the body is discretized with 4 equal 3 node triangular elements as shown in Figure 5.4.11. The element connectivity matrix is given below (Table 5.4.4):

The element stiffness matrix is calculated for each of the elements using the expression for the stiffness matrix given by

$$K_{ij}^{e} = \int_{\Omega^e} k\left(\frac{\partial N_i}{\partial x}\frac{\partial N_j}{\partial x} + \frac{\partial N_i}{\partial y}\frac{\partial N_j}{\partial y}\right) d\Omega^e .$$

The integrand of this integral expression is evaluated using Equation 5.4.40 and the shape functions given by Equation 5.4.44. Note that for this problem the element stiffness matrix can be calculated analytically. The element stiffness matrices for element 1, 2, and 4 are given as

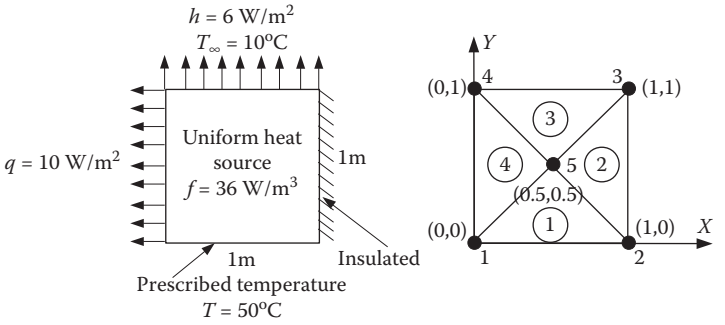

FIGURE 5.4.11 Geometry and boundary conditions of Problem 1.

TABLE 5.4.4
Element Connectivity for Problem 1

Element No.	Local Node Numbers		
	Node 1	Node 2	Node 3
1	1	2	5
2	2	3	5
3	4	5	3
4	5	4	1

$$\mathbf{K}^1 = \begin{array}{c} \\ 1 \\ 2 \\ 5 \end{array} \begin{array}{c} \begin{array}{ccc} 1 & 2 & 5 \end{array} \\ \begin{bmatrix} 5 & 0 & -5 \\ & 5 & -5 \\ \text{symm} & & 10 \end{bmatrix} \end{array}, \quad \mathbf{K}^2 = \begin{array}{c} \\ 2 \\ 3 \\ 5 \end{array} \begin{array}{c} \begin{array}{ccc} 2 & 3 & 5 \end{array} \\ \begin{bmatrix} 5 & 0 & -5 \\ & 5 & -5 \\ \text{symm} & & 10 \end{bmatrix} \end{array},$$

$$\mathbf{K}^4 = \begin{array}{c} \\ 5 \\ 4 \\ 1 \end{array} \begin{array}{c} \begin{array}{ccc} 5 & 4 & 1 \end{array} \\ \begin{bmatrix} 10 & -5 & -5 \\ & 5 & 0 \\ \text{symm} & & 5 \end{bmatrix} \end{array}.$$

In the present example, the edge 3–5 of element 3 is subjected to convection. Hence, one needs to also calculate the elemental matrix related to convection for element 3. The expression for this matrix is given by

$$H_{ij}^e = \int_{\Gamma^e} h_c N_i N_j \, \mathrm{d}\Gamma^e.$$

Note that this matrix is to be evaluated only along those boundaries on which convection boundary condition is given. The element stiffness matrix and the matrix due to convection for element 3 are given by

$$\mathbf{K}^3 = \begin{array}{c} \\ 4 \\ 5 \\ 3 \end{array} \begin{array}{c} \begin{array}{ccc} 4 & 5 & 3 \end{array} \\ \begin{bmatrix} 5 & -5 & 0 \\ & 10 & -5 \\ \text{symm} & & 5 \end{bmatrix} \end{array}, \quad \mathbf{H}^3 = \begin{array}{c} \\ 4 \\ 5 \\ 3 \end{array} \begin{array}{c} \begin{array}{ccc} 4 & 5 & 3 \end{array} \\ \begin{bmatrix} 2 & 0 & 1 \\ & 0 & 0 \\ \text{symm} & & 2 \end{bmatrix} \end{array}.$$

The element vectors due to the distributed heat source are calculated using

$$f_i^e = \int_{\Omega^e} N_i f \, \mathrm{d}\Omega^e$$

and are given by

$$\mathbf{f}^1 = \begin{array}{c} \\ 1 \\ 2 \\ 5 \end{array} \begin{bmatrix} 3 \\ 3 \\ 3 \end{bmatrix}, \quad \mathbf{f}^2 = \begin{array}{c} \\ 2 \\ 3 \\ 5 \end{array} \begin{bmatrix} 3 \\ 3 \\ 3 \end{bmatrix}, \quad \mathbf{f}^3 = \begin{array}{c} \\ 4 \\ 5 \\ 3 \end{array} \begin{bmatrix} 3 \\ 3 \\ 3 \end{bmatrix}, \quad \text{and} \quad \mathbf{f}^4 = \begin{array}{c} \\ 5 \\ 4 \\ 1 \end{array} \begin{bmatrix} 3 \\ 3 \\ 3 \end{bmatrix}.$$

Next, the element vectors due to the prescribed flux are calculated using

$$q_i^e = \int_{\Gamma^e} N_i q_n \, \mathrm{d}\Gamma^e.$$

For the present problem, a nonzero flux is prescribed on the edge 4–1 of element 4. Hence, one needs to calculate the element vector due to the prescribed nonzero flux for element 4. The element load vector is obtained as

$$\mathbf{q}^4 = \begin{matrix} 5 \\ 4 \\ 1 \end{matrix} \begin{bmatrix} 0 \\ 5 \\ 5 \end{bmatrix}.$$

Note that because the temperatures are prescribed at nodes 1 and 2 ($T_1 = T_2 = 50°C$), the flux at nodes 1 and 2 (q_1 and q_2) will be treated as unknowns. Finally, the element vectors due to the prescribed convective heat transfer are calculated using

$$h_{\hat{e}}^e = \int_{\Gamma^e} h_c T_B N_i \, d\Gamma^e.$$

As the edge 3–5 of element 3 is subjected to convection, one needs to calculate the elemental vector related to convection only for element 3. This vector is given by

$$\mathbf{h}_c^3 = \begin{matrix} 4 \\ 5 \\ 3 \end{matrix} \begin{bmatrix} 30 \\ 0 \\ 30 \end{bmatrix}.$$

Based on the discussion presented in Section 5.4.4, the elemental matrices and the vectors are assembled to get the equations of the form given in Equation 5.4.18, viz.

$$(\mathbf{K} + \mathbf{H})\mathbf{T} = \mathbf{f} + \mathbf{q} + \mathbf{h}_c,$$

where

$$\mathbf{K} = \begin{matrix} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{matrix} \begin{matrix} \begin{matrix} 1 & 2 & 3 & 4 & 5 \end{matrix} \\ \begin{bmatrix} 10 & 0 & 0 & 0 & -10 \\ & 10 & 0 & 0 & -10 \\ & & 10 & 0 & -10 \\ & & & 10 & -10 \\ \text{symm} & & & & 40 \end{bmatrix} \end{matrix}, \quad \mathbf{H} = \begin{matrix} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{matrix} \begin{matrix} \begin{matrix} 1 & 2 & 3 & 4 & 5 \end{matrix} \\ \begin{bmatrix} 0 & 0 & 0 & 0 & 0 \\ & 0 & 0 & 0 & 0 \\ & & 2 & 1 & 0 \\ & & & 2 & 0 \\ \text{symm} & & & & 0 \end{bmatrix} \end{matrix},$$

$$\mathbf{T} = \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \end{bmatrix}, \quad \mathbf{f} = \begin{matrix} 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{matrix} \begin{bmatrix} 6 \\ 6 \\ 6 \\ 6 \\ 12 \end{bmatrix}, \quad \mathbf{q} = \begin{matrix} 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{matrix} \begin{bmatrix} q_1 \\ q_2 \\ 0 \\ 5 \\ 0 \end{bmatrix}, \text{ and } \mathbf{h}_c = \begin{matrix} 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{matrix} \begin{bmatrix} 0 \\ 0 \\ 30 \\ 30 \\ 0 \end{bmatrix}.$$

As mentioned earlier, because the temperatures are prescribed at nodes 1 and 2, the flux at nodes 1, q_1, and 2, q_2, are treated as unknowns. On simplifying and taking into account the prescribed temperature boundary conditions, one obtains,

$$\begin{array}{c} \\ 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{array}\begin{array}{c} \begin{array}{ccccc} 1 & 2 & 3 & 4 & 5 \end{array} \\ \begin{bmatrix} 10 & 0 & 0 & 0 & -10 \\ & 10 & 0 & 0 & -10 \\ & & 12 & 1 & -10 \\ & & & 12 & -10 \\ & \text{symm} & & & 40 \end{bmatrix} \end{array}\begin{bmatrix} T_1 = 50 \\ T_2 = 50 \\ T_3 \\ T_4 \\ T_5 \end{bmatrix} = \begin{array}{c} \begin{array}{c} 1 \\ 2 \\ 3 \\ 4 \\ 5 \end{array} \\ \begin{bmatrix} \tilde{q}_1 \\ \tilde{q}_2 \\ 36 \\ 41 \\ 12 \end{bmatrix} \end{array}.$$

Here, $\tilde{q}_1 = q_1 + 6$ and $\tilde{q}_2 = q_2 + 6$. On solving the above set of equations for the unknown temperatures T_3, T_4, and T_5, one obtains $T_3 = 36.2°C$, $T_4 = 36.7°C$, and $T_5 = 43.5°C$. Once the temperature at the nodes is obtained, one can then obtain the temperature at any point in the body by using the element shape functions (see Equation 5.4.6). Note the same problem is solved using ANSYS, a commercial finite-element software. The geometry is discretized using 200 six-node triangular elements. A sparse direct solver is used to solve the set of linear equations. The temperatures obtained in this case are $T_3 = 36.0°C$, $T_4 = 35.5°C$, and $T_5 = 43.3°C$.

Bi-material Problem with Imperfect Interface

The purpose of this problem is to illustrate the versatility of the FEM to handle nontrivial problems in heat conduction. The two-dimensional problem considered was solved using the boundary element method in Bialecki and Kuhn (1993) and is shown in Figure 5.4.12.

The figure shows a plate with a hole made up of two different materials. The two materials share two edges: one with a perfect interface and the other with an imperfect interface. The thermal conductivity of the two materials is as follows:

Material 1:

$$k_1(T) = 70 \text{ W/mK} \quad \text{for} \quad T \le 300 \text{ K},$$
$$= 90 \text{ W/mK} \quad \text{for} \quad T \ge 600 \text{ K}.$$

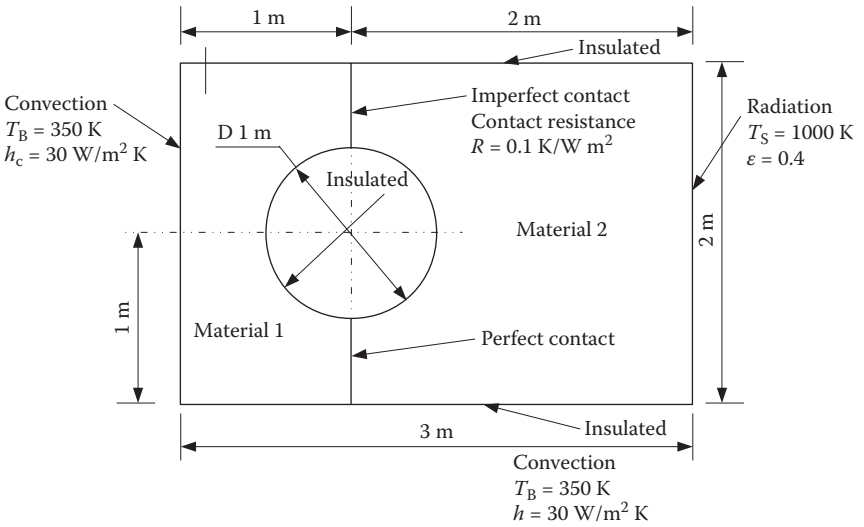

FIGURE 5.4.12 Geometry and boundary conditions of Problem 2.

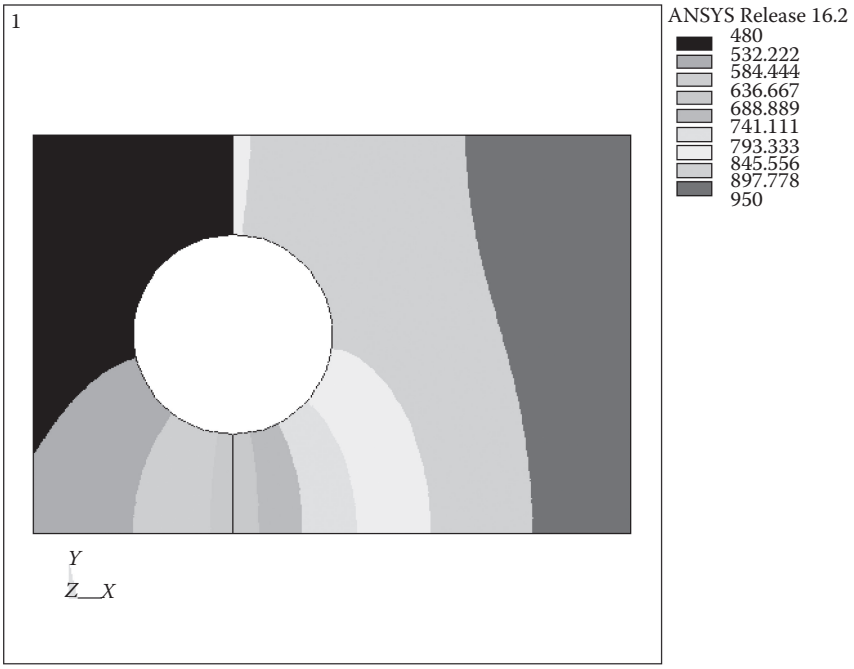

FIGURE 5.4.13 Temperature distribution in the bi-metal plate.

Material 2:

$$k_2(T) = 30 \text{ W/mK} \quad \text{for} \quad T \le 300 \text{ K},$$
$$= 70 \text{ W/mK} \quad \text{for} \quad T \ge 1000 \text{ K}.$$

The thermal conductivity $k_1(T)$ in the interval between [300 K 600 K] is obtained by linear interpolation. Similarly, the thermal conductivity $k_2(T)$ in the interval between [300 K 1000 K] is obtained by linear interpolation. Convective heat transfer takes place from the left edge of the plate, whereas radiation heat transfer takes place at the right edge. All other edges are insulated. It is desired to find the steady-state temperature distribution in the plate. Note that the presence of temperature-dependent heat conductivity and the radiation heat transfer make the problem nonlinear.

The problem is solved using ANSYS, a commercial finite-element software, and the results are shown in Figure 5.4.13.

The geometry is discretized using 4656 six-node triangular elements. The perfect and imperfect interface are modeled using contact elements. A sparse direct solver coupled with the Newton–Raphson scheme is used to solve the set of nonlinear equations. The discontinuity in the temperature field at the imperfect interface is clearly visible in Figure 5.4.13.

5.5 LATTICE BOLTZMANN METHOD

K. Hrisheekesh and Amit Agrawal

Introduction

The lattice Boltzmann method (LBM) is a relatively new approach that offers certain advantages over the traditional computational fluid dynamics to solve the Navier–Stokes (NS) equations. Unlike conventional solvers that directly discretize the NS equations, LBM recovers the NS equations at a macroscopic scale, using simplified kinetic models to capture the essential physics, often with second-order accuracy in both space and time [1]. The inherent parallelism, Poisson freedom, ease of solving multiphase flows, and handling mesoscopic features of the flow make LBM an attractive alternate computational strategy. LBM is suitable for certain classes of problems encountered in practice such as microflows, porous flows, acoustically coupled problems, and so on [2].

Background

The idea that matter was made up of atoms was controversial even at the start of the twentieth century. Philosophers such as Ernst Mach and scientists such as Wilhem Ostwald were opposed to the idea due to the lack of observability of atoms. However, gradually the overwhelming evidence made way for the atomic theory and the kinetic theory of gases was one of its early successes.

In the kinetic theory of gases, molecules are treated as point particles without structure that obey the deterministic Newtonian laws of dynamics. The particles travel in a free path and collide when they meet each other, conserving momentum and energy. Since the rules are deterministic, theoretically, it is possible to track all the molecules in a gas if one knows the position and momentum at the starting time. But the large number of molecules of the order of Avogadro number makes it impossible to track all information about the molecules. Fortunately, all the detailed dynamics is not required for practical purpose. The macroscopic behavior of the system, rather than the motion of individual particles, is of primary interest. Macroscopic quantities can be found by using a suitable averaging process on individual particles. For example, density at a point can be interpreted as the sum of the mass of particles within a small volume located at that point. Similarly, pressure experienced at a wall is interpreted as the momentum exchanged during collision of the molecules with the wall, whereas temperature gives the average kinetic energy of the molecules over a small volume. Transport coefficients can also be assigned a similar interpretation. For example, the momentum exchange between layers of moving fluid gives rise to viscosity while diffusive transport is directly attributed to the random Brownian motion of the atoms.

Lattice Gas Cellular Automaton

Historically, the LBM method evolved from the lattice gas cellular automaton (LGCA) simulations, which in itself was inspired by the kinetic theory of gases. Though no longer used, it is beneficial to understand the basic processes involved in LGCA to appreciate the LBM method itself. Note that the LBM method is at present evolved into a research field of its own and no longer relies on LGCA.

Consider a small control volume of a gas, such as shown in Figure 5.5.1. In the small volume, one can observe atoms that travel in a free path (streaming step) and collide (collision step) when they meet another atom. Under the assumption that the Newtonian mechanics holds and that the interatomic forces are conservative in nature, the collisions conserve both momentum and energy. In real gas, the molecules can collide at any angle and at any velocities indicated by the random arrows in Figure 5.5.1.

In LGCA, the region under consideration is discretized into a lattice, as shown in Figure 5.5.2. This simple lattice, shown in Figure 5.5.2, with a rather square tiling of space with streaming and collision that obey Newtonian dynamics, is known as the Hardy, de Pazzis, and Pomeu automaton, or simply

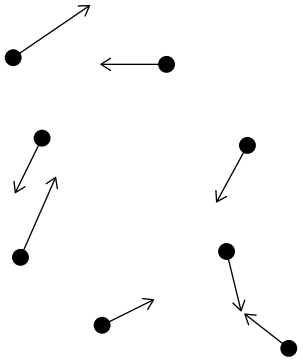

FIGURE 5.5.1 Microscopic picture of real gas molecules colliding and streaming randomly.

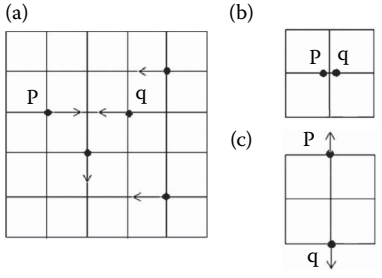

FIGURE 5.5.2 (a) Microscopic picture of a simple lattice gas—collision and streaming at discrete angles, (b) and (c) show the collision process of particles p and q shown in (a). Also known as HPP lattice, microscopic dynamics does not capture the NS equations at macroscopic level.

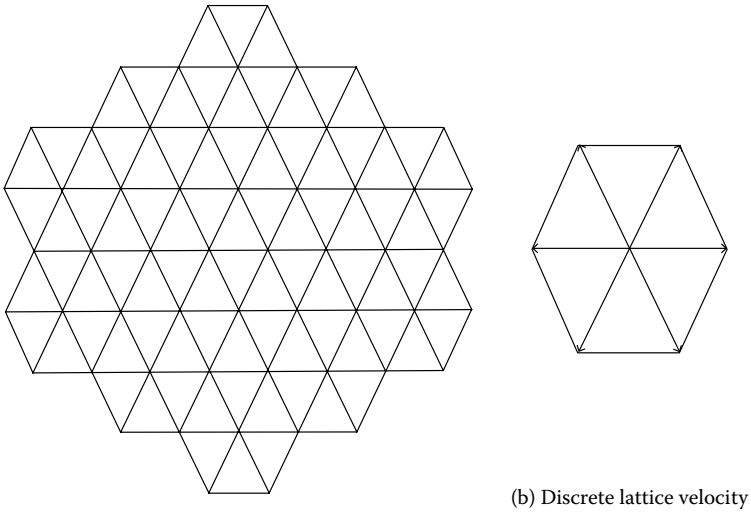
known as HPP automaton [3]. Particles occupy the nodes and have the same mass, m and same velocity magnitude, c. At each time step, they travel from one node to the other through the connected lattice edges along the prescribed direction (streaming/propagation step). When two particles meet at a node, momentum exchange happens and the direction of velocity changes (collision step). During this momentum exchange, the particles obey the mass, momentum, and energy conservation laws.

The crux of LGCA is that the evolution of a system such as the HPP automaton whose underlying microdynamics is more like a cartoon copy of the real molecular dynamics with limited angles of collision and limited magnitudes of speed, can mimic the behavior of fluid on the macroscopic scale. Then suitable microscopic averages can be applied to recover the macroscopic quantities such as pressure and velocity. However, soon after its introduction, it was found that the square lattice was insufficient to capture NS equations on the macroscopic scale. The reason is that such a square lattice does not have enough "angles" or isotropy to capture all the tensor components of the NS equation.

Frisch et al. [4] however showed that a simple automaton can reproduce the NS equations, provided that the lattice has enough symmetry (known as Frisch-Hasslacher-Pomeau (FHP) automaton [4]). It was shown that a hexagon lattice such as the one shown in Figure 5.5.3 has enough symmetry to capture all the tensor components of the 2D NS equation. The essential mechanism remains the same as streaming and collision but the collision rules are more complicated than the HPP automaton. The interested reader can find a comprehensive description of LGCA in the book by Galdrow [19].

However, the LGCA method still had several drawbacks such as the following:

1. Statistical noise—There are statistical fluctuations that may adversely affect evaluation of macroscopic quantities.



(a) FHP lattice

(b) Discrete lattice velocity vectors, FHP

FIGURE 5.5.3 FHP lattice, a lattice with sufficient symmetry to capture the NS equations at the macroscopic scale

2. Lack of Galilean invariance—When the flow Mach number becomes high, the LGCA model displays anomalous problems because of lack of Galilean invariance.
3. Low Reynolds number—The viscosity of the fluid depends on the mean free path of the fluid. In the case of lattice gases, the mean free path is the length of its edges. This dependence of viscosity on lattice geometrical parameters restricts the accessible Reynolds number.
4. Exponential complexity—There is no lattice with enough symmetry for 3D simulations. Thus, a 4D lattice has to be used. This causes the running time to be enormous even for simple problems.
5. Spurious invariants—The invariants for NS equations without sources and sinks are mass, momentum, and energy. But it was found that the LGCA has spurious invariants other than mass, momentum, and energy.

Lattice Boltzmann Method

It was noted that several of the problems of LGCA arise because of the direct use of tracking information for each particle. As mentioned previously, this is mostly unnecessary and one can employ statistical methods to obtain accurate macroscopic information with reduced computational complexity. In the statistical theory of atomistic mechanics, one is no longer interested in individual particles but in the probability of finding an atom of a particular momentum, at a particular location.

Kinetic Theory, Boltzmann Equation, and Chapman–Enskog Procedure

Based on the kinetic theory of gases, Ludwig Boltzmann gave the equation that represents the evolution of the probability density function over time as

$$\underbrace{\frac{\partial f}{\partial t}+\frac{\vec{P}}{m}\frac{\partial f}{\partial \vec{x}}}_{\text{I}}+\underbrace{\vec{F}\frac{\partial f}{\partial \vec{v}}}_{\text{II}}=\underbrace{\left(\frac{\partial f}{\partial t}\right)_{\text{coll}}}_{\text{III}}. \tag{5.5.1}$$

Equation 5.5.1 is central to the kinetic theory of gas and is known as the Boltzmann equation [2]. Here, f denotes the probability of finding a particle at a particular point in phase space, $\vec{P}$ is the momentum of the particle, m is the mass of the particle, and $\vec{F}$ is the externally acting force. In this equation, term I represents the streaming step similar to LGCA, while term II incorporates the effect of external forces such as gravity on the particle distribution function. This term is similar to the one in LGCA but will be omitted for the sake of simplicity. Term III is an important part of the equation that incorporates the effect of intermolecular collisions. In the absence of body forces, the only way for a probability density function to change is through intermolecular collisions. Each of these terms is significant in LBM also and their details will be discussed in a later section.

Solving Equation 5.5.1 is again an arduous task especially because of the nonlinear collision term. Unless an explicit expression for the collision term is given, Equation 5.5.1 would be futile. Boltzmann gave an approximation to the collision term, as a complex integral over phase space, which is however not readily amenable to an analytical solution. Bhatnagar et al. [5] presented a simple way to approximate the collision operator as

$$\left(\frac{\partial f}{\partial t}\right)_{\text{coll}} = \frac{f - f^{\text{eq}}}{\tau}. \tag{5.5.2}$$

In Equation 5.5.2, τ is the time taken for the system to attain thermodynamic equilibrium and is known as the relaxation time. The value of τ depends on the viscosity of the fluid. This timescale is independent of the timescales in macroscopic flow and represents the timescale for transport phenomena at the microscopic level.

The term f^{eq} is known as the equilibrium distribution function. Equation 5.5.1 can be exactly solved for an isolated system in thermal equilibrium. Here, the collision term must vanish as the gain or loss of distribution function due to intermolecular collisions at a point in phase space must be in balance for a system in thermodynamic equilibrium. By imposing mass, momentum, and energy conservation as constraints on Equation 5.5.1, one can obtain the equilibrium distribution function, if one knows the macroscopic variables at that particular location. This is given by the expressions

$$f^{\text{eq}} = \left(\frac{1}{2\pi mkT}\right)^{3/2} \exp\left(-\frac{P_x^2 + P_y^2 + P_z^2}{2mKT}\right), \tag{5.5.3}$$

where k is the Boltzmann constant, T is the temperature of the fluid, P denotes the momentum of the particle, and subscripts denote the direction of each momentum component. Equation 5.5.3 is the well-known Maxwell–Boltzmann distribution function.

The formal procedure to recover the NS equation from Equation 5.5.1 is known as the Chapman–Enskog expansion. The procedure involves multiscale expansion, which separates the microscopic and macroscopic time and length scales and then substitutes the multiscale operators in the relevant moments of the distribution function to obtain the spatiotemporal variations of relevant macroscopic variables. The procedure is too cumbersome to be described here. The reader can find a relatively simple, yet detailed derivation procedure in Ref. [6]. It should be noted that all the concepts that are relevant in the kinetic theory of gases, which are used for obtaining the NS equations, are also relevant to the lattice-based kinetic theory of gases, which will be discussed in the next section.

Lattice Boltzmann Method—D2Q9 as an Example

Next, we will examine the D2Q9 lattice and a relatively simple LBM method to model 2D NS equations. The D in D2Q9 represents the dimensions and 2 represents the dimensionality of the problem; further, Q9 implies that the probability density of nine velocity vectors in the phase space are being tracked. The reader may wonder why there cannot be a D2Q6 lattice, which uses the FHP lattice constraints with six velocity vectors, as in LGCA. It is indeed possible to recover the NS equations with just six velocities in the velocity phase space using a D2Q6 scheme. However, the D2Q9 comes with

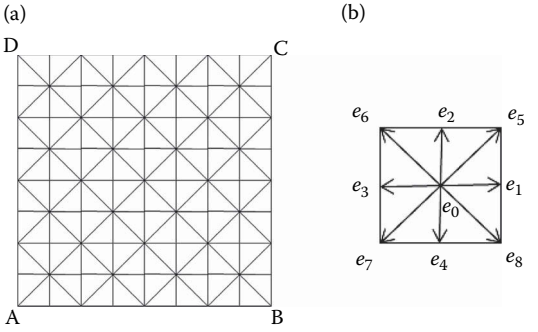


FIGURE 5.5.4 D2Q9 lattice with velocity vectors. The evolution of probability density of these velocity vectors are tracked over time and macroscopic information is recovered as moments of distribution function. (a) D2Q9 Lattice (b) Lattice Velocity Vectors, D2Q9 Scheme.

a rectangular grid that makes it easier to tile the domain and improves the accuracy of the obtained solution. Note that any arbitrary number of velocities is not admissible due to the requirements of lattice symmetry to recover the NS equations. Some of the other well-studied LBM schemes are D1Q3, D1Q5, D2Q9, D3Q15, D3Q19, and D3Q27. The list is not exhaustive. But in general, including more number of velocities in the phase space of LBM increases the computational time at the cost of increase in complexity of implementation. One, therefore, has to strike a balance between cost and accuracy.

The D2Q9 model is one of the popular methods used for solving 2D NS equations using LBM. For the sake of simplicity, it is assumed that no body forces are acting on the fluid. The 2D square lattice has nine discrete velocities for this particular model. The lattice and its discrete velocities are shown in Figure 5.5.4. The crux of LBM lies in calculating the evolution of the velocity distribution function for each of these discrete velocities.

$$\vec{e}_i = \left\{ \begin{array}{lll} (0,\ 0), & & \text{for } i\ = 0 \\ c\cos\left((i-1)\ \dfrac{\pi}{2}\right), & c\sin\left((i-1)\dfrac{\pi}{2}\right), & \text{for } i = 1-4 \\ \sqrt{2c}\cos\left((2i-9)\dfrac{\pi}{4}\right), & \sqrt{2c}\sin\left((2i-9)\dfrac{\pi}{4}\right), & \text{for } i = 5-9 \end{array} \right\}, \tag{5.5.4}$$

where $c = \delta_x / \delta_t$, δ_x is the grid spacing and δ_t is the discrete time step. Usually, unit grid spacing and unit time are used.

The evolution of the particle velocity distribution function, f_i for each of the lattice velocities for a D2Q9 model is given by the following algorithm:

- Initialize: At the start of the simulation, the initial values of macroscopic variables are given. The corresponding values of the equilibrium distribution functions can be calculated from these macroscopic variables over the entire domain.
- Streaming step: From the first step onward, the distribution functions advect from one node to the other along the direction of the corresponding velocity vector. The process is similar to the free motion of molecules in its path without collision (for example, term I in Equation 5.5.1). This step is presented as shown in Equation 5.5.5.

$$f_i\left(\vec{x}+\vec{e}_i, t+\delta_t\right) = f_i\left(\vec{x}, t\right). \tag{5.5.5}$$

- Collision step: The particles at the node collide and similar to that in LGCA, momentum exchange occurs and change in the velocity distribution functions takes place. The change in

the velocity distribution function for each velocity, due to collision, is accounted for by applying the collision operator at the local node. Here, the Bhatnagar-Gross (BGK) approximation, similar to that shown in Equation 5.5.2, is applied at each lattice. The collision step is given as

$$f_i(\vec{x},t) = f_i(\vec{x},t) - \frac{f_i(\vec{x},t) - f_i^{\text{eq}}(\vec{x},t)}{\tau}. \tag{5.5.6}$$

- The parameter τ is known as the relaxation time and is linked to the kinematic viscosity as $\vartheta = (2\tau - 1)/6$. $f_i^{\text{eq}}(\vec{x},t)$ is the equilibrium distribution function for the corresponding velocity vector $\vec{e}_i$ and can be computed once the macroscopic variables at that node are known.

$$f_i^{\text{eq}}(\vec{x},t) = \rho w_i \left(1 + \frac{(\vec{e}_i \cdot \vec{u})}{C^2} + \frac{1}{2}\frac{(\vec{e}_i \cdot \vec{u})^2}{C^4} - \frac{1}{2}\frac{(\vec{u} \cdot \vec{u})}{C^2}\right), \tag{5.5.7}$$

where ρ is the density, $\vec{u}$ is the macroscopic velocity vector at location $\vec{x}$, and w_i is a weightage factor that depends on the velocity magnitude (w_i=4/9 for i=0, w_i=1/9 for i=1 – 4, w_i=1/36 for i=5 – 8). The macroscopic variables can be computed once all the f_is are known at each node

$$\rho = \sum_{i=0-8} f_i, \rho\vec{u} = \sum_{i=0-8} f_i \vec{e}_i, P = \rho C^2. \tag{5.5.8}$$

Here, $C = 1/\sqrt{3}$ is the speed of sound for the D2Q9 lattice and P is the hydrostatic pressure. Note that the pressure is recovered through its relationship with density. It recovers the NS equations with an error proportional to the square of the Mach number. As long as the velocity scales in the lattice are negligible compared to the lattice speed of sound, the D2Q9 scheme recovers the NS equations in the incompressible limit.

- The propagation and collision steps are repeated until the specified time.

It can be shown using the Chapman–Enskog procedure applied to the lattice that the algorithm recovers the fully compressible NS equation as given here:

$$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u}{\partial x} + \frac{\partial \rho v}{\partial y} = 0, \tag{5.5.9}$$

$$\frac{\partial \rho u}{\partial t} + \frac{\partial \rho uu}{\partial x} + \frac{\partial \rho uv}{\partial y} = -\frac{\partial p}{\partial x} + \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{xy}}{\partial y}, \tag{5.5.10}$$

$$\frac{\partial \rho v}{\partial t} + \frac{\partial \rho uv}{\partial x} + \frac{\partial \rho vv}{\partial y} = -\frac{\partial p}{\partial x} + \frac{\partial \sigma_{yx}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y}. \tag{5.5.11}$$

In the aforementioned equations, the pressure and velocity are linked through an isothermal equation of state $p = \rho C^2$. One advantage of the compressible formulation is that the LBM can be used in direct acoustic simulations.

Note that Equation 5.5.7 used for calculating the equilibrium function is a truncated series expansion of Equation 5.5.3. This way of calculating the equilibrium preserves the lattice symmetry requirement needed to recover the NS equation and is simpler than calculating the exponential function. However, this introduces a small error in the viscous term in the derived equations, which is proportional to Ma^3, where Ma denotes the Mach number of the flow. It should be noted that the

LBM method is fully compressible in nature and can therefore describe compressible phenomenon such as pressure wave propagation as well. However, the Mach number is restricted to low subsonic flow ($Ma < 0.3$) due to the isothermal nature of the flow and also due to the error in the viscous term owing to the approximation in the equilibrium distribution.

Accuracy and Stability

The LBM method is more faithful to the original kinetic equation 5.5.1 than to the NS equation [7]. Further, unlike conventional solvers, LBM does not discretize the spatiotemporal terms of the NS equations directly. Essentially, there are two ways to describe the accuracy for LBM. In the first case, LBM is viewed as a discretization of the Boltzmann equation and its accuracy is evaluated with respect to the Boltzmann equation. It is second-order accurate in space and time, when considered as the discretization of the Boltzmann equation [1]. However, when applied to macroscopic problems, the accuracy is compared with similar problems that are solved with conventional solvers. Succi [1] stated that for simple problems with turbulence, LBM gives quasi-spectral accuracy. Marie et al. [8] have studied the LBM method for the acoustic problem and found that the LBM is less dissipative than high-order schemes and less dispersive than a second-order scheme in space with a three-step Runge–Kutta scheme in time. Suffice to say that by using the LBM method, one can obtain, in general, second-order accuracy in both space and time for NS equations as well, though in certain cases, it can give exceedingly better accuracy.

It should be noted that similar to conventional solvers, the LBM method is also subjected to stability issues. For example, in the D2Q9 scheme with the BGK collision term, the problem becomes unstable if the value of relaxation time τ is less than 0.5. This lower limit on relaxation time simply implies that viscosity cannot be zero. In practice, the stability issue arises at a finite viscosity close to zero. One way to improve the stability of the LBM method is to use a collision operator that uses multiple relaxation times (see d'Humières [18]), instead of a single relaxation time employed in the BGK model [9]. In addition, there is also the entropic LBM that uses the counterpart of the H-theorem in kinetic theory, which asserts that kinetics of atomic motion proceeds to decrease the quantiy H, defined as $\int f \ln f d^3v$, to improve the stability of the algorithm [1].

Boundary Conditions in LBM

In a fluid dynamics problem, proper implementation of boundary conditions (BCs) is essential for obtaining the flow field solution. Usually certain macroscopic variables are specified on the boundary. One simple way to implement the BCs is to compute the equilibrium distribution function at the boundaries and propagate those distribution functions to the interior. Usually, such approaches have first-order accuracy. There are several other approaches as well, such as the Zou–He method, Inamuro method, regularized BC (see Zou–He [21] and Latt [10]). In all methods, the primary issue in implementing the BCs is computing the incoming particle velocity distribution functions. Some of the commonly used macroscopic BCs and their implementation are discussed in the following subsections.

No-Slip Wall

The no-slip BC is obtained using the bounce-back scheme. In the bounce-back scheme, the particle hits the wall and reverses the velocity as shown in Figure 5.5.5. Therefore, the corresponding distribution functions also reverse. The bounce-back scheme on the macroscopic scale retrieves the no-slip BC. Usually, the wall is assumed to be in mid-grid so that the bounced-back particle reaches exactly back into the adjacent fluid node. The mid-grid scheme has second-order accuracy [2]. The on-grid scheme is also possible but the accuracy reduces to first order.

Slip Wall

The slip BC is implemented easily using specular reflection (see Figure 5.5.6). Often in microflows, partial bounce back and reflection are employed to obtain Maxwell's BCs at the wall.

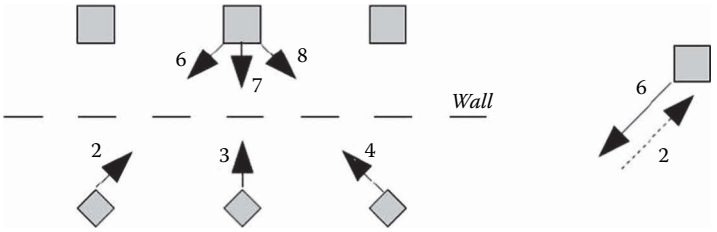

FIGURE 5.5.5 The shaded squares represent the fluid nodes adjacent to wall. The diamond nodes are solid nodes. The population f_6 strikes the wall reverses the momentum and bounces back as f_2 at a macroscopic level this is equivalent to no slip boundary condition.

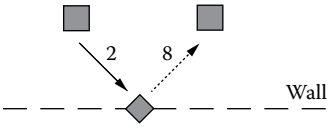

FIGURE 5.5.6 The shaded squares represent the fluid nodes adjacent to the wall. The diamond nodes are solid nodes. The population f_2 strikes the wall and reflects in a specular manner to reach f_8 at the adjacent fluid node. It retrieves slip boundary conditions at the macroscopic scale.

Velocity BCs

At velocity inlet, all velocity components are known. Once again, the equilibrium distribution functions can be calculated and propagated inward. However, there are also other methods such as the Zou–He, Inamuro BCs that can give better accuracy than simply using equilibrium distribution functions. Description of these methods is beyond the scope of the present work. The reader can refer to Latt [10] for details.

Periodic BC

In the periodic BC, the particles that leave from part of the system enter through the other part of the system. This is most readily implemented by supposing the periodic boundary nodes as adjacent to each other and exchanging distribution functions accordingly. For example in Figure 5.5.5, the particles that leave face BC enter through AD when periodicity along horizontal direction is required.

It should be noted that the BCs listed here are some of the simple BCs encountered in practice. When more complex BCs are encountered, one can always use the corresponding macroscopic information and use suitable interpolation and extrapolation schemes to achieve higher order accuracy. Characteristic-based methods and incorporation of acoustic BCs for aeroacoustic calculations are some of the new developments in BC implementation of LBM methods.

Example Problems

The LBM method eliminates almost all the difficulties associated with LGCA. The simplicity in implementation and high parallelizability of both streaming and collision steps involved in the algorithm imply that LBM can be efficiently used in modern-day parallel machines. Already several open-source implementations of LBM such as OpenLB [12], Palabos [13], and Sailfish [14] provide fully parallel, efficient CPU/GPU (central processing unit/graphics processing unit) implementation of several LBM models. Snapshots of some of the practical and complex problems which were solved using LBM are given in Figures 5.5.7 through 5.5.9 taken from references [15–17] respectively. The interested reader can get hands-on experience of the LBM method with the use of open-source programs (see Refs. [12–14]) that are freely available and fairly well documented.

Concluding Remarks

During the past three decades, LBM has transgressed from just a novel approach to solve NS equations to a solver that is capable of solving industrial level problems. Already both commercial and open-source libraries (see Refs. [11–13]) are available in the market, which use the inherent strengths of LBM such as simplicity and ease of parallelization. The research aspect of LBM is also currently strong, with the use of novel thermal models, multiphase flows, turbulence modeling,

non-Newtonian fluid flows, and so on. Owing to the several advantages of LBM discussed here, we expect the use of this technique for computation of fluid flow and thermal problems to grow further with time.

5.6 IMMERSED BOUNDARY METHODS FOR FLUID-STRUCTURE INTERACTION SIMULATIONS

Rajneesh Bhardwaj and Atul Sharma

Introduction

Immersed boundary (IB) methods refer to a class of methods in which the flow and/or structure dynamics of an "immersed" or "embedded" structure, inside a fluid domain, is solved on a standard coordinate (mostly Cartesian)-based grid—the grid does not conform to the shape of the structure [1]. The method is more commonly used for moving as compared to stationary structures. The computational modeling of such *moving boundary* or *fluid–structure interaction* (FSI) problems involves calculation of fluid dynamic forces exerted on the immersed complex geometry structures, which may result in large-scale flow-induced structural deformation. The structure typically exhibits geometric as well as material nonlinearity and should be accounted for in the modeling of such systems. In the case of biological systems, the structures may be multilayered, anisotropic, and heterogeneous, and this increases the complexity of modeling the structure dynamics. Typical examples include flow-induced vibration of vocal folds in the larynx [2], cardiac hemodynamics [3], fish fins during propulsion [4,5], deformation of mitral and aortic valves by blood flow [6], deformation of insect wings [7], interaction of a blast wave with the human eye [8,9], energy harvesting devices [10], thermoregulation in elephants via flapping of their large ears [11], thermal transport enhancement in microchannels using oscillating synthetic cilia [12], and thermal augmentation using vortices generated due to flow-induced deformation of thin structures [13,14].

The other class of methods, known as arbitrary Lagrangian–Eulerian (ALE) methods, involves body-fitted grids conforming to the shape of the body. The grids for ALE and IB methods in the fluid domain are compared in Figure 5.6.1. The ALE method uses the Lagrangian formulation of the Navier–Stokes equations for structure dynamics and the Eulerian formulation of the Navier–Stokes equations for fluid dynamics [15–17]. The two formulations are employed with a weak coupling or a strong coupling. The main issue, however, is the time-wise distortion of the body-fitted grid during a remeshing procedure—needed to ensure a body-fitted grid around the moving structure. In this regard, Tezduyar et al. [18] proposed an ALE finite-element formulation for the fluid as well as the structure domain in which the remeshing criterion was based on element size. Furthermore, Souli et al. [19] used an ALE formulation with smoothing algorithms to control the distortion of the mesh. The time-wise varying grid generation requires more computational time, and it may introduce numerical errors due to the mapping of the solution from the old to the new grid.

On the other hand, in IB methods, the governing flow and structure equations are solved on a time-wise fixed non-body-fitted Cartesian grid. Fluid–structure interface is tracked in Lagrangian framework; except some recent work, such as that by Shrivastava et al. [20], which uses the level-set method on an Eulerian equation for the interface evolution. IB method was proposed by Peskin [21,22] to simulate cardiovascular dynamics, and this method and its variants such as distributed Lagrangian multiplier/fictitious domain (DLM/FD) methods, have been reported and utilized for solving several problems (see review on IB methods in Refs. [1,23,24]). Note that the IB method can easily be integrated into the existing flow solvers based on finite-difference methods [25–30].

In the case of the body-fitted grid, since the solid–fluid interface coincides with the boundary of the solid, the implementation of the solid wall boundary condition is straightforward. This is also true for the finite-volume method based on implementation of the conservation laws in the fluid control volumes (CVs); whereas, in the case of the non-body-fitted Cartesian grids in IB methods, partially filled (containing both fluid and solid) CVs that are encountered here need special treatment to ensure compliance with the conservations laws. Special treatment is also needed to accurately implement a boundary condition (BC) at the moving solid–fluid interface. Furthermore, a solid CV,

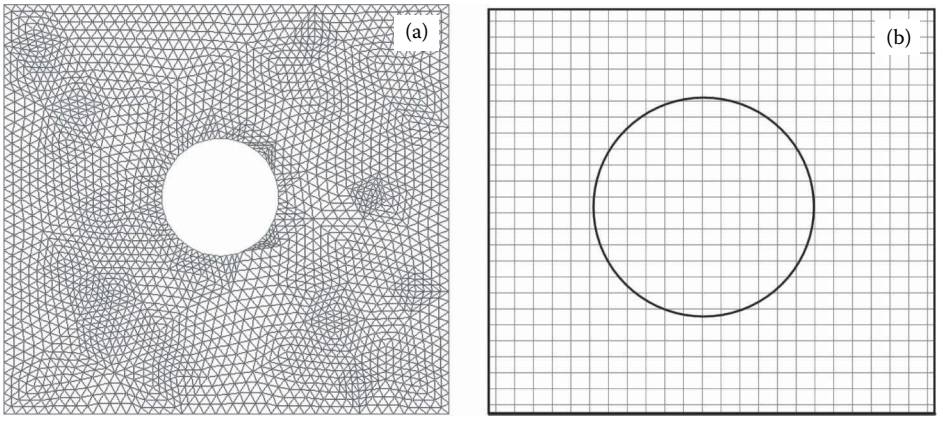

FIGURE 5.6.1 (a) Body-fitted time-wise varying unstructured grid for the ALE method and (b) non-body-fitted fixed Cartesian grid for the IB method.

a fluid CV, and a partially filled CV may interchange their identification as time progresses in a moving boundary problem. This is because certain solid CVs get exposed to fluid, and vice versa. Thus, the type of CV changes with time and needs to be properly accounted for in the IB method.

The advantages of the IB method are the simplicity of the grid (Cartesian), ease of programming due to well-defined discretization stencil, ease of computation due to numerically well-behaved coefficient matrix and reduced computation effort per grid point, and no remeshing needed for a moving boundary problem. On the other hand, some of the disadvantages include special treatment for the imposition of BCs and no control on the grid for local clustering (refinement of the grid locally).

Miital and Iaccarino [1] classified IB methods into two broad categories, namely, *continuous forcing approach* and *discrete forcing approach*. In the former, the effect of fluid–structure interface is modeled using a source term in the momentum equation. On the other hand, in the latter, the governing equations are first discretized on the Cartesian grid without treating the IB; further, discretization in the cells near the IB is adjusted for the presence of IB [1]. Due to the smoothening of the forcing function that is required across the IB in the continuous forcing approach, sharp representation of IB is not possible [1] and sometimes, this approach is referred to as the *diffuse-interface IB method*. In the discrete forcing approach, since the IB is directly treated, it is referred to as the *sharp-interface IB method*.

The sharp-interface discrete-forcing approach is further classified mainly as *ghost-cell method* and *cut-cell method*; the latter method is based on the finite-volume approach and the former method is mostly dependent on the finite-difference method. Furthermore, in the former method, the relevant boundary conditions (BC) at the IB are applied (on the ghost grid points) through an interpolation stencil; while in the latter, cells that are "cut" by IB are identified and absorbed by the neighboring cells. The cut-cell method uses the body-fitted grid for a layer of CVs enveloping the solid body and Cartesian CVs in the other regions. The main advantage of the cut-cell method over the ghost-cell method is the improvement in the global and local conservation of mass and momentum. However, extending the cut-cell method to three dimensions, reshaping/reconstruction of CVs, and discretization of the full Navier–Stokes equations on such CVs can prove to be difficult for complex shaped structures. Both the ghost-cell and the cut-cell methods use a Lagrangian method for the time-wise variation of the solid–fluid interface; whereas, a recent level set-based IB method [20] uses an Eulerian level-set equation for the temporal evolution of the interface.

The scope of this chapter is to present both CFD development and application aspects of the IB method. For the CFD development, both the diffused-interface continuous-forcing and sharp-interface discrete-forcing approaches are presented. Furthermore, the discrete forcing approach is presented for three different methods: ghost-cell, cut-cell, and level set-based IB methods.

Thereafter, advanced modeling issues in the IB method are presented for the treatment of moving boundaries and coupling with a structural solver. The CFD application of the IB method is treated for both rigid and deformable moving structures, considering some scientifically exciting and engineering-relevant fluid dynamics and heat-transfer problems.

Continuous Forcing Approach

In this approach, the fluid flow is governed by the incompressible Navier–Stokes equations, which are solved on a stationary Cartesian grid. The governing equations are given as

$$\frac{\partial v_i}{\partial x_i} = 0, \tag{5.6.1}$$

$$\frac{\partial v_i}{\partial t} + \frac{\partial v_i v_j}{\partial x_j} = -\frac{1}{\rho}\frac{\partial p}{\partial x_i} + \nu \frac{\partial^2 v_i}{\partial x_j^2}, \tag{5.6.2}$$

where $i, j = 1, 2$, and 3; v_i are the velocity components, p is the pressure, ρ is the fluid density, and ν is the kinematic viscosity. In this approach, the forcing function (f_b) is included as a source term in the aforementioned continuous governing equations, $L(U) = f_b$. The resulting equations are solved for the whole domain ($\Omega_f + \Omega_b$). Note that $f_b = (f_p, f_m)$, where f_p and f_m are forcing functions applied to the continuity and momentum equations, respectively. Thus, in the continuous forcing approach, forcing is applied to the continuous governing equation before discretization. The application of this (continuous forcing) approach to the elastic and rigid structures are presented separately in the following subsections.

Elastic Structure

The continuous forcing IB method was proposed by Peskin [21,22] to simulate a coupled FSI involving blood flow and muscle contraction in a beating heart; it is generally suitable for flows with immersed elastic boundaries. The IB (wetted surface of the blood vessels) is represented by a set of elastic fibers, and the location of these fibers is obtained in a Lagrangian fashion. The effect of IB on the surrounding fluid is captured by a force distribution f on these fluid particles, calculated using a constitutive model, say Hooke's law, and it can be represented in terms of the Dirac delta function, δ, as follows [1]:

$$\vec{f}(\vec{x}, t) = \sum_k \vec{F}(t)\delta\left(\left|\vec{x} - \vec{X}_k\right|\right), \tag{5.6.3}$$

where the coordinate X_k of the kth Lagrangian particle is expressed as [1]

$$\frac{\partial \vec{X}_k}{\partial t} = \vec{u}(\vec{X}_k, t). \tag{5.6.4}$$

The localized force term is used as a source term in the Navier–Stokes equation. Providing sharp interface at the IB by the Dirac delta function creates a numerical instability during the numerical solution of the Navier–Stokes equation. Thus, as discussed by Xu and Wang [31], the communication between the fluid and the IB is realized by spreading the force from the Lagrangian grid to the Cartesian grid and interpolating the velocity from the Cartesian grid to the Lagrangian grid.

As discussed by Mittal and Iaccarino [1], since the locations of the Lagrangian particles do not coincide with the Cartesian grid, the forcing function is distributed over a band of cells around each Lagrangian particle and requires smoothing of the forcing function across the IB. Thus, the representation of the IB is diffused and not sharp. The choices of several distribution functions are available in a review paper [23].

Rigid Structure

The aforementioned method for the elastic structure is applied for the rigid structure by considering the fiber to have high stiffness. Consequently, the governing equations of the fluid motion become very stiff and pose numerical difficulties in obtaining their solution.

Another approach to solve for a rigid structure is to employ a specific version of the model developed by Goldstein et al. [32]. This model gives good results at low Reynolds number but leads to stability problems at high Reynolds numbers.

Discrete Forcing Approach

The governing equations for the flow are 3D, unsteady, incompressible, Navier–Stokes equations, described by Equations 5.6.1 and 5.6.2. As discussed earlier, this approach can be classified into three categories, namely, ghost-cell, cut-cell, and level set-based IB method; each of these is dealt with separately in the ensuing subsections.

Ghost-Cell-Based IB Method

In a significant paper, Mittal et al. [27] proposed a sharp-interface IB-based method, where the Navier–Stokes equation (Equation 5.6.2) are discretized in space using a cell-centered, colocated (non-staggered) arrangement of primitive variables u_i and p. A second-order central difference method is used for all spatial derivatives, and the time integration is performed with the second-order Crank–Nicolson method for the convective and viscous terms. In addition, the face-center velocities, U_i, are computed as proposed by Zang et al. [33], to improve the mass conservation.

The unsteady Navier–Stokes equation is time-marched using a fractional step scheme, which involves two steps: solving an advection–diffusion equation followed by a pressure Poisson equation. During the first step, both the convective and the viscous terms are treated implicitly using the Crank–Nicolson scheme to improve the stability. In the second step, the pressure Poisson equation is solved with the constraint that the final velocity be divergence-free. The surface of the immersed body is represented as an unstructured surface mesh that consists of triangular elements (Figure 5.6.2), immersed in a nonuniform Cartesian grid-based fluid domain.

The ghost-cell method involves first a Lagrangian technique (ray tracing algorithm) for the representation of an instantaneous interface (by identifying the solid and fluid grid points); then, the method leads to the identification of the ghost from the solid grid points; and finally, obtaining the image of the ghost grid points. The resulting solid, fluid, ghost, boundary intercept, and image grid points are shown in Figure 5.6.3. The figure shows the ghost grid points as those solid grid points that have at least one neighboring CV in the fluid. In the method of Mittal et al. [27], a "normal probe" is extended from a ghost grid point to intersect with the immersed boundary at a point, called as the "body intercept", shown in Figure 5.6.3. The probe is extended into the fluid to the

FIGURE 5.6.2 Typical surface mesh with triangular surface elements is shown for a plate attached to a cylinder and can be used in the sharp-interface IB-based method proposed by Mittal et al. [27].

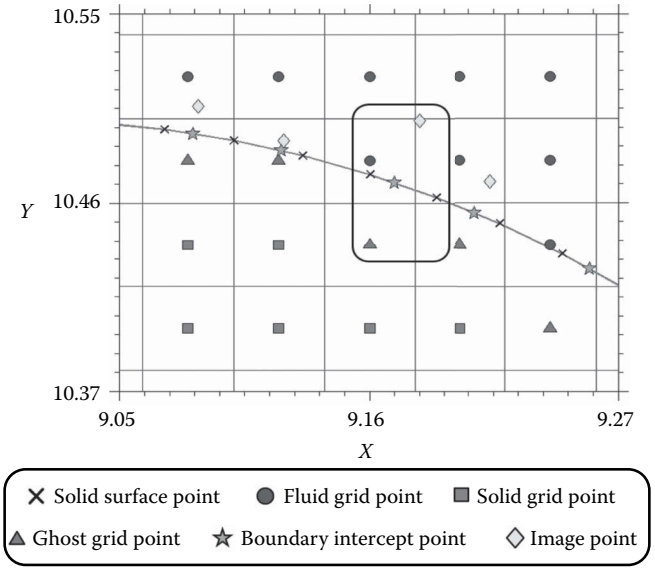

FIGURE 5.6.3 Different types of grid points defined for the implementation of the ghost-cell-based IB method [26].

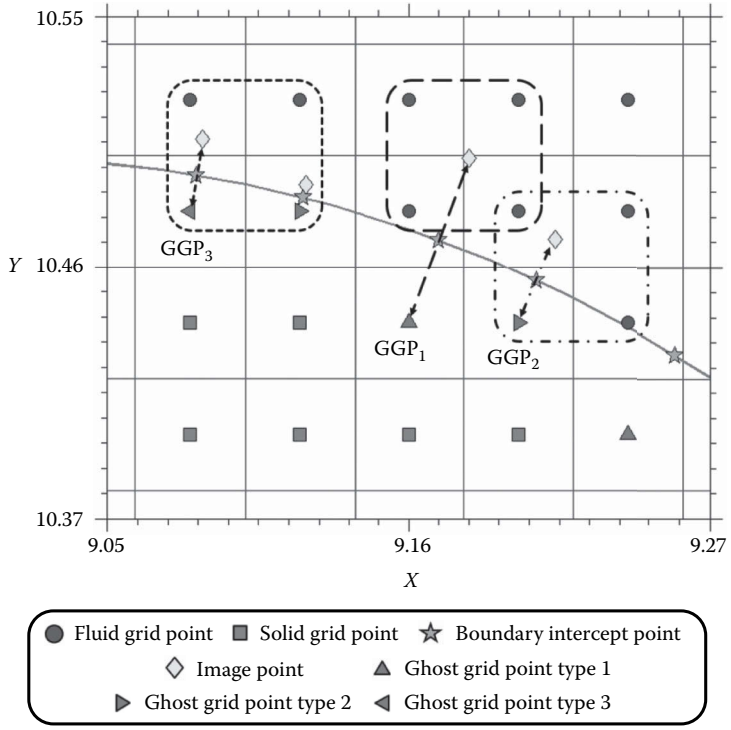

FIGURE 5.6.4 Three different types of ghost grid points, corresponding to the explicit or implicit computational stencil for the bilinear interpolation based on determination of their image point values [26].

"image point" such that the body intercept lies midway between the image and the ghost points, shown in Figure 5.6.3.

Figure 5.6.4 shows three different types of *computational stencils,* for the computation of the flow properties at the image point, which results in the three types of ghost grid points. The various types of ghost grid points, shown as GGP_1 and GGP_2 (and GGP_3) in the figure, lead to an explicit and implicit computation for the flow properties at the image point, respectively. The computation involves bilinear (for 2D here) or trilinear (for 3D) interpolation procedure, using the neighboring grid point values seen in the stencils. The interpolated value of the flow properties at the image point is used to determine the ghost grid point values for the imposition of the solid wall boundary condition (Dirichlet or Neumann type). As shown by Mittal et al. [27], this procedure leads to a nominally second-order accurate specification of the boundary condition of the immersed boundary.

Cut-Cell-Based IB Method

All the IB methods discussed earlier are not designed to satisfy the governing equations for the cells in the vicinity of the IB. The local and global conservation of mass and momentum can only be achieved by application of the finite-volume method to discretize the governing equations. This is the primary motivation of the cut-cell method.

In this method, the cells cut by IB and their centroids are identified. The region (solid or fluid) in which the cell center of the cut cell lies is treated as an independent cell and the other part of the cut cell is merged with the neighboring (fluid or solid) cell. This results in the formation of control volumes, which are of trapezoidal shape near the IB.

For the finite-volume method, one needs to evaluate mass, momentum, and pressure flux across the cell faces; the problem arises in evaluating these fluxes for the trapezoidal faces. To overcome this difficulty, Ye et al. [34] proposed a method to express any generic variable (ϕ) at the cell centers in terms of the neighboring cell values by a polynomial interpolation. The local accuracy of this method near the IB depends upon the choice of the interpolation scheme.

The cut-cell finite-volume approach was first introduced by Clarke et al. [35] and was later applied to viscous flows [34,36–38]. This method improves the global and local mass and momentum conservation as compared to the other methods. The extension of the cut-cell approach to 3D geometries is not easy because it leads to complex polyhedral cells and discretization of the Navier–Stokes equations on such cells is difficult [1]. Recently, Seo and Mittal [39] used a 3D cut-cell-based approach to enforce the geometric conservation law near the IB thereby reducing the spurious pressure oscillations due to the freshly cleared cells.

Level Set-Based IB Method

Level-set method [40] (LSM) is a widely used numerical technique for the unsteady computations of moving boundaries, not only for fluid dynamics but also for various other problems in science and engineering. For fluid dynamics, LSM was first used for the simulation of the unsteady two-phase interface in a multiphase flow situation (presented in the next section). More recently, the level-set method has been used in the IB method as the Eulerian method for tracking the unsteady solid–fluid interface; this is because the LSM is relatively easier to implement numerically as compared to the Lagrangian approach (commonly used in the ghost-cell and cut-cell methods); and it is relatively easier to implement the BC at the moving solid wall.

Choi et al. [41] and Tan et al. [42] have used the level-set method, using a discrete forcing function in the momentum equation on a Cartesian grid. Using the cut-cell method, Cheny and Botella [43] presented the level set-based IB method where the level-set function is used to represent the irregular boundary and to efficiently compute the geometrical parameters of the cut cell.

More recently, for the Cartesian grid, Shrivastava et al. [20] presented a *level set-based finite-volume IB method* where the level-set function was used for the sharp representation of the time-wise varying solid–fluid interface, and for an efficient implementation of Neumann BC at the moving boundary. Furthermore, the level-set function was used for the efficient computation of

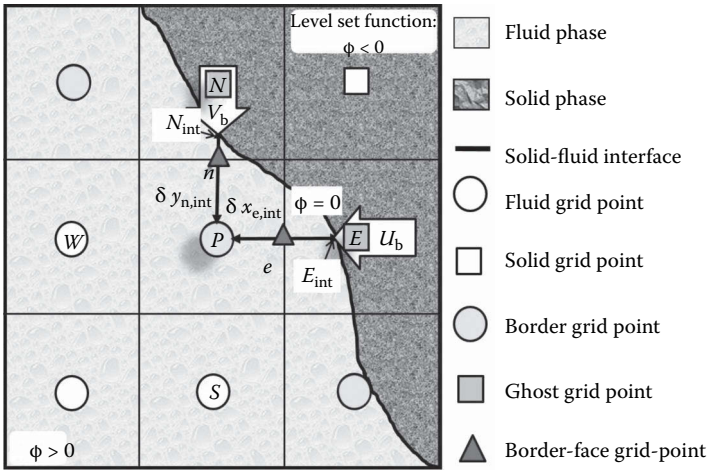

FIGURE 5.6.5 Level set-based representation of the interface and identification of the various types of grid points for the level set-based IB method [20].

the volume flux, advection flux, and diffusion flux during the implementation of the finite-volume method for the CV at a *border grid point* (Fig. 5.6.5)—the grid point in the fluid phase with at least one neighboring point in the solid phase.

For the computation of the various fluxes at those faces of the border CV adjoining the solid boundary, the solid wall BC is *directly* implemented, as discussed in the following. This is in contrast to that in the ghost-cell method, which involves an indirect implementation of the BC through the ghost grid point—not directly using the BC at the solid surface grid point (Fig. 5.6.3). Considering both the border and the ghost grid points, called interfacial points, Marella et al. [44] presented a level set-based IB method.

The interface along with the different types of grid points considered in the level set-based IB methods [20] are shown in Figure 5.6.5. For a border CV, the figure shows $\delta x_{e,int}$ and $\delta y_{n,int}$ as the distances used to compute the diffusion flux at the east and north face center—defined as the border face grid point. For these face centers, the solid wall velocity, U_b and V_b, shown in the figure are considered for the computation of momentum flux and volume flux during the solution of the momentum and continuity equations, respectively. Furthermore, during the solution of the pressure Poisson equation at the border face grid point, they [20] considered the temporal variation of the solid wall velocity and the distances ($\delta x_{e,int}$ and $\delta y_{n,int}$) while implementing a normal gradient BC for the pressure at the solid wall during the solution of the pressure Poisson equation. Thus, the solid wall BC is implemented directly in the level set-based IB method as opposed to the indirect implementation of BC in the ghost-cell-based IB method.

For the LS-based IB method, Shrivastava et al. [20] used the finite-volume method for the Navier–Stokes equations and the finite-difference method for the level-set equations; and a fully implicit and explicit method for the solution of the respective equations on a colocated Cartesian grid. They used the projection method for the solution of the pressure. For the spatial discretization, they used the fifth order Weighted Essentially Non-Oscillatory (WENO) scheme for the level-set equations, Quadratic Upstream Interpolation for Convective Kinematics (QUICK) scheme for the advection term, and central-difference scheme for the diffusion term of the momentum equations.

Numerical Modeling Issues for the IB Methods

Treatment of Moving Boundaries

Due to the motion of the solid–fluid interface in a fluid domain, a grid point that is in the solid at the previous time level n, emerges in the fluid at the present time level $(n+1)$; or vice versa [27]. This is

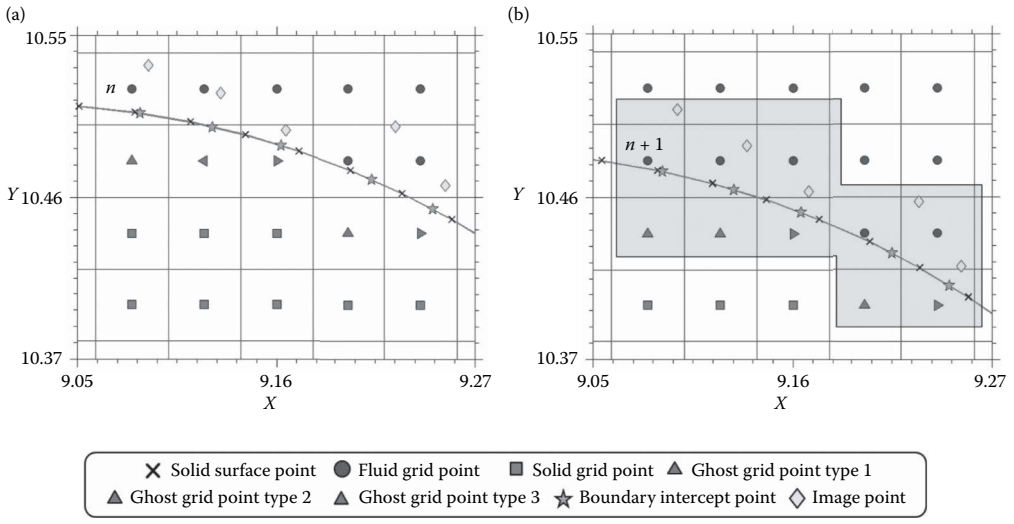

FIGURE 5.6.6 Boundary position and different points at (a) nth and (b) $(n+1)$th time step, for a downward motion of the solid body [26].

shown in Figure 5.6.6 for a downward motion of the interface, along with the time-wise change in the identity of the various grid points: ghost (of three different types), image, and boundary intercept. Note that the grid points that change their identity are shown inside the enclosed region in the figure, for the present time level $(n+1)$.

During the time interval Δt, the change in the identity of grid points from the solid phase to the fluid phase is called as the freshly cleared grid points. They are shown in Figure 5.6.7, where a freshly cleared grid point in the present time level $(n+1)$ was a ghost grid point in the previous time level n. The previous time level value of the flow property, needed for the computation of the property at the

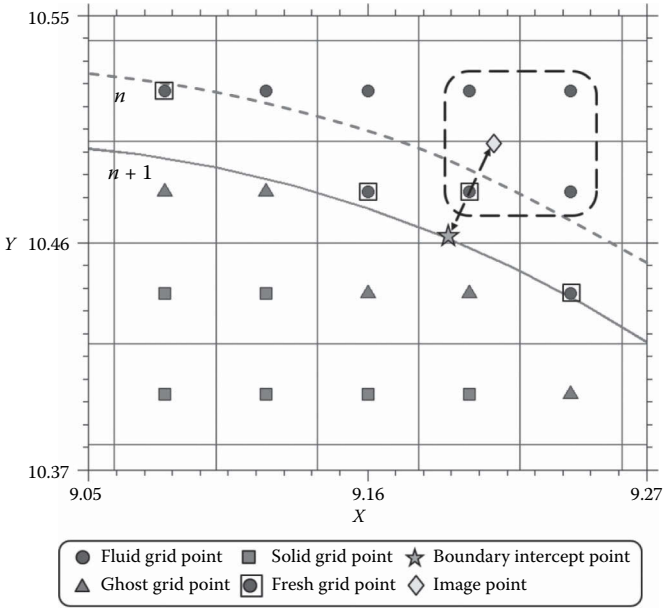

FIGURE 5.6.7 Appearance of freshly cleared grid points, after a time step, due to the motion of the boundary; and the associated computational stencil for the interpolation [26].

present time level, is obtained by the bilinear interpolation [27]; the computational stencil for the interpolation procedure is also shown in Figure 5.6.7. This treatment of the freshly cleared cell is known to result in spurious pressure oscillations. Seo and Mittal [39] used a cut-cell-based approach to enforce geometric conservation near the immersed boundary, which reduces the spurious oscillations.

Coupling with a Structure Dynamics Solver

Many previous studies have either considered rigid moving structure boundaries or ignored the internal stresses in the structure. In the latter case, a membrane of zero mass was introduced for the sake of computational tractability. However, if the structure dynamics is important and coupled with fluid dynamics, the structure solver needs to be coupled with the IB-based fluid dynamics solver. In general, for the coupling of the two solvers, there are two approaches: monolithic approach and partitioned (or segregated) approach (see Figure 5.6.8a). In the monolithic approach, the governing equations for the flow and structure domains are discretized together, and the nonlinear system of equations is solved as a whole. In the partitioned approach, the existing flow and structures solvers are utilized. However, implementation of the data exchange between the two solvers in the partitioned approach is not trivial and in general, a two-way coupling is needed to ensure the numerical stability of the FSI solver. The data exchange and algorithm in the partitioned approach are shown using a schematic in Figure 5.6.8b and c.

In order to couple the fluid and structure solvers, two coupling methods are generally utilized—explicit (or weak, one-way) coupling, and implicit (or strong, two-way) coupling, which integrate the governing equations of the flow and the structure domain explicitly and implicitly in time, respectively. The explicit coupling is computationally inexpensive and may be subject to stability constraints, which depends on the structure–fluid density ratio (ρ_s/ρ_f) [30]. The implicit coupling is needed for cases where the structure will respond strongly even with small perturbations from the fluid and vice versa; it is computationally expensive.

Some examples utilizing such coupling schemes are described here. Zheng et al. [30] proposed an FSI method, which weakly couples a sharp-interface IB method-based flow solver with a

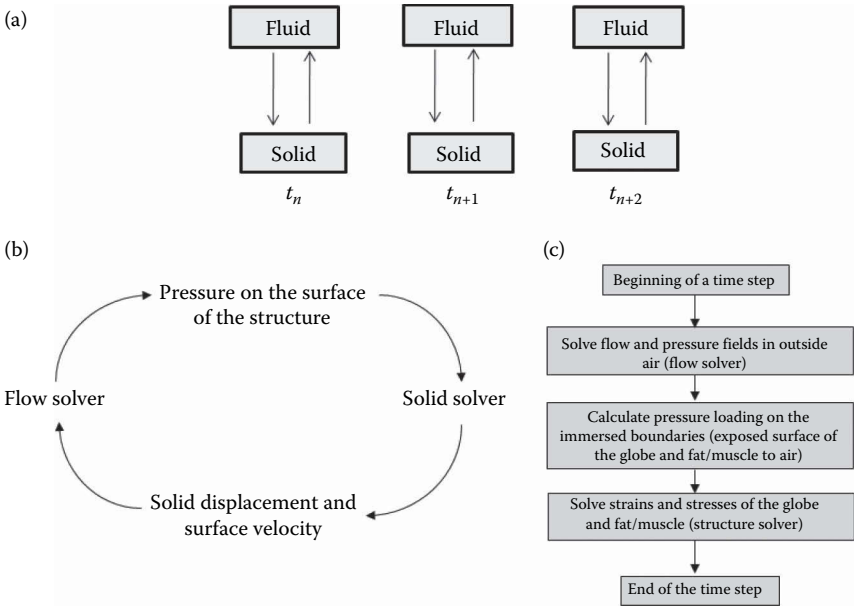

FIGURE 5.6.8 (a) Partitioned approach, (b) data exchange between flow and solid solver, and (c) algorithm of FSI solver. (Copyright Springer (2013). Reprinted with permission from Bhardwaj, R., Zeigler, K., Seo, J.H., Ramesh, K.T., and Nguyen, T.D., *Biomech. Model. Mechanobiol.*, 13, 123–140, 2014.)

finite-element structure solver. In this study, the constitutive model for the structure was based on the Kelvin–Voigt linear viscoelastic material [45]. However, this FSI solver was limited to handle small deformations of the structure and did not account for the geometric and material nonlinearity of the structure. Vigmostad et al. [6] proposed an FSI model for investigating flow fields in heart valve dynamics, using a locally refined Cartesian mesh with the sharp-interface IB method. This study utilized the implicit partitioned approach, and the 2D rod theory was used to model the structure. Recently, Bhardwaj and Mittal [46] and Tian et al. [47] have shown validation of their respective implicit partitioned IB-based solvers against an FSI benchmark proposed by Turek and Hron [48]. The FSI benchmark corresponds to the development of a self-sustained oscillation of an elastic plate attached to the lee side of a rigid cylinder, subjected to a 2D laminar flow inside a channel.

Applications of IB Methods for Moving Rigid Structures

Flow across a Linearly Oscillating Cylinder in a Stationary Fluid

The linear harmonic oscillation of a cylinder is given as $x=-A\sin(2\pi ft)$, where A is the amplitude and f is the frequency of oscillation. The diameter D and the maximum velocity u_{max} of the cylinder are taken as the nondimensional length and velocity scales, respectively. Other than the Reynolds number $\mathrm{Re}=u_{max}D/\nu$, the Keulegan–Carpenter number $K = 2\pi A/D$ is also a governing parameter here.

This problem is the widely used benchmark moving boundary problem to test the efficacy of an IB method. The numerical results are compared with the experimental and numerical results, reported by Dutsch et al. [49]. The results considered for the code validation are the variation of axial and transverse velocities at different axial locations of $-0.6D$, $0.0D$, $0.6D$, and $1.2D$, for different phase angles of the oscillating cylinder, 180°, 210°, and 330°. The benchmark result corresponds to a Reynolds number of 100 and a Keulegan–Carpenter number of 5. The code validation can be found in Ref. [20] for the LS-based IB method.

Flow across a Fish-Like Stream-Wise Undulating Foil

Using the LS-based IB method, Shrivastava et al. [20, 50] carried out 2D simulations for the free-stream flow across an undulating fish-like body modelled as an NACA0012 hydrofoil. The free-stream velocity u_∞ and chord length of the NACA0012 hydrofoil C are taken as the nondimensional velocity and length scales, respectively. The shape of the hydrofoil is transformed into a fish-like body by adding time-varying undulations (ΔY), at various X locations from the head of the hydrofoil along the axis, given as

$$\Delta Y = A(X)\sin\left\{2\pi\left(\frac{X}{\lambda}-\frac{\mathrm{St}\,\tau}{2A_{max}}\right)\right\}, \tag{5.6.5}$$

where $\mathrm{St}=\dfrac{F2A_{max}}{u_\infty}$ and A_{max} is the maximum amplitude of oscillation at the tail, X is the distance from the head of the hydrofoil along the axis, λ is the wavelength of the wave traveling across the hydrofoil, F is the frequency of undulation, τ is the nondimensional time, and St is the Strouhal number. Thus, other than the Reynolds number ($\mathrm{Re}=\rho u_\infty C/\mu$), the other governing parameters for a flow generated by a fish-like locomotion are equations of motion for undulation $A(X)$, wavelength of the wave traveling across the hydrofoil λ, frequency of undulation F, and maximum amplitude of oscillation A_{max}.

The results obtained by Shrivastava [50] for the free-stream flow across single, two in tandem, three side by side and school of fish-like undulating foil are shown in Figure 5.6.9, for vorticity contours. The figures show a reversed von Karman street, which acts as a signature for the generation of the thrust.

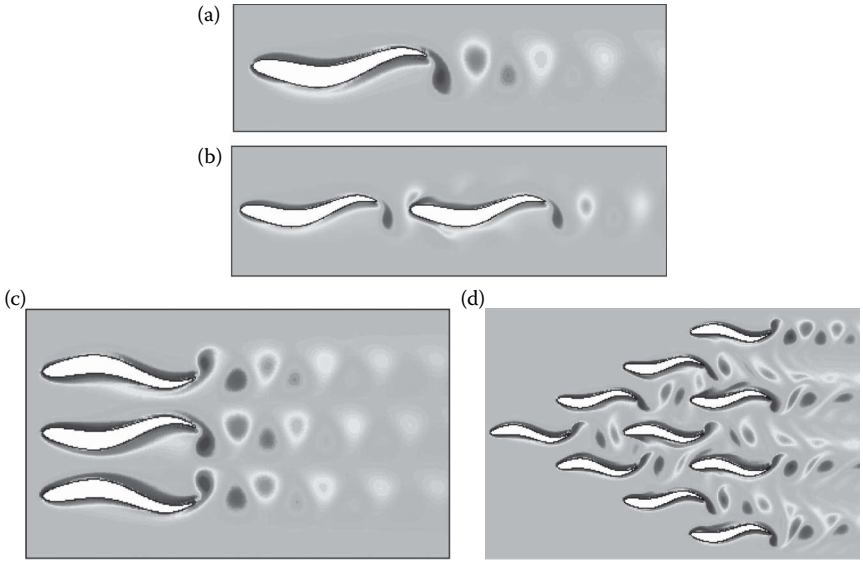

FIGURE 5.6.9 Vorticity contour for a free-stream flow across a (a) single, (b) two in tandem, (c) three side by side, and (d) school of fish-like undulating foil [50], at a Reynolds number of (a–c) 400 and (d) 1000. The other governing parameters are $\lambda = 1$, $A_{max} = 0.1$, and the Strouhal number of (a, c, d) 0.8 and (b) 0.6.

Applications of IB Methods with Moving Deformable Structures

Fluttering of an Elastic Flag Attached to a Rigid Cylinder

An FSI benchmark involving large-scale flow-induced deformation was first proposed by Turek and Hron [48], in which an elastic plate attached to the lee side of a rigid cylinder develops self-sustained oscillations in 2D laminar channel flow (shown in Figure 5.6.10). The circular cylinder is rigid and stationary while the elastic plate is deformable. The fluid is considered to be Newtonian and incompressible, while the structure is assumed to be elastic and compressible. The constitutive law for the structure is chosen as the Saint Venant–Kirchhoff law, in which the elasticity of the structure is characterized by the Poisson ratio and the Young modulus. The plane strain condition and geometric nonlinearity were considered in the structural solver.

The nondimensionalization of the parameters is based on the mean inflow velocity U_{mean} and cylinder diameter D. The Reynolds number and dimensionless Young's modulus are therefore defined

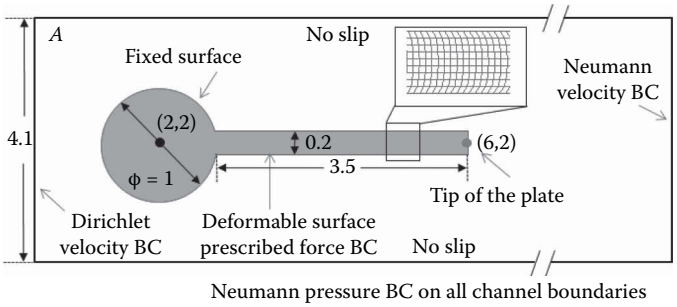

FIGURE 5.6.10 Schematic and BC of the benchmark problem. All numbers shown are dimensionless with respect to the cylinder diameter. The inset shows the finite-element mesh for the plate. (Copyright Prof. R. Mittal (2011). Reprinted with permission from Bhardwaj, R. and Mittal, R., *AIAA J.*, 50, 1638–1642, 2012.)

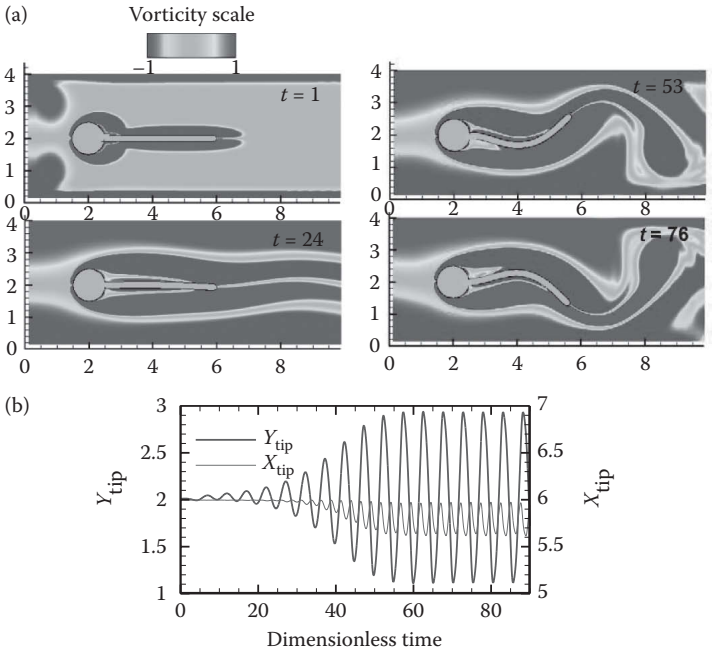

FIGURE 5.6.11 (a) The vorticity field and deformation of the elastic plate shown at different times for the baseline case. (b) Temporal variation of x and y displacements of the tip of the plate. (Copyright Prof. R. Mittal (2011). Reprinted with permission from Bhardwaj, R. and Mittal, R., *AIAA J.*, 50, 1638–1642, 2012.)

as $\mathrm{Re} = U_{\mathrm{mean}} D/\nu$ and $E = E^*/\rho_f U^{-2}$, where ν is the kinematic viscosity of the fluid [$m^2 s^{-1}$] and E^* is the Young's modulus [Nm^{-2}]. A parabolic inflow velocity profile is prescribed at the left boundary of the channel [48]:

$$v(0, y) = 1.5 U_{\mathrm{mean}} \frac{4y(H - y)}{H^2}, \tag{5.6.6}$$

where H is channel height. The usual no-slip BC are applied at the top and bottom walls. A homogeneous normal zero gradient velocity boundary condition is applied at the outflow. The other relevant BC are shown in Figure 5.6.10.

Figure 5.6.11a shows the calculated vorticity field and deformation of the plate at different time instances in Ref. [46]. Due to fluid dynamic forces, the plate starts to deform and attains a self-sustained periodic oscillation with plateau amplitude after a short time. Due to the motion of the plate, vortices shed from the tip of the plate with frequency of the order of the oscillation frequency of the plate. The time-varying y and x displacements of the plate's tip are shown in Figure 5.6.11b. The frequency of oscillation of x_{tip} is about twice of that for the y_{tip} because the plate oscillates with respect to the x-axis. The calculated values of the time period and the maximum plate displacement in Ref. [46] are about 5.155 and 0.917, respectively.

Thermal Augmentation Using Vortex-Induced Vibration

FSI of flexible thin structures immersed in a flow coupled with convective heat transfer enhances thermal transport, which could be utilized to improve the thermal performance of engineering as well as biological systems [13,14]. Soti et al. [13] numerically demonstrated large-scale flow-induced deformation as an effective passive heat-transfer enhancement technique. The authors utilized an in-house, strongly coupled FSI solver in which the flow and structure solvers are based on

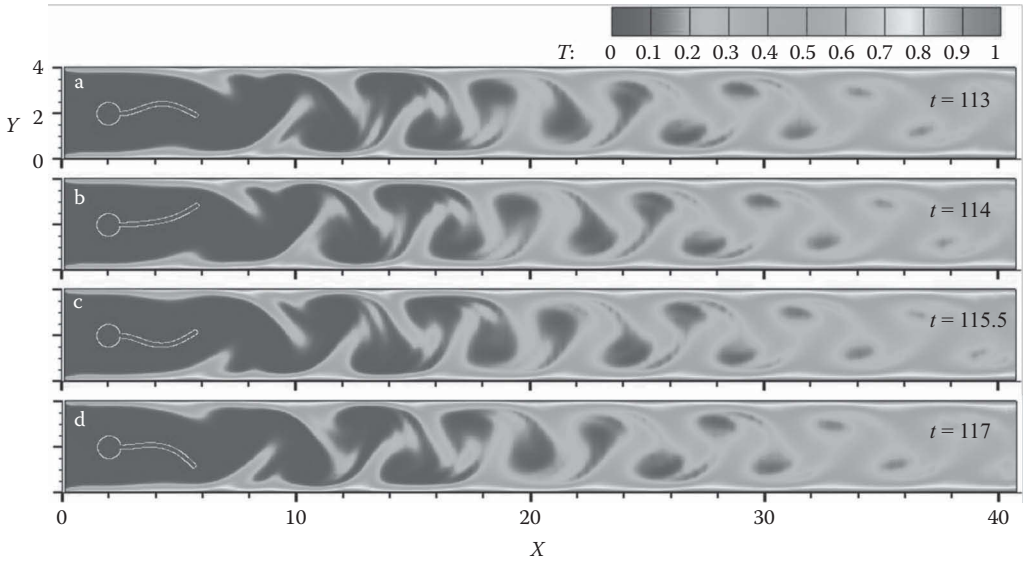

FIGURE 5.6.12 Isotherms in a channel with a cylinder attached to an elastic plate at different time instances for Re = 100 and Pr = 1. (Copyright Elsevier (2014). Reprinted with permission from Soti, A. K., Bhardwaj, R., Sheridan, J. 2015., *Int. J. Heat Mass Trans.*, 84, 1070–1081.)

the sharp-interface immersed boundary and finite-element method, respectively. They considered convective heat transfer in the FSI benchmark problem proposed by Turek and Hron [48]. The isotherms in the channel with a cylinder attached to an elastic plate at different time instances are plotted in Figure 5.6.12. The thermal augmentation is described as follows. The wake vortices past the plate sweep higher sources of vorticity generated on the channel walls out into the high-velocity regions—promoting the mixing of the fluid. The self-sustained motion of the plate assists in convective mixing, augmenting convection in bulk and near the walls, and thereby reducing the thermal boundary layer thickness as well as improving the value of the Nusselt number at the channel walls. In this study, the heat-transfer enhancement was quantified with respect to the pumping power needed and the effects of Reynolds number, Prandtl number, and material properties of the plate were investigated.

Blast Loading on Deformable Human Eye

A sharp-interface immersed boundary method-based compressible flow solver was employed by Bhardwaj et al. [8] to evaluate the influence of facial features on blast wave loading on the human eye. The flow field around the structure is compressible, and pressure fields on the structure are nonuniform and highly transient. The method proposed by Bhardwaj et al. [8] consists of the following components:

- Finite difference compressible flow solver for the propagation of the blast wave
- Finite element elasto-dynamic solver with finite deformation of the globe
- Sharp-interface immersed boundary method for FSI

Bhardwaj et al. [8] simulated the propagation of the blast wave in 3D coordinates to obtain the transient flow fields and pressure loading on the human eye. The flow fields in the sagittal plane are shown in Figure 5.6.13a, and the extensive reflections of the blast wave by the nasal and brow ridges are also shown in this figure. The blast wave reflections also produced an asymmetric pressure

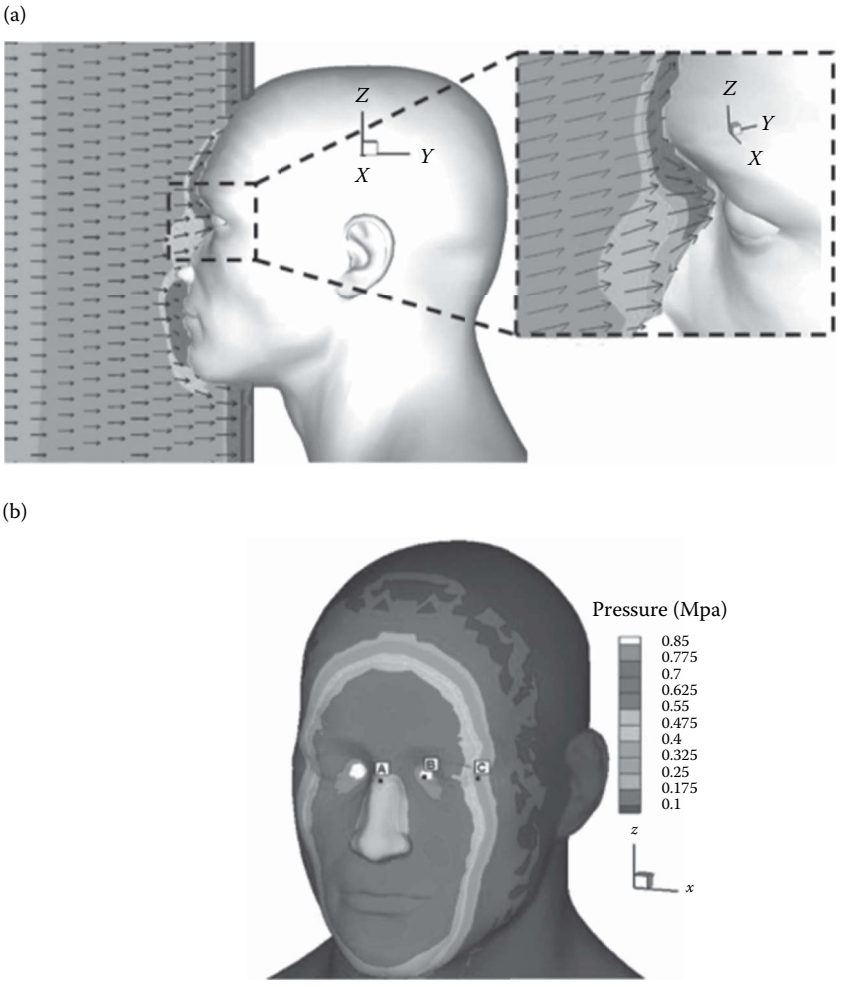

FIGURE 5.6.13 (a) Velocity vectors at every 10th grid point and pressure contours are shown in the sagittal plane on a human face in the event of a 2.5 kg TNT blast. Zoomed in view of the brow area shows the blast wave reflections. (b) Pressure contours on the face at the instance of the maximum pressure loading during the impact of the blast wave. loading on the eye (Figure 5.6.13b) that was higher, close to the nasal bone than the zygomatic bones. This study also predicted possible eye injuries and associated injury risks using the calculated intraocular pressure (IOP) and von Mises stress in the sclera.

Concluding Remarks

The continuous forcing approach is very attractive especially for flows involving elastic moving boundaries due to the ease of implementation. However, this approach treats the physically sharp interface as a diffused interface. Furthermore, this approach is generally not well suited numerically for rigid structures and/or at high Reynolds numbers. Hence, it is difficult to use the continuous forcing approach for flows with rigid bodies. Moreover, since the governing equations are solved for both fluid and solid, in this approach, there is an additional computational effort involved.

On the other hand, since BC are implemented directly in the discrete equations, numerical implementation is not so straightforward in the discrete as compared to the continuous forcing

approach. This approach allows a sharp representation of the immersed boundary and is generally more accurate for moving rigid as well as deformable boundaries. However, there is an issue of spurious pressure oscillations due to the freshly cleared cells created by moving boundaries in this approach. In order to reduce these oscillations, additional interpolations near the immersed boundary are required.

While solving the structure dynamics with the flow field in the aforementioned approaches, the numerical stability depends on the structure–fluid density ratio. The implicit coupling between the flow and structural solver may be employed to ensure the numerical stability at low-density ratio.

ACKNOWLEDGMENTS

We would like to thanks our students involved in the present developments and applications: Dr. Mukul Shrivastava, Mr. Harshil Patel, and Mr. Atul K. Soti.

5.7 NUMERICAL METHODS FOR MULTIPHASE FLOWS

Shyamprasad Karagadde and Atul Sharma

Introduction

Multimaterial interfaces invariably exist in studies involving phase-change problems and dispersed flows. These interfaces or phase boundaries introduce discontinuities in thermophysical properties and matter. Therefore, numerical solutions require additional attention to accurately track the location and shape of evolving interfaces. Moreover, the evolution of these interfaces is primarily governed by heat and mass transfer across the interfaces, which themselves are functions of both the field variables and their gradients. Evaluation of these gradients at the discontinuity (interface) poses several numerical challenges and thus needs special treatment. Two well-known phase-change problems, namely (1) boiling and (2) solidification, are used as examples throughout the remainder of this chapter. During boiling phenomena, vapor bubbles undergo growth due to the vaporization of the liquid and are also transported under the influence of forced flow or buoyancy. Some of the key aspects that dominate the evolution of the vapor bubbles are surface tension, latent heat, density, and viscosity, which have strong variation around the bubble–liquid interface. Further complications are introduced by the presence of Marangoni convection, a rigid solid wall, etc. In solidification problems, additional species conservation and differential solubility of the species in solid and liquid phases pose an added difficulty. Furthermore, when simulating microstructures, the solid–liquid interface often undergoes anisotropic growth and can be highly complex in structure.

Since multiphase flows consist of a large variation in the scales of interfaces, various classes of numerical methods have been developed in the literature. For example, in a bubble column, the scale of the interface can vary from the diameter of the bubble column to that of the smallest bubble. Such problems are simulated by a numerical method, such as two-fluid model (Wörner, 2003), which uses empirical correlations—consisting of certain modeling constants, which are determined from experimental results. Whereas, an interface resolving method is used for the multiphase flow systems, which consist of interfaces in mini- and microscales, predominantly laminar flow, and lesser number of discontinuous dispersed phase (Wörner, 2012). For such multiphase flow systems, the *scope* of this chapter is to present three interface resolving numerical methods: first, enthalpy method; second, volume of fluid (VOF) method; and third, level set method (LSM). The third method is recent as compared with the other two methods. The first is a popular method for solid–liquid phase change (melting/solidification) and the other two methods are commonly used for liquid–gas (boiling/condensation) phase-change processes, but they have also been applied to microstructure evolution during liquid to solid transformation.

The outline of this chapter is as follows: it starts with a discussion of various methods for the continuum modeling of the moving interfaces. Thereafter, a common mathematical formulation is presented for different numerical methods considered here. Finally, the three methods are presented starting with enthalpy method, followed by VOF method, and ending with the LS method (LSM). Each of the following subsections on these methods consists of their formulation, numerical methodology, and a representative application for each of the methods.

Continuum Modeling of Moving Interfaces

When heat and fluid flow equations are conventionally solved on a fixed grid in the space–time domain, the boundary/interface will, in general, be between two grid points at any given time. Therefore, special formulae are needed to evaluate the gradients of variables at the interfaces and also to account for variation in grid sizes. Alternatively, the grid itself needs to be deformed or variables to be transformed so that the interface is always on a grid line or is fixed in the transformed domain. This leads to a classification based on the methodology of characterizing the interface,

namely (1) front tracking, (2) front fixing, and (3) fixed grid methods (Crank, 1987). Front tracking methods compute the position of the interface at each step in time. Typically, front tracking methods involve field solutions on a fixed Eulerian background mesh and Lagrangian reconstruction of the interface, which is located on the fixed mesh. This interface is tracked in time by explicitly satisfying discrete forms of the interface mass, momentum, and energy balance conditions (Voller, 2008). A major drawback of this approach has been the difficulties in achieving the required level of accuracy when the interfaces evolve at much faster rates or develop complex morphologies. Furthermore, under certain conditions, the interface can also be fixed by a suitable choice of new coordinates. These approaches have found limitations in employing the method to nonanalytical interface shapes and in developing a common numerical solution platform that can address a range of multiphase flow problems. Furthermore, it may even be difficult to track the moving interface if the evolution is not smooth or monotonic with time, and particularly when sharp peaks exist or when they disappear.

Alternatively, fixed grid or fixed domain techniques have shown remarkable advantages in solving a variety of complex multiphase flow problems. These typically involve either explicit or implicit "capture" of interfaces using a bounded variable known as "order parameter" or "phase indicator" φ, $a \leqslant \varphi \leqslant b$. A nodal value of $\phi_P = a,b$ indicates the node point P in single-phase regions, and, a value $a < \varphi_P < b$ indicates that P is in the vicinity of the interface. They can also be used to evaluate interface properties such as position and curvature. Typically, the application of these methods requires differential equations to describe the conservation laws and the evolution of the order parameter. The well-known principles of volume averaging are applied for the governing equations to obtain "single-phase" formulation, and the solution of variables (velocity, pressure, temperature, concentration, etc.) is obtained by the various discretization and numerical solution techniques.

Hyman (1984) proposed a distinction based on the increasing flexibility and computational complexity. Accordingly, these are categorized into surface tracking methods, volume-tracking methods, and moving mesh (front tracking) methods. Surface tracking involves interpolation between marker particles along the interface to obtain the interface location, which is similar to the front tracking approach. Accurate resolution of subgrid structures is relatively easy due to the low dimension of such methods. These have been observed to be relatively easy to implement for simple interface evolution problems. Volume-tracking methods are particularly used where topology changes are present. The domain is subdivided into union of disjoint solution regions and the separating region is the interface, identified by marker points or volume fraction change based on the solution of an auxiliary evolution of a PDE. The interface can be reconstructed based on the phase or volume fraction information.

In the aforementioned approaches, the interface can be represented as either *sharp* or *diffuse* depending upon the width spanned by the interface. Sharp-interface representation allows the two-phase cell to be represented by only one computational grid across the interface. These methods accurately conserve mass and preserve the shape of the interface but need algorithms such as interface reconstruction, which contribute to the overall computational effort. In diffuse interface representation, the interface is spread over a few (about 2 or 3) cells around the actual interface and sharp variations in properties across the interface are smeared over this thickness. Although smearing reduces certain spurious errors (or instabilities) which occur during numerical computations, these methods are also prone to mass conservation problems. In general, for fixed domain methods, multiple phases are distinguished by an order parameter and a lower-dimensional evolution equation is solved to analyze the interface motion. This evolution equation is usually a function of the interfacial mass, momentum and heat transfer, which describes the "transport" of the interface (by advecting the phase-indicator variable).

The complete numerical solution of multiphase flows requires coupled solution of the evolution equation along with the conservation laws which may differ in respective phases (due to variation in material and thermophysical properties). The bridging of the different forms at the material interface is achieved by defining the appropriate interfacial mass, momentum and energy balance. It is generally helpful to implement the solution method if these "multifluid" relations of a particular

conservation can be merged together to obtain a single equation that is valid at every computational cell. Such forms are known as *single-field* (also referred as *single-fluid*) formulation, and are obtained by the help of volume-averaging principles (Wörner, 2003).

Mathematical Formulation

Principles of Volume Averaging

A brief overview of the volume-averaging principle and its application to governing equations in a multiphase system is presented below (Wörner, 2003). Consider a general representative volume element V bounded by surface ∂V, invariant with respect to time and space. Let the volume element contain two phases separated by a boundary. A phase-indicator function $\phi(\mathbf{x},t)$ is defined in such a way that it carries a value of 1 for phase k and 0 for the other. Let $\mathbf{x_c}$ denote the centroid of V. Any location in V is identified relative to the centroid, i.e., $\mathbf{x} = \mathbf{x}_c + \mathbf{z}$. The volume fraction of phase k within the volume element V is written as

$$f_k = \frac{1}{V}\int_V \phi(\mathbf{x},t)\mathrm{d}\mathbf{x} = \frac{V_k}{V} \tag{5.7.1}$$

Following expressions show definitions of the volume-averaging operators for any vector or scalar quantity ψ. The term ψ_k denotes the quantity in phase k.

$$\overline{\psi}_k^{\,k} = \frac{1}{V_k}\int_V \psi_k(\mathbf{x},t)\phi(\mathbf{x},t)\mathrm{d}\mathbf{x} \tag{5.7.2a}$$

$$\overline{\psi}_k^{\,V} = \frac{1}{V}\int_V \psi_k(\mathbf{x},t)\phi(\mathbf{x},t)\mathrm{d}\mathbf{x} \tag{5.7.2b}$$

There exists a linear relationship between the volume-averaged values of the quantity defined in the phase k (Equation 5.7.2a) and the overall domain (Equation 5.7.2b), i.e.,

$$\overline{\psi}_k^{\,V} = f_k \overline{\psi}_k^{\,k} \tag{5.7.3}$$

We assume that the flow is incompressible in each of the phases, and the density ρ_k in each phase k is constant. Fluid velocities in each phase are represented by $\mathbf{u}_k$. The local mass and momentum conservation equations are written as follows.

$$\frac{\partial \rho_k}{\partial t} + \nabla\cdot(\rho_k \vec{\mathbf{U}}_k) = 0 \tag{5.7.4}$$

$$\frac{\partial \rho_k \vec{\mathbf{U}}_k}{\partial t} + \nabla\cdot\rho_k\vec{\mathbf{U}}_k\vec{\mathbf{U}}_k = -\nabla p_k + \rho_k\mathbf{g} + \nabla\cdot\Omega_k \tag{5.7.5}$$

Multiplying the above equations by the respective phase-indicator function $\phi(\mathbf{x},t)$ and performing the volume averaging over V, we get,

$$\frac{\partial f_k\rho_k}{\partial t} + \nabla\cdot(f_k\rho_k\overline{\vec{\mathbf{U}}_k}^{\,k}) = \Gamma_k \tag{5.7.6}$$

$$\frac{\partial f_k\rho_k\overline{\vec{\mathbf{U}}_k}^{\,k}}{\partial t} + \nabla\cdot f_k\rho_k\overline{\vec{\mathbf{U}}_k\vec{\mathbf{U}}_k}^{\,k} = -\nabla f_k\overline{p_k}^{\,k} + f_k\rho_k\mathbf{g} + \nabla\cdot f_k\overline{\Omega_k}^{\,k} + M_k \tag{5.7.7}$$

The additional terms in the above expressions arise after simplification due to the volume averaging. Transfer of mass across the interface is represented by,

$$\Gamma_k = \overline{\rho_k(\vec{\mathbf{U}}_{ki} - \vec{\mathbf{U}}_i)\cdot\nabla\phi_k}^{V} \tag{5.7.8}$$

Due to mass conservation, jump condition is satisfied, $\Gamma_1 + \Gamma_2 = 0$. The momentum transfer across the interface is given by,

$$M_k = -\overline{(-p_k\mathrm{I} + \Omega_k)\cdot\nabla\phi_k}^{V} \tag{5.7.9}$$

The sum of M_1 and M_2 satisfies the pressure jump condition,

$$M_1 + M_2 = \frac{1}{V}\int_{S_i\cap V}(2\kappa\sigma\mathbf{n}_1 + \nabla_s\sigma)\mathrm{d}S \tag{5.7.10}$$

The second term inside the integral is zero when surface tension is assumed to be constant. By summing up the equations of conservation for individual phases, a single-field formulation can be written as.

$$\sum\left[\frac{\partial f_k\rho_k}{\partial t} + \nabla\cdot(f_k\rho_k\overline{\vec{\mathbf{U}}_k}^{k})\right] = 0 \tag{5.7.11}$$

Writing the mixture density and center-of-mass velocity for a two-phase system,

$$\rho_\mathrm{m} = f_1\rho_1 + f_2\rho_2 \tag{5.7.12}$$

$$\vec{\mathbf{U}}_\mathrm{m} = \frac{1}{\rho_\mathrm{m}}\sum_{k=1}^{2} f_k\rho_k\overline{\vec{\mathbf{U}}_k}^{k} \tag{5.7.13}$$

On simplification, we get the volume-averaged mass conservation equation as,

$$\frac{\partial\rho_\mathrm{m}}{\partial t} + \nabla\cdot(\rho_\mathrm{m}\vec{\mathbf{U}}_\mathrm{m}) = 0 \tag{5.7.14}$$

Similarly summing up and simplifying the equations for the momentum conservation and performing necessary approximations and assumptions, we obtain,

$$\begin{aligned}\frac{\partial\rho_\mathrm{m}\vec{\mathbf{U}}_\mathrm{m}}{\partial t} + \nabla\cdot(\rho_\mathrm{m}\vec{\mathbf{U}}_\mathrm{m}\vec{\mathbf{U}}_\mathrm{m}) &= -\nabla p_\mathrm{m} + \rho_\mathrm{m}\mathbf{g} + \nabla\cdot\mu_\mathrm{m}(\nabla\vec{\mathbf{U}}_\mathrm{m} + (\nabla\vec{\mathbf{U}}_\mathrm{m})^T) \\ &+ \frac{1}{V}\int_{S_i\cap V} 2\kappa\sigma\mathbf{n}\mathrm{d}S\end{aligned} \tag{5.7.15}$$

The last term on the right-hand side is often simplified to the form $\mathbf{f}_{\mathbf{sv}} = \sigma\kappa\hat{\mathbf{n}}\delta_\mathrm{s}$, where δ_s is the Dirac Delta function, representing the interfacial area per unit volume in a computational cell, and all the geometric terms in this expression are evaluated in terms of the phase-indicator function.

The energy and species conservation equations are also derived in a similar fashion to obtain the single-field governing equations, based on the interfacial heat and mass transfer that are specific to a particular process such as boiling and solidification, further details can be found elsewhere

(Wörner, 2012; Dantzig and Rappaz, 2009). For the remainder of this text, the phase volume fraction of a phase k is represented by the notation f_k. From mass conservation, the sum of phase fractions of all $n$phases in a cell is unity, i.e.,

$$\sum_{k=1}^{n} f_k = 1 \tag{5.7.16}$$

In general, any mixture property β (such as density, conductivity, and diffusivity) is represented by the volume-averaged expression

$$\beta = \sum_{i=1}^{n} \beta_i f_i \tag{5.7.17}$$

In this subsection, the notation for phases is denoted by subscripts l, s, and b representing liquid, solid, and bubble phases, respectively. Any combination of these subscripts represents the interface.

Nondimensional Governing Equations

For a single-phase flow, the well-known Navier–Stokes equations alone are solved to obtain the velocity and pressure fields. However, for two-phase flow, a governing equation for the interface is also solved using one of the interface resolving methods. The Navier–Stokes equations are coupled with the equation for the interface by invoking a *single-field formulation*, wherein a single velocity and pressure field is defined for both the fluids. Typically, constant material properties are assumed, but not equal for each phase, i.e., the bulk fluids are *incompressible*. Moreover, the interfacial mass transfer (due to phase change) and the surface tension force at interface is modeled as a volumetric source term in the continuity and momentum equation, respectively, these source terms are nonzero only at the interface. The surface tension coefficient is assumed to be constant and its tangential variation along the interface is neglected. It is assumed that interface is thin and massless with no slip in tangential velocity. The effect of radiation, viscous dissipation and the energy contribution due to interface stretching are neglected.

The analysis with dimensionless form of equations can be beneficial in studying a larger class of problems in multiphase flow and heat-transfer. The following discussion presents the dimensionless formulation of a typical boiling heat-transfer problem, and for the other cases, slight variations in the dimensionless numbers and scales may appear. The nondimensional single field governing equations for the VOF- and LSM-based simulation of multiphase flow are as follows:

Volume conservation (continuity) equation:

$$\nabla \cdot \vec{\mathbf{U}} = \left(\frac{1-\chi}{\chi}\right)\dot{M}\delta_\varepsilon \quad \left\{\dot{M} = \frac{\mathrm{Ja}}{\gamma \mathrm{Re}_l \mathrm{Pr}_l}[(\nabla\theta)_1 - \zeta(\nabla\theta)_2]\cdot\hat{\mathbf{n}}\right\} \tag{5.7.18}$$

The right-hand side of the above equation represents the change in volume of a phase ($\dot{M}$), which typically occurs during phase change or diffusion-driven phase growth. In problems involving purely advection of phases, this growth term would be zero.

Momentum Conservation Equation:

$$\frac{\partial(\rho_m \vec{U})}{\partial\tau} + \nabla\cdot(\rho_m \vec{\mathbf{U}}\vec{\mathbf{U}}) = -\nabla P + \frac{1}{\mathrm{Re}_l}\nabla\cdot(\mu_m(\nabla\vec{\mathbf{U}} + (\nabla\vec{\mathbf{U}})^T)) - \frac{\rho_m}{\mathrm{Fr}^2}\hat{j} + \frac{1}{\mathrm{We}}\kappa\hat{\mathbf{n}}\delta_\varepsilon(\phi) \tag{5.7.19}$$

where ρ_m and μ_m are the mean nondimensional density and viscosity, respectively.

Energy Conservation Equation:

$$\frac{\partial(\rho_m c_{pm}\theta)}{\partial\tau} + \nabla\cdot(\rho_m c_{pm}\vec{U}\theta) = \frac{1}{\mathrm{Re}_l \mathrm{Pr}_l}\nabla\cdot(k_m\nabla\theta) \tag{5.7.20}$$

where c_{pm} and k_m are the mean (or mixture) nondimensional specific heat and thermal conductivity, respectively.

For the above equations, using l_c as characteristic length and u_c as velocity scale, the nondimensional variables are defined as

$$\vec{U} = \frac{\vec{u}}{u_c},\ X = \frac{x}{l_c}, \tau = \frac{tu_c}{l_c}, P = \frac{p}{\rho_l u_c^2}, \theta = \frac{T - T_{SAT}}{T_W - T_{SAT}}, \dot{M} = \frac{\dot{m}}{\rho_l u_c}$$

where T_W is the constant wall temperature (as a BC), and T_{SAT} is the saturation temperature in a phase-change problem. Furthermore, $\dot{m}$ is the interfacial mass flux, obtained from the Stefan condition: $\dot{m} = (q_{int,2} - q_{int,l})/(h_2 - h_l)$—ratio of jump of conduction heat flux and jump of enthalpy at the interface (due to phase change). Furthermore, nondimensional governing parameters (Reynolds number, Re, Prandtl number, Pr, Froude number, Fr, Weber number, We, and Jakob number, Ja) are defined as

$$\mathrm{Re}_l = \frac{\rho_l u_c l_c}{\mu_l}, \mathrm{Pr}_p = \frac{\mu_l c_{p,l}}{k_l}, \mathrm{Fr} = \frac{u_c}{\sqrt{g l_c}}, \mathrm{We} = \frac{\rho_l u_c l_c^2}{\sigma}, \mathrm{Ja} = \frac{c_{p,2}(T_W - T_{SAT})}{h_2 - h_l} \tag{5.7.21}$$

Since the fluid-1 is considered as the reference fluid, note that the mean thermophysical properties in the above equation are all equal to unity for fluid-1, and are equal to the property ratio for the fluid-2; given as

$$\rho_m = \chi = \frac{\rho_2}{\rho_l}, \mu_m = \eta = \frac{\mu_2}{\mu_l}, k_m = \zeta = \frac{k_2}{k_l}, c_{pm} = \gamma = \frac{c_{p,2}}{c_{p,l}}$$

Although the surface tension force is a surface force, Brackbill et al. (1992) proposed a continuum surface force (CSF) model to represent it as a localized body force at interface—considered as the source term in Equation 5.7.19.

Enthalpy Method

During the phase change (liquid to solid) process for a pure substance, a sharp interface exists separating the liquid and solid regions. For multicomponent systems (e.g., alloys), the separation is represented by the mushy zone whose width is governed by the difference in solidus and liquidus temperatures, schematically shown in Figure 5.7.1. The first calculation of the heat flow during phase change was suggested by Eyres et al. (1946). Since then numerous modeling strategies have been developed and one of the most widely used techniques, particularly for macroscopic solidification modeling, is the enthalpy method (Voller et al., 1987, 1989). A significant advantage of the enthalpy methodology is that it does not involve a separate PDE for interface evolution, and the interface is implicitly captured by linking the temperature field with the enthalpy and liquid phase. This has been successfully implemented for a wide range of solidification problems involving alloy systems, melt convection, etc., and prediction of parameters (such as solidification time and macrosegregation) has been found to match closely with experiments.

Formulation

The principle of the enthalpy technique for pure metal solidification is as follows. The enthalpy is defined as $H = c_{p,l}T + f_l L_f$, where $c_{p,l}$ is the specific heat of the liquid, T is the temperature, and L_f

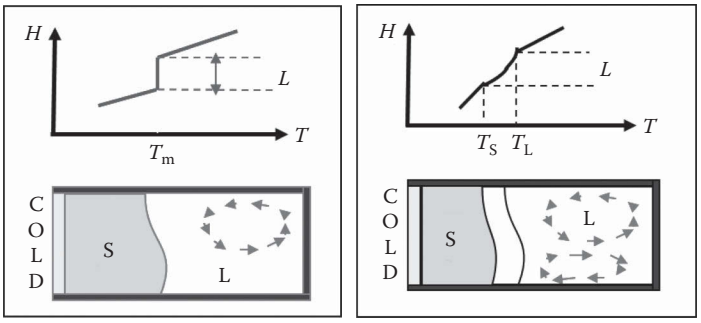

FIGURE 5.7.1 Schematic of solidification processes in (a) pure and (b) multicomponent system.

is the latent heat of fusion. The rejection of latent heat occurs at the solidifying interface, which is conducted away due to the cooling from the boundaries. The heat jump or the enthalpy is monitored to obtain the location of the interface. The classical Stefan's condition (interfacial heat balance) is given by the following relation:

$$\rho L_f \vec{\mathbf{V}}_{s-l} = k_s \nabla T\big|_{x=\text{solid}} - k_l \nabla T\big|_{x=\text{liquid}} \tag{5.7.22}$$

In this method, the volume-averaged energy conservation equation is modified to account for heat rejection at the interface, by indirectly imposing the Stefan's condition (Equation 5.7.22) via the single-field formulation, and is solved to obtain the interface location (Brent et al., 1988; Voller et al., 1989).

$$\frac{\partial(\rho H)}{\partial t} + \nabla \cdot (\rho \vec{\mathbf{U}} H) = \nabla . \left(\frac{k_m}{c_p} \nabla H \right) + S_h \tag{5.7.23}$$

where $k_m = f_s k_s + f_l k_l$ is the effective thermal conductivity of the mixture, and S_h is the source term given by the following relation.

$$S_h = \frac{\partial(\rho \Delta H)}{\partial t} + \nabla \cdot (\rho \vec{\mathbf{U}} \Delta H) \tag{5.7.24}$$

where $\Delta H = f_l L_f = f(T)$ is the latent heat content, defined as a function of temperature (for both pure systems and alloys). The fluid flow arising due to buoyancy (thermal and compositional) is modeled using appropriate (Boussinesq approximation) terms, which are generally incorporated into the momentum conservation. For isothermal phase change (pure systems), the second term on the RHS of Equation 5.7.23 vanishes. After solving Equation 5.7.23, the liquid fraction–temperature relation is utilized to obtain the interface location. Also, it may be noted that the enthalpy method is usually solved in its dimensional form along with mass and momentum conservation. Since individual growth of solid phases is not accounted for in the macro-model, the regions consisting of both solid and liquid phases are treated as a porous media with the porosity as a function of liquid (or solid) volume fraction. A well-known relation for modeling the porous medium flow is the Carman–Kozeny equation $\left(\nabla p = \left[-B \frac{(1-f_l)^2}{f_l^3} \right] \vec{\mathbf{u}}_0 \right)$, where B is a large computational number to avoid division by zero, and $\vec{\mathbf{u}}_0$ is the apparent velocity of the fluid. Hence, this popular enthalpy approach is also known as *enthalpy–porosity* formulation (Brent et al. 1988). Similarly, the conservation of species governing the mass balance of the solute (alloying element) in a binary alloy solidification problem is given as follows.

$$\frac{\partial(\rho C_m)}{\partial t} + \nabla \cdot (\rho \vec{\mathbf{U}} C_m) = \nabla \cdot (D_m \nabla C_m) + S_C \tag{5.7.25}$$

where $C_m = f_s C_s + f_l C_l$ is the mixture concentration and $D_m = f_s D_s + f_l D_l$ is the effective mixture diffusivity. The interface mass balance for the alloy element is given by a relation similar to the Stefan's condition (Equation 5.7.21) $k_p C_0 \vec{\mathbf{V}}_{s-l} = D_s \nabla C\big|_{x=\text{solid}} - D_l \nabla C\big|_{x=\text{liquid}}$, where k_p is the equilibrium partition coefficient (C_s / C_l). In contrary to the heat balance where the temperature at the interface is constant, but a discontinuity in the heat flux exists, species balance imposes discontinuity in both composition and the mass flux.

Several variations of the above formulation exist (Swaminathan and Voller, 1992; Krane et al., 1997; Chakraborty and Dutta, 2001) for macroscopic solidification problems incorporating movement of solid phase and other multicomponent alloy systems, but the essence of the method remains in estimating the temperature via enthalpy function without solving a separate equation for the evolution of phase-indicator function (liquid or solid volume fraction).

Numerical Methodology

The solution methodology for the enthalpy method is as follows:

1. Obtain the discretized forms of Equations 5.7.22 through 5.7.24 along with mass and momentum conservation equations.
2. Initialize temperature, composition and velocity fields.
3. Iteration:
   a. Update the variables (T or H, $\mathbf{u}$, C) with previous time instance
   b. Estimate the source terms for energy, mass, momentum, and species conservation
   c. Solve for T or H, $\mathbf{u}$, C
   d. Check for convergence if implicit solution and repeat steps (a)–(c).
4. Calculate the update for H or T (from the definition of ΔH).
5. Proceed to next time step.

Microscopic Model

In solidification problems, particularly in the case of alloys, the interface morphology is strongly dependent on the local cooling rate (dT / dt) and composition in the liquid ahead of the interface. At very slow (~0.1°C/s) and very high (~10^6°C/s) cooling rates, the interface remains flat, and at the intermediate values, the interface shape gradually assumes cellular, columnar dendritic and equiaxed dendritic structures, at the meso and microscopic scales (to facilitate heat transfer through larger surface areas). The macroscopic enthalpy method does not resolve these features and only provides information on an averaged value of the solid and liquid volume fractions in a given computational cell (Figure 5.7.1). For resolving and predicting the evolution (growth and motion) individual microstructural features, anisotropic crystal growth and interfacial surface energy need to be locally accounted along with the interfacial heat balance, as the growth will strongly depend on the interfacial curvature, kinetics, and alloy composition. Furthermore, due to a large disparity between the thermal and compositional diffusion rates, small grid sizes often need to be considered and adaptive meshing techniques can be very beneficial. A brief overview of microstructural simulation aspects is presented below. A detailed description of the microstructural simulation of solidification can be obtained from Voller (2008).

The microscopic modeling of solidification involves handling of more complex aspects such as anisotropy in microstructures, disparity in diffusion length scales of thermal and compositional fields and grain motion. Fully realistic simulations continue to remain a challenge for predicting accurate alloy solidification microstructures for large castings. Methods such as phase-field (Tong et al., 2001), cellular automata (Gandin and Rappaz, 1997; Wang et al., 2003; Karagadde et al., 2014), and LS (Tan and Zabaras, 2006; Theillard et al., 2014) have been extensively used for modeling microstructural evolution during solidification (Hecht et al., 2004; Rappaz, 2016). Of late, enthalpy method has also found applications in simulating the microstructural growth (Al-Rawahi

and Tryggvason, 2002; Pal et al., 2006; Voller, 2008; Karagadde et al., 2012a; Bhattacharya et al., 2014). During microstructure evolution, the interface temperature is lower than the melting point (liquidus temperature) of the alloy and the difference is given by the sum of the curvature, compositional and kinetic undercooling (Dantzig and Rappaz, 2009),

$$T_{\text{int}} = T_{\text{l}} - \kappa_{\text{s-l}}\Gamma - m\Delta C - \lambda \vec{\mathbf{V}}_{\text{s-l}} \cdot \vec{\mathbf{n}} \tag{5.7.26}$$

where $\kappa_{\text{s-l}}$ is the curvature of the solid–liquid interface (positive for a convex surface), Γ is Gibbs–Thompson coefficient which gives the extent of additional undercooling for unit curvature, m is the slope of liquidus line from the phase diagram, ΔC is the change in composition ahead of the s–l interface with respect to the equilibrium value, and λ is the kinetic coefficient (Voller, 2008). The interface temperature can be explicitly imposed while solving the enthalpy equation along with the species conservation. It is to be noted that the microscopic models represent the individual interfaces; whereas, in macroscopic solidification studies, a volume-averaged representation of the overall solid–liquid mixture is evaluated.

Application of Enthalpy Method

As an application problem, we demonstrate the simulation of solidification of aluminum in the presence of a hydrogen bubble. The hydrogen is a dissolved gas in liquid aluminum. Upon solidification, an equivalent amount of hydrogen exceeding the solubility limit is rejected into the liquid, and further diffuses into the nucleated bubbles. Subsequently, the bubbles undergo growth. There are two interfaces in this problem (solid–liquid and bubble–liquid), which are modeled using two different interface tracking methods, namely, enthalpy and LS, respectively, through a coupled approach. In this example, a 100×100 2D discretization of the domain was performed. Solidification is initiated from the left boundary, with rest of the boundaries being insulated. The evolution of solidification, hydrogen species conservation, and resulting bubble growth in liquid are captured, see Figure 5.7.2. The simulation shows segregation during solidification (distribution of species) of hydrogen (in cc/100 g of Al) ahead of the solid–liquid interface, and subsequent diffusion of hydrogen into

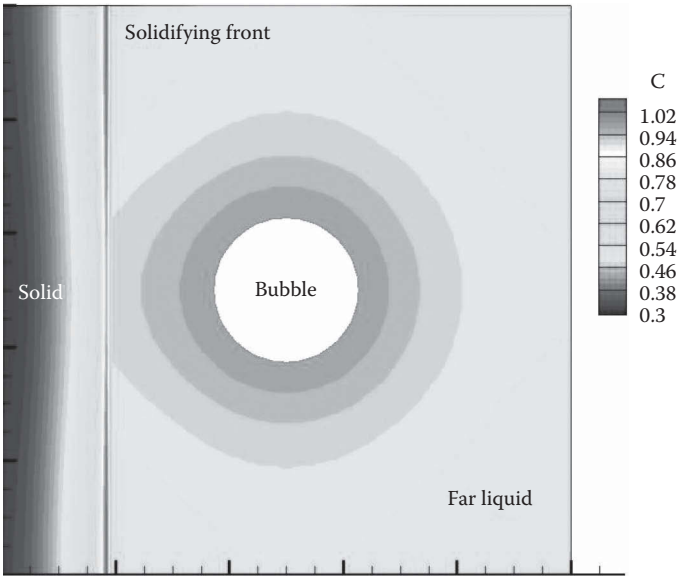

FIGURE 5.7.2 Simulation of solidification of aluminum, hydrogen species balance, and resulting growth of a hydrogen bubble.

the bubble. Higher concentration of the species can be noticed ahead of the solid–liquid interface, whereas, hydrogen depleted regions exist in the solid and also around the bubble (hydrogen is diffusing into the bubble and causing growth). Furthermore, the bubble can move under buoyancy effects and interact with the solidifying front (Karagadde et al., 2012b). This problem addresses, simultaneous mass, momentum, heat and species transfer, and demonstrates the potential of using the coupled interface tracking methods to simulate complex multiphase problems.

VOF Method

The VOF method is used primarily for sharp-interface multiphase flow problems involving both free and moving boundaries. In this method, the volume of each fluid (phase) is tracked in all cells containing the portions of the interface. The phases are distinguished by a volume or void-fraction function. This is defined for one particular fluid inside a cell and is given by material volume of that phase divided by the cell volume. The quantification is similar to any order-parameter representation, and the value is either unity or zero in any pure phase cell. It carries a value between these limits for multifluid cells. VOF methods involve solution of the evolution equation. Besides the solution of the evolution equation, which is also known as the *VOF advection equation* (Hirt and Nichols, 1981), VOF methods are successful with a good *interface reconstruction algorithm*. The reconstruction is necessary for obtaining the explicit description of the interface in each multifluid cell based on void fractions.

The development of VOF formulation is summarized by considering the methods of interface reconstruction (Gerlach et al., 2006). Some of the initial approaches consisted of representing the interface by a piecewise-constant line in every two-fluid cell. They were mainly SLIC (simple line interface calculation) of Noh and Woodward (1976) and Hirt and Nichols (1981). Youngs (1982) proposed a much improved first-order accurate method by introducing a piecewise-linear method which was shown to be very efficient and robust. Puckett et al. (1997) developed a more accurate technique known as the LVIRA (linear VOF interface reconstruction algorithm) having a second-order accuracy. Renardy and Renardy (2002) presented a technique based on piecewise parabolic segments. VOF has been successfully applied for various multiphase problems involving bubble dynamics, free surface flows, etc., particularly for incompressible flows. This implementation ensures volume (as well as mass) conservation by obtaining nondiffusive solution of the advection equation. Geometrically calculated void-fraction fluxes are estimated at the cell phases based on the reconstructed interfaces. Figure 5.7.3 shows a representation of this method and the geometric consideration of fluxes for volume fraction advection into the neighboring control volumes.

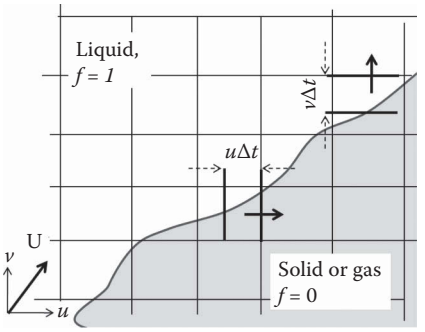

FIGURE 5.7.3 VOF advection—amount of phases advected to neighboring control volumes in *u* and *v* directions are represented.

VOF Equation

For incompressible flow, the fluid density does not change along the particle paths. The advection equation for the volume fraction f is given by,

$$\frac{\partial f}{\partial t} + \vec{\mathbf{U}}_{\text{adv}} \cdot \nabla f = 0 \tag{5.7.27}$$

Typically, the value of void fraction of liquid is chosen as $f = 1$ and of the other phase is chosen as $f = 0$. The void-fraction field f is advected using the velocity of the fluid $\vec{\mathbf{U}}_{\text{adv}}$, where $\vec{\mathbf{U}}_{\text{adv}}$ is the sum of bulk velocity $\vec{\mathbf{U}}$ (obtained from the solution of Navier–Stokes equations) and interfacial velocity due to phase change $\vec{\mathbf{U}}_{\text{PC}}$ (obtained from the Stefan condition), where $\vec{\mathbf{U}}_{\text{adv}} = \vec{\mathbf{U}} + \vec{\mathbf{U}}_{\text{PC}}$ $\left\{\vec{\mathbf{U}}_{\text{PC}} = 0.5\left(\frac{1+\chi}{\chi}\right)\dot{M}\hat{\mathbf{n}}\right\}$. The flow velocity field, along with phase-change-driven growth rate are obtained by solving the mass, momentum, and energy conservation equations; Equations 5.7.18 through 5.7.20. For cases involving advection alone, Equation 5.7.27 can be rewritten using the incompressibility condition as,

$$\frac{\partial f}{\partial t} + \nabla \cdot (\vec{\mathbf{U}}\, f) = 0 \tag{5.7.28}$$

Numerical Methodology

Figure 5.7.4 shows the interface representation in a scalar control volume. Figure 5.7.4a shows the representation for calculating the fluxes into the neighboring cells, and Figure 5.7.4b shows the representation of interface normal and its distance from the center used for the reconstruction.

The solution of VOF equation is carried out using separate update procedures for x- and y-direction. Accordingly, Equation 5.7.27 is discretized as follows:

$$f_{i,j}^{*} = f_{i,j}^{n} + \frac{\Delta t}{\Delta x}\left(\text{Flux}_{i-1/2,j} - \text{Flux}_{i+1/2,j}\right) \tag{5.7.29}$$

$$f_{i,j}^{n+1*} = f_{i,j}^{*} + \frac{\Delta t}{\Delta x}\left(\text{Flux}_{i,j-1/2} - \text{Flux}_{i,j+1/2}\right) \tag{5.7.30}$$

Here, the term *Flux* defined as $\text{Flux}_{i+1/2,j} = u_{i,j} f_{i+1/2,j}$, is computed using geometric fluxing following Puckett et al. (1997) (also see Gerlach et al., 2006) as represented in Figure 5.7.4a. In the operator split algorithm employed here, fluxing is split into x- and y-directions where the x-sweep is done first (Equation 5.7.29) in an explicit way and y-sweep is done using an implicit formulation. The directions of the sweep are swapped every alternative time step to make the advection scheme second-order accurate

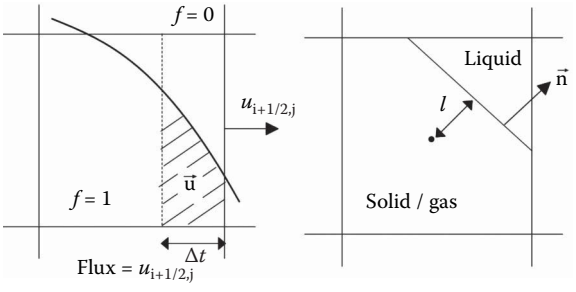

FIGURE 5.7.4 Representation of the interface in an individual control volume (From Gerlach, D. et al., *Int. J. Heat Mass Transfer*, 49(3–4), 740–754, 2006.With permission.): (a) estimation of the amount of flux into the neighboring cell and (b) linear reconstruction of the interface, showing the interface normal and the distance from the center of the cell.

in time. The details of the algorithm employed here are given in Gerlach et al. (2006). For advection of the dendrites using VOF, an extended velocity field is used. Fluid velocities in the cells adjacent to the solid boundary are imposed with the extended velocities from the dendrite particle to maintain a consistent volume fraction advection. The void-fraction field, $f_{i,j}$, by virtue of being advected geometrically, is always conserved and has values between zero and one only. However, an additional check is used to ensure that the void-fraction field does not become negative or greater than one in any grid cell.

Interface reconstruction is required after every advection sweep in order to compute the geometric fluxes accurately. Here, least-squared VOF interface reconstruction algorithm (LVIRA) of Puckett et al. (1997) is presented. The interface, in each computational grid cell, is represented by a linear segment and can be defined in 2D by the unit normal $\hat{\mathbf{n}}$ pointing into the liquid region and a distance, l, of the interface from the center (centroid in 3D) of the computational cell, as shown in Figure 5.7.4b. For e.g., in 2D calculations, a nine-point stencil around a two-phase cell is considered. A line is drawn through the stencil by using a guess $\hat{\mathbf{n}}$ (obtained by Youngs' method (Youngs, 1982)) and l, such that the void fraction at the center cell of the stencil matches the void fraction obtained after advection. The normal is estimated using the following relation.

$$\begin{aligned} n_x &= \frac{1}{8}(f_{i+1,j+1} + 2f_{i+1,j} + f_{i+1,j-1} - f_{i-1,j+1} - 2f_{i-1,j} - f_{i-1,j-1}) \\ n_y &= \frac{1}{8}(f_{i+1,j+1} + 2f_{i,j+1} + f_{i-1,j-1} - f_{i+1,j-1} - 2f_{i,j-1} - f_{i-1,j-1}) \end{aligned} \tag{5.7.31}$$

This initial guess is used to obtain the actual interface reconstruction using an optimization procedure. The least-square error (LSE) in the void-fraction field for the whole stencil is minimized to obtain the unit normal, $\hat{\mathbf{n}}$.

$$\mathrm{LSE} = \sum_{k,l=-1}^{1} (f_{i+k,j+l} - \tilde{f}_{i+k,j+l})^2 \tag{5.7.32}$$

where $f_{i+k,j+l}$ is the updated void fraction, and $\tilde{f}_{i+k,j+l}$ is the approximation estimated from the linear interface through the control volume. Geometrical construction of the interface using the normal and the distance l gives the approximation. Thus, a linear segment representing the interface in the center cell of the stencil is fixed, and this process is repeated for all the two-phase cells. This gives the correct interface normal and its location from the cell center.

Since VOF function abruptly changes across the interface, standard discretization schemes for evaluating the curvature, normal, etc., would result in large inaccuracies. Therefore, the function is smoothed in a region of finite thickness around the interface. Several methodologies exist in literature (Gerlach et al., 2006; Voller, 2008), and one of the simplest approaches is to induce the smearing by constructing a weighted averaged liquid fraction field over the nearest neighboring cells, i.e., if $\sum_{\mathrm{nb}} \beta_{\mathrm{nb}} = 1$, and $\beta_{\mathrm{nb}} \geq 0$, we have

$$g_{i,j} = \left(1 - \sum_{\mathrm{nb}} \beta_{\mathrm{nb}}\right) f_{i,j} + \sum_{\mathrm{nb}} \beta_{\mathrm{nb}} f_{\mathrm{nb}} \tag{5.7.33}$$

The Dirac delta function is evaluated as $|\mathbf{n}|$ (Gerlach et al., 2006). Similarly, interface curvature is evaluated by discretizing the following equation (for a 2D domain):

$$\frac{\left(\frac{\partial g}{\partial y}\right)^2 \frac{\partial^2 g}{\partial x^2} - 2\frac{\partial g}{\partial x}\frac{\partial g}{\partial y}\frac{\partial^2 g}{\partial x \partial y} + \left(\frac{\partial g}{\partial x}\right)^2 \frac{\partial^2 g}{\partial y^2}}{\left(\left(\frac{\partial g}{\partial x}\right)^2 + \left(\frac{\partial g}{\partial y}\right)^2\right)^{3/2}} \tag{5.7.34}$$

The solution algorithm for two-phase flow simulation, using the VOF method, is as follows:

1. Initialize the volume fraction field in the domain as per the initial interface configuration ($f=1$ in cells containing liquid and 0 elsewhere). Initialize velocities, pressure, temperature, and interfacial mass flux (if any) as zero.
2. Solve the continuity and momentum equations, to obtain new time-level velocity and pressure field. In interfacial cells, the values of curvature, normal and Dirac-delta function are evaluated from the smeared volume fraction *f*.
3. Solve the energy equation, to obtain new time-level temperature field.
4. Solve advection of VOF equation (operator split approach), by calculating the amount of volume fraction "fluxed" to the neighboring cells (in the direction of flow).
5. Perform interface reconstruction using piecewise linear interface segments.
6. Go to step 2 till the stopping criterion is met.

Application of VOF Method

An application is presented here for the simultaneous growth and motion of an equiaxed dendrite in a uniform flow field. When the fluid flow velocities are comparable to the growth rate of the solid phase (in the form of a fourfold symmetric dendrite), simultaneous advection and growth of the solid can be simulated. A coupled Enthalpy and VOF approach is used in this study. A situation of this kind can occur in solidifying melts with strong convective currents. A domain of size $1000\times1000\ \mu m^2$, with $\Delta x = 10\ \mu m$ and $\Delta t = 10^{-7}$ s, is considered. Flow is introduced in the left boundary with a velocity of 0.01 m/s and is made to exit the domain at the right face. Figure 5.7.5 shows the location of the dendrite at various time instances. This example demonstrates the capability of

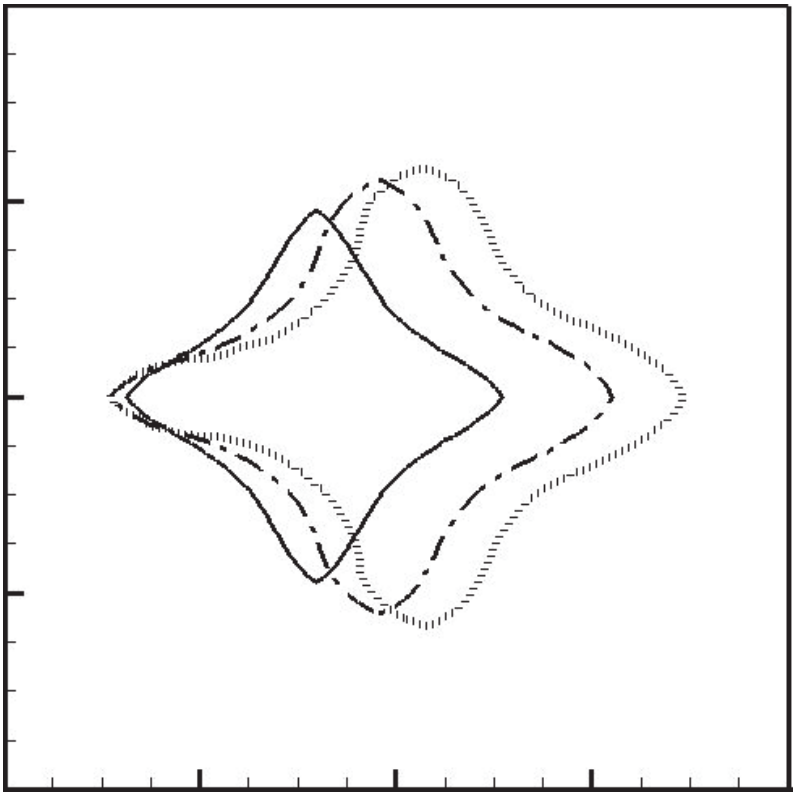

FIGURE 5.7.5 Advection of an evolving solid phase in a uniform velocity field using VOF method.

the VOF method in capturing the sharp interface, with coupled solidification and VOF advection. Further details for this implementation can be obtained from Karagadde et al. (2012a).

Level Set Method

LSM was proposed by Osher and Sethian (1988) as a general Eulerian computational technique to simulate moving interfaces and shapes—applicable to computational geometry, computer vision, material science, and computational fluid dynamics (Sethian, 1999; Osher and Fedkiw, 2003). Later, for the simulation of incompressible two-phase flow, Sussman et al. (1994) introduced the LSM along with the stream function–vorticity method.

LSM is a numerical methodology for the representation of an interface, and modeling the temporal evolution of interface, surface tension force, and interfacial mass transfer. It is based on the concept of implicit surfaces where a *normal distance function* called LS function φ is defined in a complete domain, i.e., for both fluids. The function corresponds to $\varphi = 0$ at the interface, with positive values for one of the fluids and negative values in the other fluid, shown in Figure 5.7.6a. For a circular interface of radius 5 units, Figure 5.7.6b shows the LS contours as concentric circles with an increase in its absolute value away from the interface.

The contour of $\varphi = 0$ in the domain represents the physically relevant *sharp* interface, and a numerically relevant *diffused* interface is represented by finite thickness ($-0.2 < \varphi < 0.2$, in Figure 5.7.6b), across which the fluid properties are smoothened (or averaged). This is done to avoid the numerical difficulties encountered due to the sharp change of thermophysical properties, across the interface, and nonzero surface tension force as well as volume generation/depletion (during phase change) at the interface.

The thickness across the interface is defined by normal distance across the interface and since the function φ is a normal distance function, constant thickness of 2ε across the interface is defined by the value of the function $-\varepsilon < \varphi < \varepsilon$; where ε is related to grid size and is usually taken as a factor of the grid spacing, e.g., $1.5\Delta x$. Note that, the interface thickness will be negligible on a fairly fine grid.

For LSM as well various other methods and their applications, an excellent review was presented by Wörner (2012), for multiphase flows in microfluidics and microprocess engineering. Recently, Sharma (2015) presented a detailed review of development as well as application of LSM for various types of multiphase flow.

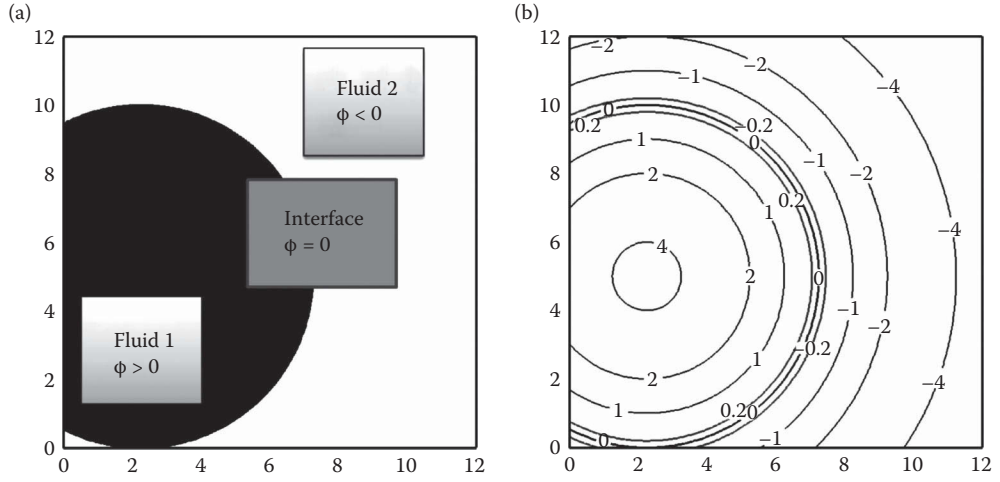

FIGURE 5.7.6 (a) LS function representation and (b) its contours for a circular interface of unit radius.

LS Functions and Equations

Along with the ease in the prescription of the thickness of the interface, the normal-distance LS function directly evaluates the normal unit vector at the interface and the curvature of the interface as follows:

$$\hat{\mathbf{n}} = \nabla\phi / |\nabla\phi| \text{ and } \kappa = -\nabla \cdot \hat{\mathbf{n}} \tag{5.7.35}$$

In addition to the LS function, the LSM considers two more mathematical functions: Heaviside and Dirac-delta functions. However, instead of their sharp definition in mathematics, they are considered diffused in LSM, called as *smoothened* Heaviside and Dirac-delta functions; their respective expressions are given as,

$$H_\varepsilon(\phi) = \begin{cases} 1 & \text{if} \quad \phi > \varepsilon \\ \dfrac{\phi+\varepsilon}{2\varepsilon} + \dfrac{1}{2\pi}\sin\left(\dfrac{\pi\phi}{\varepsilon}\right) & \text{if} \quad |\phi| \le \varepsilon \\ 0 & \text{if} \quad \phi < -\varepsilon \end{cases} \tag{5.7.36}$$

$$\delta_\varepsilon(\phi) = \frac{dH_\varepsilon(\phi)}{d\phi} = \frac{1}{2\varepsilon} + \frac{1}{2\varepsilon}\cos\left(\frac{\pi\phi}{\varepsilon}\right) \quad \text{if} \quad |\phi| \le \varepsilon$$
$$\delta_\varepsilon(\phi) = 0 \quad \text{otherwise} \tag{5.7.37}$$

The smoothened Dirac-delta function is used to model the nonzero surface tension force and interfacial mass transfer, at the diffused interface, in the momentum and continuity equation (Equations 5.7.18 and 5.7.19), respectively. Whereas, the smoothened Heaviside function is used for the gradual variation of the thermophysical properties from one to the other fluid, across the diffused interface,

$$\begin{aligned} \rho_m &= H_\varepsilon(\phi) + \chi(1 - H_\varepsilon(\phi)) \\ \mu_m &= \mu_1 H_\varepsilon(\phi) + \eta(1 - H_\varepsilon(\phi)) \end{aligned} \tag{5.7.38}$$

where $\chi = \rho_2/\rho_1$ is the density ratio and $\eta = \mu_2/\mu_1$ is the viscosity ratio; considering fluid 1 as the reference fluid. Note that the Heaviside and Dirac-delta functions are smoothened to avoid numerical instabilities, and make the numerical implementation a lot easier.

Gada and Sharma (2009) presented a physical interpretation of the value of H_ε at the centroid (face center) of a CV as volume (area) fraction, i.e., fraction of volume (surface) of the CV occupied by the fluid 1. Furthermore, the value of $\delta_\varepsilon(\phi)$ at the centroid of a CV was interpreted as interfacial area concentration, the ratio of interface area inside the CV and the volume of the CV. Furthermore, they used the physical interpretation (of the various functions) for a control volume-based derivation (commonly used in fluid mechanics and heat transfer) of the continuity equation (Equation 5.7.18) and LS advection equation (Equation 5.7.39), by applying volume and mass conservation laws to the CVs, respectively. The LS advection equation along with some additional equations needed in LSM are presented as follows:

Mass conservation (LS advection) equation:

$$\frac{\partial\phi}{\partial\tau} + \vec{\mathbf{U}}_{adv} \cdot \nabla\phi = 0$$
$$\text{where } \vec{\mathbf{U}}_{adv} = \vec{\mathbf{U}} + \vec{\mathbf{U}}_{PC} \quad \left\{ \vec{\mathbf{U}}_{PC} = 0.5\left(\frac{1+\chi}{\chi}\right)\dot{M}\hat{n} \right\} \tag{5.7.39}$$

where $\vec{\mathbf{U}}_{adv}$ is the sum of bulk velocity $\vec{\mathbf{U}}$ (obtained from the solution of Navier–Stokes equations) and interfacial velocity due to phase change $\vec{\mathbf{U}}_{PC}$ (obtained from the Stefan condition).

Reinitialization Equation:
Figure 5.7.6b shows that the line contour for $\varphi=-0.2$ and $\varphi=0.2$ are exactly in-between the contour for $\varphi=0$—before solving the LS advection equation; however, after the solution, the boundary of the numerically diffused interface does not lie exactly in-between the physically relevant sharp interface. Thus, the LS field no more remains the normal distance function, and leads to an inaccurate calculation of thermophysical properties and interface normal/curvature. This requires a repair of the LS function as the normal distance function, without affecting the sharp interface at $\varphi=0$. This is achieved by a reinitialization step, using a pseudo-transient partial differential equation based reinitialization equation. The equation, proposed by Sussman et al. (1994, 1999), is given as

$$\frac{\partial \phi}{\partial \tau_s} + S_\varepsilon(\phi_0)(1-|\nabla\phi|) = 0 \tag{5.7.40}$$

where τ_s is the pseudo time, $\phi_0\left(\vec{x}\right) = \phi(\vec{x}, \tau_s = 0)$, and $S_\varepsilon(\phi_0)$ is a smoothened sign function. The sign function was approximated numerically by Sussman et al. (1994) as $S_\varepsilon(\phi_0) = \phi_0 / \sqrt{\left(\phi_0^2 + \Delta x^2\right)}$; Δx is used to avoid dividing by zero. This equation is solved till steady state within the thickness of the interface so that $|\nabla\phi| = 1$. Moreover, the pseudo time step is taken as one tenth of LS node spacing (Sussman et al., 1994). The reinitialization is carried out in regular time intervals, often after each time step; however, less frequent reinitialization (for example, after every 10th time-step) are also common.

Sharp-Interface Treatment of the Energy Equation

Although the momentum equation (Equation 5.7.19) is solved using the averaged thermophysical properties, a sharp-interface formulation is commonly used for the solution of the energy equation; proposed by Son and Dhir (2007). Thus, Equation 5.7.20 for energy conservation is modified as

$$\frac{\partial \theta}{\partial \tau} + \nabla \cdot (\vec{\mathbf{U}}\theta) = \frac{1}{Re_p Pr_p} \nabla^2 \theta \tag{5.7.41}$$

where the subscript $p=1$ if $\varphi > 0$ and $p=2$ if $\varphi < 0$, and $\theta=0$ if $\varphi=0$. The application of the sharp-interface treatment of the energy equation for a phase-change problem leads to the calculation of the normal temperature gradient at the near-interface liquid and vapor points. However, the interfacial mass flux $\dot{M}$ needs to be calculated at all points inside the diffused-interface—for its efficient implementation in the continuity equation (Equation 5.7.18). Thus, a constant extrapolation (in the normal direction across the interface) of the near-interface normal gradient is used, so that both liquid and vapor temperature gradients are available at all points inside the diffused-interface. This is achieved by an *extension equation*, again a pseudo-transient partial differential equation (Son and Dhir, 2007), given as

$$\frac{\partial}{\partial \tau_s}\left(\frac{\partial \theta}{\partial n}\right)_p + S(\phi)\hat{n} \cdot \nabla\left(\frac{\partial \theta}{\partial n}\right)_p = 0 \tag{5.7.42}$$

where subscript $p=1$ ($p=2$) when extrapolating the liquid (vapor) side temperature gradient. Moreover, τ_s is the pseudo time, and $S\left(\phi\right)$ is a sharp sign function; equal to –1, 0, and 1 for $\varphi < 0$, $\varphi > 0$, and $\phi=0$.

Numerical Methodology

One of the biggest disadvantages of the LSM is mass error, i.e., an error in the conservation of mass (Chang et al., 1996; Sussman and Fatemi, 2000, Yap et al., 2006), with a timewise unphysical

increase or decrease in the amount of particular fluid (enclosed within an interface) as the interface evolves with time. One of the reasons for the mass error is numerical diffusion in the discretization of LS advection equation, which can be handled by using higher order advection scheme. Gada (2012) mentioned that mass error acts as an indicator of the numerical inaccuracy in the solution of LS advection equation (derived from mass conservation law; Gada and Sharma, 2009); whereas, in VOF method, there is no such indicator for the numerical inaccuracy in the solution of volume fraction advection equation.

One of the simplest approaches to reduce the mass error is the grid refinement; however, the other approaches using a higher order advection scheme and better reinitialization procedure are also available. Furthermore, without using the reinitialization equation and combining LSM with another method, hybrid methods were introduced. Since the mass error reduces with grid refinement, adaptive and dual-grid LSMs (Gada and Sharma, 2011) are found to be effective.

During the early days of LSM (Sussman et al., 1994), both LS advection and reinitialization equations were solved by second-order Essentially Non-Oscillatory (ENO) scheme (Shu and Osher, 1989). However, nowadays, LS advection equation is mostly solved with high-order schemes in time and space; third-order total variation diminishing (TVD) Runge–Kutta scheme and third-order or fifth-order Weighted Essentially Non-Oscillatory (WENO) scheme (Jiang and Peng, 2000), respectively.

One of the recent and significant developments in the LSM is the introduction of ghost fluid method, as a numerical technique for sharply enforcing the boundary or matching conditions at the interface (without being smeared out over several grid points); called *as sharp-interface LSM*, proposed by Fedkiw et al. (1999). Recently, Shaikh et al. (2016) presented a detailed numerical methodology for the sharp-interface LSM and its application to a range of heat and/or mass transfer induced Stefan problems.

The solution algorithm for two-phase flow simulation, using the LSM, proceeds as follows:

1. Initialize the LS field in the domain as per the initial interface configuration. Initialize velocities, pressure, temperature, and interfacial mass flux as zero.
2. Calculate the Heaviside function (Equation 5.7.36) and Dirac-delta function (Equation 5.7.37) from the LS field and the property field.
3. Solve the continuity and momentum equations (Equations 5.7.18 and 5.7.19), to obtain new time-level velocity and pressure field.
4. Solve the energy equation (Equation 5.7.41) using the sharp-interface LSM, to obtain the new time-level temperature field.
5. Calculate the normal temperature gradient at near-interface cells, extrapolate it to the diffused interface (Equation 5.7.42) and calculate interfacial mass flux (Equation 5.7.18) and interface velocity due to phase change.
6. Add the background velocity (from step 3) and velocity due to phase change (from step 5) at LS cell centers to obtain the total advecting velocity of LS function. Solve the LS advection equation (Equation 5.7.39) to obtain the new time-level LS field.
7. Solve the reinitialization equation (Equation 5.7.40)—to reinitialize the LS field.
8. Go to step 2 till the stopping criterion is met.

Application of LSM

The physical situation of an application for 3D film boiling is shown in Figure 5.7.7, wherein a rod is located in the pool of saturated liquid. The rod is subjected to uniform volumetric heat generation and its surface temperature is high enough to ensure an enveloping vapor film, which restricts any contact of liquid with the rod surface. The heat generated from the rod is transferred across the vapor layer to the interface; leading to phase change. Due to continuous generation of vapor, the thickness of vapor film increases, and beyond a certain thickness, the interface becomes unstable. The vapor

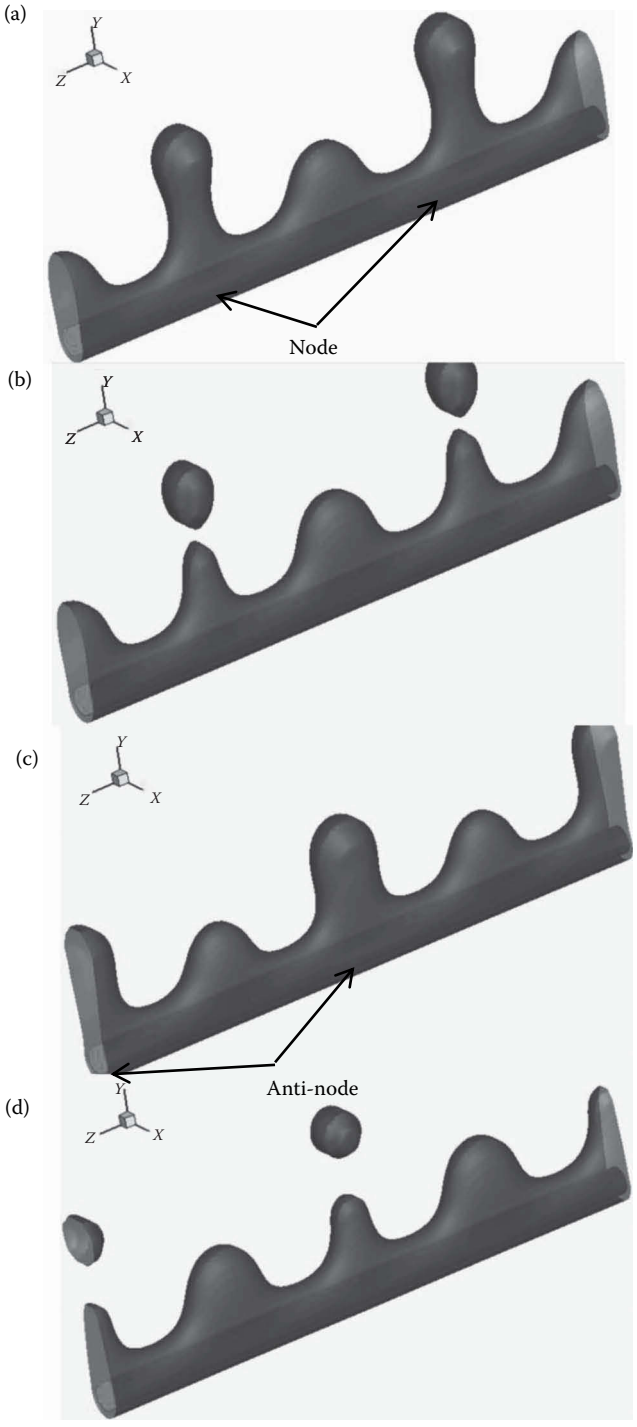

FIGURE 5.7.7 Application of a dual-grid LSM: Interface dynamics for conjugate heat transfer and 3D film boiling over a heat-generating rod (From Gada, V. H. A novel level-set based CMFD methodology in 2D/3D Cartesian and cylindrical coordinates and its application for analysis of stratified flow and film boiling. PhD Thesis, Mechanical Engineering, IIT Bombay, Mumbai, 2012.).

begins to accumulate near the crest/node of the wavy interface. Furthermore, the vapor bulb at the node grows to form a vapor bubble (Figure 5.7.7a), which ultimately breaks away beyond a certain size (Figure 5.7.7b). Thereafter, the interface retracts towards the heater rod and the bubble-release process starts at an alternate location, i.e., the antinode (Figure 5.7.7c and d).

Here, the situation is inherently 3D; where the vapor is generated at the interface enveloping the complete cylinder. However, the vapor rises up continuously due to buoyancy, leading to thinner film (and increased generation of vapor) at the bottom of cylinder. The accumulation of vapor on top of the cylinder gives rise to instability in the axial direction, leading to periodic formation and release of bubbles, which deform in all the directions. This periodic process of bubble formation and release at node and antinode, affects the temperature on the rod.

Concluding Remarks

Both numerical methodology and application of three important computational methods for simulating multiphase processes are presented here. Enthalpy method, presented here, has been widely employed for solving solid–liquid phase-change problems in multicomponent systems in macroscopic framework. VOF method as compared to LSM has a much less mass-conservation error; whereas, LSM is much easier to implement and also straightforward to extend from 2D to 3D. Thus, probably VOF method has a better formulation and LSM is numerically friendly.

Most of the numerical methods for multiphase flows exist in the context two-phase systems. Several approaches exist for obtaining phenomenological simulations of processes involving more than two phases, such as a gas, solid and liquid or multimaterial flows. Some of the recent efforts have particularly addressed such problems, for example, Karagadde et al. (2012b) presented a coupled LS and enthalpy approach to simulate growth and motion of hydrogen bubbles and their interaction with an evolving solidifying interface; Starinshak et al. (2014) presented a LSM for simulating flows involving multiple immiscible fluids. Hence, multiphase modeling approaches have demonstrated their potential to numerically simulate a variety of complex problems and processes. In future, there is a scope for numerically modeling multiphase fluid-structure interaction problems (modeling timewise varying two-fluid interface as well as solid–fluid interface), with appropriate wetting models. Furthermore, there is scope for improvements in the numerical methods to incorporate the microscopic interaction involved in moving contact line and nucleate boiling.

5.8 LARGE EDDY SIMULATION OF WALL-BOUNDED FLOWS

Amitabh Bhattacharya

Introduction

Turbulence is ubiquitous in both nature and engineering flows, and is characterized by velocity fields that contain a range of time and length scales (Pope, 2000). In this chapter, we will consider numerical simulation of incompressible isothermal flows, with velocity field $\mathbf{u}(\mathbf{x},t)$ and pressure field $p(\mathbf{x},t)$ that satisfy the Navier–Stokes equation (Cartesian tensor notation is used for Greek indices in this text):

$$\frac{\partial u_i}{\partial x_i} = 0 \tag{5.8.1}$$

$$\frac{\partial u_i}{\partial t} + u_k \frac{\partial u_i}{\partial x_k} = -\frac{\partial p}{\partial x_i} + \nu \frac{\partial^2 u_i}{\partial x_k^2} \tag{5.8.2}$$

Here, $\mathbf{x}$ denotes spatial coordinates, t denotes time, and ν is the kinematic viscosity of the fluid. The computational domain (Figure 5.8.1) is denoted as $\mathcal{D}$, with walls $\partial\mathcal{D}_w$ and inlets/outlets $\partial\mathcal{D}_f$. The boundary conditions for $\mathbf{u}$ are as follows:

$$\mathbf{u}(\mathbf{x},t) = 0 \quad \text{for} \quad \mathbf{x} \in \partial\mathcal{D}_w \quad \text{(No slip BC)} \tag{5.8.3}$$

$$\mathbf{u}(\mathbf{x},t) = \mathbf{u}^f(\mathbf{x},t) \quad \text{for} \quad \mathbf{x} \in \partial\mathcal{D}_f \quad \text{(Inlet/outlet BC)} \tag{5.8.4}$$

Solving Equations 5.8.1 and 5.8.2 via direct numerical simulation (DNS) requires a fine grid, which resolves the flow down to the Kolmogorov scales (Moin and Mahesh, 199). Particularly, at large Reynolds numbers, the ratio of large (integral scales) to small (Kolmogorov) length scales increases, requiring very large number of computational grid points and long computational times. For isotropic homogeneous turbulence, DNS computational time scales with Re_t^3 (Pope, 2000), while, for wall-bounded turbulent flows, DNS computational time scales with $Re_L^{2.4}$ (Chapman, 1979). Here, Re_t is the turbulent Reynolds number and Re_L is the Reynolds number based on streamwise length of the turbulent boundary layer, L. In large eddy simulation (LES), the goal is to reduce the computational time required to solve Equations 5.8.1 and 5.8.2 by evolving only the large scales, and model the effect of the small, "subgrid" scales on the large scales.

"Large scales" in the flow are defined via a spatial low pass filter of $\mathbf{u}(\mathbf{x},t)$ and $p(\mathbf{x},t)$, with a characteristic cutoff wavenumber $k_c = \pi/\Delta$, where Δ is the "filter width." The filtered velocity field $\tilde{\mathbf{u}}(\mathbf{x},t)$, where small-scale features of the flow have been eliminated, can be expected to have flow features with higher eddy turnover times (compared to the Kolmogorov scales). Thus, coarser spatial grid and larger time steps may be used to numerically evolve $\tilde{\mathbf{u}}(\mathbf{x},t)$. If k_c is chosen correctly, so that it lies within the inertial range of the energy spectra of the flow, the effect of the unresolved smaller scales on the larger scales can be expected to be universal [e.g., via scale similar cascade of energy from large to small scales (Kolmogorov, 1941)]. At the same time, evolving the large scales explicitly allows us to capture the effect of complex boundary conditions on the flow accurately. This makes LES models more accurate in comparison with Reynolds averaged Navier–Stokes (RANS) models, which explicitly evolve only the mean velocity $\langle\mathbf{u}(\mathbf{x},t)\rangle$, while trying to model the effect of *all* the fluctuating scales (i.e., including largest fluctuating scales) in the flow on $\langle\mathbf{u}(\mathbf{x},t)\rangle$.[1] Thus, while RANS models are computationally inexpensive compared to LES models, the model

[1] $\langle[\cdot]\rangle$ denotes ensemble average.

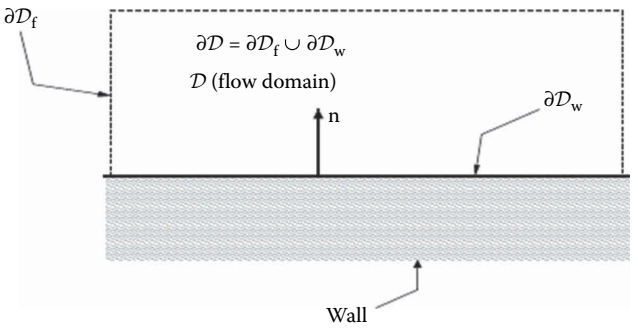

FIGURE 5.8.1 Schematic of computational domain.

constants in RANS often need to be recalibrated for different flow geometries to maintain accuracy, thus limiting its predictive capabilities.

Properties of LES Filter

For any field $\phi(\mathbf{x},t)$, the filtering operator, $\widetilde{[\cdot]}$ implies

$$\tilde{\phi}(\mathbf{x},t) = \int_{\mathcal{D}} \phi(\mathbf{x}',t) G(\mathbf{x},\mathbf{x}'-\mathbf{x}) d\mathbf{x}' \tag{5.8.5}$$

Here, $G(\mathbf{x},\mathbf{r})$ is the filter kernel (Ghosal and Moin, 1995; Sagaut, 2006), which smoothens $\phi(\mathbf{x},t)$ spatially and $\mathcal{D}$ is the flow domain (Figure 5.8.1). At any $\mathbf{x}$ location, $|G(\mathbf{x},\mathbf{r})|$ decays to zero beyond $|\mathbf{r}| > \Delta/2$. Therefore, for a given $\mathbf{x}$, the filter kernel is associated with a filter width Δ (Figure 5.8.2). In general, Δ itself will be a function of $\mathbf{x}$, i.e., $\Delta = \Delta(\mathbf{x})$. When Δ is independent of $\mathbf{x}$, the filter is said to be "homogeneous." Otherwise, the filter is called "inhomogeneous." In general, LES filters are inhomogeneous, especially in complex geometries. On a structured Cartesian computational grid, the filter kernel $G(\mathbf{x},\mathbf{r})$ is expressed as a product of three one-dimensional filter kernels $G_\alpha^{1D}(x,r)$:

$$G(\mathbf{x},\mathbf{r}) = \prod_{\alpha=1}^{3} G_\alpha^{1D}(x_\alpha, r_\alpha) \tag{5.8.6}$$

In general, $G_\alpha^{1D}(x,r)$ may be different for each α. Two popular filters are "Box" and "Gaussian" (Table 5.8.1). The important properties of homogeneous LES filters are listed here. Inhomogeneous

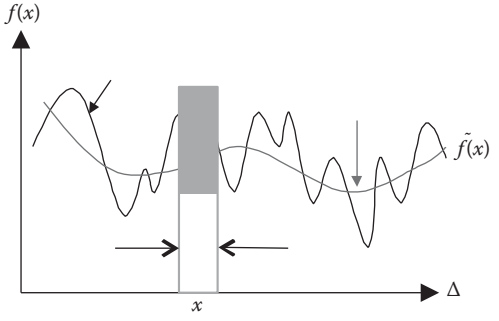

FIGURE 5.8.2 Operation of $\widetilde{[\cdot]}$ on any function $f(x)$ leads to the "filtered" function $\tilde{f}(x)$. The filter kernel $G(r)$ is small for $r > \Delta/2$. Thus, the filtering acts like a moving average and leads to the elimination of scales with size less than Δ. $\tilde{f}(x)$ is smoother compared to $f(x)$. Δ can be a function of x for inhomogeneous filters.

TABLE 5.8.1
Types of Filters. Here *H(x)* Is the Heaviside Function

Name	Filter Kernel ($G^{1D}(x,r)$)
Box	$\frac{1}{\Delta}\left(\frac{1}{2}\Delta(x)-\lvert r\rvert\right)$
Gaussian	$\left(\frac{6}{\pi\Delta(x)}\right)^2 \exp\left(-\frac{6r^2}{\Delta(x)^2}\right)$

filters will be discussed later in the text. We will therefore suppress the **x** dependence of G in the following.

The filtered field should have the same global average as the original unfiltered field. This implies $\int_D G(\mathbf{r})d\mathbf{r} = 1$. It is also easy to prove that the filtering operator is linear, i.e., $\widetilde{\phi(\mathbf{x})+\psi(\mathbf{x})} = \tilde{\phi}(\mathbf{x})+\tilde{\psi}(\mathbf{x})$. Next, if the flow domain D is infinite in space, then it is possible to show that

$$\frac{\partial\tilde{\phi}}{\partial x_k} = \widetilde{\frac{\partial\phi}{\partial x_k}} \tag{5.8.7}$$

In other words, for homogeneous filters, in the absence of any walls, the filtering operator $[\widetilde{\cdot}]$ and differentiation $\partial/\partial x_k$ commute. This property is not true for inhomogeneous filters, for which the "commutation error" $\frac{\partial\tilde{\phi}}{\partial x_k} - \widetilde{\frac{\partial\phi}{\partial x_k}}$ will not be zero in general. In the presence of boundaries, even for homogeneous filters, it can be shown that (Bhattacharya et al., 2008)

$$\widetilde{\frac{\partial\phi(\mathbf{x})}{\partial x_i}} = \frac{\partial\tilde{\phi}(\mathbf{x})}{\partial x_i} - \int_{\partial\mathcal{D}_f} G(\mathbf{x}'-\mathbf{x})\phi(\mathbf{x}')n_i d^2\mathbf{x}' - \int_{\partial\mathcal{D}_w} G(\mathbf{x}'-\mathbf{x})\phi(\mathbf{x}')n_i d^2\mathbf{x}' \tag{5.8.8}$$

The last two terms in the above equations involve values of ϕ (and not $\tilde{\phi}$) at the wall. These terms can be neglected if **x** is located at a distance much larger than Δ from the boundary, where the contribution of G to these integrals will be zero.

Filtering due to Numerical Discretization

Filtering of a spatial field essentially reduces the magnitude of the higher wavenumber modes in the field. It can be demonstrated that numerical discretization itself acts like a filter. Consider a function $\phi(x)$ that is periodic over $x \in [0,L]$ and which can be decomposed into its Fourier modes: $\phi(x) = \sum_{n=-\infty}^{\infty} \hat{\phi}_n \exp(ik_n x)$, where $k_n = 2\pi n/L$. A uniform computational grid with cell width Δ^g ensures that Fourier modes with wavenumbers $k_n > \pi/\Delta^g$ are not being represented on the grid. Thus, due to the reduction in the number of degrees of freedom, the very act of numerical discretization is equivalent to applying a low pass spatial filter on $\phi(x)$, with filter width Δ^g (Langford and Moser, 1999). Moreover, discretized differential operators acting on $\phi(x)$ may cause further attenuation of Fourier modes with higher wavenumber. For instance, if we discretize the derivative $\mathrm{d}\phi/\mathrm{d}x$ using a second-order finite-difference scheme, then we observe that

$$\left.\frac{\mathrm{d}\phi}{\mathrm{d}x}\right|_{x_i} = \frac{\phi(x_{i+1})-\phi(x_{i-1})}{2\Delta^g} = \sum_{n=-\infty}^{\infty} ik_n \frac{\sin(k_n\Delta^g)}{k_n\Delta^g}\hat{\phi}_n \exp(ik_n x)$$

Since $\sin(x)/x$ is small for $x > \pi$, it can be seen that $\sin(k_n\Delta^g)/k_n\Delta^g$ causes an attenuation of Fourier modes with $k_n \gg \pi/\Delta^g$. Thus, a finite-difference discretization of the derivative operator itself acts like a filter, although the corresponding shape of the filter kernel will depend on the specifics of the discretization scheme.

Governing Equations

We can now apply $\widetilde{[\cdot]}$ on Equations 5.8.1 and 5.8.2 and use the properties of LES filters (Equations 5.8.5–5.8.8) to obtain (Bhattacharya et al., 2008)

$$\frac{\partial \tilde{u}_k}{\partial x_k} = 0 \tag{5.8.9}$$

$$\frac{\partial \widetilde{u_i}}{\partial t} + \frac{\partial \widetilde{\tilde{u}_i \tilde{u}_k}}{\partial x_k} = -\frac{\partial \tilde{p}}{\partial x_i} + \nu \frac{\partial^2 \tilde{u}_i}{\partial x_k \partial x_k} + B_i^f + M_i + B_i \tag{5.8.10}$$

where

$$M_i = -\frac{\partial \tau_{ik}}{\partial x_k}, \tau_{ij} = -\left[\widetilde{\tilde{u}_i \tilde{u}_j} - \widetilde{u_i u_j}\right] \tag{5.8.11}$$

$$B_i(\mathbf{x}) = -\int_{\partial \mathcal{D}_w} G(\mathbf{x}' - \mathbf{x}) \sigma_{ik}(\mathbf{x}') n_k d^2\mathbf{x}' \tag{5.8.12}$$

$$B_i^f(\mathbf{x}) = -\int_{\partial \mathcal{D}_f} G(\mathbf{x}' - \mathbf{x})[u_i(\mathbf{x}')u_k(\mathbf{x}')n_k + \sigma_{ik}(\mathbf{x}')]n_k d^2\mathbf{x}' \tag{5.8.13}$$

$$\sigma_{ij} = \nu \frac{\partial u_i}{\partial x_j} - \delta_{ij} p \tag{5.8.14}$$

In Equation 5.8.10, the terms M_i, B_i, and B_f need to be modeled or specified, since they do not involve $\tilde{\mathbf{u}}$ or its gradients. M_i is the subgrid force term and is equal to the divergence of the subgrid stress τ_{ij} (Equation 5.8.11). If $\mathbf{u}$ is decomposed into its resolved $\left(\tilde{\mathbf{u}}\right)$ and unresolved ($\mathbf{u}''$) parts as $\mathbf{u} = \tilde{\mathbf{u}} + \mathbf{u}''$, then we can express the subgrid stress (SGS) as $\tau_{ij} = \widetilde{\tilde{u}_i u_{j''}} + \widetilde{\tilde{u}_j u_{i''}} + \widetilde{u_{i''} u_{j''}}$. Thus, τ_{ij} is an unclosed term since it contains information about unresolved scales; modeling this subgrid stress is one of the big challenges in LES. In the following text, we will discuss ways to model τ_{ij} in terms of $\tilde{\mathbf{u}}$. The body force due to filtered stresses at the wall, B_i, involves viscous and pressure stresses at the wall. For pressure, typically $p = \tilde{p}$ is used at the wall, which is a good approximation since pressure does not vary significantly across the height of the boundary layer. Modeling the viscous traction $\tau_i^{\nu} = \nu \frac{\partial u_i}{\partial n}$ at the wall can be more challenging since velocity gradients are steep within the viscous layer and may not be captured if the filter width Δ is much larger than the viscous length scale at the wall, $l^+ = \nu/u\tau$, where $u_\tau = \sqrt{\left|\nu \frac{\partial \langle u \rangle_i}{\partial n}\right|}$ is the wall friction velocity. One of two approaches may be taken to model σ_{ij} at the wall (Figure 5.8.3). In the first approach, $\Delta \gg l^+$ is chosen, even closer to the wall, and the unresolved viscous traction τ_i^w is modeled in terms of $\tilde{u}_i$ using the "log law" for turbulent boundary layers. This approach, commonly referred to as "wall-modeled LES," is computationally inexpensive, but may not be accurate for nonequilibrium boundary layers, where the log law is not valid in general. In the second approach, Δ is reduced near the wall to $\Delta \sim l^+$ so

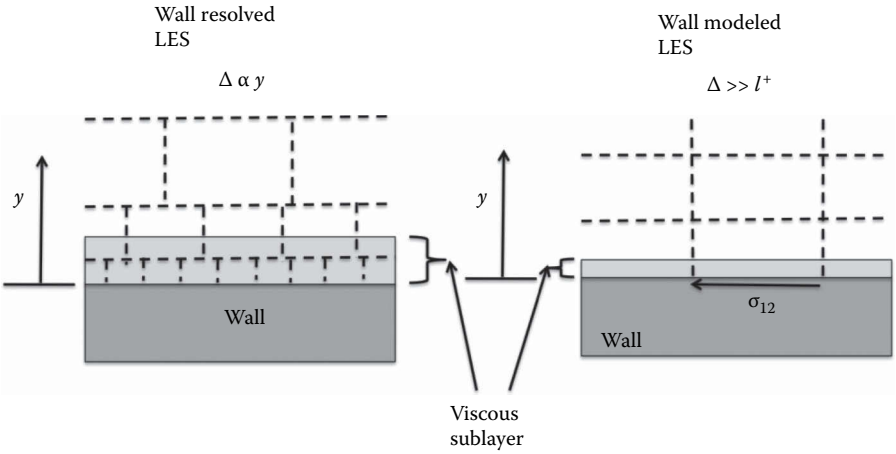

FIGURE 5.8.3 Schematic of wall-resolved (left) versus wall-modeled LES (right). The dashed lines indicate the grid cells in the mesh; note that Δ^g, the size of the grid cell may be different from Δ. The viscous sublayer, of thickness $O(l^+)$, is resolved by the grid in wall-resolved LES. In wall-modeled LES, Δ is much larger than the thickness of the viscous sublayer; in this case, the wall traction components, σ_{i2}, need to be modeled in terms of $\tilde{\mathbf{u}}$.

that the velocity gradients in the near-wall viscous layer are well captured by $\tilde{\mathbf{u}}$ and $\tilde{\mathbf{u}} = 0$ can be applied at the wall. This approach, commonly referred to as "wall-resolved LES", while yielding higher levels of accuracy, is much more computationally expensive, and requires inhomogeneous filters, which in turn may lead to large commutation errors. The body force term due to stresses at inlet/outlet boundaries, B_i^f, does not usually require any modeling, since viscous stresses are negligible away from the wall, $p = \tilde{p}$ may be assumed, and $u_i(\mathbf{x}')u_k(\mathbf{x}') = \tilde{u}_i(\mathbf{x}')\tilde{u}_k(\mathbf{x}')$ may be assumed far from the wall.

Explicit Filtering

The filter kernel $G(\mathbf{x})$ appears explicitly in the second left-hand side term in Equation 5.8.10, where $\widetilde{\tilde{u}_i\tilde{u}_k}$ has to be obtained. The filter kernel is also required in Equations 5.8.12 and 5.8.13, besides being of importance in the "dynamic Smagorinsky model" (explained later on) for obtaining C_s dynamically. In LES, like in any numerical technique, the velocity field is discretized on a computational grid. Since filtering such a discretized field using Equation 5.8.5 essentially amounts to a numerical integration over a region with size Δ, explicit application of the kernel requires the cell width of the computational grid, Δ^g, to be much less than the filter width Δ. In such approaches, the filtering operation has to be discretized. In a single direction, using a three point stencil with $\Delta / \Delta_g = \sqrt{6}$, it can be shown that both the Gaussian and the box filters can be represented as (Garnier et al., 2009)

$$\tilde{\phi}_i = \frac{1}{4}(\phi_{i-1} + 2\phi_i + \phi_{i+1})$$

This discretization has an $O(\Delta_g^2)$ error associated with it. For inhomogeneous filters, alternate representations can be used to minimize commutation error to an arbitrary order of accuracy (Vasilyev et al., 1998). Usage of explicit filtering leads to extra computational cost, since the cell width Δ^g is smaller than the filter width Δ for such an approach. In practice, $\Delta^g = \Delta$ is used more often, especially since, as explained in the section "Filtering Due to Numerical Discretization," numerical discretization itself leads to spatial low-pass filtering, with $\Delta \approx \Delta^g$.

Subgrid Stress Models

A major focus of LES has been to construct models for the SGS, $\tau_{ij} = -\left[\widetilde{\tilde{u}_i\tilde{u}_j} - \widetilde{u_i u_j}\right]$ (Equation 5.8.11), in terms of the filtered velocity field $\tilde{u}_i$. Three popular SGS models are presented below.

Smagorinsky Model

The Smagorinsky model (SM) (Smagorinsky, 1963) for SGS is given by

$$\tau_{ij} = \frac{1}{3}\delta_{ij}\tau_{kk} - 2(C_s\Delta)^2 S\tilde{S}_{ij} \tag{5.8.15}$$

$$\text{where } \tilde{S} = \sqrt{2\tilde{S}_{ij}\tilde{S}_{ij}} \quad \tilde{S}_{ij} = \frac{1}{2}\left(\frac{\partial\tilde{u}_i}{\partial x_j} + \frac{\partial\tilde{u}_j}{\partial x_i}\right), C_s = 0.16 \tag{5.8.16}$$

Here, Δ is the filter width. For anisotropic flows, where the filter width may be different in the three directions (e.g., Δ_x, Δ_y, Δ_z), we can use $\Delta = \sqrt{\frac{\Delta_x^2 + \Delta_y^2 + \Delta_z^2}{3}}$, or $\Delta = (\Delta_x\Delta_y\Delta_z)^{1/3}$. In Equation 5.8.15, the trace of the subgrid stress, τ_{kk}, does not need to be modeled, as it can be absorbed into the pressure in Equation 5.8.10. The SM essentially uses an eddy viscosity to model SGS, where the length scale and velocity scale for defining the eddy viscosity are obtained from the filter width Δ and local strain rate S. This model ensures that the net dissipation rate to subgrid scales, given by $-\langle\tau_{ij}S_{ij}\rangle = (C_s\Delta)^2\langle S^3\rangle$ is always positive, as it should be, if Δ lies within the inertial range. Moreover, equating $-\langle\tau_{ij}S_{ij}\rangle = \epsilon$, where ϵ is the viscous dissipation rate $\epsilon = \nu\left\langle\frac{\partial u_{i'}}{\partial x_k}\frac{\partial u_i'}{\partial x_k}\right\rangle$ and $u_i' = u_i - \langle u_i\rangle$, it is possible to relate C_s to the universal constant in Kolmogorov's five-thirds law, valid for homogeneous isotropic turbulence. However, the energy cascade mechanism is not valid near the wall for scales that are comparable in size to the boundary layer thickness. Therefore, $C_s = 0.16$ does not give optimal results for wall-bounded flows with homogeneous filters, especially if Δ is made proportional to the boundary layer thickness.

For wall-resolved LES, where inhomogeneous filters are used and $\Delta \approx l^+$ at the wall, the known wall asymptotics of the velocity fluctuations is used to deduce how C_s needs to be damped at the wall. Continuity equation $\nabla\cdot\mathbf{u}' = 0$ at the wall implies that $v' \sim y^2$, while $u' \sim y$ and $w' \sim y$, where y is the distance from the wall. Since the mean strain rate $\langle S\rangle$ goes to a constant at the wall, it implies an $O(y^3)$ scaling for the eddy viscosity. On the other hand, the eddy viscosity from SM goes to a constant value at the wall (since Δ and S are finite at the wall). Therefore, in wall-resolved LES with SM, the eddy viscosity is multiplied by a Van Driest damping factor:

$$f_w(y) = \left[10 - \exp\left(-\frac{yu_\tau}{25\nu}\right)\right]$$

so that the modified SM model for SGS is

$$\tau_{ij} = \frac{1}{3}\delta_{ij}\tau_{kk} - 2f_w(y)(C_s\Delta)^2 S\tilde{S}_{ij} \tag{5.8.17}$$

Dynamic Smagorinsky Model

The model constant C_s in SM is calibrated against homogeneous isotropic turbulence. The dynamic Smagorinsky model (DSM) (Germano et al., 1991) uses the scale similar nature of turbulence to obtain the value of C_s from $\tilde{\mathbf{u}}(\mathbf{x},t)$ at every time step, making the model free of any imposed

constants. The basic principle behind the model is that due to the scale similar nature of turbulence, the model constant C_s is invariant to the filter width Δ. Therefore, in this model, a "test filter" with filter width $\overline{\Delta}$ is used, such that $\overline{\Delta} = \alpha\Delta$, where $\alpha > 1$. Typically, $\alpha = 2$ is used. The intrinsic shape of the test filter kernel, $\overline{[\cdot]}$, is usually kept the same as the original filter kernel $\widetilde{[\cdot]}$. A third filter, denoted as $\widehat{[\cdot]}$, is the test filter of the original filter $\widetilde{[\cdot]}$, e.g., $\hat{u}_i = \overline{\tilde{u}}_i$. The SGS model is then assumed to have the form given by SM at both $\widetilde{[\cdot]}$ and $\widehat{[\cdot]}$ levels:

$$T_{ij} = \widehat{u_i u_j} - \widehat{\hat{u}_i \hat{u}_j} = \frac{1}{3}\delta_{ij} T_{kk} - 2(C_s \overline{\Delta})^2 \hat{\bar{S}}\hat{\bar{S}}_{ij} \tag{5.8.18}$$

$$\tau_{ij} = \widetilde{u_i u_j} - \widetilde{\tilde{u}_i \tilde{u}_j} = \frac{1}{3}\delta_{ij} \tau_{kk} - 2(C_s \Delta)^2 \tilde{\bar{S}}\tilde{\bar{S}}_{ij} \tag{5.8.19}$$

where T_{ij} is the SGS if $\widehat{[\cdot]}$ is operated on Equation 5.8.2. Now, taking a test filter of Equation 5.8.19, we get

$$\overline{\tau}_{ij} = \overline{\widetilde{u_i u_j}} - \overline{\widetilde{\tilde{u}_i \tilde{u}_j}} = \frac{1}{3}\delta_{ij} \overline{\tau}_{kk} - 2(C_s \Delta)^2 \overline{\tilde{\bar{S}}\tilde{\bar{S}}_{ij}} \tag{5.8.20}$$

Subtracting Equation 5.8.20 from Equation 5.8.18, making it trace-free, and noting that $\widehat{[\cdot]} = \overline{\overline{[\cdot]}}$, we can get

$$\Rightarrow L_{ij} - \frac{\delta_{ij}}{3} L_{kk} = 2(C_s)^2 M_{ij} \tag{5.8.21}$$

where

$$L_{ij} = T_{ij} - \overline{\tau}_{ij} = \widehat{\tilde{u}_i \tilde{u}_j} - \widehat{\hat{u}_i \hat{u}_j}$$

is called as the Leonard stress and can be completely constructed from the resolved velocity field $\tilde{u}_i$, while

$$M_{ij} = \Delta^2 \left[\overline{\tilde{\bar{S}}\tilde{\bar{S}}_{ij}} - \alpha^2 \hat{\bar{S}}\hat{\bar{S}}_{ij} \right]$$

can be calculated from the strain rate of $\tilde{u}_i$. Minimizing the error between the left-hand side (LHS) and right-hand side (RHS) of Equation 5.8.21 over all statistically homogeneous directions, we get (Lilly, 1992)

$$C_s^2(\mathbf{x}) = \frac{\langle L_{ij}(\mathbf{x}) M_{ij}(\mathbf{x}) \rangle}{\langle M_{ij}(\mathbf{x}) M_{ij}(\mathbf{x}) \rangle} \tag{5.8.22}$$

In Equation 5.8.22, the averaging operator $\langle [\cdot] \rangle$ implies averaging over statistically homogenous directions at a given time. Thus, this procedure yields C_s dynamically from the instantaneous velocity field $\tilde{u}_i$. In simulations of fully developed turbulent channel flow, it has been found that C_s reaches a value of 0.16 at the center of the channel, where the flow is homogeneous and isotropic, while it reduces to zero near the wall, as desired. Note that a positive value of C_s^2 is required to keep the eddy viscosity positive, without which the scheme becomes unstable. Equation 5.8.22 does not however guarantee a positive value of C_s^2, and, in practice, its value is clipped at zero if it becomes negative.

Most engineering flows do not have statistically homogeneous directions. In such cases, a Lagrangian dynamic averaging procedure (Meneveau et al., 1996) can be used, where the error

between LHS and RHS of Equation 5.8.21 is minimized for a fluid tracer particle over some time T_{lag}. This involves solving two additional equations for the fields $\mathcal{J}_{LM}(\mathbf{x},t)$ and $\mathcal{J}_{MM}(\mathbf{x},t)$:

$$\frac{D\mathcal{J}_{LM}}{Dt} = \frac{1}{T_{\text{lag}}}(L_{ij}M_{ij} - \mathcal{J}_{LM})$$

$$\frac{D\mathcal{J}_{MM}}{Dt} = \frac{1}{T_{\text{lag}}}(M_{ij}M_{ij} - \mathcal{J}_{MM})$$

where $T_{\text{lag}}(\mathbf{x},t) = 15\Delta(\mathcal{J}_{MM}\mathcal{J}_{LM})^{-1/8}$. The model constant is then calculated dynamically as

$$C_s^2(\mathbf{x},t) = \frac{\mathcal{J}_{LM}}{\mathcal{J}_{MM}}$$

This procedure still does not guarantee that C_s^2 is positive (and therefore requires negative values to be clipped at zero); it is also computationally more expensive, because of the two additional equations that need to be solved.

Wall Adaptive Local Eddy Viscosity Model

One of the challenges in using DSM or SM models is that the subgrid stress may not be correctly damped at lower Reynolds numbers, especially since conventional wall damping functions (Equation 5.8.4.1) require distance from the wall in "+" units as an input. This can be a serious issue in flows where transition is important (e.g., flat plate boundary layer transitioning from laminar to turbulent state in the streamwise direction). In the wall adaptive local eddy viscosity model (WALE) (Nicoud and Ducros, 1999), an eddy viscosity is devised that vanishes in an appropriate way near the wall (i.e., like $\nu_t \sim y^3$) and at low Reynolds numbers. The model, which can only be used in a wall-resolved LES, is given as follows:

$$\tau_{ij} = \frac{\tau_{kk}}{3}\delta_{ij} - 2\nu_t\tilde{S}_{ij}$$

$$\nu_t = (C_w\Delta)^2 \frac{(\mathcal{L}_{ij}\mathcal{L}_{ji})^{3/2}}{(S_{kl}S_{kl})^{5/2} + (\mathcal{L}_{mn}\mathcal{L}_{mn})^{5/4}}$$

$$\mathcal{L}_{ij} = S_{ik}S_{kj} + \Omega_{ik}\Omega_{kj} - \frac{1}{3}(S_{ik}S_{ki} + \Omega_{ik}\Omega_{ki})\delta_{ij}$$

$$S_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right), \Omega_{ij} = \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} - \frac{\partial u_j}{\partial x_i}\right)$$

where $C_w = 0.5$ is the only model constant. Unlike SM or DSM, the subgrid stress also depends on both strain rate and vorticity. Moreover, the WALE model does not explicitly depend on the distance from the wall, and works better than SM or DSM in transitional flows.

Errors in LES

Several types of errors may be present in any practical LES simulation:

Modeling error: This is the most obvious error present when τ_{ij}, B_i, and B_i^f are not well represented by models. Usually, the *a priori* modeling errors between subgrid stresses calculated from DNS and LES can be quite large. Interestingly, LES performs well in spite of such large modeling errors (Meneveau and Katz, 1999). This issue is addressed by the "Optimal LES" (OLES) formulation (Langford and Moser, 1999), in which it is argued that the "best" subgrid stress model minimizes the *a priori* error, even though this error itself may be quite large. While

a practical OLES model has been formulated for homogeneous isotropic turbulence (Moser et al., 2009), this approach requires DNS data for wall-bounded flows (Völker et al., 2002; Bhattacharya et al., 2008).

Numerical discretization error: Numerical discretization errors (Ghosal, 1996) may be present due to the order of discretization of the differential operators in Equations 5.8.9 and 5.8.10. If a second-order discretization is used for the advection term, for instance, then the error will be $O((\Delta^g)^2)$. Since the subgrid stress models in LES are usually $O(\Delta^2)$ (e.g., Equation 5.8.15), higher order (third order or higher) discretization should ideally be used to discretize the terms in Equations 5.8.9 and 5.8.10, to ensure that the numerical discretization errors do not dominate the modeled subgrid stress terms. This issue is somewhat less serious if explicit filtering with large value of Δ/Δ^g is used.

Commutation error: As mentioned earlier, the filtering operator and spatial derivative operator do not commute for inhomogeneous filters; the resulting errors (e.g., $\widetilde{\frac{\mathrm{d}\mathbf{u}}{\mathrm{d}x_i}} - \frac{\mathrm{d}\tilde{\mathbf{u}}}{\mathrm{d}x_i}$) are known as the commutation error in LES, and imply that additional terms will be present in Equations 5.8.9 and 5.8.10 for LES with inhomogeneous filters (Ghosal and Moin, 1995). It is possible to construct explicit filters carefully, so that commutation error is only $O((\Delta^g)^n)$, where n is the desired order of the error (Vasilyev et al., 1998). However, it is not possible to remove commutation error without explicit filtering approaches.

Aliasing error: This type of error occurs due to presence of nonlinear terms in Equation 5.8.10, in which the product of two functions represented by N spatial Fourier modes gives rise to a function with $2N$ Fourier modes (Ghosal, 1996). Such a product of functions cannot be represented accurately on a grid with N points due to the Nyquist sampling theorem. Explicit filtering can reduce aliasing errors since this procedure removes the high wavenumber modes ($k > \pi/\Delta$) from $\tilde{\mathbf{u}}$, thus ensuring that the computational grid can represent functions having higher number of Fourier modes compared to $\tilde{\mathbf{u}}$.

Wall Modeling

In the following discussion, we will consider flow along a wall, with the x-axis aligned along the streamwise direction, and the y-axis aligned along the wall normal direction. For simulating turbulent boundary layers at high Reynolds numbers flows, it is usually challenging to resolve the thin viscous layer near the wall. In such cases, the distance of the first off-wall grid point, y_1, is typically much larger than l^+; it is not possible to apply a no-slip boundary condition for $\mathbf{u}$ at this grid point. Instead, the wall traction $\sigma_{i2} = \nu \frac{\partial u_i}{\partial y}$ at $y=0$ has to be applied as a body force, as outlined in Equation 5.8.13. Typically, $\tilde{u}_2 = 0$ is imposed in such schemes, which a good approximation within a boundary layer. To obtain σ_{i2} for $i=1, 3$, the log law is utilized, which relates the friction velocity $u\tau$ at the wall to the average streamwise velocity $\langle u_1(\mathbf{x})\rangle|_{y=y_m}$, where the "matching distance" y_m lies in the "outer layer" ($y_m \sim 0.2\delta$) of the turbulent boundary layer, as follows:

$$\langle u_1 |_{y=y_m} \rangle = u_\tau \left[\frac{1}{\kappa} \log \frac{y_m u_\tau}{\nu} + B_i \right] \tag{5.8.23}$$

where $B_i = 5.5$. The friction velocity, $u\tau$, can be calculated from the aforementioned transcendental equation at every time step using iterative methods like the Newton–Raphson scheme (Piomelli and Balaras, 2002). In an LES simulation where the wall modeling approach is being used, typically $y_m = y_1$ is applied, and u_1 is replaced by $\tilde{u}_1$. Here y_1 is the wall normal distance of the first off-wall grid point from the wall. It has recently been reported (Kawai and Larsson, 2012) that $y_m = y_3$ (location of the third off-wall grid point) can give better results, since the SGS model does not work well near the wall. Thus, at a given x,z location, $u\tau$ can be obtained at every time step using Equation 5.8.23. $\langle \sigma_{12} \rangle$ is then obtained from (Piomelli and Balaras, 2002)

$$\langle \sigma_{12} \rangle = \text{sgn}[\langle \tilde{u}_1(y_m) \rangle] u_\tau^2 \tag{5.8.24}$$

where sgn[x] gives the sign of x. The fluctuating components $\sigma'_{i2} = \sigma_{i2} - \langle \sigma_{i2} \rangle$ are then made proportional to the wall-parallel fluctuating velocities as follows:

$$\sigma'_{i2}(x,z) = \tilde{u}'_i(\mathbf{x})\,|_{y=y_m} \frac{\langle \sigma_{12} \rangle}{\langle \tilde{u}_1 \rangle} \quad \text{for all } i = 1,3 \tag{5.8.25}$$

where $\tilde{u}'_i = \tilde{u}_i - \langle \tilde{u}_i \rangle$ is the fluctuating component of the filtered velocity. Again, $\langle [\cdot] \rangle$ may be obtained by averaging over the statistically homogeneous directions (if present). Otherwise, time averaging may also be used. The instantaneous wall-parallel tractions are then given by $\sigma_{12} = \langle \sigma_{12} \rangle + \sigma'_{12}$ and $\sigma_{32} = \sigma'_{32}$. Such wall modeling methods, while being computationally inexpensive, should ideally be used only if a high Reynolds number turbulent boundary layer is present near the wall; the method may not be accurate for separated flows and nonequilibrium boundary layers, for which the log law (Equation 5.8.23) does not apply.

Grid Generation

As mentioned earlier, the filter width, Δ, can vary with $\mathbf{x}$, and $\Delta^g(\mathbf{x})$ itself needs to be lower than or equal to $\Delta(\mathbf{x})$. Ideally, Δ should lie within the inertial range, i.e., $\mathcal{L} \gg \Delta \gg \eta$, where $\mathcal{L}$ is the local integral length scale of turbulence and η is the local Kolmogorov scale. It is, however, not easy to estimate $\mathcal{L}$ and η *a priori*. One way to set Δ is to base it on the length scale δ characterizing the flow locally. For example, for a turbulent jet, δ would correspond to the width of the jet at a given axial location, while, for a boundary layer, δ would correspond to the boundary layer thickness at that streamwise location. The variation of δ itself needs to be calculated *a priori* using standard correlations for boundary layers and free shear flows. For free shear flows, and at the outer edge of turbulent boundary layers (e.g., $y > 0.2\delta$), usually $\Delta \approx \delta/20$ can be used. While performing wall-resolved LES, one expects the most energetic scales near the wall to have size $\mathcal{L} \propto y$, and, therefore, Δ itself needs to increase linearly with y within the inner edge of the boundary later (i.e., $\Delta \propto y$) in *all* directions (Figure 5.8.3). For the first off-wall grid point, $\Delta^+ \approx 1$ is required in the wall normal direction. Since long streamwise streaks and rolls are expected in the viscous buffer layer, $\Delta^+ \approx 100$, $\Delta^+ \approx 20$ can be used in the streamwise and spanwise flow directions, respectively, at the first off-wall grid point (Choi and Moin, 2012). Again, an estimate of local $u\tau$, from known correlations, is required to obtain the values of Δ at the first off-wall grid point. Implementing a linear variation of Δ with y in all directions is usually impossible with structured grids, and is typically not implemented in practice. Usage of such a grid can lead to computational savings over DNS; the computational cost of LES for a turbulent boundary layer over a plate of length L using such a grid is proportional to $Re_L^{1.8}$, as opposed to $Re_L^{2.4}$ for DNS (Chapman, 1979). If wall modeling is used, then $\Delta \approx \delta/20$ can be used throughout the turbulent boundary layer, since, in this case, the dynamics inside the viscous buffer layer need not be resolved by $\tilde{\mathbf{u}}$ (Figure 5.8.3).

Case Study: LES of Channel Flow

Here we will briefly discuss results from LES of fully developed turbulent channel flow, in which a constant pressure gradient is used to drive the fluid in the x-direction, while the walls are present at $y=0$ and $y=2H$. The flow is statistically homogeneous in the x and z direction. The Reynolds number based on friction velocity is $Re\tau = u\tau H/\nu \approx 950$, which corresponds to a bulk Reynolds number of $Re_b = U_b H/\nu = 19{,}000$, where $U_b = \dfrac{1}{2H}\displaystyle\int_0^{2H} \langle u \rangle dy$ is the average bulk velocity. A second-order

pseudospectral solver with explicit time stepping (fourth order Runge–Kutta) is used to perform this simulation. The dynamic Smagorinsky model (DSM) is used with $\alpha=2$ for the test filter. The Smagorinsky constant C_s is calculated dynamically at every time step. In turbulent channel flow, statistical homogeneity is present in both the x- and z-directions, and therefore, Equation 5.8.22 can be used directly to compute C_s, with $\langle[\cdot]\rangle$ implying averaging in x- and z-directions. Homogeneous filter width is used, with implicit filtering, so that the grid cell width, Δ^g is the same as the characteristic filter width, Δ. The computational domain contains $167\times40\times93$ points, and periodic boundary condition is applied in the x- and z-directions. The normalized grid cell width in different directions are $\Delta_x/H=0.15$, $\Delta_z/H=0.1$, $\Delta_y/H=0.05$, $\Delta_y^+=47.5$, and Since $\Delta_y^+\gg1$, the viscous wall shear stress has to be modeled. The wall-modeled LES method is used to iteratively solve $u\tau$ (and therefore τ_w) in terms of the velocity at *iym*th off-wall grid point (Piomelli and Balaras, 2002; Kawai and Larsson, 2012). Here, we try $iym=1$ and $iym=3$ (matching at first and third off-wall grid points). The mean bulk velocity (and therefore Re_b) is fixed in the simulation, while $u\tau$ (or τ_w) is derived from the wall-modeled LES method (Piomelli and Balaras, 2002) at every time step. In Figures 5.8.4a and b, we observe that the mean velocity profile $U(y)=\langle u_1\rangle(y)$ compares well with DNS data, as well as the log law, for both the *iym* values. There is in fact not much effect of the matching location (*iym*) on the mean velocity profile.

In Figure 5.8.5, we compare the Reynolds stresses with DNS values (for the $iym=3$ case), and find a reasonable match between LES and DNS away from the wall ($y/H>0.25$). Near the wall, there is much higher discrepancy between LES and DNS Reynolds stresses, especially since the Reynolds stresses from filtered velocity is expected to be much lower than the corresponding DNS values near the wall. The disagreement between LES statistics (i.e., Reynolds stresses) with DNS statistics near the wall is not surprising, and has been observed earlier by several researchers in the past (Kawai and Larsson, 2012). In fact, if a homogeneous filter is used in wall-bounded flows, with a filter width proportional to the boundary layer thickness, then the matching of such statistics is possible only if DNS data is available *a priori* (Bhattacharya et al., 2008; Völker et al., 2002). In Figure 5.8.6a, we observe that $C_s\approx0.16$ in the log layer ($0.1<y/H<0.3$), $C_s\approx0.125$ in the center of the channel, and $C_s\approx0$ near the wall. This drastic reduction of C_s at the wall is in fact responsible for overprediction of normal Reynolds stresses near the wall, since C_s directly determines the energy dissipation rate $-\langle\tau_{ij}S_{ij}\rangle=(C_s\Delta)^2\langle S^3\rangle$ of the large-scale turbulent kinetic energy by the SGS. Nevertheless, it appears that, after an initial transient, the $u\tau$ is predicted reasonably well by the LES (Figure 5.8.6b), with less than 5% error in τ_w seen for both $iym=1$ and $iym=3$ cases.

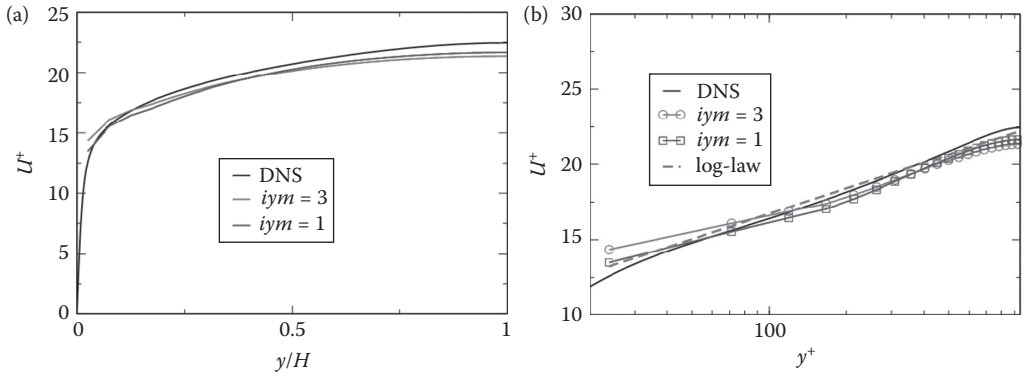

FIGURE 5.8.4 Mean velocity U^+ plotted with respect to u mean y/H on the normal scale and u mean log y^+ in the semi-log scale. Results are presented for matching points located at the first off-wall grid point ($iym=1$) and the third off-wall grid point ($iym=3$).

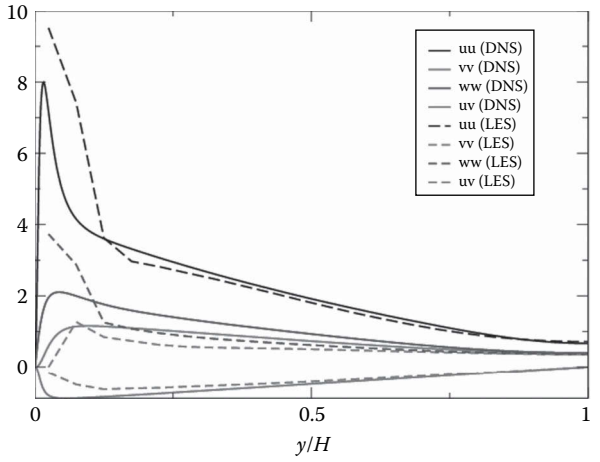

FIGURE 5.8.5 Reynolds stresses from LES compared to DNS data for turbulent channel flow.

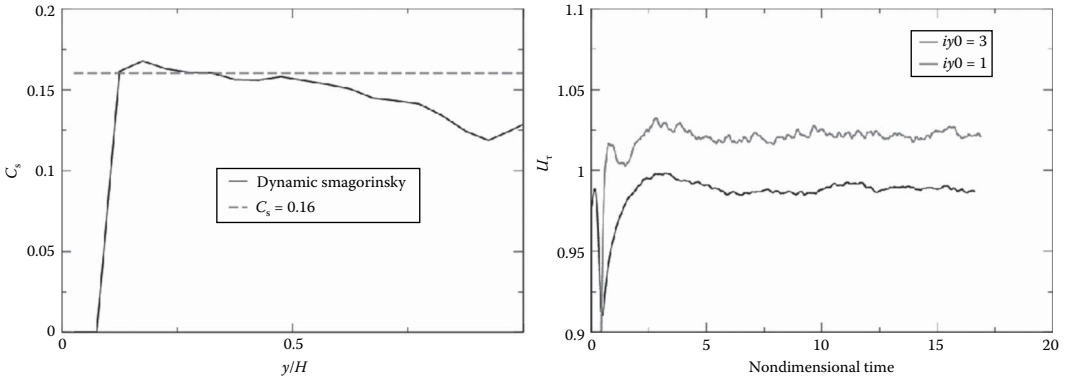

FIGURE 5.8.6 (a) C_s vs. y plotted along with reference value of C_s=0.16 and (b) $u\tau$ vs. time for matching point located at first off-wall grid point (iym=1) and third off-wall grid point (iym=3). The value of $u\tau$ = 1 in DNS.

Summary

We summarize the main points of the chapter as follows:

- LES solves equations for spatially filtered "large scales" of the velocity field, and models the effect of the small scales on the large scale, usually using eddy viscosity. It is more accurate than RANS since it attempts to model only the universal part of the energy spectrum. However, it is also much more expensive than RANS due to the larger degrees of freedom that need to be simulated.
- Ideally, explicit filtering, with a large value of Δ/Δ_g should be used to reduce errors. However, in practice, explicit filtering is not used due to the higher degrees of freedom (and therefore larger computational costs) involved.
- Wall-resolved LES models are somewhat less expensive than DNS. Choosing the correct mesh and grid size is crucial toward obtaining accurate results.
- Wall-modeled LES models are extremely inexpensive compared to wall-resolved LES. However, they may not be suitable for separated flows and equilibrium boundary layers.

5.9 SOFTWARE AND COMPUTER CODES

Atul Sharma

Although various proprietary (or commercial) and free (or open-source) codes as well as software packages are available for problems in fluid dynamics and heat transfer, more commonly used ones are presented in this subsection—separately for the mathematical software, and CFD software and codes.

Mathematical Software

Some of the popular commercial mathematical software, for problems in heat transfer, are MATLAB® (programming, modeling, and simulation tool, developed by the MathWorks, Natick, MA, USA: http://www.mathworks.com), Maple (a general-purpose computer algebra system, developed by Maplesoft, Waterloo, Canada: http://www.maplesoft.com), and Mathematica (a computational software program based on symbolic mathematics, developed by Wolfram Research, Champaign, IL, USA: http://www.wolfram.com).

Widely used *open-source* mathematical software, for a heat-transfer study, are Scilab, acquired by ESI Group, Paris, France (for numerical computation and simulation: http://www.scilab.org), GNU Octave (mathematical modeling and simulation software http://www.gnu.org/software/octave), and Sage (System for Algebra and Geometry Experimentation: http://www.sagemath.org). Note that the mathematical software presented here are general-purpose, not only applicable to heat transfer but also applied for various problems in science and engineering.

Computational Fluid Dynamics Software and Codes

Commercial CFD software, widely used for a heat-transfer study, are FLUENT and CFX (both from ANSYS, Canonsburg, PA, USA: http://www.ansys.com), STAR-CD (from CD-adapco now part of Siemens PLM Software, Plano, TX, USA: http://mdx.plm.automation.siemens.com), CFD-ACE+ (from ESI Group, Paris, France: http://www.esi-cfd.com), TransAT (from ASCOMP GmbHa, Zurich, Switzerland: http://www.ascomp.ch), and solidworks Flow Simulation (from solidworks, Waltham, MA, USA: http://www.solidworks.com. The CFD solver for all these software packages is based on a finite-volume method-based algebraic formulation on a structured/block-structured or unstructured grid. A commercial software based on finite element method is COMSOL Multiphysics (from COMSOL, Burlington, MA, USA; for various applications including CFD: http://www.comsol.com), and a software based on the lattice Boltzmann method is PowerFLOW (from Exa Corporation, Burlington, MA, USA: http://www.exa.com).

Widely used *open-source* CFD codes/software are OpenFOAM, acquired by ESI Group, Paris, France (http://www.openfoam.com; see also http://www.extend-project.de), SU2 (Stanford University Unstructured: http://su2.stanford.edu), and PyFR (developed by the Vincent Lab at Imperial College London: http://www.pyfr.org). For multiphase flow, a freely available, very advanced state-of-the art adaptive 3D VOF method-based code is the Gerris Flow Solver, created by Stéphane Popinet, UPMC, Paris, France (http://www.gfs.sourceforge.net) and its successor Basilisk (http://basilisk.fr).

TABLE A.1
Properties of Dry Air at Atmospheric Pressure

Symbols and Units

K = Absolute temperature, °K

C = Temperature, °C

F = Temperature, °F

ρ = Density, kg/m^3

c_p = Specific heat capacity, kJ/kg·K

c_p/c_v = Specific heat capacity ratio, dimensionless

μ = Viscosity, N·s/m^2 × 10^6 (for N·s/m^2 (= kg/m·s) multiply tabulated values by 10^{-6})

k = Thermal conductivity, W/m·K × 10^3 (for W/m·K multiply tabulated values by 10^{-3})

Pr = Prandtl number, dimensionless

H = Enthalpy, kJ/kg

V_s = Sound velocity, m/s

TABLE A.2
Ideal Gas Properties of Nitrogen, Oxygen, and Carbon Dioxide

Symbols and Units

T = Absolute temperature, °K

$\bar{h}$ = Enthalpy, kJ/kmol

$\bar{u}$ = Internal energy, kJ/kmol

$\bar{s}^{\circ}$ = Absolute entropy at standard reference pressure, kJ/kmol K

$\bar{h}$ = Enthalpy of formation per mole at standard state = 0 kJ/kmol

T	$\bar{h}$	$\bar{u}$	$\bar{s}^{o}$	T	$\bar{h}$	$\bar{u}$	$\bar{s}^{o}$

TABLE A.3
Psychrometric Table: Properties of Moist Air at 101,325 N/m²

Symbols and Units

P_s = Pressure of water vapor at saturation, N/m²

W_s = Humidity ratio at saturation, mass of water vapor associated with unit mass of dry air

V_a = Specific volume of dry air, m³/kg

V_s = Specific volume of saturated mixture, m³/kg dry air

h_a^a = Specific enthalpy of dry air, kJ/kg

h_s = Specific enthalpy of saturated mixture, kJ/kg dry air

s_s = Specific entropy of saturated mixture, J/K·kg dry air

Note: The P_s column in this table gives the vapor pressure of pure water at temperature intervals of 5 °C. For the latest data on vapor pressures at intervals of 0.1°C, from 0°C to 100°C (see Wexler, A., and Greenspan, L., *J. Res. Nat. Bur. Stand.,* 75A(3):213–229, 1971).

[a] For very low barometric pressures and high wet-bulb temperatures, the values of h_a in this table are somewhat low; for corrections, see Psychrometric Tables, in "ASHRAE Handbook of Fundamentals", American Society of Heating, Refrigerating and Air-conditioning Engineers, 1972.

TABLE A.4
Water Vapor at Low Pressures: Perfect Gas Behavior $pv/T = R = 0.46151$ kJ/kg·K

Symbols and Units

t = Thermodynamic temperature, °C

T = Thermodynamic temperature, K

pv = RT, kJ/kg

u_0 = Specific internal energy at zero pressure, kJ/kg

h_0 = Specific enthalpy at zero pressure, kJ/kg

s_l = Specific entropy of semiperfect vapor at 0.1 MN/m^2, kJ/kg·K

ψ_l = Specific Helmholtz free energy of semiperfect vapor at 0.1 MN/m^2, kJ/kg

ζ_l = Specific Gibbs free energy of semiperfect vapor at 0.1 MN/m^2, kJ/kg

p_r = Relative pressure, pressure of semiperfect vapor at zero entropy, TN/m^2

v_r = Relative specific volume, specific volume of semiperfect vapor at zero entropy, mm^3/kg

c_{p0} = Specific heat capacity at constant pressure for zero pressure, kJ/kg·K

c_{v0} = Specific heat capacity at constant volume for zero pressure, kJ/kg·K

$K = c_{p0}/c_{V0}$ = isentropic exponent, $-(\partial \log p/\partial \log v)_s$

TABLE A.6
Properties of Superheated Steam

Symbols and Units

T = Temperature, °C

T_{sat} = Saturation temperature, °C

ν = Specific volume, m^3/kg

u = Internal energy, kJ/kg

h = Enthalpy, kJ/kg

S = Entropy, kJ/kg·K

p = Pressure, bar and μPa

T(°C)	υ, m^3/kg	u, kJ/kg	h, kJ/kg	s, kJ/kg·K	υ, m^3/kg	u, kJ/kg	h, kJ/kg	s, kJ/kg·K
	p = 0.06 bar = 0.006 MPa (T_{sat} = 36.16°C)				p = 0.35 bar = 0.035 MPa (T_{sat} = 72.69°C)

TABLE A.7
Chemical, Physical, and Thermal Properties of Gases: Gases and Vapors, Including Fuels and Refrigerants, English and Metric Units

Common Name(s)	Acetylene (Ethyne)	Air (mixture)	Ammonia, anhyd.	Argon
Chemical Formula	**C_2H_2**		**NH_3**	**Ar**
Refrigerant Number	**—**	**729**	**717**	**740**
	Chemical and Physical Properties			
Molecular weight	26.04	28.966	17.02	39.948
Specific gravity, air = 1	0.90	1.00	0.59	1.38
Specific volume, ft^3/lb	14.9	13.5	23.0	9.80
Specific volume, m^3/kg	0.93	0.842	1.43	0.622
Density of liquid (at atm bp), lb/ft^3	43.0	54.6	42.6	87.0
Density of liquid (at atm bp), kg/m^3	693.	879.	686.	1,400
Vapor pressure at 25°C, psia			145.4	
Vapor pressure at 25°C, MN/m^2			1.00	
Viscosity (abs), lbm/ft·s	6.72×10^{-6}	12.1×10^{-6}	6.72×10^{-6}	13.4×10^{-6}
Viscosity (abs), centipoises[a]	0.01	0.018	0.010	0.02
Sound velocity in gas, m/s	343	346	415	322
	Thermal and Thermodynamic Properties			
Specific heat, c_p, Btu/lb·°F or cal/g·°C	0.40	0.2403	0.52	0.125
Specific heat, c_p J/kg·K	1,674	1,005	2,175	523
Specific heat ratio, c_p/c_v	1.25	1.40	1.3	1.67
Gas constant *R*, ft-lb/lb·°R	59.3	53.3	90.8	38.7
Gas constant *R*, J/kg·°C	319	286.8	488	208
Thermal conductivity, Btu/h-ft·°F	0.014	0.0151	0.015	0.0102
Thermal conductivity, W/m·°C	0.024	0.026	0.026	0.0172
Boiling point (sat 14.7 psia), °F	−103	−320	−28	−303
Boiling point (sat 760 mm), °C	−75	−195	−33.3	−186
Latent heat of evap (at bp), Btu/lb	264	88.2	589.3	70.
Latent heat of evap (at bp), J/kg	614,000	205,000	1,373,000	163,000
Freezing (melting) point, °F (1 atm)	−116	−357.2	−107.9	−308.5
Freezing (melting) point, °C (1 atm)	−82.2	−216.2	−77.7	−189.2
Latent heat of fusion, Btu/lb	23.	10.0	143.0	
Latent heat of fusion, J/kg	53,500	23,200	332,300	
Critical temperature, °F	97.1	−220.5	271.4	−187.6
Critical temperature, °C	36.2	−140.3	132.5	−122
Critical pressure, psia	907	550	1,650	707
Critical pressure, MN/m^2	6.25	3.8	11.4	4.87
Critical volume, ft^3/lb		0.050	0.068	0.0299
Critical volume, m^3/kg		0.003	0.00424	0.00186
Flammable (yes or no)	Yes	No	No	No
Heat of combustion, Btu/ft^3	1,450	—	—	—
Heat of combustion, Btu/lb	21,600	—	—	—
Heat of combustion, kJ/kg	50,200	—	—	—

Appendix B: Properties of Liquids

TABLE B.1
Properties of Liquid Water

Temp. °F	At 1 atm or 14.7 psia				At 1,000 psia				At 10,000 psia			
	ρ	c_p	μ	k	ρ	c_p	μ	k	ρ	c_p	μ	k^a
	Symbols and Units:											
	ρ = density, lb_m/ft^3. For g/cm^3 multiply by 0.016018. For kg/m^3 multiply by 16.018.											
	c_p = specific heat, Btu/lb_m R = cal/g·K. For J/kg·K multiply by 4186.8.											
	μ = viscosity. For lbf·s/ft^2 = slugs/s·ft, multiply by 10^{-7}. For lb_m·s·ft multiply by 10^{-7} and by 32.174. For g/s·cm (poise) multiply by 10^{-7} and by 478.80. For N·s/m^2 multiply by 10^{-7} and by 478.880.											
	k = thermal conductivity, Btu/hr-ft R. For W/m·K multiply by 1.7307.											
32	62.42	1.007	366	0.3286	62.62	0.999	365	0.3319	64.5	0.937	357	0.3508

Note: From: "1967 ASME Steam Tables," American Society of Mechanical Engineers, Tables 9, 10, and 11 and Figures 6, 7, 8, and 9; The ASME compilation is a 330-page book of tables and charts, including a $2\frac{1}{2} \times 3\frac{1}{2}$ -ft Mollier chart. All values have been computed in accordance with the 1967 specifications of the International Formulation Committee (IFC) and are in conformity with the 1963 International Skeleton Tables. This standardization of tables began in 1921 and was extended through the International Conferences in London (1929), Berlin (1930), Washington (1934), Philadelphia (1954), London (1956), New York (1963), and Glasgow (1966). Based on these worldwide standard data, the 1967 ASME volume represents detailed computer output in both tabular and graphic form. Included are density and volume, enthalpy, entropy, specific heat, viscosity, thermal conductivity, Prandtl number, isentropic exponent, choking velocity, p–v product, etc., over the entire range (to 1500 psia, 1500°F). English units are used, but all conversion factors are given.

[a] At 7500 psia.

TABLE B.2
Physical and Thermal Properties of Common Liquids

INTERNATIONAL SYSTEM OF UNITS (SI)

The International System of Units (SI) was adopted by the 11th General Conference on Weights and Measures (CGPM) in 1960. It is a coherent system of units built from seven *SI base units*, one for each of the seven dimensionally independent base quantities: the meter, kilogram, second, ampere, kelvin, mole, and candela, for the dimensions of length, mass, time, electric current, thermodynamic temperature, amount of substance, and luminous intensity, respectively. The definitions of the SI base units are given below. The *SI derived units* are expressed as products of powers of the base units, analogous to the corresponding relations between physical quantities but with numerical factors equal to unity.

In the International System, there is only one SI unit for each physical quantity. This is either the appropriate SI base unit itself or the appropriate SI derived unit. However, any of the approved decimal prefixes, called *SI prefixes*, may be used to construct decimal multiples or submultiples of SI units.

It is recommended that only SI units be used in science and technology (with SI prefixes where appropriate). Where there are special reasons for making an exception to this rule, it is recommended always to define the units used in terms of SI units. This section is based on information supplied by IUPAC.

DEFINITIONS OF SI BASE UNITS

Meter: The meter is the length of path traveled by light in vacuum during a time interval of 1/299,792,458 of a second (17th CGPM, 1983).

Kilogram: The kilogram is the unit of mass; it is equal to the mass of the international prototype of the kilogram (3rd CGPM, 1901).

Second: The second is the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom (13th CGPM, 1967).

Ampere: The ampere is that constant current, which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section and placed 1 m apart in vacuum, would produce between these conductors a force equal to 2×10^{-7} N/m of length (9th CGPM, 1958).

Kelvin: The kelvin, unit of thermodynamic temperature, is the fraction 1/273.16 of the thermodynamic temperature of the triple point of water (13th CGPM, 1967).

Mole: The mole is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kg of carbon-12. When the mole is used, the elementary entities must be specified and may be atoms, molecules, ions, electrons, or other particles, or specified groups of such particles (14th CGPM, 1971). Examples of the use of the mole are as follows:

- 1 mol of H_2 contains about 6.022×10^{23} H_2 molecules, or 12.044×10^{23} H atoms.
- 1 mol of HgCl has a mass of 236.04 g.
- 1 mol of Hg_2Cl_2 has a mass of 472.08 g.
- 1 mol of Hg_2^{2+} has a mass of 401.18 g and a charge of 192.97 kC.
- 1 mol of $Fe_{0.91}$ S has a mass of 82.88 g.
- 1 mol of e^- has a mass of 548.60 μg and a charge of –96.49 kC.
- 1 mol of photons whose frequency is 10^{14} Hz has energy of about 39.90 kJ.

Candela: The candela is the luminous intensity, in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} Hz, and that has a radiant intensity in that direction of (1/683) watt per steradian (16th CGPM, 1979).

NAMES AND SYMBOLS FOR THE SI BASE UNITS

Physical Quantity	Name of SI Unit	Symbol for SI Unit
Length	meter	m
Mass	kilogram	kg
Time	second	sec
Electric current	ampere	A
Thermodynamic temperature	kelvin	K
Amount of substance	mole	mol
Luminous intensity	candela	cd

SI DERIVED UNITS WITH SPECIAL NAMES AND SYMBOLS

Physical Quantity	Name of SI Unit	Symbol for SI Unit	Expression in Terms of SI Base Units
Frequency[a]	hertz	Hz	s^{-1}
Force	newton	N	$m \cdot kg \cdot s^{-2}$
Pressure, stress	pascal	Pa	$N \cdot m^{-2} = m^{-1} \cdot kg \cdot s^{-2}$
Energy, work, heat	joule	J	$N \cdot m = m^2 \cdot kg \cdot s^{-2}$
Power, radiant flux	watt	W	$J \cdot s^{-1} = m^2 \cdot kg \cdot s^{-3}$
Electric charge	Coulomb	C	$A \cdot s$
Electric potential, electromotive force	Volt	V	$J \cdot C^{-1} = m^2\ kg \cdot s^{-3}\ A^{-1}$
Electric resistance	Ohm	Ω	$V \cdot A^{-1} = m^2 \cdot kg \cdot s^{-3} \cdot A^{-2}$
Electric conductance	Siemens	S	$\Omega^{-1} = m^{-2} \cdot kg^{-1} \cdot s^4 \cdot A^2$
Electric capacitance	Farad	F	$C \cdot V^{-1} = m^{-2} \cdot kg^{-1} \cdot s^4 \cdot A^2$
Magnetic flux density	Tesla	T	$V \cdot s \cdot m^{-2} = kg \cdot s^{-2} \cdot A^{-1}$
Magnetic flux	Weber	Wb	$V \cdot s = m^2 \cdot kg \cdot s^{-2} \cdot A^{-1}$
Inductance	Henry	H	$V \cdot A^{-1} \cdot s = m^2 \cdot kg \cdot s^{-2} \cdot A^{-2}$
Celsius temperature[b]	degree Celsius	°C	K
Luminous flux	lumen	lm	$cd \cdot sr$
Illuminance	lux	lx	$cd \cdot sr \cdot m^{-2}$
Activity (radioactive)	Becquerel	Bq	s^{-1}
Absorbed dose (or radiation)	Gray	Gy	$J \cdot kg^{-1} = m^2 \cdot s^{-2}$
Dose equivalent (dose equivalent index)	Sievert	Sv	$J \cdot kg^{-1} = m^2 \cdot s^{-2}$
Plane angle	radian	rad	$1 = m \cdot m^{-1}$
Solid angle	steradian	sr	$1 = m^2 \cdot m^{-2}$

[a] For radial (circular) frequency and for angular velocity, the unit rad s^{-1}, or simply s^{-1}, should be used, and this may not be simplified to Hz. The unit Hz should be used only for frequency in the sense of cycles per second.

[b] The Celsius temperature θ is defined by the equation

$$q/°C = T/K = 237.15$$

The SI unit of Celsius temperature interval is the degree Celsius, °C, which is equal to the kelvin, K. °C should be treated as a single symbol, with no space between the ° sign and the letter C. (The symbol °K, and the symbol °, should no longer be used.)

UNITS IN USE TOGETHER WITH THE SI

These units are not part of the SI, but it is recognized that they will continue to be used in appropriate contexts. SI prefixes may be attached to some of these units, such as milliliter, ml; millibar, mbar; mega-electronvolt, MeV; and kilotonne, kt.

Physical Quantity	Name of Unit	Symbol for Unit	Value in SI Units
Time	minute	min	60 s
Time	hour	h	3600 s
Time	day	d	86,400 s
Plane angle	degree	°	(π/180) rad
Plane angle	minute	′	(π/10,800) rad
Plane angle	second	″	(π/648,000) rad
Length	angstrom[a]	A	10^{-10} m
Area	barn	b	10^{-28} m^2
Volume	liter	l, L	dm^3 = 10^{-3} m^3
Mass	ton	t	Mg = 10^3 kg
Pressure	bar[a]	bar	10^5 Pa = 10^5 N m^2
Energy	electronvolt[b]	eV (= e × V)	≈ 1.60218×10^{-19} J
Mass	unified atomic mass unit[b,c]	u (= m_a(12C)/12)	≈ 1.66054×10^{-27} kg

[a] The angstrom and the bar are approved by CIPM for "temporary use with SI units," until CIPM makes a further recommendation. However, they should not be introduced where they are not used at present.

[b] The values of these units in terms of the corresponding SI units are not exact, since they depend on the values of the physical constants e (for the electronvolt) and N_A (for the unified atomic mass unit), which are determined by experiment.

[c] The unified atomic mass unit is also sometimes called the dalton, with symbol Da, although the name and symbol have not been approved by CGPM.

CONVERSION CONSTANTS AND MULTIPLIERS

Recommended Decimal Multiples and Submultiples

Multiple or Submultiple	Prefix	Symbol	Multiple or Submultiple	Prefix	Symbol
10^{18}	exa	E	10^{-1}	deci	d

[a] Boldface numbers are exact; others are given to 10 significant figures where so indicated by the multiplier factor.

Temperature Factors

$°F = 9/5(°C) + 32$

Fahrenheit temperature = 1.8(temperature in kelvins) − 459.67

$°C = 5/9[(°F) - 32]$

Celsius temperature = temperature in kelvins − 273.15

Fahrenheit temperature = 1.8(Celsius temperature) + 32

Conversion of Temperatures

From	To		From	To	
Fahrenheit	Celsius	$t_c = \frac{t_F - 32}{1.8}$	Celsius	Fahrenheit	$t_F = (t_c \times 1.8) + 32$
				Kelvin	$T_K = (t_c + 273.15)$
	Kelvin	$T_k = \frac{t_F - 32}{1.8} + 273.15$	Kelvin	Rankine	$T_R = (t_c + 273.15) \times 1.8$
				Celsius	$t_c = T_K - 273.15$
				Rankine	$T_R = T_k \times 1.8$
	Rankine	$T_R = t_F + 459.67$	Rankine	Fahrenheit	$t_F = T_R - 459.67$ F
				Kelvin	$T_K = \frac{T_R}{1.8}$
